The O isotope ratios of the calcite grains significantly vary with the $\delta^{18}O$ values ranging from ~22 to ~38 ‰. The O isotope ratios plot on a single trend line in an O three-isotope plot with a slope of ~0.61, slightly steeper than the terrestrial fractionation line, reflecting a progressive O-isotope exchange between initially ^{16}O-poor water and ^{16}O-rich rock [4,5]. The $\delta^{18}O$ values also vary within single calcite grains, demonstrating crystal growth from a relatively dark CL core to a red CL periphery.

The $\delta^{13}C$ values of the calcite grains range from 17 to 32 ‰. This range is much smaller than that observed for different carbonate grains or bulk meteorite samples by previous studies. Especially, the $\delta^{13}C$ variations within individual grains are only 4 ‰at most except for one grain. Previous studies have suggested that the observed $\delta^{13}C$ variation was produced by the Rayleigh-type isotopic fractionation by the escape of ^{13}C-poor methane [2], or equilibrium isotopic fractionation reflecting variable formation temperatures of carbonates [3]. However, the small intra-grain $\delta^{13}C$ variations associated with the large $\delta^{18}O$ change observed in this study cannot be explained by such processes. Instead, here we propose that the $\delta^{13}C$ values of dissolved carbon species in aqueous solutions were locally heterogeneous, and did not significantly change during carbonate formation.

Characteristics of Oxygen isotope ratios of chondrules and isolated olivine grains from Tagish Lake C2 chondrite

*Takayuki Ushikubo[1], Makoto Kimura[2]

1. Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology, 2. National Institute for Polar Research

Recent studies on oxygen isotope systematics of chondrules show that chondrules in individual chondrite groups have characteristic distributions in their oxygen isotope ratios and Mg# (molar % of MgO/(MgO+FeO)) [1, 2]. The correlations between Mg# and $D^{17}O$ values (= $d^{17}O_{VSMOW}$ - 0.52 ×$d^{18}O_{VSMOW}$) of chondrules can be explained by mixing of ^{16}O-rich anhydrous dusts and an ^{16}O-poor oxidizing agent (most likely H_2O ice) in chondrule forming regions [3]. Based on similar Mg# - $D^{17}O$ correlations between CR chondrite chondrules and cometary silicate particles from comet Wild 2, it has been proposed that many of cometary silicate particles formed in the outer regions of the asteroid belt [e.g. 4, 5]. The Tagish Lake meteorite (ungrouped C2) is an appropriate sample to investigate the Mg# - $D^{17}O$ systematics of silicate particles formed in the outer regions of the asteroid belt because the Tagish Lake meteorite probably derived from a D-type asteroid [6]. Previous oxygen isotope studies on olivine grains from Tagish Lake and Tagish Lake-like meteorites [e.g. 7] show that their Mg# - $D^{17}O$ systematics are similar to that of CR chondrite chondrules. Here, we report new oxygen isotope data of olivine grains from the Tagish Lake meteorite for better understandings of the Mg# - $D^{17}O$ systematics of silicate particles in the outer regions of the asteroid belt.

Two polished epoxy mounts of the Tagish Lake meteorite, TL-KC-1 (8mm ×5mm) and TL-KC-2 (4mm × 3mm), were prepared for this study. Due to extensive aqueous alteration in the Tagish Lake parent body, phyllosilicates and other secondary phases such as magnetite and carbonates replace primary anhydrous phases. However, remaining olivine grains in chondrules and matrix tend to have sharp grain boundaries and no apparent evidence for the Mg-Fe exchange between olivine grains and matrix was observed. No alteration features were observed in these grains. Forty chondrules and isolated olivine grains (hereafter “ferromagnesian inclusions”) were selected for oxygen isotope measurements (34 type I [Mg#>= 90] and 6 type II [Mg#<90]). Oxygen isotope ratios of olivine grains were measured with an ion microprobe, CAMECA IMS 1280-HR at Kochi Institute. A 20 kV accelerated Cs^+ primary beam (~30 pA, ~3 um in diameter) was used. The analytical conditions were similar to those in [1].

Oxygen three-isotope ratios of ferromagnesian inclusions from Tagish Lake are distributed along the PCM (primitive chondrule minerals) line [1]. Most type I ferromagnesian inclusions are relatively ^{16}O-rich ($D^{17}O$ = -7.4 to -3.9‰) and type II ferromagnesian inclusions are relatively ^{16}O-poor ($D^{17}O$ >= -3‰). Of six type II ferromagnesian inclusions, two inclusions have $D^{17}O$ ~ 0‰, which are recognized in in Tagish Lake-like meteorites, CR chondrites, and cometary silicate particles, but are almost absent in other carbonaceous chondrites [e.g., 2-5, 7]. The present results are further evidence for the link between ferromagnesian inclusions accumulated into asteroids in the outer regions of the asteroid belt (possibly D-type asteroids) and silicate particles accumulated into cometary nuclei in the Kuiper belt. As discussed in [4, 5, 8], type II silicates are common in cometary silicate particles, which is distinct from ferromagnesian inclusions in Tagish Lake(-like) meteorites and CR chondrites. Most cometary silicate particles formed in H_2O ice enriched oxidizing regions. Such regions were probably farther than where typical ^{16}O-rich type I chondrules of carbonaceous chondrites formed.

Extreme ^{16}O-rich CAIs in Isheyevo chondrite

*Naoya Sakamoto[1], Noriyuki Kawasaki[2]

1. Creative Research Institution, Hokkaido University, 2. Natural History Sciences, Hokkaido University

Oxygen in the solar system is believed to be formed by mixing of ^{16}O-rich and ^{16}O-poor reservoirs [e.g. 1 and references therein]. The ^{16}O-poor end member ($\Delta^{17}O$ = +85‰) was found from magnetite in cosmic symplectite and infers that the ^{16}O-poor reservor is H_2O [2]. Nevertheless candidates of ^{16}O-rich end member were reported from one chondrule named a006 ($\Delta^{17}O$ = -37‰) [3], 4 Ca-Al-rich inclusions (CAIs) ($\Delta^{17}O$ = -37 to -32‰) [4,5] and the Sun ($\Delta^{17}O$ = -28‰) [6] relative to other CAIs ($\Delta^{17}O$ = -23‰) [e.g. 7], characteristics of the reservoir are unclear because of the diversity of few samples. In this study, we surveyed extreme ^{16}O-rich CAIs in Isheyevo chondrites to investigate the ^{16}O-rich end menber.

Thirteenthick sections of Isheyevo chondrite were newly prepared. X-ray elemental maps were obtaind for whole sections by FE-SEM-EDS. Al-rich inclusions on the sections were picked up as many as possible for isotope analysis in order to prevent biased sample selection. Oxygen isotope analysis for the inclusions were performed by SIMS.

Oxygen isotopic compositions of 263 CAIs were measured and 4 extreme ^{16}O-rich CAIs were found. Two CAIs are composed of grossite core rimmed by spinel, melilite and Ti-rich diopside layer and others lack diopside and/or melilite. While the heterogeneous composition of grossite ($\Delta^{17}O$ = -36 to -32‰) would be affected by altered feature of grossite, the spinel grains have uniform ^{16}O-rich compsition ($\Delta^{17}O$ = -37‰). If we draw a line in 3 oxygen isotope diagram with the extreme ^{16}O-rich spinel and spinel in chondules near the CAI, the slope is in good agreement with a slope of olivine in a006 chondrule and porphiritic olivine chondrule infer that the oxygen isotopic composition of the spinel grains maintain the signature of an^{16}O-rich end member of the Solar System.

Variations in initial $^{26}Al/^{27}Al$ ratios among fine-grained CAIs in the reduced CV chondrites

*Noriyuki Kawasaki[1], Changkun Park[2], Naoya Sakamoto[1], Hisayoshi Yurimoto[1,3]

1. Hokkaido University, 2. KOPRI, 3. ISAS/JAXA

Ca-Al-rich inclusions (CAIs) are oldest solids formed in the Solar System [1] and composed of high-temperature condensates from a solar-composition gas [2]. Most of CAIs are thought to have contained detectable amounts of live ^{26}Al, a short-lived radionuclide with a half-life of ~0.7 Myr, at their formation [3]. Recent high-precision $^{26}Al–^{26}Mg$ mineral isochron studies using secondary ion mass spectrometry (SIMS) revealed detailed distributions of initial $^{26}Al/^{27}Al$ values, $(^{26}Al/^{27}Al)_0$, for individual CAIs in the reduced CV chondrites [e.g., 4–9]; coarse-grained, igneous CAIs and fluffy Type A CAIs show similar variations in $(^{26}Al/^{27}Al)_0$ respectively, which range from ~5.2 to ~4.2 $\times10^{-5}$. In this study, we obtained new $^{26}Al–^{26}Mg$ mineral isochrons of five fine-grained, spinel-rich CAIs (FGIs) from the reduced CV chondrites Efremovka, Vigarano and TIL 07007 by *in situ* measurements using a SIMS instrument (CAMECA ims-1280HR installed at Hokkaido University). Since FGIs are likely to be condensates from a solar nebular gas, $^{26}Al–^{26}Mg$ mineral isochrons of them enable a more systematic comparison of $(^{26}Al/^{27}Al)_0$ between CAIs formed by condensation and by melt crystallization than has previously been achieved. The obtained $^{26}Al–^{26}Mg$ mineral isochrons for five FGIs give $(^{26}Al/^{27}Al)_0$ of (5.19 ±0.17) $\times10^{-5}$, (5.00 ± 0.17) $\times10^{-5}$, (4.53 ±0.18) $\times10^{-5}$, (4.43 ±0.31) $\times10^{-5}$, and (3.35 ±0.21) $\times10^{-5}$. The $(^{26}Al/^{27}Al)_0$ for two FGIs are essentially identical to the whole-rock CAI value of $(^{26}Al/^{27}Al)_0$ ~ 5.2 $\times10^{-5}$ [10, 11], while those for other three FGIs are clearly lower than the whole-rock CAI value. The range of $(^{26}Al/^{27}Al)_0$ values for the FGIs, from (5.19 ±0.17) to (3.35 ±0.21) $\times10^{-5}$, corresponds to a formation age spread of 0.44 ±0.07 Myr. These variations are slightly larger than those for igneous CAIs ranging from ~5.2 to ~4.2 $\times10^{-5}$ [5, 6]. Our data imply that CAI condensation events continued for, at least, ~0.4 Myr at the very beginning of our Solar System, if ^{26}Al was distributed homogeneously in the forming region. Alternatively, the observed variations would also raise a possibility of heterogeneous distributions of ^{26}Al in the forming region, corresponding to a range over, at least, $3.4 \times10^{-5} < (^{26}Al/^{27}Al)_0 < 5.2 \times10^{-5}$.

Petrographic study of compact type A CAIs with partial melting process

*Akimasa Suzumura[1], Yusuke Seto[2], Shoichi Itoh[1]

1. Graduate school of Science, Kyoto University, 2. Graduate school of Science, Kobe University

Refractory inclusions (Ca-Al-rich inclusions (CAIs)) in chondritic meteorites are the oldest substances formed in the Solar System (Connelly et al., 2012). Coarse-grained CAIs are classified into three subtypes, type A, B and C, according to their petrologic features (e.g., Grossman 1975). Compact type A CAIs (CTAs) are expected to be formed in the earliest stage of solar nebula and experienced a partial melting at least once (e.g., Simon et al., 1999). Yurimoto et al. (1998) have explained the heterogeneous oxygen isotope distributions among constituent minerals in Compact Type A CAIs have formed by the partial melting model. The indicator of partial melting is necessary to discuss the formation of the entire CAIs. However, there are only a few studies that referring to the formation processes of CTAs from the perspective of crystal growth in partial melting states (Ito et al., 2004, Park et al., 2012, Kawasaki et al., 2017). Generally, spinel in CTAs are poikilitically enclosed by melilite or fassaite, and estimated to be first crystallized mineral from CAI melt (Stolper, 1982). Namely, spinel in CTAs is expected to preserve valuable information of the thermal histories such as partial melting processes. Therefore, we focus on the petrological and mineralogical feature of spinel grains in CTAs. The studied CTA (KU-N) is included in a polished thin section of North West Africa 7865 reduced CV3 carbonaceous chondrite. Yoneyama et al. (2016) had studied the same CTA, and concluded that they experienced multiple partial melting. We have undertaken petrographic and mineralogical investigations of the CTA (KU-N-02) focusing on micro-textures resulting from partial melting (local compositional zoning, grain morphology and relationships of crystallographic orientation), using a polarizing microscope, scanning electron microscope (SEM) and electron back scatter diffraction (EBSD).

In the KU-N-02 CTA, spinel crystals are enclosed by melilite or fassaite. The former (up to 50 μm in size) is substantially euhedral but the edges are rounded, while the latter (about 10 - 100 μm in size) are almost euhedral with sharp edges. On the surfaces of both type of spinel grains, small perovskite particles with sizes of several μm are ubiquitously present.

In interior KU-N-02 CAI, single crystal melilite with spinel inclusions showed a remarkable compositional zoning Single crystal melilite show core-to-rim normal zoning, with decreasing Al and increasing Mg from core to rim. In the melilite single crystal, the area of about 10 μm wide around the spinel surfaces has Åk-rich compositions in comparison. By EBSD analyses, Åk-rich melilite crystal orientation and Åk-poor melilite crystal orientation is same. Therefore, Åk-rich melilite part (~10μm) surrounding spinel are crystallized after Åk-poor melilite. Because of these results, it is difficult to explain how Åk-rich part surrounding spinel in a melilite crystal crystallized by a single stage cooling. This texture indicates that the boundary area between spinel and melilite had eutectically melted at high temperature by some heating process, and then Mg/Al contents had been redistributed to melilite and spinel during rapid cooling. Accordingly, this partial melting probably resulted in the unique morphology and the crystallographic orientation relationship of the spinel enclosed by melilite and Local composition zoning of the melilite.

[A-OS13] Ocean circulation and material cycle in coastal seas

convener:Kiyoshi Tanaka(University of Tokyo), Akihiko Morimoto(Ehime University), Yuichi Hayami(Saga University), Kazuhiko Ichimi(Seto Inland Sea Regional Research Center, Kagawa University), Chairperson:Kiyoshi Tanaka, Akihiko Morimoto

Coastal seas have high biodiversity and high productivity, while various environmental problems such as eutrophication, red tide, and hypoxia are caused by human activity. In order to understand material cycle and various phenomena and to maintain sustainable environment in coastal seas, interdisciplinary research is needed. In the present session, we invite researchers who are interested in physical phenomena, material cycle, biological responsive dynamics, and their interactions in coastal seas. Neither study area nor study method is confined. We welcome presentations of wide-range topics to communize our knowledge in coastal seas.

On-demand development of bay-scale models using the Japanese Coastal Ocean Monitoring and Forecasting System

*Kei Sakamoto[1], Hideyuki Nakano[1], Shogo Urakawa[1], Takahiro Toyoda[1], Hiroyuki Tsujino[1], Goro Yamanaka[1]

1. Meteorological Research Institute

We have developed the "Japanese Coastal Ocean Monitoring and Forecasting System" (MOVE/MRI.COM-JPN) to reproduce oceanic conditions across the coastal seas around Japan, based on an ocean model with horizontal resolution of approximately 2 km and a 4-dimensional variational data assimilation system. The Japan Meteorological Agency plans to use this system as a platform for various coastal marine operations, and details of the system are explained in Sakamoto et al. (2019) and Hirose et al. (2019) (submitted to Ocean Dynamics). However, the model resolution of 2 km is a minimum necessary requirement for continental shelf regions in contact with open oceans and relatively large inland seas such as the Seto Inland Sea, and it is a future task to provide information targeting bay-scale regions which are more closely related to society, including small bays, inland seas and straits. As a solution, a model covering the entire coastal seas around Japan with a resolution of several hundred meters is planned, but a current ordinary computer cannot perform its enormous calculations. In this respect, it seems feasible to deploy an array of bay-scale models of high resolution and small domain, which are nested from MOVE/MRI.COM-JPN, but management costs of a lot of models are concerned in that case. Therefore, we are considering an approach to develop bay-scale models on demand for a future expansion of MOVE/MRI.COM-JPN. As a first step towards this, we began developing a package that can quickly build a bay-scale model. Currently, the package consists mainly of three elements. The first is our numerical model MRI.COM. In addition to an offline-nesting function, it is possible to introduce dynamics important in coastal seas of Japan, such as river runoff, sea ice, tides and the inverse barometer effect. The second is a package of pre-processing and analysis tools named "MRI.COM eXperimental Environment". This helps a model developer to easily create model configurations such as topography data. The third is analysis data of the coastal seas around Japan produced by MOVE/MRI.COM-JPN. By using this data for the initial value and lateral boundary condition of a bay model, we can start a model experiment anytime after 2008. Using this package, we have created a Nagasaki Bay model with resolution of 100 m and an Osaka Bay model with resolution of 200 m. We reproduced seiches called "Abiki" by the Nagasaki Bay model, and the storm surge caused by Typhoon Jebi in September 2018 by the Osaka Bay model. The poster presentation will also show these results.

Long term measurement of the current at the bay head in the Suruga Bay, Japan. part 2

*Takaaki Katsumata[1,4], Masato Niki[2], Akihiko Tanaka[1], Hiroyuki Tan[1,3], Kyoko Takashima[2], Takashige Sugimoto

1. Liberal Arts Education Center, Shimizu Campus, Tokai University., 2. School of Marine Science and Technology, Tokai University, 3. Japan Unmanned Vehicle exploration Agency, 4. NPO, the association for the environmental conservation of the ocean

The Suruga Bay is located on a southern coast in the main island of Japan, and the bay facing to the Kuroshio front. Fishery in the bay are strongly influenced by a variables of rivers inflows and intruding of Kuroshio water (Sugimoto et al., 2009; Tanaka et al.,2009; Katsumata, 2016). But we have a little knowledge for these variations. Therefore, we measured the profile of the current by ferry mounted ADCP, at the line of the “Suruga Bay Ferry” cruise cross the bay head from a western coast to eastern coast, i.e., Shimizu Port to Toi Port, since 2008. We currently continuing measuring the current in the bay about near 10 years. The anticlockwise circulation at the bay head of the Suruga Bay has at least 100 m thick from surface layer. The circulation in bay head has clearly seasonal variation, it is relate difference of stratified period and non-stratified one. This current data include the period of typical large meander of Kuroshio.

Keywords: Ferry mount ADCP, Suruga Bay, typical large meander path of Kuroshio

Bottom-water intrusion and subsequent water exchange induced by Yamase around Mutsu Bay

*Satomi Fujisaki[1], Atsuhiko Isobe[1], Izumi Ogida[2], Yuki Kosaka[2]

1. Kyushu university, 2. Aomori Prefectural Fisheries Research Institute

Bottom-water intrusion in the Bungo channel, which is the cold-water intrusion onto the continental shelf from the Kuroshio intermediate layer, was studied by Takeoka et al. (2000). The bottom-water intrusion in the Bungo channel occurs when the Kuroshio Current passes along the Kyushu of the Bungo channel (Kaneda et al., 2002). In the case of Mutsu Bay, bottom-water temperature fluctuated by more than 3 degree Celsius during summer (June –September). However, Tsugaru Warm Current is not so strong compared with Kuroshio and, thus, we had to find other mechanisms for the bottom-water intrusion to occur. We here focused on Yamase which is a cold, moist and westward wind blowing from the Okhotsk Sea during summer and analyzed water temperature, current velocity and wind velocity.

Ocean buoy automatic monitoring system (hereinafter, buoy system) at three points of Mutsu Bay (Tairadate, Aomori, Higashiwan) have observed water temperature, current velocity, salinity, and so forth at a depth of 1m, 15m, 30m every single hour. An observation ship “Natsudomari” records water temperature, salinity, and so forth at eleven points of Mutsu Bay once a month. Water temperature and current velocity from 2008 to 2017 (buoy system), water temperature from 1981 to 2016 (Natsudomari), water temperature from 1981 to 2010 (Japan Oceanographic Data Center (J-DOSS)) and water temperature deviation in August from 2008 to 2017 in Tsugaru Strait (Hokkaido Research Organization) were obtained. Wind data at Oma observatory free of terrain-derived disturbances was obtained from the Japan Meteorological Agency.
A correlation analysis of time series between water temperature (5 –15 days) at Tairadate, Aomori, Higashiwan and zonal wind at Oma was performed. The days when daily average easterly (westerly) wind velocity was greater than 2 m/s was referred to as “eastern (western) wind day”. Composite maps of cross sections of water temperature in Tsugaru Strait and Mutsu Bay was created on the eastern and western wind day, respectively. The relationship between annually average bottom-water temperature at Aomori and Higashiwan and eastern winds at Oma was investigated during summer (June –September) from 2008 to 2017. Water temperature in 2011 was excluded because water temperature in Tsugaru Strait was extraordinarily low.

Long-period bottom-water temperature (about 10 days) at Tairadate and Aomori, both of which are located in western Mutsu Bay, remarkably fluctuated, that is, bottom-water intrusion occurred in the western part of Mutsu Bay. The correlation coefficients between the bottom temperature and Oma winds were 0.68 at Tairadate (a significance level of 0.05) and 0.75 at Aomori (a significance level of 0.05). Consequently, it was suggested that zonal wind induced bottom-water intrusion in western Mutsu Bay. Moreover, the composite maps stated that cold-water < 10 degree Celsius intruded onto the bottom of Mutsu Bay from Tsugaru Strait during eastern wind days. These findings suggest that westward Yamase triggers bottom-water intrusion in Mutsu Bay. However, as bottom-water temperature become lower, bottom-water intrusion was prevented even when Yamase blows continuously.

The Generation Process of the Bottom Intrusion in the Bungo Channel

*Kana Maetani[1], Akihiko Morimoto[2], Xinyu Guo[2], Toru Miyama[3]

1. Graduate School of Science and Engineering, Ehime University, 2. Center for Marine Environmental Studies, Ehime University, 3. Japan Agency for Marine-Earth Science and Technology

Introduction

The Bungo Channel is one of the two channels that connect to the Pacific Ocean and the Seto Inland Sea, and located between Kyushu and Shikoku Islands. Marine environment in the Bungo Channel is strongly influenced by the disturbances from open ocean. It is known that a cold-water intrusion from open sea, called a “Bottom Intrusion”, occurs in the lower layer from summer to autumn (Kaneda *et al.,* 2002). Since the Bottom Intrusion is difficult to observe because of its occurrence position, generation mechanism and intrusion process of the Bottom Intrusion have not been revealed yet. However, recently the Bottom Intrusion has been reproduced in numerical models with high resolution and high accuracy. Therefore, there is a possibility that we can figure out its three-dimensional structure and generation processes by analyzing model outputs. However, there is a possibility that the Bottom Intrusion and the intrusion of the cold-water in the numerical model do not have the same mechanism in real ocean. At first, we compare model output and observed data that derived from a mooring system at the central part of the Bungo Channel. After conforming reproduction of the model in terms of the Bottom Intrusion, we analyze the model output to understand the intrusion process of cold-water into the Bungo Channel.

Data

The observation data used in this study were measured by ADCP (Acoustic Doppler Current Profiler), thermometer and salinometer that were moored at the central part of the Bungo Channel, from 6 July to 17 October, 2016. We also used a model output of JCOPE-T-NEDO that is developed by JAMSTEC.

Results and Discussion

We analyzed two cases of the Bottom Intrusion that occurred 14 August and 10 September in 2016 because variations in current velocity and water temperature in the model consist well with those in observation. In these two cases, the cold-water mass was supplied to the shelf slope nearby N32.72˚, E132.45˚, and was crossed the 200m isobath by the anticlockwise flow in the shelf slope. As a result, a density gradient between the cold-water mass and relatively light water in the Bungo Channel was generated. The density gradient makes a northeastward density driven current in the lower layer in the Bungo Channel, and the current advects the cold-water mass into the Bungo Channel.

Furthermore, it is found from observation data that there is a case that northward flow became stronger in not lower layer but middle layer. When the northward flows became stronger in middle layer, a northeast flow also developed in northwestern part of the Bungo Channel. When strong northward flow occurred in the middle layer, water temperature in the central part of the Bungo Channel was not always dropped. This might be because the water mass transported by the strong northward flow in the middle layer came from shallower depth in the shelf edge compared with the case of Bottom Intrusion. However, the reason why velocity increased at middle layer is not clear at the moment, so that proceeding analysis is needed in addition to the Bottom Intrusion.

Characteristics of bottom intrusion in the Bungo Channel

*Akihiko Morimoto[1], Shuya Fujita[1], Hidetaka Takeoka[1], Xinyu Guo[1]

1. Ehime University

Bungo Channel is located between Kyushu and Shikoku and faces to the Pacific Ocean. A cold water mass with high nutrients intermittently intrudes into the Bungo Channel from summer to autumn. The phenomenon is called “Bottom Intrusion (BI)”. According to Kaneda et al., (2002), the BI occurs in neap tide of summer with the current of 15 cm/s. However, when we analyzed moored current and water temperature data at the central part of the Bungo Channel, we could not see the relation between the BI and moon age. There is a possibility that the discrepancy between our analysis and Kaneda et al. (2002) is caused by the different year data. In the present study, we reexamine the characteristics of the BI, especially relationship between the BI and moon age, using long-term water temperature data.

At the Uchiumi in the central part of the Bungo Channel, multilayer water temperature has observed since 1995. At other five stations (Hoketsu, Yusu, Shitaba, Fukuura, Okinoshima), Ehime University has also observed multilayer water temperature since 2008. In the present study, we analyze the deepest data at each station to understand the characteristics of the BI. We defined the BI as follows. Water temperature continually drops for 30 hours and its drop range is more than 0.5 ℃. At first, we analyzed water temperature data at 60 m depth in Uchiumi from 1997 to 2011. The BI occurred evenly in every moon age, we could not recognize the relation between BI and neap tide as Kaneda et al, (2002) pointed out. In addition, such kind of relation was not seen in other stations except in Yusu. Water temperature drops in Uchiumi were from 0.5 –7.0 ℃. We thought range of water temperature drop might affect to the relation. Therefore, we divided two cases, drop range is more or less than 2 ℃. We could not see the relation of neap tide in both cases. Furthermore, we investigated the relation between the BI and neap tide in each year, but we could not recognize the relation.

From the above analysis, it was found that the BI occurs without relation of moon age. However there is the relation only in Yusu. A vertical mixing area is located west of Yusu. Therefore, the BI might be blocked by the strong mixing associated with spring tide. This is why the BI occurs in neap tide in Yusu. Kaneda et al., (2002) clearly showed the relation between BI and moon age. The relation at Uchiumi was for only two years of 17 years. We will discuss why there was the relation in 1995-1996.

Role of Kuroshio Current in fish resource variability off southwest Japan

*Yushi Morioka[1], Sergey Varlamov[1], Yasumasa Miyazawa[1]

1. Japan Agency for Marine-Earth Science and Technology

Western boundary currents in the subtropics play a pivotal role in transporting warm water from the tropics that contribute to development of highly diverse marine ecosystem in the coastal regions. As one of the western boundary currents in the North Pacific, the Kuroshio Current (hereafter the Kuroshio) exerts great influences on biological resource variability off southwest Japan, but few studies have examined physical processes that attribute the coastal fish resource variability to the basin-scale Kuroshio variability. Using the high-quality fish catch data and high-resolution ocean reanalysis results, this study identifies statistical links of interannual fish resource variability off Sukumo Bay, Shikoku island of Japan, to subsurface ocean temperature variability in the Kuroshio. The subsurface ocean temperature variability off the south of Sukumo Bay exhibits vertically coherent structure with sea-surface height variability, which originates from the westward-propagating oceanic Rossby waves generated through surface wind anomalies in the Northwest Pacific. Although potential sources of the atmospheric variability remain unclarified, the remotely-induced oceanic Rossby waves contribute to fish resource variability off Sukumo Bay. These findings have potential applications to other coastal regions along the western boundary currents in the subtropics where the westward-propagating oceanic Rossby waves contribute to the coastal ocean temperature variability.

[A-OS13] Ocean circulation and material cycle in coastal seas

convener:Kiyoshi Tanaka(University of Tokyo), Akihiko Morimoto(Ehime University), Yuichi Hayami(Saga University), Kazuhiko Ichimi(Seto Inland Sea Regional Research Center, Kagawa University), Chairperson:Akihiko Morimoto, Yuichi Hayami

Coastal seas have high biodiversity and high productivity, while various environmental problems such as eutrophication, red tide, and hypoxia are caused by human activity. In order to understand material cycle and various phenomena and to maintain sustainable environment in coastal seas, interdisciplinary research is needed. In the present session, we invite researchers who are interested in physical phenomena, material cycle, biological responsive dynamics, and their interactions in coastal seas. Neither study area nor study method is confined. We welcome presentations of wide-range topics to communize our knowledge in coastal seas.

Variation in hypoxic water mass in Ariake Sea -what consumed the dissolved oxygen?-

*Yuichi Hayami[1], Naoki Fujii[1], Hiroyuki Takasu[2], Yu Umezawa[3], Minoru Wada[2]

1. Saga University, 2. Nagasaki University, 3. Tokyo University of Agriculture and Technology

In the inner most area of Ariake Sea, the estuarine circulation is dominated in summer. Therefore, the suspended material is transported toward offshore in the surface layer and toward inward and accumulated in the bottom layer. Simultaneously, there is a conspicuous spring-neap variation where stratification is enhanced and bottom water hypoxia develops in neap tide and stratification is reduced and hypoxia is moderated in spring tide. However, it was not clarified that such variation in hypoxia was driven only by the physical process or affected by some biological process such as biological oxygen demand. In order to clarify the variation in mass transport and ecosystem, we made surveys in the inner most area of Ariake Sea in the summer of 2018. We made 6 transect surveys with a boat during a spring-neap cycle during continuous measurements of temperature, salinity, currents, DO and turbidity with moorings.

During the mooring observation period, as a typhoon attacked Ariake Sea on 27 July, most of the mooring instruments were once recovered. The surface mooring instruments was set again on 30 July, and other ones were set again on 1 August. Another typhoon attacked on 14 August but the mooring observation was continued. Between these 2 typhoons, transect surveys were conducted on 1, 5, 8 and 12 August during low tide. It was in neap tide on 5 August and in spring tide on 12 August. The water column was well mixed in the morning of 1 August at the mooring station (Stn. 3) due to strong tidal mixing in spring tide and wind induced mixing by the typhoon. The temperature decreased and salinity increased in the bottom layer toward neap tide. Stratification was strongest on 8 August. Then the stratification became weaker and the water column was entirely mixed again on 11 August. The bottom water DO decreased from 1 August and became lower than 3 mg/L on 4 August. The bottom DO was kept lower than 3 mg/L until 10 August. In the surface layer, the bloom of *Chattonella* sp. occurred from late July. It continued at least until 13 August. The results of the transect survey indicated that the cold and saline water intruded from offshore to enhance the stratification and formed hypoxic water mass. On 12 August, stratification weakened and the hypoxic water mass was disappeared in the coastal area. But, in the offshore area, weak hypoxic water mass was formed. High turbidity layer was formed over the bottom in the coastal area on 1 August. But the turbidity decreased on 5 and 8 August. The turbidity increased again and became highest on 12 August. The experiment to estimate the oxygen demand of the bottom water was conducted on the each survey day. The oxygen demand decreased from 1 to 5 August then increased and became maximum on 12 August. In order to estimate the contribution of bacterial respiration and chemical oxygen consumption to the total oxygen demand in water, we made incubation experiment with Chloramphenicol and formalin. Chloramphenicol was added to stop the bacterial respiration. Formalin was added to measure the chemical oxygen consumption. The bacterial respiration occupied about 80 % of the total oxygen demand on 6 August. However, almost all the oxygen demand was occupied by the respiration except for the bacterial respiration on 13 August. There was almost no chemical oxygen demand on each date. There was a high correlation between chlorophyll a concentration and oxygen demand (R=0.90). There was a correlation between turbidity and oxygen demand. But it was weaker than chlorophyll a (R=0.61).

The hypoxic water mass was generated by the cold and saline water intrusion occurred between spring

©2019. Japan Geoscience Union. All Right Reserved.

tide and neap tide. However, the oxygen demand in the bottom water decreased in this period. It indicated that the formation of hypoxia was generated by the physical process and the change in oxygen demand did not affected. The oxygen demand in spring tide was larger than in neap tide. It would be due to the active resuspension of organic matter by the strong tidal mixing. There was a high correlation between chlorophyll a and oxygen demand of water. But most of the oxygen demand when the hypoxic water mass was formed was bacterial respiration. The contribution of the phytoplankton respiration was small. They suggested the oxygen demand was mainly generated by the decomposition of organic matter derived from phytoplankton by bacteria. The red tide of *Chattonella* sp occurred continuously during the observation period. The maximum chlorophyll a concentration reached 72.3 ug/L. The organic matter supply from the red tide would fuel the oxygen consumption in the bottom layer.

Influence of Nori aquaculture-induced change in light environment on phytoplankton dynamics

*Naoya Minamiura[1], Soichi Yamaguchi[1]

1. Kyushu University

In the Ariake Sea in winter, Nori aquaculture is conducted actively, and its production is the largest in Japan. On the other hand, color bleaching of Nori due to red tide occurrence has become a big problem. From previous research, it is known that the red tide occurrence involves the improvement of the light environment. At the time of Nori aquaculture season, Nori aquaculture net is set densely in the coastal area, and leaf blade is attached to the net and it grows. It can be easily imagined that such net and leaf blade have great influence on the light environment in water, but there are no examples studied so far. In this study, by continuous on-site observation of the photon quantum amount in the Nori aquaculture area and the non-Nori aquaculture area, the influence of Nori aquaculture on the light environment is evaluated, and the influence is evaluated by dynamic growth of leaf blade as a function. We investigated how phytoplankton dynamics by incorporating these results into numerical simulation changes.
We installed a photon meter (DEFI2-L by JFE Advantech Co., Ltd.) and pressure gauge (DEFI2-D10 by JFE Advantech Co., Ltd.) respectively in the sea area just under the Nori aquaculture and in the non-Nori aquaculture area possessed by the Saga Prefecture Fisheries Experiment from January 15 to 25 in 2019. This continuous observation was carried out at 5 second intervals. As a result of the observation, it was revealed that the photon quantum amount decreased by about 75% on average just under Nori aquaculture area. The reduction of this photon (light shielding factor y) was expressed as a function of the leaf length (x unit: cm), and the following equation was obtained.

$y=0.86e^{-0.1\times x}$

Next, we developed a numerical ecosystem model that takes this light shielding factor into consideration and examined how it affects phytoplankton dynamics. Calculation was carried out separately into two patterns with and without light shielding factor in Nori aquaculture area. In consideration of the light shielding factor, the phytoplankton biomass was reduced in the vicinity of the Nori aquaculture area in the inner part of Ariake sea, compared to the case without consideration. This indicates that Nori aquaculture suppresses the growth of phytoplankton by deteriorating the light environment in water.

Enhanced West Philippine Sea intrusion diminishes hypoxia conditions in the Pearl River estuary

*Hon-Kit Lui[1,2], Chen-Tung Arthur Chen[1], Wei-Ping Hou[2], Jian-Ming Liau[2]

1. Department of Oceanography, National Sun Yat-sen University, 2. Taiwan Ocean Research Institute, National Applied Research Laboratories

The hypoxia condition (dissolved oxygen <2 mg/L) in the Pearl River estuary is worsening in the past decade, partly due to the rising anthropogenic activities. For instance, excess nutrients cause enhanced biological productivity in the surface ocean. Yet, dead phytoplankton sink to the bottom of the coastal zone, where they decompose and consume oxygen. If the oxygen consumption rate exceeds the supply rate, then hypoxia or even anoxia may develop, leading to so-called dead zones. Here we show that a strong invasion of high dissolved oxygen but low nutrients West Philippine Sea seawater into the South China Sea in the form of Kuroshio occurred around 2003-2004. Apparently due to the oxygen supply carried by the remnants of the intruded Kuroshio, little hypoxia developed off the Pearl River estuary, where the anoxic condition develops in some years with weak Kuroshio intrusion.

Reconstructing past ocean currents in the coastal regions is needed to better understand the relationship between oceanographic changes and coastal ecosystems. Seawater radiocarbon is a unique proxy to understand the properties of water masses. However, the knowledge of the water mass distribution is limited to the low latitude regions as the only well-established proxy for it is reef-building corals. Alternative archives are required for high latitude regions. Here we measured $\Delta^{14}C$ values of three abalone shells using accelerator mass spectrometry (AMS) and counted the shell growth checks which were made in the winter season. Abalone shells were obtained from Otsuchi Bay, where the cold Oyashio Current and the warm Kuroshio Current converge. The Oyashio Current has more depleted radiocarbon than the Kuroshio Current. We compared $\Delta^{14}C$ values of abalone shells with the sea surface temperature anomaly in Sanriku region. $\Delta^{14}C$ values of abalone shells range from 5.4 ‰to 31‰ and indicated seasonal variations. $\Delta^{14}C$ values decreased by about 5 ‰in shell growth checks that indicates winter season.We found this decrease of $\Delta^{14}C$ values of abalone shells are consistent with the significantly mixing of water brought by the Oyashio Current. $\Delta^{14}C$ value of abalone shells clearly shows the Oyashio Current inflow in 2013, 2015 and 2017 and it can be used to reconstruct fluctuations between past water masses. In addition, the $\Delta^{14}C$ values of abalone shells are possibly affected by their habitat. Abalone at 2 m to 6 m depth exhibited higher $\Delta^{14}C$ values than those in abalone at 6 m to 10 m depth. This trend resulted from cold water from the Oyashio Current having a greater influence on deeper water. These radiocarbon records indicate past seawater conditions in northern Japan, where the Oyashio and Kuroshio currents converge, can be reconstructed using abalone shells.

Spreading of Radioactive Cesium off Joban coast through Large River Discharge

*Kiyoshi Tanaka[1], Seiya Nagao[2], Yujiro Kitade[3], Masato Niki[4], Takaaki Katsumata[4], Toru Miyama[5]

1. University of Tokyo, 2. Kanazawa University, 3. Tokyo University of Marine Science and Technology, 4. Tokai University, 5. Japan Agency for Marine-Earth Science and Technology

A hydrographic observation was conducted off the Joban coast during September 7 to 12, 2011 (six months after the 2011 Great East Japan Earthquake), using a CTD profiler and a ship-mounted ADCP (R/V Tansei-Maru cruise KT-11-22). At the same time, water-samplings for radioactive cesium measurements were conducted at a depth of 10 m. The radioactivity of cesium (134Cs and 137Cs) was measured for the AMP/Cs compound using gamma-ray spectrometry at the Low Level Radioactivity Laboratory of Kanazawa University. There was a negative correlation between the radioactive cesium and salinity in the sea surface (at the depth of 10 m), indicating more radioactive cesium was included in less saline water. Abundant freshwater is discharged from three large rivers (Tone, Naka, and Kuji Rivers) into the observational area. What is important is that several days before the observation, there was extremely heavy rainfall in the upper reaches of the rivers, which resulted in that discharge of the Tone River exceeded 2000 m^3/s on September 4. Therefore, it was suggested that the highly concentrated radioactive cesium in the sea surface originated from the land through the rivers. Moreover, it was shown that spreading of the river water and radioactive cesium is strongly influenced by the Kuroshio Current.

Development of a river-ocean seamless model for simulating river discharges around Kyushu

*Takahiro Tsutsumi[1], Shinichiro Kida[2], Ryusuke Kuroki[3], Yosuke Alexandre Yamashiki[3]

1. Interdisciplinary Graduate School of Engineering Science, Kyushu University, 2. Research Institute for Applied Mechanics, Kyushu University, 3. Graduate School of Advanced Integrated Studies in Human Survivability, Kyoto University

Regional-scale torrential rainfalls cause river discharges that are capable of abruptly changing the oceanic condition over a wide area. It is necessary to simultaneously solve multiple rivers for capturing such events that are also often associated with flooding over land. Many coastal areas are also affected by multiple rivers but many of the conventional river-models to simulate the influence of rivers on a regional scale. The object of this research is to develop a river-ocean seamless model for simulating river discharges around Kyushu during and after weather events. By using an Isopycnal-Layered model following Kida and Yamashiki (2015), we developed a model that focuses on the island of Kyushu and the heavy rain event in September 2015. The model reproduces the increase in river flow due to the heavy rain and when compared to observations, we found some rivers to show slow water propagation speed from upstream to downstream, while some rivers reproduce the actual observation well. We plan to conduct a sensitively experiment to verify the cause behind this difference in the reproducibility of the model.

[A-OS15] Freshwater discharge through rivers and estuaries to the ocean

convener:Shinichiro Kida(Research Institute for Applied Mechanics, Kyushu University), Dai Yamazaki(Institute of Industrial Sciences, The University of Tokyo), Yosuke Alexandre Yamashiki(Earth & Planetary Water Resources Assessment Laboratory Graduate School of Advanced Integrated Studies in Human Survivability Kyoto University), Humio Mitsudera(Institute of Low Temperature Science, Hokkaido University), Chairperson:Shinichiro Kida(RIAM, Kyushu University), Humio Mitsudera(Hokkaido University, Institute of Low Temperature Science), Yosuke Yamashiki(GSAIS Kyoto University)

The water cycle from land to the ocean involves complex dynamics of rivers and buoyancy driven flows in estuaries and the ocean. Recent progress in satellite observations and numerical models are beginning to illuminate how this water cycle occurs on various time scales globally and regionally. This session welcomes various process studies that investigate the dynamics and material circulation related to the freshwater cycle from land to the ocean such as surface runoff, river transport, estuarine circulation, and coastal river plumes based on numerical, observational, or theoretical studies.

The forefront research for flow and water quality estimations in coastal area using geo-stationary and polar orbital satellites data

*Yuji Sakuno[1]

1. Graduate School of Engineering, Hiroshima University

Continuous estimation of the flow velocity and water quality distribution in a wide area at high resolution is extremely important in order to understand the natural phenomena occurring at the interface between the river and the ocean. In recent years,satellite remote sensing is expected as a powerful tool to grasp such phenomena. In this presentation, a case study of flow velocity estimation using the stationary meteorological satellite "Himawari-8" data, which observes sea surface temperature (SST) at 10 minute intervals at first. A strong flow velocity distribution of about 0.5 m/s was detected by applying the image correlation method to continuous SST images in the southern part of the Lombok Straits of Indonesia in the study area. Such a method can measure the flow velocity distribution of wide channel at low cost, so it is particularly effective in waters where there is a remarkable water temperature difference. Meanwhile, the heavy rain in western Japan occurred in July 2018, and a large amount of sediment from the land flowed out to the Seto Inland Sea. As a result, oyster beds for aquaculture were broken or red tide damage caused by a large amount of nutrient salt was occurred. The state of such huge flood were monitored by the polar orbital earth observation satellite such as Landsat-8, Sentinel-2 (10 m to 30 m spatial resolution) and GCOM-C (250 m spatial resolution). The polar orbital satellite has lower observation frequency than geostationary satellite, but there is an advantage that detailed distribution of sediment discharge from river and red tide distribution can be visualized. Combining such stationary / polar orbital satellite data, measured data, numerical model and other technologies will make it possible to monitor coastal environments connecting the open ocean and rivers more quickly and in detail in the future.

Rainfall-Runoff-Inundation Processes and Modeling in a Humid Tropical River Basin

*Takahiro Sayama[1], Kodai Yamamoto[2], Ryoko Araki[2], Apip Apip[3], Eva Mia Siska[1], Kaoru Takara[4]

1. Disaster Prevention Research Institute, Kyoto University, 2. Graduate School of Engineering, Kyoto University, 3. LIPI, Indonesia, 4. Graduate School of Advanced Integrated Studies in Human Survivability, Kyoto University

Large-scale plantations of palm and acacia trees have caused 50 % reduction of natural forests in the 25 years between 1985 to 2009 in Sumatra, Indonesia. Deforestation of natural forest might have changed water cycle in the area including runoff and evapotranspiration, which may lead to possible changes in flood and drought conditions. Downstream parts of river basins in Sumatra spreads wetlands with rich ecosystems, though such environment have degraded due to land cover changes over the last few decades to agricultural areas. Drying the wetlands by drainage for rice cropping and other agricultures caused various issues including peatland fire and haze in surrounding regions. In addition to the land cover change, climate change may give significant impact on the hydrologic cycle in this region. Climate change in humid tropical region in South East Asia has been difficult to be predicted due to local atmospheric cycle. Furthermore, hydrologic process understandings and their representations by simulation models are the important scientific step toward adequate assessment of land cover and climate changes. Among various hydrologic processes, rainfall-runoff processes in tropical climate conditions characterized also by deep weathered soil layers have been poorly understood. Our study is conducted based on field investigation with respect to rainfall-runoff processes in the mountainous hillslope in Sumatra to understand the fundamental characteristics of rainfall-runoff in this region, and to represent the feature particularly with a thick soil layer, in our distributed hydrologic model. After the calibration and validation of the model at the river basin scale in the Batanghari River basin, we assess the impact of the climate change by inputting the rainfall.

Some findings from the field monitoring are summarized below. According to a simple cone penetration experiment, the soil depths in the hillslope were estimated to be about 1.5 ~ 4.5 meters. Furthermore, the soil sample experiment at surface, 30 cm and 60 cm depths showed that saturated hydraulic conductivities were as high as 7,200 mm/h while the volumetric water content maintain also high (0.45~0.50) with negative suction between 1~10 m. Such characteristics should be explained due to the aggregated soil in humid tropics. In our site, the foot of the slope (SK1) has thicker soil layer (4.5 m), while it is reduced to 1.5 m about 20 m upstream along the hillslope (SK3). Groundwater table exists at the depths of about 3 ~ 4 m depth consistently at SK1 (bottom) and SK2 (middle) and the groundwater table responses rapidly to rainfall. With the high saturated hydraulic conductivity and high infiltration rate, especially in the natural forest area, we conceptualize the rainfall-runoff in this region is dominated by fairly quick vertical infiltration into the thick soil layer and the recharge to the groundwater table. Based on the above process understandings, we represent the process in the Rainfall-Runoff-Inundation (RRI) model to the entire Batanghari River basin to simulate streamflow at the river basin scale.

Role of river inflows from Kamchatka Peninsula in the Okhotsk Sea

*Toru Miyama[1], Humio Mitsudera[2]

1. Application Laboratory, Japan Agency for Marine-Earth Science and Technology, , 2. Institute of Low Temperature Science, Hokkaido University

The Okhotsk Sea is a unique ocean in that sea ice forms at the lowest latitude in the world. The sea ice formation plays important roles in water mass formations not only in the Okhotsk Sea but also in the North Pacific Ocean. The river inflows from the surrounding coasts affect the sea ice formation by changing stratification. Especially, the contribution from the river inflow from the Amur River on the western side of the Okhotsk Sea has been widely discussed. The roles of the Amur River in chemical and biological cycles have been also investigated. On the hand, the role of the river inflows from the Kamchatka Peninsula on the eastern side of the Okhotsk Sea is not well known.
In this study, we simulated the northern part of the Okhotsk Sea to investigate the roles of river inflows from the Kamchatka Peninsula. FVCOM (Finite-Volume, Primitive equation Community Ocean Model; Chen et al. 2003) was used. JRA55-do (Tsujino et al., 2018) was used for the atmospheric forcing. The river inflow dataset also came from JRA55-do based on Suzuki et al. (2017). The unstructured horizontal grid spacing was decreased from about 9.0 km at the southern boundary to about 1.4 km along the northern boundary.
The model runs with and without the river inflows from the Kamchatka Peninsula were compared. The salinity significantly increased without the river inflow along the coast of Kamchatka (by more than 1 unit at maximum). The salinity increase also spread toward the western Okhotsk Sea. With these changes in salinity, ice formation in the Okhotsk Sea was also affected.

Keywords: Okhotsk Sea, sea ice, river inflow

CHLOROPHYLL ESTIMATION OF LAKE AND COASTAL WATER USING REMOTE SENSING APPROACH

*Shweta Yadav[1], Yamashiki Yosuke[1], Junichi Susaki[1], Kanako Ishikawa[2], Yoh Yamashita[1]

1. Kyoto University, 2. LBERI

Chlorophyll-a is an optically active compound (OAC) commonly used as a proxy for phytoplankton biomass in an aquatic environment. Retrieving the concentration of chlorophyll-a remains a challenge due to the presence of several OAC particularly in water bodies which are in proximity to the land-based activities. In this study, an effort has been made to estimate the chlorophyll-a concentration of both the freshwater Lake Biwa and the coastal water of Wakasa Bay in Japan. A spectral decomposition algorithm was used to determine the chlorophyll-a using the satellite images. The algorithm was applied to the satellite images from two different sensors namely Landsat-8 /OLI and Sentinel-2A/MSI. The satellite-derived chlorophyll-a concentration for the lake and coastal water from two different sensors were compared to assess the performance of both the sensors. The accuracy of the chlorophyll-a results derived from the images was evaluated with the in-situ measurement data of the chlorophyll-a for the Lake Biwa and the coastal water of Wakasa Bay. Both satellite sensors appear to give the best results for the coastal water ($R^2 > 0.80$) with an RMSE < 0.3 μg/L. However, slight underestimation of chlorophyll-a noted for the Landsat-8 image with an increase in chlorophyll-a concentration. For the lake water, Sentinel-2A results were relatively better ($R^2 > 0.70$) than Landsat-8, with an RMSE of < 1.0 μg/L. The obtained results will be useful to evaluate the primary productivity of both freshwater and coastal water body.

Maritime-continent coastal region as land-sea-air triple boundary layer and bio-anthroposphere

*Manabu D. Yamanaka[1]

1. Research Institute for Humanity and Nature / Professor Emeritus of Kobe University

Imbalance of radiative processes determining climate is compensated by atmospheric-oceanic circulations and latent heating. The latent heat generated mainly by equatorial cumulonimbus clouds concerns both overheating and circulation pumping. Since the equatorial atmosphere is almost free from Coriolis force making cyclones, the diurnal-cycle sea-land heat contrast is the most principal mechanism to generate cumulonimbus and thus rainfall. The earth’ s longest coastline of Indonesian maritime continent (IMC) generates the largest regional rainfall and latent heat controlling the global climate (Yamanaka et al., 2018, *Prog. Earth Planet. Sci.*, **5**(21), 1-28). Massive fresh water sustains the biosphere with biodiversity over the peatland of major islands of the IMC, which also concern the carbon cycle through making peats and coals as geologically long-term reservoirs. We homo sapiens originated from the tropical Africa and evacuated to the temperate zone, where coexistence with other species was easier and thus proliferation and civilization were achieved with making the tropics a field for grabbing both alive and fossilized bio-resources. On one hand, the human population is governed by the rain water for survival, agricultural and industrial use. On the other hand, the human activity after the industrial revolution has been consuming the fossil fuels, and has been modifying the peatland for plantations, which release massive greenhouse gases. Such interactions are being studied mainly in the eastern coast of Sumatera and the southern coast of Kalimantan, under an interdisciplinary project (RIHN Tropical Peatland Society Project, 2017-21). Based on rainfall variabilities of mesoscale (with radars, and as functions of coastal distance), intraseasonal to interannual scales (based on operational data) and interdecadal to centennial scales (by historical data rescue), we may discuss a “saturation” of anthroposphere in the tropical coastal region such as the IMC peatland.

River-ocean interaction at the Ganges-Brahmaputra river mouth

*Shinichiro Kida[1], Dai Yamazaki[2]

1. Research Institute for Applied Mechanics, Kyushu University, 2. Institute of Industrial Sciences, The University of Tokyo

The Ganges-Brahmaputra river is a major source of freshwater for the Bay of Bengal. River discharge occurs through the Ganges-Brahmaputra Delta, which consists of multiple river mouths. The seasonal cycle of this river discharge is observed with a minimum from late winter to early spring and a maximum from late summer to early fall. The seasonal cycle of the sea surface height for the Bay of Bengal, on the other hand, shows the presence of the Kelvin waves propagating from the equatorial Indian Ocean. We investigated how these two processes may interact at the river mouths based on a high-resolution numerical model that resolves the various channels of the Ganges-Brahmaputra Delta. The model simulates the basic seasonal cycle of the river discharge that is comparable to observations, with a river plume forming from the major river mouth and along the coast. Preliminary results suggest significant river-ocean interaction in narrow channels and, at times, reverse the direction of the river flow.

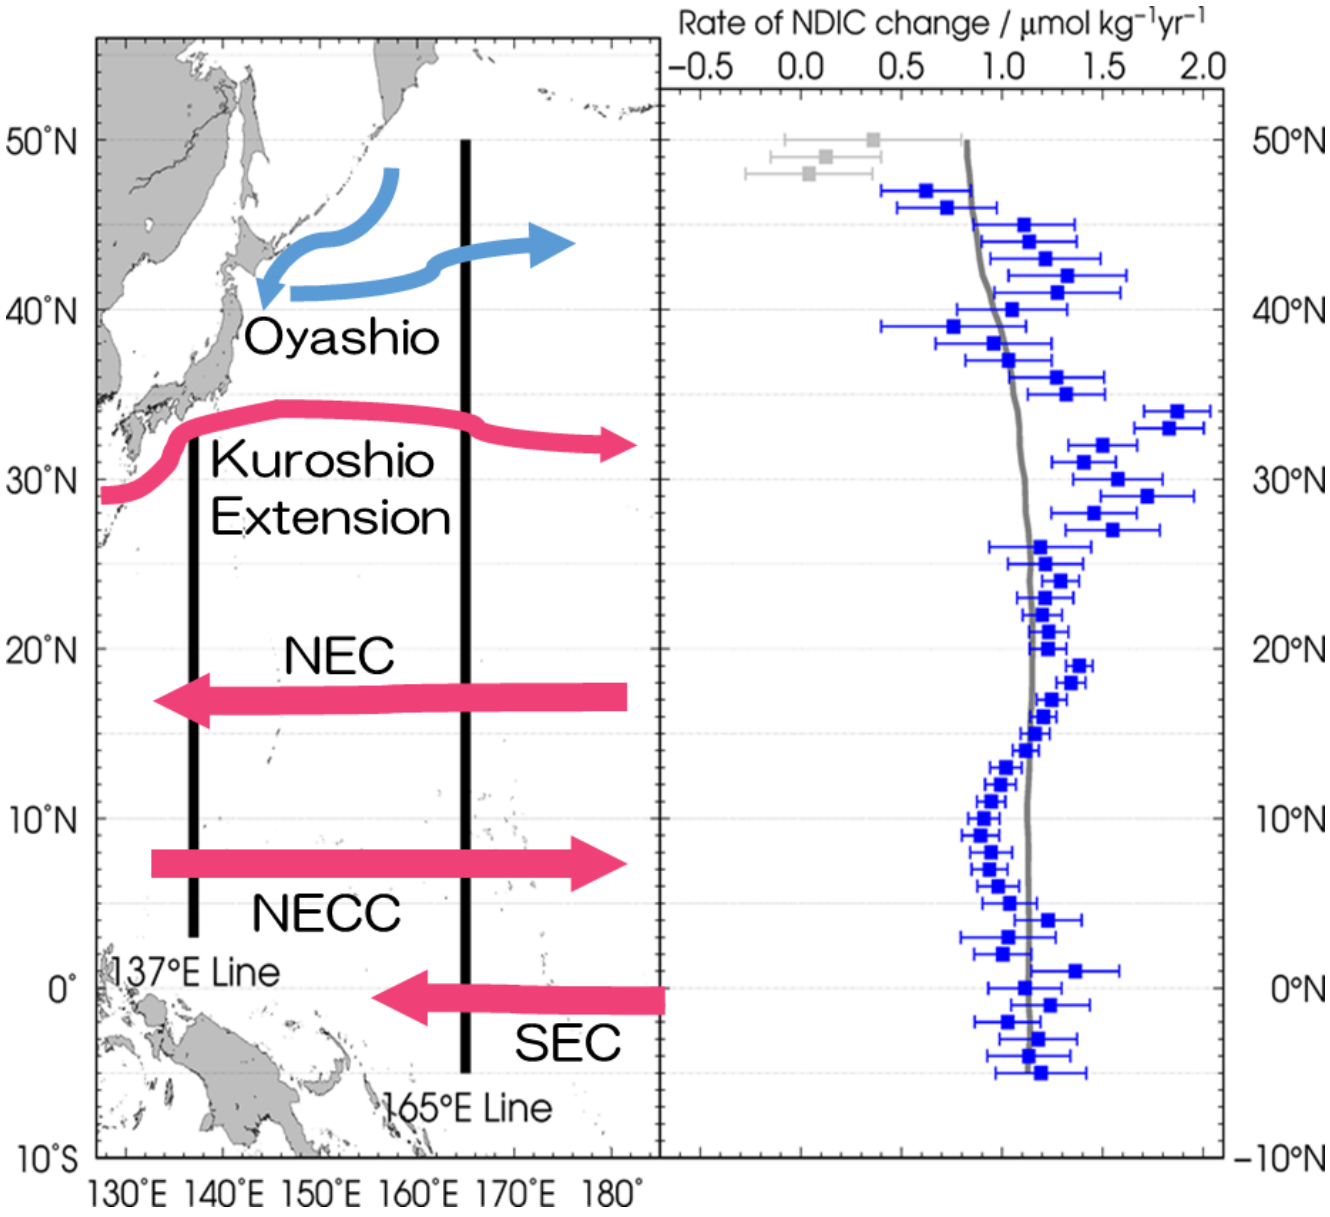
Variability of the growth rate for dissolved inorganic carbon in surface seawater along the 165˚E line

*Chiho Tanizaki[1], Hisashi Ono[2], Masao Ishii[2], Atsushi Kojima[1], Shinji Masuda[1], Kazutaka Enyo[1], Daisuke Sasano[1], Toshiya NAKANO[1]

1. Japan Meteorological Agency, 2. Meteorological Research Institute, Japan Meteorological Agency



The atmospheric concentration of carbon dioxide (CO_2) has reached 146% of the pre-industrial level resulting from the increase of CO_2 emissions by human activities. On the other hand, the ocean has absorbed about 30% of the anthropogenic CO_2, which leads to the regulation of the atmospheric CO_2 increase (IPCC, 2013). Midorikawa et al. (2012) found that the increase of the partial pressure of oceanic CO_2 (pCO_2^{sea}) along 137˚E recently decelerates though that of atmospheric CO_2 accelerates. The variability of pCO_2^{sea} is affected by the changes in sea surface temperature and salinity, dissolved inorganic carbon (DIC), and total alkalinity, and the investigation of the DIC changes in the surface seawater helps us to understand the oceanic absorption of atmospheric CO_2. In this study, the variability of DIC in surface seawater is examined from subarctic to equatorial region along 165˚E, one of the repeat hydrographic sections of Japan Meteorological Agency (JMA).

Using the observation data collected by JMA’s Research Vessels in the 165˚E section and surface ocean CO_2 atlas (SOCAT) version 6, we calculated the mean trend of DIC in surface seawater during the period of 1996-2017. We found that DIC increases slower around 10˚N, and faster around 30˚N than atmospheric CO_2. Also, DIC growth rate is similar to the rate of atmospheric CO_2 increase in the equatorial region.

The variability of the DIC trend averaged for 10 years indicates that the DIC growth rate has increased in the equatorial region and decreased around 30˚N.

Seasonal variations of oceanic CO_2 disequilibrium and anthropogenic CO_2 in the subarctic North Pacific

*Bofeng Li[1], Shukuta Satori[1], Kasai Hiromi[2], Hiroshi Kuroda[2], Taniuchi Yukiko[2], Daisuke Hasegawa[3], Yutaka Watanabe[1]

1. Hokkaido University, 2. Hokkaido National Fisheries Research Institute, Japan Fisheries and Education Research , 3. Tohoku National Fisheries Research Institute, Japan Fisheries and Education Research

Assuming that the CO_2 above the surface mixed layer depth (MLD) mixes very well with air, we used a simple and new method to estimate air-sea CO_2 disequilibrium value at the MLD (C_{diseq}) as follow [*Li et al.*, 2019];

$$C_{diseq} = C_{MLD} - C_{sat,\,MLD} - C_{soft,\,MLD} - C_{carb,\,MLD}$$

where C_{MLD} is the observed dissolved inorganic carbon (DIC); $C_{sat,\,MLD}$ is saturated DIC; $C_{soft,\,MLD}$ is derived from the remineralization of organic matter; $C_{carb,\,MLD}$ is derived from the dissolution of $CaCO_3$ in the MLD. We collected the DIC and total alkalinity (TA) samples in the subarctic North Pacific in four seasons, and measured all the DIC and TA by using semi-closed cell simultaneous method [*Li et al.*, 2016].

C_{diseq} in this region changed from −38.29 to −56.93 μmol kg^{-1} in wintertime and from −9.65 to 1.02 μmol kg^{-1} summertime, indicating a strong seasonal change in C_{diseq}. Appling these values of C_{diseq} to the approach for estimating C_{ant} in this region, we also found a strong seasonal variation in C_{ant}.

An evaluation of current and future ocean acidification based on pCO_2 database around Okinawa Island

*Naohiro Kosugi[1], Hiroyuki Tsujino[1], Masao Ishii[1]

1. Meteorological Research Institute

1. Introduction

Ocean acidification is caused by the dissolution of anthropogenic CO_2 into seawater. When CO_2 is dissolved in seawater, pH and the carbonate ion concentration decrease. A variety of marine organisms may be adversely affected since they use calcium carbonate as the main component of hard tissues such as shells and skeletons.

Coral reefs in the tropical zone are thought to be vulnerable to ocean acidification as they have a skeleton of aragonite which is a form of calcium carbonate. Ocean acidification will have adverse impacts on not only coral reefs but also whole tropical ecosystem since coral reefs are important for spawning, hatching, and habitat for many organisms.

Many coral reefs exist around Okinawa and bring a lot of benefits there by fishery and tourism. Geographically, coral reefs around Okinawa are located at the higher latitudinal area where the water temperature drops largely in winter.

In this study, we use the Surface Ocean CO_2 Atlas (SOCAT) database to evaluate the progress of ocean acidification around Okinawa from the 1980s to the present. Based on the results, we project the progress of acidification under future CO_2 concentration scenarios. This projection will reproduce seasonal variation in pCO_2 and aragonite saturation (Ω_A) there more realistically than existing predictions on a global scale.

2. Methods

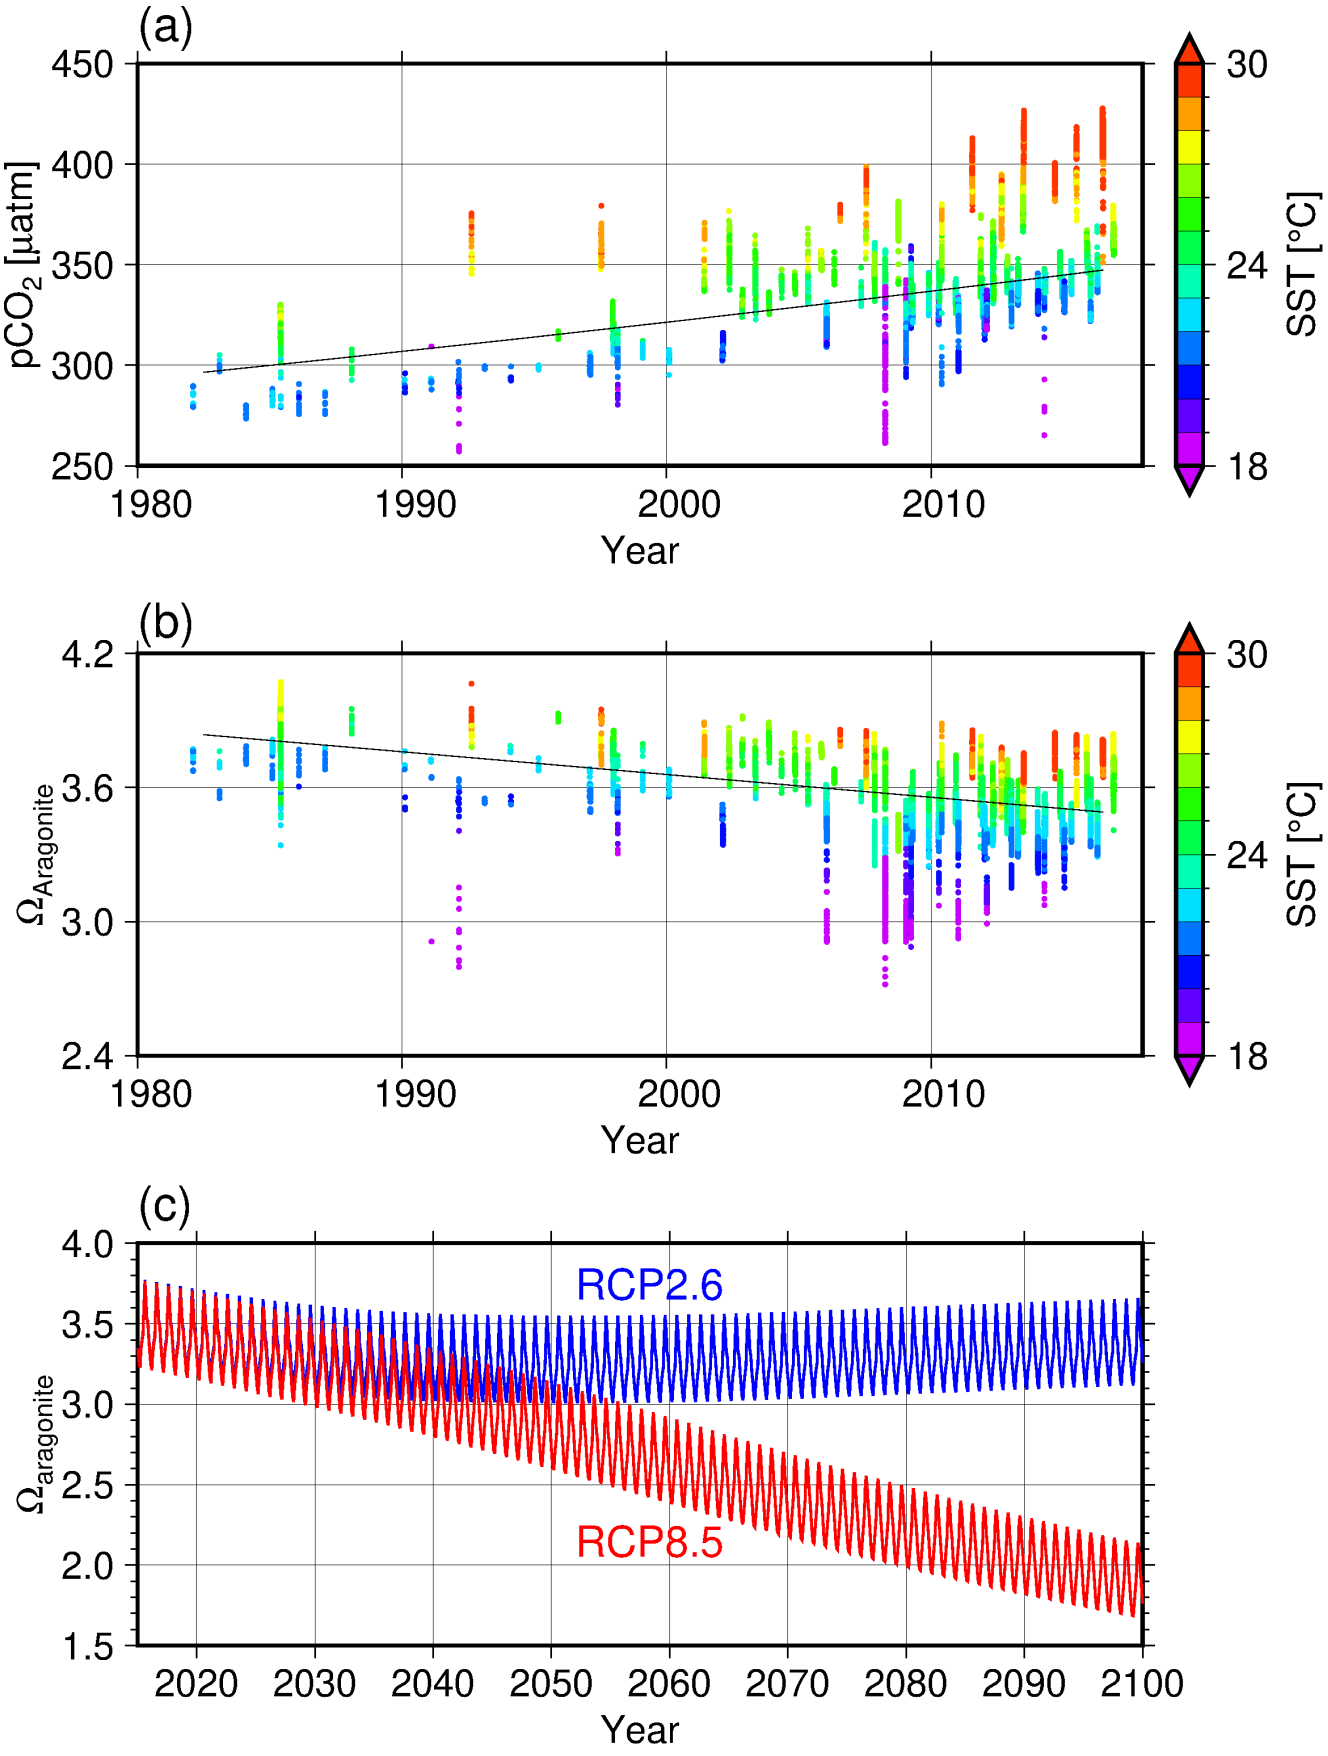
The data of surface water temperature (SST), salinity (SSS) and pCO_2 around Okinawa (24-30˚N, 123-130˚E) were extracted from SOCAT database. We used the results of hydrographic observations conducted by the Japan Meteorological Agency in the same area between 2010 and 2017 in order to derive an empirical equation between salinity and total alkalinity (TA). Ω_A were calculated from pCO_2 and estimated TA using the CO2SYS program.

3. Results

In 1982-2016, pCO_2 showed a long-term trend of increase (Fig. a). At the same time, pCO_2 was high in summer and low in winter. Long-term and seasonal variation in pCO_2 was separated by using the method by Ishii et al., [2011]. As a result, the component of the long-term trend was +1.49±0.26 μatm/year (95% CI). This was as high as the rate of increase in atmospheric pCO_2 at Mauna Loa in Hawaii in the same period (+1.73±0.04 μatm/year).

TA was basically proportional to salinity (TA = 2297.1 / SSS * 35). In some areas near the shelf in the East China Sea, however, there was a positive anomaly from this relation. This may be due to the influence of river water originated from the Changjiang River. Another equation was applied (TA = 1347 + 897.6 / 34.2 * SSS) to the data to the north of 26˚N with SSS < 34.2 from July to September.

As for Ω_A, a long-term trend -0.0102±0.0018/year was calculated in the same manner as pCO_2. Previous studies showed that the coral reef habitat coincided with the area where Ω_A does not fall seasonally below 3.0 [Kleypas et al., 1999]. In the present situation, Ω_A around Okinawa island (SST > 21˚C in winter) was kept at 3.0 or more throughout the year.



©2019. Japan Geoscience Union. All Right Reserved.

4. Future projections
We can project the fluctuation in the ocean pCO_2 and Ω_A under future CO_2 concentration scenarios assuming that the current difference between in pCO_2 in the atmosphere and the ocean (ΔpCO_2) will not change in the future. Monthly ΔpCO_2 was averaged from the SOCAT database. CO_2 concentrations for the Representative Concentration Pathways (RCPs) were used to calculate atmospheric pCO_2 up to 2100 [Meinshausen et al., 2011]. Climatology of SST and SSS from 1982 to 2014 was calculated from Northwest Pacific Ocean Long-term Reanalysis Data Set (FORA-WNP30) and applied to the prediction. In the RCP 2.6 scenario, Ω_A will be at 3.0 or larger during this century. However, in the RCP 8.5 scenario, Ω_A will drop seasonally below 3.0 in the north of Okinawa island around 2030. In that scenario, Ω_A will be lower than 3.0 throughout the year in the 2060s (Fig. C). If the current increase in atmospheric CO_2 continues, coral reefs around Okinawa will be seriously affected by ocean acidification in the near future. On the other hand, there is a possibility that a suitable environment for coral reefs around Okinawa can be maintained under a strict emission reduction.

5. Figure captions
(a) pCO_2 around Okinawa during 1982-2016 from SOCAT database. SST is shown in color. Black line indicates the deseasonalized trend of pCO_2.

Reconstruction of spatiotemporal change of anthropogenic fixed nitrogen in the western North Pacific

*Yutaka Watanabe[1], Kouichi Fujita[1], BOFENG LI[1]

1. Hokkaido University

We constructed parameterizations for the estimation of ocean fixed nitrogen (N) in the western North Pacific. Parameterizations (N_p), determined as a function of temperature (T), potential density (sigma-theta) and dissolved oxygen (DO), provided strong correlations with direct measurements for ocean nitrogen (N_p = −2.24T −4.70sigma-theta −0.0970DO + 182.2; the coefficient of determination (r^2) = 0.988; the root mean square error (RMSE) = 1.25 umol kg^{-1}). Predicted N values were consistent with previous independent hydrographic observations, generally within the above error. By applying T, sigma-theta and DO time-series data from ship observations to our parameterization, large seasonal variations in N were demonstrated in detail. Using the parameterization technique along with the time series of observed N (N_{obs}) found the significant increasing rate of oceanic anthropogenic fixed nitrogen (N_{anth}) in the past four decades in the western North Pacific subtropical region.

On the mechanism of significant increasing trend of silicate in intermediate layer of Oyashio region

*Tsuneo Ono[1]

1. Fisheries Research and Education Agency

A large multi-decadal increasing trend of Silicate was found in the intermediate later of Oyashio region [Whitney et al., 2013]. The rate of silicate increase was significantly rather than those observed in other nutrients under the asamption of normal Redfield ratio, but mechanism of such large Si increase has long remaind unknown.
Here, I demonstrate that the observed silicate increase can be exprained by the facts that 1)Rapid warming of intermediate waters of Okhotsk Sea had deepen isopycnal surfaces and 2)this causes steep increase of silicate concentration in the water that mixes with Oyashio waters on a same density surface.

Keywords: long-term trend, silicate, Oyashio, Okhotsk Sea

Systematics of aluminum, manganese, iron, cobalt, and lead in the North Pacific Ocean observed during ocean-section study of GEOTRACES Japan

*Yoshiki Sohrin[1], Linjie Zheng[1]

1. Institute for Chemical Research, Kyoto University

Trace metals in seawater are critical parameters in oceanography as trace nutrients for organisms, tracers in the modern ocean, and proxies in paleoceanography [1]. The international study programme GEOTRACES based on intercalibrated methods is revealing global distributions and temporal variations of trace metals in the ocean (http://www.geotraces.org). We have developed a method for multielemental determination of Al, Mn, Fe, Co, Ni, Cu, Zn, Cd, and Pb in seawater using NOBIS Chelate-PA1 resin [2, 3], and revealed basin-scale and full-depth sectional distributions of the trace metals in the North Pacific during three GEOTRACES Japan cruises of R/V Hakuho Maru: a 160°W section during KH-05-2, a 165°E section (GP18) during KH-11-7, and a 47°N section (GP02) during KH-12-4. The elements showed different speciations and distributions. The fraction of labile particulate (lp) species was calculated as the difference between the total dissolvable (td) species and dissolved (d) species. The lpM/tdM ratio, where M refers to an element, is highest for Al, at 0.66 ±0.31 (average ±sd, n= 489), and lowest for Pb, at 0.02 ± 0.08 (n= 575). The distribution of each element is uniquely related to ocean circulation. We propose that the enrichment factor of dM, defined as EF(dM) = $(dM/dAl)_{seawater}/(M/Al)_{upper\ crust}$, where $(M/Al)_{upper\ crust}$ is the molar ratio in upper crustal abundance, can be a good parameter for the sources. As an example, the EF(dPb) found in this study is on the same order of magnitude as the EF values for aerosols found in the literature, suggesting that the deposition of aerosols is a major source for dPb. The lpFe dominates tdFe and is strongly correlated with lpAl: lpFe = 0.543 lpAl −0.12, r^2= 0.968, n= 510. The results also indicate that the dFe concentration corrected for lithogenic contribution improves the linear relationship with phosphate. Thus, we suggest that the mechanism controlling a scavenged element of Al significantly affects the biogeochemistry of Fe. Based on the concurrent observation of these metals, we confirm that the width of the boundary scavenging zone is approximately 500 km off the Aleutian shelf. We estimate an inventory of tdFe in the North Pacific as 1.1 ×10^{12} mol, and this is approximately four times that of dFe. The results emphasise the potential importance of lpFe in the ocean iron cycle.

[A-OS19] Dynamics of oceanic and atmospheric waves, vortices, and circulations

convener:Yuki Tanaka(Graduate School of Science, The University of Tokyo), Ryo Furue(APL/JAMSTEC), Yukiharu Hisaki(University of the Ryukyus), Norihiko Sugimoto(Keio University, Department of Physics), Chairperson:Norihiko Sugimoto, Ryo Furue

Oceanic and atmospheric dynamics aims at abstracting general principles from observed phenomena and constructing a system of mathematical models, thereby leading to the understanding, prediction, and parameterization of those phenomena. It provides perspectives for the advancement of sciences in various areas such as wind waves, swells, internal waves, Rossby waves, equatorial waves, tides, eddies, meandering of jets and fronts, general circulation, boundary layers, and ocean-atmosphere coupled modes. It has also been and will continue to be benefited by new uses of ideas and methods from such theories as resonance, nonlinear interaction, spectral analysis, probability, statistics, and dynamical systems. In this session, we solicit presentations on observational, experimental, numerical, and theoretical studies of oceanic and atmospheric dynamics and on exploratory use of new ideas and methods. We also welcome presentations on interdisciplinary studies in fields such as ecosystems, climate, and environment.

This study derived Ekman pumping velocity without assuming that the velocity in the free atmosphere is not slow to be neglected and not homogeneous. Unlike the classic solution that is widely recognized, the solution can be unstable when the flow in the free atmosphere satisfies some conditions. The solution shows that the flow is more likely unstable when the velocity is fast and spatial variation of relative vorticity is large. One example that would be applied to Earth’ s atmosphere is secondary eyewall formation in tropical cyclone, which has been one of the hottest topics in typhoon research field in the last decades. The authors successfully showed the secondary eyewall formation in simulated cyclones is attributed to the Ekman pumping instability.

Extratropical Cyclone Structures around Japan -Comparison between Extratropical Cyclones Developing around Japan and those in Northwestern Atlantic Ocean-

*Eigo Tochimoto[1], Hiroshi Niino[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

Extratropical cyclones (ECs), which have horizontal scale of several thousands and time scale of a week, develop mainly in mid-latitude. They affect daily weather and sometimes cause extreme rainfall and severe winds, which result in meteorological disasters. ECs also affect climate variability: They interact with low-frequency variability such as North Atlantic oscillation. It is also pointed out that diabatic effects associated with ECs contribute to the initiation of atmospheric blocking.

Generally, there are two major conceptual model of ECs. The first model is Norwegian model, which was proposed in the beginning of 20 century. In this model, cold fronts catch up with warm fronts, and then occluded fronts form in the mature stage of ECs. The second model is Shapiro-Keyser model, which was proposed in 1990’ s. In this model, an occluded front does not form, and bentback fronts extending rearward from the EC center develop. These two conceptual models are proposed mainly with the results of studies in the Northwestern Atlantic Ocean and Europe. Although the Northwestern Pacific is one of the major storm tracks, difference in EC structures between Northwestern Atlantic and Northwestern Pacific Oceans have not been well understood. In addition, a considerable number of ECs also passes over the Sea of Japan and Okhotsk Sea. Thus, the objective of our study is to clarify the differences in structures between ECs that develop around Japan and those develop in Atlantic Ocean

Firstly, ECs are automatically detected with the tracking method developed by Hodges (1994, 1995, 1999). Secondly, ECs that develop in Okhotsk Sea or the Sea of Japan (OJC), Northwestern Pacific (POC) and Northwestern Atlantic (AOC) were selected based on the locations where the ECs underwent the maximum deepening rate (in Bergeron; Sanders and Gyakum 1980). In the present study, only ECs with Bergeron larger than 0.5 are used to examine the structures of fully-developing ECs. In the composite analysis, physical variables are superposed with respect to the cyclone center. Furthermore, to examine differences in frontal characteristics between POCs and AOCs, atmospheric fronts are objectively detected with a method using thermal front parameter (e.g., Schemm et al. 2015).

The composite analysis shows clear differences in structures between OJCs, POCs and AOCs: OJCs have relatively strong cold fronts compared to warm fronts at KT, especially in Spring. On the other hand, both warm and cold fronts develop well for POCs and AOCs. Differences in frontal characteristics between POCs and AOCs are most notable in warm fronts. Warm fronts for AOCs tend to extend eastward or east-northeastward from the EC center, while those for POCs southeastward. It is also noted that bentback fronts for AOCs are stronger than those for POCs.

An analysis using a frontogenesis function shows that this difference in warm front is mainly due to the effect of shear deformation: the shear deformation in the southeast quadrant of POCs is larger than that of AOCs, resulting in development of the warm fronts in the southeast quadrant of the EC center for POCs, which are most notable in warm fronts.

Application of a new wave energy flux formulation to assessment of tropical wave propagation dynamics: Diagnostics for the tropical synoptic-scale wave disturbances in the Maritime Continent-northern Australian region

*Fukutomi Yoshiki[1], Hidenori Aiki[1]

1. Institute for Space-Earth Environmental Reasearch, Nagoya University

A two-dimensional (horizontal) wave energy flux (WEF) formulation derived by Aiki et al. (2017, PEPS) is used to diagnose the dynamics of the tropical synoptic-scale waves (TSWs) propagating across the Maritime Continent and northern Australian (MCNA) region. The new WEF vectors are considered to be useful to assess energy dispersion characteristics of various types of waves in both the tropics and extratropics. The WEF is defined by adding a rotational flux term that includes Ertel potential vorticity (EPV)-based flow to the eddy geopotential flux. We computed eddy components of EPV-based stream function and corresponding wind fields from the atmospheric reanalysis (JRA-55) data using a numerical inversion technique to estimate the additional rotational flux term. The TSWs analyzed in this study have periods of about 2-8 days and zonal wavelengths of about 3000-4000 km (Fukutomi 2018, submitted to JGR). These waves propagate westward at approximately 8 m/s along the mean monsoon westerly flow extending from the Indian Ocean to the western Pacific. Wave troughs and ridges form a well-organized wave train in the MCNA region. Eastward amplification of wave troughs and ridges due to group propagation occurs along the monsoon westerly flow. WEF diagnostics confirm that wave energy propagation facilitates the downstream development of the synoptic-scale wave train and the mean monsoon westerly flow acts as a tropical waveguide. Distribution and behavior of the WEF vectors are compared with those of traditional wave activity and energy flux vectors. Applicability of this new tool to other types of the tropical waves and extratropical waves is also discussed.

Direct measurement of turbulent fluxes at sea-air interface by micrometeorological technique

*Fumiyoshi Kondo[1], Shujiro Komiya[2], Kosuke Noborio[3], Hidenori Aiki[4], Kunio Kutsuwada[5], Mitsuo Uematsu[6], Osamu Tsukamoto[7]

1. Japan Coast Guard Academy, 2. Max Planck Institute for Biogeochemistry, 3. Meiji University, 4. Nagoya University , 5. Tokai University, 6. The University of Tokyo, 7. Okayama University

Accurate parameterizations of sea–air momentum, sensible and latent heats, trace gases (e.g. greenhouse gases including CO_2 and CH_4), and aerosol fluxes are important in sea–air interaction. Coupled ocean–atmosphere global climate models require high accuracy of the net surface heat flux for the prediction of climate change, and process–based understanding of particle formation from bubble bursting to realistically predict the climate effect of marine aerosols. Precise measurements of the CO_2 gas transfer across the air–sea interface provide a better understanding of the global carbon cycle. The eddy covariance technique is the definitive method to directly determine these sea–air fluxes, but it requires measurements of the vertical and downwind components of air velocity, air temperature, humidity, trace gases, and aerosol over a sufficiently long averaging period (> 30 min) and with sufficient frequency response (< 10 Hz). One of the greatest difficulties in measuring sea–air flux by the eddy covariance technique over the open ocean is the apparent wind velocity caused by the wave–induced platform motion. As a result, the uncorrected eddy covariance results are all strongly biased, and especially represent unrealistic momentum fluxes. Improved ship motion correction scheme with Kalman filter results in a significant reduction in both the bias and the scatter of momentum fluxes. Previous studies over the oceans have shown that the eddy covariance CO_2 flux was larger than the bulk CO_2 flux estimated by the mass balance technique. Our results suggest that the density correction due to the air pressure fluctuation, which is assumed to be negligible in the WPL correction, is required to evaluate the accurate eddy covariance CO_2 flux over the ocean.

Swell-Dominant Surface Waves Inherent in the Shape of the Rias Coast facing the western North Pacific

*Kosei Komatsu[1,2], Takaki Fujii[1,2], Kiyoshi Tanaka[2]

1. Graduate School of Frontier Sciences, The University of Tokyo, 2. Atmosphere and Ocean Research Institute, The University of Tokyo

Real-time monitoring of wind and surface waves in Otsuchi Bay, a ria located in the northeastern portion of Japan, had been continued over four years since October 2012, using a mooring buoy with an ultrasonic anemometer and a single-mode GPS wave sensor. The monitoring revealed that waves in the bay were dominated by swells propagated from the northeastern offshore region in all seasons. Time-lag correlation coefficient between the significant wave height in the bay and the offshore wind velocity component blowing in the direction to the bay was maximized in the region approximately 300 km northeast of the bay, from which waves developed by the local wind are accessible within the corresponding time-lag to the bay at a speed of the group velocity of the swell observed in the bay. As an interesting feature common to swell-dominant waves observed in the rias bays adjacent to Otsuchi Bay, the region of the significant correlation between the wave height and the offshore wind velocity extends to the direction that faces the bay mouth. It implies that the source region of the swell depends heavily on the coastal shape of the bay. Consequently, the relation between the offshore wind field and the decay-rate of the swells propagating to Otsuchi Bay indicates that the source region of the swell influential in the bay is located in the offshore region several hundreds of kilometers northeast of the bay, which is on the typical migration route of high and low pressures in the Northern temperate zone.

Variabilities of the Sea Surface Height in the Kuril Basin of the Okhotsk Sea: Coherent shelf-trapped mode and Rossby wave-like mode

*Vigan Mensah[1], Kay I. Ohshima[1]

1. Institute of Low Temperature Science

Time series analysis of Sea Surface Height anomaly (SSHa) is conducted in the Kuril Basin of the Sea of Okhotsk. The mapping methodology of the satellite-derived SSHa data is optimized to mitigate the effects of sea ice on the SSHa field during winter and the early spring. In particular, we found that conducting an objective mapping of along-track SSHa data with correlation length and time scales adapted to the Kuril Basin considerably reduces the number of missing data days in this region. A Complex Empirical Orthogonal Functions (CEOF) is then used to analyze the SSHa field, and the first 3 modes, representing 54 % of the total variability are delineated here. The focus is brought on the first and third modes. The first mode mainly represents the coherent variability trapped over the shelves all along the coast and Kuril Islands. Both seasonal (high over the shelves in winter) and interannual variations are strongly correlated with the alongshore wind stress. These variations can be well explained by the arrested topographic waves. The third mode is a propagating mode, with trains of southwestward propagating anomalies. Their characteristics are consistent with those of westward propagating Rossby waves, whose energy propagates from the Kuril Straits towards the Kuril Basin.

Mon. May 27, 2019 10:45 AM - 12:15 PM JST | Mon. May 27, 2019 1:45 AM - 3:15 AM UTC | 301A 3F

[A-OS19] Dynamics of oceanic and atmospheric waves, vortices, and circulations

convener:Yuki Tanaka(Graduate School of Science, The University of Tokyo), Ryo Furue(APL/JAMSTEC), Yukiharu Hisaki(University of the Ryukyus), Norihiko Sugimoto(Keio University, Department of Physics), Chairperson:Yukiharu Hisaki(琉球大学理学部), Hidenori AIKI

Oceanic and atmospheric dynamics aims at abstracting general principles from observed phenomena and constructing a system of mathematical models, thereby leading to the understanding, prediction, and parameterization of those phenomena. It provides perspectives for the advancement of sciences in various areas such as wind waves, swells, internal waves, Rossby waves, equatorial waves, tides, eddies, meandering of jets and fronts, general circulation, boundary layers, and ocean-atmosphere coupled modes. It has also been and will continue to be benefited by new uses of ideas and methods from such theories as resonance, nonlinear interaction, spectral analysis, probability, statistics, and dynamical systems. In this session, we solicit presentations on observational, experimental, numerical, and theoretical studies of oceanic and atmospheric dynamics and on exploratory use of new ideas and methods. We also welcome presentations on interdisciplinary studies in fields such as ecosystems, climate, and environment.

Dynamics of water exchange processes at a deep submarine canyon off the western coast of the Sakhaline which causes the origin of the cold water belt along the Soya Warm Current

*Humio Mitsudera[1], Hiroyuki Iida[2]

1. Institute of Low Temperature Science, Hokkaido University, 2. Graduate School of Environmental Science

A cold water belt (CWB) is observed off the Soya Warm Current, the former of which appears from the west coast of the Sakhaline Island. Observations of the CWB (Kuma et al., 2016; Iida et al., 2018) indicates that the CWB, characterized by a cold and saline water (temperature 7℃, and salinity 34.0), is derived from the lower part of the thermocline in the Japan Sea basin. This implies that the cold and saline water in the Japan Sea basin should overcome the shelf break, which is not easy in general, and be transported to the vicinity of the coast of Sakhaline. The aim of this study is to elucidate mechanisms of water exchange between the Japan Sea basin (continental slope) and the continental shelf.

We first analyzed the output of a general circulation model OFES with the 1/30° resolution. It was found that the water over the continental slope enters the continental slope at a deep submarine canyon off the Kholmsk city on the west coast of the Sakhaline. Further, a barotropic model using Princeton Ocean Model (POM) with a realistic topography shows the exchange at the canyon in a similar manner to OFES, even though water exchange would not readily occur at the shelf break because of a potential vorticity (PV) barrier. We thus conducted numerical experiments using idealized topographic features mimicing the canyon off the Kholmsk in order to understand the barotropic exchange processes. The throughflow across the Soya Strait occurs owing to the adjustment of sea level difference between the Japan Sea and the Sea of Okhotsk by long shelf waves. It was found that the shelf waves are scattered into the second and third mode waves at the canyon, which have large transport over the continental slope; the scattered flow over the continental slope directed southward, and enters the continental shelf at the canyon. Further, nonlinearity is important in the vicinity of the canyon during the scattering process. Specifically: 1) nonlinearity produces a wave guide across the shelf break overcoming the PV barrier, by bringing low PV water from the continental slope to the continental shelf; 2) High-order mode waves (higher than 4^{th} mode) are retarded from propagation because of the background flow caused by 1^{st} -3^{rd} modes, making the flow over the continental slope steady. The nonlinear steady flow over the slope upwells at the canyon and connects to the flow over the shelf, and consequently flows through the strait.

Finally. hydrographic data during 1960-1985, archived at the Japan Hydrographic Data Center, was analyzed. Potential temperature and salinity from July to October was used. It was confirmed that the upwelling occurs at the canyon off the Kholmsk.

Generation Mechanism of Tropical Instability Waves in the Equatorial Pacific Ocean

*Yuki Tanaka[1], Toshiyuki Hibiya[1]

1. Graduate School of Science, The University of Tokyo

Tropical instability waves (TIWs) are prominent features observed in the eastern to central equatorial Pacific, which typically have a wavelength of ~1000 km and a period of ~25 days, propagating westward at a speed of ~0.5 m/s. Although TIWs are thought to be generated by meridional shear between the westward-flowing South Equatorial Current (SEC) and the eastward-flowing North Equatorial Countercurrent (NECC), the decisive parameter responsible for the occurrence of the instability has not yet been fully understood. Because the meridional and vertical momentum and heat transfer by TIWs are essential to drive the equatorial ocean circulation and affect the air-sea interactions related to the global climate, a better understanding of the generation mechanism of the TIWs is prerequisite for improving models' capability to predict climate variations.

In this study, we show that a linear stability analysis using a 1.5-layer shallow water model with a zonal mean flow on the equatorial beta plane can successfully predict an unstable mode whose phase speed and meridional structure are both very similar to those of the TIWs simulated in an eddy-resolving ocean general circulation model (OGCM), although the wavelength and the growth rate are somewhat larger and smaller, respectively. This unstable mode can be interpreted as resulting from a coupling between a Rossby wave propagating eastward in the negative potential vorticity (PV) gradient just north of the equator (~1°–3.5°N) while advected westward by the SEC, and a Rossby wave propagating westward in the positive PV gradient further north (~3.5°–8°N) while weakly advected eastward by the NECC. The unstable mode tends to have smaller growth rate as the negative PV gradient becomes weaker, and even disappears when it is completely absent.

The negative PV gradient just north of the equator thus plays an essential role in forming the unstable mode. Actually, the seasonal and interannual variability of the TIWs simulated in the OGCM is shown to be significantly controlled by the strength of the negative PV gradient, suggesting the possibility that it can serve as a key parameter for a dynamically based parameterization of the heat and momentum transfer associated with TIWs in coarse-resolution OGCMs.

Annual Rossby waves below the pycnocline in the Indian Ocean

*Motoki Nagura[1]

1. Japan Agency for Marine-Earth Science and Technology

In-situ observations in the Indian Ocean had long been limited to sporadic ship observations, which hampered the progress of observational research of basin-wide circulation and variability. The implementation of Argo profiling float program since 2004 dramatically improved this situation, and now abundant in-situ observations obtained from Argo floats are available. This study uses the resulting temperature and salinity observations between the sea surface and 2000 m depth and float trajectories at 1000 m depth to examine annual variability in pressure and horizontal velocity. Annual variability below the pycnocline is large in amplitude in the Arabian Sea and between 10˚S and 20˚S in the South Indian Ocean. Wavenumbers were estimated by fitting a straight line to annual harmonic phase. Results showed that vertical wavenumber tends to decrease poleward in both hemispheres, and vertical wavelength is more than tripled from about 5,000 m at 5˚N/S to 16,000 m at 20˚N/S. The inverse radius of deformation squared (defined as f^2m^2/N^2) does not show clear dependence on latitude, because poleward increase in the magnitude of the Coriolis parameter (f) compensates for poleward decrease in vertical wavenumber (m), and Brunt-Väisälä frequency (N) varies little meridionally in the analysis domain. According to the dispersion relation of linear, quasi-geostrophic Rossby waves at a rest state, these meridional structures in m and deformation radius result in steeper angle of ray trajectory at a higher latitude in the longitude-depth plane. Energy estimated from in situ observations shows a consistent pattern with this expectation. The line of constant phase of annual pressure harmonic is steeper in angle at higher latitudes, which is also expected from the uniform deformation radius and constant N. This result indicates that energy penetrates deeper at higher latitudes.

Eddies observed by Argo floats

*Katsuro Katsumata[1]

1. JAMSTEC

Eddies play an important role in the oceanic general circulation theory, specifically its meridional overturning component. Due to the limited spatial extent, however, synoptic observation of the eddy field has been difficult and its quantitative arguments have depended mostly on numerical simulation outputs. Argo floats, which revolutionalised phycical oceanographic observations, demonstrate their capability in the eddy observation (albeit at limited depths).
Under the Temporal Residual Mean framework, the most natural coordinate system for ocean circulation theories, we estimated the eddy transport above the mean 1000 dbar surface by using the hydrographic and drift velocity data from Argo floats. Eddy transport is strong in the western boundaries and in the Southern Ocean. In the midlatitude oceans, it is weaker and equatorwords. In the southern part of the Antarctic Circumpolar Current (ACC), it is larger than 10 Sv poleward.
In the Southern Ocean, we can discuss the vertical transport of zonal momentum input by the westerly wind and responses of the ACC to variable wind localised to topographic features.

Rhythmic Phenomena in Nonlinear Systems and Oceanic General Circulation

*Shinya Shimokawa[1], Tomonori Matsuura[2]

1. National Research Institute for Earth Science and Disaster Prevention, 2. University of Toyama

Various oscillation phenomena such as transition between meander and non- meander paths of western boundary current such as the Kuroshio exist in the oceanic general circulation. These phenomena can be related to nonlinear rhythmic phenomena such as synchronization, stochastic resonance and stochastic synchronization. Synchronization 1) is a phenomenon for an adjustment of rhythms of two or more self-sustained oscillating systems, which have different periods. Stochastic resonance 2) is a phenomenon in which a kind of noise amplifies and elicits weak signals under detection thresholds. Both phenomena are observed in various nonlinear systems such as climate system, living system, and electric circuits. Also, the coupling of both phenomena was found and is called stochastic synchronization 3).

Thus, we investigate the responses of oceanic double-gyre to external wind forcing with and without noise using a 1.5 layer quasi-geostrophic model, and considered the possible role of nonlinear rhythmic phenomena in oceanic general circulation 4)-7). The variable parameter is the amplitude of external seasonal forcing, α, the amplitude of red noise, ε, and the Reynolds number, Re.

Synchronization at two times the period of the forcing occurs at a parameter range of α and Re without noise (ε =0). For cases with adequate (not too weak and not too strong) noise, potential signals in the system appear at the front as actual signals (i.e., stochastic resonance) such as intermittent large variations in energy. Also, by adding red noise to external forcing, synchronization (i.e., stochastic synchronization) occurs when the amplitude of external forcing is smaller than that in the case without noise. These results suggest that potential signals in the system are amplified and appear as stochastic resonance or synchronization in relation to the added noise.

Control of the ocean circulation by bottom topography and generation of mesoscale disturbances

*Yuri Kase[1], Tomonori Matsuura[1]

1. National university corporation University of Toyama

One of the representative ocean current in the North Pacific is the Kuroshio. The Kuroshio which is the western boundary current of the North Pacific subtropical gyre leaves off the coast of Choshi, Chiba Prefecture, and it will be the eastward Kuroshio extension. At about 160° E, the Kuroshio-extension current encounters the Shatsky rise extending north and south, and fluctuation of flow path and generation of mesoscale disturbances due to flow-topography interaction is seen around this topography. We study the mechanism of phenomena as geophysical fluid dynamics in the North Pacific, mainly generation of mesoscale disturbances due to flow-topography interaction in rotating stratified fluid, by modeling which is target of the North Pacific.

We simulated four cases with different ocean bottom topography using the eddy resolving 3-layer QG model (Hogg et al., 2010) based on the quasi-geostrophic vorticity equation for the generation of the mesoscale disturbances accompanied the main flow path variation.

In Figure 1, the strong flow in each case is seen near the west-coast and mid-latitudes, and in case 1 where no topography is given, the most noticeable double gyre and the zonal strong flow as the gyre's front are seen. It can be inferred that this double gyre corresponds to the North Pacific subtropical gyre / subpolar gyre, and the flow on the front corresponds to the Kuroshio extension because we give the wind stress corresponding to the North Pacific about this time. On the other hand, in case 2, 3, and 4, which topography is given in each case, the strong flow near the mid-latitude is obstructed or meandered depending on the topography, and there is the long-lived eddy as an anticyclonic eddy over the topography. Especially, paying attention to the meandering flow behind the topography, and comparing case 3 and case 4, we can see that the addition of "corn" to "kamaboko" strengthens the flow of two wavelengths behind "kamaboko" (in case 4 of Figure 1).

Figure 2 shows the spatial patterns of the 10 years mean values of the squared disturbances of the potential vorticity in layer 1. The higher value area has the stronger and finer mesoscale disturbances. The development of the mesoscale disturbances in each case is seen at the west-coast, the mid-latitude area and the area surrounding the topography, corresponding to the strong flow as seen in Figure 1. In addition, when comparing case 3 and case 4, the addition of "corn" to "kamaboko" strengthens the meandering flow which has two wavelengths behind "kamaboko" (in case 4 of Figure 1), and the mesoscale disturbances are developed along the flow (in case 4 of Figure 2). From these results, it is suggested that the baroclinic instability is strengthened around the topography. We think the mechanism as described later; flow is disturbed by the influence of the topography, and the interface (of two layers) height anomaly increases, so the potential energy becomes large (strengthened baroclinic instability), and then the enlarged potential energy is released as kinetic energy (resolution of the baroclinic instability), and the mesoscale disturbances develop. It was suggested that how to change the flow and the degree of strengthened its baroclinic instability depend on the shape, arrangement and combination of the topography. And it was found that the bottom topography plays an important role in the generation of mesoscale disturbances.

©2019. Japan Geoscience Union. All Right Reserved.

Hereafter, by modeling which is given “kamaboko”, “corn” as a bottom topography imitating the Izu Ridge and the Shatsky rise (Tam massif) in the North Pacific, respectively, and simulating in some cases which have defferent positions (latitude / longitude) and heights of the topography, we presume that it is possible to realize the application of the mechanism of phenomena from the simulation results to the real phenomena.

Discussion

The use of natural abundances of stable isotopes to elucidate the nitrogen dynamics in plant-soil systems

*Keisuke Koba[1]

1. Center for Ecological Research, Kyoto University

Nitrogen (N) dynamics in terrestrial ecosystems are quite complex because of its high turnover due to the high biological N demand by plants and microbes. The uses of the natural abundance of stable N and oxygen (O) isotopes have been carried out in many ways to elucidate the N dynamics in intact terrestrial ecosystems. The methodological progress ("denitrifier method") can allow us to measure not only N but also O isotope ratios with samples with low N amounts. We applied this analytical method to elucidate the fate of nitrate. Among many fates of nitrate in terrestrial ecosystems, plant nitrate uptake is quite difficult to evaluate. In this talk, I will introduce our results on the uptake of the soil nitrate by tundra plants where soil net nitrification rates are quite low.

Keywords: stable isotopes, soil nitrate

Reconstruction of local temporal variation on atmospheric sulfur hexafluoride concentration in the Kyoto Basin by multiple environmental tracer and mass transport analyses

*Koki Kashiwaya[1], Taishi Hori[1], Ryuta Hazama[2], Yoichi Sakuma[3], Katsuaki Koike[1]

1. Kyoto University, 2. Osaka Sangyo University, 3. Tokyo Institute of Technology

Groundwater is a valuable water resource and understanding groundwater flow regime is indispensable to maintain its quantity and quality at favorable conditions and to achieve its sustainable use. Residence time is an indicator reflecting flow regime of groundwater and various environmental tracers can be used to estimate residence time. Sulfur hexafluoride (SF_6) is one of such dating tracer and is frequently used to estimate residence time of relatively young groundwater. SF_6 residence time is estimated by comparing temporal variation curve of atmospheric SF_6 concentration with concentration obtained from measurement of groundwater sample. Groundwater dating with SF_6 is sometimes difficult in urban areas because of locally elevated atmospheric SF_6 concentration and/or contamination. If local temporal change of atmospheric SF_6 concentration can be reconstructed, and if contaminated samples can be detected, they help to increase accuracy of groundwater dating with SF_6. Therefore, we tried to estimate local temporal change of atmospheric SF_6 concentration in the Kyoto Basin. Groundwater samples were collected from 47 wells in the basin and concentrations of tritium and SF_6 were determined. Air samples were also collected at three points to reconstruct the variation curve. Additionally, groundwater flow and mass transport analyses were conducted using MODFLOW and MT3DMS. The groundwater flow and mass transport models were calibrated by comparisons with actually measured water levels and tritium concentrations. Several temporal variation curves of local temporal variation on atmospheric SF_6 concentration were considered, and using these curves, mass transport analysis of SF_6 was conducted. Finally, the calculated and actually measured SF_6 concentrations in groundwater were compared and the temporal variation curve with which error between the calculated and measured values was minimum was selected. In the presentation, residence time of groundwater in the Kyoto Basin is presented and plausibility of the selected temporal curve is discussed.

Quantitative reconstruction of the humidity in the moisture source region based on the ^{17}O-excess in precipitation on a subtropical island

Yuina Uechi[1], *Ryu Uemura[1]

1. University of the Ryukyus

A high-precision analysis of the triple oxygen isotope composition of water provides a new tracer denoted as ^{17}O-excess. In theory, the ^{17}O-excess can be interpreted as variations in the relative humidity in moisture source regions for precipitation. However, recent studies on ^{17}O-excess in the precipitation in polar and dry regions suggest the importance of snow formation and raindrop re-evaporation processes. To date, whether humidity in the moisture source region can be quantified based on observations of ^{17}O-excess in precipitation has not been proven. Here, we show a 2 year record of the ^{17}O-excess in precipitation on a maritime island in the East Asian monsoon region, Okinawa, Japan. We demonstrate that the reconstructed relative humidity is quantitatively consistent with observations in the oceanic moisture source region. This result suggests that the ^{17}O-excess in precipitation on the subtropical island is determined largely by diffusional fractionation during evaporation in the ocean. These results suggest that the ^{17}O-excess in precipitation in tropical and subtropical regions is a unique quantitative tracer for the relative humidity in oceanic moisture source regions and thus will be a useful tracer and proxy for hydrological and paleoclimate studies.

Identification of deep groundwater recharge system in an intermontane basin

*Takashi Nakamura[1], Kei Nishida[1], Naim Mohamad[2], Bijay Man Shakya[1], Kazuyoshi Asai[4], Sresh Das Shrestha[3]

1. ICRE, University of YAMANASHI, 2. University of Yamanashi, 3. CDG, Tribhuvan University, 4. Geo-Science Laboratory

This study focuses on identifying the deep groundwater recharge system in Kathmandu Valley, Nepal using various environmental tracers. The Kathmandu Valley is one of the largest intermontane basin that covers an area of 625 km^2. The average altitude of the valley floor is 1350 m above sea level and is surrounded by the hills rising more than 2800 m. Rainfall in the basin is mostly seasonal with roughly 80% of the 1755 mm average annual total arriving between June and September during monsoon season. Groundwater samples were collected from 10 deep tube wells covering almost all parts of the valley and 2 shallow dug wells located at the central part of the valley. All the collected samples were then subjected to the analysis of major dissolved ions, hydrogen and oxygen stable isotopes and radiocarbon.

Groundwater ion composition using Hexa-diagram showed that the deep groundwater of the Kathmandu Valley tends to be relatively young in the outer peripheral area. Meanwhile for the groundwater located in the central area tends to be older. However, for the shallow wells located at the central area, the higher values of ion composition were derived from the effect of human activities. Relatively high pMC values obtained from radiocarbon were detected from the shallow groundwater at central part of the valley and from the deep groundwater samples those were collected from the peripheral area. On the other hand, the deep groundwater at the central part of valley was observed with low pMC values.

Relatively heavier stable isotopes of hydrogen were observed from both the deep groundwater and the shallow groundwater in the central part of the valley. Along with the pMC values, these results also suggests the possibility of vertical groundwater recharge from the shallow groundwater to the deep groundwater in central part of the valley. However, isotopically depleted groundwater recorded from the peripheral areas also concludes the recharge in this basin occurs from the mountain areas.

AKNOWLEDGMENTS: This study was supported by the JSPS KAKENHI Grant Number is 18K11617. It was also partly supported by the Science and Technology Research Partnership for Sustainable Development Program (SATREPS, Project Manager: Professor Narendra Man Shakya and Professor Futaba Kazama) of the Japan International Cooperation Agency (JICA)/Japan Science and Technology Agency (JST).

Discussion

The discharge rate of the Arima-type deep brine discharge in Ooshika-mura, Nagano Prefecture

*Fumitake Kusuhara[1]

1. Central Research Institute of Electric Power Industry

Arima-type hot spring water is thought to originate from the dehydration from the hydrous minerals in a subducting slab. In the present research, this dehydrated saline water is called “ADB (Arima-type Deep Brine)”. It is important to estimate the amount of the discharge of ADB in order to understand the water circulation in subduction zones. Few studies, however, have been conducted on such estimation because the chemical and isotopic compositions of the ADB is unknown.Ooshika-Mura is located at the southern part of Nagano prefecture, central Japan. It is thought that the ADB is diluted by local meteoric water, gushes out at several points (e.g. the Kashio hot spring, famous as the Arima-type hot spring), and flows into the 4 rivers in the region. In the present research, the flow rate and Cl- concentration of river water is measured at several points along each river. The flow rate of the ADB is estimated at each observation point, based on the results of above measurements and the previous study on the chemical and isotopic composition of the ADB in the researched region. These estimated flow rate values are regarded as the discharge rate of the ADB discharge inside the upstream watershed areas. The ADB discharge rate over the whole area of Ooshika-Mura is estimated approximately 0.8 L/s, by summing up each flow rate at the most downstream point of each river. The estimation is consistent with previous calculation of the dehydration rate from subducting slabs. More than 50% of the discharged ADB in the whole area concentrates within a few kilometers of the confluence of Kashio River and Shiokawa River. The fault plane of the MTL intersects with the Shiokawa River at the area, which is consistent with the ADB discharging model in Kii peninsula, shown by the previous study.

Sublacustrine hydrothermal system of the active crater lake, Yudamari of Aso Volcano inferred from Mg budget of the lake

*Shinji Ohsawa[1], Takeshi Saito[2], Kazuhiro Amita[3]

1. Institute for Geothermal Sciences, Graduate School of Science, Kyoto University, 2. Academic Assembly School of Science and Technology, Shinshu University, 3. Graduate School of Engineering Science, Akita University

The crater lake, Yudamari, formed in the first crater of Mt. Nakadake, Aso Volcano, contains a large amount of dissolved components such as chloride ion (Cl) and magnesium ion (Mg), without the surface outflow of the lake. This kind of water quality is formed under the influence of subaqueous volcanic gas flowing into the lake. From analysis of the isotope composition of the Yudamari water samples (δ D and δ^{18}O), it was found that a large change occurred in the water isotope composition when the lake which became extremely acidic caused the dissolution of chemical components from rocks (oral presentation in the same session last year). In the period when the lake became extremely acidic, the volume of the lake and the water budget were demanded in detail (Saito et al., 2008). We calculated the Mg balance of the lake including the hydrological parameters reported there, and found that a large amount of Mg from 5 to 10 tons per day was eluted from the rock to the lake. Assuming chemical composition and density of the original rock subjected to the acid leaching and converting the Mg leaching amount to the volume of the rock, it is 50 to 200 cubic meters. This is an amazing phenomenon in which a cubic rock from 3 to 6 m is completely altered in one day. The elution of such a large amount of rock components is not caught up in the dissolution reaction only on the bottom surface of the lake. It strongly supports the existence of the subaqueous hydrothermal system that the lake water circulates continuously and reacts with the rock, for example, it is often assumed under the lake of a high temperature and strongly acidic crater lake called active crater lake similar to Yudamari.

Spatial distribution of chemical compositions, hydrogen and oxygen isotopic ratios of stream water of the Shimanto River area, southwestern Japan

*Masaaki Takahashi[1], Hinako Shimizu[1], Kohei Kazahaya[1], Masaya Yasuhara[2,1]

1. The National Institute of Advanced Industrial Science and Technology, 2. Rissho University

109 river water samples were collected from 101 locations in the Shimanto River system and adjacent streams in the western part of Kochi Prefecture and southern part of Ehime Prefecture in December 2007, November 2008, and December 2009, for the purpose of understanding how the distribution of δD and δ^{18}O can be explained by geographical parameters (latitude (LAT), altitude (ELV) and inland degree (Distance from the nearest seashore; DS)) and meteorological parameters (mean annual temperature (MAT) and mean annual precipitation (MAP)), and what is the difference in those explanatory variables of the distribution of δD and δ^{18}O compared to the national level. As a result, it was found that the spatial distribution of δD, δ18O of stream water in the Shimanto area can be shown in detail by using ELV and DS as geographical parameters and MAP as meteorological parameters as explanatory variables.

An isotopic study on shallow groundwater origins in a densely-populated area in Shinagawa, central Tokyo, Japan

*Masaya Yasuhara[1], Akihiko Inamura[2], Takashi Nakamura[3], Kazuyoshi Asai[4]

1. Rissho Univ., 2. Geological Survey of Japan, AIST, 3. Yamanashi Univ., 4. Geo Science Laboratory

Stable isotopes (δ D and δ^{18}O) and hydrochemical tracers (electric conductivity, NH_4^+, NO_3^-, Cl^-) of water were applied to quantify 1) rainfall infiltration (natural recharge), 2) water supply leakage, and 3) sewage leakage in a shallow aquifer in a densely-populated area in Shinagawa, central Tokyo, Japan. Despite of a quite small area about 0.5 km (E-W) by 1 km (N-S), shallow groundwater took on a wide range of values: 28 ~70 mS/m electric conductivity, 0.0 ~9.1 mg/L NH_4^+, 0.1 ~ 36.2 mg/L NO_3^-, 4.8 ~46.6 mg/L Cl^-, and -8.7 ~-7.4‰ δ^{18}O. A ternary mixing model was used based on the Cl^-concentration and d^{18}O of three plausible origins of groundwater to estimate fractions of each component in shallow groundwater in the study area. As a result, a fraction of sewage leakage in groundwater proved large for one well as much as 70%, while for some wells rainfall infiltration contributed more than 80% of water to the formation of groundwater. These remarkable differences in contribution of urban leakage to the shallow aquifer may result from the different state of the water infrastructure in the vicinity of the respective wells.

Keywords: Tokyo, shallow groundwater, origins of groundwater, water leakage, sewage leakage, isotope

The sources of landslides occurred by the 2018 Hokkaido Eastern Iburi Earthquake

*Satoshi Ishimaru[1], Wataru Hirose[1], Gentaro Kawakami[1], Ryo Takahashi[1], Yoshihiro Kase[1], Ken'ichi Koshimizu[1], Hiromichi Koyasu[1], Masahiro Chigira[2], Jun Tajika[3]

1. Geological Survey of Hokkaido, 2. Kyoto University, 3. Docon Co., Ltd.

An earthquake of M6.7 was occurred at 37km depth in East Iburi, Hokkaido, on September 6, 2018. This earthquake caused numerous landslides in Azuma town with seismic intensities of 7 or 6+. The number of landslides reached 8000 in area of 20km by 20km. The type of these landslides is almost debris slide on the base of tephra layers, excluding rock slide and rock fall near the epicenter.

1 Distribution of tephra layers

Thick tephra layers interleaved with kuroboku, cover on hill slopes in the area of numerous landslides. The tephras derived from Shikotsu caldera and surrounding volcanoes, about 50 km west of Atsuma town. Main tephra layers in the hillslope are Spfa1 pumice of 48ka from Shikotsu caldera, En-a pumice of 20ka from Eniwa volcano, and Ta-d pumice of 9ka, Ta-c pumice of 3ka, Ta-b pumice of AD1667, and Ta-a pumice of 1739 from Tarumai volcano. En-a layer is thick, 1m more, in the northern area with numerous landslides, and Ta-d layer is thick, 1m more, in the southern area. These tephra layers are the main parts of landslides by this earthquake.

2 Tephras on hillslope with geomorphological evolution

Slope surficial deposit moved active affected by solifluction due to freeze-thaw cycles in the last glacial period, more than 10ka. For the reason, Spfa1 and En-a could not remain on hillslopes, except for valley head slopes and the foot of the slope accumulated surficial deposits, or crest slopes. On the other hand, the lower part of slopes was eroded by increased fluvial activity related to warmer and wetter during the late glacial period. Therefore, Spfa1 and En-a from the last glacial period do not cover on the lower valley-side slopes, but Ta-d covers on slope deposits on weathered rock there.

En-a covering the slope, for example valley head slope, is underlain by the reworked Spfa1. The volcanic soil with Spfa1 contains easily water and has slippery. On the other hand, Ta-d often is underlain by reworked En-a on the lower valley-side slope. These reworked tephras and the unit of the base of Ta-d layer with high absorbability, described below, would be slide layers in this earthquake.

3 Cases of landslides

Cases of landslides of thick Ta-d in the southern area of the disaster area and of thick En-a in the northern area are shown below.

3.1 The southern part covered thick Ta-d

A landslide at Asahi, located at the west side of Yoshino at the most severe disaster, was occurred on a flat slope at the lower valley-side slope. The collapse was occurred from the lower convex break of slope. It is 35m high, 35m wide, and 90m long. The vertical surface of the 3m thick soil layers with tephras, is exposed at the both sides of the landslide. Pale yellowish water-rich volcanic ash with striations adhere to the slip surface on thin slope deposit on weathered rock. The sliding surface was in a fine-pumice layer containing much moisture at the lowest part of Ta-d layer, according to outcrop observation of both sides of this failure. The upper part of Ta-d layer of 130cm thick, is redish brown pumice with weathered clay, and the lower part of it is dull gray coarse pumice with high permeability. The moving body slid and deposited as almost kept stratigraphic structure.

3.2 The northern area covered thick En-a

A landslide at the right bank of the upper Abira river is at 80m high, 45m wide, and 230m long. The collapsed debris buried the Abira river. The landform of the slope was divided into upper and lower parts

©2019. Japan Geoscience Union. All Right Reserved.

by a break line of inclination. The source of collapse was mainly the upper, a valley head slope, shaped shallow flat slope which is covered by En-a. The lower part was a V-shaped valley before the earthquake. The moving body run on the upper of V-shaped slope along the valley and deposited over the Abira river. Acording to observation of the exposed outcrops by the failure, thin Ta-d and the above layers cover on En-a of 130cm thick. En-a is pumice of 1-2mm diameter with rich-pyroxene. The sliding surface was on the lower volcanic ash, mixed glassy Spfa1, beneath En-a.

4 Shapes of slope failures in each southern and northern area of the disaster area

In the southern part of the disaster area, almost slopes except of steep are covered thick Ta-d. The main source of collapses is thick Ta-d by the earthquake. Therefore, the collapses were occurred numerous on the slope covered by thick Ta-d, especially the lower valley-side slope, which is steep. On the other hand, in the northern area of disaster area, because Ta-d layer is thin, even though it is on the lower valley-side slope, the collapse of Ta-d is rare. The collapses of thick En-a on the valley head slopes are unevenly distributed. Because each geomorphological unit at the source of collapses in the northern and the southern is different, their shapes are different in each region.

Feature of landslide of pyroclastic fall deposits induced by 2018 Hokkaido Eastern Iburi Earthquake, and its relation with damage

*Jun Tajika[1], Kazuo Amemiya[2], Masahiro Chigira[3], Satoshi Ishimaru[4], Akio Koike[1], Hidetoshi Kon[1], Kenji Kizaki[5], Nobuo Yamane[6]

1. Docon Co.,Ltd., 2. Bousai Chishitsu Kogyo Co.,Ltd., 3. Kyoto University, 4. Geological Survey of Hokkaido, HRO, 5. Kizaki PE Office, 6. Terre Research Co.

Many landslides occurred by the 2018 Hokkaido Eastern Iburi Earthquake around Atsuma-cho . Rapid landslide consisting of Holocene pyroclastic fall deposit (Debris slide by the classification of Varnes, 1978) gave the human damage of 36 above all. We show the topographical and geological cause and morphological characteristic of the landslides and discuss about relations with the human damage.

Tephra mainly derived from Shikotsu, Eniwa and Tarumai volcanos cover on sedimentary rocks for Neogene of the base in Atsuma area. Among these tephra, the Tarumai d pyroclastic fall deposit (Ta-d: 9ka) thickly distributes in this area as a central axis of distribution. Ta-d (thickness 1-2m), the tephra (Ta-c,-b,-a) and black soil (total thickness approximately 1.5-3m) which did mantle bedding was translationally sliding as landslide body. The sliding layer was formed in several centimeters above from the base of the Ta-d pumice at the slope where Ta-d directly covered the mudstone and mudstone rubble. The thickness of the layer was 1-3cm and is made of creamy clay including the halloysite. In addition, the sliding layer was formed in the weathered volcanic soil including pumice derived from Eniwa a and Shikotsu 1 Tephra in the area where the Ta-d covers up the volcanic soil.

The landslides in Atsuma area into following 7 types based from form and another feature of the slide, i.e. 1) Type Gv: Extremely gentle, shallow valley from, 2) Type Sv: Gently shallow valley form. 3) Type Dv: Deep valley form with alluvial cone or landslip lobe 4) Type Hv: Hanging valley form, 5) Type Ps: Planer slope, 6) Type Cf: Complex of Some valley form collapses along the small stream, and 7) type Ol: Gently landslide caused by overlapping of other slides.

Although there is difference in some clarity, the cutting of the layered bedding of Ta-d is often seen at the slope end in these slopes. The valley wall slope that Ta-d covers is eroded by small stream in the Type Cf. Because the thinning and omission of Ta-d occur at an exit of the hanging valley in the Type Hv , it is in a near condition for "lower part cutting". In addition, the convex break of slope angle and a man-made small cut is often observed in the foot of the collapse scarp with the Types Sv, Dv and Ps.

The landslide body of each type was moved with mostly maintaining of bedding form from the source area to the depositional area. The terminal form of slides has many variations, i.e. from stacking of plural sliding bodies which make thrust on the front, to separating and crushed into many blocks. Fluidized slide material such as the Type Cf made depositional lobes like a debris-avalanche or a debris-flow deposit in the terminal area. The distance from the base of slope to the tip of the sliding body of Types Cf, Hv and Dv were generally longer than the type Ps. The thickness of landslide body was about 1.5-3m which was reflected from the total thickness of stratified Ta-d and other tephra and black soil, and reaches 3-5m in the part which some bodies stacked at the terminal. The damaged buildings were located at the mouth of small stream and were located in the accumulation area of the landslides. Height of the first floor of the house is almost about 3m.

©2019. Japan Geoscience Union. All Right Reserved.

The geological cause of landslide is that The Ta-d tephra distributes widely with the mantle bedding. The pumice of Ta-d is weathered and halloysite formed in it. Furthermore, the tephra was cutting in the foot of slope in many places by natural and artificial process. On the other hand, the Eastern Eburi Earthquake showed that a landslide will occur by all means in the sloping ground including extremely gentle area that pyroclastic fall deposit cover with mantle bedding when the large-scale inland earthquake occurs. Because it is impossible to predict earthquake, inhabitants of the slope area cannot evacuate beforehand. The preventive measures construction is not necessarily realistic. It is necessary to avoid building house at the mouth of small valley and to make a bedroom in the places more than second floor for reducing human damage.

Influence of slope cutting on failures induced by the July heavy rain, and the Iburi-tobu earthquake, 2018.

*Hidehisa Nagata[1]

1. Fu-Sui-Do Company Limited

Many cases of failure induced by slope cutting have been also reported in the past. Some examples are added here by the July heavy rain from June 28 to July 8 and the Hokkaido Iburi-tobu earthquake on September 6, 2018. In the July heavy rain, many slope failures occurred widely main in western part of Japan including Hiroshima, Ehime and Gifu Prefectures. The Iburi-tobu earthquake caused collapses in high density in the hilly area around at Atsuma Town, Hokkaido.

Case A (Hokkaido): a failure that 20 m in width and 50 m in length caused by the Iburi-tobu earthquake. It is smaller scale one in the many failures by the earthquake. Similar to many other cases, sliding surface is the base of Tarumai-d tephra (9ka) lying under 2.5 m from the earth surface. The slope toe has been cut about 3 m in height for a hut. As a result, inclined weak layer became to daylight in the cutting slope.

Case B (Ehime Prefecture): a 30 m wide failure occurred on an orange grove slope by the July heavy rain. It is initially surface failure 0.5 m in depth, although the secondary 2 m deep failure continued on the left side. A trail for working passes at the top of the failure, and a pipe for sprinkling was buried along the trail. Leaked water from the pipe might cause the initial failure, so many small gullies run from the top. Otherwise, groove into strongly weathered Cretaceous sandstone is possible factor of the failure.

Case C (Gifu Prefecture): a forest road shoulder composed of highly weathered Jurassic Hida Granite was collapsed 25 m in width. The failure occurred on a shallow valley slope and the road passes through the upper part of the slope in up-hill grade. Although this valley has only small catchment area originally, rain water was drained from upper neighboring valley through the road and flowed out to the road shoulder along small undulations on the road. This large quantity of water caused the failure. Involving catchment area was enlarged at least 8.5 times than before the road opened.
There are many sites needed slope cutting for architecture and civil structure and dense network of forest road is required for proper management of forestry and agriculture. However, any slope cutting causes hydrological and geomorphological changes despite of its scale. When large impacts like heavy rain or earthquake occur, modified landforms can be a factor of landslide. Slope failures are induced by daylighting of weak layer in the case A, and by flowing water in the upper part of slope in the cases B and C. Moreover, construction of the forest road made drainage area increase by capture of the upper neighboring valley in the case C. On the planning of slope cutting, appropriate design, construction and maintenance should be taken considering microlandforms, subsurface geological properties and structures.

Slope failures occurred in the southwest part of the Izu-oshima Island in geological time, NE Japan

*Takehiko Suzuki[1], Masahiro Chigira[2]

1. Faculty of Urban Environmental Sciences, Tokyo Metropolitan University, 2. Disaster Prevention Research Institute, Kyoto University

So-called “loam” composed of primary fall-out tephras and tephric soil deposits (tephric loess) is one of the factors cause earthquake-induced landslide. To evaluate potential of slope failure by this combination in the Japanese Island, earthquake-induced landslides potential assessment should be examined in relevant areas, considering frequency of landslides in geological time. To estimate this, we examined unconformities within “loam” on the Izu-oshima Island, Tokyo, where thick loam has been formed during last 19 ka. We identified at a maximum six unconformities suggesting possibility of occurrences of landslides during the period between 19-1.8 ka.

The strain rate observation by the borehole inclinometer on the bedrock creep slopes in Akadani-west area

*Atsuhiko Kinoshita[1,2], Yasutaka Tanaka[2], Wataru Sakurai[1], Taro Uchida[1], Koichiro Hayashi[3], Yasuuchi Kubota[3], Katsushi Kawato[4]

1. National Institute for Land and Infrastructure Management, 2. Sediment Disaster Prevention Technology Center, Kinki Developing Regional Bureau, Ministry of Land, Infrastructure, Transport and Tourism , 3. OYO Corporation, 4. NIPPON ENGINEERING CONSULTANTS CO., LTD.

In the disaster around Kii Peninsula in 2011, many deep-seated landslides were occurred. In order to reduce the damage, it is necessary to establish the method of the extracting dangerous slopes and to consider the countermeasures in advance. So far, the method of reading the micro topography from the topographic map such as the laser profiler, the method of judging the degree of danger from geological / topographical overview have been proposed. On the other hand, there are few cases where the strain rate was observed at the landslide dangerous slope such as the bedrock creep slope. For this reason, the validity of the past method has not been fully verified. In this study, we conducted the boring survey and observed the strain rate by borehole inclinometer on two slopes of Akadani-west area. Also, based on this observation value, the validity of the risk method by the past study was examined.

First, we calculated the strain rate (the value obtained by dividing the length of the landslide scarp by the slope length) from the topographical data obtained by the laser profiler at the two slopes in Akadani-west area. We also evaluated the risk of the two slopes using the method to evaluate the risk from geology and topography by Chigira et al. In addition, we conducted the airborne electromagnetic survey, and the degree of strain was also investigated from the resistivity distribution of the ground. By these methods, after evaluating the degree of risk, two boring investigations were conducted on each of the two slopes. At the borehole location, the strain rate was observed by the borehole inclinometer. Through these, the consistency of the observed data and the risk assessment results was verified.

The strain rate of Akadani-west I district was 4.1%, and the risk by the method by geology / topography was IV. The strain rate of Akadani-west II district was 2.7%, and the risk by the method by geology / topography was II. From this, we have found that the degree of the risk in the Akadani-west I district is higher than that of II by the risk assessment by the past research. In addition, the strain rate by the borehole inclinometer was 0.6mm/year, 1.0mm/year in Akadani I and II districts, respectively. For this reason, we have found that the danger level in the Akadani-west II district is higher by the observed data. On the other hand, in the resistivity distribution by the airborne electromagnetic survey, a large change in resistivity was seen in Akadani-west II area, and it was found that the consistency with the actual observed data was obtained. From this, we have found that there is a possibility that the degree of the risk can be accurately evaluated by combining the plural methods.

Assessing Potential Landslide Areas Due to Earthquake Using Three-Dimensional Resistivity Datasets from Across a Wide Area

*Yusuke Sakai[1], Taro Uchida[1], YASUMASA FUJIWARA[2]

1. National Institute for Land and Infrastructure Management , 2. Eight-Japan Engineering Consultants

In recent years, sediment disasters due to earthquake have often occurred, including in the 2011 Great East Japan Earthquake, the 2016 Kumamoto Earthquake, the 2018 Hokkaido Eastern Iburi Earthquake. Measures for preventing and reducing the damage of sediment disaster due to earthquake are an urgent issue, because Nankai Trough Earthquakes are expected in the future. A variety of methods for assessing seismic landslide susceptibility have been proposed and their accuracy verified. In those methods, topographic parameters such as inclination of slope, curvature of slope, and relief are commonly used as controlling factors.

It has also been reported that underground structure has a large impact on seismic landslide occurrence, as in the case of the landslide that occurred around the Aso Volcanological Laboratory of Kyoto University in the 2016 Kumamoto Earthquake. Therefore, underground structure can be considered critical information for improving the predictability of potential landslide areas. However, geological maps only plot spatial patterns of the underground condition, and boring is required to obtain point information of underground structure in the depth direction. This lack of three-dimensional information of underground structures is one of key obstacles to evaluating potential landslide areas due to earthquake across a wide area.

Therefore, we used resistivity spatial patterns measured by airborne electromagnetic survey (AES). Airborne electromagnetic survey Based on electromagnetic induction, AES is an exploration technique for obtaining three-dimensional resistivity across a wide area by measuring the response to an induced electromagnetic field with an electromagnetic sensor from a helicopter.

The purpose of this study was to test the applicability of three-dimensional resistivity data to assessing seismic landslide susceptibility. We used three-dimensional resistivity data from the central cone of Aso Volcano measured before the 2016 Kumamoto Earthquake and landslide distribution maps made from airborne laser scanner datasets and orthoimages from before and after the earthquake. We identified the three-dimensional resistivity patterns in seismic landslide areas before landslide occurrence. Based on our findings, we argue the applicability of three-dimensional data for assessing seismic landslide susceptibility.

Prediction of shallow landslides and debris flow by rainstorm: dynamic hazard mapping toward disaster mitigation

*Yuki Matsushi[1]

1. Disaster Prevention Research Institute, Kyoto University

This study demonstrates a strategy for predicting location, timing, and magnitude of rainfall-induced shallow landslides and areas affected by subsequent debris flows. Spatial distribution of soil layers was modeled for evaluating thickness of sliding material on hillslopes, which provides a basis for predicting source area and volume of shallow landslides and simulating subsurface hydrological processes. Soil accumulation in hollows was calculated on a geographic information system using a 1 m-meshed digital terrain model with soil production by bedrock weathering and transport by soil creep. The output was validated by a ground-based survey in the actual terrain in a selected watershed. The shear strength of the bulk soil was evaluated by direct shear tests using undisturbed specimens, and quantification of soil reinforcement by tree roots through an in-situ survey at soil pits. Hydrological monitoring was carried out at representative hillslopes for modeling fluctuation in subsurface pore-water pressure by rainwater infiltration. By coupling all of those data and modeling, we analyzed the hillslope instability, and then compared the output with a landslide inventory map to confirm the accuracy and precision of the prediction. Time-series change in areas of debris flow runout was estimated based on assumed equivalent coefficient of friction as a function of hillslope wetness in the watershed. Such dynamic mapping of geohazard fills a demand in disaster mitigation in local communities for increasing events of heavy rainfall.

A future direction of remedial measures for sediment disaster reduction from the viewpoint of enhancing a workable early warning system

*Masaru Kunitomo[1,2,3,4], Shigetaka Takiguchi[1,2,3,4], Fumiaki Akazawa[1,2,3,4], Kazuyuki Imai[1,2,3,4]

1. Ministry of Land, Infrastructure, Transport and Tourism, 2. Water and Disaster Management Bureau, 3. Sediment and Erosion Control Department, 4. Sediment and Erosion Control Planning Division

Due to “Heavy rain of July 2018”, more than 2500 sediment disasters occurred mainly in the western part of Japan. The number is equivalent to approximately 2.3 times of the annual average. Why were such a lot of people killed in this disaster, despite various measures for precaution?

The Ministry of Land, Infrastructure, Transport and Tourism (MLIT) established a committee in order to take remedial measures for sediment disaster reduction from the view point of enhancing a workable early warning system, after not only revealing the facts on cause of the disaster but reviewing our measure have been taken.

With understanding that the lack of residents’ awareness of sediment disaster risk may be a major cause of this disaster, on the other hand, mutual assistance plan among local community may work well for evacuation at the sites with no victim, the committee proposed the MLIT to;
Build the early warning system nationwide based on a community mutual assistance plan for evacuation, Get residents to aware of their risk on sediment disasters, Enhance the national and prefectural support system to build the capacity of municipalities and residents, Improve the accuracy of sediment disaster alert to encourage residents at risk to evacuate precautionary, Build disaster-prevention facilities such as debris basins to reduce evacuation risk and to prevent crucial infrastructures from debris flows as well as sediment-rich flood, with the object of climate change adaptation. As a remedial measures for sediment disaster reduction from the viewpoint of enhancing a workable early warning system.

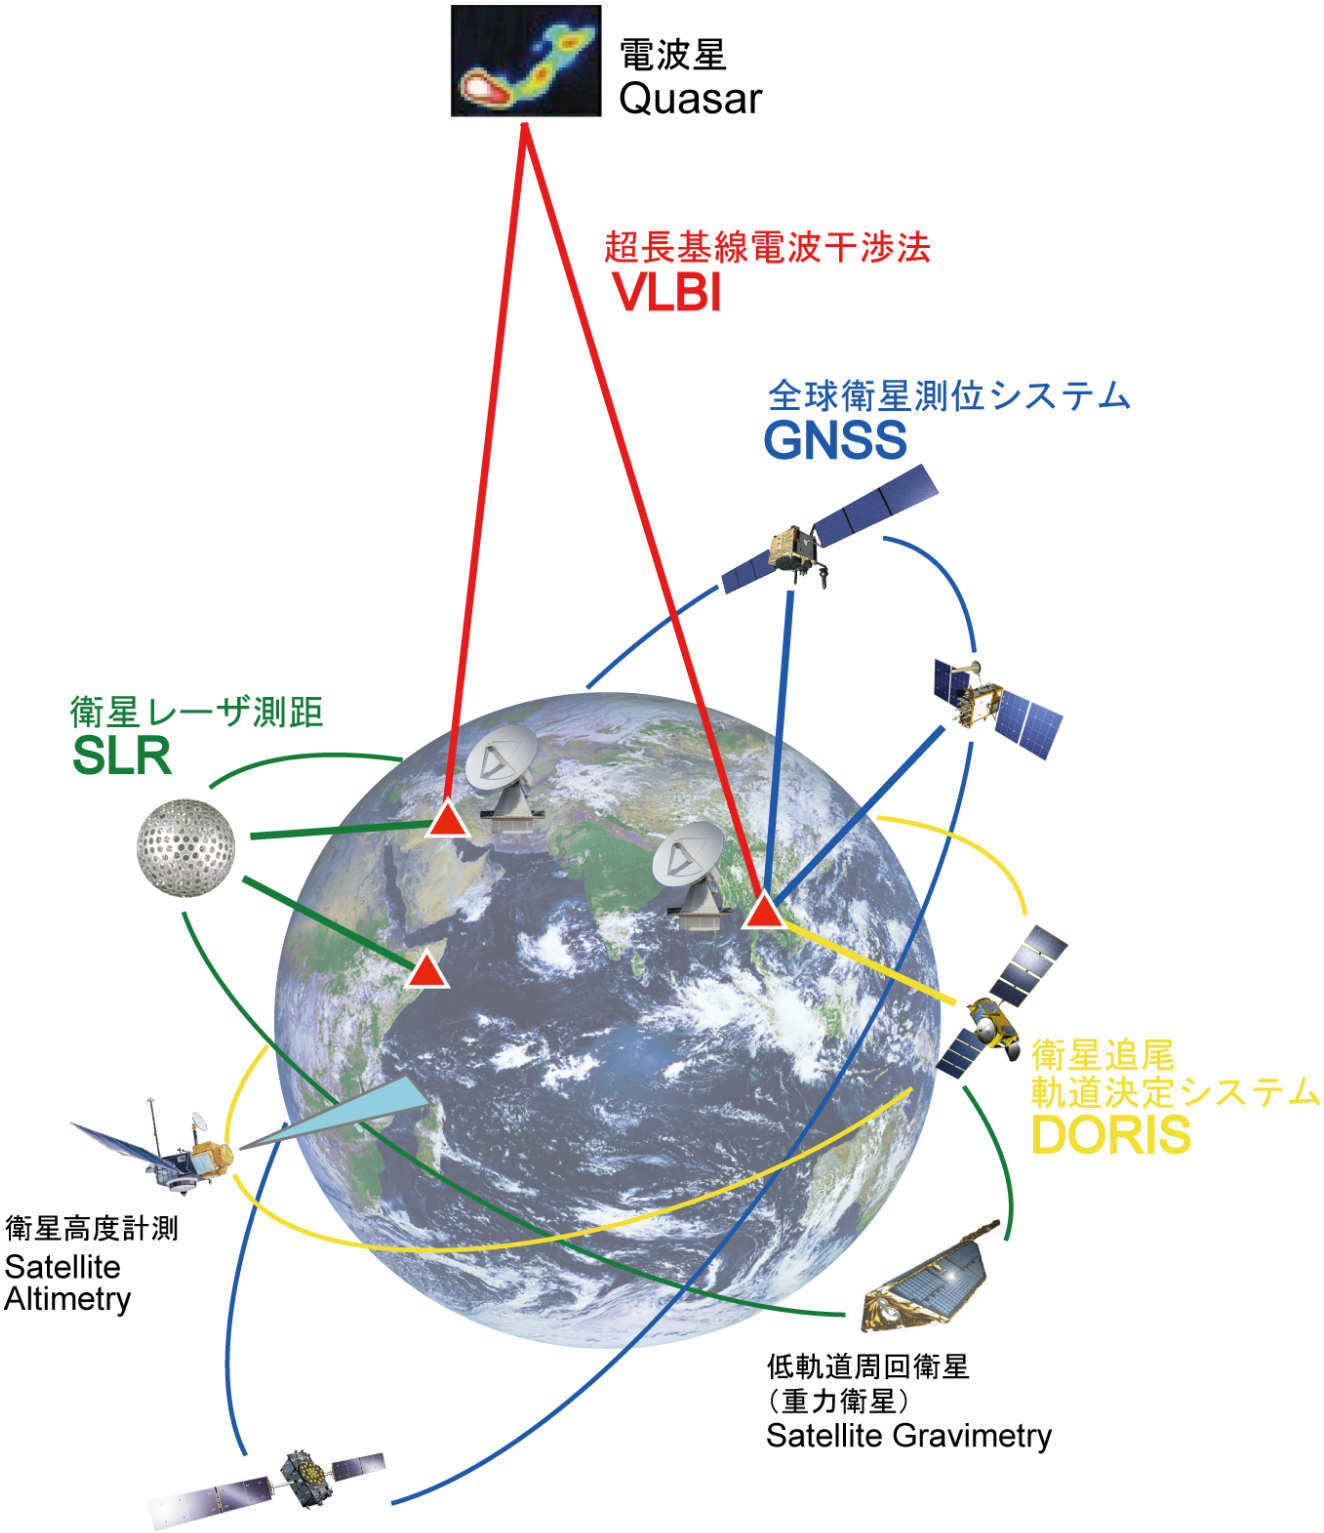
Discussion

Activities and future perspective of GGOS Working Group Japan



*Basara Miyahara[1]

1. GSI of Japan

Global Geodetic Observing System (GGOS) is a fundamental framework for integration of global geodetic observations such as GNSS, VLBI, SLR, DORIS, gravity measurements and so on. The main objective of the system is to measure and monitor shape, rotation, gravity field of the earth and its changes. GGOS integrates various international organizations related geodetic observation such as International GNSS Service (IGS), International VLBI Service for Geodesy and Astrometry (IVS), International Laser Ranging Service (ILRS) and so on in order to coordinate and promote global geodetic observations. International Terrestrial Reference Frame (ITRF) which is a de-facto standard for Global Geodetic Reference Frame (GGRF), reference frame for earth’s shape and variation which was endorsed by the United Nations General Assembly in 2015, is also one of the main achievements of GGOS observation. GGOS is essential basic infrastructure for measuring and monitoring of earth’s shape and its change.
The objective of GGOS, that is to continue to measure and monitor earth’s shape and its change can be possible only with continuous global geodetic observation with high quality and enough spatial coverage. Such observation cannot be possible without continuous geodetic observation by countries all over the world. Therefore, several agencies in Japan such as Geospatial Information Authority of Japan (GSI), Japan Coast Guard, National Institute of Information and Communications, National Astronomical Observatory of Japan, National Institute of Polar Research, and Japan Aerospace Exploration Agency have been individually conducting geodetic observation such as GNSS, VLBI and SLR in Japan and Antarctica, and participating in global geodetic observation through international organizations such as IGS, IVS, and ILRS and so on. Several researchers with universities have also participated in the organizations as chairs and board members. In addition, we established a working group on GGOS, GGOS-WG of Japan under IAG Subcommittee in Science Council of Japan in 2013 in order to facilitate information sharing and strengthen collaboration between the agencies for further contribution to GGOS. The WG submitted a status report of geodetic observatories of Japan to GGOS in 2014 and updated it in 2017. The WG has also held a session on GGOS at annual meetings of Japan Geoscience Union (JpGU) since 2015. The theme of GGOS has also added in annual meeting of the Geodetic Society of Japan since 2018. Furthermore, GGOS invited the WG as the first GGOS Affiliate, which is a regional component of GGOS aiming to strengthen regional participation to GGOS and the WG has participated in and contributed to activities of GGOS from regional and national perspectives. As the first GGOS Affiliate, the WG hosted the GGOS annual meeting, GGOS Days 2018 in Tsukuba, Japan and discussed the future activities of GGOS for more strengthened collaboration between GGOS and the WG. In the meeting, current status and issues of network, observation, products and standard were discussed activities of three of four Focus Areas, 1. Unified Height System, 2. Geohazards, 4. Geodetic Space Weather were reported. Some members also reported the possibility of establishment of new GGOS affiliates in DACH countries, Scandinavia, Latin America and North America. The members agreed on the new WG in GGOS which will work on DOI of geodetic data. An update of GGOS guide book was also discussed in the meeting. In addition to the above activities, the WG organized special issue on GGOS in Journal of the Geodetic Society of Japan and also developed a Japanese brochure of GGOS in 2018 to facilitate understanding of the role and significance of GGOS for science and society. In 2018, some members of the WG participated in several international conferences related to GGOS and facilitated exchange of the latest information on geodetic observation. In 2019, we will continue sharing of information and strengthening collaboration in Japan and strengthen collaboration between GGOS and GGOS-WG of Japan.

VLBI-GNSS Co-location Survey at the Ishioka Geodetic Observing Station

*Saho Matsumoto[1], Michiko Umei[1], Haruka Ueshiba[1], Shinobu Kurihara[1], Tadao Kikkawa[1], Takahiro Wakasugi[1]

1. GSI of Japan

The International Terrestrial Reference Frame (ITRF) is realized by a combination of four space geodetic observing techniques (VLBI, SLR, GNSS and DORIS), where VLBI contributes in determining scale and EOP, and SLR contributes in determining scale and the center of mass. To perform this combination, it is necessary that relative coordinates between these space geodetic observing stations are precisely known at co-location sites.

The Ishioka Geodetic Observing Station operates the two space geodetic observing stations, VLBI and GNSS. Ishioka station is a fundamental site on a geodetic perspective since the VLBI station is one of the VGOS (VLBI Global Observing System) stations which is promoted by IVS (International VLBI Service for Geodesy and Astrometry) as the next-generation standards, and the GNSS station "ISHI" is registered as one of the IGS (International GNSS Service) sites. To measure the relative coordinate between the VLBI invariant point (IVP) and the GNSS reference point, we conducted the co-location survey in November 2018 in Ishioka station. In this survey, we adopted two methods to determine the IVP. One is "outside method" where we observe the target attached on the antenna movable part (near the counterweight) with "Total Station" at the reference pillars installed around the antenna. The other is "inside method" where we observe the targets attached near the IVP from the inside of the antenna cabin. "Inside method" was adopted for the first time in Ishioka station so we discussed the way of observation, computation and evaluation of error.

In this talk, we will report a co-location survey result in November 2018 and discuss details on two different methods.

Research of Crustal Deformation Model for Next Version of Japanese Geodetic Datum

*Kensuke Kokado[1]

1. GSI of Japan

Geospatial Information Authority of Japan (GSI) maintains the Japanese horizontal and vertical datum reference system and provides the accurate positions of control points including GNSS CORSs (Continuously Operating Reference Stations) as basic survey result based on the reference system. By utilizing the survey results as the reference position of various surveys and maps, people can receive location information service which positions are aligned with each other nationwide. Along with the progress of Global Navigation Satellite System (GNSS) and the satellite positioning techniques in recent years, it is expected that location information service will be developed using the high accuracy GNSS positioning.

However, there is some gaps due to the crustal deformation between the position of the survey results such as map and the measurement position of the GNSS positioning, which will be used in location information service. Therefore it is necessary to correct the crustal deformation that occurred between the reference date of map and the measurement date of the GNSS positioning in order to match the measurement position by GNSS with the map.

In order to properly correct the above gaps due to the crustal deformation, GSI plans to develop advanced correction system instead of the existing semi-dynamic correction system. For the system development, we have been researching the crustal deformation model considering not only steady crustal deformation but also postseismic deformation of the 2011 Tohoku-Oki earthquake or coseismic deformation of the other earthquakes caused along an active inland faults.

In this presentation, we will focus on the postseismic deformation of 2011 Tohoku-Oki earthquake among the contents of the research, and report the progress of the research to create the crustal deformation model in the Tohoku region.

Construction of a laser-strainmeter network for accurate seismic and geodetic observations

*Akito Araya[1], Akiteru Takamori[1], Wataru Morii[2], Akio Katsumata[3], Akio Kobayashi[3], Takeo Ito[4], Takashi Okuda[4], Makoto Okubo[5]

1. Earthquake Research Institute, University of Tokyo, 2. Disaster Prevention Research Institute, Kyoto University, 3. Meteorological Research Institute, Japan Meteorological Agency, 4. Graduate School of Environmental Studies, Nagoya University, 5. Natural Science Cluster, Kochi University

Laser interferometers are widely used for precise measurements of displacement with reference to wavelength of light. As their geophysical application, a laser strainmeter is used for measuring deformation of the ground by sensing distance between two separated points, enabling to detect small strain changes over wide frequency range [1]. The advantages of the laser strainmeter over conventional strainmeters using mechanical references are high resolution with a long baseline, resonance-free response of optical reference, and low-drift detection using stabilized laser wavelength. Apart from the instrumental detectability, local noise sources, such as changes in temperature, air pressure, and ground water level, will affect both the instrument and the ground, and should be properly evaluated to examine the measured strain data. For this purpose, we constructed a network of laser strainmeters deployed at three underground sites in Japan: Kamioka (Gifu Pref.), Inuyama (Aichi Pref.), and Tenryu-Funagira (Shizuoka Pref.). These strain data are analyzed to evaluate performance of instruments installed at these sites as well as to identify common geophysical signals.

At Kamioka site, two laser strainmeters with baselines of 100m and 1500m are in operation [2, 3]. At Inuyama and Tenryu-Funagira sites, a 30-m strainmeter and a 400-m one are installed, respectively [4]. These strainmeters clearly detect earth tides, and their amplitudes are consistent with the calculation based on the tidal force, the standard Earth's model, and the topographic effects around the sites. Using the site effects, coseismic strain steps observed by the strainmeter network are compared with fault parameters estimated from seismic observations and the detectability of the fault mechanisms using the strainmeter network is estimated. For long-term strain changes, local disturbances of the sites and detectability of the network are estimated using GNSS data. In the presentation, we discuss detectability of the strainmeter network for seismic and geodetic signals and prospects for monitoring crustal activities using long-baseline laser strainmeters.

UNAVCO GNSS Data: Real-time High-rate Streams, Geodetic Earthquake Magnitudes, Cloud Computing and Future Machine Learning Frameworks

*David A Phillips[1], Kathleen Hodgkinson[1], David Mencin[1], Charles Meertens[1], Thomas Herring[2], Walter Szeliga[3], Timothy Melbourne[3], Mark Murray[4], Glen Mattioli[1], Christine Puskas[1]

1. UNAVCO, Inc. Boulder, 2. Massachusetts Institute of Technology, 3. Central Washington University, 4. USGS

UNAVCO provides a diverse suite of geodetic data, derived products and cyberinfrastructure services to support the geodetic community, Earth science research and education. We present here an overview of recent developments related to real-time GNSS data streams, GNSS earthquake magnitude estimation, a new project focusing on machine learning for geoscience and hazards research, and cloud based GNSS data analysis experiments. UNAVCO operates the National Earth Science Geodetic Facility through a cooperative agreement with the U.S. National Science Foundation (NSF) and NASA.

Real-time (<2 seconds) high-rate (1 Hz) GNSS (RT-GNSS) data streams are now provided from ~900 UNAVCO sites. Streams include raw data in BINEX and RTCM3, and PPP solutions in ITRF2008 via Trimble PIVOT RTX software. Most UNAVCO RT-GNSS sites are within the Network of the Americas (NOTA). NOTA, which includes the historic Plate Boundary Observatory (PBO) network, is an extensive network of GNSS reference stations and other geophysical instruments in the United States, Mexico, Central America, the Caribbean and parts of South America. The network advances research into Earth systems from the core to the atmosphere. Recent advances include improved plate tectonic models, understanding earthquakes and slow slip/episodic tremor, measuring surface water load, deciphering ionospheric dynamics and measuring changes in permafrost. Beyond research the network provides information for earthquake and tsunami early warning systems (EWS), severe weather and space weather forecasts, volcanic activity alerts, drought and flood monitoring and other risk assessments. UNAVCO data are open access; an objective of the geodetic community is to enhance data access and data use for global hazard risk reduction.

Following an earthquake, RT-GNSS data streams can record peak ground displacement (PGD) measurements from long-period surface waves and provide a source-scaling relation that does not saturate with event magnitude. “Geodetic magnitudes” derived from RT-GNSS data can be estimated within seconds to minutes after an earthquake, and can improve earthquake and tsunami EWS. Dynamic displacements estimated in real time show reasonable agreement with post-processed estimates. And while individual position estimates have large errors, RT-GNSS solutions offer excellent operational potential for EWS, including the use of PGD to directly invert for finite-fault solutions. We will show PGD and geodetic magnitude estimate results from recent earthquakes including the 2018-11-30 Mw 7.0 Anchorage, Alaska earthquake. PGD’s from this earthquake were calculated automatically from the RT-GNSS displacement traces, which were large enough and recorded by enough sites to determine that, using GNSS data only, the event was ~M7 within 120s.

As the number of RT-GNSS sites increases, the volume of data and the complexity of automated analysis increase as well. When other data streams are factored in, such as seismic, ocean bottom pressure and satellite radar, the shear volume and complexity of these data streams, coupled with the need to model, analyze and assess hazards in a matter of only minutes, makes geophysical applications to hazards early

warning a Big Data problem. To address this, UNAVCO is collaborating in an NSF project called “GeoSCIFramework: Scalable Real-time Streaming Analytics and Machine Learning for Geoscience and Hazards Research.” This project unites computer scientists and geoscientists to develop a data framework for generalized real-time streaming analytics and machine learning for geoscience and hazards research. The goals of this project, which was just initiated, will be presented.

In addition to real-time products, UNAVCO also provides post-processed position time series and velocities from 2000+ GNSS stations. These products are based on daily solutions generated using GIPSY PPP and GAMIT/GLOBK double-difference network software. This software is currently run on local computing clusters. As part of an NSF funded project called GeoSciCloud, we are testing our GIPSY and GAMIT workflows in two cloud computing environments: Amazon Web Services and NSF’s Extreme Science and Engineering Discovery Environment (XSEDE). The IRIS seismic data facility is a collaborative partner on this project and conducted similar experiments using seismic software and data. We summarize our latest findings from these cloud computing experiments including performance and cost relative to local systems.

On application of GNSS-techniques for early tsunami warning in the Sea of Japan

*Grigorii Viktorovich Nechaev[1,2,3], Nikolai Shestakov[2,3], Hiroaki Takahashi[1], Mako Ohzono[1]

1. Institute of Seismology and Volcanology, Graduate Schooll of Science, Hokkaido University, 2. Far Eastern Federal University, 3. Institute for Applied Mathematics FEB RAS

Tsunami hazard threatens an extensive coastlines located in the seismically active areas. About 250000 persons were killed by tsunami only with the beginning of 21th century. Thus, the problem of reliable early tsunami warning is very important nowadays.
The most of working tsunami early warning systems (TEWS) are based on seismic methods that often cannot provide a reliable and accurate warning due to different reasons. The GNSS-based TEWS recently has been developed and they are free of many shortcomings of seismic methods. Such systems utilize coseismic shifts measured by onshore GNSS-networks for tsunami modeling. The TEWS operating now, for example, REGARD [Kawamoto S. et al., 2017], are mainly focused on detection of huge Mw8-9 class subduction zone earthquakes. They are not designed to process relatively small events, which can produce coseismic displacements less than 10 cm, despite on RTX-techniques or recently developed methods [Fratarcangeli F. et al., 2018], which can detect site position changes of 1-2 cm in horizontal and 3-4 cm in vertical components. However, devastating tsunamis regularly appear in the Japan Sea. They are caused by shallow thrust seismic events with magnitudes Mw6.2-7.8. These quakes generate tsunamis more effectively than Pacific ones with the same magnitude.The epicenters of tsunamigenic earthquakes are distributed along the western coast of Honshu, south-west of Hokkaido and Sakhalin Islands. Nevertheless, tectonics and seismicity of the Japan Seahaven't been sufficiently investigated still and tsunamigenic seismic events can occur along the north-western margin of the sea. For example, the potentially tsunamigenic Mw~6 shallow seismic event occurred near the northeastern coast of Primorye on Nov. 11, 1990.
In this work we explored: 1) the capacity of GNSS-based TEWS application using data about historical Mw 6.2-7.8 Japan Sea crustal seismic events. The appropriate coseismic displacement fields were calculated and analyzed. Possible hypothetic tsunamigenic seismic sources were also considered; 2) the optimal GNSS-site distribution for earthquake source parameters obtaining based on existing and prospective GNSS-networks configuration in the region.
We obtained, that historical tsunamigenic earthquakes occurred along the eastern margin of the Japan Sea induced coseismic displacements ranging from 1 cm to a few decimeters through the northern Honshu and western Hokkaido. Even 1964 Oga-oki, Mw7.0 event caused up to 4 cm surface offsets on the Honshu Island coast. Southwestern Sakhalin Island are also might be affected by centimeter level coseismic movement invoked by the shallow Mw 6.2-7.3 earthquakes appeared in the north of the Sea of Japan and Tatar strait. Hypothetical events with Mw > 7.5 and located in the north-west of the sea may excite displacement varying from 1 to 4 cm in Russian Primorye and Hokkaido Island. A set of inversion tests lead us to a conclusion that GEONET GNSS-network might be used to model tsunamigenic earthquake sources with Mw>7.0-7.8 distributed along the eastern margin of the Japan Sea. Working and prospective GNSS-networks located along the western coast of the sea and Sakhalin Island might be involved into processing of seismic events with Mw ≧ 7.3 appeared in the northern part of the sea.

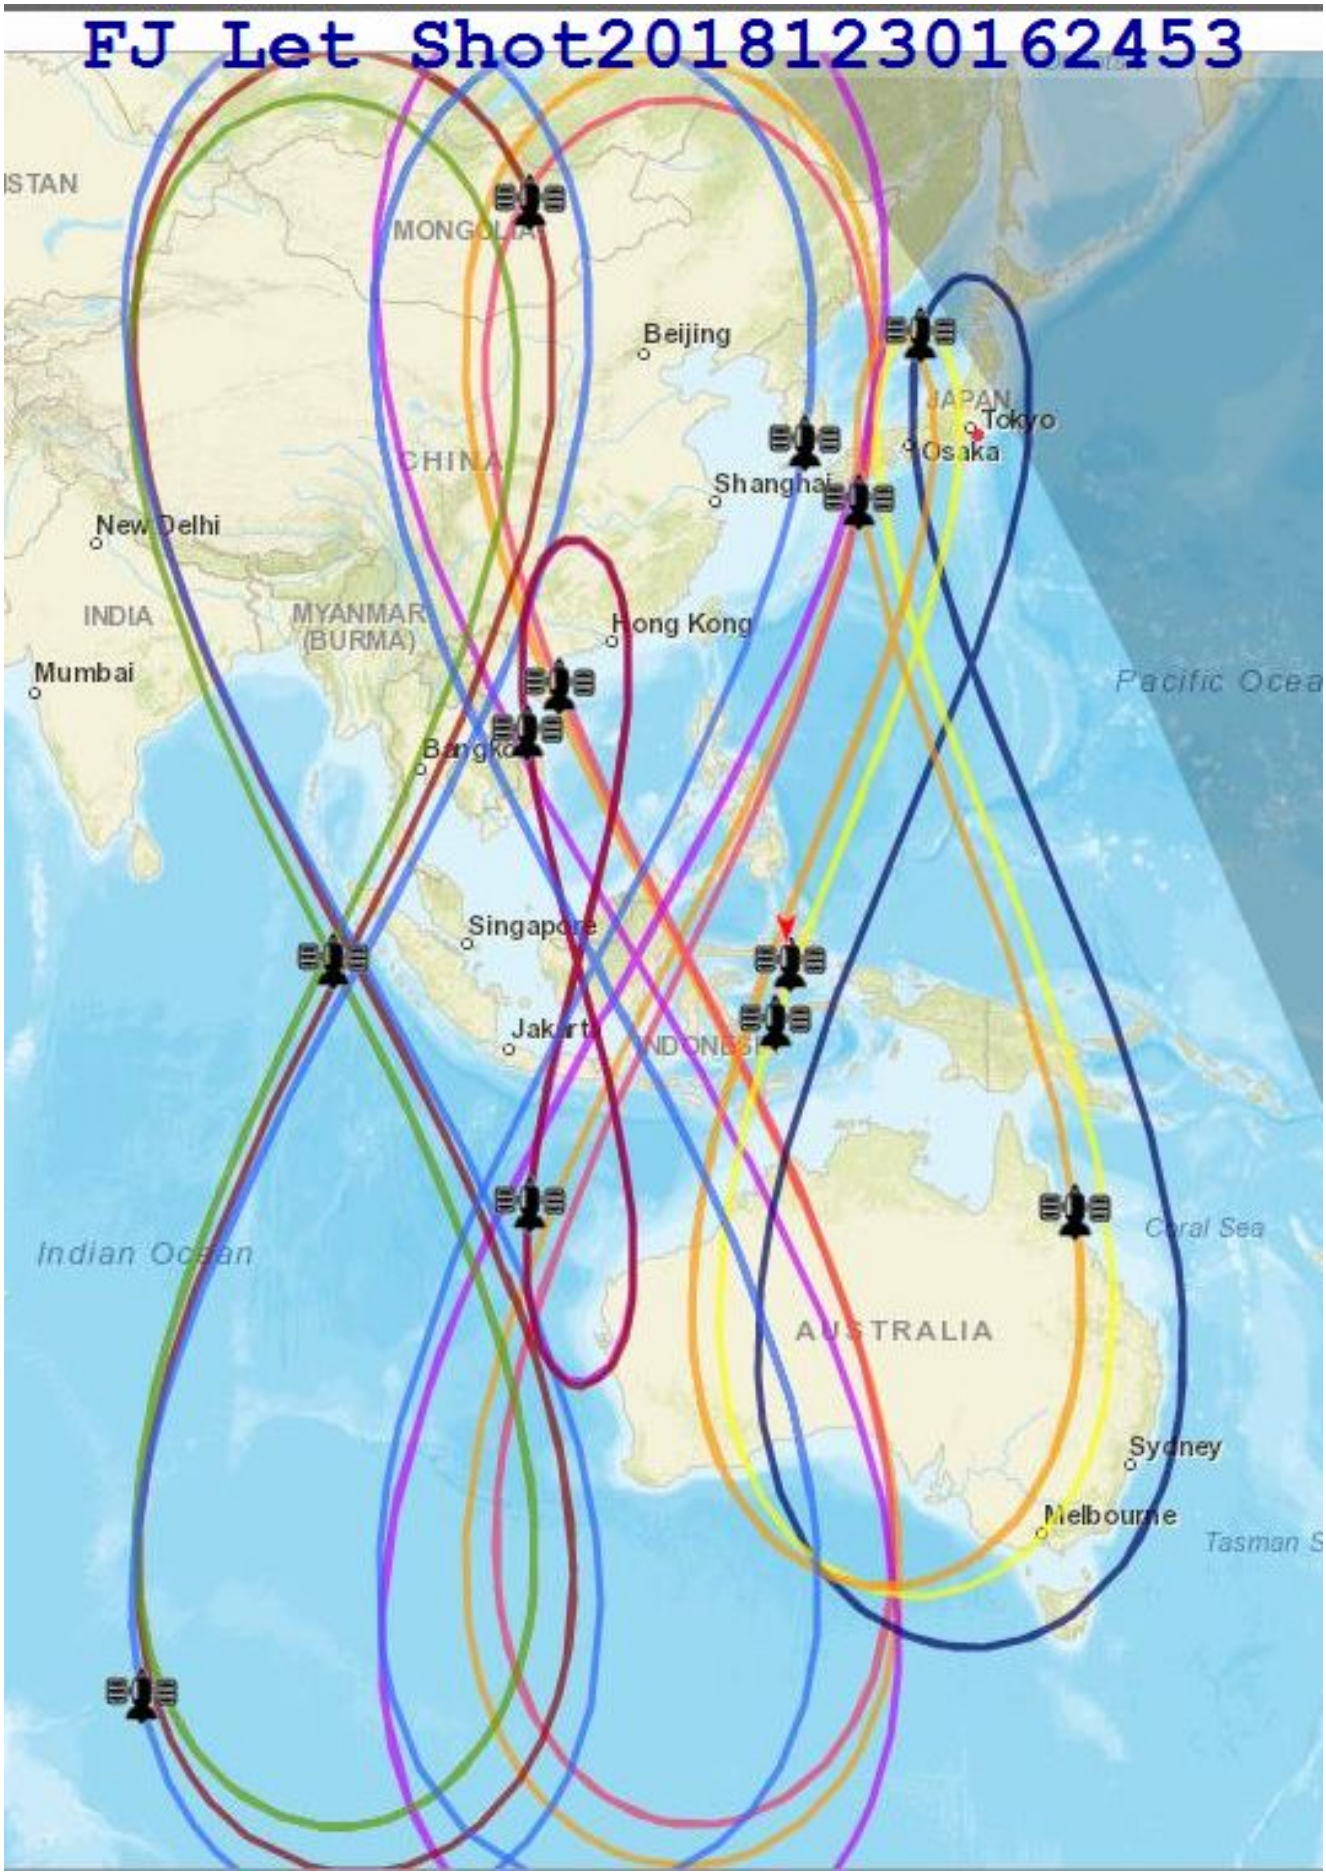
Measurements of occurrence of solar conjunction with the orbits of Asian QZSS/IGSO satellites



*Fujinobu Takahashi[1]

1. Yokohama National University

On the space PNT in the 20th century, the MEO satellite system represented by GPS space segment of USA has played a major role. In the 21st century, Japan's QZSS (Michibiki) satellite system and IGSO space segment of China and India are now appearing. The feature of the MEO satellite system is a scheme that the positioning accuracy is determined by randomly selecting MEO satellites above the elevation limit and by the satellites combination of smaller DOP. This is one of the stochastic based on the group of the randomly selected satellites, rather than the orbital theory of the satellite. Meanwhile the orbital motions of QZSS/IGSO of new 21st century are very slow over the respective earth regions. The more theoretical methods using satellite orbit models are available and the more reproducible analytic methods are possible. The author will report the measuring results of the orbital motion and the solar conjunctions of Asian QZSS/IGSO satellites over more than a year.

Sea level evaluation in northern Australian coast

*Yuta Tokui[1], Kosuke Heki[1]

1. Hokkaido University

Sea surface heights (SSH) are observed by satellite ocean altimetry, and it changes by two major causes. They are barystatic changes e.g. inflow of melt water from land ice, and thermal expansion of sea water, and they can be observed by GRACE and Argo floats, respectively. The three quantities behave differently from region to region, and their mutual link is important to understand regional characteristic of oceans. Here we study sea level changes in northern Australian coast (consisting of the Arafura, Timor, and Solomon Seas and the Gulf of Carpentaria). This region is characterized by large seasonal changes in SSH and gravity, and influenced by multiple climate changes such as ENSO (El Nino and Southern Oscillation) and IOD (Indian Ocean Dipole). First, we compare three changes (altimetric, thermosteric and gravity) to evaluate sea level budget. We found that SSH changes mainly come from steric changes excluding Gulf of Carpentaria where barystatic changes prevail. Next, we use the Empirical Orthogonal Functions (EOF) approach to identify the major modes of the seasonal and interannual variability. Seasonal changes in SSH are strong in Gulf of Carpentaria. The 1 st EOF of gravity indicates that main seasonal change occur in phase in the land and the sea. We also found that long-term precipitation variability appears as the 2nd EOF. The EOF analysis further showed that non-seasonal altimetric and gravity changes are driven mainly by climate changes, mainly ENSO in SSH and PDO in gravity.

Implications from geomagnetic observation for the interannual fluctuations of Earth rotation

*Seiki Asari[1], Masanori Kurihara[1], Kenji Morinaga[1], Shingo Nagamachi[1]

1. Kakioka Magnetic Observatory, Japan Meteorological Agency

Kakioka Magnetic Observatory has a history of magnetic observation over as long time as more then a century. It has supported a progress of scietific researches and industry by providing accurate data, developing observation technology, certifying measurement instruments, as well as playing a geodetic role as a magnetic reference station of Japan. The observatory is even increasingly expected to stay as one of world's principal observatories, with the increase of demands for prompt data issuance to serve as reference for the recent satellite magnetic observations.

Geomagnetic variations consist of different components with varying sources and timescales. The accumulation of enormous amount of data from the recent satellite observations in the late years have drawn attentions to the interannual variations of the geomagnetic main field originating in Earth core. These variations had not been well recognised, with their tiny signals hidden by the magnetic perturbations from the magnetosphere. If these signals are resolved more clearly, they can be a precious key to reveal the interannual phenomena in Earth fluid core such as hydromagnetic waves. Imaging of the core fluid flow relies entirely on mangetic observations, as the seismic and gravitational observations do not provide high enough sensitivity, while the net fluctuations of the core may be analysed by using Earth rotation variation.

Currently, monthly mean database for the past half century has been under construction at Kakioka Magnetic Observatory such that they are optimised for better identifying the interannual main field variations. It has been found that approximately 70 percent of the external field perturbations can be eliminated from monthly data at any observatories at low- and mid-latitudes. A better mapping of the fluid core flow may be possible for even longer period. In this presentation, a report for the progress and prospect is given, together with discussion on implications for the interannual Earth rotation fluctuations through the core flow map imaged from magnetic observations. A spatiotemporal features of the westward core fluid jet at the polar region in the northern hemisphere, which may be responsible for both the rapid changes in both the geomagnetic main field and the length-of-day.

[S-SS11] Seismic wave propagation: Theory and Application

convener:Kiwamu Nishida(Earthquake Research Institute, University of Tokyo), Kazuya Shiraishi(Japan Agency for Marine-Earth Science and Technology), Takao Nibe(JAPEX), Kaoru Sawazaki(National Research Institute for Earth Science and Disaster Resilience), Chairperson:Tsutomu Takahashi(JAMSTEC)

Seismic wave propagation provides rich information of earth's heterogeneities and the excitation sources. In order to extract the information, integrated studies are needed among mathematical/numerical studies based on the wave theory, miniature physical experiments using rock specimens, and practical data analyses. Furthermore, it is greatly beneficial to conduct comparative studies of various kinds of waves, such as elastic, acoustic, traveling ionospheric disturbances, and oceanic waves. This session widely invites presentations about the theories and applications related to seismic and other geophysical waves.

Power Spectrum of Random Heterogeneity of the Solid Earth

*Haruo Sato[1]

1. Tohoku Unvieristy

Recent observations focusing on scattering of seismic waves revealed the existence of random heterogeneities in the solid earth medium. The radiative transfer theory (RTT) has been often used for the study of the propagation and scattering of wavelet intensities. For the statistical characterization of the power spectral density function (PSDF) of the random fractional fluctuation of velocity inhomogeneities in a 3-D space, we use von Karman type with three parameters: the RMS fractional velocity fluctuation, the characteristic length, and the order of the modified Bessel function of the second kind. This model leads to a power-law decay of PSDF at wavenumbers higher than the corner.

We compile reported statistical parameters of the lithosphere and the mantle based on various types of measurements. Reported exponents of wavenumber are distributed between -3 and -4, where many of them are close to -3. Reported RMS fractional fluctuations are of the order of 0.01 -- 0.1 in the crust and the upper mantle. Reported characteristic lengths distribute very widely. In order to grasp the spectral characteristics, eliminating strong heterogeneity data and the lower mantle data, we have plotted all the reported PSDFs of the crust and the upper mantle against wavenumber for a very wide range.

We find that the envelope of those PSDFs is well approximated by the -3rd power of wavenumber. In theory, we need to re-examine the applicable range of the Born approximation in the RTT when the wavenumber of a wavelet is much higher than the corner. In observation, we will have to measure carefully the PSDF on both sides of the corner. It is interesting to study what kinds of geophysical processes created the observed power-law spectral envelope in different scales and in different portions of the solid earth medium.

Estimation of spatio-temporal changes of seismic scattering property associated with the 2008 Iwate-Miyagi Nairiku earthquake from sparse modeling of seismic ambient noise CCFs

*Takashi Hirose[1], Hisashi Nakahara[1], Takeshi Nishimura[1], Michel Campillo[2]

1. Graduate School of Science, Tohoku University, 2. University Grenoble Alpes, CNRS, ISTerre

In recent years, spatial distributions of seismic velocity and/or seismic scattering property changes associated with volcanic activities and earthquakes have been investigated by linear least-squares inversions using seismic ambient noise cross-correlation functions (CCFs) and sensitivity kernels (e.g., Obermann et al., 2013; Obermann et al., 2014). However, spatial distributions of medium changes are not easily estimated in the regions where only a small number of stations are set up. Here, we use sparse modeling (L_1 norm regularization) to estimate model parameters for a small data set (e.g., Tibshirani, 1996), and evaluate the minimum number of stations for these studies. We apply the sparse modeling to the 2008 M_w 6.9 Iwate-Miyagi Nairiku earthquake that occurred on 14 June 2008, and estimate the spatial distribution of seismic scattering property changes from decoherence (waveform changes) data of seismic ambient noise CCFs. Since we have enough seismic stations, we can compare the results from the sparse modeling and those from an ordinary linear least-squares inversion with L_2 norm regularization which has been widely used to solve linearized problems.

Seismic ambient noise CCFs were calculated at 0.5-1 Hz band for the pairs among 17 Hi-net stations during the years of 2007 and 2008. We firstly calculate decoherence values between reference CCFs (Jan-Dec, 2007) and target CCFs in two time periods of May 1 to June 13 (Period I) and June 15 to July 31 (Period II) in 2008, respectively. We then calculate the differences of decoherence values of Period I and Period II, and use them as observed decoherences. Totally, 450 observed decoherence values are analyzed. Finally, we divide the study area into 63 small cells with a size of $0.15^\circ \times 0.15^\circ$ and estimate scattering coefficient changes, Δg, for each small cell by comparing the observed and synthesized decoherence values. Here, we estimate synthesized decoherence values using 2-D decorrelation kernels (Margerin et al., 2016).

The result from the linear least-squares inversion with L_2 norm regularization shows that large Δg values are estimated around the epicenter of the main shock. The region of the largest Δg value is located at the south of the epicenter also from the sparse modeling. The maximum Δg value is about 0.035 km^{-1}, which is almost equivalent to the total scattering coefficient at this region. To know a minimum number of stations for the estimation, we selected the stations which locate within 30 km, 40 km, and 50 km from the epicenter (5, 7, and 13 stations, respectively), and conducted the same estimations for each case using the sparse modeling. We confirmed that 7 stations were necessary to recover the similar result.

The regions with large Δg values are well correlated with the region where large peak ground acceleration and large seismic velocity decreases are obtained (Takagi et al., 2012; Hobiger et al., 2014). This consistency suggests that strong motion by the main shock introduce not only large seismic velocity decreases but also large seismic scattering property changes in the shallow medium at the south of the epicenter. The sparse modeling will be useful to locate a change region of seismic scattering property changes from a sparse seismic network with several seismic stations.

Surface roughness of the Philippine Sea plate at Nankai subduction zone

*Tsutomu Takahashi[1], Ayako Nakanishi[1], Shuichi Kodaira[1], Yoshiyuki Kaneda[2]

1. JAMSTEC, 2. Kagawa University

Seismic fault surfaces have roughness over a broad spatial scale range. In this study, we measured surface roughness of subducting Philippine Sea plate along several seismic survey lines at Nankai trough. Surface geometry of the subducting plate have been estimated by analyzing both the wide-angle refraction and high-resolution seismic-reflection surveys by Nakanishi et al. (2018). They estimated velocity structures from the former data with consideration for travel times of reflected waves from the top of the Philippine Sea plate of the latter data. Uncertainties of their geometry of the Philippine Sea plate can be examined by the uncertainties of velocity structures in the overriding continental plate.
First, we examined the P-wave velocity structures in the continental plate. Power spectra of the velocity fluctuations obey a power-law at small wavenumbers. We also find a clear decrease of power spectral density at larger wavenumbers. Cutoff wavenumber of this change almost corresponds to the inverse of receiver interval. Such decrease of power spectral density is probably caused by a spatial smoothness constraint of velocity estimation. Then, we examined the surface geometries at wavenumbers smaller than the cutoff wavenumber. Power spectra of surface geometries shows self-affine property. We applied bandpass filters for geometry data and mapped the root mean squared amplitudes of filtered geometries as surface roughness. Roughness is large at Hyuga-nada, and becomes small near the trough-axis off south of Shikoku. The small roughness area off Shikoku shows low activity of regular and slow earthquakes. Meanwhile, Hyuga-nada area shows high activity of low frequency earthquakes (Yamashita et al. 2015). Since surface roughness is relevant to a small-scale stress concentration on faults, this result implies an importance of surface roughness for seismicity.

Source location of volcanic earthquakes and tremors at Sakurajima volcano based on seismic correlation

*Theodorus Permana[1], Takeshi Nishimura[1], Hisashi Nakahara[1]

1. Solid Earth Physics Laboratory, Department of Geophysics, Graduate School of Science, Tohoku University

Precise source locations of volcanic tremors and earthquakes are one of the most basic information that is important to understand the volcanic process. The spatio-temporal changes of these source locations may provide insights into the eruption mechanism and the movement of volcanic fluids. However, the determination of those source locations is quite challenging due to the difficulties to distinguish their seismic phases and precisely measure the arrival times. Recently, we developed a hypocenter determination method for volcanic earthquakes and tremor, which adopts seismic interferometry processing technique for calculating cross-correlation functions (CCFs) and the source-scanning algorithm (SSA) (Permana et al., in preparation). Here, we apply our method to observed data recorded at Sakurajima volcano. We first locate volcano-tectonic earthquakes (VTs) and evaluate the location errors by comparing the results with the hypocenters determined by a phase-picking method. Then, we locate volcanic tremors and discuss their source locations, which cannot be obtained from phase-picking methods due to indistinguishable phase arrivals.

We analyze VTs that occurred during a rapid dike intrusion on August 15, 2015. Our result shows the hypocenters are distributed beneath the Mt. Minamidake mainly at 0-4 km depths. Our source locations are consistent with the hypocenters obtained by using the method of Hirata and Matsuura (1987), and the errors are estimated to be 2 km or less.

We determine the source locations of two kinds of tremors occurred on August 22-25, 2017. The first is a 13.5 hours long continuous tremor accompanying Strombolian eruptions on August 22-23. The second is a series of intermittent tremors that are recorded following the explosion earthquakes associated with Vulcanian eruptions which followed the continuous tremor. We calculate the CCFs at 1-3 Hz by using 20 s time windows with 19 s overlap for these tremors and stacked them to obtain average CCFs. Our results show that the source locations of the first 6 hours of continuous tremor, which are determined every 10 minutes, are located beneath Mt. Minamidake at depths from about 3 km to below the active crater. The sources of the following continuous tremor are located at shallower depths, from about 2 km depth to the ground surface on the southern flank of Mt. Minamidake. The sources of 61 segments of the intermittent tremors are densely distributed at 0-2 km depth beneath Mt. Minamidake.

The observed tremors are related to the eruptive activities at Sakurajima volcano and their sources are expected to be located at the eruptive conduit. Our estimated sources are distributed at the shallow depths beneath the active craters within the estimated errors. Therefore, our results show the prospect of our method as an alternative for tremor source location determination and volcano monitoring. The depth range of our results for continuous tremor also coincides with the previous studies on the generation depth of volcanic earthquakes.

Crustal Structure Investigation in Northern Taiwan - Localized Wavefield Inversion of TAIGER T6 Wide Angle Refraction/Reflection Data

*Fandy Adji Fachtony[1], How-wei Chen[1]

1. Institute of Geophysics, National Central University

TAIGER T6 transects is one of the four crustal-scale Wide Angle Refraction/Reflection (WARR) survey lines under **TA**iwan **I**ntegrated **GE**odynamics **R**esearch (TAIGER) project conducted in 2008 in Taiwan. The north main array consist of four shot points (N1, N2, N3, and N4) across northern Taiwan from west to east. A total of 456 geophones deployed with receiver interval of ~200m on average. However, the recorded data suffers from crooked survey line geometry, uneven shot energy, noise level and currently available poorly defined 3D reference velocity model. Near-surface static effects caused by the irregular source and receiver spacing, strong lateral velocity variations and rapid topography changes produce apparent 3D wave propagation so that the standard seismic data processing or travel-time inversion could not be fully applied. To compensate above-mentioned drawbacks, Localized Slant Stack Transformation (LSST) for data pre-processing was applied to separate signal from interfering noise that has big amplitude and minor T-X curve difference. LSST is slowness and offset range-based plane wave destruction and construction techniques. The pros and cons of LSST will be discussed for TAIGER-T6 line.
For stable wavefield inversion, sufficient spatial sampling and events enhancement is essential. Wavefield inversion utilize the complete-cycle of wavelet information without picking compared to tomography study that rely on the travel time picks with potential reading errors. Velocity estimation is performed via wavefield transformation from τ-p data domain to τ-p-z solution domain through downward continuation and the application of imaging condition ($\tau = 0$). Ray tracing is performed for quality control and to quantify the separated static effects produced from source, receiver and velocity changes. Feasibility studies of three crustal scale synthetic models containing: (1) flat layers without topographic, (2) flat layers with topographic, (3) laterally varying topographic velocity models. Synthetic data is produced from Specfem2D computations. Effects of source and/or receiver static, velocity variation, and the combination of all were studied. Wavefield inversion is stable for all test models. Inverted 1D velocity becomes less smooth when static effects are included with and without static corrections. Real data implementation for all shots were cross-checked through numerical travel-time curve with acceptable error bound. Furthermore, the bottoming point of each ray through seismic ray tracing can be mapped along with the velocity information to construct quasi-2D velocity model. Inverted velocity depth profile from wavefield inversion provide higher resolution compared to the existing tomography velocity model across northern Taiwan area.

Self-organized criticality induced by randomness in block-spring models and the Gutenberg=Richter law

*Hidetsugu Sakaguchi [1]

1. Kyushi University

The Block-spring model is a simple mathematical model for earthquakes proposed by Burridge and Knopoff. Later, Carlson and Langer performed numerical simulations of a uniform block-spring model with velocity-weakening friction. They found that the slip-size distribution obeys a power law in a small scale. Their model exhibits a kind of spatio-temporal chaos and the slip size distribution is dur to the chaotic behavior. Many authors studied a variety of block-spring models. In this presentation, we will show numerical results of a block-spring model with quenched randomness in the velocity-strengthening friction. When the pulling force is stationary, there is a continuous transition from a state pinned by the quenched randomness to a sliding state. When the external force is applied through a spring, the pinning and sliding repeat randomly. The effective pulling force fluctuates around the critical value of the pinning-depinning transition. The phase transition is self-organiized even if the parameter is not controlled. As a result of the criticality, the slip size distribution obeys a power law. We consider that the power law is caused by the self-organized criticality to the pinning-depinning transition in the random media. Our model is related to the asperity theory in that the spatial inhomogeneity is important.

[S-SS11] Seismic wave propagation: Theory and Application

convener:Kiwamu Nishida(Earthquake Research Institute, University of Tokyo), Kazuya Shiraishi(Japan Agency for Marine-Earth Science and Technology), Takao Nibe(JAPEX), Kaoru Sawazaki(National Research Institute for Earth Science and Disaster Resilience), Chairperson:Kiwamu Nishida(東京大学地震研究所)

Seismic wave propagation provides rich information of earth's heterogeneities and the excitation sources. In order to extract the information, integrated studies are needed among mathematical/numerical studies based on the wave theory, miniature physical experiments using rock specimens, and practical data analyses. Furthermore, it is greatly beneficial to conduct comparative studies of various kinds of waves, such as elastic, acoustic, traveling ionospheric disturbances, and oceanic waves. This session widely invites presentations about the theories and applications related to seismic and other geophysical waves.

Land-Atmosphere Interaction in the low-frequency seismic band and inversion for shallow elasticity structure

*Toshiro Tanimoto[1], Jiong Wang[1]

1. Department of Earth Science, University of California, Santa Barbara, CA93106, USA

For frequencies below 0.05 Hz, except for the hum signals generated by ocean waves, the atmosphere is the main source of seismic noise. Some characteristics of atmosphere-generated seismic noise have been reported (e.g., Zürn et al., 2007; Zürn and Wielandt, 2007) but recent data from co-located pressure and seismic sensors allow us to improve our understanding of this interaction. We report our analysis of data from the EarthScope Transportable Array (TA) and some global permanent stations that are equipped with pressure and seismic sensors.

We first point out that coherence between surface pressure and vertical seismic data shows two broad peaks, a lower frequency one that rises below about 0.002 Hz and a higher frequency peak that reaches its maximum about 0.02 Hz. There is a minimum of coherence between them at about 0.003-0.004 Hz.

We noted that there is basically no phase-shift between pressure and vertical seismic displacement for the lower frequency peak while there is a 180-degree phase shift between pressure and vertical displacement for the higher frequency peak at about 0.02 Hz. Two peaks show a completely opposite relationship between pressure and vertical displacement. The zero phase-shift for the lower frequency peak is consistent with the mass-attraction effect due to density perturbations in the atmosphere and the 180-degree phase shift for the peak about 0.02 Hz is consistent with elastic deformation caused by surface pressure.

They suggest that these are two competing forces generated by the atmosphere, one that tends to attract the sensor mass upward by density perturbations in the atmosphere and the other that tends to push down the ground due to high pressure. The mass-attraction effect wins for the lower frequency peak and the ground deformation effect wins for frequencies above 0.01 Hz. The existence of the minimum between the two peaks indicates that relative size of these forces switches at about 0.003-0.004 Hz (already pointed out by Zürn and Wielandt, 2007).

The size of the higher frequency peak (at about 0.02 Hz) is strongly influenced by the elasticity of near-surface materials; at many sites with STS-1 sensors, this high frequency peak is often hard to identify as the sites are mostly at hard-rock sites, meaning there is little deformation due to atmospheric pressure. On the other hand, some EarthScope TA sites are at soft sediment sites and show a large (and dominant) peak at about 0.02 Hz. For such soft sites, we can derive shallow structure from pressure and seismic data.

We will present an inversion scheme to invert data from this higher frequency peak. Basic data are the ratios between vertical seismic data to pressure data and also between horizontal seismic data to pressure data for frequencies between 0.005 Hz and 0.05 Hz. The method is an iterative nonlinear inversion from a starting model using depth sensitivity kernels that are computed at each iteration step. The framework of inversion is similar to surface-wave phase velocity inversion. The product is a layered elasticity structure beneath a co-located station.

Noise correlation analysis of S-net records

*Ryota Takagi[1], Genti Toyokuni[1], Mare Yamamoto[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

We applied noise correlation analysis to continuous records of Seafloor Observation Network for Earthquakes and Tsunamis along the Japan Trench (S-net) to estimate crustal structure beneath the offshore region of northeast Japan. We used three-component records from 2017 to 2018 provided by National Research Institute for Earth Science and Disaster Resilience (NIED) and converted wavefoms from XYZ to UNE components. We analyzed accelerometer records because signal-to-noise ratio of accelerometer is higher than that of velocity sensor in the periods longer than a few seconds. The noise cross-correlation functions show periodic pulses every 60 seconds and a single pulse at zero lag. The periodic pulses and zero lag pulse can be attributed to coherent periodic noise and random noise, respectively, due to electric perturbation in instruments. The periodic noise depends on station, component, and time period. The random noise appears to be common only within stations along the same cable lines. We removed the periodic noise by computing cross-correlation functions of the difference waveforms between the records of one day and the records of one day before. The cable-dependent random noise was removed by fitting an empirical function to cross-correlation functions in the frequency domain. The noise reduction and staking within station separation bins enable us to extract Rayleigh and Love waves up to about 30 seconds. In the shorter period than 10 seconds, we found multiple modes of Rayleigh waves with group velocities of about 1.5 km/s and 0.3 km/s, which may have energy in ocean layer and sediment. In addition, we found Rayleigh waves propagating from coastal stations to deep offshore stations at the period around 4 seconds, whereas Rayleigh waves mainly propagate from deep offshore stations to coastal stations at the period around 8 seconds. The extracted surface waves may be useful to estimate crustal structure beneath the offshore region along the Japan trench.

Acknowledgement: We used continuous records of S-net managed by NIED. We thank NIED for providing the data.

Atmospheric waves from the gas explosion in Sapporo on December 16, 2018, recorded by seismometers

*Kazunori Yoshizawa[1]

1. Faculty of Science, Hokkaido University

A large gas explosion occurred in Hiragishi, Sapporo, on December 16, 2018, which blew up a two-story building in the hypocenter with more than 50 injured, although no casualty was reported miraculously. Damages to window glasses of neighboring buildings were reported in the radius of about 100 meters around the hypocenter due to strong blast waves from the explosion.

The infrasound waves from this explosion have been recorded in several seismometers installed on the ground surface of Ishikari Lowland (including the one in the campus of Hokkaido University) even at stations more than 60 kilometers away from the hypocenter, which has traveled with a speed of about 330 m/s. It is well known that atmospheric infrasound waves from large volcanic eruptions and/or meteor blast can travel very long distances, which can be observed with broad-band seismometers. Although this explosion in Sapporo is much smaller than such natural phenomena, the observed seismic records are likely to be caused by the air-earth coupled ground motions due to the infrasound waves from the explosion.

The observed infrasound/acoustic signals from this explosion cannot be observed in seismometers installed underground in and around Sapporo. Also, we cannot see any clear elastic wave (P-wave or surface waves) from this explosion. Only several seismometers installed on the ground surface have recorded the infrasound signals that are characterized by strong spectral peaks in a frequency range between 5 and 30 Hz. We can also identify the directional dependence of the observed waveforms; i.e., the amplitudes of infrasound signals are more attenuated and scattered in the north of hypocenter. This may be affected by winds and/or propagation paths, in particular, the urban area of Sapporo with tall buildings spared over the north of hypocenter.

Time-lapse monitoring of seismic velocity associated with the 2011 Shinmoedake eruption using seismic interferometry

*Kiwamu Nishida[1], Yuta Mizutani[1]

1. Earthquake Research Institute, University of Tokyo

In recent years, the number of applications of seismic interferometry is increasing. In the analysis, the cross-correlation function between ambient noise records of a pair of stations can be regarded as a virtual seismic waveform recorded at one station when the source is placed at the other station. Since, in any time period, the seismic velocity around the station pair can be estimated from the cross-correlation function calculated without an earthquake, the seismic interferometry has been applied in many studies to monitor the temporal change of the seismic velocity. A number of studies have monitored the seismic velocity change in the volcanic region with seismic interferometry and detected the temporal change in seismic velocity associated with the eruption (Brenguier et al., 2008; Rivet et al., 2015). Inferred seismic velocity changes in the volcanic region frequently show the seasonal variations, which were caused by precipitation. The amplitude of seasonal fluctuation has the same order of magnitude of velocity change associated with the eruption. Therefore, in order to detect the transient velocity change accompanying the eruption, it is important to evaluate the seasonal fluctuation due to precipitation quantitatively and remove it appropriately from the estimated seismic velocity change. In this study, seismic interferometry was applied to a seismic array around Shinmoedake to monitor the seismic velocity change, aiming at detecting the velocity change associated with the Shinmoedake eruption in 2011. First, a cross-correlation function was calculated for each pair of stations using continuous ambient noise data for 8 years from May 2010 to April 2018. The stretching method (Sens-Schönfelder and Wegler, 2006) was applied to the calculated cross-correlation function to estimate the temporal change of the seismic velocity. From the estimated seismic velocity change by the stretching method, the seasonal variation affected by precipitation was detected as in the previous study (Wang et al., 2017). Therefore, the effect of precipitation was quantitatively evaluated using pore pressure model (Roeloffs, 1988; Talwani et al., 2007). After the effect of precipitation was subtracted, the seismic velocity change associated with the eruption was detected in several pairs. In order to constrain locations of the seismic velocity change in space, the horizontal and depth sensitivity kernel was calculated. The kernels suggested that structural changes would not occur in the depth of 1-3 km in the southeastern side and in the depth of 1-2 km in the northwestern side of Shinmoedake.

Temporal variations of seismic velocity and azimuthal anisotropy in near-surface rock and soil at KiK-net downhole array sites

*Taka'aki Taira[1], Li-Wei Chen[1], Hiroe Miyake[2]

1. Berkeley Seismological Laboratory, University of California, Berkeley, 2. The University of Tokyo

Measuring stress and damage induced seismic velocity and anisotropy in crustal structure and their temporal behaviors provide insights into the underlying mechanisms of healing processes and its evolution, which would lead to a better understanding of earthquake cycle. We analyze three-component surface and borehole seismic data collected by KiK-net (Kiban-Kyoshin Net) to explore temporal variations in P- and S-wave velocity and S-wave azimuthal anisotropy (strength of anisotropy and polarization direction of the fast S wave) through coda wave interferometry. Our preliminary focus is on Hokkaido sites that experienced ground motion from the 2003 magnitude (M) 8.3 Tokachi-Oki and the 2018 M 6.0 Hokkaido Eastern Iburi earthquakes. Following Chen et al. (2017, EPSL), we analyzed all available KiK-net seismic waveforms in a frequency band of 1-15 Hz from 1997 through 2018 (more than 700 events) and evaluated seismic velocity and azimuthal anisotropy between surface and borehole sensors at 22 KiK-net sites. Median P- and S-wave velocity stacked by all measurements at each site are good agreement with them obtained from borehole logging data provided by NIED (National Research Institute for Earth Science and Disaster Resilience). We find that a number of KiK-net sites recording peak ground acceleration (PGA) higher than ~500 cm/s^2 (at surface sensor) exhibit clear S-wave velocity reductions following the 2018 Hokkaido Eastern Iburi mainshock. Station IBUH03 (located at Atuma town) also shows a sudden decrease of S-wave velocity following the 2003 Tokachi-Oki earthquake (PGA = ~350 cm cm/s^2 at station IBUH03). Reductions of S-wave velocity were about 6.5% for both mainshocks. However, there are a number of differences between two earthquakes. Our preliminary analysis suggests that the polarization direction of fast S-wave was systematically changed from 50 degrees to 10 degrees (measured clockwise from the north) following the 2018 earthquake and no notable change of P-wave velocity was observed. On the other hand, for the Hokkaido earthquake case, station IBUH03 appears to have a large variability in the polarization direction and displays a P-wave velocity reduction of about 4.5%. Our observation suggests a temporally increase of randomly oriented fractures following the 2003 Tokachi-Oki earthquake and also may suggest that the stress changes from the 2018 Hokkaido Eastern Iburi earthquake created water-saturated cracks oriented at ~10 degrees from north.

Denoising Ambient Seismic Field Correlation Functions with Deep Autoencoders

*Loic Viens[1], Chris Van Houtte[2]

1. Disaster Prevention Research Institute, Kyoto University, 2. GNS Science

In the last decade, seismic interferometry has become an established technique for monitoring the temporal changes of the Earth’s physical properties. This technique relies on measuring time shifts of seismic waves present in Green’s functions, which are generally approximated by cross-correlating 1-h long ambient seismic field records at two stations. To increase the accuracy of the phase information of hourly cross-correlation functions, pre-processing is generally applied to the recorded ambient seismic field, such as 1-bit normalization and/or pre-whitening. Despite this, hourly cross correlation functions often need to be stacked over a few hours/days to increase their signal-to-noise ratio and measure reliable phase shifts. We introduce a new technique for improving the time resolution of seismic monitoring, which denoises cross-correlation functions using deep autoencoders. Autoencoders are composed of an encoding function, which computes a compressed representation of the input data, and a decoding function which reconstructs a simplified representation of the input data. Both the encoder and decoder parts are composed of a stack of densely-connected neural network layers. Such an algorithm can be trained to denoise corrupted versions of their inputs, which in our case are correlation functions with low signal-to-noise ratio. We apply our deep denoising autoencoder on synthetic and real single-station cross-correlation functions computed from a few MeSO-net stations located in the Tokyo Metropolitan area. The denoised waveforms allow us to compute more precise relative velocity change (dv/v) than with the raw waveforms. The great advantage of this technique is that the algorithm can be trained within a few seconds and can be used to denoise near-real-time data, which could be useful for volcano monitoring.

Determination of dynamic characteristics of existing buildings at various site conditions in Eskisehir, Turkey

*Onur Kaplan[1], Seiji Tsuno[2], Hiroaki Yamanaka[3], Mehmet Safa Arslan[4], Oguz Ozel[4]

1. Eskisehir Technical University, 2. Railway Technical Research Institute , 3. Tokyo Institute of Technology , 4. Istanbul University

The fundamental vibration period of a building is a crucial parameter for earthquake engineering. The equivalent seismic lateral force is determined from a design spectrum in most static design methods. Accordingly, the earthquake force is a function of the fundamental vibration period of the building. The fundamental period of an existing building can be determined by both forced and ambient vibration measurements. In this study, ambient vibration measurements were conducted at 17 existing buildings including different structural styles (masonry and reinforced concrete) and heights (7 to about 65 meters) which are located at different site conditions in Eskisehir, Turkey. In ambient vibration measurements, two accelerometers were placed on the top of the buildings and one accelerometer was placed on the ground. The fundamental vibration periods and the dampings of the measured buildings were evaluated. The fundamental vibration periods of the buildings were evaluated by picking the peaks of the spectral ratios of Fourier spectra on the top floor of buildings to those on the ground. The dampings of the measured buildings were estimated by fitting the spectral ratios calculated using a single degree of freedom system to the spectral ratios observed, in the process of trial and error (Iwata and Tsuno, 2013). In order to understand the site conditions near the buildings, array microtremor observations by small-scale arrays of 1.5 to 16 meters were performed on the free field. SPAC method was used to obtain the phase velocities of Rayleigh waves and the S-wave velocity profiles were estimated using those phase velocities in the inversion technique. Tsuno et al. (2018) derived an equation of T=0.016H from 10 building measurements carried out in Eskisehir, Turkey. In this study, 7 more measurements were added to the previous measurements of Tsuno et al. (2018) thus, according to findings of this study, the equation of T=0.0165H was proposed to estimate the fundamental vibration period (T, in seconds) of an existing building in Eskisehir, Turkey with respect to its height (H, in meters). This equation is still in need to improve with additional measurements, which could represent most of the building heights in the Eskisehir building inventory. The calculated dampings of the measured buildings have a general tendency that the higher the buildings, the smaller the dampings.

ICDP DSeis 10: Near-field Observations for the M5.5 Orkney, South Africa Earthquake

Tatsunari Yasutomi[1], *James Mori[1], Hiroshi Ogasawara[2]

1. Earthquake Hazards Division, Disaster Prevention Research Institute, Kyoto University, 2. Ritsumeikan University

We examined the near-field records for the 2014 Orkney earthquake (M5.5) to infer source properties for this moderate-sized earthquake. The event was the largest recent earthquake associated with the deep gold mines of the region. Different from usual normal-faulting events that are induced on known structures of the mines, the M5.5 earthquake took place significantly below the mining horizon with a strike-slip mechanism on an unknown geologic structure. Seismic activity close to the Moab Khotsong and Great Noligwa mines is very well monitored by instruments installed on the surface and in the mine tunnels. The high sample-rate (6 khz) geophones installed in the mine at depths of 1 to 3 km provide high-quality recordings of the mainshock and aftershocks.

The waveforms show that there is a small foreshock (about M1.8) located 1.6 km south of the mainshock hypocenter and at 0.6 sec before the mainshock. There is no evidence of any unusual character of the foreshock, or any significant deformation between the foreshock and mainshock.

Using lower frequency (<2.0 hz) data, the nearfield waveforms can be modeled using a finite fault slip inversion. The results show a slip distribution with two main patches of larger slip, which are located a few kilometers to the north and to the south of the hypocenter. The area of the fault plane is relatively large for a M5 earthquake and this gives a rather small static stress drop.

Number of earthquakes from seismic activity model of the national seismic hazard maps for Japan

*Nobuyuki Morikawa[1], Junichi Miyakoshi[2], Hiroyuki Fujiwara[1]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Ohsaki Research Institute, Inc.

In this paper, as a part of the verification of the probabilistic national seismic hazard maps for Japan, we compare the earthquake occurrence ratio from seismic activity model in the national seismic hazard maps for Japan and that from earthquake catalog data.
As the number of earthquakes from seismic activity model of the national seismic hazard maps for Japan 2018 version, the expected value in 30 years is calculated for each magnitude and expressed by the cumulative number of earthquakes. The procedure is as follows.
1. For earthquakes with nonstationary seismic activity model adopted, set the probability of occurrence of earthquake in 30 years from January 2018 as the expected value of the number of earthquakes.
2. Earthquakes in Nankai Trough (M8-9 class), in Sagami Trough (M8-class), Mega-earthquake along the Kuril trench, and large plate-boundary earthquakes in Tokachi-oki and Nemruo-oki, the whole 30 years of the earthquake occurrence probability by the weight of each occurrence pattern as the expected value of the earthquake number in 30 years, respectively.
3. For the earthquakes in which the Poisson process is adopted, use the 30 year earthquake number based on the occurrence frequency of earthquakes.
Here, we prepare three datasets of cumulative earthquake number. The first is based on the “average case”, the second is based on the “maximum case”, and the third is based on the “averaged hazard” models.
For the earthquake catalog to be compared, we combine earthquakes with M 6.0 or more from 1885 to 1925 by Utsu (1982) and Japan Meteorological Agency earthquake data of M 5.0 or more from 1926 to 2010. At this time, aftershocks are removed according to the same rules as the national seismic hazard maps for Japan.
For shallow crustal earthquakes, the number of earthquakes from the model and the catalog are consistent at less than M 7.0 for the “average case”, and are consistent at less than M 7.7 for the “maximum case”. However, on a larger magnitude, there is a tendency for the model to have a smaller number of earthquakes. For earthquakes in Philippine Sea Plate, the number of earthquakes from the model and the catalog are consistent at M 8.0 and below. However, on a larger magnitude, the number of earthquakes in the model is extremely large. This is caused by the modeling of the large occurrence probability based on the time predictable model for the Nankai Trough earthquake. The number of earthquakes from the “average hazard” model decreases at M 8.0 or more. For earthquakes in the Pacific plate, the number of earthquakes from the model and the catalog are consistent at less than M 7.0. However, on a larger magnitude, the number of earthquakes from the model is somewhat larger. For M 7.8 and more, the model has changed based on the new long-term evaluation of earthquakes along the Kuril Trench by Headquarters for Earthquake Research Promotion of Japan, and the increase in number of earthquakes is also affecting.
On the other hand, when the period of the earthquake catalog is expanded until 2015, after the 2011 great Tohoku earthquake, the number of earthquakes from the model becomes smaller than that from the catalog for earthquakes in the Pacific and Philippine Sea plates. This is due to a large number of aftershocks and induced earthquakes of the 2011 Tohoku earthquake. How to incorporate the earthquake catalog after the great Tohoku earthquake into the seismic activity model in the seismic hazard assessment is a very important task.

Comparative examination of the Probabilistic Seismic Hazard Maps in Japan with observed maximum seismic intensities for various periods

*Takamoto Muneta[1], Kazuki Koketsu[1]

1. Earthquake Research Institute, The University of Tokyo

The accuracy of the Probabilistic Seismic Hazard Maps in Japan (PSHMJ), which is being published by the Headquarters for Earthquake Research Promotion of the Japanese government, was examined by comparing the observed maximum seismic intensities with the PSHMJ. Miyazawa and Mori (2009) compared those only for about 500 years from 1498, and Kondo (2017) compared those for 30 years from 1890, 1920, 1950, or 1980. However, in this study, we compared those for 30, 60, 90, and 120 years from 1890, to show how the accuracy varies for various periods.

Following Kondo (2017), for synthetic seismic intensities, we combined the hazard curves in the engineering bedrocks for PSHMJ (Miyakoshi et al., 2016), the site amplification factors (Wakamatsu and Matsuoka, 2013), and the relationship of seismic intensities and peak ground velocities (Midorikawa et al., 1999; Fujimoto and Midorikawa, 2005). As in Miyazawa and Mori (2009), the Poisson distribution was assumed, and phenomena of return periods of 30, 60, 90, and 120 years were related to those with probabilities of exceedance in 30 years of 64, 45, 28, and 22%, respectively. Observed seismic intensities were derived from the JMA seismic intensity database (Ishigaki and Takagi, 2000; Ishigaki, 2007) and the reports of large earthquakes between 1944 and 1964 (Usami, 1985; Harada et al., 2016). The derived dataset consists of observed seismic intensities at 110 points. This observed dataset was compared with the synthetic seismic intensities at the corresponding points in PSHMJ.

As an index of the comparison, we first calculated the root mean square of differences between observed and synthetic seismic intensities. The results are 1.2, 0.8, 0.7, and 0.7 for return periods of 30, 60, 90, and 120 years, respectively. Since large earthquakes, which can lead to large seismic intensities, are phenomena happening once in several hundred years (plate boundary earthquakes) or once in several thousand years, it is expected that a smaller root mean square is obtained for a longer return period. The above results mostly meet this expectation, but they do not approach 0.4 to 0.5 for a return period of 500 years (Miyazawa and Mori, 2009) being saturated at 0.7 for 90 and 120 years. We secondly performed regression analyses, and similar saturation was also found. For example, the small number of observed seismic intensities can cause this problem, and therefore it will be considered further.

Acknowledgments: J. Miyakoshi provided the hazard curves, and T. Kondo provided computer codes etc. Discussion with J. Miyakoshi and H. Fujiwara is helpful for this study.

A Study on the Ground Motion Characteristics close to the Basin Edge

Ryota Hamabe[2], *Shinichi Matsushima[1], Takashi Azuma[3], Florent De Martin[4]

1. Disaster Prevention Research Institute, Kyoto University, 2. Graduate School of Engineering, Kyoto University, 3. National Institute of Advanced Industrial Science and Technology, 4. French Geological Survey

The 1995 Kobe Earthquake brought significant damage around the Kobe area in Japan. It was notable that a “Damage Belt” with an area with a width of 1km and length of 20km was formed. The main cause of this phenomenon was called the “Basin-Edge Effect”, which is a result of the constructive interference of seismic waves owing to the basin edge structure, i.e. the interference between the direct S-wave propagating upward and the basin-induced/diffracted surface waves propagating laterally. Therefore, this phenomenon should not limited to the Kobe area. In this study, we conduct a ground response analysis at sites close to the basin edge, assuming various types of basin structures, to understand the influence of the subsurface structure to the characteristics of the ground motion close to the basin edge. Also, the observed microtremor Horizontal-to-Vertical spectral ratio (MHVR) will be used to understand the relation between the shape of the MHVR and the basin edge shape. A method to estimate the region of amplification of ground motion due to the Basin-Edge effect at the basin edge estimated from MHVRs will be introduced.

Spectrum Characteristics of MeSO-net seismograms –Effect of Underground Installation -

*Ryoichi Nakamura[1], Hiroshi Tsuruoka[1], Aitaro Kato[1], Shin'ichi Sakai[1], Naoshi Hirata[1], Takahiro Shiina[1]

1. Earthquake Research Institute, The University of Tokyo

1. Introduction

In the Kanto district, high-density seismographs with about 300 accelerometers by MeSO-net have been deployed, and records from 2008 have been accumulated. By analyzing the MeSO-net records integrating with those obtained in K-NET and KiK-net, which is operated near the ground surface, it will able to largely improve structural images in seismic attenuation. However, MeSO-net is installed at a depth of 20 m and there is a problem to integrate records obtained at the surface. In this study, we investigated relative amplification factors among MeSO-net sites and compared the factors to those estimated at the surface sites, K-NET and KiK-net.

2. Method and Data

Observation records which are obtained at two closely located sites by the same earthquake have almost the same propagation paths, so the difference of the two site records can represent a difference of site amplifications because effects of source radiation and attenuation along paths are canceled out. Based on this idea, some studies have been investigated relative amplification factors between the sites. Recently, Ikeura and Kato (2011) proposed a new method that regards site pairs as a network and estimates relative ground amplification factors by using least squares method within the network.

In this study, the relative amplification factors in MeSO-net was examined by using the Ikeura and Kato's method. In order to compare with the amplification factors on the surface, the ground record of K-NET and KiK-net was also included in the analysis. The ARTB method (Herman, 1980) was used for least squares estimation. A distance between sites to pair is 10 km or short. The Fourier spectrum of every 1 Hz from 1 Hz to 10 Hz were used for the data. The strong motion records of MeSO-net from 2011 to 2015 and K-NET/KiK-net from 1996 to July 2016 were selected. Earthquakes with Mj 4 or more and depths less than 200 km were used. We only adopted records which the maximum acceleration amplitude is 100 Gal or less to exclude the nonlinearity effects resulted in strong ground motion. Finally, we used site pairs of 962,422 with 394 observation sites of 394, which include MeSO-net site of 297.

3. Results

In this study, first, we performed numerical experiments to vilify the validity of results given by the ARTB. The geometries of site and earthquake used in the experiments are the same to the actual investigation. After 50 times iteration, it is confirmed that synthesized dataset well reproduce the relative site amplifications assumed in artificially.

Then, we conducted 100 times iteration for the actual observation records to obtain the relative ground amplification. Fig.1 shows an example of the result at 5 Hz. Here we compare the relationship with the average S wave velocity to 30m depth (AVS 30) provided from the JSHIS. The amplification factors at the

©2019. Japan Geoscience Union. All Right Reserved.

ground surface (K-NET and KiK-net) is about 3 times larger than that at the underground (MeSO-net) on average. The amplification rate tends to decrease with increasing velocities of the AVS 30. This trend is consistent with the relationship for the PGV data expected based on Fujimoto and Midorikawa (2006) (black solid line in Fig. 1).

We confirmed that the residuals in the attenuation tomographic inversion can be greatly reduced by giving the relative amplification factors obtained in this study as a priori information.

4. Conclusions

Relative amplifications of ground motion were investigated for observation sites of the MeSO-net, K-NET and KiK-net by using the site-pair network and the least squares method. As a result, it was found that amplification factor in the MeSO-net of which seismographs are deployed at the underground, 20 m depth, is about 1/3 comparing with those of ground surface recorded in the K-NET and KiK -net on average.

Discussion

Interpretation of attenuation of high-frequency waves from the intraslab, interplate, and outer-rise earthqukakes of Northeastern Japan

*Yasumaro Kakehi[1], Yu Ogasawara[1]

1. Graduate School of Science, Kobe University

Previous studies (e.g. Tsumura et al., 2000) have shown the backarc side of Northeastern Japan has lower Q-value than the forearc side and remarkably low-Q zones exist just beneath and slightly backarc-side of the volcanic front. On the backarc side, high-frequency seismic waves attenuate due to the low-Q medium, and the contrast is seen between the high-frequency wave amplitudes on the backarc side and those of the forearc side, where such attenuation does not occur. In this study, characteristics of the spatial distribution of peak ground acceleration and the attenuation relation from 3 types of earthquakes: intraslab, interplate, and outer-rise earthquakes, are investigated using high-density strong motion data of NIED K-NET and KiK-net. The number of studied earthquakes is 15 in total. The most clear contrast between the forearc and backarc sides is seen in the intraslab earthquakes with deep focal depths, and the contrast is also clear in the outer-rise earthquakes though the contrast is not so clear as that in the intraslab earthquakes. On the other hand, the contrast is observed also in the interplate earthquakes, but it is less clear than that in the outer-rise earthquakes. The length of seismic wave path propagating in the low-Q region on the backarc side is long in the case of intraslab earthquakes with deep focal depths, and in the case of interplate and outer-rise earthquakes, both of which have shallow focal depths, the lengths of seismic wave path are shorter than the case of intraslab earthqukaes and are approximately the same. Therefore, it is reasonable that the contrast in outer-rise earthquakes is less clear than that in intraslab eartgquake. It is incomprehensible, however, that the contrast in interplate earthquakes is less clear than that in outer-rise earthquakes. To understand this mystery, we newly take the contribution of the attenuation due to the geometrical spreading factor into consideration. In case of interplate earthquakes whose epicenters are close to the land, the curvature of hypocentral distance contors in the land area (where the observation stations are located) is large. Therefore, attenuation due to the geometric spreading factor is large at the northern and southern ends of the Northeastern Japan arc, where hypocentral distances are large than those in the central part of the island arc, the amplitude difference between the forearch and backarc sides is masked. On the other hand, in case of outer-rise earthquake whose epicenter is far away from the land, the curvature of hypocentral distance contors in the land area is very small and the geometrical spreading factor hardly varies throughout the Northeastern Japan arc. Therefore, the mask effect due to the geometric spreading factor at the norther and southern ends of the Northeastern Japan arc does not work effectively. That is, due to the mask effect of the geometric spreading factor, the contrast between the forearc and backarc sides in interplate earthquakes becomes less clear than that in outer-rise earthquakes, where the mask effect does not work. Furthermore, as to the PGA attenuation relation, an apparent effect appears in the case of outer-rise earthquakes that makes the amplitude difference between the forearc and the backarc sides apparently emphasized than it is, as pointed out by Ogasawara and Kakehi (2018, SSJ Fall Meeting). Thus, the difference of the contrast of seismic shaking on the forearc side and that of the backarc side of Northeastern Japan due to the 3 types of earthquakes is interpreted unifiedly by considering the following 3 factors: (1) the length of seismic wave path propagating in the low-Q region, (2) the mask effect due to the geometrical spreading factor, and (3) the apparent effect in the case of outer-rise earthquakes whose hypocentral distances are systematically large.

Effect analysis of soil interlayer on seismic dynamic response and failure mode of metro station structure

*Shuai Huang[1], Yuejun Lyu[1], Yanju Peng[1]

1. Institute of Crustal Dynamics,China Earthquake Administration

When the metro station structure is built in the site with weak interlayer, the metro station structure shows different patterns of destruction. In this article, based on the nonlinear elastic-plastic finite element model for metro station, considering the structure-soil dynamic interaction, the influence laws of the weak interlayer on the dynamic response and failure mode of the metro station structure under near and far-field earthquakes are studied. We found that the weak interlayer in the middle of the metro station has the greatest effect on the displacement, dynamic amplification factor and internal force of the metro station which leads to the poor anti-seismic performance of the metro station structure, and the metro station is more vulnerable to damage under near-field earthquake. When there is a middle interlayer, the maximum horizontal displacement of the metro station increases 63% at most compared to no interlayer under near-field earthquake. The interlayer below the metro station has a minimal impact on the dynamic amplification factor which shows that the existence of the interlayer below the metro station could reduce the vibration of the metro station to a certain extent. At last, indoor shaking table test for metro station was done, through which we determined the position of initial failure and the failure mode of the metro station structure under earthquake, and shaking table test results demonstrate the validation of the numerical simulation results.

Investigation on the Applicability of V_{S30} Estimation Models for the Beijing Plain Area

*Yi Fang, Yanju Peng, Zhijie Jiang

Using three models which respectively are bottom-layer constant velocity model, velocity gradient model and the extrapolation model with the travel-time averaged shear-wave velocities at two different depths, we investigate the data from 460 boreholes in Beijing plain area that the shear-wave velocity profile reaches at least 30 m. Through a detailed research, we found that the last method can estimate V_{S30} with high accuracy. It does not need any regression analysis to derive empirical relations from a large number of data. Meanwhile, this method is not regionally dependent, and has a remarkable improvement in the accuracy, therefore, it is potentially useful for many parts of the world including Beijing. It provides a basis for site classification, and then extends its application to evaluation of site effect in a rapid assessment of earthquake damage, thus being worth to be extensively applied.

Early prediction of PGA and Sa using ANN

*Ting Yu Hsu[1]

1. Taiwan Tech

In order to perform on-site earthquake early warning, in this study, we develop a novel approach to predict the peak ground acceleration (PGA) and pseudo-spectral acceleration (Sa) using the first few seconds of P-wave features. The Fourier spectrum amplitude (FSA) and phase (FSP) are handled separately and then combined together to predict the acceleration time history, then the PGA and Sa can be estimated accordingly. The FSA is predicted using the artificial neural network (ANN) with the predominant period, peak acceleration amplitude, peak velocity amplitude, peak displacement amplitude, cumulative absolute velocity, integral of the squared velocity, and FSA of the first three seconds of P-wave as input. The mean and standard deviation of the group delay time of phase spectrum of each separated frequency range decomposed by wavelet transform is employed as the prediction target, then the FSP can be generated using these mean and standard deviation of the group delay time. The FSP is predicted using another ANN model using similar P-wave features as the FSA ANN model. The earthquake records of the Taiwan Strong Motion Instrumentation Program from 1992 to 2006 were used to train and validate the proposed approach, and the promising accuracy of PGA and Sa prediction is obtained.

Analysis of strong-motion acceleration records based on the Generalized Pareto distribution

*Hisashi Nakahara[1]

1. Solid Earth Physics Laboratory, Department of Geophysics, Graduate School of Science, Tohoku University

Owing to K-NET and KiK-net managed by NIED, high-quality strong ground motion data have been accumulating in Japan in these two decades. Analyzing these data set, I investigate the upper limit of ground accelerations of near-field strong motion records in Japan. I apply the Generalized Pareto distribution (GPD) to amplitude distributions of ground accelerations exceeding given threshold levels, and estimate the parameters of GPD. Especially, the shape parameter of GPD is very important for this purpose. If the shape parameter is negative, an upper limit exists in the distribution. If the shape parameter is greater or equal to 0, there is no upper limit.

Among the strong motion database from K-NET and KiK-net, I select 98 strong motion records whose peak ground accelerations exceed 1g. I finally use 77 strong motion records after eliminating records contaminated by other events like aftershocks and those whose duration times are too short to have enough data. Positive values and negative values of ground accelerations are independently analyzed. I use the absolute value for the negative amplitude. Changing the threshold value of ground acceleration from 10 to 300 gal, I fit GPD to the data exceeding the threshold, and estimate the minimum threshold over which the estimated parameters of GPD (the shape parameter, the scale parameter, and the mean excess) will not change much. I also confirm the goodness of fit of GPD by checking P-P plots and Q-Q plots visually.

GPD explains amplitude distributions of 77 acceleration records. For the positive amplitudes of accelerations, 48 records show the upper limits. For the negative amplitudes of accelerations, 53 records show the limits. In total, about 70 % records show the limit in ground accelerations. The range of the limit is mostly smaller than about 6000gal. However, a few results with very small negative shape parameters suggest much larger limits. These results should be regarded practically as no limits. For the rest of about 30 % records, the existence of the limit is not statistically supported. However, there should be the upper limit in ground accelerations from the viewpoint of physics. So it is necessary to clarify reasons why about 30 % records do not suggest the upper limit in ground acceleration.

Acknowledgment:

I used strong motion records obtained by K-NET and KiK-net, NIED.

Repeated measurements of the Self-Potential at Akita-Yakeyama, Iwate and Kurikoma volcanoes

*Shin'ya Sakanaka[1], Yasiaki Sawada[3], Kenta Kato[2], Inoue Yusuke[1], Kobayashi Takuya[1], Ryuichi Takei[1], YUYA TADA[2], Muhammad Faizul Nizam Bin Zainudin[2], Tomoya Moriwaki[2]

1. Graduate school of International Resource Sciences, Akita University, 2. Faculty of International Resource Sciences, Akita University, 3. Faculty of International Resource Sciences, Akita University (gradusted in 2018)

We will report the SP (Self-Potential) anomalies at Akita-Yakeyama, Iwate, and Kurikomayama volcanoes. They are active volcanoes along the boundary of Akita and Iwate prefectures and their volcanic activities are relatively high recently.

SP measurements and SP anomalies at those volcanoes were reported by some researchers. We are still carrying out the SP measurements there repeatedly so as to monitor the activities of the volcanoes.

We conducted the SP measurements along the mountain trail from Tamagawa hot spring to Goshougake hot spring at Akita-Yakeyama in 2007 and 2017. At Mt. Iwate the SP measurements were conducted along the Yakebashiri trail up to the summit in 1999, 2004 and 2017. At northern part of Mt. Kurikoma we walked from the Nagorigahara moor, went through the summit and returned back anti-clockwised along the trail with SP electrodes in 2018. The result of the previous SP measurement in Kurikoma volcano can be found in the part of the Aizawa (2010) and we can investigate the time-lapse SP anomalies on these volcanoes.

We adopted the leap-frog measurement method with a 50 m cable, copper-copper sulfate electrodes, and a digital multi-meter (voltmeter). The latitude and longitude data were recorded by the handy GPS receiver (like as Garmin product). Although in the measurements of the leap-frog method might be easily piled up each error of the measured value at a site, a short cable can be easier handled than a longer cable over the length of a couple of kilometers using by the total-potential measurement method. The long and thin cable is sometimes cut apart by animals or human beings and unfortunately we have to return back to the cut point all the way to fix it.

On the compiling the SP data in different years we draw the SP curves along the cumulated distance. Since the cumulated distances of the SP measurements are sometimes up to several kilometers, the lengths of the cumulated distance are sometimes different by more than 100 m in the data of the respective years. We measure the SP on the same mountain trail but the end of the cable at each measurement is not always at the same point and the SP paths are slightly different in year to year on the measurements. This is the reason why the difference of the cumulated distance in different years. The problem might be happened also with the measurements of the total-potential method. To solve it, we set a model path with the function of the cumulated distance on the trail map in advance and the measured site were relocated (projected) onto the model path referred by GPS locations. After that we successfully and comfortably compare the SP data on the same trails.

At Akita-Yakeyama and Iwate volcanoes, we cannot find out the outstanding time variations of SP anomalies but the acquired SP data can be use the monitor the active volcanoes.

Evaluation of surface conductivity of unsaturated Berea sandstone and porous glasses

*Ryosuke Umezawa[1], Makoto Katsura[1], Satoru Nakashima[1]

1. Department of Earth and Space Science, Graduate School of Science, Osaka University

Electrical conduction of rocks composed of insulating minerals are known to depend on degree of water saturation, distribution of pore water, pore size and pore structure. Electrical conduction in rocks is considered to be composed of conductions in bulk water and on mineral surfaces. The electrical double layer (EDL), a layer with adsorbed ions on mineral surfaces (Stern layer) and gradients of ion concentrations (diffuse layer), has thickness characteristic length of the diffuse layer (Debye length). Surface conduction becomes important, when bulk water in rock pore decreases, such as in unsaturated rocks and less porous rocks with thin grain boundary water. Since quantification of dissolved ions in rocks with thin grain boundaries is difficult, quantitative description of surface conduction remains poor.
In this study, in order to examine surface conduction with known dissolved ion concentrations, electrical conductivity of a sandstone and porous glasses were measured for varying water saturation and ion concentrations. Berea sandstone (predominant pore diameter: about 40 μm) and Shirasu porous glass (SPG) membranes (SPG technology; uniform pore sizes: 1.0, 0.5, and 0.2 μm) were saturated with aqueous solutions having varying NaCl concentrations (0, 0.001, 0.01, 0.1 mol L^{-1}). Electrical conductivity values were measured for frequencies from 0.1 Hz to 1 MHz while drying.
Effects of surface conduction of Berea sandstone and SPG membranes were compared by their specific surface conductivity values, which were evaluated by conduction models using surface complexation model, and were discussed in relation to water film thickness and Debye length.

Keywords: Water saturation, electrical conductivity, ion concentration, Debye length, surface conductivity

Observational and theoretical waveforms of electromagnetic signals generated by the motional induction effect before the arrival of seismic waves

*Ken'ichi Yamazaki[1]

1. Disaster Prevention Research Institute, Kyoto University

Earthquake ruptures and consequent ground motions generates variations in the electromagnetic (EM) field by means of variety of conversion processes in the Earth’s crust. The generated EM signals are referred to as seismo-EM signals. Some of the earlier works have reported seismo-EM signals that are observed prior to the arrival of seismic waves [e.g. Iyemori et al. 1996 (JGG); Honkura et al. 2002 (EPS); Okubo et al. 2011 (EPSL)], which are sometimes referred to as “early seismo-EM signals”. Theoretical calculations have been conducted to identify the generation mechanisms of the observed seismo-EM signals assuming some of candidate conversion mechanisms including the electrokinetic effect [Haartsen and Pride 1997 (JGR)], the motional induction effect [Gao et al. 2014 (JGR)], the piezomagnetic effect [Yamazaki 2016 (GJI)] and the piezoelectric effect [Ogawa and Utada 2000a (PEPI), 2000b (EPS)]. However, definitive answers have not been obtained, particularly for the case of early seismo-EM signals.

The objective of this work is to compare theoretical time-series of seismo-EM signals arising from the motional induction effect with observational one by means of simple numerical models. In an earlier work, Gao et al. [2014] consider the same problem by assuming uniform full-space model with analytical solutions. Their results imply that theoretical early seismo-EM signals in this situation are far smaller than observed ones. In the present work, I consider a model composed from conductive half-space that represents the Earth’s crust and another half-space that represents the air as an insulator. In frequency domain, governing equations in this situation are reduced to ordinary differential equations by applying the Hankel transform, which can be solved analytically. Seismo-EM Solutions of the original equations are then obtained after the inverse Hankel transform. Time-series of seismo-EM signals are then obtained after the inverse Fourier transform.

The comparisons between observed and theoretical seismo-EM variations are performed for two cases: one is the phenomena observed at the time of 1999 Izmit earthquake, Turkey [Honkura et al. 2002], and the other is that observed at the time of 2008 Iwate-Miyagi earthquake, Japan [Okubo et al. 2011]. Early seismo-EM signals observed for these two earthquakes have different characters. For the case of Izmit earthquake, signals appeared only after seismic waves reach close to the observational site. In contrast, for the case of Iwate-Miyagi earthquake, EM signals emerges just after the onset of seismic ruptures. Numerical calculations assuming the motional induction effect reasonably account the feature of signals for the Izmit earthquake, but do not account that for the Iwate-Miyagi earthquake.

Effect of reference data on geomagnetic transfer functions

*Shinya Sato[1], Tada-nori Goto[1]

1. Kyoto Univesity, Graduate School of Engineering

It is well-known that inter-station transfer functions (TFs), which are derived generally using two sites (as following Schmucker 1984; Neska 2006), are effected by source field. Also, we sometimes use three sites for deriving TFs in order to reduce the noises mixed in geomagnetic data. These 2 or 3 sites-based TFs have been used for evaluating the spatial characteristics of source field. However, the 3 sites-based TFs (i.e., using site 1, site 2 and reference site) do not always reflect the source field’s condition between site 1 and site 2, and can possibly be effected by the source field’ characteristics at reference site. Also, the evaluation of source field’s condition at time-frequency domain (i.e., at the stage of spectra or spectrograms) will be more accurate. Therefore, for the evaluation we used Multi-Channel Nonnegative Matrix Factorization (MC-NMF, suggested by Sato and Goto 2018), which can extract components included in several geomagnetic spectrograms. Moreover, we derived the condition of geomagnetic events’ spatial-characteristics, which triggers the effect of reference data on 3 sites-based TFs. In order to verify that the TFs are effected by the reference site, we derived the temporal changes in 3 sites-based TFs replacing the reference sites. As a result, we founded that the TFs changed not only temporally but dependent on the reference site and the interpretation of source field’s spatial characteristics was different dependent on the reference site. For exposing the cause, we evaluated the spatial-characteristics of geomagnetic events using MC-NMF. The evaluated spatial-characteristics of geomagnetic events were corresponding with the condition triggering the effect of reference data on TFs as mentioned above. We succeeded to expose the cause of TFs’ variation triggered by reference data evaluating the spatial-characteristics of geomagnetic events at time-frequency domain. Using TFs together with MC-NMF, the interpretation of source-field’s spatial characteristics will be with high accuracy.

Reliability estimation of magnetotelluric inversion result based on the Principle Component Analysis and Markov Chain Monte-Carlo method

Hisatoshi Koji[1], *Tada-nori Goto[1]

1. Graduate School of Engineering, Kyoto University

Magnetotelluric (MT) method is used for detection of electrical conductive materials such as fluid, clay, partial melt and so on. Subsurface resistivity structure is generally estimated by an inverse algorism, based on the least-square scheme using observed apparent resistivity and phase. The reliability of the optimal model in the inversion procedure should be discussed together with seeking the “better” model having the lower data misfit than the optimal model. However, the sophisticated method is not well developed for the magnetotelluric survey, except for the simple test based on a number of forward modeling, constrained inversions and so on, or simple visualization of sensitivity of model parameters. In this study, for a quantitative visualization of reliability of optimal model parameters, we propose a new way of the numerical test of the model based on the Markov Chain Monte-Carlo (MCMC) methods. Since the MCMC cannot solve a number of unknowns in model parameters, we adopted the principle component analysis (PCA) to reduce unknowns in the model obtained by MT inversion code. First, for testing the PCA ability in subsurface image analysis, various two-dimensional (2-D) resistivity models are decomposed by PCA. As a result, we succeeded to extract the “major features” of 2-D resistivity model, especially by using first to third principle components. Then, we tested the MCMC algorithm with changing parameters of “major features” of 2-D model, such as its resistivity, width, thickness, horizontal and vertical locations. In a case of a simple two-prism model, we confirmed that the reliability of low and high resistive anomalies are shown in the probability density functions obtained by MCMC. We also found that some parameters (e.g., thickness and resistivity of an anomalous body) indicate a tread-off relationship as mentioned in the previous studies, and also found the reliable range of parameters even under the trade-off. We then applied this technique to the magnetotelluric data obtained at a field experiment. In consequence, anomalies in the optimal model are detected properly by PCA, and the reliable range of model parameters based on the MCMC method are similar to those inferred by the conventional forward calculations. We conclude that our proposed method can be widely applied to magnetotelluric exploration, even to the three-dimensional inversion.

Probing one-dimensional electrical anisotropy in the oceanic upper mantle from seafloor magnetotelluric array data

*Tetsuo Matsuno[1], Kiyoshi Baba[2], Hisashi Utada[2]

1. Kobe Ocean Bottom Exploration Center, Kobe University, 2. Earthquake Research Institute, The University of Tokyo

Electrical anisotropy in the oceanic upper mantle provides important clues on mantle structure and dynamics if it is confirmed from seafloor magnetotelluric (MT) data. Here we try to probe electrical (azimuthal) anisotropy in the oceanic upper mantle by analyzing recent seafloor MT array data from the northwestern Pacific at 130-145 Ma seafloor. We propose a method, in which an isotropic 1-D model is first obtained from seafloor MT data through iterative correction for topographic distortion, then anisotropic properties are inferred as deviations from the isotropic 1-D model. We investigate the performance of this method through synthetic forward modeling and inversion, using plausible anisotropic 1-D models and actual 3-D bathymetry and topography for the target area. Synthetic tests reveal that the method can detect the electrical anisotropy in the conductive upper mantle or the electrical asthenosphere. We also compare the performance by using two rotational invariant impedances and two topographic correction equations. An application of the method to two seafloor MT array data in the northwestern Pacific reveal anisotropic inversion models, showing the possible presence of electrical anisotropy in two layers in a conductive mantle of <100 Ω-m at 50-250 km depth. Anisotropic signals are larger in shallower layers for both array areas, while anisotropic azimuths (or most conductive directions) and depths to the two layers are different for two array areas even at similar seafloor ages with the horizontal distance of ~1,000 km. Most conductive directions mostly align rather to directions of past seafloor spreading or their perpendicular directions, than a direction of current plate motion and are inconsistent with fastest directions of seismic azimuthal anisotropy. The electrical anisotropic signals may dominantly result from mantle dynamics in array-scale (~500 km or over), like small-scale convection and the formation of seafloor in the past, over in Pacific basin scale.

The Analysis of magnetotelluric sounding data on Kikai submarine caldera.

*Toki Hirose[1], Tetsuo Matsuno[2,1], Nobukazu Seama[1,2], Yuki Okizono[4], Hiroshi Ichihara[3], Hiroko Sugioka[1,2], Yoshiyuki Tatsumi[2,1]

1. Department of Planetology, Graduate School of Science, Kobe University, 2. Kobe ocean Bottom Exploration Center, Kobe University, 3. Graduate school of environmental studies, Nagoya University, 4. Department of Planetology, Faculty of Science, Kobe University

Kikai submarine caldera locates on the south waters of Kagoshima. The caldera was formed after super eruption on 7.3ka, and have formed huge lava dome since the eruption(Tatsumi et al., 2018). A main aim of this study is to determine the electrical resistivity structure beneath the Kikai caldera, and estimate the distriution of melt, magma chamber and thermal anomaly. As one step to the main aim, this study presents the results of calculations of apparent resistivity and phase, and estimating 1D inversion resistivity structure models after their correction for topographic distortion.
Measurements of the time variations of electric and magnetic fields at the seafloor were conducted at 10 sites with a sample rate of 8 Hz for about 20 days. At the four of those after the surveys, measurements were switched to the sample period of 60 s for about half year. Observed data with sample rate of 8 Hz were processed as followings: (1) downsampled to 1 Hz, (2) corrected by comparing the instrument clocks with GPS time, (3) detrended for longer-periods than 1 day, and (4) corrected instrument inclines. The instrument coordinates were transformed to geographic coordinate system. After these processing, we extracted the data without noises which attribute to the shaking of instrument and calculated magnetotelluric(MT) inpedances, apparent resistivity, and phase using the BIRRP method(Chave and Thomson, 2004). Kanoya magnetic observatory was used as the magnetic remote reference.
Estimated apparent resistivities were characterized with respect to periods and elements, whose characteristics are commonly found at all the sites. With respect to periods, off-diagonal apparent resistivity ranges 1Ωm to 10Ωm at the periods of 21s, and increases to 10Ωm to 100Ωm at a longer periods of 1024s. As for elements, diagonal elements are smaller than non-diagonal elements by a degree of magnitude. Estimated phases were characterized by xy and yx elements that are within the range of the first quadrant and the third quadrant respectively.
Effect of topography on MT impedances are modeled with with FS3D(Baba and Seama, 2002). Using The results of FS3D and the method of removing of topographic distortion(Nolasco et al., 1998), MT impedance are corrected for bathymetry. Using the corrected MT impedance, the 1D electrical resistivity structure models at the observation sites are estimated by OCCAM1D inversion program(Constable et al., 1987). The 1-D structure models are compared to 3-D electrical resistivity structure model(Matsuno et al., presented at this meeting) .

Role of Fluids in the earthquake generation: The Nagamachi-Rifu reverse fault, NE Honshu, Japan

*Sabri Bulent Tank[1], Yasuo Ogawa[2]

1. Bogazici University, 2. Tokyo Institute of Technology

The Japanese island arc was drastically influenced by the occurence of the 2011 Tohoku-Oki earthquake (M9) which also effected the volcanic activity and modified the local seismicity both of which are proven to be related to crustal fluid distribution. Therefore, for understanding the dynamic behavior of the region and for making further comparisons, developing an electrical conductivity model that enables to image the fluid’ s presence and capacity by means of analyses based on high-quality magnetotellurics data collected prior to the Tohoku-Oki earthquake at 61 sounding locations near the Nagamachi-Rifu Fault, Northeast Honshu, Japan, became an important task. Magnetotelluric data collected along three profiles that orthogonally cross the almost NE-SW geo-electric strike were used to image the epicentral region of this active reverse fault and its vicinity. State-of-the-art three-dimensional data-space inversion schemes were applied on the wide-band magnetotellurics data to map the fluid-rich and/or -depleted zones. Inversions included 0.3 Ohmm cells with realistic bathymetry on both sides of the initial model representing the Japan Sea in the west and Pacific Ocean in the east to realize the ocean effect. Resulting models were compared with prior and post seismicity of the main event.

Audio-frequency Magnetotelluric Survey of the Tsuyama-hoppou Fault, Yamasaki Fault Zone, southwest Japan.

*Satoru Yamaguchi[1], Daisuke Takakuwa[2], Akira Mimura[1], Kazuki Fkue[1], Shigehiro Katoh[3], Hideki Murakami[4], Shinichi Takakura[5]

1. Department of Geosciences, Graduate School of Science, Osaka City University, 2. Faculty of Science, Osaka City University, 3. The Museum of Nature and Human Activities, 4. Science and Technology Unit, Research and Education Faculty, Kochi University, 5. Geological Survey of Japan, Institute of Advanced Industrial Science and Technology

The Yamasaki fault zone (YFZ) is a ~80 km long, typical left-lateral strike-slip fault zone extending WNW from eastern part Okayama prefecture to southeastern part of Hyogo prefecture. The YFZ consists of the Nagisen fault zone, the main part of the YFZ, and the Kusadani Fault. The Nagisen fault zone show different features in fault activity (e.g. general strike, mean slip rate, the latest event) and seismic activity. Fewer earthquakes are occurred around the Nagisen fault zone compared with around the main part of the YFZ, and the Kusadani Fault.
Earthquake Research Committee (2013) reported that the Nagisen fault zone consists of the Nagisen Fault and Tsuyama-hoppou Fault (abbreviated as TYN Fault here after) and Okada *et al*. (2016) further divided the Nagisen Fault into the Koegatawa Fault, Nagiike Fault, and Nagisen Fault (we referred to them as Nagisen Fault Group here after) and reported fault displacement is recognized along the Nagisen Fault Group. While the TYN Fault is classified into the fault of Certainty II and Degree of activity C, and is annotated as “no fault activity after Middle Pleistocene is recognized” (The Research Group for Active Faults of Japan, 1991). That is, the TYN Fault is still an unknown fault and further survey is required.
Fukue *et al*. (2018) made a magnetotelluric (MT) survey using an audio-frequency MT (AMT) method, which is suitable for revealing shallow part (0 - 2 km in depth) with high spatial resolution, along the line across the Nagiike and Nagisen Faults, then established the two-dimensional resistivity model (NGS model). They pointed out that the Nagiike Fault is recognized as an clear resistivity boundary but that the Nagisen Fault is not recognized in the model.
Aiming to reveal subsurface structure of the unknow TYN Fault, we made an AMT survey along the line of ~4 km long across the TYN Fault and determined the two-dimensional resistivity model along the line. In this paper, we present outline of observation, procedures of data & model analysis, and the resistivity model, then discuss the subsurface structure of the TYN Fault comparing the NGS model.

In December 2018, we have conducted broad-band magnetotelluric (MT) observation around Hinagu fault and Uto Peninsula, which are close to the focal regions of the 2016 M_{JMA} 7.3 Kumamoto earthquakes. Since the resistivity structure of these regions are not well imaged by the previous 3-D inversion by using the 80 MT sites (Aizawa et al., 2017, Sgepss fall meeting), we acquired the new data by using the Metronix ADU-07 system and the telluric loggers (NT System Design ELOG1K). We will present new 3-D resistivity structure and argue its relationship to the hypocenters that are relocated by using the double difference method and 3-D seismic velocity structure (Shito et al., 2017, GRL).

Acknowledgment

We are greatly indebted to the land owners for their permission for field campaigns. The geomagnetic data used for the remote-reference processing were provided by the Kakioka Geomagnetic Observatory of JMA. This work is partly supported by MEXT KAKENHI Grant Number JP16H06298, the Ministry of Education, Culture, Sports, Science and Technology of Japan under its Earthquake and Volcano Hazards Observation and Research Program, and Earthquake Research Institute, The University of Tokyo under Joint Usage Program.

San'in Kaigan Geopark Museum of the Earth and Sea

In order to contribute to a reduction in damage caused by earthquakes and volcanic eruptions, heterogeneities of crustal and upper mantle structure should be clarified based on fundamental investigations of electrical resistivity structure in Chugoku and Shikoku regions, southwestern Japan arc.
Our research group has shown that there is a clear relationship between resistivity and seismicity in the San'in and Shikoku regions. In the eastern part of San'in region, it was found that a conductive area exists in the deep crust part under the seismic region, which is a resistive area, along with the seismic activity area stretching nearly in the east and west direction. Assuming that inland earthquakes occur because of local stress concentration caused by heterogeneity beneath a seismic activity band(Iio, 2009), it is necessary to improve spatial data and to clarify the heterogeneity in this area hereafter.
On the other hand, in the Shikoku district, it was suggested that the distinctive low resistivity region exists in the upper crust mainly from the survey results in the outer belt, and that there is a clear relation between the low resistivity and low seismicity in the central and the western area. In order to understand the earthquake phenomenon, it is important to clarify the generation environment and the principle as well as the activity style of the slow earthquake (Obara(2017)).
In this background, a Magnitude (M6.6) Earthquake in the Central Tottori Prefecture on October 21, 2016 occurred. In order to elucidate the heterogeneous structure of the lower crust beneath the seisimic region, we set up several survey lines across the central focal region of the Chubu region to carry out wideband MT observation at 12 sites in the observations gap area around this region.
By integrating the existing MT data, we tried model analysis using the program code of Ogawa and Uchida (1996) assuming that this region had a two-dimensional structure of EW strike direction harmonious with the seismic active band. According to the 2D model, we confirmed the southern limit of the low resistivity part existing in the deep crust of the focal region.
In the Chugoku and Shikoku district, we aimed to determine the 3D resistivity structure as a whole, and as in the 2017 research, 1D Occam inversion analysis based on determinant impedance was performed and integrated with existing MT data to estimate the preliminary spatial resistivity structure distribution. As a result, in San'in region, it is generally harmonious with the former studies, the low resistivity region in the deep crust continues to exist in the east-west direction with a certain scale.
In the Shikoku district, the resistivity in the mid crust shows the existence of a relative high/low resistivity boundary in the vicinity of the MTL is prominent, consistent with the existing research. Although there is a observation gap on the Seto Inland Sea side, continuity to the south of the low resistivity region of the San'in region is suggested with respect to the northern extension of the high resistivity crust. Moreover, when we look at the correspondence with the epicentral distribution of the crustal earthquake at this depth, there is clear correspondence with the high resistivity region in the north side of inner zone around

the Median Tectonic Line. This relevance is common knowledge with that in the San'in region.

Fluid distribution beneath central and southern Kyushu imaged by 3-D electrical resistivity model

*Maki Hata[1], Hiroshi Munekane[2], Hisashi Utada[1], Tsuneomi Kagiyama[3]

1. Earthquake Research Institute, the University of Tokyo , 2. Geospatial Information Aurhotiry of Japan, 3. Aso Geopark Promotion Council

The island of Kyushu is characterized by a high concentration of active Quaternary volcanoes along a volcanic front of N30˚E–S30˚W associated with the subduction of the Philippine Sea Plate. Some of the active volcanoes exist in southern Kyushu (the southern volcanic region), whereas no volcano exists in central Kyushu (the non-volcanic region). Most of volcanoes in the southern volcanic region exist in the Kagoshima Graben, whose formation was created with ejecting huge pyroclastic flows by the Quaternary volcanism. The Kirishima volcano group appears in Kakuto-Kobayashi caldera on the northern edge of the graben. Shinmoe-dake of the Kirishima volcano group experienced a magmatic eruption of the VEI 3 in 2011 and ash emissions in March 2018. Moreover, Iwo-yama of the Kirishima volcano group experienced hot material ejections in April 2018. Besides, Sakurajima volcano in the southern part of the graben has experienced 153–1,355 small eruptions per year for the last 10 years (the Japanese Meteorological Agency).
The Philippine Sea Plate, whose subduction involves the formation of the volcanic island of Kyushu, in and around Kyushu is classified into three portions: a younger portion, an older portion, and the other part of the Kyushu–Palau Ridge between the two portions. A non-volcanic region distributes in central Kyushu above a junction where the three portions of the subducting Philippine Sea Plate contact with each other. Owing to the subduction of the Philippine Sea Plate, moment magnitude 7-class thrust earthquakes have repeatedly occurred in the Hyuga-nada, lying offshore of the southeast Kyushu. In addition, recent studies using continuous global-navigation-satellite-system data have revealed that long-term slow slip events and short-term slow slip events occur in the Hyuga-nada. Besides, most of the earthquakes in the land area occur along three tectonic lines: Oita-Kumamoto tectonic line, Usuki-Yatsushiro tectonic line and Butsuzo tectonic line.
Fluid distribution in the mantle wedge is an essential factor for the seismic activity and magmatism leading to volcanic activity. Electromagnetic sounding data have high sensitivity to a few percent of interconnected fluids (aqueous fluid and melt). In this study, we generated a three-dimensional (3-D) electrical resistivity model by inverting magnetotelluric data, which covers the active southern volcanic region and the non-volcanic region, to examine the fluid distribution in the mantle wedge beneath Kyushu. We find three important conductive features in the 3-D model. A magma system and a fluid system imaged as two vertical conductors relating to slab-derived fluid, which exist along the volcanic front beneath the southern volcanic region and the non-volcanic region, respectively. The other conductor, relating to the presence of slab-derived fluid and serpentinite in the mantle wedge, appears at a blank area of the slow slip events.

Lithology and zircon U-Pb geochronology of Paleoproterozoic and Paleozoic granitic complex in Maizuru Terrane from Tsuwano area, Shimane Prefecture, SW Japan

*Kosuke Kimura[1], Yasutaka Hayasaka[1], Tomoyuki Shibata[1], Kenta Kawaguchi[1], Hiroshi Fujiwara[1]

1. Hiroshima University

Maizuru Terrane is geographically distributed from Oshima Peninsula of Fukui Prefecture to western Shimane Prefecture, Southwest Japan. Maizuru Terrane is divided into three subzones, the Northern zone, Central zone, and Southern zone. Northern zone is mainly composed of granitic rocks and metamorphic rocks that derived from continental crust, and Siluro-Devonian granitoids have been reported from Maizuru-Oe area which is the type locality of the Maizuru Terrane (Fujii et al., 2008; Tsutsumi et al., 2014). Recently, Kimura et al. (2018) reported granitic complex from Tsuwano area, Shimane Prefecture. This complex contains not only Paleozoic granitoid that show same age of the Maizuru granite but also the late Paleoproterozoic granitoid and orthogneiss those are unreported so far from the basement rock distributed in Honshu island.

The granitic complex occurs in Tsuwano area is distributed discontinuously along with the northern margin of Maizuru Terrane, and about 2 km long. This complex occurs as lenticular blocks in a narrow zone of several hundred meters in width. This complex is mainly composed of granitic rocks and mafic rocks that intruded into granitic rocks, and suffered cataclasis in the major part. From the viewpoint of their age and lithology, this granitic complex could be divided into three groups, which are as follows:

1) early Paleoproterozoic metaquartzite: Quartz completely recrystallized and doesn’t show the dust rim. Grain boundary shows sutured texture. Detrital zircon grains show reddish brown color and rounded shape. Zircon U-Pb concordant ages are only older than 2.4 Ga, and the probability density curve shows two large peaks around 2.5 Ga and 2.7 Ga.

2) late Paleoproterozoic granitoids and orthogneiss: These rocks are most common in the granitic complex. These rocks show various lithology. Orthogneiss show banded structure and granoblastic texture. Zircon grains show reddish brown color and core-rim structure, and zircon U-Pb ages range 1.85-1.83 Ga. Furthermore, 2.8-2.05 Ga inherited ages are also yielded.

3) early Paleozoic rocks: These Paleozoic rocks are less in amount than Paleoproterozoic rocks in Tsuwano area. Paleozoic rocks are subdivided into plutonic rocks and volcaniclastic rocks. Plutonic rocks are leucocratic granodiorite and metagabbro. Their zircon U-Pb ages range from 423-411 Ma. On the other hand, volcaniclastic rock is felsic tuff that shows light brown to light greenish gray color, and this lithology varies from glassy to crystalline. Zircon U-Pb ages range from 424-413 Ma.

Metaquartzite have only older than 2.4 Ga concordant ages in spite of 1.85 Ga rocks are most common in this granitic complex. Therefore, the sedimentation age of metaquartzite is considered to be between 2.4

©2019. Japan Geoscience Union. All Right Reserved.

to 1.85 Ga. On the other hand, detrital monazite and zircon ages reported from orthoquartzite pebble that occur in the conglomerate layer of Tetori and Muro groups show 1.8 Ga peak (Yokoyama et al., 2002; Hisada et al., 2010). Therefore, metaquartzite occur in Tsuwano area have a different origin that of these orthoquartzite pebbles.

Ages of 2.7, 2.5 and 1.8 Ga that measured from metaquartzite and late Paleoproterozoic rocks are consistent with similar rocks reported from North China Craton.

Zircon U-Pb ages of early Paleozoic rocks range from ca. 424-411 Ma. These ages and occurrence of this granitic complex are consistent with that of Northern zone from Maizuru-Oe area. Therefore, the granitic complex of Tsuwano area can be compared with Northern zone of Maizuru Terrane.

Tectonic significance of new Zircon U-Pb ages of sedimentary complexes in the northern Hidaka Belt, central Hokkaido, northern Japan

*Futoshi Nanayama[1,5], Toru Yamasaki[1], Jun Tajika[2], Hideki Iwano[3], Tohru Danhara[3], Takafumi Hirata[4]

1. Geological Survey of Japan, AIST, 2. Docon Co. Ltd, 3. Kyoto Fission-Track Co.Ltd, 4. Tokyo Univ., 5. CWMD, Kumamoto Univ.

The Hidaka belt in the central axis zone of Hokkaido has been one of the areas where geological research is most delayed in Japan, and their depositional ages and tectonic settings were not clear untill now. It has been considered as late Cretaceous accretionary complex like the Shimato belt in southwestern Japan. In this study, zircon particles are extracted from turbidite sandston beds of eastern Rurochi Formation, central Kamiokoppe Formation and western Iwaonai Flysch and zircon U-Pb ages were measured by LA-ICP-MS method. As a result, age values of 52.4 ±0.5 Ma from Rurochi Formation, 54.9 ±0.3 Ma from Kamiokoppe Formation and 47.3 ±0.5 Ma from Iwaonai Flysch were obtained respectively. Looking down the entire Hidaka belt including the age data of the southern part of the Hidaka belt reported by Nanayama et al. (2018), the following four points have been clarified.
(1) Clastic rocks (Hidaka Supergroup) distributed in the Hidaka belt are within the age of Paleocene ~ early Eocene.
(2) The Hidaka belt is distributed widely across the east-west width of more than 100 km. However, its internal structure and age differences are not clear, and it can not be explained by the accretionary growth model which becomes younger in the eastward.
(3) There is no significant age difference in the eruption age of the three bands of in situ basalts (N-MORB) recognized in the Hidaka belt (Miyashita et al., 1997), and if this is explained by the ridge subduction model, It can be explained only one event.
(4) The Hidaka Supergroup was a sedimentary body mainly composed of turbidite facies filled in the sea area between the Paleo-Japan arc and the Paleo-Kuril arc in Paleocene ~ early Eocene age. After 47 Ma, according to the joining of two arc-trench systems, significant deformation was occurred it. So, it is considered to be "collision complex".

New age constraints and tectonic significance of Late Oligocene marine biosiliceous deposits in the Hidaka Belt, northeastern Hokkaido, northern Japan

*Futoshi Nanayama[1,6], Hiroshi Kurita[2], Toru Yamasaki[1], Jun Tajika[3], Hideki Iwano[4], Tohru Danhara[4], Takafumi Hirata[5]

1. Geological Survey of Japan, AIST, 2. Niigata Univ., 3. Docon Co. Ltd, 4. Kyoto Fission-Track Co. Ltd, 5. Tokyo Univ., 6. CWMD, Kumamoto Univ.

The Tatsuushi Formation distributed in the Kitami-Monbetsu area consisted of siliceous mudstone, and has been incorporated into the Hidaka Supergroup along associated with the surrounding the Uenkotan and Rurochi Formations (Tajika and Iwata, 1994). In this study, the depositional age of the Tatsuushi Formation was examined by three methods. Detrital zircon grains are separated from turbidite sandstone and a U-Pb age of 27.2 ±0.1 Ma is obtained by the LA-ICP-MS method. Dinoflagellate cysts indicate late Oligocene and early Miocene, respectively. Therefore, the U-Pb age is shown as the depositional age of this formation. The depositional age of the Hidaka Supergroup has been reported Paleocene to Early Eocene so far. Therefore, it is difficult to include this formation in Hidaka Supergroup. The Tatsuushi Formation can be compared to the Erimo Formation in the soutjern Hidaka Belt (Kurita and Kusunoki, 1997) and the lower part of the Tsubetsu and Kawakami Groups based on their depositional ages and affinity of the lithology (Kurita et al., 1998) distributed along the Abashiri tectonic line as the right-lateral strike-slip fault since late Oligocene. These siliceous mudstones may have been formed by the upwelling flow caused by the bottom deepwater brought from the Sea of Okhotsk by the opening of the Kuril basin.

This work was supported by JSPS KAKENHI Grant Number 16K05585.

Late Cretaceous sea-level changes and tectonic history recorded in the forearc sedimentary successions of the Northeast Japan

*Jun Arimoto[1], Reishi Takashima[2], Hiroshi Nishi[2], Yuji Orihashi[3], Toshiro Yamanaka[4]

1. Department of Earth Science, Graduate School of Science, Tohoku University, 2. The Center for Academic Resources and Archives, Tohoku University, 3. Department of Earth and Environmental Sciences, Graduate School of Hirosaki University, 4. Tokyo University of Marine Science and Technology

Elucidating tectonic history of the Cretaceous East Asian continental margin provides us essential information to understand the origin of modern Japanese islands and paleo-biogeography of terrestrial fauna and flora, with implications for connection with the Eurasia continent. One of the keys to reconstruct the geologic history of the NE Japan is the Upper Cretaceous to Paleogene siliciclastic sedimentary successions that filled a N-S trending large fore-arc basin (the Yezo forearc basin) along the Pacific margin. The Futaba, Kuji, and Yezo groups are known as representative strata among these successions, and have been well studied. Especially the Kuji and Futaba groups were accumulated in shallow-marine and non-marine environments, and their facies changes were reflected by relative sea-level changes attributed to global eustacy and regional tectonic uplift/subsidence. The previous studies for these two groups, however, have not fully made it clear that the observed depositional changes were derived from local tectonic effects or global eustatic sea-level changes due to lack of precise age controls. To address this issue, here we provide the latest age model of the Kuji Group and partly revised regional sequence stratigraphic correlation. Comparing our age-calibrated depositional sequences of the Kuji Group with an available global sea-level reconstruction would separates the influence of eustacy from that of regional tectonics which formed the Yezo forearc basin sedimentary successions.

The Kuji Group is distributed along the northeastern coastal area of the Iwate prefecture. The group mainly comprises sandy siltstone, coaly mudstone, sandstone and conglomerate, with intercalated coal and felsic tuff beds. The total thickness is over 700 m. It unconformably overlies the pre-Cretaceous accretionary complex and lower Cretaceous granitoids, and is unconformably overlain by the Paleogene siliciclastic succession. The Kuji Group is divided into three lithostratigraphic units: the Tamagawa (marine and non-marine), Kunitan (marine), and Sawayama (non-marine) formations, in ascending order. The overall succession consists of at least four largely upward-fining sequences. Previous studies on sedimentary facies analysis divided them into five depositional sequences derived from the third-order sea level change (DS1 to DS5) (Ref. 1).

The newly established age model, based on carbon isotope stratigraphy and U–Pb ages, indicates that the depositional sequences in the Kuji Group is correlated with the middle Turonian to middle Campanian stages. The DS2 to DS4 in the Kuji group are likely coeval with the depositional sequences of the adjacent Futaba Group (the Coniacian to Santonian stages) (Ref. 2). Relative sea-level changes recognized in the DS1 to DS4 are mostly consistent with the second- and third-order global eustatcy (Ref. 3). In contrast, the DS5, equivalent to the Sawayama Formation of the Kuji Group, represents lowstand systems tract (non-marine fluvial facies) with maximum thickness of 200 m. Similarly, development of shallower facies is implied in the Hakobuchi Formation (the Campanian stage; Ref. 4) of the Yezo Group, accumulated in the northern sub-basin. These coeval relative sea-level falls are apparently inconsistent with contemporaneous global transgressive trend, and thus are interpreted to reflect basin-wide uplift of the forearc region in the early Campanian. Here we provide a new constraint for the age of the major tectonic event occurred in the Late Cretaceous East Asian continental margin, possibly related to the change in

©2019. Japan Geoscience Union. All Right Reserved.

subducting oceanic plate motion (e.g. Ref. 5).

Paleo-stress analysis in coherent zone, an exhumed Cretacesou accretionary complex, Shimanto Belt, in Konan city and Geisei villege, Kochi prefecture, SW Japan

*Makoto Hashiguchi[1], Yoshitaka Hashimoto[1]

1. Kochi University

Stress state in a subduction zone can be exchanged between reverse-fault and normal-fault regimes with an earthquake cycle. A similar change in paleostresses has been also obtained in some exhumed accretionary complexes (e.g., Hashimoto et al., 2014). However, most of previous studies in exhumed accretionary complexes cover only mélange zones exposed to the coastline. Therefore, in this study, we examine the paleostress change in a coherent zone. In order to investigate a spatial relationship, we analyzed the paleostress in the coherent zone adjacent to a mélange zone.

The study area is in Konan City, Yasu Town and Geisei Village in Kochi Prefecture, Southwest Japan where the Cretaceous northern Shimanto Belt is cropped out. The geology of the study area is composed of the coherent and mélange zones in the northern and the southern sides, respectively. The coherent zone consists mainly of alternating layers of sandstone and mudstone. The strike and dip of bedding are about N 37 ˚E and 75 ˚S, respectively. The age of the coherent zone has been reported as Cenomanian–Campanian (100 Ma–72 Ma) from microfossils (Taira et al., 1988). As a result of the micro-fault analysis, six stress state (stress 1, 2, 3, 4, 5, and 6) were obtained. Four stresses (stress 1, 3, 5, and 6) could be reasonbale because many unique faults, which are micro-faults with misfit angle of less than 30 degree only in individual stress state, are found. Stress 2 and stress 4 are not treated as reasonable stress solutions because the number of the unique fault is small. Stress 1 and stress 3 are the reverse-fault stress regimes. Stress 5 is obscured for fault types. Stress 6 is a normal-fault stress regime.

In order to constrain stress magnitude, stress polygon was employed. Furthermore, a liner function between SHmax and Shmin can be obtained from the estimated paleo-stress, which can be drawn in the stress polygon. Sv is calculated from density and paleo-maximum depth (5.5 km from vitrinite reflectance). Stress magnitude would be constrained from the overlapping area between the stress polygon and the liner function. According to the results, the stress for the reverse fault regimes is larger than that for the normal fault stress regime. In addition, assuming that the reverse fault changed to a normal fault, the validity of the difference of shear stress (stress drop) was examined. The stress drop is estimated from the difference in the radius of Mohr circles ((SHmax - Shmin) / 2) between the normal fault and the reverse fault stress regimes. The stress drops between stress 1 (reverse fault) and stress 6 (normal fault) ranges, and stress 3 (reverse fault) and stress 6 (normal fault) range 1.8-14.0 MPa and 43 - 63 MPa, respectively. Susan L. et al. (2018) showd the distribution of stress drops from geophysical observations in trench type earthquakes rangeing approximately 0.01–100 MPa. The stress drops obtained from our results are consistent with the range of 0.01-100 MPa. Therefore, it is possible for our results to be related to earthquake cycles.

In conclusion, we would like to emphasize that the exchange of stress accompanying earthquake cycles occurs even in the coherent zone as the same as that observed in mélange zones based on the differences in stress magnitude between the reverse and normal fault stress regimes and the reasonable range of stress drop. The interpretation that the exchange of stress observed in the mélange zone and

©2019. Japan Geoscience Union. All Right Reserved.

also in the coherent zone implies that the exchange in stress state could be recorded after the mélange zone were located adjacent to coherent zonet. In other words, it is suggested that the micro-faults we examined in this study were activated within an accretionary wedge at the critical stress states.

Relationship between accretion of limestone blocks and subduction tectonics in Japan

*Koji Wakita[1]

1. Yamaguchi University

Detailed mechanism for accretion of limestone and basalt is not elucidated yet. Seamount collapse occurs in the tectonic erosion convergent margin such as the Japan trench, but the seamount accretion does not happen in accretionary convergent margin such as the Nankai trough. How are the limestone and basalt blocks preserved in accretionary complexes? The key to understand the reason of accretion of limestone and basalt is the tectono-stratigraphic position of limestone and basalt blocks. In the most of the Japanese accretionary complexes, limestone and basalt blocks occur in the youngest unit of each complex. The cessation of the development of the accretionary complex must be associated with the special tectonic setting, which caused less supply of detrital materials from the provenance area. Flat slab subduction is one of the candidates to cause the less igneous activities in the provenance area. The flat subduction may be caused by the subduction and accretion of buoyant body such as ocean plateau. This subduction and accretion of oceanic plateau caused the cessation of accretionary process, and may have allowed to preserve limestone and basalt block in the accretionary complexes in Japan.

Discussion

Discovery of faulted basin margin from the middle Miocene Tottori Grope, Tottori Prefecture, Southwest Japan and its significance

*Yuta Maruyma[1]

1. Shimane Umiversity

Some Miocene sedimentary basins in the San’in region extend N-S or NE-SW and, have been called the indentation of sedimentary basins. Several studies speculated that these basins were aulacogenes formed in association with the Japan Sea opening event, or extensional basins opened parallel to the rifting axis before the rotation of Southwest Japan. The little sedimentary geological and chronological studies for this type of sedimentary basins remain their evolution to have been still unknown. The precise reconstruction of evolution of these sedimentary basins leads to understanding of the deformation of Southwest Japan crust associated with the Japan Sea opening event and thus to know the concrete Japan Sea opening process. The geological information in the marginal part of such type of basin fills is indispensable in order to elucidate their evolution.

A sedimentary basin, extending almost N-S and called the Tottori Indentation, is spread in the eastern part of Tottori Prefecture, Southwest Japan. Because the sediments of this basin have not been suffered from extensive intrusion of the volcanic rocks in its southeastern part, unlike the other basin fills in the Shimane Prefecture, this is an ideal sediment succession as the target of the sedimentary basin analysis in order to know the evolution of this type of sedimentary basins. The present study conducted geological survey of the Tottori Group using a conventional sedimentary geological method (facies analysis) for reconstruction of the sedimentary environment of the southeastern part of the Tottori Group (Iwami Formation).
The Iwami Formation of the Tottori Group is made up from the Entsuji Conglomerate and Sandstone Member (EM) and Fuganji Mudstone Member (FM). The FM contains both freshwater and marine mudstones. New faults with large displacement on and near the boundary with the underlying rocks are discovered. One represents the boundary between the granitic rock and the EM sandstone with thin vertical veneer of the deformed Kawabara Volcanic Rock Member of the underlying Yazu Formation along the fault. The other is running within the EM sandstone. The presence of gravels of debris fall origin in the FM mudstone near the fault and the talus deposits together with the presence of the deformed Yazu Formation along the fault imply that the fault started to be activated after the Kawabara Member phase and may have been active during the Fuganji period to have formed the slope along the fault. As the result, the block to the west of the fault subsided to have formed a lacustrine basin. Another faults are also expected along the boundary between the basement rock or the Yazu Formation and the Iwami Formation based on the presence of small slump structures indicating a slope that dipped away from the boundary in the southeastern part of the group. Additional study is necessary in order to elucidate the basin type (e.g. strike slip basin or half graben) and to determine the specific timing of basin generation. The present study is financially supported by the Grant-in-aid for scientific research from the San’in Kaigan UNESCO Global Geopark Promotion Council.

Fault activity during Quaternary Period off the Shimane Peninsula based on the profiles acquired by the high-resolution seismic survey

*Masaaki Tanaka[1], Norihiro Matsuda[1], Masaru Nakamura[1], Yuichi Shimizu[1], Masanori Shimazaki[2], Kazuhito Hatakeyama[2]

1. The Chugoku Electric Power Co., Inc., 2. Sogo Geophysical Exploration Co., Ltd.

A number of faults are shown off the Shimane Peninsula by Tamaki *et al.* (1982), Japan Coast Guard (1991, 1992), Tokuyama *et al.* (2001) and others. The Chugoku Electric Power Co., Inc. (Energia) carried out seismic reflection survey by using mainly Sparker in 1981 in the area including some faults described by the above-mentioned authors. The investigated area was about 60 kilometers long along the shoreline and about 30 kilometers long perpendicular to the shoreline. Seismic survey lines were deployed at the interval of about 1 to 4 kilometers in it. Since then, Energia has continually been investigating to grasp more detailed locations and characteristics of the faults in the area by using the latest technology such as multi-channel seismic system and so on. Furthermore, Energia has referred to the concepts of sequence stratigraphy in its interpretation to improve the reliability of the evaluation for fault activity. Government organization MLIT, Cabinet Office and MEXT referred to the Energia's fault evaluation in their document published in 2014.

Structures found off the Shimane Peninsula mostly extend ENE-WSW, forming reverse faults and flexures. Ito and Arato (1999) and others indicate that the stress field off the San-in district was north-south compression during Late Miocene epoch and has been east-west compression since Pliocene epoch, and many folds and reverse faults extending ENE-WSW in this region were developed during Miocene epoch. Therefore, most faults off the Shimane Peninsula are considered to develop around Late Miocene epoch under the north-south compression stress field and end their activity by Latest Miocene epoch. However, Middle to Upper Pliocene (Unit-B) off the Shimane Peninsula is distributed in a narrow area, and it is also extremely thin. These factors have made the evaluation for fault activity during Quaternary period difficult.

On the basis of the above information, we conducted seismic survey in 2014 by using various sound sources off the Shimane Peninsula to grasp the detailed geological structure from shallow to deep. We also conducted bottom sampling for dating on the seismic line at about 7 kilometers off the coast of Kashima town in Matsue city. The samples collected in Unit-A were analyzed by tephrochronology and radiocarbon dating. As a result, we found the Sanbe-Unnan (SUn : about 50ka. Machida and Arai, 2011) tephra and a few samples dated as Late Pleistocene. This shows that most Unit-A is possibly Upper Pleistocene except its surface portion. We confirm that the conventional sparker profiles cannot distinguish Unit-A in more detail, but the high-resolution profiles acquired by multi-channel boomer system can distinguish it into more units : Middle to Upper Pleistocene and Holocene.
From the above, we confirm that faults existing within the area where Middle to Upper Pleistocene, have been inactive at least since Late Pleistocene epoch. Pleistocene possibly exist much more widely compared to the previous interpretation off the Shimane Peninsula. Additional multi-channel high-resolution boomer seismic survey may contribute to reveal the detailed fault activity under the east-west compressive stress field in Quaternary period.

Paleomagnetic directions of early Miocene sediments in central Japan and tectonic implications

*Hiroyuki Hoshi[1], Takuro Matsuo[2]

1. Department of Earth Sciences, Aichi University of Education, 2. Aichi Prefectural Kariya High School

We present new paleomagnetic data obtained from early Miocene (~18-17 Ma) sediments in three areas (Iwamura, Tengudana and Niinotoge) in central Japan. Oriented cores consisting mainly of mudstones and intercalated fine felsic tuffs were collected at more than 50 sites. Stepwise thermal demagnetization of both natural and isothermal remanent magnetizations suggests magnetite as a main magnetic carrier, with possible presence of greigite in rock samples from some sites. Site-mean directions of characteristic remanent magnetization components are all reverse polarity, suggesting deposition within the same reverse polarity chron, probably Chron C5Dr. Declinations of the site-mean directions are mostly southwesterly and deflected clockwise from the expected direction, indicating clockwise rotation after deposition. These declinations are similar to those from early Miocene and older rocks of the main part of the SW Japan arc, while they are significantly different from the undeflected paleomagnetic direction from Tomikusa, located 10-20 km northeast of Niinotoge. Thus, the Iwamura, Tengudana and Niinotoge areas are located on the main part of the SW Japan arc. It is suggested that the main part of the SW Japan arc has its eastern "rotational" boundary with a differentially rotated piece of crust between Niinotoge and Tomikusa.

Revised Cenozoic chronostratigraphy and tectonics in the Yatsuo Area, Toyama Prefecture, central Japan

*Takeshi Nakajima[1], Hideki Iwano[2], Tohru Danhara[2], Tohru Yamashita[2], Yukio Yanagisawa[1], Yoshihiro Tanimura[3], Mahito Watanabe[1], Takayuki Sawaki[1], Satoshi Nakanishi[4], Hiroyuki Mitsuishi[4], Okiyuki Yamashina[4], Seiichi Imahori[5]

1. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, 2. Kyoto Fission-Track Co., Ltd., 3. National Museum of Nature and Science, 4. JX Nippon Oil & Gas Exploration Corporation, 5. JX Nippon Oil & Gas Exploration Technical Services Corporation

Cenozoic chronostratigraphy of the Yatsuo Area in Toyama Prefecture is revised based on U-Pb and fission-track (FT) dating on the same zircon grains from tuff beds using LA-ICP-MS, mineralogical analysis of tuff beds and diatom biostratigraphy. The results reveal followings. Syn-rift volcanism (the Iwaine Formation) started at around 17.5 Ma. The Ikahama unconformity between the syn-rift Higashibessho Formation and the post-rift Tenguyama Formation was a relatively short duration (c. 0.5 m.y.) tectonic event around 15 Ma. The Otogawa Formation unconformably overlying the Tenguyama Formation is divided into Middle Miocene (Serravallian) lower portion and Late Miocene upper portion with a possible unconformity between them. The age of the Mita Formation ranges from 4 to 2 Ma and unconformably overlies the Otogawa Formation. Local correlation of a key tuff bed MT2 in the Mita Formation in previous reports was misleading and needs to be reassessed.

Facies and sequence stratigraphic analysis of the lowermost Nirehara Formation clarifies that the Nirehara Formation comprises many depositional cycles formed by sea level or lake level fluctuation in a coastal or lacustrine fan delta environment. The results also suggest that the Nirehara Formation was formed in an early rift basin, which is overlain by the syn-rift Yatsuo Group with an unconformity. Detrital zircon U-Pb and FT dating of sandstone in the Nirehara Formation suggests that possible source of sandstone was the Nohi Rhyolite.

Regional correlation of onshore and offshore Cenozoic chronostratigraphy in the Hokuriku district shows multistage rifting during Oligocene-Middle Miocene opening of the Sea of Japan. The regional correlation also suggests that post-rifting compressive tectonics was also incremental associated with fluctuation of strength and direction of compressive stress fields.

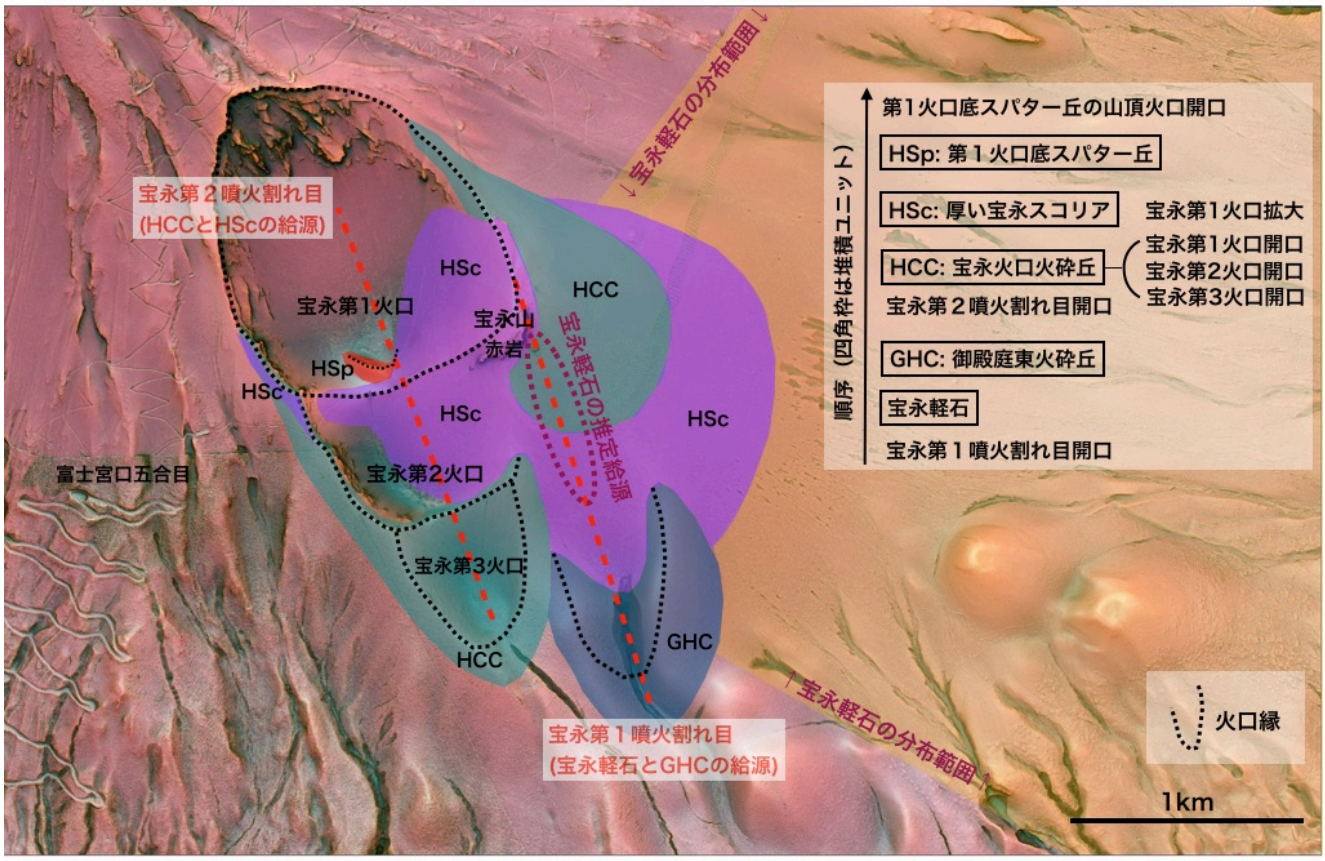
A working hypothesis for source craters and sequence of the 1707 Hoei eruption of Fuji Volcano, Japan

*Masato Koyama[1]



1. Shizuoka Univ.

The 1707 Hoei eruption, one of the most voluminous and violent eruptions of Fuji Volcano, has been considered to have occurred from the NW-SE trending three craters (Hoei craters) on the southeastern flank of the volcano and to have made the bulge (Hoei mound) at the edge of the craters. The Akaiwa rock, located near the summit of the Hoei mound, has been thought to be an outcrop of older strata, which have unconformable relationship with overlying deposits.
On the basis of careful geomorphological and geological survey including SfM(Structure from Motion) technology with UAV photos, the strata exposed on the Akaiwa rock are revealed to be part of the proximal deposits of the Hoei eruption. Moreover, another NW-SE eruptive fissure is estimated to have opened between the Hoei mound and the Gotenniwa Higashi pyroclastic cone in the initial stage of the Hoei eruption and to have been buried by the subsequent eruptive deposits from the Hoei craters. The hypothesis of this fissure can resolve the problem thatlocation of a source crater of the basal pumice layer of the distal Hoei pyroclastic deposits is still unclear.

Consideration of the formation process of Mt.Hoei, Fuji volcano

*Akira Baba[1], Toshitsugu Fujii[1], Tatsuro Chiba[2], Mitsuhiro Yoshimoto[1], Fumikatsu NISHIZAWA[1], Hidetoshi Shibuya[3]

1. Mount Fuji Research Institute, 2. Asia Air Survey Co., Ltd., 3. Department of Earth and Environmental Sciences, Faculty of Advanced Science and Technology, Kumamoto University

It is important to review the sequence of each eruption in the past in order to mitigate volcanic hazard in the future. Especially the Hoei eruption is regarded to be important because it represents large scale explosive eruption that is rare in the eruptive history of Fuji volcano, but may cause extensive disaster in the metropolitan area. Mt.Hoei has been considered to be protuberance formed during the Hoei eruption and to be composed of Old Fuji formation (Tsuya, 1955). The protuberance has been considered as a kind of bulge accompanied by lateral intrusion of degassed magma (Miyaji et al., 2011). Koyama (2018) suggested the bulge by intrusion of magma could cause sector collapse and the evacuation plan for such sector collapse should be made. In this presentation, we will discuss the genesis and the formation process of Mt.Hoei based on new data obtained from geological survey, geochemical analysis and palaeomagnetic measurements of the constituents of Mt. Hoei and the ultraproximal deposits of Hoei eruption.

Mt.Hoei located at the northeast of Hoei craters, consists of pyroclastic rocks including mainly dense blackish-grey scoriaceous lapilli, spatters, volcanic bombs capturing gabbro and gabbroic fragments. From these observations, microscopy, whole rock chemical composition analysis, palaeomagnetic measurements and XRD analysis results, Mt.Hoei (Akaiwa) is presumed that ultraproximal fall and surge deposits by phreatomagmatic eruptions, compared with Ho-Ⅲ(Stage 2) of Miyaji et al.,(2011) from petrography and chemical composition. In addition, 2nd and 3rd crater ridge, the wall of the erosion valley of Gotenniwa consists of fallout deposits of Hoei eruption, corresponding to Ho-Ⅰ to Ⅲ(Stage 1) of Miyaji et al.,(2011). Although the white and banded pumice layer cannot be confirmed at the base of the erosion valley of Gotenniwa at the present moment, the deposits show a gradual compositional change from andesite to the basalt (SiO_2 = 62.8 to 52.2 wt%) upward. The paleomagnetic directions obtained from the spatter cone in the 1st crater of Hoei, the deposit around the summit of Mt.Hoei and the fallout deposit at erosion valley of Gotenniwa coincides with 1707 A.D.of the paleomagnetic secular variation curve (JRFM 2K.1).

We estimated the formation process of Mt.Hoei based on these new findings, isopach maps of Hoei eruption(Miyaji et al., 2011), the model of magmatic development of Hoei eruption (Fujii, 2007 ; Yasuda et al.,2015), and historical records and drawings (Koyama, 2009). Mt.Hoei is not a bulge caused by the magmatic intrusion, but a pyroclastic cone of Hoei eruption formed in only 9 days.

1. The basaltic magmas contacted and mixed with the dacitic magma, white-banded pumice squirted from the vicinity of the 1st crater and was swept in the east direction by the westerlies (December 16th around 10 to 17 o'clock, Unit A, B of Miyaji et al.,(2011)).
2. As the crater expanded, the side of the mountain of the first crater was also scraped off, and abundant accessory materials were ejected in the east-south direction together with the essentials, and deposited near crater to form Mt.Hoei (December 17th before daylight, Unit C ~ F of Miyaji et al, (2011)).
3. The vent transitioned to the 2nd crater due to the landslide at the 1st crater edge or expansion of the vent. (December 17 to 19 th, Unit G ~ I of Miyaji et al, (2011))
4. The vent transitioned to the 1st crater due to the accessory materials of landslide were gradually ejected, Mt.Hoei (Akaiwa) was formed by intermittent phreatomagmatic eruptions (December 19-25 th, Unit J ~ M of Miyaji et al, (2011)).

©2019. Japan Geoscience Union. All Right Reserved.

5. As crater is restricted to the 1st crater, inflow of accessory materials stopped and Plinian eruption of basaltic magma continued for 6 days and ended (December 25 - 30 th, Unit N ~ Q of Miyaji et al, (2011)).

Airborne LiDAR Bathymetry reveals underwater topography of Lake Motosu
- The level of water raised by lava inflow -

*Tatsuro Chiba[1], Sin-ichi kaneta[1], Makoto Ohashi[1]

1. Asia Air Survey Co., Ltd.

1. Introduction

Lake Motosu is a dammed lake located northwest of Mt. Fuji, the elevation of the lake is about 900m. Aokigahara lava flow, which is occurred by the eruption of 864 AD, flood into the lake, and the northeast lake shoreline is seen like cut off by the truncated arc. Though regarding the characteristics of this lava flow, there is a study by Obata and Unno (1999), no survey of the shallow part of the lake had been conducted. Generally, the level of lake water is the possibility of rising up by the entry of a large amount of debris or lava flows. Of course, it is not a kind of transient phenomenon like Tsunami, but the possibility to rise permanently because of the bottom of the lake getting shallow. Airborne LiDAR Bathymetry measurement was carried out in order to investigate whether the level of water of Motosu Lake changes during Aokigahara lave flow entry, and the results are as bellows.

2. Airborne LiDAR Bathymetry

Airborne LiDAR Bathymetry, as follows ALB, is a measurement method aiming to measure depth and topography of shallow water along river and coast. The equipment used in this research consists of two pair of laser ranging systems for ground measurement using NIR laser and underwater measurement using visible range (532nm). The measurable depth depends upon the transparency of the object greatly. It was expected to be measurable up to 15m depth since Lake Motosu has high transparency throughout the year and is visible around 14-16m depth. The measurement carried out on 9th September 2017. Since the area terrain is heavily rough, Helicopter, which is easy to control flight height, is used and flew 11 courses.

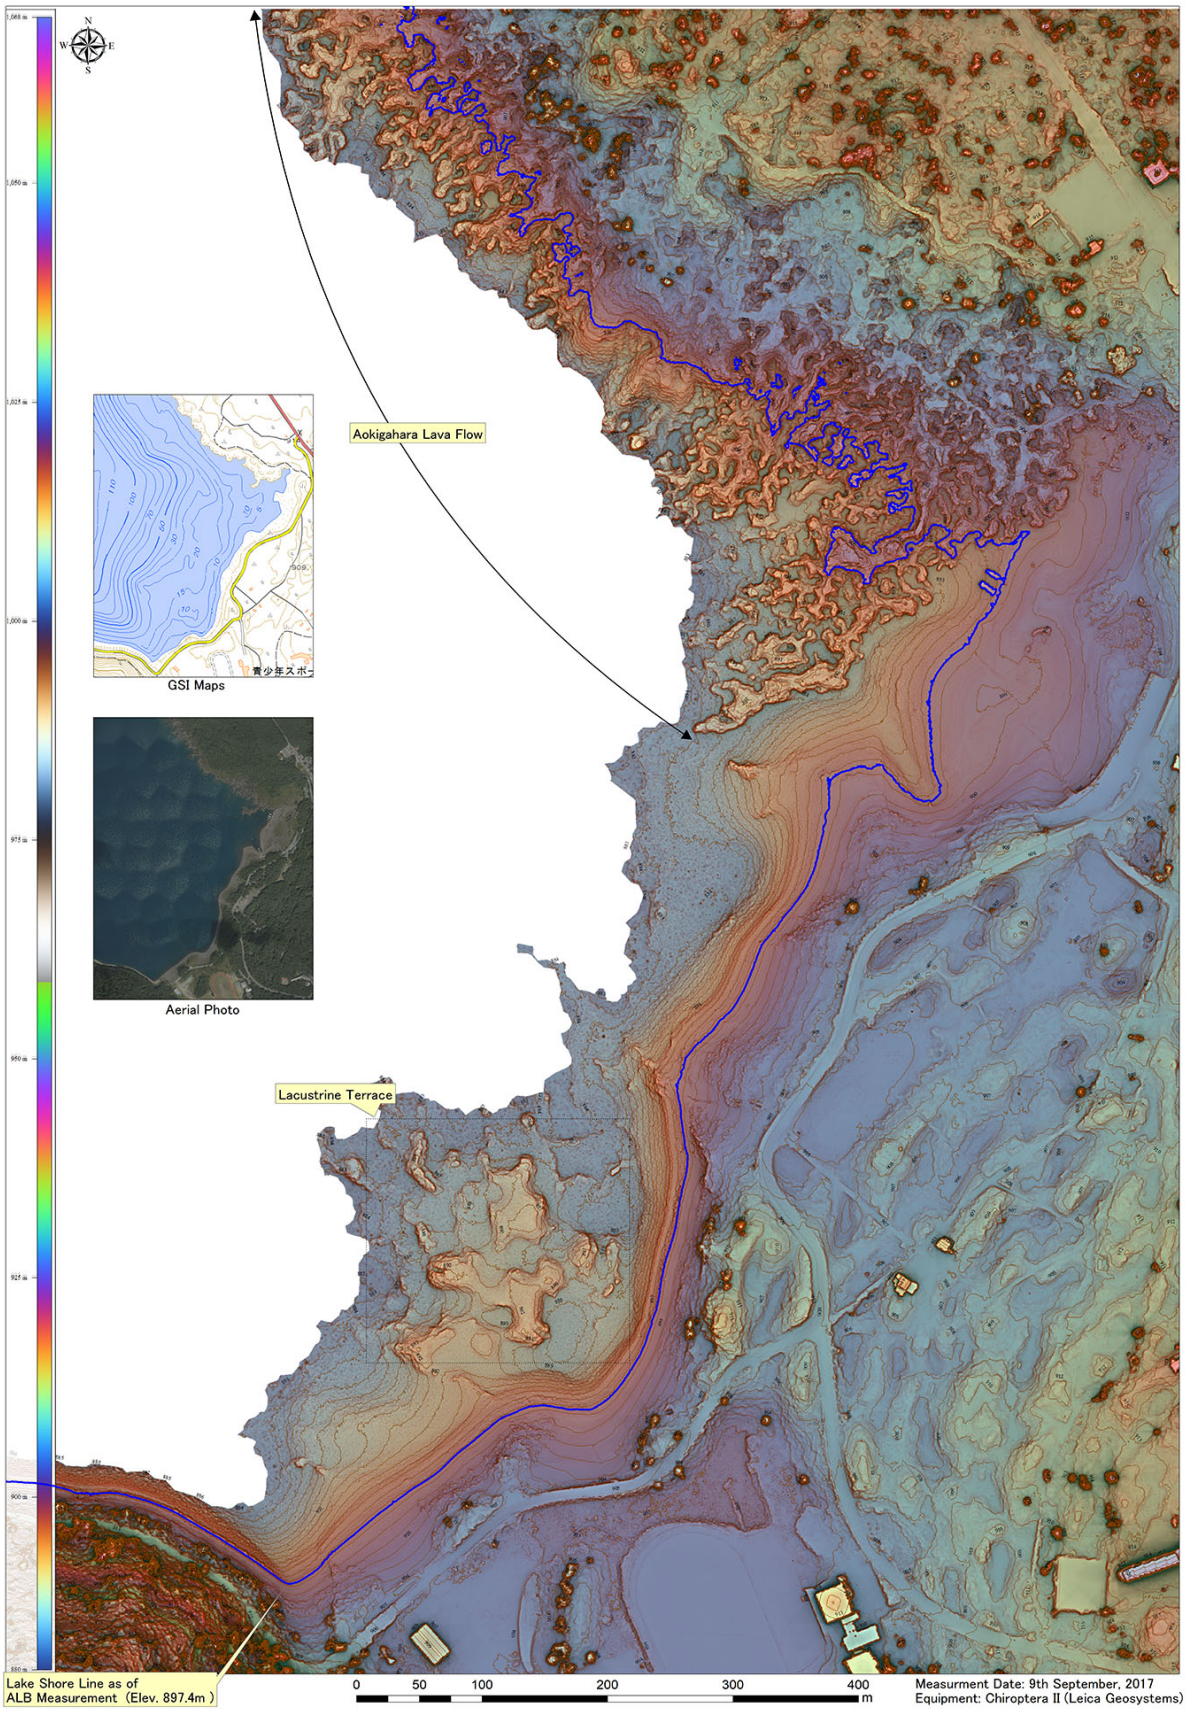
3. Bathymetry

For ALB measurement, the position of the aircraft is determined by kinematic GNSS survey based upon GNSS-based Control Station, objective terrain of the ground and the seafloor are measured by both the data of the initial navigation device and the two channels of laser ranging device. The density of point-clouds was 10 to 100 points/m^2 on land and 1 to 5 points/m^2 on water. The maximum water depth was measured to be 11-15m. Based on pon point-clouds data, the topography of the lake bottom is totally different between the northern and southern measurement range. On the northern side, unique irregularities of Aokigahara lava can be seen from land to underwater. There is no change between the border of the surface of the lake and reach to around 15m continuously. On the other side, the topography of the southern side of the lacustrine terrace, there can be seen slightly higher hill than the seafloor closer to the lakeshore. Not less than two stages of rectangular flat surface can be seen on the northern slope of the hill.

4. Conclusion

On the northern side of the measurement range, there found lava topography divergent like branch coral and split on the center part, and there found red oxidized portion, so it is clear that the lava landscape was deposited on land (Obata and Unno, 1999). Continuously tracking terrain similar to this topography

©2019. Japan Geoscience Union. All Right Reserved.



to 15m water depth suggests that the level of water at the time of lava flow was at least 15m lower than the current one. Underwater archeology surveys are also conducted around the southern lacustrine terrace (Kamikuissiki Village Board of Education, 1999). Relics including turtle type earthenware have been ensured so far, most of relics were identified as the age of the beginning of the early stage of Kofun Period. Many of them are completed and it seems to have been submerged since there is no inconsistency that the time is the invasion time of Aokigahara lava flow in the Heian era. It is to be wished that the detailed investigation confirms the red oxidized portion of the underwater lava topography and the research of the possibility of flat surface to be the construction of the submerged village in the future.

Volcano monitoring using satellite thermal infrared imagery of CIRC (Compact Infrared Camera)

*Yuki Takakura[1], Koji Nakau[1], Junichiro Ishizawa[1]

1. Japan Aerospace Exploration Agency

Although volcanic activities are monitored by various approaches, it is difficult to observe some volcanoes in Japan using ground equipment (e.g. remote islands or submarine volcanos). In such case, satellite imagery is one of the powerful tools to monitor them. Satellite can observe extensive area simultaneously, including many volcanos. Thus, we can capture geothermal activities; lava flow, pyroclastic flow or heat of crater even at night.

To prevent or to mitigate volcanic disaster, the disaster management agencies needs ready-to-use dataset; information extracted from satellite imagery. Therefore, we developed “Volcano Monitoring System” (released in Sep 2018; https://kazan.jaxa.jp/); which system provides such information and visualized satellite infrared imagery of CIRC and other satellites. CIRC is uncooled microbolometer thermal infrared sensor for the earth observation and it is on board ALOS-2 satellite (Advanced Land Observing Satellite 2). On the Volcano Monitoring System, we can browse satellite RGB or infrared imagery as a map and get the variation of volcanic activity’s indices automatically extracted from satellite imagery. To produce concrete indices for volcano monitoring, we are studying several approaches of satellite infrared data processing in cooperation with the disaster management agencies. In such study, we are focusing on 12 volcanoes which are defined among us. In this presentation, we introduce “Volcano Monitoring System” and some volcanic events captured by CIRC.

Impact absorption properties of wooden buildings roof subjected to ballistic block collision

*Kohei Tateyama[1], Hiroyuki Yamada[2], Mitsuhiro Yoshimoto[3], Ryo Honda[3], Toshitsugu Fujii[3]

1. Ritsumeikan University, 2. National defense academy, 3. Mount Fuji Research Institute, Yamanashi Prefectural Government

Volcanic disasters include various factors such as eruption, lava flow, pyroclastic flow, debris avalanche, debris flow and so on. Especially, at the phreatic eruption of Mt. Ontake in September 27, 2014, most of the damages were caused by clashes of ballistic block. In order to prevent these damages, it is suggested that evacuation to a mountain hut is effective. Thus, evaluation of impact absorption properties for wooden buildings (e.g. mountain hut) against ballistic block collision is necessary. Previously, we reported the protective abilities of as-built wooden buildings, which were reinforced with high performance fabric using aramid fiber. In addition, the penetration boundary energy for a 15 mm thick wooden building roof was reported. However, the impact absorption properties of various type wooden buildings has not been clarified enough. Therefore, in this study, impact absorption properties of wooden buildings roof subjected to ballistic block collision was experimentally investigated.

A collision test was carried out at the velocity of 10 to 90 m/s using a large scale launching system. In this system, a projectile was accelerated by compressed air and then collided with the target. The projectile velocity was measured using two lasers and light receiving parts. In many cases, size of the ballistic block is almost the fist size (ϕ100 mm) under phreatic eruption. Therefore, Vitrified whetstone similar to the common ballistic block (density: 2400 kg/m^3) was used as the projectile, and the diameter was determined ϕ90 mm (mass: 2.66 kg). For the target, typical wooden roof structure (e.g. cedar boards, waterproof sheet, galvalume steel plate and cedar rafter) was used. Two types of thickness of cedar board (15 mm and 18 mm) were prepared. The thickness of the waterproof sheet and galvalume steel plate were 1.0 mm and 0.4 mm, respectively. The dimensions of the specimen were 600 mm ×600 mm. The components were fixed with nails and its spacing was approximately 150 mm. In addition, specimens in which two cedar plates were superimposed was also prepared. There are two kinds of superimposing methods: a ” staggered structure “ that is alternately superimposed on one another, and a "cross structure" in which plates are orthogonalized.

Collision test results revealed penetration boundary energies of 15 mm and 18 mm specimens, respectively. In previous study, it was shown the maximum collision energy of volcanic ballistic block (ϕ 2-64 mm) was 1700 J (in the case of ϕ64mm, 100 m/s), and average collision energy was less than approximately 1200J in many cases. From the result, it was revealed that the roof of cedar board having a thickness of 15 mm and 18 mm could prevent penetration of volcanic ballistic block. In addition, it was found that by superimposing the cedar boards, impact absorption properties can be improved simply. At the time of superimposition, the impact absorption properties was hardly improved in the ” staggered structure”. However, in the "cross structure", it was confirmed that the impact absorption properties were greatly improved. From this it was found that the "cross structure" is better when reinforcing by simple superimposition.

Earthquake Research Institute, University of Tokyo

Moto-Shirane volcano, which is part of Kusatsu-Shirane volcano, erupted on 23 January 2018 after 1500 years dormancy. One parson died and 11 other people were injured by the ballistic ejecta of this phreatic eruption. We report the results of a survey on the distribution of ballistic rocks around the crater and climbing trails and ski courses on May 10 - 12, 2018 and October 23 - 25, 2018.The maximum size of the ballistic rocks was measured at a total of 191 sites and the number density of the rocks (>64mm) was measured at a total of 64 sites. Ballistic rocks of the eruption are distributed within 500 meters around the main crater and is mainly distributed from north to northeast. The maximum size of ballistic rock was 4.8 m which fell to the western crater rim, and near the main crater was 3.4 m. The flight-distance of ballistic rocks with a major axis of about 20 cm, 50 cm, 100 cm, 200 cm are 400 to 650 m, 400 m, 350 m, 150 m, respectively. It suggests that the initial velocity of ballistic rocks of each size is different.

Developing Ash-fall impact forecasting content.

*Tomohiro Kubo[1], Yosuke Miyagi[1], Setsuya Nakada[1], Eisuke Fujita[1], Masamitsu Miyamura[1]

1. National Research Institute for Earth Science and Disaster Prevention

The falling ash is expected to cause extensive damage over a wide area, because the ash widely spread out. For example, the highway road was closed to traffic due to falling ash, because the falling ash causes a car slip accident. In Mt.Aso 2016 Eruption, the Aso-shi lost power, because the ash fall an electric power substation. On the other hand, the wooden houses may be collapsed by over volcanic ash load. In addition, the buildings that are constructed by Reinforced Concrete or Steel such as a hospital, an office or a city hall are not collapsed, but the building equipment on the roof supposes to be damaged by the falling ash. Thus, we research the impact of the building equipment function due to falling ash by experimental study.

We report the experimental result of a cooling tower by falling ash. In addition, we report the prototype ash-fall impact forecasting content for the infrastructure and the building equipment, based on the Central Disaster Management Council report and the experimental result.

Keywords: ash-fall, damage estimation, volcano disaster countermeasure, experiment, building equipment

New Websites and a Pamphlet of IVHHN

*Yasuhiro Ishimine[1]

1. Research and Education Center for Natural Hazards, Kagoshima University

I will present an outline of new websites and a pamphlet of International Volcanic Health Hazard Network (= IVHHN), both of which have been translated into Japanese by the author. IVHHN is an IAVCEI commission which has been launched in 2003 and focuses on research and dissemination of information on volcanic health hazards. Dr. Claire Horwell and some other leading members of IVHHN have conducted a research project entitled “A New Evidence Base for Respiratory Health Interventions in Volcanic Eruption Crises”, which is called HIVE project for short, with a grant from Enhancing Learning and Research for Humanitarian Assistance (ELRHA), a global charity organization in 2015-2018. IVHHN has revised its websites and published in August 2018 to include new outcomes obtained from HIVE project. It is notable that the new websites include the guideline on recommended facemasks for respiratory protection during ashfall on the basis of the field research in Indonesia, Mexico and Japan carried out as a part of HIVE project. The guideline advises residents to stay indoors to reduce exposure to volcanic ash if possible and wear a well-fitting industry-certified facemask such as a N95 mask, or a DS2 mask, which is Japanese standard equivalent to N95, when they are cleaning up volcanic ash or stay outdoors for a long time. The guideline also mentions that industry-certified facemasks are not usually designed to fit children’s face, and thus, they are not effective for children. The new IVHHN websites add the guideline and some other scientific protocols for assessing volcanic health hazard. They also adopt a responsive layout to works well on smartphones. The websites also contain three new videos which describe the experience of coping with volcanic ash, how to protect yourself from breathing ash and how to properly fit a facemask. Subtitles are available in English by clicking on the CC button or you can switch to Spanish or Bahasa in the Settings button. They are also available on YouTube and Vimeo. As the author has been a member of IVHHN since 2005 and managed Japanese IVHHN website. he translated the revised English websites into Japanese and published in January 2019. The new Japanese pages is published newly obtained internet domain at http://www.ivhhn.jp/, while the Japanese website has been published at http://www.geocities.jp/ychojp/ivhhn/ for twelve years. The author printed 2,000 copies of the Japanese version IVHHN guideline on the protection from breathing volcanic ash as a pamphlet. A half of the copies were distributed at the general disaster drill on large-scale eruptions of Sakurajima held on 12 January 2019.IVHHN now prepare for another guideline on the health effects of volcanic gases, which has already been reviewed by the author and some other members of an IVHHN expert panel. The author also provides IVHHN with some photos of fumaroles taken at volcanic areas in Japan.

State of river water pollution derived from the recent volcanic activity of Mt Iwo-Yama, Kirishima volcanoes

*Yoshikazu Kikawada[1], Haruka Yamamoto[2], Wei Deng, Megumi Fukai

1. Faculty of Science and Technology, Sophia University, 2. Graduate School of Science and Technology, Sophia University

Mt Iwo-Yama belonging to the Kirishima Volcanoes erupted in 2018 for the first time in 250 years. The recent activity of the volcano has a profound effect on the regional economy, especially in the fields of agriculture and tourism. With the phreatic eruption in April 2018, muddy thermal water spouted out from the newly opened vents resulting pollution in the downstream river. As a result, about 1,400 farmers in the downstream area abandoned rice cultivation in 2018.
The muddy water from the newly opened vents is strongly acidic and high in the concentrations of chloride and sulfate with a remarkable amount of arsenic and some kinds of heavy metals. The mud from the vents is mainly composed of grayish argillaceous particles and elemental sulfur suggesting that it is originated from highly-altered zone related to the geothermal reservoir beneath the volcano.
The vents are still busy gushing the muddy thermal water and vapor/steam as of mid-February 2019, ten months after the eruptive events. Based on our continuous investigation, the overflowing water from the vents is constantly strongly acidic (pH <1) and contains a relatively high concentration of arsenic, although the overflow rate is not constant and changes on occasion. The results of our latest chemical analysis show the water contains around 5 mg/L arsenic. Besides, the spring water in the west flank area of the volcano, which is one of the headwaters of the local river, has become strongly acidic with a rise of volcanic activity. That spring water is also one of the reasons for water pollution in the downstream. As a result, even recently the river water pollution in the foot of the volcano is sometimes reported. The river water pollution thus remains as a problem to be solved both environmentally and economically.

Development of information tools for evacuation and rescue in the event of volcanic disaster

*Yosuke Miyagi[1], Setsuya Nakada[1], Tomohiro Kubo[1], Mitsuhiro Yoshimoto[2], Ryo Honda[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Mount Fuji Research Institute, Yamanashi Prefectural Government

Integrated Program for Next Generation Volcano Research (IPNGVR) conducted by Ministry of Education, Culture, Sports, Science and Technology, Japan started in 2016. This project takes notice to not only observation and prediction researches but also research for countermeasure technology of volcano disasters. National Research Institute for Earth Science and Disaster Resilience (NIED) has been in charge of one of the main theme which is named “Development of countermeasure technology for volcano disasters”. In this theme, we develop an information tool for volcano disasters, in which we consider disaster management personnel in local governments as users, and we try to provide appropriate information for them in both the event of disaster and normal times.

In the tragic disaster of Ontake Volcano in 2014, it was difficult for local governments to grasp whereabouts of climbers and to conduct rescue and search for victims. Even recently, climbers can approach to an active vent in many volcanoes in Japan, for example Mt. Fuji, it is quite important to grasp whereabouts of climbers in the event of disaster for proper decision of rescue and search. Experiments to acquire data of climbers in Mt. Fuji have conducted since 2015, named “Mt. Fuji Challenge”. Mt. Fuji is active volcano and gets more than 200,000 of visitors including climbers from all over the world each year. In experiments, we distribute beacons to climbers and receivers which are set in mountain trails detect signals from the beacons, then we can grasp the number and location of climbers who have the beacons. Numbers of beacon which we distributed were 2,300 in 2017 and 14,000 in 2018.

The tool developed in our research use the data from the above experiments as input data, and visualize on GIS software. As a result, it is possible to grasp whereabouts of climbers on map information, including trails, shelters and hazard information from hazard map. Even in normal times, information from the tool can be used for evacuation plans, including establishment of shelters or evacuation routes, instituted by local governments. And, by combining with hazard simulations, we can infer casualties in the event of disaster.
In this presentation, we introduce a summary of the experiments in Mt. Fuji in 2018, and report a progress of the development of the tool.

Ignimbrite, tephra-fall, caldera and fatalities of major volcanoes in the East and Southeast Asia

*Shinji Takarada[1], Joel Calupas Bandibas[1]

1. Geological Survey of Japan, AIST

Large-scale caldera-forming eruption can cause major destruction within 10 to several 100-km radius from the erupting volcano. The information about the area affected by ignimbrite and tephra falls and size of caldera are useful for future volcanic hazard assessment. Hence, the compilation of data about the distribution of ignimbrite and tephra fall, shape and size of caldera and fatalities caused by volcanic eruptions in East and Southeast Asia is very important.

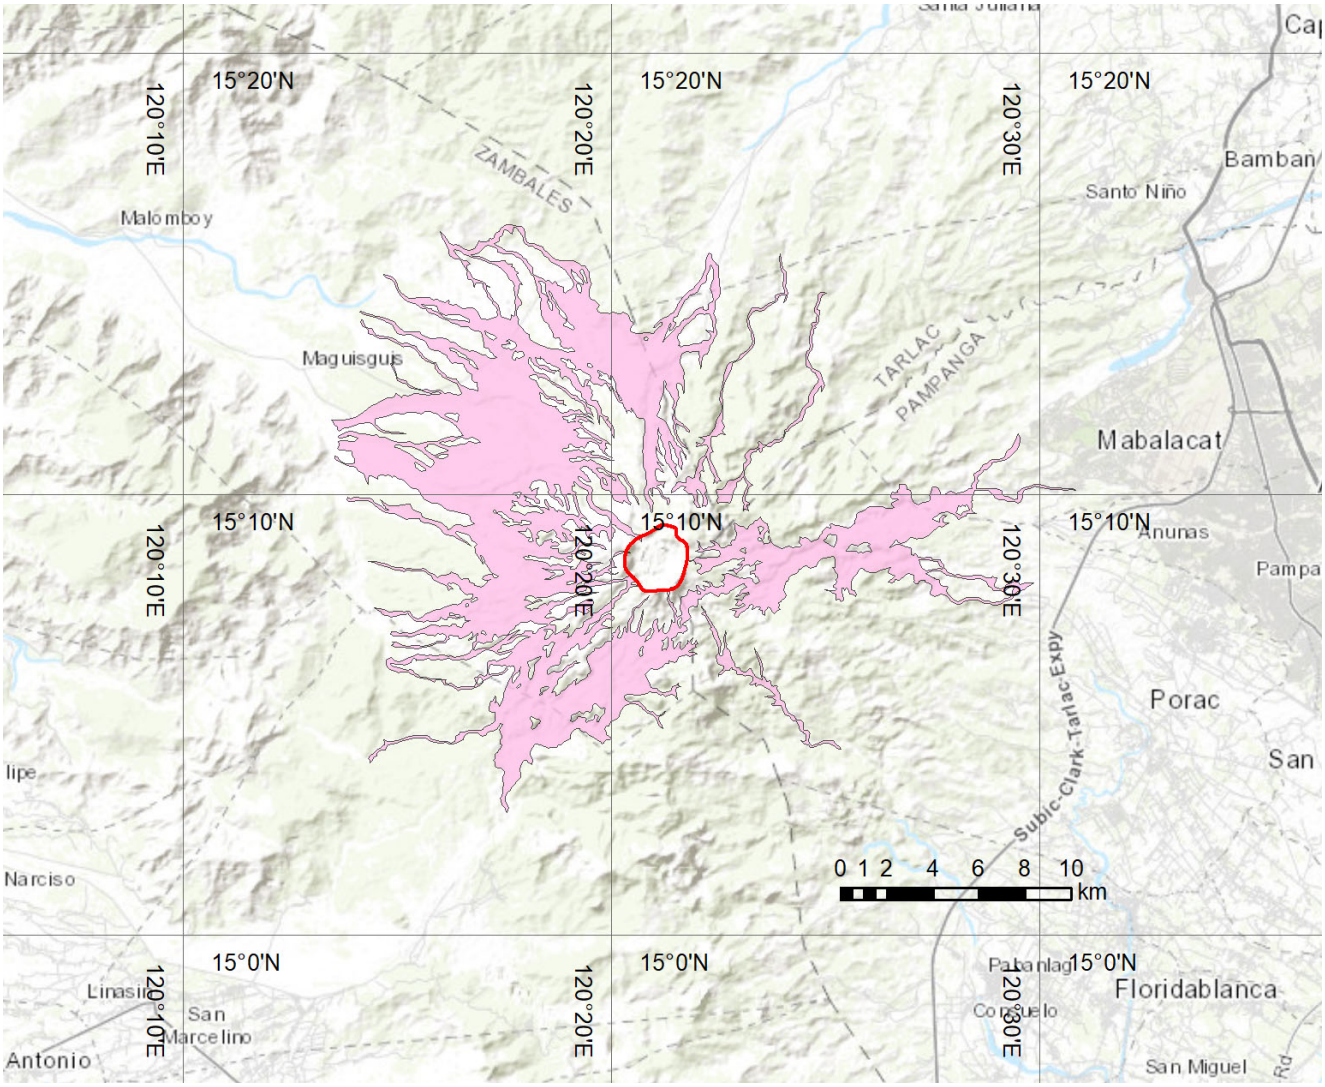
The G-EVER Promotion Team of the Geological Survey of Japan, AIST is implementing the Asia-Pacific region earthquake and volcanic hazards mapping project, which compiles earthquake source regions, active faults, tephra falls, caldera, ignimbrite, and fatalities caused by earthquake and volcanic events, in collaborations with geohazard research institutes in the Asia-Pacific region. The G-EVER Promotion Team published the 1:10M Eastern Asia Earthquake and Volcanic Hazards Information Map in 2016 (Takarada et al., 2016). The contents of the map can also be viewed or downloaded using the Asia-Pacific Region Earthquake and Volcanic Hazard Information System at http://ccop-geoinfo.org/G-EVER/. The distribution of ignimbrite and tephra fall, shape of caldera and fatality data are updated and available on the site in 2019.

Ignimbrite: The distribution of large-scale ignimbrites (VEI>6) in East and Southeast Asia are compiled. Ignimbrites data are obtained from 19 volcanic caldera-forming eruptions in the region such as Toba 74 ka, Changbaishan 946AD, Tambora 1815AD, Rinjani-Samalas 1257AD, Aso-4, Aso-3, Aira-Ito, Kikai-Koya, Kikai-Nagase, Ata, Toya, Shikotsu 4.6 ka, Kutcharo I, Kutcharo IV, Krakatau 1883AD, Rabaul 7c, Pinatubo 1991AD, Hakone-Tokyo, and Towada-Hachinohe.

Tephra falls: The distribution of large-scale tephra falls (VEI>6) in East and Southeast Asia are compiled. Tephra falls data are obtained from 24 volcanic caldera-forming eruptions in the region such as Toba 74 ka, B-Tm 946AD, Tambora 1815AD, Rinjani-Samalas, Krakatau 1883AD, Rabaul 7c, Pinatubo 1991AD, Long Island 1660AD, Witori-Kimbe2, Ulleung-Oki and Ulleung-Yamato.

Caldera: The shape of major calderas (VEI>6) in East and Southeast Asia are compiled. There are 23 caldera data obtained from volcanoes such as Toba, Tambora, Aso, Aira, Kikai, Ata, Toya, Shikotu, Akan, Kutcharo, Taal, Krakatau, Rinjani-Samalas, Pinatubo, Rabaul, Long Island, Dakataua, Wiroti, Billy Michel, Towada, Mashu, and Moekeshi.

Fatalities: The number of volcanic eruption fatalities and their causes (i.e. pyroclastic flow, debris avalanche, tephra fall, lahar, tsunami, volcanic gas and other reasons) since 1400AD in East and Southeast Asia are complied. The 13 events at 9 volcanoes in Papua New Guinea, 3 events at 2 volcanoes in Solomon Islands, 6 events at 3 volcanoes in Vanuatu, 74 events at 27 volcanoes in Indonesia, 20 events at 6 volcanoes in the Philippines and 36 events at 21 volcanoes in Japan (152 events at 67 volcanoes in total) were compiled.



The data in ESRI shapefile and other formats are available for download at the Asia-Pacific Region

On the climber’ s attitudes to the Volcanic mitigation for active volcanoes.

*Hideyuki Itoh[1], Chizuru Totani[2], Mizuho Arai[2]

1. Faculty of policy studies, Iwate prefectural University, 2. Asia air Survey, Co.Ltd.

Following the Ontake disaster on September 27,2014, the act on active volcano special measures law was revised in 2015, local governments well informed of hazardous area, items for smooth alert evacuation by distributing volcanic hazard map. On the other hand, it is hard to say that the method of transmitting volcanic disaster information to climber is sufficiently under the present circumstances, it is urgent to provide information smoothly in emergency and evacuation method.

We carried out questionnaire survey on the climber in order to know the attitudes to the volcanic mitigation for active volcanoes. 74 respondents were collected at Kurikoma volcano, and 84 respondents were collected at Akita-Komagadake volcano.

At the result, climber in Akita –Komagadake, more than 62 percent of respondents visited from both Iwate and Akita prefecture, whereas in Kurikoma volcano, 56 percent of respondents visited from Kanto area by the large –scale bus with a sightseeing tour.

More than 67 percent of climbers have not issued climbing notifications in both volcanoes.
It is clear that the 40 percent of respondents in Kurikoma volcano, 25 percent of respondents in Akita –Komagadake climber are not recognized where they are climbing as active volcano, and eruption alert level is not also well understood.

[S-VC38] Active Volcanism

convener:Yuta Maeda(Nagoya University), Takahiro Miwa(National research institute for earth science and disaster prevention), Takeshi Nishimura(Department of Geophysics, Graduate School of Science, Tohoku University), Chairperson:Takehiko Suzuki, Maya Yasui

This session discusses various aspects of active volcanisms including, but not limited to, recent and historical eruptions, various phenomena associated with the volcanic activities, underground structures of the volcanoes, and developments of new instruments based on geophysical, geochemical, geological, and multidiscipline approaches. We also welcome studies on understanding and predicting the transitions of the eruptive activities from observational, theoretical, and experimental approaches.

Discussion

Tephrochoronology in the southwest part of basaltic Izu-oshima volcanic island during last 20,000 years, off Tokyo, Pacific Ocean

*Takehiko Suzuki[1], Satoshi Terayama[1], Jun Matsukaze[1], Yuichi Kato[1]

1. Faculty of Urban Environmental Sciences, Tokyo Metropolitan University

The Izu-oshima volcano (110 km SSW of Tokyo) in northern Izu-Bonin Arc, is one of the most active Quaternary volcanoes in Japan. This volcano originating from basaltic magma has frequently erupted; that is, 12 times of major eruptions occurred after 2 ka. Studies of its eruption history have been carried out by Nakamura (1964), Kawanabe (2012) and so on. However, precise ages of eruption preceding the caldera formation occurred at 1.8 ka have not been determined. Here, we re-examine the chronological framework of eruption history of the Younger Edifice of pre-caldera.

Fall-out tephras are typically exposed along so-called Great Cut of Beds in SW part of the island. Previous studies by Tazawa (1990) and Uesugi et al. (1994) have described this outcrop, numbering each tephra layer using serial numbers (O1–95 and Osb96–127). All tephras except O55 and O58 are proximal fall-out tephras composed of scoriaceous lapilli and/or scoriaceous ash. Due to the large number of tephras and lithological similarity, it is difficult to confirm each tephra defined by previous studies except several characteristic ones such as O95, O58, and O55. O55 and O58 are rhyolitic tephras from Nijima island and Omuro-dashi submarine depression, respectively (Saito et al., 2007).

Uesugi et al. (1994) estimated the age of the lowest tephra to be 25 ka or older by using 15 radiocarbon ages. However, this estimation is not reliable because it was determined using two oldest conventional radiocarbon ages (non-calibration) of 14–13 ka for the same horizon (just above O64) and under the assumption that the frequency of the tephra occurrence (154 years interval) is constant.
In this study, radiocarbon dating was performed for organic tephric loess collected from 9 horizons above O55 and 16 under O55. The oldest radiocarbon age is 18,598–18,287 cal BP, determined at the horizon 4 m below O95. The age of O95, the most prominent scoria fall deposit, is most likely to be 16–17 ka judging from several radiocarbon ages. It is 2400–3700 years younger than the estimated age (19.4–19.7 ka) by Uesugi et al. (1994). We also recognized widespread K-Ah tephra using volcanic glass geochemistry. Two radiocarbon ages determined at 45 cm above and 55 cm below K-Ah are 6,882–6,747 cal BP and 8167–8021 cal BP, respectively. These ages are concordant with revised age of K-Ah (7,307–7,196 cal yrs BP; McLean et al., 2018), indicating the age of horizon detected K-Ah is older than estimated age of 6,330±85 yBP by Uesugi et al. (1994). These results indicate that the interval between O95 and K-Ah is shorter (67–75%) than previous estimation, suggesting higher frequent occurrence of the eruptions in this period.

Tephrostratigraphy at Daisan-yama and Jinai-jima, and correlation with eruption deposits from Mamashitaura Volcanoes in Niijima Volcano, Izu-islands

*Makoto Kobayashi[1], Masanori Murata[1], Kaori Aoki[1], Daisuke Ishimura[1,2], Takehiko Suzuki[1,2]

1. Research Center for Volcanic Hazards and Their Mitigations, Tokyo Metropolitan Univ., 2. Department of Geography, Tokyo Metropolitan Univ.

In this study, we established tephrostratigraphy at both sites of Daisen-yama and Jinai-jima, and correlated with eruption deposits from Mamashitaura volcanoes based on the characteristics of the mineral compositions, the refractive indexes and major chemical element compositions of the volcanic glass shards. We are aiming to clear long-term eruption history of Niijima volcano.
We recognized deposits associated with at least 20 eruption deposit events at Daisan-yama and Jinai-jima. Based on the stratification of widespread tephra AT, it is considered that the history of the explosive eruption of Niijima volcano and the surrounding volcanoes during late Quaternary (past about 50,000 years) are preserved at these sites. At the both sites, as the ca. 20ka tephra layers, there are coarse fall-out ash deposits containing accretionary lapilli (N), fine fall-out ash deposits (P; Kozushima-Chichibuyama A (Suga et al., 1992)), AT, fine fall-out ash deposits containing pumices (S; Kozushima-Chichibuyama B (Suga et al., 1992)), pyroclastic surge deposits that squeezes phalanx of pumices with diameter several cm (T), fall-out ash deposits containing volcanic lapilli and pumices (V) and pyroclastic surge deposits (X) in descending orders. At Jinai-jima, as lower tephra layers, there are pyroclastic deposit containing many altered volcanic lapilli and blocks (Y) and pyroclastic surge deposit (Z) covering Jinai-jima lava.
Ito and Isobe (2007) suggested that eruption deposits from Mamashitaura Volcanoes were divided into upper Mamashitaura Volcano (cummingtonite rhyolite; ca. 20 ka) and lower Mamashitaura Volcano (biotite rhyolite; >ca. 35 ka) based on the difference of mineral compositions, paleo-soil layers and ^{14}C ages of charcoals contained therein. We recognized that upper Mamashitaura Volcano deposits composed of pyroclastic surge and pyroclastic cone deposits including rhyolite blocks and lapilli, that the lower layer contained more altered brown volcanic breccia (basalt?). On the other hand, lower Mamashitaura Volcanoes deposits composed of pyroclastic flow and pyroclastic surge deposits with a thickness of 20 m or more, and the debris flow containing many volcanic blocks covering them.
We collected data mineral compositions, refractive indexes and major chemical element compositions of glass shards for Daisan-yama and Jinai-jima tephras (T, V, X etc.) and Mamashitaura Volcano deposits. Tephra-T contains many minerals of hornblende and cummingtonite, and is characterized by refractive indexes (1.497-1.500), K_2O contents (3.0-3.3 wt.%) and CaO contents (0.7-1.0 wt %). These characteristics closely resemble features of some of upper Mamashitaura Volcano deposits. On the other hand, the lower tephras V and X are similar to lower Mamashitaura Volcano deposits in point of contain biotite in addition to hornblende and cummingtonite, but the refractive indexes and CaO contents of the volcanic glass shards are significantly different. This suggests that it is difficult to correlation them.
As a result of currently in progress, it is highly likely that T-tephra is eruption deposits from upper Mamashitaura Volcano, and it is appropriate to think that the age is 30,000 to several thousand years ago. On the other hand, we can’t recognize eruption deposits from the lower Mamashitaura Volcano at Daisan-yama and Jinai-jima.

Constration of pre-eruptive process using crystal clot: A case study of Unzen 1991-95 eruption

*Kurumi Iwahashi[1], ATSUSHI YASUDA[1]

1. Earthquake Research Institute,The University of Tokyo

1.Introduction

Magma mixing is thought to be the major eruption triggers of arc volcanoes. This process can control whether magmas will erupt or stall in the crust. However, magma mixing processes have not been revealed well. Therefore, it is important to reveal mixing process at magma reservoir.
For this purpose, we focus on Unzen 1991-95 eruption. This eruption is characterized by continuous growth of dacitic lava domes and pyroclastic flows caused by collapse of the lava domes. During the eruption, two vulcanian eruptions were recognized. Previous studies proposed that magma mixing between nearly aphyric, mafic and crystal-rich, silicic end-members occurred in the magma chamber (e.g., Sato et al., 1999). Because there are lots of geophysical and geological studies, this eruption is suitable for getting more detailed information about pre-eruptive processes.
Recent studies demonstrated that igneous amphiboles are powerful tools to constrain pre-eruptive magmatic conditions (e.g., Ridolfi and Renzulli, 2012; Putirka, 2016). For example, empirical equations relating temperature and SiO_2 content of co-existing melt with amphibole composition were proposed by Putirka (2016). By using these equations, we can constrain physicochemical conditions of melts in which individual phenocryst crystallized.
Our previous results suggest that the 1991-95 magma was formed by three-component mixing, in which contribution of the newly-recognized 3rd endmember magma (MT magma) (Iwahashi et al., JpGU2018). Products of 1991-95 eruption often contain crystal clots. They consist of amphibole, plagioclase and Fe-Ti oxides. Because magma reservoir of Unzen volcano is thought to be mushy (e.g., Nakamnura et al., 1995), crystal clots are possible to be part of mushy magma reservoir. Therefore, in this study, we expect to get more detailed information about pre-eruptive process of 1991-95 eruption using crystal clots in addition to amphibole phenocrysts.

2.Methods

We used 11 dacitic samples erupted at different times during the 1991-95 eruption. All of these samples contain crystal clots. They are composed of amphiboles, plagioclases, Fe-Ti oxides and interstitial glass. The major element compositions of amphibole phenocrysts and constituent minerals and glasses in crystal clots were measured by using EPMA at ERI, University of Tokyo.

3.Results

Amphiboles in crystal clots are classified into four types; Type A, Type B, Type C, Type D. Amphibooles of Type A has zonal structure, Type B has reaction rim, Type C has both zonal structure and reaction rim and Type D is almost homogenous. These amphiboles are classified magnesiohornblende and tchermakite based on their compositions. There is an apparent compositional gap between these two clusters. Crystallization temperatures are estimated to be ~750-800ºC and ~850-950ºC for magnesiohornblendes and tchermakites, respectively. Amphiboles in crystal clots reveal temperatures of ~750-800ºC. Estimated SiO_2 contents of melts coexisted with amphiboles (SiO_2^{melt}) are ~66-73wt.% and ~60-67wt.% for magnesiohornblendes and tchermakites, respectively. On the other hand, SiO_2 contents of interstitial melts are ~68-72wt.%. Almost all plagioclases in crystal clots have oscillatory zoned texture. An content (=100*Ca/Ca+Na) of these rim are 60-75.

©2019. Japan Geoscience Union. All Right Reserved.

4.Discussion

H_2O saturation depth estimated for the interstitial melt compositions are consistent with that of main magma chamber in which the silicic endmember magma was thought to be stored.
On the other hand, zonal texture of amphibole often cut by other crystals and this implies that MT magma reservoir may present before 1991-95 eruption. In addition, comparison of temperatures estimated by amphiboles with phase diagram by Noguchi et al.(2008) indicate that there may be almost no plagioclases in MT magma reservoir.
In addition to these results below, we plan to present some new picture of pre-eruptive process at 1991-95 eruption and MT magma reservoir.

Keywords: pre-eruptive process, crystal clot, amphibole

Petrological study of Pinatubo 1991 eruption ~ Discussions of magma plumbing model~

*Tomohisa Tamura[1,2], Mitsuhiro Nakagawa[2]

1. West Japan Engineering Consultants, Inc., 2. Earth and Planetary System Science, Hokkaido University

Introduction

Pinatubo volcano which locates at Northern Luzon island, Philippines caused cataclysmic eruption on June 15, 1991. This eruption includes the four main eruptive products, dome lava andesite on June 7 (J7-LD), basaltic mafic enclave in J7-LD (J7-ME), andesitic scoria from first Plinian eruption on June 12 (J12-P) and dacite pumice from climactic Plinian eruption on June 15 (J15-C). J15-C is separated into two types which constitute gray, precise and phenocryst-poor pumice (J15-CP) and white, bubbly and phenocryst-rich pumice (J15-CR). There are many petrological studies of Pinatubo volcano 1991 eruption, and magma plumbing model of this eruption is established by Pallister*et al.* (1996). Their model indicates magma mixing that andesitic magma is generated by mixing between felsic magma and mafic magma in magma reservoir. However, we carry out whole rock and mineral compositions of 1991 products in detail, and obtain the new findings of magma plumbing model of 1991 eruption.

Analytical methods

We made many thin sections and observed them under polarizing microscope, and counted the modal compositions of phenocrysts.Whole rock and mineral compositions were determined by X-ray fluorescence (XRF) and Scanning electron microscope / Wavelength dispersive X-ray spectroscopy (SEM-WDS) at Hokkaido University, respectively.

Results and Discussions

1991 products mainly include plagioclase and amphibole phenocrysts, and there is a few olivine, clinopyroxene, biotite, quartz and opaque minerals. For Harker diagram of major elements, all products stand in a straight line and it means magma mixing trend. J15-C composition, however, has compositional variation and another trend which crosses the mixing trend. J7-LD and J12-P also have slightly crossed compositional variation. This crossed trend and compositional variation are clearly confirmed in K_2O and Rb contents. The contents of amphibole and biotite which include many potassium do not relate the compositional variation. Therefore, felsic magma of Pinatubo volcano has had the compositional heterogeneous before mafic magma injected into felsic magma reservoir.

Plagioclase and amphibole cores have wide compositional range. According to calculating the equilibrium melt compositions from plagioclase and amphibole cores, we estimate the two felsic endmember that are less-evolved melt, D1 and more-evolved melt, D2. Their melt compositions correspond with glass compositions hosted in melt inclusions of plagioclase and amphibole crystals. Above discussion indicates that felsic magma has the heterogenous, and we estimate that the heterogeneous felsic magma was generated by mixing between D1 and D2.

For minerals of 1991 products, normal and reversal zonings coexist and are repeated from line profile analyses. The melt composition and temperature of magma were heterogeneous and convection occurred in magma reservoir because the composition of plagioclase depends on the melt composition and temperature of magma.

Conclusions

The compositional variation of dacitic magma is consistent with one of minerals, plagioclase and amphibole, for example. The felsic magma has compositional heterogeneous before mafic magma injection, and two different compositional endmember magma coexist (D1 and D2). The continuous compositions of felsic magma were generated between D1 and D2 because of the convection in magma

©2019. Japan Geoscience Union. All Right Reserved.

reservoir. Before 1991 eruption, mafic magma injected into the heterogeneous felsic magma and mixed together, so that andesitic magma which has slightly compositional variation was generated.

Rediscovery of the Higuruma Debris Avalanche Deposit in Asama-Kurofu Volcano

*Maya Yasui[1], Masaki Takahashi[1], Tatsuo Kanamaru[1]

1. College of Humanities and Sciences, Nihon University

Asama-Kurofu volcano experienced a large-scale sector collapse in its later stage indicated by a horse-shoe shaped caldera and debris avalanche deposit in the distal flank. The area immediately east of the collapsed caldera is occupied by younger volcanic edifices of Hotokeiwa and Maekake. The medial area that is a flank slope of the former Kurofu is thickly covered with the younger deposits from Hotokeiwa and Maekake. Therefore, few information was available for the distribution and thickness of the debris avalanche deposit. Hummocky topography develops on the eastern area of Maekake and Hotokeiwa volcanoes. Geological survey especially in the valley bottom in the hummocky area in the Gunma Prefecture Asama Dairy Farm, the Nagakurayama National Forest, and its vicinity was carried out in this study. Outcrops of the deposits those occurrences were typical of debris avalanche were occasionally found in the valley bottom. In addition, 50-meter deep borehole core sample was taken on the ENE flank slope of Maekake volcano. This is a part of the “integrated program for next generation volcano research and human resource development” supported by ministry of education, culture, sports, science and technology, Japan. Thick debris avalanche deposit of 27 meters was recognized in the lower half of the borehole core sample. That is, weakly stratified and partly solidified tuff breccia that is characterized by heterogeneous matrix and occasional mega-blocks is observed. Whole-rock chemical analyses of the blocks from these deposits show that they are the same as those of the Asama-Kurofu and Asama-Sennin volcanoes. The distribution of “Higuruma debris avalanche” was shown on Yagi (1936) ‘s geologic map but few descriptions were made about it. The deposit confirmed in this study corresponds to the Higuruma debris avalanche and the description including thickness will be a clue for understanding the scale of the sector collapse.

Hydrothermal system of Tokachidake volcano, Japan: Examination from multi-disciplinary surveys

*Ryo Takahashi[1], Noritoshi Okazaki[1], Makoto Tamura[1]

1. Geological Survey of Hokkaido, Hokkaido Research Organization

Tokachidake volcano, located in central Hokkaido, Japan, has had intermittent magmatic eruptions during the 20th century. Recently, increases in seismic activity, ground inflation around the active craters and chemical changes of thermal waters are observed, and hence, a magmatic eruption in the near future is of concern. The 1926 eruption induced a large-scale lahar (Taisho lahar). Uesawa (2014) proposed that large amounts of thermal water were released as a hydrothermal surge from the interior of the volcanic edifice, expanding the scale of the Taisho lahar. In addition, chemical and thermal changes related to volcanic activity were observed in thermal waters around the volcano (Takahashi et al., 2015). These phenomena are deeply related to hydrothermal systems. Therefore, to detect precursor activities precisely at Tokachidake volcano, we should understand the subvolcanic hydrothermal systems. In this study, we performed multi-disciplinary surveys, such as magnetotelluric (MT) survey, geological investigations and thermal water and fumarolic gas observations, to examine the subvolcanic hydrothermal systems.

We performed MT survey at 13 stations along an NW-SE survey line across the volcano, and detected several conductive zones in the edifice. A conductive zone was detected at more than 3–4 km depth beneath the summit crater area (deep conductive zone). Volcanic earthquakes did not occur in this conductive zone, but their hypocenters were distributed surrounding the zone. This would indicate that the outer margin of the conductive zone is coincident with the brittle-ductile transition zone. Another conductive zone is distributed at 300–1,500 m depth beneath the summit crater area (shallow conductive zone).

In order to discuss the shallow hydrothermal system, we investigated phreatic ejecta, the 1926 debris avalanche deposits and accessory ejecta, all of which record subsurface hydrothermal environments. As a result, we revealed that an alteration zone with a pyrophyllite+quartz assemblage occurs at depths of >500 m beneath the crater area (Takahashi & Yahata, 2018). This zone reflects a high-temperature environment (200–300 ˚C). Also, fumarolic gas observations suggest that high-temperature (200–300 ˚C) hydrothermal systems exist the shallow subsurface. We can consider that the shallow hydrothermal system inferred from these investigations is coincident with the shallow conductive zone detected by MT survey.

We have observed the thermal waters around Tokachidake volcano over a period of more than three decades. At Fukiage spa area, thermal waters caused chemical and thermal changes by the supply of the magmatic NaCl-type thermal water associated with the increase in volcanic activity (Takahashi et al., 2015). A distribution area of the NaCl-type thermal water around magma would be detected as a conductive zone because thermal waters with high temperature and high NaCl concentration show high conductivity. Thus, we can consider that the deep conductive zone is interpreted as a distribution area of the NaCl-type thermal water.
In consequence of multi-disciplinary surveys at Tokachidake volcano, we revealed the subvolcanic hydrothermal systems. We should continue careful observations and revise the model to understand more precisely the volcanic activity of the volcano.

Fumarole and hot spring activities after the 2015 eruption of Hakone Volcano and their relationships with the seismicity and crustal deformation

*Kazutaka Mannen[1], Masatake Harada[1], Yohei Yukutake[1], George Kikugawa[1]

1. Hot Springs Research Institute of Kanagawa Prefecture

A very small phreatic eruption occurred at Hakone volcano in 2015. Before the eruption, in Owakudani, where the eruption center formed, there has been no significant fumarole activity; however, more than 20 craters and fumaroles formed associated with the eruption and they still remain active. We have routinely measured the steam temperatures emitted from the fumaroles and analyzed chemical composition of hot spring and surface waters every two weeks since we were permitted to enter the eruption center. In this presentation, we show the temporal changes and its relationship with the seismic activity and crustal deformation.

1. Steam temperature of fumaroles
Among the more than 20 fumaroles, we have measured 10 fumaroles that are significant and accessible (Mannen et al., 2019). We have only two stable fumaroles named 15-12 (since May 1, 2017) and 16-1 (since January 11, 2018) for routine measurement.

The temperature of 15-12 was higher than 150 ºC before August 2017. However, the temperature lowered gradually up to 120 ºC until the late 2018. The temperature of 16-1 was approximately 140 ºC when we started measurement. However, the steam temperature also lowered gradually and marked 130 ºC in the late 2018.

On the other hand, fumaroles named 15-1 and 15-14B continuously emit high temperature steams and higher than 150 ºC even in the late 2018 without significant decline although steam vents of these fumaroles are unstable and migrate frequently. We suppose that the steam temperature and emission are on decline since detection of high temperature steam is getting difficult and extinction of fumarolic activity is common recently. The highest temperature ever recorded was 162.0 ºC from 15-1 observed on August 23, 2017.

2. Chemical composition of hot springs and surface waters
In Owakudani area, we routinely correct and analyze waters from 13 sources including natural springs, stream water and artificial hot springs, which is made by mixing of steam emitted from steam well and water (Kikugawa et al., 2019). The stream water, watershed of which includes the eruption center, shows high Cl content associated with the 2015 volcanic unrest ($Cl/SO_4 > 1.0$; Mannen et al. 2018). The Cl concentration lowered to the background level ($Cl/SO_4 \sim 0.2$) until early 2017; however, increased slightly from November 2017 to January 2018 ($Cl/SO_4 \sim 0.3$). The artificial hot springs from No. 52 steam well also showed significant rise of electric conductivity and Cl content and decline of pH.

Our measurement of volcanic gas from underfloor of a building in Owakudani shows continuous decline of CO_2/H_2S ratio after the eruption. The decline rate seemed to lower in 2017; however, it was not clear. On the other hand, Daita et al. (2018) reported that CO_2/H_2S ratio of volcanic gas from Kamiyu, north of Owakudani showed rise from around June 2017.

3. Seismicity and crustal deformation in 2017
In Hakone volcano, earthquake swarm, deep low frequency earthquakes and increase of baseline length across the volcano have observed before increase of geothermal activity (Harada et al. 2018; Mannen et al. 2018). After the 2015 eruption, there has been no earthquake swarm; however, there were slight increase of seismicity from the late April to the early May in 2017 beneath Mt. Kintoki (Yukutake et al. 2018). Before the earthquake swarm, in the mid-April, deep low frequency earthquakes (DLF) was found active by matched filter method (Yukutake, 2017). The baseline length across Hakone volcano started to increase from the early May in 2017 and ended in the late November of the year with total stretch of 12 mm (the total stretch during the 2015 eruption and unrest was 21 mm). In the period, there is no significant change in steam temperature. Increase of hydrothermal activity was implied by the changes in chemical compositions of artificial hot spring water and surface water in the late April and in November respectively.

The observed trend of the weak change in 2017 are similar to that of the volcanic unrests in 2013 and 2015. We thus suppose that there was a small increase of volcanic activity in 2017. Comparing to the changes in 2013 and 2015, seismicity and stretch rate of the baseline in 2017 are notably lower. Daita et al (2018) also pointed out that the increase in CO2/H2S ratio in 2017 was significantly lower than that observed in 2013 and 2015. Such differences observed in 2017 may imply that the magma-hydrothermal system of Hakone volcano has altered by the 2015 eruption (Daita et al, 2018).

A possible geothermal source at around 4 km depth estimated by the seismic observation in Ibusuki geothermal area

*Junzo Kasahara[1,3], Yoko Hasada[2,1], Hiroyasu Kuzume[1]

1. ENAA, 2. Daiwa Exploration and Consulting Co., 3. Shizuoka Univ.

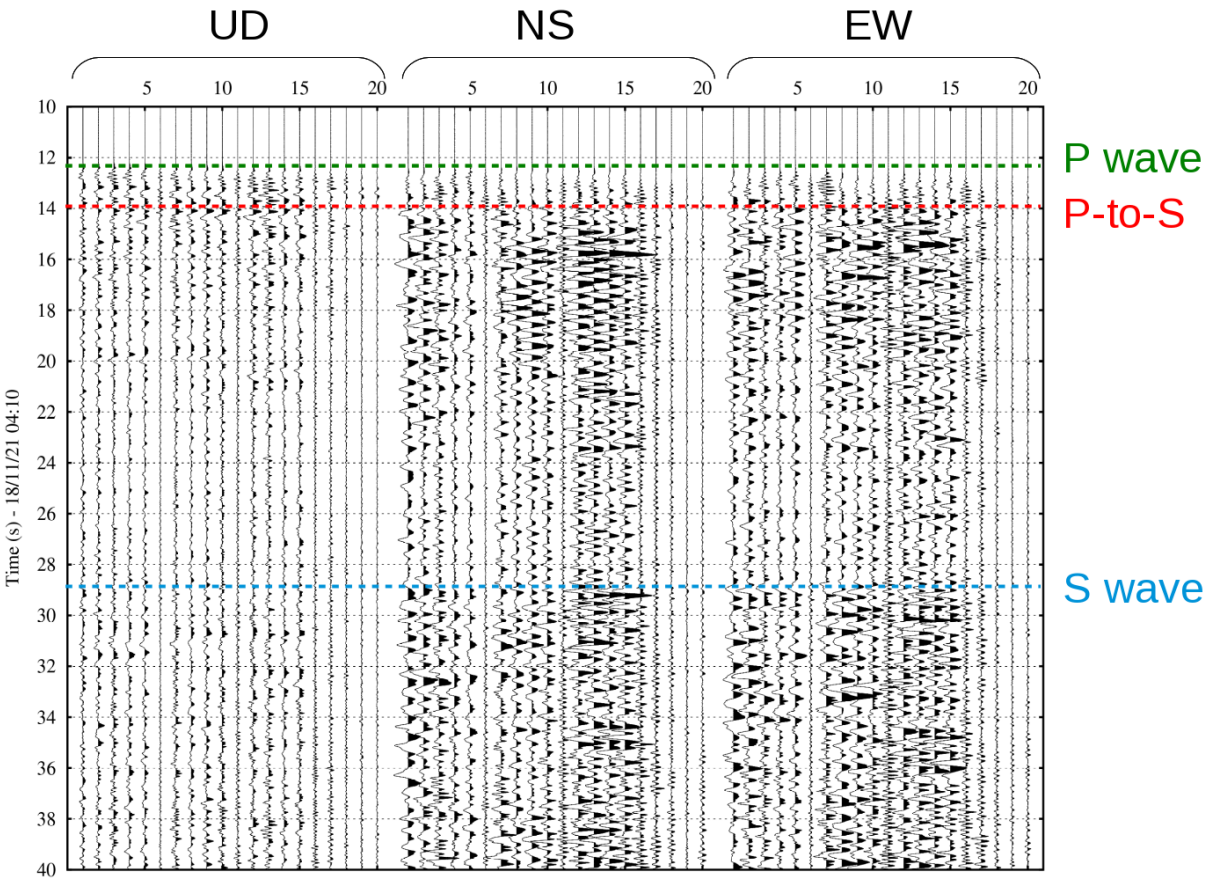
Introduction: The Medipolis is located in Ibusuki geothermal area, Japan. There are three geothermal boreholes in the field. The geothermal characteristics of the boreholes were studied by NEDO (2008-2010). The IK-1 borehole is commercially used for the electric power generation. The IK-4 is used for observation. The depths of three boreholes are around 1,500 m. The temperature of the boreholes was approximately 250˚C around the 900 m-depth and the production depth for the steam is around 1,200 m. The temperature model by NEDO (2008-2010) proposes a hot reservoir around the NE direction of IK-1 and IK-4 boreholes although it is not confirmed by real drillings.

To know the precise geothermal characteristics of this field, we conducted a seismic observation by a fiber-optic distributed acoustic sensor (DAS) and ground surface seismometers in November 2018.

Field observation: We installed 20 sets of 3C seismometers along the 2 km-long EW line and deployed a fiber-optic cable for the DAS and distributed temperature (DTS) measurements down to 977 m depth. We measured the temperature and seismic signals using the same fiber-optic cable for DAS and DTS. The total DAS observation period is 4.5 days. The interval of ground surface seismometers is approximately 100 m. We observed seven natural earthquakes by DAS and surface seismometers. The largest observed earthquake is M5.2 which occurred west of Tanegashima with 123 km focal depth. The temperature of the IK-4 was measured as 264˚C by DTS at the 914 m depth.

Observed waveforms: The first arrivals of the M5.2 earthquake measured by DAS are traveling from the 977 m depth to the wellhead with the velocity of 4 km/s~3 km/s. There are no evident reflections from the deeper zone than 1,000 m. In addition, any evident attenuation of seismic waves is not identified in the high temperature zone around the 914 m-depth.

Surface seismometers show unusual waveform characteristics. Although the amplitudes of the P-wave first arrivals of M5.2 earthquake on vertical seismometers are small, the EW and the NS seismometers show small P first arrivals and succeeding large amplitude phase with a second delay. Because this phase is recognized only on EW and NS components, this phase is possibly P-to-S converted phase. The aftershocks of the M5.2 Tanegashima also showed similar waveforms as those of the M5.2 event. Other earthquakes also showed similar characteristics on the horizontal components.



Interpretation of P-to-S converted phase: We examined the cause of estimated P-to-S conversion. The delay time from the P first arrival to the P-to-S converted phase is estimated as ~0.8 s. We assumed a low Vp/Vs zone at the 4 km-depth with 500 m thick and calculated synthetic waveforms generated by deep seismic sources corresponding to natural earthquakes. The seismic velocity profile estimated by the DAS observation is used in the calculation. The models can explain the observed characteristics such as small P amplitude and large P-to-S converted phase on horizontal components, when incident seismic wave is slightly oblique to the low Vp/Vs zone. We also estimated borehole waveforms and ground surface waveforms.

©2019. Japan Geoscience Union. All Right Reserved.

Discussion and conclusions: According to the simulation, there is a chance to prove the presence of the low Vs zone at the 4 km-depth. Because the temperature around ~900 m is 264˚C, the low Vs zone might be useful for a future geothermal energy source. For either case, more detailed study of the proposed low Vs zone is required.

Acknowledgements: This study is supported by the New Energy and Industrial Technology Development Organization (NEDO). Medipolis Energy Co. kindly allowed the use of their IK-4 geothermal well for this study. Mr. Kimura provided us with the Schlumberger hDVS measurements. WELMA Co. provided us with the borehole fiber-optic system and measurement of temperatures in the borehole. The staff of West Japan Engineering Consultants, Inc., helped us during the field study.

Time variation in the chemical and isotopic composition of fumarolic gases at Kusatsu-Shirane volcano Japan

*Takeshi Ohba[1], Muga Yaguchi[2], Nozomi Numanami[1], Kotaro Toyama[3], Hirochika Sumino[3], Urumu Tsunogai[4], Masanori Ito[4], Ryo Shingubara[4]

1. Department of chemistry, School of Science, Tokia University, 2. Meteorological Research Institute, JMA, 3. The University of Tokyo Graduate School of Arts and Sciences Department of Basic Science, 4. Nagoya University Graduate School of Environmental Studies

At Kusatsu-Shirane volcano Japan, the intense seismic activity took place in 2014 and 2018. To investigate the relationship between the activity and the chemistry of fumarolic gas, the gas samples have been repeatedly analyzed. A monotonic decrease in CO2/H2O, He/H2O and N2/H2O ratios since July 2014 to November 2017 suggests the decline of magmatic component. On contrary CH4/H2O ratio significantly increased during the seismically quiet period, suggesting the reduced condition in hydrothermal system favoring to the formation of CH4. The high N2/He ratio in the quiet period suggests the addition of component originating in crustal rock hosting hydrothermal system. The N2/He ratio in 2018 was definitely lower than the ratio in 2014, indicating the evolution of magma brought by the degassing. The δD(H2O), δ18O(H2O) and CO2/H2O ratio of fumarolic gas were modeled with the following processes; the generation of vapor phase after the mixing between magmatic gas and a cold groundwater with meteoric origin, the addition of vapor phase with meteoric origin, and the partial condensation of water vapor near surface. Only a single magmatic gas is necessary for the above modeling.

Behavior of Arsenic and Mercury related to hydrothermal activities in Kirishima, Satsuma Iwojima, and Yamagawa, Kyushu Japan

*Motoya Habuchi[1], Harue Masuda[1], Tsuyoshi Shintani[1], Shuzo Furuya[1], Keigo Mori[1], Jun-ichiro Ishibashi[2], Takeshi Matsushima[2], Akinori Takeuchi[3], Syogo Oshima[4], Reo Ikawa[5]

1. Osaka City University, 2. Kyushu University, 3. National Institute for Environmental Studies, 4. West Japan Engineering Consultants, Inc., 5. National Institute of Advanced Industrial Science and Technology

Arsenic and mercury behave in similar manners during migration from the deep to the surface of the Earth with magmatic and associating hydrothermal activities. In this study, we sampled total 57 hydrothermal and local meteoric waters from Kirishima, Satsuma-Iwojima and Yamagawa in November 2017 to December 2018 to trace the migration processes of arsenic and mercury related to the volcanic and its associating hydrothermal activities. We analyzed concentrations of major components, arsenic and mercury and hydrogen and oxygen isotope ratios.
The highest temperature of hydrothermal water, which was taken from the craters phreatically exploded in the April 2018, was 94.5 ˚C and the pH was 0.8-1.7. The maximum concentrations of chloride ion and sulfate ion were 300 mM and 190 mM, and the positively linear relationship between these two components indicated the simple mixing of acidic hydrothermal fluid and local meteoric water. In many high temperature hydrothermal waters, $\delta^{2}H$ and $\delta^{18}O$ were in the range of magmatic water, -25 to -5‰ and +4 to +9 ‰. Total arsenic concentration in the hydrothermal waters was 1210-4640 μg/l, which had a positively linear relationship with sulfate ion concentration. Dissolved and suspended total mercury concentrations in hydrothermal waters were 0.5-85 ng/l and 0.5-826 ng/l, respectively. Since highly mercury concentrated hydrothermal water also contained high arsenic, these were derived from the same magmatic fluid. Chloride and sulfate ion concentrations of hot spring waters derived from fumarole in Kirishima and Kurinodake were < 0.2 mM and 26 mM at the maximum. Total arsenic concentration was 0.58-24 μg/l, and total suspended mercury concentration was 1980 ng/l at the maximum. Hot spring waters in Satsuma Iwojima and Yamakawa,contained high total arsenic concentration when the seawater directly infiltrated and the highest concentration was 2500 μg/l for the one of hot spring water in Satsuma Iwojima. In these areas, the highest total dissolved mercury concentration was 177 ng/l for a hot spring water with pH of 1.4 in Satuma Iwojima. Both arsenic and mercury are rising up from the deep with magmatic fluid. However, the two elements may behave differently along the migration path; mercury moves preferentially with vapor and removed from the water during flowing path on the surface, while arsenic preferentially behaves with hydrothermal water and remains as a dissolved phase in the surface water.

The chemical composition of thermal waters from spring and hot pool at Mt. Iwoyama of Kirishima volcano

*Muga Yaguchi[1], Takeshi Ohba[2], Kotaro Toyama[3], Fukuoka Regional Headquarters JMA[4], Kagoshima Meteorological Office JMA[4]

1. Meteorological Research Institute, 2. Tokai University, 3. Graduate School of the University of Tokyo, 4. Japan Meteorological Agency

Mt. Iwoyama of Kirishima volcanic complex is an active volcano where fumarolic activity restarted in December 2015 at summit crater. After the restart of the fumaroles, volcanic activities at the surface, such as the expansion of fumarolic area, the appearance of thermal springs and water quality changes in springs around Mt Iwoyama have been observed. In April 2018, small phreatic eruptions occurred at the south of the summit and west flank of Mt. Iwoyama, and boiling hot pools have appeared in some of the newly created craters after the eruptions. In this study, the chemical composition of water samples collected from a natural spring site on the west flank of Mt. Iwoyama and hot pools in the newly created craters have been analyzed to obtain information for evaluation of volcanic activity at this mountain.

Between August 2016 to March 2018 (about a month before the eruption), the Cl/SO_4 of the spring water increased from 0.07 to 0.9. About a month after the eruption, the ratio increased to 1.6 as of May 2018, and remain between 1.2 and 1.6 since then to January 2019.

Cl/SO_4 molar ratio of hot water pool in one of the southern craters was 1.3 in May 2018 and 1.8-2.3 in January 2019. The ratio of hot water pool in the western crater was 1.3 in July 2018, 1.9 in October 2018 and 2.2 in January 2019. The increase of Cl/SO_4 molar ratio may be caused by several reasons, for example, the ascent of volatile-rich magma or chemical composition change of volatiles along with the progress of degassing.

Re-examination of origin of the variety in magmatic-hydrothermal fluids

*Hiroshi Shinohara[1]

1. Geological Survey of Japan, AIST

A variety of magmatic-hydrothermal fluids, including volcanic gases, hot spring waters and geothermal waters, is created from a magma and we will re-evaluate those origins with particular interest on variation of Cl/S ratios. Giggenbach (1996) classified fluids in a magmatic-hydrothermal system as 1) Acid Cl-SO_4 water, 2) Neutral NaCl water, 3) Bicarbonate water and 4) Steam heated acid SO_4 waters. The acid Cl-SO_4 waters are formed by condensation of magmatic gases discharged from a magma. The neutral NaCl waters are formed from the acid water through neutralization and S-mineral deposition due to water-rock interaction at lowering temperature. The bicarbonate waters and acid SO_4 waters are formed by mixing of CO_2 or H_2S derived from vapor separation of a deep hydrothermal system with meteoric water or the neutral NaCl waters. The principal differentiation process is the neutralization and S-mineral deposition of the acid Cl-SO_4 water under a temperature gradient to create the neutral NaCl water. However, we also need to consider other factors than the temperature dependence.

Water-rock reactions also have pressure dependent. HCl content in hydrothermal fluids has a negative pressure dependence; a hydrothermal solution has a larger HCl content at a lower pressure than at a higher pressure (Shinohara and Fujimoto, 1996; Botcharnikov et al., 2015). The pressure dependence implies that hydrothermal fluids discharged from a magma at a high pressure tend to have less acid than volcanic gases discharge at the surface. The average Cl/S ratio of the Japanese volcanic gases is about 0.2 (Shinohara 2013), whereas the ratio is about 0.5 in melt inclusion of basaltic magmas and is about 10 in those of silicic magmas. Therefore, a hydrothermal fluid formed by a complete solidification of the magma will have Cl/S ratio much larger than those of volcanic gases or the acid Cl-SO_4 waters. These evidences suggest that the acid Cl-SO_4 waters and the neutral NaCl waters have distinct origins with different condition of a magma degassing. Compilation of chemical compositions of hot spring waters and hydrothermal waters in Japan show a clear two frequency peaks of acid and near neutral pH with a gap at pH 4-5 (Muraoka et al., 2007). This pH distribution also suggests that the distinct origin of the two types of the hydrothermal fluids.

Measuring the electrical resistivity of rocks is a powerful and reliable method used to investigate volcanic edifices at depth. The electrical resistivity has two main contributions: (i) the conduction in the bulk pore fluid, associated to saturation, the ionic strength, and temperature of pore water, and (ii) the surface conductivity, related to the formation of secondary minerals. In volcanic environments, these two contributions are controlled by numerous interactions between hydrology, geology, tectonic settings and magmatic forcing. As a consequence, the evaluation of electrical resistivity images is strongly non-unique, and its interpretation remains complex.

Here, we propose a new approach to address this issue. First, we performed a 3-D electrical resistivity imagery of the Miyake-jima volcano using Magnetotellurics. Next, we combined the resistivity model obtained with hypocenters distribution. We revealed the sharp boundary between the saturated and unsaturated region, and a large conductive hydrothermal system connected to the main fumarolic area through a fractured region. Finally, we created a multiphase flow model of the volcano that constrains the resistivity model in term of temperature, fluid content and alteration.

MT survey and 3-D resistivity structure in the Niseko area, southwestern Hokkaido

*Makoto Tamura[1], Toru Mogi[2], Junna Kanahiro[2], Daisuke Oka[1], Junya Maruyama[1], Takahiro Suzuki[1], Noritoshi Okazaki[1]

1. Geological Survey of Hokkaido, Hokkaido Research Organization, 2. Division of Sustainable Resource Engineering, Fucluty of Engineering, Hokkaido University

In the Niseko area, southwestern Hokkaido, there are many volcanoes distributed along East-West direction that is so called “Niseko volcanic group”. And many hot springs are distributed around Iwaonupuri and Niseko-Annupuri volcano. Recently, geothermal explorations for energy development have been performed in this area.
During such situation, we are carrying out the priority research “Modelling of geothermal structure and assessment of geothermal resource potentials in the Niseko area” for sustainable application of geothermal resources. In this presentation, we show the MT survey and the 3-D resistivity structure analysis result as a part of this research.
We performed wideband MT survey at 18 stations in 2017 and 24 stations in 2018 around the Niseko area. Five components of electromagnetic fields were measured by ADU-07e and ADU-08e (manufactured by Metronix Geophisics). We obtained 32Hz data that was recorded for more than 5 days, 1024Hz data that was recorded more than 5 nights (1:00-5:00 : LT) and 32kHz data that was recorded one hour. Horizontal components of magnetic field data recorded at Ookura Vil., Yamagata Pref. were used for the remote reference processing of 32Hz and 1024Hz data. For 32kHz sampled data, we measured data at the same time in multiple stations for the remote reference processing. Also, we performed noise elimination processing for 50Hz electrical power lines.
MT responses at the frequency band of 12288-0.000488Hz were estimated using the robust time series processing code BIRRP (Chave and Thomson, 2004). Furthermore, we tried to obtain a 3-D resistivity structure with the aid of the ModEM inversion scheme (Egbert and Kelbert, 2012). Topographic effects might strongly affect the MT impedances because the survey area is located from the top to the foot of the volcano. In order to consider the topography into the 3D inversion, we used inland DEM data of 10m spacing provided by Geospatial Information Authority of Japan, and the seabed data of 500m spacing provided by Japan Coast Guard. Three-dimensional inversion was performed using four components of the tensor impedance from the field records.
In the results, we detected several conductive zones. A conductive zone was detected from the surface to several kilometers depth beneath the Iwaonupuri volcano. This would indicate volcanic hydrothermal system or hydrothermal rock alteration area. Also, we detected conductive zones around Ooyunuma Pond that is a hot spring bog, and southern foot of the Niseko-Annupuri volcano area where many hot springs are distributed. These conductive zones would indicate thermal water aquifers or related altered area.

Acknowledgement
The MT equipments (ADU-07) were used by Joint Usage Program in Earthquake Research Institute, University of Tokyo. Also, we used Magnetic field data of Geothermal Energy Research & Development CO., Ltd., for remote reference processing. We would like to thank these institutions.

Hydrothermal fluid activity of the Tatun Volcano Group, Taiwan, revealed by self-potentials and seismicity

*Hong-Jia Chen[1], Zhi-Xian Yang[1], Chien-Chih Chen[1,2], Cheng-Horng Lin[3,4]

1. Department of Earth Sciences, National Central University, Taiwan., 2. Earthquake-Disaster & Risk Evaluation and Management, National Central University, Taoyuan, Taiwan., 3. Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan., 4. Taiwan Volcano Observatory at Tatun, Taipei, Taiwan.

The objective of our research was to unravel the evolutions of the hydrothermal activities in the Tatun Volcano Group, Taiwan. We observed the significant variations of monthly earthquake counts, daily cumulative earthquake counts, and self-potential power spectral densities (PSDs) after April 21, 2016, providing strong evidence to identify hydrothermal fluid activities. This was further confirmed by the simulated electrical impedances using the resistivity forward modeling. Thus, an upward hydrothermal fluid movement is required to generate weaker PSDs of self-potentials at different frequencies. Herein, we concluded that geoelectric monitoring, along with seismic monitoring, help to understand the evolution of a hydrothermal system beneath a volcanic region.

Utilizing the electrical conductivity distribution to unravel the hydrothermal system beneath Mt.Hasan composite volcano and its vicinity, southwest Cappodocia, Turkey

*Sabri Bulent Tank[1], Mustafa Karas[1]

1. Bogazici University

The electrical conductivity structure in the vicinity of Mt.Hasan composite volcano at Central Anatolia, Turkey was imaged by means of wide-band magnetotellurics data collected at 38 sounding locations and three-dimensional numerical modeling. The primary aim in this study was to decipher the major elements that drive a hydrothermal system beneath study area in detail. Therefore, following the dimensionality analyses performed by plotting induction arrows and phase tensor ellipses, the electromagnetic impedance data were numerically modeled in the data-space for imaging (i) the shallow and (ii) the deep electric structure with different frequency tables. While the former approach, provided information on the the thickness of a surficial (surface-to-2 km) and widespread welded ignimbrite layer, the latter approach, revealed the geometry of the deeper two layers beneath the ignimbrites that make up the clay cap. These layers that are found on the top of one another are interpreted as smectite (<10 Ohmm) and smectite-illite mixed (<10-15 Ohmm) layers. And finally beneath the smectite and smectite-illite layers, there is a cone-shaped anomaly (10 –60 Ohmm) that may have been serving as a reservoir for different vents in the area.

Three-dimensional Magnetotelluric Inversion to map geothermal structures in Eburru Geothermal field, Kenya.

*JUSTUS MAITHYA[1], Yasuhiro FUJIMITSU[2]

1. Graduate School of Engineering, Department of Earth Resources Engineering, Kyushu University, 2. Faculty of Engineering, Department of Earth Resources Engineering, Kyushu University

To explore the geothermal system in Eburru geothermal field in an attempt to delineate possible heat sources and fluid flow pathways governing the system, 107 Magnetotelluric (MT) soundings were deployed in the field. The MT data was analyzed using phase tensor to determine the dimensionality of the subsurface resistivity structure. These data were inverted to a fully three-dimensional resistivity model. Overall, the inverted resistivity model fits the MT data very well as evidenced by the data misfit curves. Consequently, 2-D inversion were carried out and a joint interpretation was made on the basis of the two models. The preferred 3-D model images a resistive top layer overlying a very conductive layer (~ 10 ohm.m) interpreted as the hydrothermally altered clay cap of the system and a moderate resistivity layer (about 30 ohm.m). These layers are underlain by a higher resistivity zone (~ 100 ohm.m). To characterize the resistivity structure in the field, resistivity profiles were extracted from the 3-D model in order to cut across the known geological structures. The profiles analysed show a deep reaching conductive channel connecting two conductors located at ~ 1 km from the surface and at a depth of ~ 4 km. This channel can be interpreted as potential path way used by geothermal fluid to migrate to the surface and manifests as fumaroles and hot spring. The occurrence of fumaroles along faults suggests leakage of steam where the cap is likely to have been cut by the faults. The resultant 3-D resistivity models are generally similar to the two-dimensional (2-D) inversion models, however, the deeper portion of the 3-D model seems to be more realistic than that of the 2-D model.

[S-TT45] Synthetic Aperture Radar

convener:Youhei Kinoshita(University of Tsukuba), Yu Morishita(Geospatial Information Authority of Japan), Shoko Kobayashi(Tamagawa University), Takahiro Abe(Earth Observation Research Center, Japan Aerospace Exploration Agency), Chairperson:Shoko Kobayashi(Tamagawa University), Kazuya Ishitsuka(Kyoto University)

ALOS-2 and Sentinel-1A and 1B, which have highly enhanced capacity compared to previous SAR satellites, were launched in 2014, and their utilization has been widely expanding as the data has accumulated for approximately four years. Other long-operating SAR satellites like TerraSAR-X and Cosmo-SkyMed also contribute to expanding the SAR utilization. Now we are facing a new and abundant era of the satellite SAR, along with a worldwide trend to an open and free data policy of satellite data, with next-generation advanced SAR satellite plans by several countries, and with several plans to construct SAR constellations by private sectors. In addition, SAR technologies with other platforms, such as ground-based SAR with high temporal resolution and UAV (Unmanned Aerial Vehicle) SAR with flexible operability, have also been developed and used for various targets. These facts indicate that the SAR utilization has become widespread in both basic researches (e.g., earth science) and diverse applications (e.g., disaster prevention and forest monitoring). In this session, we would like to widely invite research and application results with regard to SAR, sharing our knowledge and having a discussion for the advancement of the SAR utilization.

1. TokyoDenki University

Synthetic Aperture Radar, SAR, is a sensor that irradiates radio waves (microwaves) and receives radio waves reflected and returned from the ground surface.

It is characterized that SAR can observe the target regardless of weather and day and night. Even when the plume is blowing hard, SAR signal can penetrate through the clouds and smokes and can observe the crater.

The Kilauea volcano to be investigated is one of the five shield volcanoes that made up the Island of Hawaii on Hawaii Island. It is an active volcano that is presumed to have formed about 600,000 years ago, and is presumed that it appeared on the sea surface about 100 thousand years ago and the eruption is still continuing, but the eruption of 2018 stopped the flow of the lava did. The Kilauea is known for its calm eruption, but since 1983 it continues to erupt almost continuously, depending on the direction of the lava flow, lava may swallow the settlement and destroy the settlement.

This research will detect the deformation of the volcanic mountain by using the interferometric SAR technique. INSAR uses two types of data with different times and finds variates from the differential distance between from the satellite to the target (phase difference).

Using this method, we measure the crustal deformation with accuracy of several mm to several cm by capturing the variation near the crater of Kilauea volcano which can not be investigated locally. We will quantitatively evaluate the crustal deformation around the crater using image data of two periods including the eruption occurrence period from October 9, 2014 to July 31, 2018.

As a result, the crater was subsided by 6.5 cm from November 25, 2014 to March 27, 2018 in the ascending orbit, and it was subsided by 9 cm during the period from October 9, 2014 to December 14, 2017 in descending orbit.

As a future task, since we observed fluctuations in the north direction other than vertical component fluctuations in the crater, we plan to conduct research including the relation with the ground characteristics of Hawaii Island.

ALOS-2 observation of the 2017 Sefidsang earthquake, northeastern Iran: a blind shallow-dipping thrust event near the Eastern Kopeh Dagh

*Nematollah Ghayournajarkar[1], Yo Fukushima[2]

1. Graduate School of Science, Tohoku University, 2. International Research Institute of Disaster Science, Tohoku University

The Iranian plateau is deformed between the converging Arabian and Eurasian plates. Their convergence is principally taken up by the active Makran subduction zone to the South, in addition to shortening and strike-slip faulting accommodated by crustal structures, which are non-uniformly distributed in several continental deformation domains such as the Zagros, Alborz and Kopeh Dagh mountain ranges. During the last decade, several studies carried out in the Zagros, Alborz and central Iran have produced a better understanding of active deformation in these zones. Conversely, such detailed studies are less common in northeast Iran.
Indeed, despite all the efforts made by previous workers to shed light on active tectonics in northeast Iran, this region still suffers from a lack of detailed structural and kinematics data and should be considered as a concealed segment in the geodynamic puzzle of the Arabia-Eurasia collision. This matter is made worse by the facts that northeast Iran is the second populated region and one of the most seismically active deformation domains in the country that has experienced at least nine large earthquakes (M >= 7) during the last six centuries (Tchalenko, 1975; Ambraseys and Melville, 1982; Berberian and Yeats, 1999, 2001).
On 5 April 2017, an Mw 6.1 earthquake occurred in the northeastern region of Iran, about 90 km southeast of the city of Mashhad, the second most populous city in Iran with a population of over 3 million people. The epicenter (35.776 N, 60.436 E, USGS) was at a remote mountainous area, about 30 km northeast of the Sefidsang district where approximately 5000 people live, and the depth was about 13 km. This earthquake raised an opportunity to study the deformation pattern in the SE of the Kopeh Dagh Mountains.
Space geodetic observations of ground deformation provide important data to investigate the seismogenic fault and the subsurface deformation mechanics. Here we used ALOS-2 synthetic aperture radar data to produce SAR interferograms using the GMTSAR software (Sandwell et al., 2010) to investigate coseismic and postseismic deformation associated with the 2017 Sefidsang earthquake. The ascending and descending interferograms were produced and both indicate thrust-dominated slip that is consistent with seismic data sets, with the maximum line-of-sight coseismic displacement of 9.9 and 13 cm, respectively. The obtained coseismic deformation maps have good consistency with Sentinel-1 interferograms that showed maximum line-of-sight displacement of 10.5 and 13.7 cm for ascending and descending interferograms, respectively (Xu et al., 2018).
We also used ascending SAR data acquired on 2017/06/24 to 2018/12/22 for evaluating the postseismic deformation caused by this earthquake. The produced interferogram does not show any displacement more than the noise level (~1 cm).

InSAR ground displacements and slip distribution associated with secondary fault slips of the 2016 Kumamoto earthquake

*Yo Fukushima[1], Daisuke Ishimura[2]

1. International Research Institute of Disaster Science, Tohoku University, 2. Department of Geology, Tokyo Metropolitan University

By using interferometric synthetic aperture radar (InSAR) and field reconnaissance surveys, activation of numerous secondary faults associated with the occurrence of the 2016 Kumamoto earthquake has been identified (e.g., Fujiwara et al., 2016, EPS). In this study, we investigated the characteristics of the displacements of secondary faults around the Miyaji district, Aso, within the Aso caldera, and further inverted for the slip distribution of the secondary faults.

In this study, we used RINC software (Ozawa et al., 2016, EPS) to produce three interferograms with different line-of-sight directions, and unwrapped with SNAPHU (Chen and Zebker, 2000). The unwrapped interferograms are “un-referenced”, and each of them contains an unknown offset. The offset values were estimated using the daily coordinates data (F3 solution) of the GEONET network provided by the Geospatial Information Authority of Japan, and are subtracted from the interferograms. Finally, displacements along three line-of-sight directions are decomposed into EW, NS, and UD components, and EW and NS components were further used to derive the horizontal displacements in N50E direction, parallel to the secondary faults in Miyaji. The main characteristics of the ground displacements are as follows. (1) Two strands of parallel displacement discontinuity traces, corresponding to the surface fault, are observed, with a separation of around 0.8 km. (2) The length of the northern and southern strands of traces are around 1.3 km and 2.3 km. (3) Each of the two strands of traces are composed of multiple en-echelon traces. (4) The fault displacements of the northern strand were up to 5 cm for both vertical (northern side downward) and right-lateral directions. (5) The fault displacements of the southern strand were up to 8cm for vertical (northern side downward) and 10cm for right-lateral directions.

Next, we simultaneously estimated the slip distribution and geometry of the two faults (Fukushima et al., 2013, 2018), after removing long wavelength displacements by polynomial fitting. As for the fault geometry, we assumed that the top of the faults reach the averaged location of the fault strands and we set the dip angles as model parameters. We conducted non-negative least squares inversion for the fault slip, prohibiting reverse and left-lateral faulting based on the observed ground displacements. Two types of inversions were made on the assumption of the rake angle; one is assuming a uniform rake angle for all the fault elements, and the other is solving for the vertical and left-lateral slips. The two types of inversions both succeeded in explaining the ground displacement data, so we adopted the result of the simpler model with uniform rake angle as our preferred model.

In our preferred model, two faults dip northward with the southern one having a lower angle (48 degrees) than the northern one (67 degrees), making two faults merge at a depth of approximately 1.3 km. The lower limit of the slip area on the southern fault coincided the merging depth of 1.3 km, and the maximum slip of 25 cm was obtained at a depth of approximately 0.7 km. The slip on the northern fault was limited to shallower than 0.4 km with smaller slips of up to 12 cm.

Surface displacements at the Kumamoto plain using persistent scatterer interferometry and comparison with groundwater levels

*Kazuya Ishitsuka[1], Takeshi Tsuji[2]

1. Kyoto Univ., 2. Kyushu Univ.

After the 2016 Kumamoto earthquake, change in groundwater levels has been observed at the Kumamoto plain, which is likely associated with the alteration of the aquifer system by the earthquake. Surface displacement can occur due to groundwater level changes at a confined aquifer because pore pressure changes lead to the deformation of its granular skeleton. Persistent scatterer interferometry (PSI) using a satellite imaging is a powerful method to estimate spatial and temporal pattern of surface displacements. In this study, we estimated surface displacement at the Kumamoto plain from May 2016 to June 2017 using PSI analysis of ALOS-2/PALSAR-2 images. Moreover, we compared the displacement pattern in the period after the earthquake with the displacement from Jan. 2007 to Jan. 2011 using ALOS/PALSAR images.

As a result of analysis, we estimated surface displacement with the magnitude of about 2-3 cm along the Futagawa and Hinagu fault systems. We interpreted that the displacements along the fault traces were due to the afterslip. On the other hand, we also found surface displacements apart from the fault traces. For example, surface uplift up to 4 cm/year was observed during about 1 year after the earthquake around the west flank of Aso volcano. The displacement began several months after the earthquake, and generally correlated with the areas of groundwater level increased. Since the displacement pattern was not observed in ALOS/PALSAR results, we speculated that the displacement was induced by the groundwater level changes by the earthquake. In addition, we estimated the skeletal storage coefficients from surface displacements and groundwater levels, and found that the coefficients differed by the earthquake at several locations, indicating the temporal alteration of permeability or compressibility of the aquifer. Our results demonstrate the effectiveness of the surface displacement monitoring combined with groundwater level data at the aquifer system.

Acknowledgements: The ALOS-2/PALSAR-2 level 1.1 data used in this study were provided by the PIXEL (PALSAR Interferometry Consortium to Study our Evolving Land Surface) group in cooperative research with the Earthquake Research Institute, University of Tokyo. The ALOS-2/PALSAR-2 data belongs to the Japan Aerospace Exploration Agency. The groundwater level data used in this study were measured by several public institutes, and the data were corrected by the working group in Japan Association of Groundwater Hydrology.

Forest fire detection in the low biomass dry forest with JICA-JAXA Forest Early Warning System in the Tropics (JJ-FAST).

*Manabu Watanabe[1], Christian Naohide koyama[1], Masato Hayashi[2], Izumi Nagatani[2], Takeo Tadono[2], Masanobu Shimada[1,2]

1. School of Science and Engineering, Tokyo denki university, 2. JAXA/EORC

JICA-JAXA Forest Early Warning System in the Tropics (JJ-FAST, [1]) is first and only one SAR-based deforestation detection system monitoring tropical forest globally. The JJ-FAST started from November 2016, and has a merit to operate not only in dry season, but also in rainy season. The current system uses change of gamma_0 for deforestation detection. Watanabe et al. [2] pointed out the JJ-FAST detected not only the deforestation sites, but also detected severely damaged forest fire sites occurred in a dense forest. In this paper, detectability of forest fire in the low biomass dry forest with JJ-FAST system were examined.

JJ-FAST detected 168 deforestation sites between Nov. 11 and Dec. 23, 2018 in South Africa. MODIS burned area product [3] obtained between Oct. 10 and Dec. 31, 2018 were overlapped and confirmed that the almost all the polygons detected by the JJ-FAST deforestation detection algorithm were overlapped with the burned area detected by MODIS. The forest fire area were also identified by Sentinel-2 data. BBC news [4] reported severe wildfire occurred in George, South Africa on Oct. 30, and the area was also coincident with the one detected by the JJ-FAST algorithm. The JJ-FAST algorithm also detected 82 deforestation sites in Mozambique between Aug. 13 and Nov. 5, 2018. These sites were also overlapped with the MODIS burned area. From these facts, we concluded that the current JJ-FAST deforestation detection algorithm could detected severely damaged forest fire area in the low biomass dry forest. It is known that forest fire in dense forest is detected by increase of radar backscattering in HH polarization [2]. This is explained that forest fire makes forest canopy dry and induces more double bounce scattering, implying the increase of backscattering in HH polarization. In the case of low biomass dry forest, forest fire makes forest canopy dry and induces lower volume scattering in a tree canopy layer, implying the decrease of backscattering in HV. The decrease of volume scattering also occurred in the dense forest. But higher density of burned trees left on the ground still induces brighter radar reflection in HV and make it difficult to detects the forest fire sites in HV polarization.

Nominal operation results of Japanese ALOS-2

*Shinichi Sobue[1]

1. Japan Aerospace Exploration Agency

The Advanced Land Observing Satellite-2 (ALOS-2) was successfully launched on 24th May 2014. The mission sensor of ALOS-2 is the Phased Array type L-band Synthetic Aperture Radar-2 called PALSAR-2 which is the state of the art L-band SAR system. Until now after the successful completion of initial checkout after launching, ALOS-2 has been contributed to a lot of emergency observations for natural disasters, not only in Japan but also in the world. Furthermore, based on the Basic Observation Scenario (BOS) of ALOS-2, 10m global map data and other mode data are routinely collected and archived. This paper describes the results of ALOS-2 operation in nominal operation phase.

[S-TT45] Synthetic Aperture Radar

convener:Youhei Kinoshita(University of Tsukuba), Yu Morishita(Geospatial Information Authority of Japan), Shoko Kobayashi(Tamagawa University), Takahiro Abe(Earth Observation Research Center, Japan Aerospace Exploration Agency), Chairperson:Yohei Kinoshita(RESTEC), Takahiro Abe(JAXA)

ALOS-2 and Sentinel-1A and 1B, which have highly enhanced capacity compared to previous SAR satellites, were launched in 2014, and their utilization has been widely expanding as the data has accumulated for approximately four years. Other long-operating SAR satellites like TerraSAR-X and Cosmo-SkyMed also contribute to expanding the SAR utilization. Now we are facing a new and abundant era of the satellite SAR, along with a worldwide trend to an open and free data policy of satellite data, with next-generation advanced SAR satellite plans by several countries, and with several plans to construct SAR constellations by private sectors. In addition, SAR technologies with other platforms, such as ground-based SAR with high temporal resolution and UAV (Unmanned Aerial Vehicle) SAR with flexible operability, have also been developed and used for various targets. These facts indicate that the SAR utilization has become widespread in both basic researches (e.g., earth science) and diverse applications (e.g., disaster prevention and forest monitoring). In this session, we would like to widely invite research and application results with regard to SAR, sharing our knowledge and having a discussion for the advancement of the SAR utilization.

Estimation of velocity distribution of Shirase Glacier derived from SAR data obtained by ERS-1/2 tandem mission

*Koichiro Doi[1,2], Yuichi Aoyama[1,2], Kazuki Nakamura[3], Tsutomu Yamanokuchi[4], Kazuo Shibuya[1]

Shirase Glacier is one of the fastest flowing ice stream in Antarctica flowing into the southernmost of Lutzow-Holm Bay in Dronning Maud Land, East Antarctica. It is important to clarify the spatial flow rate distribution with a high resolution to investigate causes of the fast flow and the temporal flow rate changes. In order to make a high resolution flow velocity map, we apply a usual interferometric Synthetic Aperture Radar (InSAR) technique to the obtained data. However, since flowing velocity of the ice stream is greater than 2 km/year (Nakamura et al., 2007, Aoyama et al., 2016), it is difficult to estimate the flow velocity by applying an InSAR technique to the ordinal repeat cycle SAR mission data.

Tandem mission by European Satellite of Remote sensing (ERS)-1/2 was conducted in 1996 and 1999. In this tandem mission, ERS-2 had flown after ERS-1 in the same orbit with an interval of one day, and many InSAR pairs with one day temporal baseline were obtained through the mission.

We successfully obtained two SAR interferograms over Shirase Glacier using this tandem mission InSAR pairs acquired at 1996/06/02-1996/06/03 and 1999/11/14-1999/11/15. We estimated surface displacements along range direction (direction of radar illumination) by applying differential InSAR (DInSAR) with a TanDEM-X 90m DEM (Rizzoli et al., 2017) to remove topographic phase. We also estimated displacements along azimuth direction (direction perpendicular to range direction) by applying a split beam interferometry (SBI) (Bechor and Zebker, 2006) technique to the two InSAR pairs. By combining the range and azimuth displacements, spatial flow velocity distributions can be derived with a high resolution.

In the presentation, we will show two dimensional flow velocity maps with a resolution of approximately 20 m at the two periods and discuss spatial and temporal velocity changes. We will also compare the obtained flow velocity with those by in-situ GNSS measurements in the glacier.

Heavy rainfall-induced displacement of more than 2.5m in the Kushiro Marsh in 2016, detected by ALOS-2 SAR

*Satoshi Fujiwara[1], Yu Morishita[1], Takayuki Nakano[1], Yuji Miura[1], Yasuaki Kakiage[1], MURAMATSU Hiroki[1], Hiroshi Une[1]

1. GSI of Japan

The Kushiro Marsh in eastern Hokkaido is the largest wetland in Japan. Monitoring changes in environmental conditions is important to support preservation of the wetland. In the summer of 2016, Hokkaido was affected by several typhoons and suffered record-breaking heavy rainfall. We constructed ~50 ALOS-2 SAR interferograms, covering the Kushiro Marsh for the period 2014 to 2018, including the summer of 2016. A time series of vertical displacement of the wetland detected by the interferograms corresponded with water level changes in the rivers in the wetland. This implied that the SAR data had successfully detected the height change of the water surface in the wetland. Between August 6, 2016 and September 5, 2016, an area of the wetland (~1 km) to the southeast of Akanuma shifted ~2.7 m horizontally in the downstream direction, which coincided with a large and rapid increase in the water level caused by the heavy rains. This large displacement remained after the water level decreased. Prior to this large horizontal shift, an uplift of ~10 cm was identified in almost the same region. This uplift might have been caused by the leaking of groundwater from the basement of the Akanuma pond, and implied that the peat layer, which had a thickness of several meters floated slightly, like a floating islands, possibly causing the large horizontal shift.

Surface deformation of Asama Volcano, Japan, detected by time-series InSAR combining persistent and distributed scatterers, 2014-2018

*Yosuke Aoki[1], Xiaowen Wang[1]

1. Earthquake Research Institute, University of Tokyo

Asama volcano, located in Central Japan, is one of the most active volcanoes in Japan. Surface deformation at Asama volcano has rarely been documented because of its high topography and snow cover at the summit. In this study, we present first Interferometric Synthetic Aperture Radar (InSAR) observation of ground deformation of Asama volcano with 120 Sentinel-1 SAR images from both ascending and descending tracks and 20 ALOS-2 images from a descending track acquired between 2014 and 2018. We exploited both persistent and distributed scatterers to overcome SAR signal decorrelation and applied the three-dimensional unwrapping method to retrieval displacement time series efficiently. Our observations reveal asymmetric deformation at Asama volcano with two main deformation regions at the northeast and southeast flanks of the volcano, respectively. The northeast flank (NEF) exhibits line-of-sight (LOS) extensions in all the three SAR datasets with maximum velocities of 14, 10, and 12 mm/year for the descending ALOS-2, ascending and descending Sentinel-1 measurements, respectively. The southeast flank (SEF) shows LOS extension in the ascending observations and LOS shortening in the descending observations with velocities between -12 and 9 mm/year, respectively. Decomposition of the LOS displacements reveals nearly pure vertical subsidence at the NEF, while the SEF also shows an evident eastward component other than vertical subsidence. Comparisons of the vertical subsidence at two continuous GPS stations near the summit crater with our InSAR observations indicate small discrepancies smaller than 3 mm/year. We interpret that the subsidence at the NEF is primarily due to the cooling contraction of pyroclastic deposits emplaced in the 1783 eruption, and the SEF is susceptible to flank instability. The asymmetric deformation of the volcano may also be related to the hydrothermal activity that is controlled by the underground structure of the volcano. This study highlights that much more efforts should be taken to monitor the slope instability of Asama volcano in the future.

Improvement of Airborne L-band-SAR (Pi-SAR-L2) Coherence by Pixel by Pixel Resampling

*Makoto Murakami[1], Masato Furuya[1], Taku Ozawa[4], Youichiro Takada[1], Yosuke Aoki[3], Masanobu Shimada[2], Shohei Narita[1]

1. Hokkaido University, 2. Tokyo Denki University, School of Science and engineerring, 3. Earthquake Research Institute, The University of Tokyo, 4. National Research Institute for Earth Science and Disaster Resilience

1. Introduction

Although Airborne SAR is advantageous in terms of flexibility of flight path direction and observation scheduling, the deviation from the flight path linearity due to the perturbation by wind irregularity makes interferometry difficult. We have been working on a development of L band airplane SAR interferometric technique with an aim to use it for volcanic deformation monitoring. The most effective way to improve the coherence between 2 airborne observations is precise coregistration of the slave image against the master image. We here present a new method of precise coregistraion for airborne SAR interferometry using pixel by pixel resampling capability of RINC software package developed by Taku Ozawa at NIED. We demonstrate the usefulness of this technique utilizing airborne repeat path SAR data acquired by JAXA’ s airborne L-band SAR system (pi-sar-l2) over southern Kyushu volcanoes (Sakurajima volcano, Kirishima volcano and Unzen volcano) .

2. The classic coregistration method

Because the flight path of satellite is relatively smooth, the coregistration between master and slave images based on two dimensional quadratic function fitting is sufficient. Our interferometric process for airborne SAR started with the same technique. However, our preliminary tests suggested the insufficiency of this classic method for airborne SAR failing to faithfully follow high frequency component of pixel offset caused by irregularity of the airplane flight path due to the wind fluctuations especially in along-track direction.

3. Precise coregistration method using pixel by pixel matching technique

©2019. Japan Geoscience Union. All Right Reserved.

To improve the effectiveness of coresistration, we employ an additional step to fit the two dimensional pixel offset field after the primary fitting using a quadratic function. In the process of the additional fitting for the the primary fitting residuals, we use an empirical smooth function fitting capability of Matlab software package. Thus we calculate the offset values between master and slave for every pixel of master image and then we carry out coregistration using pixel by pixel resampling capability of RINC software package. This additional procedure significantly improves the coherence as we see below.

3. Demonstration of Usefulness of New method using data over Kirishima volcano

We tested the usefulness of the new method for the repeat path SAR data acquired on 2014 and 2016 over the Kirishima volcano complex. The figure shows the comparison of the coherence between the results of classic and new methods. The area of good coherence increases significantly in the image derived by the new method in the right hand, where brighter colorization corresponds to better coherence. The improvement of the lower half of the image is obvious. Although there still remain stripes of worse coherence which run in the direction perpendicular to the azimuthal axis, the width of those stripes is reduced. This bad coherency seems to be caused by abrupt change of flight speed of the airplane. In this particular observation, our target is Iwoyama dome which is a nest of recent phreatic activity, and the coherence there is actually greatly improved by the new method resulting in better understanding of the ongoing inflation mechanism which will be reported elsewise. In the presentation, we will show the test results using other data sets and discuss the usefulness of the new methods.

Ionospheric delay estimation in SAR interferometry: Significance of the method using the split-spectrum double-difference interferogram

*Taku Ozawa[1]

1. National Research Institute for Earth Science and Disaster Resilience

Split-spectrum method is used as a useful method in reducing the ionospheric delay which is one of the major error factors in SAR interferometry (e.g., Brcic et al., 2010; Rosen et al., 2010; Gomba et al., 2016). This method divides chirp signal of SAR into high and low bands, and generates interferograms for each bands. The ionospheric delay and crustal deformation components are extracted from them. Generally, the ionospheric delay component phai,iono can be estimated from

$\Phi_{iono}=f_L f_H(\Phi_L f_H - \Phi_H f_L)/(f_0(f_H^2-f_L^2))$ -(1)

where f0, fl, fh are center frequencies of full, lower, and higher bands. phai,l phai,h are phase differences of interferograms for lower and higher bands. Empirically, for interferometric pairs with high coherence, the ionospheric delay component can be accurately estimated from this equation. However, that with low coherence, the accuracy degrades mainly due to the difficulty of unwrapping. Then Wegmüller et al. (2018) proposed the method using following equation,

$\Phi_{iono}=A\Phi_0 + B(\Phi_H-\Phi_L)$ -(2)

where phai,0 is phase difference of full-band interferogram, and A, B are coefficient derived from center frequencies. In general, the better coherence is obtained for interferometric pair with wider bandwidth, and therefore the first term is relatively easier to unwrap than that with divided frequencies. Since the second term falls within the value of $-\pi$ to $+\pi$ in most cases, it is possible to easily obtain the phase difference. Furthermore, since A is approximately 0.5, equation (2) can be approximated to

$2\Phi_{iono}=\Phi_0 + 2B(\Phi_H-\Phi_L)$ -(3)

As mentioned before, the second term can easily estimate the phase difference, and then it is possible to obtain an interferogram showing only the ionospheric delay component without unwrapping.

Now, we are developing ionospheric delay estimation tools based on the above three equations. In this presentation, we describe the results of test analysis on several pairs using tools under development. In this analysis, SAR images divided the band in half are used. For high and low frequency pairs, interferograms are generated. After removing orbital and topographic fringes, the spectrum filter (Goldstein and Werner, 1998) is applied to them. From these interferograms, ionospheric delay is estimated using each equation. An outlier removing filter and a Gaussian filter are applied to ionospheric delay image.

First, as a pair with relatively high coherence, the interferometric pair of ALOS-2/PALSAR-2 images which observed Azuma-yama on September 9, 2014 and August 11, 2015 was analyzed. About this pair, almost the same results were obtained from analysis using each equation. However, as a result from interferometric pair which observed on March 7, 2016 and April 18, 2016, included large crustal deformation associated with the 2016 Kumamoto earthquake, differences were obtained in results from analysis using each equation. In particular, in the analysis using Eq. (1), the unwrapping error in the vicinity of the fault seems to have a big influence. In manual analysis, if the error is correctly masked, it is considered that roughly the same result as equation (2) is obtained. In a result from equation (3), the ionospheric delay component was obtained even in the vicinity of the fault. However, in other interfering pairs with particularly poor coherence, the ionospheric delay could not be properly estimated by the analysis using Equation (3) in some cases.

Although there are few analysis cases at the present time and more case analysis is required, it is generally felt that the method based on equation (2) can estimate the ionosphere delay with relatively high

©2019. Japan Geoscience Union. All Right Reserved.

accuracy. However, in cases where large crustal deformation are included such that unwrapping is difficult, the method based on equation (3) may be better. It may be necessary to select a method which is appropriate for a case.

Detecting surface displacement accosiated with the 2018 slow slip event around Boso peninsla by use of Sentinel-1 InSAR with atmospheric correction

*Youhei Kinoshita[1], Tadahiro Nimura[1], Ryoichi Furuta[1]

1. RESTEC, Remote Sensing Technology Center of Japan

The slow slip, also denoted as the slow eathquake, is known to release accumulated strain energy with no or slight seismic wave radiation. The slow slip is usually detected by highly accurate geophysical measurements such as the Global Navigation Satellite System (GNSS) and seismometers because of very small surface deformation on the order of millimeters to centimeters, and small ground oscillation (named as a tremor). Until now, several papers reported slow slip events, for example, at Tokai area (e.g. Yamamoto et al. 2005, EPS; Ozawa et al. 2016, EPS), Cascadia (e.g. Dragert et al. 2004, EPS; Hawthorne and Bartlow 2018, JGR), and Nankai Trough (e.g. Kobayashi 2017, EPS; Ozawa 2017, EPS). The area around Boso Peninsla is also a location where slow slip events have occuered with intervals of several years (Fukuda 2018, JGR). However, most of the reffered papers here used GNSS observations that have a limitation of low spatial resolution (Usually a few tens of kilometers between ground stations). In this study we conducted the InSAR analysis to detect the surface displacement accosiated with the 2018 slow slip event near the Boso peninsla by use of Sentinel-1 observations and numerically-derived atmospheric models.

In the InSAR andalysis we used Sentinel-1 TOPS IW data with three satellite paths (path 39, 141, and 46). Paths 39 and 141 are ascending direction and path 46 is descending direction. The interferometric analysis was conducted by GAMMA software with the 1-arcsecond SRTM DEM for the topographic fringe simulation. All of the InSAR pairs have absolute perpendicular baselines below 200m, indicating most InSAR pairs showed good coherence. Because the expected surface displacement has an amplitude of 2cm or below (by GNSS observations), we performed the stacking analysis for each paths to enhance the detectability of line-of-sight (LOS) displacements. In addition, we applied the MSM-based atmospheric delay correction to each interferograms to further increase the detectability of the surface displacement signal.

The stacking result showed that the surface displacement signal with an amplitude of approximately 1 cm in the LOS direction was clearly detected in path 141. The displacement signal extended spatially to approximately 20 km in both north-south and east-west direction. The spatial distribution and amplitude of InSAR-detected displacement was consistent with the GNSS observation. On the other hand, There were no clear displacement signal in the stacked interferogram in paths 39 and 46. This would be due to the significant atmospheric delay effect in several interferograms of these paths. Therefore we only used the stacking interferogram in path 141 for the fault modeling.

We also performed the assessment of the atmospheric delay correction effectiveness. Phase standard deviations (SDs) calculated on the area outside of the expected displacement signal clearly showed the effectiveness of the atmospheric delay correction. Before the correction, SDs of the stacked interferograms were 5.9 cm, 7.5 cm, and 4.2 cm for paths 39, 46, and 141, respectively, which decreased to 2.7 cm, 4.6 cm, and 1.6 cm after the correction. Although the spatial and temporal resolutions of MSM were 10 km and 3 hours that were not significant for the InSAR atmospheric delay modeling, it showed good performance for the InSAR stacking.

Based on the derived displacement signal in path 141, we performed a forward modeling to estimate preliminary fault parameters using the simple Okada fault model. The estimated fault model suggested

©2019. Japan Geoscience Union. All Right Reserved.

that the upper-left corner of the fault was located at 140.8 degrees in longitude and 34.98 degrees in latitude with the depth of 15 km, which was consistent with the boundary of the Phillipine plate. The fault length and width were set to 50 km and 30 km with the dip angle of 18 degrees. The estimated slip amount was 13 cm with the rake of 105 degrees, which was equivalent to the moment magnitude of 6.6.

Mon. May 27, 2019 1:45 PM - 3:15 PM JST | Mon. May 27, 2019 4:45 AM - 6:15 AM UTC | A08 TOKYO BAY MAKUHARI HALL

[S-TT46] Seismic Big Data Analysis Based on the State-of-the-Art of Bayesian Statistics

convener:Hiromichi Nagao(Earthquake Research Institute, The University of Tokyo), Aitaro Kato(Earthquake Research Institute, the University of Tokyo), Takuto Maeda(Graduate School of Science and Technology, Hirosaki University), Keisuke Yano(The university of Tokyo), Chairperson:Nana Yoshimitsu(Earthquake Research Institute, The University of Tokyo), Takeru Matsuda(Graduate School of Information Science and Technology, The University of Tokyo)

Recently, a big seismic database has been being constructed that collects data of vibrators implemented in such as buildings, lifelines and smartphones, in addition to seismic data of the conventional continuous/temporal dense seismic observation arrays. Development of methodologies and algorithms, which are inadequate at this moment, optimized to comprehensively analyze the seismic big data is essential in order to utilize the big database as much as possible for prevention/mitigation of earthquake disasters and clarification of earthquake phenomena. On the other hand, recent progress of Bayesian statistics is significant, which is the mathematical basis of various methodologies, such as machine learning, especially deep learning, to extract valuable information from big data. The state-of-the-art of Bayesian statistics is expected to substantially advance seismic big data analyses.
This session mainly accepts presentations that focus on analyses of seismic big data, especially related to analysis methods based on Bayesian statistics such as machine learning, sparse modeling and data assimilation, and their applications to real seismic data. Presentations related to mathematical or statistical theories beneficial to data analyses, feasibility studies of algorithms eventually applicable to real seismic data, and the current status of seismic observations and analysis results are also highly welcome.

Bayesian inference is a powerful tool in inversion analyses of geophysical problems. In Bayesian inference, we always encounter a problem in determining the relative weight between observed data and prior information. ABIC (Akaike's Bayesian Information Criterion) gives an objective solution to this problem by maximizing the marginal likelihood for the relative weight. In principle, ABIC gives us an inverse solution that mostly follows observed data when we have enough amounts of data with good accuracy, and gives us an inverse solution that mostly follows prior information when observed data are insufficient and/or inaccurate.

In inversion analyses using ABIC, we do not manually adjust the relative weight. Hence, geophysically unrealistic results are quite easily obtained. Because of that, someone may think that inversion analyses using ABIC is difficult in dealing with or even unreliable. However, this is an excellent point of ABIC. If we obtain a geophysically unrealistic result, this implies that some problems are hidden in this analysis.

In this talk, we show some examples of the invention of inversion methods inspired by ABIC, including the discovery of the importance of modeling errors. As shown by these examples, we can get closer to the true solution not by manually adjusting the relative weight to obtain a seemingly good-looking result, but by determining the relative weight statistically. It is a harder way to determine the relative weight statistically, but we should pursue this way to understand geophysical problems more appropriately.

A seismic wavefield estimation in a dense seismograph network: An optimization for the MeSO-net

*Takahiro Shiina[1], Takuto Maeda[2], Masayuki Kano[3], Aitaro Kato[1], Naoshi Hirata[1]

1. Earthquake Research Institute, The University of Tokyo, 2. Graduate School of Science and Technology, Hirosaki University, 3. Graduate school of science, Tohoku University

MeSO-net (Metropolitan Seismic Observation network) is a dense seismograph network deployed in and around Tokyo, Japan [Kasahara et al., 2009; Sakai and Hirata, 2009]. Station separation of the MeSO-net is about 5 km on average and ~2 km at the densest area. Recently, some reconstructing method of seismic wavefield in such dense seismograph networks have been developed [e.g., Langston, 2007; Kano et al., 2017]. Kano et al. [2017] proposed a wavefield imaging method based on the data assimilation: they demonstrated the reconstructions of wavefield up to ~1 Hz using the MeSO-net. Their method can simultaneously determine layered structures and location of the hypocenter. Seismic wave gradiometry (SWG) method is also well known as another method for estimating 2D seismic wavefield. The SWG method has low computational cost and can apply to observations without assumptions of hypocenter and structural heterogeneity. Therefore, the SWG method will be useful for monitoring wavefield and investigating ground motions without source data as prior information.
We adopt the SWG method developed by Maeda et al. [2016] to estimate seismic wavefield within the MeSO-net. In this method, amplitude and its spatial gradients of seismic wave at grid points are estimated from observed amplitude at surrounding stations. Interpolation coefficients used for the estimation are determined by the weighted least squares technique and are only depended on a grid-station distance.
In order to optimize the interpolation coefficient, we perform the analysis based on numerical modeling. The finite difference modeling, the OpenSWPC [Maeda et al., 2017], is used to simulate seismic waves at any grid points and sites of which locations correspond to the MeSO-net stations. For the simulated waveforms, we adopt bandpass filter of 0.1-0.2 Hz which is lower than the upper-limit frequency of our numerical modeling, ~0.25 Hz. Then, we synthesize waveform at a grid point from simulated ones at surrounding sites by the SWG method. As the weighting function imposing to the least square, we assume the 2D Gaussian form with respecting to the grid-station distance. The 2D Gaussian weight is characterized by the lengths in two orthogonal axes, long and short arms, and a rotation angle of the short axis in the clockwise direction from the north. The ” optimization” in this study is to find the three parameters which maximize the three-components cross-correlation coefficient between the SWG-synthesize and the simulated waveforms at the grid point. We investigate the parameters by the grid search technique.
We carry out the numerical simulations for hypocenters of 12 directions with 30 degree interval. The hypocenters are located at a depth of 10 km and a distance of 150 km from the center of the MeSO-net. In this case, the determined Gaussian weight realize the highest reproducibility of the seismic wavefield for wave incidence from an arbitrary direction. The obtained Gaussian weights mark small and isotropic shapes near the central area of the MeSO-net, whereas they mark large and elliptical shapes around edges of the network. These shapes of the optimum weight would represent the configuration of the MeSO-net stations and demonstrate that the high-reproducible area of seismic waveform is expanded. Moreover, we confirmed that the accuracy of the seismic wavefield estimation can improve when selecting the interpolation coefficients coinciding with the incoming direction of the seismic waves.

Uncertainty quantification based on 4DVar data assimilation for massive simulation models

*Shin-ichi Ito[1], Masayuki Kano[2], Hiromichi Nagao[1]

1. The University of Tokyo, 2. Tohoku University

Data assimilation (DA) is a fundamental computational technique that integrates numerical simulation models and observation data on the basis of Bayesian statistics. Originally developed for meteorology, especially weather forecasting, DA is now an accepted technique in various scientific fields. One key issue that remains controversial is the implementation of DA in massive simulation models under the constraints of limited computation time and resources. This work proposes a DA technique based on a four dimensional variational (4DVar) method for massive autonomous models that produces optimum estimates and their uncertainties within reasonable computation time and resource constraints. The uncertainties are given as several elements of an inverse Hessian matrix, which is the covariance matrix of a normal distribution that approximates the target posterior probability density function in the neighborhood of the optimum. The proposed method based on a second-order adjoint method allows us to directly evaluate the elements of the inverse Hessian matrix without computing all of its elements. Some numerical tests assuming a massive simulation model confirm that the proposed method works well and enables us to evaluate the uncertainties of the parameters involved in the assumed model faster than the conventional DA approaches. Such information regarding uncertainty is valuable, as it can be used to optimize the design of experiments.

Bayesian approach for statistical modeling and forecasting of aftershock activities

*Takahiro Omi[1]

1. Institue of Industrial Science, the University of Tokyo

A large earthquake triggers a considerable number of aftershocks, which potentially cause additional damage in the affected area. It is therefore important to forecast aftershock activities as early as possible after a main shock. A basic method for forecasting aftershocks was proposed in 1989. However, for practical application of aftershock forecasting, we have to additionally consider (i) the missing of early aftershocks (ii) the forecast uncertainty. We consider such features by taking Bayesian statistical approach. In this talk, we briefly explain our forecasting method and demonstrate its utility.

Bias Correction for the Distribution of Aftershocks Within Short-Term Period Immediately After Large Main Shock

*Kosuke Morikawa[1], Hiromichi Nagao[2], Shin-ichi Ito[2], Shin'ichi Sakai[2], Naoshi Hirata[2]

1. Osaka University, 2. Earthquake Research Institute, The University of Tokyo

The main shock of a large earthquake often makes it difficult to identify a number of subsequent aftershocks. Knowing the distribution of magnitudes and arrival times of the aftershocks is essential to figure out the characteristics of the sequence of earthquakes, which enables us to predict the frequency of earthquakes depending on space and time. Such the distribution of aftershocks should be estimated within a couple of days eventually since most of the large aftershocks occur within one day from the main shock. However, an exact count of all aftershocks right after a main shock is very hard due to large signal-to-noise ratio, so that an estimated distribution of the aftershocks is usually biased.

An adoption of a likelihood that incorporates models of the detection rate of aftershocks can be a solution to correct the bias, but the simultaneous dependency on both magnitudes and arrival times of the aftershocks makes this difficult. Thus using nonparametric models for the detection rate is unrealistic though misspecification of the model may lead to a severe biased estimator.

In this study, we propose two detection rate models that are individually conditional on the magnitudes and the arrival times. The Generalized Moments of Methods (GMM)-type estimator overcomes the difficulty in estimation due to the imcompletely defined joint distribution. With the use of prior information, the distribution of the aftershocks can be effectively estimated within short-time period.

Deep-learning-based Earthquake Detection for Continuous Seismic Network Records

*Keisuke Yano[1], Takahiro Shiina[2], Sumito Kurata[1], Aitaro Kato[2], Fumiyasu Komaki[1], Shin'ichi Sakai[2], Naoshi Hirata[2]

1. Graduate School of Information Science and Technology, The University of Tokyo, , 2. Earthquake Research Institute, The University of Tokyo

Over the last decade, continuous seismic data have been enormously acquired on seismic networks consisting of multiple sensors at distributed locations. Analyzing these data efficiently and thoroughly offers substantial benefits to seismology. The first important step in the analysis is earthquake detection, that is, detecting earthquakes in continuous massive datasets.

In this talk, we present a deep-learning-based scheme for earthquake detection from continuous records in a seismic network. We work with a convolutional neural network (CNN), which is one of the most powerful supervised learning techniques, to capture features discriminating between earthquakes and noises. Our scheme has an advantage of utilizing multiple stations in a seismic network to discriminate between earthquakes and noises.

We apply our scheme to continuous data on Metropolitan Seismic Observation network (MeSO-net) from September 4, 2011 to September 16, 2011. We show our scheme improves on CNNs based on few stations especially in preventing mis-detection. In addition, the trained network in the last fully connected layer has quasi-sparsity, by which we identify features important for CNN to recognize earthquakes.

[S-CG56] Ocean Floor Geosciences

convener:Kyoko Okino(Atmosphere and Ocean Research Institute, The University of Tokyo), Chairperson:Arata Kioka, Atsushi Noda

Most of Earth's volcanism and much of its tectonic activity occur on and beneath the seafloor. Various phenomena on the seafloor are closely linked to plate tectonics, Earth and atmosphere. Seafloor rocks and sediments record Earth's evolution and heat and material fluxes on the Earth. Ocean Floor Geosciences session covers a broad range of research on LIPs, crustal movement and structure etc. Any fields of research and approach are welcomed. The session aims to encourage discussion among scientists from different study fields and to integrate our understanding of ocean floor. The session is co-chaired by K. Tadokoro (Nagoya Univ.), O. Ishizuka (AIST), T. Toki (Univ. Ryukyus), and N. Takahashi (JAMSTEC).

Observational plans of the South Sandwich Arc by R/V Hakuho Maru: Toward understanding formation and evolution of the world southernmost arc-trench system

*Asuka Yamaguchi[1], Kenichiro Tani[2], Minoru Ikehara[3]

1. Atomosphere and Ocean Research Institute, The University of Tokyo, 2. National Museum of Nature and Science, 3. Center for Advanced Marine Core Research, Kochi University

The South Sandwich arc-trench system, located in between South America and Antarctica, is one of the unexplored subduction zones of the world. It was originated in Mesozoic fragmentation of Gondwana, and Neogene westward subduction of South American plate causes formation of South Sandwich volcanic arc and back-arc opening of West and East Scotia Sea. The formation of Scotia Sea is closely related to the opening of Drake Passage Gateway, and thus it caused the development of the Antarctic Circumpolar Current and affected the earth’ s climate. However, detail back-arc opening process of Scotia Sea is poorly understood. Sediment accumulated in the South Sandwich Trench is expected to contain large amount of diatom and IRD (ice-rafted debris), but the nature of the sediment in the trench is unknown because of the lack of sediment cores.
On 2019 December-2020 January, R/V Hakuho Maru will visit the South Sandwich Arc and Weddell Sea as a part of around the world cruise for her 30th anniversary. During this cruise, we plan to take 1) dredge samples of forearc high of South Sandwich Arc possibly recording initiation process of oceanic island arc, as well as 2) sediment cores in South Sandwich Trench as an input to a subduction zone in polar region. By comparing the findings during this cruise to accumulated knowledge on backarc-arc-trench system around Japan, we try to understand the formation and evolution of the world southernmost arc-trench system.

Seismic imaging of the source zone of the 2011 Tohoku-oki earthquake

*Dapeng Zhao[1], Xin Liu[1]

1. Department of Geophysics, Tohoku University

The great 2011 Tohoku-oki earthquake (*Mw* 9.0) is the best-documented megathrust earthquake in the world, but its causal mechanism is still in controversy because of the poor state of knowledge on the nature of the megathrust zone. *Zhao et al*. (2011) used seismic tomography to study structural heterogeneity in the megathrust zone and suggested that lateral structural variations atop the subducting Pacific slab, such as the subducted seafloor topography, seamounts and sediments, affected nucleation of the 2011 Tohoku-oki earthquake. In contrast, *Bassett et al*. (2016) used residual topography and gravity data to constrain the Tohoku forearc structure and proposed that variations in the forearc lithology of the overriding Okhotsk plate were the main cause of along-strike variations of the Tohoku-oki slip behavior. In this work we constrain the structure of the Tohoku forearc using seismic tomography, residual topography and gravity data. We apply a tomographic method (*Zhao et al*., 2002) to invert 144,354 *P*-wave arrival-time data recorded at 382 permanent seismic stations in Tohoku from 4760 local shallow and intermediate depth earthquakes that occurred during January 2000 to June 2016.

Our results reveal a close relationship between structural heterogeneities in and around the megathrust zone and rupture processes of the 2011 Tohoku-oki earthquake (*Liu and Zhao*, 2018). Its mainshock nucleated in an off-Miyagi area with high seismic velocity, low seismic attenuation and strong seismic coupling, indicating a large asperity (or a cluster of asperities) in the Tohoku megathrust zone. Strong coseismic high-frequency radiations also occurred in high-velocity patches, whereas large afterslips took plate in low-velocity areas, which may reflect changes in fault friction and lithological variations. These results indicate that structural anomalies in and around the Tohoku megathrust originate from both the upper Okhotsk plate and the lower Pacific plate, which controlled the generation and rupture processes of the 2011 Tohoku-oki earthquake. This huge earthquake was caused by collision of harder rocks in both the upper and lower plates.

This work sheds new light on the causal mechanism of megathrust earthquakes. It also suggests that the location of a future great earthquake may be pinpointed by investigating the detailed structure of the megathrust zone.

In this presentation, we will also show our new results obtained by adding the data recorded by the S-net that has been installed in the eastern Japan forearc region under the Pacific Ocean.

Drastic export of organic carbon to hadal trench driven by megathrust earthquake

*A. Kioka[1], T. Schwestermann[1], J. Moernaut[1], K. Ikehara[2], T. Kanamatsu[3], C. M. McHugh[4], C. dos Santos Ferreira[5], G. Wiemer[5], N. Haghipour[6], A. J. Kopf[5], T. I. Eglinton[6], M. Strasser[1,5]

Despite a growing understanding of pivotal role of the carbon cycle in governing the Earth system, the nature and quantification of carbon supply to hadal environments remains poorly constrained. The giant 2011 Tohoku-oki earthquake has been inferred to remobilise fine-grained, young surface sediment enriched in organic matter from the slope into the >7 km deep Japan Trench. Yet, this hypothesis and assessment of its significance for the carbon cycle has been hindered by limited data density and resolution in the hadal zone. Here we combine new high-resolution bathymetry data with subbottom profiler images and sediment cores taken during 2012–2016, in order to map for the first time the spatial extent of the earthquake-triggered event deposit along the hadal Japan Trench. We quantify a sediment volume of ~0.2 km^3 deposited from spatially-widespread remobilisation of young surficial seafloor slope sediments triggered by the 2011 earthquake and its aftershock sequence. The mapped volume and organic carbon content in sediment cores encompassing the 2011 event reveals that this single tectonic event delivered >1 Tg of organic carbon to the hadal trench. This carbon is comparable to high carbon fluxes described for other Earth system processes, shedding new light on the impact of large earthquakes on long-term carbon cycling in the deep sea.

How do trench-fill sediments subduct under the accretionary wedge?

*Atsushi Noda[1], Hiroaki Koge[2], Yasuhiro Yamada[3], Ayumu Miyakawa[1], Juichiro Ashi[2]

1. National Institute of Advanced Industrial Science and Technology, 2. Atomosphere and Ocean Research Institute, The University of Tokyo, 3. Japan Agency for Marine-Earth Science and Technology

Ancient exhumed accretionary complexes sometimes have combinations of low-grade accretionary rocks from trench-fill turbidites, high-pressure/low-temperature metamorphic rocks including psammitic schists, and forearc basin deposits composed of sandy submarine fan deposits, whose provenance and depositional ages are similar to each other. For example of the southwestern Japan, sandstones in the Shimanto Accretionary Complex and psammitic schists in the Sanbagawa Metamorphic Complex are derived from terrigenous trench-fill deposits showing the similar geochemical and geochronological characteristics each other; the former is composed of accretionary rocks at the shallow part of the subduction zone and the latter comprises metamorphic rocks subducted to deeper than 10~km. Generally, at accretionary-type subduction zones, because weak layers within sediments deposited on the oceanic plate are used as a decollement, the lower pelagic and hemipelagic sediments can subduct beneath accretionary wedge through the subduction channel, but the upper terrigenous sediments are accreted at the toe of the wedge. Growth of accretionary wedge enabled to develop a forearc basin between the wedge and the backstop. At tectonically erosive subduction zones, most of the trench-fill sediments can subduct beneath the frontal prisms, but accretionary wedge cannot be grew at the same time. Therefore, it is difficult to explain coexistence of growth of accretionary wedge derived from coarse-grained trench-fill sediments and subduction of them deeper than seismogenic zone at the same time. In this study, we attempt to identify an importance of seafloor roughness for transportation of trench-fill sediments to deep during subduction. For this purpose, we conducted sandbox analogue experiments by using an unfixed rigid backstop on a subduction channel with the cases of smooth surface (Exp. A) and rough surface representing a seamount or ridge on subducting lower plate (Exp. B). The results of Exp. A showed progressive thickening of the accretionary wedge pushed the backstop down, meaning stepping down of the decollement and narrowing the subduction channel. On the other hand, Exp. B showed a subducting seamount lifted up the backstop, stepped up the d{\'e}collement, and then widened the subduction channel. Subduction of a rigid material like a chain of seamounts is a possible mechanism to open subduction channels for transportation of terrigenous sediments from the trench to high-pressure condition. Significant sediment supply to the trench and rough surface of subducting oceanic plate are required to enable subduction of protolith of HP-LT metamorphic rocks, accretion of trench-fill sediments at the shallow part, and formation of forearc basin simultaneously.

Formation process of a slope basin in the Nankai Accretionary prism reconstructed from high-resolution SBP integrated with core data of ODP Site 1175 and Site 1176

*Yuichi Okuma[1], Asuka Yamaguchi[1], Hiroaki Koge[1], Rina Fukuchi[1], Juichiro Ashi[1]

1. Atmosphere and Ocean Research Institute, the University of Tokyo

Upper plates of subduction zones record various phenomena associated with plate subduction. Geological records of slope basins overrapping accretionary prisms are useful to reconstruct tectonic activities of decollements and/or splay faults. In general, low-frequency sources are preferred for seismic reflection profiling to avoid attenuation in the water. However, low-frequency sources permit limited resolution of profiles due to trade-off relationship of frequency and resolution. For this reason, only limited studies focused on detail structures of the shallow portion of the deep-sea slope basins (e.g., Tsuji et al., 2014, *EPS*). In this study, we conducted interpretation of subsurface structures and reconstructed the formation process of the slope basin on the Nankai accretionary prism using high-resolution cross section images obtained by deep towed subbottom profiler on the R/V Hakuho-maru KH-16-5 cruise around the Nankai Trough off Muroto. This slope basin is located at 80 kilometers to southwest of the cape Muroto and a depth of 3000 m, and 8 kilometers long in northwest-southeast and 6.5 kilometers long in northeast-southwest forming an ellipse shape. An obvious strike-slip fault including normal-slip orientation at 1 kilometer seaward from the basin and a splay fault at 2 kilometers from the strike-slip fault are confirmed by Underwood et al. (2003, *JSR*), there is a high possibility that the basin records those activities. Moreover, Kodaira et al. (2000, *Science*) reported the existence of a subducted seamount at north of the slope basin, which means that subduction of this seamount had an impact on formation of the basin. Two cores from Site 1175 and Site 1176 were obtained by Ocean Drilling Program (ODP) Leg 190 around the basin, we also compared the result of interpretation to depositional structures and age. The high-resolution cross section shows a splay fault, strike-slip fault and hillock associated with minor faults including a strike-slip fault with reverse fault component at the center of the hillock. In the landward region from the strike-slip fault on the hillock, structures indicating relative subsidence of landward margin of the basin were confirmed. Additionally, basin strata show the evidence of landward migration of a depocenter in that region, which is coincident with the structures in the seismic profiles (Shipboard Scientific Party, 2001). The dip angle near the Site 1175 increase with depth, which suggest continuous tilting. Only normal faults exist in the landward region from the top of the hillock. Especially, four normal faults getting through to the seafloor are attributed to successive faulting because the displacement of those faults increase with depth. In addition, landslide deposit flowed from landward slopes is ascertained in the cross section. On the other hand, the reverse fault group being part of a splay fault is included in the trenchward region from the strike slip fault. The subbottom profile shows the evidence of obvious reverse and normal faulting around that region. Notably, reverse faulting is dominant in trenchward-half of the hillock, although no faults are getting through to the seafloor. The reflecting surfaces correspond with volcanic ash or sand layers by comparison both reflection surfaces and stratigraphic succession of cores on the Site 1175 and Site1175. Depositional age from analysis of ash suggest that the tilting in landward region from the strike-slip fault was getting low in activity and calmed within 28 ka. It is difficult to presume the moment of initiation of tilting due to depth limit of SBP, however, the basin already started tilting when the 105 ka surface deposited because that tilting of the surface confirmed around Site 1175. Additionally, the number of faults cutting surface younger than 28 ka is less than those cutting older than that surface, and no faults except the well-developed strike-slip fault at the center of the hillock reach the

©2019. Japan Geoscience Union. All Right Reserved.

seafloor. Therefore, those results indicate that a high likelihood of that the tilting at shallow portion of the basin caused by faulting of the splay fault, and suggest that the tilting had initiated before deposition of 105 ka surface and stopped by 28 ka at the latest. In this way, deep towed SBP integrated with core data has a great potential for reconstructing high time-resolution basin growth and fault activity.

About the turbidity current considered that it occurred in the northern Suruga Bay, Central Japan by the typhoon No.24. -The traces of the accidents and the phenomenon at the sea floor detected the OBSs Array-

*Nakao Nagisa[1], Hisatoshi Baba[2], Hiroshi Sato[3], Kayoko Tsuruga[4], Izumi Sakamoto[2], Takahito Nishimiya[5], Masanao Shinohara[3], Shintaro Abe[6]

1. Tokai University, 2. Department of Marine and Earth Science, Tokai University, 3. Earthquake Research Institute, University of Tokyo, 4. Tokyo University of Marine Science and Technology, 5. Meteorological Research Institute, Japan Meteorological Agency, 6. Association for the Development of Earthquake Prediction

In August 2018, Structural exploration based on "The integrated research project for the Fujikawa fault zone" began in the northern Suruga Bay. We installed 18 pop-up type Ocean Bottom Seismographs (OBSs) in this survey line (from Shimizu to Heda). In addition, we installed 4 OBSs in other survey lines for the observation of seismic activities around the Suruga Bay.

The typhoon No.24 passed off in the vicinity of the Suruga Bay from September 30th to October 1st 2018. After passing off that, various accidents of OBS occurred. Those accidents of OBS are as follows:

1. 4 OBSs drifted on the coast.

2. The movement of the installation position of the 2 OBSs was confirmed.

3. 1 OBS did not have a transponder response and it was missing.

4. The two OBSs have a transponder response, but they do not pop-up.

From this and the above, in this study, we considered OBS to have an accidentally due to a phenomenon occurred at the seafloor in the northern part of Suruga Bay by typhoon 24.

We analyzed using seismic wave, submarine topography and mud and considered them.

・According to the waveform record obtained by OBS, the accidenty spread from the central part of Suruga Bay of the extension of the Fujikawa estuary.

・It was a tilt that caused turbidity flow to occur by hanging from the Fujikawa estuary to the survey line.

・When the bottom sampling was done at the installation point and recovery point, the same particle size was present.

From the above,the cause of the accidenty in the OBS in the northern Suruga Bay is presumed to have flowed into the Suruga bay, where the sediments originating from the Fujikawa streamed OBSs.

©2019. Japan Geoscience Union. All Right Reserved.

From this, there is a high possibility that a turbid flow has occurred in northern Suruga Bay.

Mon. May 27, 2019 10:45 AM - 12:15 PM JST | Mon. May 27, 2019 1:45 AM - 3:15 AM UTC | A05 TOKYO BAY MAKUHARI HALL

[S-CG60] Investigation of inputs to subduction zones: Influence of tectonic processes on the incoming plate

convener:Makoto Yamano(Earthquake Research Institute, the University of Tokyo), Tomoaki Morishita(School of Geoscience and Civil Engineering, College of Science and Technology, Kanazawa University), Gou Fujie(Japan Agency for Marine-Earth Science and Technology), Chairperson:Shigeaki Ono(Japan Agency for Marine-Earth Science and Technology)

Various tectonic processes occur on the seaward side of the trench associated with bending of the incoming oceanic plate, e.g., fracturing of oceanic crust, infiltration of water, and intraplate volcanism. Investigation of these processes and their influence on the incoming plate provides important information on the boundary condition at the trench, inputs to subduction zones. Variation in inputs should significantly affect geophysical/geological phenomena around the plate interface and geochemical cycles in subduction zones. We welcome contributions from a broad range of earth science (geophysics, geology, petrology, and so on) discussing topics related to inputs to subduction zones such as occurrence of tectonic processes due to bending of the incoming plate, modification of the incoming plate by the processes, relationship between the processes and the inherited structure of the incoming plate, and influence of the processes on the subduction plate interface. We hope discussions are made on studies of a variety of subduction zones, including the Japan Trench and the Nankai Trough, and comparative studies among different subduction zones.

The Chile triple junction (CTJ) is a unique place where a spreading center of mid-ocean ridge is subducting near the Taitao peninsula. Around CTJ, presence of high heat flow on the continental slope (Cande et al., 1987, J. Geophys. Res.) and near-trench young granitic rocks on the Taitao peninsula (Anma and Orihashi, 2013, Geochem. J.) suggests the thermal and petrological impact of subducting ridge on the continental side. The tectonic history of the southeast Pacific since early Cenozoic to the present suggests that ridge subduction continuously occurred along the Chile trench, which migrated northward (Cande and Leslie, 1986, J. Geophys. Res.), which can contribute to growth of the continental crust (Iwamori, 2000, EPSL).
In January 2019, the MR18-06 cruise Leg 2 was conducted at the Chile Triple Junction, as a part of 'EPIC' expedition by using R.V Mirai of JAMSTEC. During the leg, we completed 4 SCS lines, 6 piston coring, 6 heat flow measurements, 2 dredges, and underway geophysics observations, as well as deployment of 13 OBSs. The primary object of heat flow measurement at CTJ is to better constrain the thermal regime around CTJ by adding new data right above CTJ. The key question is whether CTJ is thermally dominated by ridge activity (magmatic, tectonic, and/or hydrothermal) or by subduction initiation (tectonic thickening, accretion, and/or erosion). The ultimate goal is to model the temperature at the plate interface from the heat flow and other data, and to infer how the thermal regime at CTJ contributes the seismogenic behavior at the M~9 megathrust zone.
Our preliminary analysis shows high and variable heat flow around CTJ. It is generally consistent with previous heat flow along line 751 (Cande et al., 1987). With SCS and piston core data, a reasonable thermal model can be constructed around CTJ. (Acknowledgment) we thank the Hydrographic Department of Chile (SHOA), for allowing to enter the Chilean EEZ and territory for our survey.

Heat flow measurement on the seaward side of the Kuril Trench off Hokkaido

*Kouta Sasaki[1], Makoto Yamano[1], Yoshifumi Kawada[2], Masataka Kinoshita[1], Kiichiro Kawamura[3]

1. Earthquake Research Institute, the University of Tokyo, 2. International Research Institute of Disaster Science, Tohoku University, 3. Yamaguchi University

To understand thermal structure of subduction zone, heat flow on the surface of incoming oceanic plate serves as an important boundary condition. On the surface of oceanic plate, observed value of heat flow is generally consistent with prediction of the plate cooling model (e.g., Stein and Stein, 1992). Yamano et al. (2014) revealed extensive high heat flow anomaly on the seaward side of the Japan Trench, where the very old Pacific plate (~135 Myr) subducts beneath northeast Japan, and some possible causes of the anomaly have been examined. Fujie et al. (2013, 2015) pointed out seismic velocity structure anomalies in the crust and the uppermost mantle seaward of the Japan and Kuril trenches and attributed them to increase in water content as a result of bending of the incoming oceanic plate. Kawada et al. (2014) examined influence of hydrothermal circulation in a permeable layer in the oceanic crust as a possible source of the high heat flow anomaly. They showed that hydrothermal circulation in the permeable layer thickening toward the trench axis in concordance with the seismic velocity anomaly pumps up heat efficiently and raises heat flow on the seafloor.

Infiltration of water into the crust is inferred seaward of the Kuril Trench as well based on the seismic velocity anomaly. Nakanishi (2011) argued that the direction of bending-related faults on the oceanward slope of the Kuril and Japan trenches is well correlated with the angle between the trench axis and the ancient spreading ridge axis, which varies along the trenches. It is also speculated that the trench-ridge angle is a major controlling factor of incoming plate hydration (Fujie et al., 2018). These studies suggest that it is indispensable to examine heat flow distribution seaward of the Kuril Trench, where few data have been obtained, for investigation of water and heat transport processes associated with plate bending.

In this study, we conducted heat flow measurement on the seaward of the Kuril trench off Hokkaido on KH-18-5 cruise of R/V Hakuho-maru. We measured geothermal gradient with a 3 m long temperature probe at eight sites and with a piston corer at four sites within about 120 km of the trench axis. We attempted penetration of the temperature probe several times at each site at intervals of 300 to 500 m. Few penetrations were successful within 60 km of the trench axis probably because thick layers of volcanic ash prevented the probe from penetrating into the sediment. Thermal conductivity was measured on piston core samples.

Most of the obtained 25 new heat flow values are roughly consistent with typical values for ocean basins older than 100 Myr (~50 mW/m^2), while high heat flow, 90 to 100 mW/m^2, was observed at one station about 70 km from the trench axis. This result indicates that the degree of heat flow anomaly on the seaward side of the Kuril Trench is lower than that in the counterpart of the Japan Trench.

Comparison of experimental and intermediate-depth earthquake b-value: difference in hydration degree of the oceanic mantle between Tohoku and Hokkaido

*Saeko Kita[1], Thomas P. Ferrand[2]

1. International Institute of Seismology and Earthquake Engineering, BRI, 2. ERI, University of Tokyo

We examine b-values of the lower-plane events than beneath Tohoku. Using the acoustic emission (AE) experimental result, the b-values for intermediate-depth intraslab earthquakes in the Pacific slab beneath the Tohoku and Hokkaido regions, northeastern Japan and find a difference in the b-values of lower-plane events in the double seismic zone. Lower-plane events reveal significantly larger b-values beneath Tohoku (0.96) than Hokkaido (0.86), implying that the brittle deformation beneath Hokkaido is more localized and leads to higher ratio of relatively large lower-plane events by Ferrand et al. [2017, Nature Communications], we also found that the b-values for experimental earthquakes increase with increasing antigorite content in serpentinized peridotite. A comparison of experimental and natural earthquake b-values implies that lower- plane peridotite is more hydrated beneath the Tohoku region, which is consistent with the difference in oceanic-plate velocity structures near the trench identified in Ocean Bottom Seismometer studies off Tohoku and Hokkaido by Fujie et al. [2017, Nature communications]. Since the density of fracture zones offshore Tohoku is larger than offshore Hokkaido, the extent of hydration of the oceanic mantle beneath Tohoku could be larger than beneath Hokkaido.

Variations in bend faulting and the nature of the incoming oceanic plate off northeast Japan arc

*Gou Fujie[1], Koichiro Obana[1], Yojiro Yamamoto[1], Tomoaki Yamada[2], Takehi Isse[2], Shuichi Kodaira[1], Seiichi Miura[1]

As the inputs to subduction zone, the nature of the incoming oceanic plate, such as relief, thermal state, lithology, and the water content, affects subduction zone processes, including arc magmatism and interplate and intraplate seismic activities. Thus, regional variations in the nature of the incoming oceanic plate have a potential to cause regional variations in such subduction zone processes.

To reveal the nature of the incoming oceanic plate and its regional variations off northeastern Japan arc, we have conducted extensive controlled-source seismic experiments at the northwestern margin of the oceanic Pacific plate. First, we conducted seismic experiments at around the junction of the Kuril and Japan trenches. We observed seismic structural changes owing to the plate bending-related faults just prior to subduction at both trenches and found the structural changes caused by bend faulting are more significant in the Japan trench side than that in the Kuril Trench side, indicating that plate hydration before subduction is remarkably higher in the Japan Trench than in the Kuril Trench. These observed differences can be explained by the type of the bend faults, newly created faults (Japan Trench) or reactivated abyssal-hill faults (Kuril Trench). As the type of bend faults are determined by the angle between the current trench and the ancient spreading ridge, this angle is one of key factors controlling the hydration of the incoming oceanic plate.

In 2017 and 2018, we conducted additional seismic experiment at the trench-outer rise areas of the southern Japan Trench off Fukushima. This was our first seismic survey in the trench-outer rise region of the southern Japan trench. The strike of the Japan trench differs between the northern part and the southern part, indicating that the angle between the current trench axis and the ancient spreading ridge also differs between the northern part and the southern part. In addition, unlike the northern part of the Japan trench, a large seamount chain exists in the trench-outer rise region of the southern Japan Trench. The primary aim of our new seismic survey in the southern part of the Japan Trench is to clarify the differences between the northern and the southern part of the Japan trenches.

We applied traveltime tomographic inversion to the wide-angle reflection and refraction seismic data and developed a P-wave velocity (Vp) model. The obtained Vp model clearly shows the reduction in Vp near the trench axis caused by bend faulting. The Vp reduction patterns are closely akin to that in the northern Japan trench area. The angle between the current trench and the ancient ridge axis differs between the northern and the southern Japan trench, but the type of bend faults are the same. Our new observation confirmed that the type of bend faults is a key controlling factor on the bend faulting and plate hydration prior to subduction.

In addition to the structural changes caused by bend faulting, we observed curious features in crustal Vp structure. In the area far from the trench axis off Fukushima, our Vp model shows velocity reversal within the oceanic crust which is suggested by the "shadow zones" of the crustal refractions. We have observed similar velocity reversal within the oceanic crust in the areas far off Iwate, but not in the areas far off Miyagi. These observations suggest that the oceanic crust are intrinsically inhomogeneous in the

©2019. Japan Geoscience Union. All Right Reserved.

northwestern part of the Pacific plate.

In this presentation, we will show the variations in the Vp model in the northwestern part of the Pacific plate including the structural changes caused by bend faulting and the velocity reversal within the crust, and discuss the possible impact as the subduction inputs.

Seismicity in the trench-outer rise region off Fukushima and Ibaraki, southern Japan Trench

*Koichiro Obana[1], Gou Fujie[1], Yojiro Yamamoto[1], Yuka Kaiho[1], Yasuyuki Nakamura[1], Seiichi Miura[1], Tsutomu Takahashi[1], Shuichi Kodaira[1]

After the 2011 Tohoku-oki earthquake, seismicity within the incoming Pacific plate is active in the trench-outer rise region along the Japan Trench. These earthquakes were characterized by normal-faulting focal mechanisms and could provide information about potential source faults of large outer-rise normal-faulting earthquakes. We have conducted earthquake observations in the southern part of the Japan Trench, off Fukushima and Ibaraki region(36º—38º N) by using ocean bottom seismographs (OBSs). The observations were conducted from March to July, 2017. We have deployed 35 OBSs including 14 ultra-deep type OBSs, which can be deployed in the trench-axis area where the maximum water depth was about 7800 m. Earthquakes were detected from continuous OBS records and phase arrival times were picked manually. Then, we relocated earthquakes by using double-difference tomography technique. In the tomography analysis, we used the initial velocity model based on an active seismic study conducted in the study area. Finally, we have obtained hypocenter location of about 1400 earthquakes. We also estimated focal mechanisms by using P-wave first-motion polarities in vertical component seismograms. The results show several linear earthquake clusters in the trench-outer rise region extended in roughly N-S and NNE-SSW directions. Pre-dominance of the normal-faulting focal mechanisms indicate that the earthquakes in the trench-outer rise region were explained by bending-related normal-faulting. The earthquake cluster oriented N-S direction was almost parallel to the strike of the northern Japan Trench, whereas NNE-SSW oriented linear clusters were almost parallel to the strike of the southern Japan Trench. Although the strike of the Japan trench changes from N-S in the north to NNE-SSW in the south at around 38º N, linear clusters parallel to both directions suggest existence of the complicated fault system in the trench-outer rise region in this area. Previous OBS observations along the Japan Trench showed that there was almost no seismicity along the plate boundary and within the overriding plate closed to the trench axis. The trench landward seismicity close to the trench axis observed only within the subducting Pacific plate. However, shallow earthquakes, which could occur along the plate boundary or within the overriding plate, close to the trench axis were observed landward slope of the Japan Trench south of 36.7º N. Seafloor geodetic studies indicated that seaward motion in the landward slope along the southern part of the Japan Trench, while landward motion were observed along the central part of the Japan trench. The characteristic shallow seismicity beneath the landward slope close to the trench axis might relate to the different displacement of the trench landward slope in the southern part of the Japan Trench.

Influence of water–rock interactions on the strength of outer-rise faults

*Ken-ichi Hirauchi[1]

1. Department of Geosciences, Faculty of Science, Shizuoka University

Knowledge of the amount of water stored in oceanic plates is important for understanding subduction zone water budgets (e.g., Hatakeyama et al., 2017, *Sci. Rep.*). Beneath the outer rise, the incoming oceanic plate bends down into the trench, resulting in the formation of extensional normal faults (i.e., outer-rise faults). Seismic reflection studies have shown that these normal faults penetrate into the upper mantle and act as a permeable fluid pathway. How deep outer-rise faults can develop primarily depends on the depth extent of strain localization within the oceanic lithosphere. Infiltration of seawater into outer-rise faults may promote the growth of mechanically weak hydrous phases such as talc and serpentines, perhaps leading to further strain localization. In order to understand effects of water–rock interactions on the strength of the upper mantle, I have conducted high-pressure deformation experiments on simulated peridotite fault gouges in the presence of hydrothermal water (Hirauchi et al., 2016, *Nat. Commun.*). I found that at a temperature of 500˚C and a confining pressure of 1 GPa, the development of talc-bearing, localized shear zones leads to an order-of-magnitude reduction in strength. This finding indicates that water–rock interactions along outer-rise faults play a role in deepening the fault depth and increasing water budgets in the oceanic upper mantle.

[S-CG60] Investigation of inputs to subduction zones: Influence of tectonic processes on the incoming plate

convener:Makoto Yamano(Earthquake Research Institute, the University of Tokyo), Tomoaki Morishita(School of Geoscience and Civil Engineering, College of Science and Technology, Kanazawa University), Gou Fujie(Japan Agency for Marine-Earth Science and Technology), Chairperson:Makoto Yamano(Earthquake Research Institute, University of Tokyo)

Various tectonic processes occur on the seaward side of the trench associated with bending of the incoming oceanic plate, e.g., fracturing of oceanic crust, infiltration of water, and intraplate volcanism. Investigation of these processes and their influence on the incoming plate provides important information on the boundary condition at the trench, inputs to subduction zones. Variation in inputs should significantly affect geophysical/geological phenomena around the plate interface and geochemical cycles in subduction zones. We welcome contributions from a broad range of earth science (geophysics, geology, petrology, and so on) discussing topics related to inputs to subduction zones such as occurrence of tectonic processes due to bending of the incoming plate, modification of the incoming plate by the processes, relationship between the processes and the inherited structure of the incoming plate, and influence of the processes on the subduction plate interface. We hope discussions are made on studies of a variety of subduction zones, including the Japan Trench and the Nankai Trough, and comparative studies among different subduction zones.

The structure of an incoming oceanic plate influences various seismic behavior in subduction zones. In the outer-rise region of the Japan Trench, young intraplate volcanism, called “petit-spot” volcanism, has been reported (e.g., Hirano et al., 2006). However, to date, only a few geophysical studies have focused on petit-spot volcanism and its modifying effects on the structure of the oceanic crust. In 2017, Japan Agency for Marine-Earth Science and Technology (JAMSTEC) conducted an active-source seismic survey in the trench-outer-rise region of the Japan Trench during cruise KM17-05 of R/V *Kaimei* (Ohira et al., 2018). For refraction studies, a large tuned airgun array with a total volume of 10,600 cubic inches was towed at 10 m depth and fired every 100 m. The seismic data were recorded on 40 OBSs deployed along a 100-km-long line (line A4) with a spacing of 2 km. The multi-channel seismic (MCS) reflection data were collected by R/V *Kairei* using a 6,000-m-long, 444-channel streamer cable during cruise KR11-05 and KR15-07. On the MCS reflection section, we imaged opaque reflections at the top of the oceanic crust and a weak or absent Moho reflection under petit-spot volcanoes. The P-wave velocity model obtained from first-arrival traveltime tomography showed the large velocity reduction at the top of the oceanic crust near petit-spot volcanoes. This velocity reduction can be interpreted as fractures, hydration, and high porosity associated with petit-spot volcanic activity, as well as by the development of bend faulting (e.g., Fujie et al., 2018) and ancient fractures (Fujie et al., 2016). Our results suggest that petit-spot volcanism is one of the contributing factors leading to structural variation and modification of the incoming oceanic plate prior to its subduction. In 2018, additional new seismic reflection data from 25 –50 km interval of profiles were acquired during cruise KM18-06 of R/V Kaimei to cover the outer-rise region from 38°N to 36°N at the south of the petit-spot region. The new data provide along-strike structural variations attributed to petite-spot, bend fault and seamount.

Dependence of calculation parameters on tsunami height from the outer-rise earthquakes

*Toshitaka Baba[1], Naotaka YAMAMOTO CHIKASADA[2], Yasuyuki Nakamura[3], Gou Fujie[3], Koichiro Obana[3], Seiichi Miura[3], Shuichi Kodaira[3]

1. Graduate School of Science and Technology, Tokushima University, 2. National Research Institute for Earth Science and Disaster Resilience, 3. Japan Agency for Marine-Earth Science and Technology

Huge subduction zone earthquakes often induced outer-rise earthquakes occurring on the sea side from the trench axis. An outer-rise earthquake of M8 class which becomes a pair of the 2011 Tohoku earthquake has not yet been occurred. We should pay much attention on the next outer-rise earthquakes and resulting tsunamis in the Japan Trench. A data base (DB) retrieval type system is common for real-time tsunami prediction. It is necessary to incorporate various kinds of earthquake scenarios into DB without deficiencies. However, we have no clear answer to questions such as to how many every kilometer to be set in the depth of the fault stored in the DB in order to guarantee the prediction accuracy of a tsunami. Therefore, in this study, sensitivity analysis of calculation parameters was carried out for tsunamis caused by the outer-rise earthquakes.

We set nine basic fault models of the outer-rise earthquakes with reference to the results of crustal structure surveys and ocean bottom seismic observations. Each basic fault model was composed of multiple small subfaults of about 20 km in length, and the top end of the small subfaults were all set to be 0.1 km under the seafloor, the slope angle was 60 ˚, and the rake angle was 270 ˚. The strike angle of the subfaults were based on seafloor topography and crustal structure surveys. Magnitude (M) of the modeled outer-rise earthquake was calculated from the total fault length (L) using an outer-rise earthquake scaling law complied by Álvarez-Gómez et al. (2012). The fault width (W) was constrained at the lower end of the seismogenic layer, but it was given as L/W = 1 until reaching the lower end. The thickness of the seismogenic layer was set at 35 km. Slip amount was calculated from the fault area and M. Crustal deformation due to the faulting was calculated assuming a semi-infinite homogeneous elastic medium (Okada, 1985). The initial sea surface distribution was obtained considering the effect of tsunami excitation by horizontal movement of the slope (Tanioka and Satake, 1996) and the hydraulic filter (Kajiura, 1963) on the calculated seafloor crustal deformation. For tsunami calculations, the nonlinear shallow water equations were solved on a finite difference scheme.

Tsunamis were calculated by changing the calculation parameters and methods of the basic model one by one. The investigated cases were when using the dip angle of (1) 45 ˚or (2) 75 ˚against the dip angle of 60 ˚of the basic model, (3) when using the model approximated by single subfault, (4) when ignoring the effect of horizontal movement of the slope , (5) when ignoring the hydraulic filter, (6) when using different fault scaling laws, and (7) when using the nonlinear dispersive equations in the tsunami calculations. For the coastal tsunami height, the residuals from the basic model were evaluated by the root mean square error normalized by average tsunami height (NRMSE).

In this study, the difference in the coastal maximum tsunami height between the basic model and the derived model was large when (6) the fault scaling law was different (NRMSE ~ 0.50). This is followed by (7) without dispersion (NRMSE = 0.28), (5) without hydraulic filter (NRMSE = 0.21), (1)(2) when using the different dip angle in the subfault (NEMSE ~ 0.15), and (3) when approximating with a single fault (NRMSE = 0.10). Since the outer rise earthquake is a high-angle fault occurring in the relatively flat ocean, the effect of horizontal movement of the slope is relatively small (NRMSE = 0.025).

Bathymetry data analysis and multi-channel seismic reflection survey in the 1933 Sanriku earthquake (Mw 8.4) rupture region

*Tomoko Hanyu[1], Jin-Oh Park[1], Yukari Kido[2]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Japan Agency for Marine-Earth Science and Technology

In the northern part of the Japan Trench, the 1933 Showa-Sanriku earthquake (Mw 8.4), a normal-faulting earthquake such as large tensional outer-rise earthquake, occurred 37 yr after the 1896 Meiji-Sanriku tsunami earthquake (Mw 8.0) that ruptured plate-interface. Both earthquakes generated tsunamis that caused serious damages along the Sanriku coast of northeast Japan. As such, similar large-scale outer-rise earthquake is predicted to occur after the 2011 Tohoku-Oki earthquake (Mw 9.0). However, evolution process of the outer-rise earthquake fault has been poorly understood so far. From seismological data, Kanamori (1971) indicated that the faulting, with the average slippage on the fault plane, dipping 45˚ towards N 90˚W, amounts to 3.3 m, took place over the entire thickness of the lithosphere that caused the Showa-Sanriku earthquake. However, the large fault that penetrated from seafloor to upper mantle has not been identified yet. In order to obtain detailed images of the normal faults that cause the outer-rise earthquakes of the Japan Trench, we will carry out a multi-channel seismic reflection survey using R/V Shinsei-maru in April 2019. Before the survey, fine scale bathymetry data sets (90 meters grid), which were compiled and provided by JAMSTEC (after Kido et al., 2011), are used for the analysis of seafloor structure. In this study, we applied second-order differentiation to detect the horst-graben structures with slope at a steep angle.

The characteristics of horst-graben structures and inherited seafloor spreading fabric in our study are well concordant to those of Nakanishi (2011). In the region between 37.5˚N–40˚N, the horst-graben structures with trend of N20˚E–N30˚E are sometime broken continuity by the abyssal hills with trend of N50˚E–N70˚E and fault structures with trend of N20˚W. In a part of this region, between 38˚N–39˚N, was considered that this region was formed as a result of the ridge propagation (Nakanishi, 2011). The structure boundary on the crustal surface and Moho is observed by the OBS survey (Fujie et al., 2016) that located at a fracture zone associated with the ridge propagation, although the length of the distorted crustal surface and Moho across the fracture zone is extended about 60 km. Note that, Nakanishi (2011) suggested that the fault structures with trend of N20˚W are inherited seafloor spreading fabric and reactivated by the subduction. On the other hand, Kobayashi et al. (1998) interpreted that these faults are formed by the orientation change of the plate strength which is caused by the trend change of the trench axis from south to north along the Japan Trench. A few faults with slope angle of more than 50 degrees are recognized, but there is lack of continuity. Around the 39.5˚ N, continuous horst-graben structures with slope angle of about 30 degrees are confirmed. These continuous horst-graben structures have average vertical displacement of about 200 m. The longest horst-graben structure has length of about 250 km, and the northern portion of this fault reaches the hypocenter of Showa-Sanriku earthquake. It remains uncertain whether this structure is actually continuous or just apparently continuous. Because of the overlying sediment and lower resolution than that of seismic reflection data, the accurate slope angle and vertical displacement could not be obtained from only the bathymetry data. While, the large horst-graben structures could be detected by the bathymetry data and analysis of the bathymetric data is useful for planning the observation lines and pick-up the specific observation data set from the database. We will present the results of the bathymetry data analysis and preliminary results of the multi-channel seismic reflection survey in April 2019, and discuss the normal fault behavior associated with the outer-rise earthquakes.

Sedimentation process and deformation process before sinking of sediment on oceanic plate: examples in northwest Pacific Ocean and Sumatra

*Kiichiro Kawamura[1]

1. Yamaguchi University

The sediments covering subducting oceanic plate are pressed into continents. Sometimes it forms an accretionary prism, and they may collapse into submarine landslides in some cases. Also, it may become a fault zone during the further subducting process. Thus, the sediment on the subducting oceanic plate plays an important role in the continental deformation process in the subduction zones. From the above viewpoint, it is a currently required research topic to compare sedimentological, mineralogical and mechanical characteristics of sediment on the subducting plate before and after subducting. In this paper, I report the characteristics of sediments before subducting in the Northwest Pacific and off Sumatra in detail.

As a sedimentary feature, in the northwest Pacific, the effect of the bottom current is large, and it appears in sediments and ocean bathymetry as shown below. In this area, the Pacific plate is subducting into the Izu-Ogasawara Trench on the south part, the Japan Trench and the Kuril Trench in the northern part. In this area, a strong north - south bottom current along the trench axis has been observed at about 6000 m in water depth (Lee et al., 2003, etc), from the north to the south on the land side (Owens and Warren, 2001). Furthermore, in the deep ocean of the Pacific Ocean, flow from west to east is reported (Fujio and Yanagimoto, 2005).

18 sediment samples have been collected using a 4-m piston corer system. The samples are composed mainly of diatomaceous hemipelagic clay and volcanic ash layers. The volcanic ash layer is dated using the glass refractive index measurement. Various sedimentary structures are found in the clay layer, and in particular, on the trench axis, eroded surfaces are seen, suggesting the influence of bottom currents along the trench axis. The effect of the bottom current also is detected in the magnetic susceptibility anisotropy data. In addition, it is suggested that topographical features by the bottom current is also found from an asymmetric depression and/or moat (depth of several tens of meters, width of several kilometers) around a knoll. Thus, from sediments and submarine topography, The sediment and topographic features would suggest that we could understand the predominant bottom current directions in the northwest Pacific during the geological time scale of several thousand years.

As a mechanical feature, burial consolidation and/or diagenesis are one of the important processes in sediments before subducting. It is known that when deposits are consolidated during burial, dehydration progresses in response to stress and the microstructure gradually changes accordingly. They are called to be a card house structure in the shallow part, a book house structure in the middle part, and a shale-like (preferred horizontally orientation) structure in the deep part. They would be proceed by creeping by particle rotation and sliding and are generally considered to be secondary consolidation that occurs after primary compaction caused by reduction of excess pore fluid pressure. Burial consolidation causes gradual hardening of sediments, but the rate of change of its mechanical properties varies depending on various factors such as deposition rate, geothermal gradient, pore water chemical composition, particle composition. For example, the shale-like structure occurs at an void ratio of about 1.0 in the input

©2019. Japan Geoscience Union. All Right Reserved.

sediments of the Izu-Ogasawara trench and occurs at about 0.5 off Sumatra. In addition, in the Izu-Ogasawara Trench and the input sediments off the coast of Sumatra, various deformation structures of the normal fault system are observed as a deformed structure before subducting.

By clarifying the sedimentary features such as the input sediments and the surrounding seabed topography, it is possible to interpret the difference of the deposition rate, the distribution area of the layer thickness of the sediment and so on. In addition, the mechanical characteristics represent the pre-additional deformation process before subducting, that is, in the area where the accretionary prism body is developing. The detailed characteristics of the sediments before subducting as described above will be important information for comparing deposits after subducting.

Exploring more asthenospheric melt: the preliminary report of KS-18-9 cruise, R/V Shinseimaru

*Naoto Hirano[1], Taku Yutani[2,1], Yuki Katsuragi[1], Jeffrey Anthony Oalmann[3], Fidel Costa Rodriguez[3], KS-18-9 Onboard Scientific Party

1. Tohoku University, 2. University of Bayreuth, 3. Nanyang Technological University

The petit-spot magmas originate from the asthenosphere, ascending along the flexed zone of the outer-rise prior to plate subduction (Hirano *et al.*, 2006, *Science* 313, 1426; Valentine & Hirano, 2010, *Geology* 38, 55; Yamamoto *et al.*, 2014, *Geology* 42, 967; Machida *et al.*, 2015, *EPSL* 426, 267). This forms a unique opportunity to examine the asthenosphere below the ocean in a region outside of the well-examined but spatially restricted areas of MORs and hotspots. Recent researches, however, indicates that most of petit-spot erupted on concavely flexed plate are highly reacted with the depleted lithosphere during the magma ascending to surface. Geochemical composition of entrained xenolith from depleted mantle is disturbed by wall-rock interaction (Pilet *et al.*, 2016, *Nature Geosci.* 9, 898). From the observation that silica-poor alkaline melt is shifted to silica-rich subalkaline melts as a result of metasomatic interaction with lithospheric peridotite, the wall-rock interaction with silica-poor and strongly alkaline melts produces melts such as the majority of those at petit-spot lavas in NW Pacific (Pilet *et al.*, 2008, *Science* 320, 916). Experimental studies conducted by Machida *et al.* (2017, *Nature Comm.* 8, 14302), moreover, reported that the NW Pacific petit-spot melts were last equilibrated with peridotite at 1.5–2 GPa corresponding to the mid-depth or lower part of NW Pacific lithosphere as well. The melt fractionation must occur at depths greater than the mid-lithosphere because the geobarometer of peridotitic xenoliths shows the deepest 43 km (Yamamoto *et al.*, 2014) in spite of the lack of olivine phenocrysts. The most of petit-spot magma fractionated in mid- or lower lithosphere with some metasomatic reactions with depleted mantle at lower lithosphere during the magma-ascending to surface.

We newly discovered the directly ascending petit-spot melt from asthenosphere (Sato *et al.*, 2018, *Int'l. Geol. Rev.* 60, 1231). The lavas, silica-poor and strongly alkaline with phenocrystic olivines, are completely discriminated from the majority of previously reported petit-spot. They selectively erupt atop the outer-rise wherein the lithosphere behaves entirely in an extensional regime during the ascent of melt from asthenosphere. We conducted several dredge samplings in order to access the asthenosphere more directly, by the research cruise KS-18-9, R/V *Shinseimaru*, in August 2018, supported by AORI, Tokyo University, and the JSPS Japanese-German Graduate Externship. Special thanks to shipboard scientific party (S. Machida, N. Akizawa, T. Ishii, A. Matsumoto, M. Kaneko, Y. Sato, Y. Nakano, T. Yutani, K. Azami, S. Sakai, Y. Katsuragi), captain A. Tsuji, and crews on KS18-09, R/V Shinsei.

The petit-spot rocks are dredged at a lava field displayed by multibeam survey without any topographic highs, which are small blocks surrounding very fresh glass with less palagonitic alteration and manganese coating, implying the lavas are quite young. The quenched glass rinds were analysed for major and trace elements by an electoron microprobe at University of Bayreuth, Germany (co-work with T. Yutani), and an inductively coupled plasma–mass spectrometer (LA-ICP-MS) at Nanyang Technological University, Singapore (co-work with F. Rodriguez, J. Oalmann, Y. Katsuragi), respectively. As we gained "directly ascending petit-spots" from several volcanoes on this cruise, it is possible to recognize their source and melting process from their geochemical variations. The strongly alkaline lavas, directly ascending petit-spot, show clear trend in Zr/Hf, Sm/Hf ratios and HREEs, implying the carbonatite addition with the depth in source mantle. We present here the several processes of lithospheric flexure, metasomatized

lithosphere, magma-fractionation, and finally, upwelling directly from asthenosphere occur prior to trench-oceanward slope, which would be significant components into the incoming oceanic plate.

Inputs of Argon on oceanic plate at subduction zones

*Shigeaki Ono[1]

1. Japan Agency for Marine-Earth Science and Technology

It is known that noble gases are key tracers to understand the evolution of the mantle because of their inertness nature and isotope variations. However, a mechanism of recycle of noble gases in the deep mantle is still open question. Argon is one of noble gases and has three isotopes, ^{36}Ar, ^{38}Ar, and ^{40}Ar. Holland and Ballentine [2006] proposed that Ar from the mantle is identical to seawater component. This indicates that the seawater recycling dominates a behavior of Ar in the mantle. In contrast, the systematic analysis for noble gases indicates that ocean island basalt has a primordial signature which is different from atmosphere component [Mukhopadhyay 2012]. The recycling of Ar between the Earth’ s surface and the deep mantle has been discussed using the isotope data of noble gases. However, it is difficult to understand a mechanism of recycling of Ar because of a lack of knowledge for physical and chemical properties of Ar at high pressure and high temperature.

In this study, we used density functional theory to investigate the melting temperature and thermal pressure of Ar. We also performed the high-pressure experiments to determine the room-temperature equation of state for Ar. The combination of the first-principles molecular dynamics calculations and the high-pressure experiments led us to determine reliable physical properties, such as the equation of state and the melting temperature, over a wide range of pressures and temperatures.

The equation of state of Ar has been investigated to 382 GPa and 3000 K using the diamond anvil cell experiments and the first-principles molecular dynamics method. A large volume dependence of the thermal pressure of Ar was revealed at pressures higher than 200 GPa. A significant temperature dependence of the calculated effective Grüneisen parameters was confirmed at high pressures. This indicates that the conventional approach to analyze thermal properties using the Mie-Grüneisen approximation is likely to have a significant uncertainty in determining the equation of state for Ar, and that an intrinsic anharmonicity should be considered to analyze the equation of state. A melting temperature of Ar was estimated from calculation data, and a significant pressure dependence was confirmed. If the pressure-temperature path of the subducted slab is lower than critical condition, ~750 K and ~7.5 GPa, solid Ar can be carried down into the deep mantle. Melting of solid Ar in the upwelling mantle plume occurs at the bottom of the transition zone.

[S-CG61] Dynamics in mobile belts

convener:Yukitoshi Fukahata(Disaster Prevention Research Institute, Kyoto University), Toru Takeshita(Department of Natural History Sciences, Graduate School of Science, Hokkaido University), Hikaru Iwamori(Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology), Chairperson:Toru Takeshita, Kenta Kobayashi

The dynamic behaviours of mobile belts are expressed across a wide range of time scales, from the seismic and volcanic events that impact society during our lifetimes, to orogeny and the formation of large-scale fault systems which can take place over millions of years. Deformation occurs on length scales from microscopic fracture and flow to macroscopic deformation to plate-scale tectonics. To gain a physical understanding of the dynamics of mobile belts, we must determine the relationships between deformation and the driving stresses due to plate motion and other causes, which are connected through the rheological properties of the materials. To understand the full physical system, an integration of geophysics, geomorphology, and geology is necessary, as is the integration of observational, theoretical and experimental approaches. In addition, because rheological properties are greatly affected by fluids in the crust and fluid chemical reactions, petrological and geochemical approaches are also important. After the 2011 great Tohoku-oki earthquake, large-scale changes in seismic activity and regional scale crustal deformation were observed, making present-day Japan a unique natural laboratory for the study of the dynamics of mobile belts. This session welcomes presentations from different disciplines, such as seismology, geodesy, tectonic geomorphology, structural geology, petrology, and hydrology, as well as interdisciplinary studies, that relate to the dynamic behaviours of mobile belts.

Fault zone development in the West Tottori area, Japan

*Kenta Kobayashi[1]

1. Department of Geology, Faculty of Science, Niigata University

Several kinds of investigations were carried out in the NW-SE trending aftershock area of the 2000 Tottori-ken Seibu earthquake (Mj7.3) and along the Nichinanko lineament (L=15km) which runs the SW of the aftershock area. The earthquake occurred in a place where no active fault is identified, with the exception of some short lineaments (e.g. Kanayama lineament: L=2km) in the direction of NW-SE. After the earthquake, many NW-SE to WNW-ESE trending surface ruptures were found in the aftershock area (e.g. Ryokusuien in central part of the area). They indicated sinistral slip sense. On the other hand, brittle fault rock zones are distributed in Late Cretaceous to Paleogene granitic rocks. Miocene rhyolite, basalt-andesite and aplite dikes intrude the granitic rocks, also deformed along the faults. Most fault planes with WNW strike indicate sinistral slip, and most of those with ENE strike show dextral slip. The determined paleo stress field is strike slip type of N-S tension, congruents with the 2000 Tottori-ken Seibu earthquake. However, along a few fault planes with WNW strike the early dextral slip is detected (e.g. Ryokusuien). Brittle fault rock zones are also distributed along the NW-SE trending Nichinanko lineament. Along the lineament, a wider mixture zone is formed. Fault planes with NW strike indicate sinistral slip.

XRD analysis showed that the gouge in the central part of the aftershock area is mainly composed of illite and chlorite (Kobayashi et al., 2006; Manaka et al., 2012), while the gouges in the NW and SE parts of the aftershock area (Kaneki et al., 2019) and those along the Nichinanko lineament (Manaka et al., 2012) are rich in halloysite. Chemical processes are different between these fault rock zones. In the central part of the aftershock area, most gouges were formed at a higher temperature than the neighborhood. On the other hand, the latest gouge is rich in smectite at Ryokusuien.

These facts suggest that the maturity of the fault zone along the aftershock area has been a low level, WNW strike fault planes (R1 shears) and ENE strike fault planes (R2 shears) formed predominantly. Therefore, the early kinematic (dextral) and chemical (illite-chlorite forming hydrothermal alteration) processes are remained. On the other hand, the activity along the Nichinanko lineament has been a higher level in a shallower depth (halloysite-smectite forming environment), NW strike fault planes (Y surfaces) formed predominantly, the remarkable Nichinanko lineament developed. In addition, the Komachi-Ohdani lineament system (L=12km) which runs the NE of the aftershock area also developed. How these fault zones have developed over a long period of time will be discussed.

Inerastic deformation around focal area of the 2000 Western Tottori EQ (M7.3) detected by “0.1 manten” Hyper Dense Seismic Observation (2)

*Satoshi Matsumoto[1], Yoshihisa Iio[2], Shin'ichi Sakai[3], Aitaro Kato[3], Takuo Shibutani[2], Yuto Hayashida[4], Group for 0.1 manten Hyper dense seismic observation

1. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, 2. Disaster Prevention Reasearch Institute, Kyoto University, 3. Earthquake Research Institute, University of Tokyo, 4. Graduate School of Science, Kyushu University

Seismic observation with high resolution and sensitivity is a key to solve a question how the crust deforms inelastically and accumulate stress in the seismogenic zone. We have completed a seismic observation for one year at one thousand sites (0.1 Manten seismic observation) in an aftershock area of the 2000 Western Tottori earthquake (M7.3). The seismic network with radius of about 18 km covered entire aftershock area of the M7.3 event. Automatic-detecting procedure was applied to the seismograms in order to detect small earthquakes. Over 5000 events of natural earthquakes were obtained during the observation. Sensitivity of the network is high and its detection limit for small earthquake was about magnitude of -1.0. Focal mechanism of the earthquake with magnitude range below zero could be determined. In this study, we showed inelastic deformation due to seismic activity of the small earthquake around the fault of the main shock.
The detected aftershock activity is higher at north of the large slip area of the main shock than at other area. Taking into account the activity just after the main shock, we found inelastic strain rate inferred from the aftershock reveals spatial heterogeneous distribution. The rate is smaller than inverse of the lapse time from the main shock, indicating that inelastic deformation due to the aftershock continue long duration compared with other part of the fault. This area corresponds to the hypocentral area of the preceding activity toward the main shock of the Western Tottori earthquake. These suggests that the high inelastic strain rate area at the north of the asperity of the main shock behaved as low strength area relaxing stress at the part and resulted stress loading to the asperity. Comparing the rate with it estimated from the preceding activity to the main shock, the rate at present is similar order to one before the mainshock. It suggests a possibility that loading processes exists below the low-decay rate zone where seismic activity observed prior to the main shock.

Non-double couple micro-earthquakes in the focal area of the 2000 Western Tottori earthquake (M7.3) by "0.1 manten" hyper dense seismic observation

*Yuto Hayashida[1], Satoshi Matsumoto[2], Yoshihisa Iio[3], Shin'ichi Sakai[4], Aitaro Kato[4], Group for "0.1 Manten" hyper dense seismic observation Group registration

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University, 2. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, 3. Disater Prevention Research Institute, Kyoto University, 4. Earthquake Research Institute, the University of Tokyo

Earthquakes with non-double couple (NDC) component could provide information such as geometric fault complexity, tensile failure, and fluid flow in faulting.

In this study, we found definite micro-earthquakes with NDC in the aftershock area of the 2000 Western Tottori earthquake (M 7.3) based on polarity analysis for first P-wave motion data from “0.1 manten” hyper dense seismic observation. The observation composed of a thousand seismic stations successfully provided with high resolution focal mechanisms of a lot of micro-earthquakes in the area.

We attempted to model the events with NDC by tensile-shear faulting, shear-tensile faulting, and multiple events with pure double couple focal mechanisms. We analyzed 8 events that distributes the entire after shock area.

Plausible models for the events occurring at shallower and deeper depth are the faulting with tensile crack and the multiple shear faulting models, respectively. The results suggest that fluid contributes to the crack opening at the shallow part. In contrast, fluid pressure does not sufficient to open tensile crack at the deep part. Therefore, the depth of the boundary may relate to the pressure of fluid at the earthquake fault. In addition, the events with large NDC component were located around co-seismic large slip area of the mainshock of the Western Tottori earthquake. This suggests that fluid exits around the co-seismic slip area.

Stress field in the Western Tottori and Western Shimane regions deduced by the dense seismic observations

*Yoshihisa Iio[1], Manten seicmic observation group, Manten seismic observation group in the Western Tottori region

1. Disater Prevention Research Institute, Kyoto University

We estimate the stress field in the Western Tottori and Western Shimane regions by precisely analyzing focal mechanisms from dense seismic observations installed in and around the seismic belt in the San-in district, Japan. In this region, we installed a Manten seismic observation network with 50 high-gain short period seismometers in 2009, and another Manten seismic observation network with 81 high-gain short period seismometers in 2015. In this study, we utilize data from these Manten seismic observation networks and nearby permanent seismic stations, and also those obtained by the group for the dense aftershock observations of the 2000 Western Tottori Prefecture earthquake. It was inferred by previous studies that the azimuths of the maximum compressional stress axis in the seismic belt are oriented in a WNW–ESE direction, while they are aligned in almost the EW direction i in the south of the seismic belt, in the inland plate along the Nankai Trough. This spatial change in the stress field in and around the seismic belt was qualitatively explained by the aseismic slip in a ductile fault zone in the lower crust beneath the seismic belt. The results obtained in this study are summarized as follows. In the region from the aftershock area of the Western Tottori prefecture earthquake to the vicinity of Sanbe-san, rotation of $\sigma 1$ direction was observed. On the south side of the region, the direction of $\sigma 1$ is N 90 ˚E to N 110 ˚E, whereas in the region it is N 100 ˚E to N 140 ˚E, which is a rotation of 20 to 30 ˚. Rotation is large on the west side of the aftershock area of the Western Tottori prefecture earthquake and in the vicinity of Sanbe-san and small between them. In the area around the Shinji Rift zone on the north side of this area, although the number of data is small, the direction of $\sigma 1$ is N 120 ˚E to N 140 ˚E, and the rotation is the largest among the entire area. In this way, in this area, the rotation of the direction of $\sigma 1$ is seen in the central part of the San-in earthquake zone, and among them, the rotation is locally large in the west side of the aftershock area of the Western Tottori prefecture earthquake and in the vicinity of Sanbe-san. In addition, $\sigma 1$ turns greatly around the Shinji Rift zone north of the seismic belt.

In the lower crust beneath the vicinity of the seismic belt, a low velocity zone of about 50 km in width is estimated at a depth of 25 km (Tsuda et al., 2017). In the upper crust, large low velocity anomalies are seen along the Shinji Rift Belt. The stress field in this area may be formed by shortening in the orthogonal direction of the Shinji groove belt in addition to the slow slip immediately beneath the seismic belt Kawanishi et al. (2009) estimated the stress field with the seismic zone as a region, but it became clear that there is an internal structure in it.

Modeling the spatiotemporal change in stress field around Hinagu fault zone through the 2016 Kumamoto earthquake sequence, in central Kyushu, Japan

*Ayaho Mitsuoka[1], Satoshi Matsumoto[2], Azusa Shito[2], Yusuke Yamashita[3], Manami Nakamoto[4], Masahiro Miyazaki[3], Shin'ichi Sakai[5], Yoshihisa Iio[3], Group for urgent joint seismic observation of the 2016 Kumamoto earthquake

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University, 2. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, 3. Disaster Prevention Research Institute, Kyoto University, 4. Association for the Development of Earthquake Prediction, 5. Earthquake Research Institute, The University of Tokyo

For a purpose of understanding physical process of earthquake generation, knowledge of stress condition around a fault is required. We estimated stress field and discussed its spatiotemporal change around Hinagu fault zone that was the hypocentral area of the 2016 Kumamoto earthquake sequence.
The 2016 Kumamoto earthquake sequence occurred around Hinagu and Futagawa fault zones in Kumamoto prefecture, central Kyushu Island, Japan. The largest foreshock with Mj 6.5 (Mj: magnitude by Japan Metrological Agency) on April 14, 2016 was located Hinagu fault zone. The mainshock (Mj 7.3) generated slip at both Hinagu and Futagawa fault on April 16, 2016. After that, many earthquakes occurred around these faults until now.
In this study, we estimated the spatiotemporal change in the deviatoric stress field and its differential stress. For discussing the temporal change in the target region, we divided time sequence into three periods: (1) prior to the sequence (i.e. before Mj 6.5 event), (2) between the foreshock and the mainshock, and (3) after the mainshock. We compared the deviatoric stress fields with the co-seismic stress change by faulting of this sequence. From focal mechanism solutions from January 1, 1993 to December 31, 2017, we estimated the deviatoric stress field using the method by Matsumoto [2016]. We adopted fault slip models of the fore- and mainshock, which is the slip distribution projected result by Asano and Iwata [2016] on the fault geometries determined from the distribution of hypocenters. We performed a grid search procedure for the differential stress at each spatial block with horizontal size of 0.05˚in latitude and longitude, and 5 km in depth.
As a result, we captured the stress condition in the both period (1) and (3). Before the foreshock (i.e. period (1)), the differential stress around the fore- and mainshock faults is higher than the other region, its value is from several MPa to several tens of MPa. On the other hand, the differential stress in south area of Hinagu fault zone ranges from about 0.1 to 1 MPa. We found the foreshock and mainshock occurred in the state of high differential stress.
After the mainshock (i.e. period (3)), the spatial heterogeneity of the differential stress still remained. However, the differential stress at the area around the hypocenters of the fore- and mainshock is about half of that before the foreshock. At the southeast area of Hinagu fault, the differential stress is about twice of that before, so potential of occurring earthquake becomes relatively high compared with the prior state to this sequence.

Development of the Median Tectonic Line Fault zone in Mie Prefecture, Southwest Japan : A Possible Interpretation for Strain Localization and Softening

*Toru Takeshita[1], Dong Van Bui[1], Thomas Anthony Czertowicz[1], Shun Arai[2], Takafumi Yamamoto[3], Jun-ichi Ando[3], Norio Shigematsu[4], Koichiro Fujimoto[5]

We have investigated the development of the Median Tectonic Line (MTL) fault zone in the upper-plate Ryoke granitoids in Mie Prefecture, southwest Japan. In the study area, although c. 80 m thick cataclasite develops in direct proximity to the MTL, mylonitic rocks were pervasively formed before the formation of cataclasite, which can be divided into protomylonite distributed from the MTL to the point 300 m north from it and mylonite distributed from the latter point to the one at c. 800 m further north from the MTL. However, in the protomylonite zone, ultramylonite with the thickness up to c. 50 m is developed in direct proximity to the MTL, which occur as clasts in the cataclasite zone. We also have found that the protomylonite originates from tonalite, while the mylonite originates from granite. Hence, the boundary between the protomylonite and mylonite exactly coincides with the protolith boundary.

We analyze both microstructures and c-axis fabrics in recrystallized quartz grains from the protomylonite and mylonite zones along the MTL. In the protomylonite, sizes of recrystallized grains formed by subgrain rotation (SGR) recrystallization are low ranging between 7-14 microns. In particular, in the ultramylonite, the recrystallized grain sizes ranges between 4-11 microns. The quartz c-axis fabrics mostly show a Y-maximum pattern. On the other hand, the mylonite zone can be divided into two subzones in terms of quartz microstructures. In the subzone from 300 m to 490 m from the MTL, the microstructures are characterized by elongated grains (S-type) with finer recrystallized grain sizes varying between 11-20 microns formed by SGR. On the other hand, in the zone from 490 m to 800 m from the MTL, the microstructures are characterized by relatively equant grains (P-type) with coarser recrystallized grain sizes varying between 49-107 microns and lobate grain boundaries formed by grain-boundary migration (GBM) recrystallization. In both mylonite subzones, a Y-maximum quartz c-axis fabric dominates.

We further analyze microstructures of K-feldspar, and infer deformation temperatures based on the two-feldspar geothermometry after Stormer (1975) and Stormer and Whitney (1985) in the mylonite zone which originated from granite. While K-feldspar porphyroclasts are broken in the S-type mylonite subzone, they are plastically deformed to a sigma shape in the P-type mylonite subzone. Myrmekite pervasively develops at the periphery of K-feldspar porphyroclasts from the entire mylonite zone. Using the chemical compositions of K-feldspar and plagioclase in myrmekite, we infer the deformation temperatures in the mylonite zone. At the northernmost P-type mylonite subzone, the deformation temperatures are calculated at 500 ˚C, which decrease to 400 ˚C at the boundary between the P- and S-type mylonite subzones, and further decrease in the S-type mylonite zone, ranging between 350-400 ˚C.

Plastic deformation is dominant in the granite than in the tonalite at higher temperatures than 500 ˚C, leading to the formation of mylonite in the former area alone, perhaps because granite including abundant K-feldspar is rheologically weaker than tonalite. Subsequently, with decreasing temperature,

©2019. Japan Geoscience Union. All Right Reserved.

plastic deformation becomes localized in the southern part of the mylonite zone. At 400 ˚C, only the S-type mylonite subzone continues to deform, and the protomylonite starts to deform at higher stresses than in the S-type mylonite subzone. With further decreasing temperatures, the plastic deformation of S-type mylonite subzone is abandoned at 350 ˚C, and the further plastic deformation only occurs in the ultramylonite at 300-350 ˚C, leading to the formation of very fine-recrystallized quartz grains and type-I crossed girdle quartz c-axis fabric with R-maxima, which is further followed by cataclasis. We currently do not have a good idea on why the zone of plastic deformation suddenly jumps from the southernmost S-type mylonite subzone, which is 300 m apart from the MTL, to the protomylonite zone in direct proximity to the present MTL, forming ultramylonite. However, since a type-I crossed girdle quartz c-axis fabric with R-maxima is developed in the ultramylonite, it can be inferred that water weakening of quartz either by decreasing the strength of slip systems or facilitating dynamic recrystallization occurs in the protomylonite zone, which could have been caused by infiltration of water along newly formed fractures.

[S-CG61] Dynamics in mobile belts

convener:Yukitoshi Fukahata(Disaster Prevention Research Institute, Kyoto University), Toru Takeshita(Department of Natural History Sciences, Graduate School of Science, Hokkaido University), Hikaru Iwamori(Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology), Chairperson:Tomomi Okada, Ryosuke Ando(Graduate School of Science, University of Tokyo)

The dynamic behaviours of mobile belts are expressed across a wide range of time scales, from the seismic and volcanic events that impact society during our lifetimes, to orogeny and the formation of large-scale fault systems which can take place over millions of years. Deformation occurs on length scales from microscopic fracture and flow to macroscopic deformation to plate-scale tectonics. To gain a physical understanding of the dynamics of mobile belts, we must determine the relationships between deformation and the driving stresses due to plate motion and other causes, which are connected through the rheological properties of the materials. To understand the full physical system, an integration of geophysics, geomorphology, and geology is necessary, as is the integration of observational, theoretical and experimental approaches. In addition, because rheological properties are greatly affected by fluids in the crust and fluid chemical reactions, petrological and geochemical approaches are also important. After the 2011 great Tohoku-oki earthquake, large-scale changes in seismic activity and regional scale crustal deformation were observed, making present-day Japan a unique natural laboratory for the study of the dynamics of mobile belts. This session welcomes presentations from different disciplines, such as seismology, geodesy, tectonic geomorphology, structural geology, petrology, and hydrology, as well as interdisciplinary studies, that relate to the dynamic behaviours of mobile belts.

Occurrence of any conspicuous ramp on the low angle basal detachment causes hindrance on the overall wedge progression and behaves as an asperity by localizing stress in the inter-seismic gaps. The mid-crustal ramp on the Main Himalayan Thrust (MHT) results in strain partitioning by focusing seismicity, including 2015 magnitude 7.8 Gorkha earthquake in the central Nepal Himalaya. However, the ramp structure is laterally discontinuous; even absent in some parts of the Himalaya (e.g. western Bhutan). Interestingly, it has been widely shown that the geometry of the basal detachment (in terms of presence or absence or geographic location of the ramp) provides first order control on the along strike variations in the structure, topography, low-temperature thermochronological ages, precipitation, exhumation and erosion patterns. Motivated by the absence of any mechanical explanation for these peculiar observations, we compare physical and numerical experiments with the geology of the frontal eastern Himalaya to show how the mechanically weak coal bearing Gondwana horizon controls the position of the basal detachment in space and time. Our modelling results confirm that the initial spatial distribution of the Gondwana horizon strongly influences the position of the mid-crustal ramp at different geographic location which resulted in segmented MHT structure (Fig. 1). The numerical modelling largely validates the physical experiments and explains the rock uplift and river incision pattern recorded in the Nepal Himalaya.

Control of fault weakening on the structural styles of underthrusting-dominated non-cohesive tectonic wedges

*Arthur Bauville[1], Mikito Furuichi[1]

1. Department of Mathematical Science and Advanced Techology, JAMSTEC

Underthrusting is a typical process at compressive margins responsible for nappe stacking and sediment subduction. Despite being essential for orogenesis, and the subduction cycle, the mechanics of underthrusting is still incompletely understood. The critical taper theory predicts that underthrusting occurs only in the limit where $\mu_b'=\mu'$, with μ' and μ_b' the inner and basal effective coefficient of friction, respectively. Paradoxically, in nature, underthrusting is associated with weak faults. For instance, at erosive subduction margins, sediments are dragged in subduction, while normal faulting in the middle prism suggests the plate boundary is weak. Wang et al., (2010) have proposed that dynamic fault strength variations during the earthquake cycle can reconcile these observations. In their model, underthrusting occurs during earthquakes when the fault is strong and normal faulting occurs in the prism during the interseismic period when the fault is weak. However, recent evidence (Gao and Wang, 2016) suggests that plate boundaries are relatively weak also during earthquakes.
In this contribution, we investigate the control of permanent fault weakening on the dynamics of a strong-based ($\mu_b'=\mu'$,) non-cohesive tectonic wedge. We control the wedge material strength by a spatially constant fluid overpressure factor (λ^*, and fault strength by a strain weakening factor (χ). We investigated the problem in two steps. First, we used the critical taper theory to determine a mechanical mode diagram that predicts structural styles. This diagram is deduced from the function $\Delta\alpha(\beta,\chi,\lambda^*)$ which is the difference in taper angle at a given β, between the compressively critical taper of a strong-based wedge and the extensionally critical taper of a weak-based wedge ($\mu_b'=(1-\chi)\mu'$). Then, we performed numerical simulations of accretionary wedge formation to establish the characteristics of these structural styles regarding wedge and fault geometry. We determined there is a continuum of structural styles with three end-members occurring at the theoretically determined mechanical mode transitions.

Style 1 is characterized by thin tectonic slices and little to no underthrusting.
Style 2 is characterized by thick slices and nappe stacking.
Style 3 is characterized by the complete underthrusting of the incoming sediments.

The model gives a mechanical explanation that reconciles underthrusting with weak faults. In agreement with observations, the model predicts the occurrence of style 2 in strong-based sandbox experiment. Finally, we argue that style 3 is triggered by any mechanism, such as material weakening, erosion or sedimentation, that limits the surface angle such that the incoming material is always significantly under-critical.

The *M* 7.8 Kaikoura earthquake occurred in the northern South Island on 3 Nov., 2016, involving the rupture of > 20 faults. To understand the complexity of the Kaikoura earthquake, details of fault geometry, seismic velocity distribution and stress field are necessary. We have undertaken seismic tomography and stress tensor inversion using focal mechanisms along the c. 200 km length of the rupture zone.

Data from both 51 temporary stations and 22 GEONET stations were collected from March 2011 to December 2017. Hypocenter locations and the three-dimensional velocity structure were determined using the method of Zhang and Thurber (2003 and 2006).

The hypocenter of the Kaikoura earthquake and aftershocks near the Kekerengu fault locate along lineaments where seismic velocity changes horizontally.

In the uppermost crust, lower velocities occur beneath the Emu Plain and Cape Campbell. Higher velocities occur in and around Kaikoura.
In the middle to lower crust, high Vp/Vs occurs not only in and around the hypocenter but also along the northern part of the rupture zone.
In the lowermost crustal or uppermost mantle, high Vp occurs east of the Kekerengu fault and south of the Hope fault and beneath the Canterbury plains faults. This high Vp likely corresponds to the Pacific plate.

These complexities in the seismic velocity structure may relate to the multi-rupture character of the Kaikoura earthquake. In particular, spatial correlations between rupture areas and high Vp/Vs suggests the involvement of overpressured fluid in the nucleation and propagation of rupture segments, which is also supported by the reactivation of unfavourably oriented strike-slip ruptures, many lying at c.70˚ to regional sigma-one stress trajectories.

Dynamic Rupture Simulation Reproduces Spontaneous Multifault Rupture and Arrest During the 2016 Mw 7.9 Kaikoura Earthquake

*Ryosuke Ando[1], Yoshihiro Kaneko[2]

1. Graduate School of Science, University of Tokyo, 2. GNS science

The 2016 Kaikoura (New Zealand) earthquake is characterized as one of the most complex multifault rupture events ever observed. We perform dynamic rupture simulations to evaluate to what extent relatively simple forward models accounting for realistic fault geometry can explain the characteristics of coseismic observations. Without fine parameter tuning, our model reproduces many observed features including the multifault rupture, overall slip distribution and direction, and the locations of the maximum slip and rupture arrest. In particular, our model shows spontaneous arrest of dynamic rupture at the both ends of the ruptured fault system due to smaller prestress levels expected from a regional tectonic stress field. Both the simulated and the observationally inferred source time functions show similar double peaks with a larger second peak. The results illuminate the importance of the 3-D fault geometry in understanding the dynamics of complex multifault rupture.

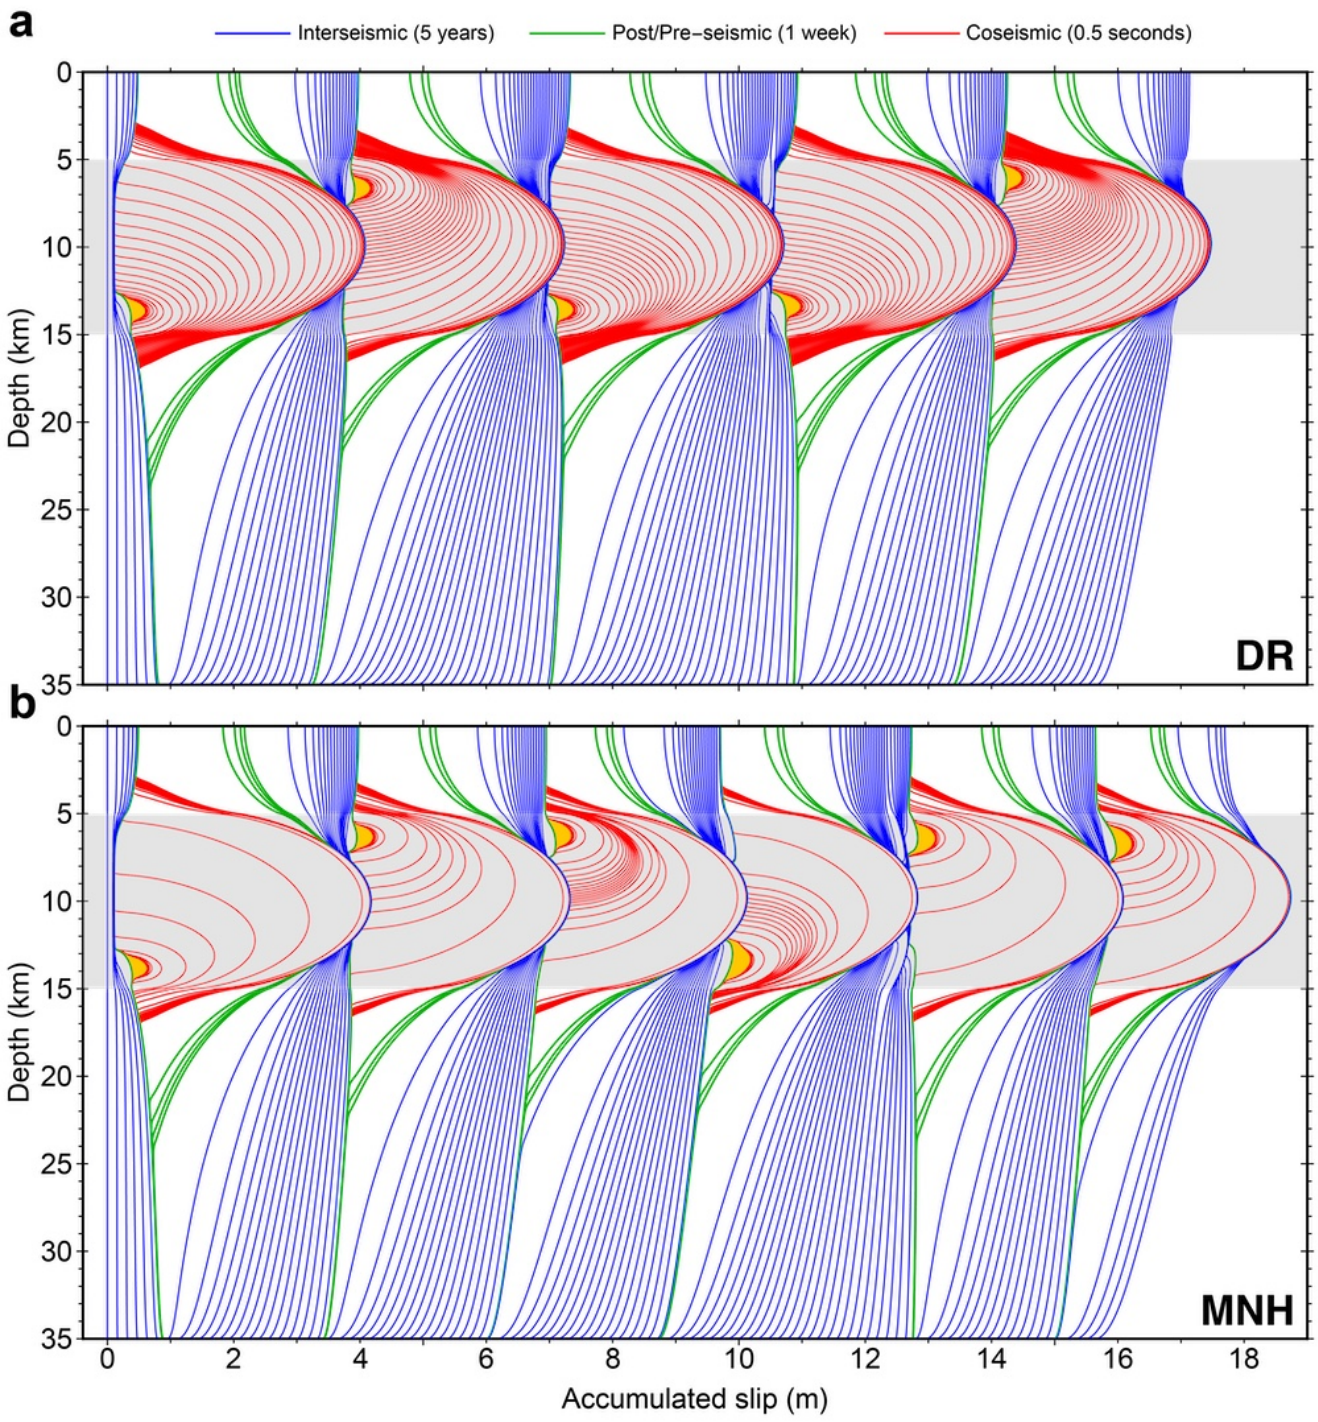
Ductile deformation explains the physics of friction and genesis of earthquakes

*James Daniel Paul Moore[1], Stefan Nielsen[2], Lars N Hansen[3]



1. Earth Observatory of Singapore, 2. University of Durham, 3. University of Oxford

Seismic hazard presents a significant global threat to both life and property, with increased urbanisation in the twenty-first century only intensifying the risk as populations concentrate near fault lines. It is therefore imperative to develop a clear understanding of the physical origins of earthquakes, with their associated hazards, and use that knowledge to work towards building more resilient societies. To this end, we show that ductile deformation on contact regions within fault zones explains the physics of fault friction, and the genesis of earthquakes. We find the empirical framework of rate-and-state friction may be derived from grain-scale creep processes, and that earthquakes are the macroscopic manifestation of ductile deformation at microscopic contacting regions. The governing equations are well behaved at low slip rates, the seismogenic layer emerges as a consequence of the pressure-temperature dependence of ductile creep processes, and we offer an explanation for the temporal distribution of earthquake clustering.

The physical origins of the laws of friction that govern the genesis of earthquakes have long been the subject of discussion and debate. Here we demonstrate that the empirical framework of rate-and-state friction is a natural consequence of grain-scale processes, and that fault slip is the macroscopic manifestation of creep on contact asperities, modulated by grain-size processes, at the microscopic scale.We find that common rate-and-state parameters derived from laboratory data and geodetic observations are entirely commensurate with known flow laws: diffusion creep, dislocation-accommodated grain-boundary sliding, and dislocation creep. Additionally, we find that the temperature, grain size, and stress dependence of these flow laws naturally give rise to the full spectrum of fault behaviour from stable creep, through slow slip and tremor, to bilateral ruptures. In particular a seismogenic layer emerges spontaneously from the interplay of these creep mechanisms, for which the stability is primarily determined by the grain-size dependence of the active flow law. Our framework unifies the work of friction experiments for localised deformation and flow laws governing distributed deformation, whilst simultaneously addressing a number of shortcomings of the Dieterich-Ruina form of rate-and-state friction, such as the non-physical divergence as the sliding velocity tends to zero. We present very close equivalence between rate-and-state friction and established flow laws, and provide an explanation for the emergence of the seismogenic layer.

The seismic moment, stress drop, and strain energy release for the rupture of asperities

*Mitsuhiro Matsu'ura[1]

1. Institute of Statistical Mathematics

Seismic moment and stress drop are known as the most fundamental physical quantities characterizing seismic events. The seismic moment of an event is clearly defined as the product of its rupture area (S), average fault slip (D), and the rigidity of the surrounding elastic medium (Aki, 1966; Kostrov, 1974), but the stress drop is not (Madariaga, 1979), which depends on adopted source models. In the simplest case of a circular crack model with uniform stress drop, the stress drop is proportional to D and the inverse of the square root of S, and so independent of seismic moment (e.g., Kanamori & Anderson, 1975). However, with the simplest model, Nadeau & Johnson (1998) found a clear dependence of average stress drop on seismic moment from a detailed analysis of repeating earthquakes along the Parkfield segment of SAF. This empirical scaling relationship for average stress drop is contrary to what is commonly assumed in seismology: that is the stress drop is independent of earthquake size.

Since then, many seismologists (e.g., Sammis & Rice, 2001; Anooshehpoor & Brune, 2001; Beeler, Lockner & Hickman, 2001; Johnson & Nadeau, 2002) tried to explain the observed size-dependence of stress drop by theoretically considering the loading and rupture processes of asperities, but didn't succeed. The size-dependence of stress drop seems to result from an inappropriate assumption for background slip rates [1]. Aside from that, in these theoretical studies, the asperity is modeled as a completely locked small patch surrounded by freely creeping zones. In such modeling, steady tectonic loading causes stress singularity just inside the locked patch and broad slip-deficit distribution on the surrounding freely creeping zones. The rupture of the asperity suddenly releases the concentrated stress at the small locked patch and causes fault slip so as to cancel the slip deficit distributed on the surrounding zones without stress drop. Even in such a case, we can clearly define the seismic moment by multiplying the integral of coseismic slip over the whole fault plane by the rigidity of the surrounding medium. In contrast, the definition of average stress drop is multiple (Noda, Lapusta & Kanamori, 2013), which suggests that the static stress drop on fault may not be the fundamental physical quantity.

Recently, on the basis of theoretical consideration to the equation of motion in continuum mechanics, we derived a fundamental equation that the volume integral of static stress changes caused by a seismic event over the whole elastic region is mathematically equivalent to its moment tensor [2]. Applying the fundamental equation to the energetics of shear faulting, we can obtain a quantitative relationship between the work done for shear faulting and the change in elastic strain energy in the surrounding region. This means that we should use the volume integral of static stress changes or the total strain energy change as the fundamental physical quantity characterizing seismic events.

Yonaguni-jima Island, Okinawa prefecture is an island located at the westernmost tip of Japan and belongs to the Southern part of the Ryukyu arc. In Yonaguni-jima Island, many normal faults cut the Miocene Yaeyama Group and the Quaternary Ryukyu Group to make the diamond island shape. The fault found at the Sanninudai located in the southeastern part of the Yonaguni-jima Island has all parts of the fault zone; fault gouge part, fault damage zone, wall rock zone. The fault found at the Sanninudai can be activated by the stress field similar to the one in the Okinawa Trough (active back arc basin). Our results indicate that the stress field in the Yonaguni-jima Island may be different from the one in island part of the South Ryukyu arc (e.g., Miyako-jima Island and Ishigaki-jima Island). The relationship between the width of the fault zone and the length of the fault and the relationship between the total displacement and the width of the fault core are similar to them of the typical characteristics of faults. Based on our results, we discuss the possibility that the fault found at the Sanninudai is a suitable site to understand the crustal dynamics (back arc opening) of subdaction zone.

1. Fossa Magna Museum, 2. National Research Institute for earth Science and Disaster Resilience, 3. Kanazawa University, 4. Jiji Press

1. Background
The Itoigawa Geopark in Niigata Prefecture features an educational park centered on a fault exposure of the Itoigawa-Shizuoka Tectonic Line (ISTL) called the Fossa Magna Park which was first opened in 1990. It is a roughly 10 minute walk from the main parking lots along National Route 148 to the fault exposure. One of the interpretive panels near the exposure features a QR code inviting visitors to examine the 'NIED Quake map!', a page which records seismic activity managed by the National Research Institute for Earth Science and Disaster Resilience (NIED). This report presents one example of academic study using the 'NIED Quake map' with high school students.

2. Earthquake and Fault Study Example (Private High School in Kanagawa Prefecture)
(1) Explanation of the Fossa Magna and Earthquakes (Via Outdoor Interpretive Panels)
The students learn that the ISTL forms the western fault boundary of the Fossa Magna, that has a very close connection to the formation of the Japanese Archipelago, and that the movement of faults causes earthquakes and particularly large fault movements cause the faults to reach the surface where they are called active faults, and that these movements over time form and shape the land around us.
(2) Information from 'Quake map!'
The students use their own smartphones to access the 'NIED Quake map!' site where they can observe the earthquake activity for past ten years in the Itoigawa Area. Through this the students understand the following:
There are many earthquakes occurring around us, even if we don't feel them.
There are distinct areas where earthquakes do and don't occur.
There are earthquakes which concentrate in a line or elliptical shape.
Inland earthquakes occur at depths shallower than 10 km.
There are earthquakes which occur both along and away from active faults.
Along the same active fault, there are areas that do and do not have earthquakes.
Itoigawa experiences no historically large earthquakes, so there is no active fault.
Areas which experienced historic earthquakes have a greater concentration of earthquakes.
Afterwards, the students look at the 5 year, 1 year, 30 day, weekly and 24 hour maps. On the 24 hour map they can see recent earthquakes, where many students are surprised by how many earthquakes occur without being felt.
(3) Fault Exposure
The students see that the fault exposure is crumbling and the rocks have been broken. The gaps among the fault breccia are filled with even more broken fine material (fault gouge) which can be easily depressed with a finger. In fault gouge, striations which show the direction of fault movement can be observed, so the students can understand how fault gouge was formed by the crushing of rock by fault movement. An earthquake of magnitude 7 causes a change in elevation of about 1.5 to 2 m, so the gap seen along the ISTL (over 6,000 m) can be understood to have formed over 3000-4000 fault movements. Through this the students can imagine how deep the Fossa Magna is. They can also understand how faults

expand.

3. Conclusion
The earthquake distribution map of 'NIED Quake map!' allows for visual understanding of Japan's most tectonically active places and is a valuable tool for understanding the connection between earthquakes and faults. Studying the fault exposure allows seeing only the result of geological processes, but using 'Quake map', the students get a better image of these processes and how they are continuing beneath us. Hopefully further experience in using 'Quake map' for high school students can be used to improve its use in earthquake risk reduction education.

The Opening of ‘NIED Quake map!’ and result of questionnaire survey about interest of local seismicity

*Makoto MATSUBARA[1], Azusa Nishizawa[1], Shin Aoi[1], Ko Takenouchi[2], Yoshihiro Hiramatsu[3], Kazuyuki Nakagawa[4]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Fossa Magna Museum, Itoigawa City, 3. School of Geosciences and Civil Engineering, College of Science and Engineering, Kanazawa University, 4. Jiji Press

1. Introduction
The Seismological Society of Japan (SSJ) established the committee to support the activity of Geopark in order to notify people of the current condition of seismology with the same perspective of people. Geoparks are single, unified geographical areas where sites and landscapes of international geological significance are managed with a holistic concept of protection, education and sustainable development. There are many both natural and cultural heritages of earthquakes in Geoparks. However, there is also a lack of introduction to recognize the local seismicity.
National Research Institute for Earth Science and Disaster Resilience (NIED) opened the web site named as 'NIED Quake map!' to visualize the local seismicity at a geosite in July 2018. It is easy to observe current seismicity detected by Monitoring of Waves in Land and Seafloor (MOWLAS) and historical earthquakes. This shows the seismicity in central Japan around the Itoigawa Global UNESCO Geopark through the QR code on the guide plate at the Fossa Magna Park.

2. 'NIED Quake map!'
This page first shows the local seismicity in one year. The color and size show the depth and magnitude of the earthquake, respectively. The latest earthquake is shown with the star. There are volcanoes, active faults, and rivers to grasp the place. People can recognize the seismicity within the ground with seeing both the memorized large earthquakes and no feeling microearthquakes.

3. Results of views
We confirm about 20-30 accesses from the outside. In the case of the field trip by the group at Fossa Magna Park, there were 50-60 accesses.

4. Cooperation with geopark
NIED concluded the Comprehensive Partnership Agreement with Japan Geopark Network (JGN) on the use of the data and research results at the Geoparks on October 13, 2018. NIED also concluded the memorandum regarding the use of the 'NIED Quale map!' NIED plan to open web sites according to request from the Geoparks through JGN.

5. Questionnaire survey about interest of local seismicity and expansion of 'NIED Quake map!'
The committee of the SSJ gave seminars of seismology for Geoparks. We explained the use of the historical earthquakes in 2018 and conducted the questionnaire survey for regions composing the Japan Geopark Network, which consists of the UNESCO Geoparks, the Japan Geoparks, and associate members for proceeding to be Japan Geoparks. We obtained the answer from 26 Geoparks and seven associate members. We note as Geopark both Geopark and the associate members.
There are geosites of historical earthquake in 46 % of Geoparks. About 91 % of Geopark have interest in the local seismicity, however, there are some display of local seismicity in only 27 Geoparks. About 82 % Geoparks have an interest to introduction of local seismicity, however, it depends on the cost. Geoparks

©2019. Japan Geoscience Union. All Right Reserved.

only share the cost for display of local seismicity since NIED construct and manage the web site of the 'NIED Quake map!' NIED plans to construct and supply the web sites in accordance with the request from the Geoparks

Keywords: NIED Quake map!, display of local seismicity

Bandaisan Geopark's traveling exhibitions and lectures on "Debris avalanche in the world"

*Hiroshi Sato[1], Tadahide UI[2]

1. Mt.Bandai Museum, 2. CeMI

Bandaisan Geopark was built with the aim of showing visitors how the landform and people's lives were affected by the mountain collapse which occurred 2 times in 50,000 years ago and 1888. Mt. Bandai Museum is the core exhibition facility.
The year 2018 marked a turning point, 130 years after the collapse, and 30 years after the museum opened.
Since rock avalanches (debris avalanche) occur only about once in 100 years in Japanese Island, a special exhibition was held at the Museum to highlight the avalanche, which is not well known to the public. In addition, the traveling exhibition was also carried out in the volcanic museum in the whole country.
Believing that this traveling exhibition would promote cooperation and mutual understanding among the geoparks that participated in the event, we also held symposiums for public and lectures for school children.
In this presentation, the outline of planned exhibition, symposium and lectures are introduced, and the difference of understanding of volcano by region is introduced from the participant’ s questionnaire carried out in delivery lectures.

PLANETARY SCIENCE Education in Geoparks-Science Festival for Youth Formation experiment of Izumo Plain in Shimane convention

*Kunihiro Abe[1]

1. Shimane Penunsula Shinjiko Narumi, Kuibiki Geopark Promotion Committee

The Shinji Lake Nakaumi Geopark, Shimane Peninsula, has been certified as a Japan Geopark for the third year. The Geopark certification in Shimane Prefecture will be second after the Oki Global Geopark. Although the popularity of the Oki Geopark has been recognized by the prefectural residents, the Shinji Lake Nakaumi is still strong in the Shimane Peninsula. In conjunction with cognitive activities, the Promotion Council is strongly required to utilize geoparks and to promote educational activities. The 18th Annual Science Festival for Youth at the Shimane Convention, the booth of the Shimane Peninsula and the Shinji Lake Nakaumi Geopark exhibited in Shimane Prefecture, the booth of the "Shinji Lake, the birth of the Izumo plain" and it is compatible to, 360 ×270 ×By making the basin topography of the Hiikawa and Shinmon River with the sand in the mold of 120cm, fixing the watering hose to the headwaters of the two rivers, and continuing watering, the sediment is gradually deposited in the waters sandwiched between the Chinese mountains and the Shimane Peninsula, according to the sedimentary experiment by running water. It is the one to understand the state that the Shinji Lake is formed with the passage of time while observing the process that the Izumo plain is done. The west side of Izumo Taisha is a plain and it is not a sea area. The effects of the eruption of Mijar volcano, located in the Kamimon Basin, cannot be ignored. Photos and materials of the Shinji Lake Nakaumi of the geopark that the Izumo plain was formed between the Shimane Peninsula and the Chugoku Mountains located in the north by the volcanic activity of Mt. Hiikawa, the Kamikadawa River, the granite of the Chugoku Mountains, and the Sanjar Mountain which formed the Izumo plain known for Tsukiji Matsu The experiment was performed while contrasting it with the rock sample.

Investigating the mechanism maintaining a subsurface ocean is necessary to understand the condition under which aqua planets can form. Recent planetary exploration missions suggest the presence of subsurface oceans in several outer Solar System bodies. Most of them are icy satellites of giant planets, and tidal heating is considered to play a major role in maintaining their subsurface oceans. The presence of a subsurface ocean is also suggested for Pluto, though tidal heating is negligible. In order for heat-depleted Pluto to possess a subsurface ocean, thermal convection should not occur in the ice shell above the ocean, suggesting its high viscosity. This suggestion is consistent with studies of viscous relaxation of the ice shell. This may be due to a high concentration of contaminants, such as ammonia, in the ocean, resulting in an extremely low temperature ocean; however, ammonia is not observed on Pluto’ s surface, and comets, whose bulk chemistry should be similar to that of Pluto, contains ammonia only little. Thus, the reason why Pluto possesses a subsurface ocean is a mystery.

Here we propose a thin gas hydrate layer exists between the ice shell and a subsurface ocean, and it prevents freezing of a subsurface ocean. Gas hydrates act as a thermal insulator because of its low thermal conductivity. We perform numerical calculations of long-term thermal evolution and show that a warm ocean and a cold ice shell can be maintained for a long time and that the freezing of the ocean is ineffective. We also perform numerical calculations of long-term viscoelastic deformation and show that the significant viscous relaxation requires billions of years. Our proposal does not require large amounts of contaminants. Comets contain a few % of methane with respect to water, for example, and this concentration is sufficient for creating a thin gas hydrate layer prohibiting the ocean freezing. Some gas species are easily trapped in gas hydrates while others are not, and this selective trapping may explain a large difference in volatile compositions of comets and Pluto’ s surface. The subsurface ocean maintenance mechanism we propose here would also be applicable to larger icy bodies other than Pluto. In addition, our proposal may explain the diversity of surface chemistry of Kuiper Belt Objects.

Isotopic measurement of gas hydrate sample simulating environment of icy satellite and icy planet: Equipment development and consideration for observation method

*Kushi Kudo[1], Atsushi Tani[1], Naohiro Yoshida[2,3]

1. Graduate School of Human Development and Environment, Kobe University, 2. Department of Chemical Science and Engineering, School of Materials and Chemical Technology, Tokyo Institute of Technology, 3. Earth–Life Science Institute

According to recently observation using Cassini, icy satellites and icy planets are known for having plume including the organic matter, liquid internal ocean and rocky crust (e.g. Porco et al. 2006; Waite et al. 2006, 2009, 2017). From this fact, extraterrestrial life is regarded as being likely to exist in icy satellites and icy planets. Especially in plume gas species, methane (CH_4) is regarded as one of the candidate of signature of biological activity due to CH_4 formation reaction by methanogen. However CH_4 gas in plume is consisted of not only microbial origin but also primitive CH_4 and hydrothermal formation and this fact does not let CH_4 detection is sufficient for conclusion for existence of biological activity by microbe. Therefore, we consider evaluation of the elementary process of CH_4 isotopic fractionation ($\delta^{13}C$, δD of CH_4) via room experiment important for isotopic observation of icy satellite and icy planet in nearly future.

In this study, we focus on CH_4 hydrate which is reservoir to produce the plume (Kieffer et al. 2006) and want to evaluate isotopic fractionation with its formation. Isotopic fractionation with hydrate formation has been found at only δD of CH_4 (~10‰) at the Earth condition (P: ~10 MPa) (e.g. Hachikubo et al. 2007, 2015; Lapham et al. 2012). In the case of condition of icy satellite and icy planet, pressure range of icy satellite and icy planet is wider than of the Earth, and therefore we need to estimate isotopic fractionation at 10–100 MPa scale. Thus we started design for cell for hydrate formation experiment at ice crust condition (P: ~150 MPa). In presentation, we will mainly introduce progress of the equipment development and observation method.

As next stage, we are also planning analyze isotopic fractionation of surface rocky core, and CH_4 translation process using 3-D flow simulation for evaluate CH_4 isotope changing in icy satellite and icy planet. We will subject to Enceladus, Europe and Triton as target.

Keywords: isotopic observation, isotopic fractionation, methane, icy satellite and icy planet, gas hydrate

Dynamics of icy crust of the Enceladus with tidal heating and asymmetric distribution of heat generation in the rocky core

*Kaho Harada[1,2], Takashi Nakagawa[3], Manabu Morishige[2], Shigenobu Hirose[2]

1. Keio University, 2. JAMSTEC, 3. University of Hong Kong

We investigate the dynamics of icy crust of the Enceladus, that is the sixth-largest moon of the Saturn, for understanding the diversity of the surface geology found from the planetary explorations. Especially, we have an interest in the ‘Tiger Stripes’ found around the south pole with heat release of 15.8 GW. The mechanism of formation of the Tiger Stripes is recognized as active terrains caused by thermal convection of icy crust driven by tidal heating. However, such active terrains caused by the tidal heating could not be explained by the tidal heating solely because they are only found around the south pole. Several researches concerning the convective dynamics of icy crust on the Enceladus have suggested some north-south asymmetries, for example in the thickness of icy crust or viscosity, but they have not been well-understood for the origin.

Here, to resolve the formation mechanism of Tiger Stripes, we propose the hypothesis on the north-south asymmetric distribution of heat producing elements in Enceladus’ s rocky core. We assume that the more heat producing elements can be concentrated into the southern hemisphere. Since, regarding the formation mechanism of the Enceladus, the rocky core would not be likely to experience the large-scale melting events such as the magma ocean, the Enceladus still tends to maintain the chemical structure of the early distribution. Hence, the current chemical structure of rocky core may be heterogeneous, which can lead to north-south asymmetric distribution of heat generation. We test the hypothesis for using a numerical model of icy crust dynamics including tidal heating and north-south asymmetric distribution of heat generation in the rocky core. For tidal heating of the icy crust, we impose an analytical solution of tidal deformation considering viscoelasticity in a thin shell on the surface (e.g., Ojakangas and Stevenson, 1989). For north-south asymmetric distribution in heat generation in the rocky core, we set the temperature of the bottom of the icy crust as 273 K in the northern hemisphere, 283 K in the southern hemisphere.

Our results indicate that heat upwelling around the south pole and heat downwelling around the north pole when we assume tidal heating and north-south asymmetric distribution of heat generation. Rather, the asymmetric distribution of heat generation is more important for finding the more active dynamics around the south pole. A quantitative test indicates that the plume heat flow coming from the south pole region is about 300 GW, which is about 20 times as large as the observational constraints (15.8 GW). This suggests that the amplitude of heterogeneous heat generation is too large. Again, although the amplitude of heat transfer of plume in southern hemisphere is too large, the geographical distribution of plumes can form the north-south asymmetric distribution of heat generation. Therefore, this hypothesis provided here would be promising to reveal the origin of the hydrogen plumes on the Enceladus found by the Cassini mission.

Chlorine-bearing aqueous fluid at crust/mantle boundary in mid-ocean ridge hydrothermal system: a case study of crustal diopsidite from Oman ophiolite

*Norikatsu Akizawa[1], Akira Miyake[2], Akira Tsuchiyama[2]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Graduate School of Science, Kyoto University

Hydrothermal circulation in the mid-ocean ridge system is responsible for elemental enrichment, and modification of original chemical composition of the oceanic crust. In recent times, deep-rooted hydrothermal circulation down to crust/mantle boundary has been introduced regarding geological investigations and numerical models. The deep-rooted hydrothermal circulation in the mid-ocean ridge system can be one of the necessary mechanisms generating plate tectonics due to mantle hydration lowering mantle viscosity. In order to assess the mechanism of the mantle hydration in the mid-ocean ridge system, chemical composition of mantle-buffered hydrothermal fluids must be characterized. Here, we present a series of intense investigations for aqueous fluid inclusions in crustal diopsidites from Oman ophiolite. The crustal diopsidite is considered as a reaction product between gabbro (lowermost crustal material) and seawater-derived hydrothermal fluids en route from the mantle to the crust. Considering that Cr-rich minerals such as chromian spinel (Cr-spinel) and chromian garnet (uvarovites) are contained in the crustal diopsidites, the hydrothermal fluids involved were enriched in Cr. A few micrometer-sized inclusion of aqueous fluid with chromian spinel grains was frozen with a nitrogen gas-cooled cold stage, and investigated with a focused ion beam equipped with a scanning electron microscope and an energy dispersive X-ray spectrometer (cryo-FIB-SEM-EDS system). The results showed that the Cr-spinel-bearing aqueous fluid inclusion contains Cl. Regarding the mass and chemical composition of the Cr-spinels in the aqueous fluid inclusion, Cr content in the aqueous fluid was estimated at ~71400 ppm. Although Cr is considered relatively insoluble in aqueous fluids, solubility of Cr depends strongly on the activity of Cl due to complexation reactions with Cl. We propose a possibility that seawater-derived hydrothermal fluids penetrated throughout the crustal section reacted with Cl-bearing magma portion. Flow direction of the hydrothermal fluids probably changed from downward to upward in response to the heat release of the magma to the hydrothermal fluid.

Phase relation of the $MgSO_4$-H_2O system under high pressure

*Tadashi Kondo[1], Keita Harada[1], Miki Sirata[1], Takumi Kikegawa[2]

1. Department of Earth and Space Science, Graduate School of Science Osaka University, 2. Institute for Material Structure Science, KEK

Resent planetary exploration projects suggest existence of internal ocean in the several icy satellites. Spectral analysis of surface material of such satellite indicate sulfate materials as solute in the water ocean. Salts change generally the phase relation such as melting temperature and generation of a kind of hydrate, and affects the internal structure of the satellite. For the $MgSO_4$-H_2O system, which was considered as a possible major component in internal ocean, Nakamura and Ohtani (2011) has proposed the phase relation under pressure condition up to 4.5 GPa with existence of epsomite($MgSO_4 \cdot {}_7H_2O$), and discussed a deep internal ocean in the Ganymede. However, the X-ray diffraction pattern they reported as epsomite includes many unidentified diffraction peaks. In this study, we re-examined the phase relation in the system $MgSO_4$-H_2O under pressure by optical observation, micro-Raman, X-ray diffraction at synchrotron facility. High pressure experiments was performed using diamond anvil cell(DAC) up to about 5GPa at room temperature for 5 to 25wt% $MgSO_4$ solution. The results show a quite different phase relation from Nakamura and Ohtani(2011) in $MgSO_4$-rich side and solidified phases. The eutectic composition is almost same as previous report, but pentahydrate($MgSO_4 \cdot 5H_2O$) is newly observed as coexisting phase with Ice VI-VII in solid, and also liquidus phase in $MgSO_4$-rich solution. We observed direct conversion from low-pressure pentahydrate to high-pressure pentahydrate which reported by Wang et al.(2018). We also evaluate the relative density difference between liquid and solid for all composition by gravitational method in DAC. Ice VI is always denser than liquid while hydrate is always less denser than liquid. We will discuss internal structure and evolution of icy satellite based on this new results.

Keywords: Europe, high-pressure experiment, structure of internal ocean

The Origin of Earth's Volatile Composition: Effects of Impact-induced Atmospheric Erosion and Core Formation

*Sakuraba Haruka[1], Hiroyuki Kurokawa[2], Hidenori Genda[2], Kenji Ohta[1]

1. Tokyo Institute of Technology, 2. Earth-Life Science Institute

Unveiling the origin of Earth's volatile composition is crucial for understanding how Earth developed its habitable environment. Carbon (C), nitrogen (N), and hydrogen (H) are the backbone for the chemistry of life and main components of the atmosphere and oceans (e.g., Katling & Casting, 2017). The volatiles in rocky planets are thought to have been delivered by chondritic materials. However, the elemental composition of the bulk silicate Earth (BSE) shows the depletion of C and N relative to H, a high C/N ratio, and a low C/H ratio compared to chondrites (e.g., Hirschmann, 2016; Bergin et al., 2015).

The volatiles delivered to the accreting planet were potentially lost to space by impacts or sequestered in the core. In order to understand how these processes affect the Earth's volatile composition, we modeled both the main accretion stage and the late accretion stage. The former considered the elemental partitioning between the atmosphere, MO, and metal which segregates into the core (e.g., Hirschmann, 2016; Bergin et al., 2015). The latter considered the partitioning between the atmosphere, oceans, and carbonate (the crust) (e.g., Sakuraba et al., 2019). By calculating the evolution for the range of partitioning coefficient, solubilities, and impactor properties, we evaluated how the resulting volatile composition of BSE depends on these input parameters.

As a result, we succeeded to reproduce the elemental composition of major volatile elements in current BSE from a chondritic source when we chose the appropriate parameter values. While the elemental fractionation during the main accretion ended up with the excess of N/C, the preferential loss of N from the atmosphere during the late accretion reproduced BSE's volatile pattern. During the main accretion, C was most affected by the core segregation because C is the most siderophile among the volatile elements. During the late accretion, N was most affected by the atmospheric erosion because C and H were trapped in the surface reservoirs. The different BSE's composition patterns were obtained depending on parameters such as impactor's composition, impactor's size-distribution, and element partitioning properties. Our results suggest that the current Earth's composition can be obtained by the homogeneous accretion of chondritic planetesimals.

Finding of oxidized sulfur species in carbonates from a Martian meteorite Allan Hills 84001 using μ-XANES

*Kajitani Iori[1], Gaku Tanabe[1], Ryoichi Nakada[2], Tomohiro Usui[3], Mizuho Koike[3], Fumihiro Matsuura[4], Tetsuya Yokoyama[1]

1. Tokyo Institute of Technology, 2. Japan Agency for Marine-Earth Science and Technology, 3. Institute of Space and Astronautical Science, 4. Earth-Life Science Institute

The widespread evidence of liquid water on Mars has led to detailed studies of Martian habitable surface environments [1]. Among them is the geochemical study of carbonate in the 4-billion-year old meteorite Allan Hills (ALH) 84001 because the carbonate is interpreted to have formed from fluids in the early stage of Mars history (~4 Ga) [2]. This study examined speciation of sulfur in carbonates of ALH 84001 as a proxy to trace the chemical evolution of fluids that formed the ALH 84001 carbonates.

We conducted sulfur K-edge (2472 eV) micro X-ray absorption near edge structure (μ-XANES) analysis at BL27SU at SPring-8. X-ray beam was focused using a K-B mirror to a final spot size of 15 (H) ×15 (V) μm^2. Prior to the μ-XANES analysis, X-ray fluorescence mapping which was scanned in 20 μm step was obtained to determine the analytical spot with referring to the petrological observation and backscattered electron images using electron prove micro analyzer (EPMA).

A diagnostic signature of oxidized sulfur [S(VI)] was observed in all the analytical points, whereas X-ray absorption peaks corresponding to S(-II) and an organic sulfur (Di-n-octadecyl disulfide) were observed in some analytical spots. We propose two possible processes for the incorporation of S(VI) species in the carbonate grains of ALH 84001 on the Martian surface: (co-)precipitation of sulfate minerals with the carbonate or substitution of sulfate ion for carbonate ion (carbonate associated sulfate: CAS). The incorporation of trace amount of sulfate minerals is consistent with the widespread distribution of sulfate-bearing deposits in Noachian terranes [3]. However, any type of sulfate minerals has not been observed in the carbonate grains of ALH 84001 even using the transmission electron microscope observations [4]. On the other hand, the CAS-bearing carbonates are common on Earth, though the concentration of CAS in carbonate is typically low (~100s-1,000s ppm) [5]. We conducted thermodynamic calculations under conditions proposed to explain the ALH 84001 carbonates [6, 7]. The thermodynamic calculations indicated that sulfur mainly occurred as sulfate ion in water at Eh-pH conditions where the ALH 84001 carbonate precipitated. This result suggests a possibility that the observed S(VI) species could have occurred as CAS in the ALH 84001 carbonates under the fluid conditions ranging from 6 to 9 for pH and -0.25 to 0 for Eh (V).

A study on Martian water environment based on the μ-XRF-XANES analysis for the secondary minerals formed in a nakhlite meteorite (Y 000593) vein

*Keika Suzuki[1], Hiroki Suga[1], Akira Yamaguchi[2], Tomohiro Usui[3], Oki Sekizawa[4], Kiyofumi Nitta[4], Yoshio Takahashi[1]

1. University of Tokyo, 2. National Institute of Polar Research, 3. JAXA, ISAS, 4. JASRI/SPring-8

Martian meteorite nakhlite has attracted attention because it has various secondary mineral assemblages (such as iddingsite) formed by water-rock reaction on the Mars. The iddingsite holds physicochemical information of water when it formed on Mars. However, the formation processes of the minerals are not clear because both carbonates (precipitate under reductive alkaline conditions) and sulfates (precipitate under oxidative acidic conditions) that cannot coexist under an equilibrium condition were found. Among these minerals, sulfate minerals are considered as a terrestrial contamination in several researches in contrast to carbonate minerals accompanied with various secondary minerals such as saponite and serpentine. Here, we examined trace element distribution within the carbonate phases in Y 000593 by FE-SEM-EDS/FE-EPMA and synchrotron-based μ-XRF-XANES in order to determine the transition history of the Eh-pH conditions during the carbonate formation, which reconcile the coexistence of carbonate and sulfate phases in the iddingsite. The detailed understanding of environment (*e.g.,* fluid chemistry) allows us to give a new constraint on the physicochemical evolution of the water that altered the nakhlite body during the last ~6.5 million years.

The polished thin section (PTS: #58-1 in NIPR) of Y 000593 was used for this study. First, the identification of secondary mineral phases in the iddingsite were conducted by FE-SEM-EDS and FE-EPMA at the University of Tokyo. After that, we investigated distribution of trace elements by μ-XRF-XANES at BL37XU of SPring-8, and BL-4A/15A of KEK-PF. Subsequently, we tried to constrain the iddingsite formation environment (such as Eh-pH conditions) from the proportion of secondary minerals.

Carbonates ($FeCO_3$, $MnCO_3$, $CaCO_3$), iron oxides (FeOOH), clay minerals (Fe-rich saponite), and Si-rich vein were identified in the iddingsite from the outside to the center of vein by FE-SEM-EDS and FE-EPMA analysis. In particular, carbonate aggregates were mainly composed of $(Mn,Fe)CO_3$ and $(Ca,Fe)CO_3$. This result suggested that the iddingsite was altered by CO_2-rich reductive alkaline fluid (Eh≦0.2: pH=9.0~11) [Brookins, 1998]. The difference between distributions of Mn and Ca suggests that fluid with different Eh-pH conditions flowed several times or water condition was changed during carbonate formation because $(Mn,Fe)CO_3$ and $(Ca,Fe)CO_3$ cannot overlap in the Eh-pH diagrams ($(Mn,Fe)CO_3$ precipitate at Eh=-0.4~-0.0: pH=9.0~9.5; $(Ca,Fe)CO_3$ precipitate at Eh=-0.3~-0.1: pH=6.5~9.0). The μ-XANES analysis revealed that Cr(III) coexisted in $(Mn,Fe)CO_3$, since Cr cannot be enriched in MnO_2 in general. It is presumed that Mn precipitated originally as MnOOH, which was transformed into $MnCO_3$ in the presence of alkaline fluid. In $(Ca,Fe)CO_3$, 20% of Fe was present as FeOOH. It was implied that FeOOH is precursor of the $FeCO_3$. In addition, we detected S(VI) in the iddingsite, of which chemical species are the clay mineral adsorbent (Fe-rich saponite), $Mn^{2+}(Mn^{3+})O_4$, and $MnCO_3$ by XANES fitting. This results suggested that sulfate-bearing alkaline fluid flowed in the final stage of the iddingsite formation. Besides, its concentration decrease from the mesostasis phase. Therefore, S(VI) in the clay minerals portion related to the FeS in the mesostasis, and apart of FeS might flowed out as alkaline fluid.

From this study, we conclude that the carbonates in iddingsite formed by reductive alkaline fluid (Eh≦0.2: pH=9.0-11), opposite to sulfate formation. However, it is still not clear whether these carbonate minerals were locally formed or widespread in the nakhlite from the spatial distribution point of view. Therefore, we are trying to observe the 3D structure/elemental distribution of the iddingsite by XAFS-CT method in order to clarify the fluid path related to the formation process of the carbonate minerals.

Influence of water and clay minerals for slope angles on Mars

*Yuhki Matsuoka[1], Ikuo Katayama[1], Rina Noguchi[2], Tomohiro Usui[2]

1. Department of Earth and Planetary Systems Science, Hiroshima University, 2. Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency

An internal frictional angle is determined from a frictional coefficient, which is largely influenced by water and clay minerals. Pore water reduces effective stress, then slope angles becomes smaller. Therefore, slope angles are approximately 25 under hydrostatic condition in contrast with ~35 under dry condition. Most mineral exhibit a constant frictional coefficient μ=0.6-0.85, whereas clay minerals are characterized by a markedly lower frictional coefficient ~0.1 at presence of water (e.g. Behnsen and Faulkner, 2012; Moore and Lockner, 2004). Since a slope angle is roughly equivalent to an internal frictional angle, it is considered that slope angles are affected to become smaller by presence of water and clay minerals including water.
Clay minerals are widely recognized on Mars (Ehlmann and Edwards, 2014) by infrared spectroscopic tools. We focus on a slope angle of Martian topography and research the areas where water might exist.

We focus on Recurring Slope Lineae (RSL) which might suggest the existence of flowing water on Mars (e.g. McEwen et al., 2011; Stillman et al., 2017). Some RSL are found in Coprates Chasma, eastern part of Valles Marineris. We compared slope angles of RSL confirmed points with not confirmed points.
We measured slope angles about 10 points in Coprates Chasma. Slope angles are 31-37 in almost all points and there is no tendency by the presence of RSL and hydroxylated silicates. Therefore, we considered that the contributions of water and clay minerals for slope angles are not prominent in Coprates Chasma.
Furthermore, we verified whether there is contribution of water for slope angles on other areas where water might exist in the same way.

Dark Streak Features in Mongolia: Implications for Formation Mechanisms of Recurring Slope Lineae on Mars

*Maya Nakamura[1,2], Yasuhito Sekine[1], Keisuke Fukushi[3], Noriko Hasebe[3], Davaadorj Davaasuren[4], Yoshio Takahashi[2], Hitoshi Hasegawa[5], Takuro Ogura[6], Koki Morida[3], Tuvshin Gerelmaa[4]

Department of Global Environment and Disaster Prevention, Kochi University, 6. Department of Socio-Cultural Environmental Science, The University of Tokyo

Recurring Slope Lineae (RSL) are dark, narrow features that appear and lengthen on steep (~30°) slopes in warm seasons and fade in cold seasons of Mars (e.g., McEwen et al., 2011). Although the formation mechanism of RSL is still in debate, several processes have been proposed, including liquid brine flows triggered by melting of subsurface ice (a wet process) (e.g., Stillman et al., 2016), and granular flows on slopes (a dry process) (e.g., Schmidt et al., 2017). However, neither wet nor dry processes can explain all of the observables of RSL. In especially, the wet process seems to be inconsistent with the absence of absorptions due to liquid water on RSL and the fact that RSL appear only on steep slopes (McEwen et al., 2014).

Here, we report RSL-like dark streak features in cold, arid areas of Khangai Mountains, Mongolia, on Earth. In this area, discontinuous permafrost and underground ice melt seasonally (Szuminska, 2016). We find that dark streak features in this area show seasonal variation similar to RSL on Mars. Although the slope angles of the terrestrial analogues (~10°) are shallow, the observed similarities in morphology and seasonal activity suggest that the streak features in Mongolia can be promising terrestrial analogues of RSL on Mars.

We also conducted geological survey for the terrestrial RSL analogues found in Mongolia in August 2018. By analyzing the visual images taken by a unmanned aerial vehicle, a three-dimensional topographic structure was constructed. In the geological survey, we measured water contents of soils on site on and outside the dark streak features. The mineralogical compositions and grain size distributions were measured for the collected soil samples.

Although no water flowed during the survey, dark streak features appeared in the terrestrial RSL analog sites in Mongolia. The upstream of the dark streaks are dented in a few centimeters, which becomes shallower toward the downstream. These observations suggest that erosion of surface soils occurred along with the dark streak features in the past. This view is supported by our results of the flow accumulation analysis. Although the formation of the dark streaks relate with water flow, darkening itself is not caused by the presence of liquid water. Water contents in surface soils on the dark streaks show no significant difference from those outside the streaks within errors. The surface of the dark streaks contains less bright sands and more dark silts than the surfaces outside the dark streaks. These results suggest that selective traction of the bright sand-sized grains by surface runoff results in remnant of the dark silt-sized grains on the slopes, which darkens the streak features after dryness. The required friction velocity for the traction is estimated to be ~20 mm/sec, consistent with flow rate due to melting of ground ice in the research area.

Based on the formation mechanism of the terrestrial RSL analogues, we can address the two issues in the

©2019. Japan Geoscience Union. All Right Reserved.

wet process for RSL formation on Mars; 1) no remote-sensing detection of liquid water, and 2) the fact that RSL appear only on steep slopes. At RSL sites on Mars, a thin layer of fine soils is considered to cover basaltic bedrocks on the slopes (Ruff and Christensen, 2002). If liquid brine flows due to melting of underground ice, this can remove fine sands on the slopes. Consequently, dark streak features appear on the slopes due to exposure of underlying basaltic bedrocks after dryness of brine. Given the difference in gravity between Earth and Mars, we suggest that a friction velocity of surface runoff similar to the terrestrial RSL analogs can be achieved when a slope with angle > ~25–30° on Mars, if the depth and width of water flow are same. Our results suggest that RSL on Mars would appear only on steep slopes due to its low gravity.

The occurrence of perchlorate salt in and around the Taklimakan Desert, China

*Haibo Qin[1,2], Shitong Yang[1], Qing Chang[3], Chihiro Miyamoto[1], Yoshio Takahashi[1]

1. Department of Earth and Planetary Science, Graduate School of Science, 2. State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, 3. Japan Agency for Marine-Earth Science and Technology

The formation and preservation of perchlorate (ClO_4^-) in arid and semi-arid deserts on Earth is of growing concern, because the desert could serve as a viable analog for Martian landscape where high perchlorate has been recently discovered. In this study, perchlorate in samples collected from the Taklimakan Desert, Xinjiang, NW China was extracted by water and then measured by IC-MS/MS. The Cl speciation was determined by Cl K-edge XANES analysis to provide direct spectroscopic evidences for the presence of perchlorate. Results showed that the moraine sample contains a higher perchlorate concentration and the ClO_4^-/Cl^- ratio in comparison with sand, river sediment and loess samples. Furthermore, $KClO_4$ was identified as the dominant perchlorate species in the hotspot of moraine sample by μ-XANES analysis, which is significantly different from the dominant presence of $Ca(ClO_4)_2$ and $Mg(ClO_4)_2$ species on Martial soil. This result could be explained by the lowest solubility for $KClO_4$, while other perchlorate salts would be easily leached and mobile on Earth in contrast to Mars where much lesser liquid water is present in the history and present-day. Thus, the finding in this study would provide important insights into the prevalence of perchlorate on Mars.

Measurement technique to quantify OH radicals photochemically generated on the ice surface

*Akihiro Yabushita[1], Hiroaki Nishimoto[1], Akira Harata[1]

1. Interdisciplinary Graduate School of Engineering Sciences, Kyushu University

Reaction processes of many molecules are presumably involved in oxidative atoms/molecules generated by photodecomposition of molecules adsorbed on cold dust grains. Hydroxyl (OH) radicals are considered as one of them. The chemistry of OH radicals plays a key role in the radiolysis and photolysis of water-rich ices of astrochemical origin. Measurements of OH radical in water-ice in the laboratory have been done by UV, EPR, X-ray absorption, and infrared absorption measurements. However, quantification of OH radicals on the ice surface has not yet been made. In the present work, we have tried to develop the measurement technique to quantify OH radicals photochemically generated on the surface of ice film. In this technique, OH are converted to the different molecule by utilizing the chemical reaction, and monitored through reflection absorption infrared spectroscopy. We have investigated the effect of ice temperature on abundance of OH radicals on the ice surface at 8-70 K. In addition, the effect of ice surface morphology on abundance of OH radicals has been studied by preparing the amorphous solid water and polycrystalline ice. The present study experimentally shows both the temperature and surface morphology plays an important role in abundance of OH radicals on the ice surface.

convener:Keisuke Koba(Center for Ecological Research, Kyoto University), Hideaki Shibata(Field Science Center fot Northern Biosphere, Hokkaido University), Naohiko Ohkouchi(Japan Agency for Marine-Earth Science and Technology), Youhei Yamashita(Faculty of Environmental Earth Science, Hokkaido University), Chairperson:Keisuke Koba(Kyoto University), Yoshiyuki Inagaki, Kazumichi Fujii

Biogeochemistry is an interdisciplinary study field including ecology, geochemistry, oceanography, limnology, hydrology, soil science and environmental sciences. Respective researches have tended to be conducted separately so far. This session aims to provide a common platform for biogeochemists of different disciplines, which facilitates the interactive discussion and information exchanges for further development of biogeochemical studies.

Root functional traits could vary among plant species. Root traits are known to respond to a decrease in nutrient availability along with soil aging and plant succession, while root plasticity of single tree species to soil aging is still unclear on a soil profile scale. We investigated whether trees develop finer root architecture along with soil aging in coniferous forest dominated by single species (*Pinus sylvestris*) in Estonia. We measured depth distribution of root biomass and traits (specific root length and tissue density). We compared ca. 100, 300, and 500 years old soils (podzols) on two coastal dune chrnosequence that differ in abundance of soil clay or Al and Fe oxides; Hiiumaa island (facing Balt Sea) and Juminda (facing Finland Gulf), where ridge-swale topography has been developed by isostacy. On Juminda chronosequence where oxalate-extractable P (oxide-bonded) is accumulated in the shallow subsoil, fine roots are concentrated in oxide-rich soil horizons. On oxide-poor Hiiumaa chronosequence where P is translocated in the deeper soil, fine roots are concentrated in organic horizon. Tree roots could change root distribution and surface area depending on extent of P occlusion in clays or leaching in soil aging. Tree community shift toward finer root architecture along with migration of Al and Fe oxides or selection of individuals with finer root structure could occur.

Nitrogen transformation process in newly created salt marsh in the aftermath of the 2011 Great East Japan Earthquake

*Keitaro Fukushima[1], Kazuma Hashimoto[2], Megumi Kuroiwa[3], Katsuhide Yokoyama[2], Yuichi Suwa[3]

1. Center for Ecological Research, Kyoto University, 2. Graduate School of Urban Environmental Sciences, Tokyo Metropolitan University, 3. Faculty of Science and Engineering, Chuo University

Dissimilatory nitrate reduction to ammonium (DNRA) is one of the most important processes of nitrate removal in an anaerobic condition. The 2011 Great East Japan Earthquake and subsequent tsunami attack widely created the intertidal salt marsh along the coast due to sea water intrusion and large ground subsidence. It is necessary to elucidate the ecosystem functions of the newly created salt march. Salt marsh is located in the conjunction point of river and sea, therefore the conversion of dissolved inorganic nitrogen concentrations and forms in the salt marsh may directly impact the productivity and biodiversity of marine ecosystems. However it is still unknown that the role of this specific salt marsh in nutrient dynamics. In September 2017, the surface sediments were collected at the intertidal and subtidal points of the salt marsh, and their potential rates of denitrification, DNRA, and anaerobic ammonium oxidation (Anammox) were estimated by using a 15N tracer technique. As for the nitrate-nitrogen removal in the sediments, the rate of DNRA was ranged from 24.8 to 177 nmol g-1 h-1, while the denitrification rate was ranged from 2.9 to 32.8 nmol g-1 h-1. Our results demonstrate that the DNRA would be significantly important in nitrate removal, and it also suggests that the conversion of inorganic nitrogen form nitrate to ammonium in the salt marsh might affect the species composition of phytoplankton and the primary production in the marsh and the coastal area connected with the marsh.

Succession of soil nitrification potential at a glacier foreland in Svalbard

*Kentaro Hayashi[1], Yukiko Tanabe[2,3], Keisuke Ono[1], Maki Asano[4], Shohei Hattori[5], Masaki Uchida[2,3], Masahito Hayatsu[1]

1. Institute for Agro-Environmental Sciences, NARO, 2. National Institute of Polar Research, 3. SOKENDAI, 4. University of Tsukuba, 5. Tokyo Institute of Technology

Glaciers in Svalbard particularly in the western part of the archipelago has experienced retreating since 20th century. It is concerned that the retreat has been accelerated recently. Glacier retreat on the land uncovers the ground surface under ice. This is a restart of soil genesis as the past soil was lost due to ice erosion. What does happen in nitrogen cycle of the redeveloping soil, and how does ongoing climate warming affect the redeveloping soil nitrogen cycle? In the present study, we focus on nitrification as a source of nitrate. Nitrification is a two-step microbial process consisting of ammonia oxidation to nitrite and nitrite oxidation to nitrate, in which ammonia oxidation is the rate limiting step. Nitrifiers are basically autotrophic and therefore contribute to soil nitrogen cycle from the early stage of soil genesis. It is also interesting that nitrifiers exist across the two domains, bacteria and archaea. The purposes of the present study are to investigate nitrification properties (ammonia oxidation potential [AOP] and flora of nitrifiers) and their time-series changes in the surface soil in the foreland of East Brøgger Glacier near Ny-Ålesund, Svalbard and to elucidate responses of the nitrification properties to environmental manipulations (passive warming and accompanied changes in soil moisture) using open top chambers (OTC). We have been conducting a field experiment at two permanent exclosures established by NIPR in the foreland, i.e., Site 1 (N78˚54'46", E11˚50'18") and Site 2 (N78˚54'54", E11˚49'38"). It is inferred from aerial photos that Site 1 lost its ice coverage between 1969 and 1977, and Site 2 in 1950s or 1960s. Although the foreland was abundant with rocks and stones, the surface was partly covered with mineral soil consisting of fine sand and silt. The field experiment started in July 2015. A passive warming plot and a control plot were set at each site. Twenty polyvinylchloride cores filled with 4-mm sieved and well mixed surface soil collected at each site were set at each of the warming and control plots, of which 5 cores were used to measure soil temperature and volumetric water content and the rest 15 cores were for determining nitrification properties of topsoil (0-2 cm) and subsoil (2-4 cm) collecting 3 cores every July. The field experiment will be end in the summer of 2020. AOP was determined as the nitrite production rate of soil by aerobic shaking incubation with substrate (ammonium sulfate) at 10 and 20 ˚C. Nitrifiers' flora, i.e., gene abundance and species composition of ammonia oxidizing bacteria and archaea will be identified after the completion of field experiment. Annual mean warming effects of the OTC were 0.4–0.5 ˚C at Site 1 and 0.5–0.7 ˚C at Site 2; however, stronger warming effect appeared in the snow season. OTC effects to soil moisture were moistening at the warming plots for the first year, but it turned into drying after that. The determined AOPs at Site 2 were roughly double of those at Site 1. Differences in AOP between the warming and control plots and between the topsoil and subsoil were not significant. The time-series changes in AOP were not monotonous. Meanwhile, AOPs at 20 ˚C were significantly larger than those at 10 ˚C for sites, topsoil and subsoil, and time-series changes. Annual mean soil temperatures at the two sites were from −1.5 to 0.3 ˚C, from 5 to 6 ˚C in the snowless season, and 14 ˚C as the maximum daily mean. The positive response of AOP to a high temperature of 20 ˚C implies that future climate warming accelerates soil nitrification in the foreland. Although it is early to conclude, the succession of AOP at 10 ˚C was unclear and that at 20 ˚C showed an increasing trend. This study was supported by Grants-in-Aid for Scientific Research (No. 26304018) provided by the Japan Society for the Promotion of Science. This study was also partly supported by the National Institute of Polar Research, Japan, through Project

Soil organic carbon (SOC) is generated from organic components by receiving biological and chemical transformations in soils. In volcanic ash soils, mean resident time of SOC is generally long, so the mechanisms of the long lives are of interest for the development of techniques for carbon sequestration in soils. In the present study, we aim to elucidate the transformation process of SOC by fractionating SOC representing the transition stage of the original organic components and characterized the SOC fractions by isotopic and nuclear magnetic resonance spectroscopic analyses.

In this study, we analyzed SOC from a buried soil layer formed between 6,200 and 9,400 cal yBP, because the SOC can be well conserved without the influence of serious human activity. In addition, the age of those buried SOC can be determined by ^{14}C analysis with high accuracy. The soil samples were collected from a buried soil horizon (six samples collected from the depth between 152 and 182 cm at 5 cm intervals) close to Towada volcano, Japan. From each of the soil sample, SOC were extracted and fractionated by precipitation with controlling pH of the extracted solution (Hiradate *et al.*, 2007), resulting in humin, humic acid, and four fulvic acid fractions (two hydrophilic fulvic acid fractions: FA_1 and FA_2, and two hydrophobic fulvic acid fractions: FA_3, and FA_{IHSS}). The SOC fractions were freeze-dried and analyzed for determining $\delta^{13}C$ and $\delta^{15}N$ values by using isotope ratio mass spectrometer and for ^{14}C dating by using accelerator mass spectrometer. Solid-state ^{13}C CPMAS NMR analysis was also conducted to investigate the structural characteristics and quantify the carbon species of the SOC fractions.

The $\delta^{13}C$ values of humic acid, FA_1, FA_2, FA_3, and FA_{IHSS} fractions were -23.85±0.36, -20.75±0.32, -21.10 ±0.38, -22.81±0.41, and -23.22 ±0.33‰, respectively, while $\delta^{15}N$ values were 3.00±0.37, 8.16±1.73, 9.66±0.54 , 4.73±0.83, and 5.20±0.54‰, respectively. The ^{14}C age of humic acid, FA_1, FA_2, FA_3, and FA_{IHSS} fractions was 6130±300, 5630±240, 5400±200, 5410±230, and 5680±260 cal yBP, respectively. Decomposition and recycling of plant residues during the transformation of SOC result in enrichment of heavier carbon and nitrogen isotopes due to preferential stabilization (Wada *et al.*, 2013). Therefore, the increase of $\delta^{13}C$ and $\delta^{15}N$ values in SOC fractions corresponds to successive transformation of SOC. The slope of the relationship between $\delta^{13}C$ and $\delta^{15}N$ values was 1.69, and the results were similar to the result of Wada *et al.* (2013), indicating successive transformation of SOC from plant organic matter to hydrophilic fulvic acid fraction. The hydrophilic fulvic acid fraction would be more microbially processed than hydrophobic fulvic acid and humic acid fractions. Because the humic acid fractions were rich in aromatic structure, they would be formed in the early stage of the formation right after C fixation by plants and chemically stabilized in the soil horizon by fire event etc. The hydrophobic fulvic acid horizons, which are less rich in aromatic C but relatively rich in aliphatic C, would be formed by microbial transformation

©2019. Japan Geoscience Union. All Right Reserved.

and stabilized by chemical and physical factor. The hydrophilic fulvic acid fractions, which are rich in *O* -alkyl C, would be microbially metabolized many times and stabilized physically in the soil horizons.

The validity of the chemical fractionation of SOC on the soil dynamics study has been discussed and sometimes regarded as questionable, but at least in our study on a buried volcanic ash soil, the chemical fractionation procedure successfully separated SOC receiving different metabolisms and having different genesis and chemical structural features.

General pattern of carbon and nitrogen isotopic variation across a wide range of soils and its controlling factors

*Rota Wagai[1], Masako Kajiura[1], Yudzuru Inoue[2], Maki Asano[3], Chie Hayakawa[4]

1. NARO, Institute for Agro-Environmental Sciences, 2. Nagasaki Institute of Applied Science, 3. University of Tsukuba, 4. University of Tokyo

Organic matter (OM) in soil represents the largest carbon pool on land. The production of CO2 via microbial degradation of soil OM therefore has a strong impact on global C cycle and anticipated global warming. Previous studies have shown that any soil holds multiple OM pools of varying stability against microbial attack. Growing number of studies suggests protective effect of specific mineral phases and mineral matrix. OM, however, interacts with soil minerals in highly complex ways including co-precipitation of organic ligands with multivalent metals at molecular scale and physical aggregation of OM with mineral particles at micron and larger scales.

Here we examined the relationship between the isotopic compositions (C-13, C-14, and N-15) and mineralogical characteristics (surface area and elemental composition, pedogenic metal oxides) among density fractions using a range of surface soils of contrasting mineralogy including volcanic soils rich in short-range-order minerals and much more weathered soils from both agricultural and natural systems. Each soil was separated into 4-7 density fractions after mechanical shaking with sodium polytungstate. From LF to higher-density fractions, We assessed how C aging is related to C13 and N15 enrichment and to what extent these isotopic variations among the fractions were controlled by the mineralogical characteristics.

Nutrient sources in some Japanese forest ecosystems: the contribution of precipitation, weathering and litter fall

*Yoshiyuki Inagaki[1], Kazumichi Fujii[1]

1. Forestry and Forest Products Research Institute

Base cation such as calcium and potassium is important nutrient for tree growth in forest ecosystems. Major sources of base cation to forest soil are precipitation, weathering of parent material and litter fall. Weathering rate of base cation is estimated from the input from precipitation, runoff from stream and uptake by vegetation. For plant uptake two different properties, i.e., long-term accumulation in plant biomass and annual uptake should be quantified. Nutrient cycling of many Japanese forest ecosystems has been studied but information about the contribution of these sources is limited. This study compared three nutrient sources in four forest ecosystems in Japan. These forests are Oyasan (Gunma Pref.), Kamikamo (Kyoto Pref.), Kiryu (Shiga pref.) and Takatori (Kochi Pref.). We calculated nutrient budget of potassium, calcium and magnesium. The rate of rock weathering of base cation ranged from 0.22 to 4.37 kmolc ha^{-1} yr^{-1} and increased in the order of Kamigamo < Kiryu <Oyasan < Takatori. In potassium cycling, the contribution of litter fall was greater than that of weathering or precipitation. The runoff of calcium and magnesium from soil was greater in Takatori, where the rate of weathering was high. Although the rate of weathering varied substantially among forest ecosystems, the annual flux of litter fall was relatively constant. Similar calculation was applied for nitrogen cycling and the source from soil was treated as that from nitrogen accumulated during the past pedogenesis. Nitrogen input from the accumulated soil source was 36 % in Oyasan whereas that in other three forestswas 0%. Oyasan was considered as a nitrogen-saturated forest and the result of the study suggest the ecosystem relies on different nitrogen source.

[M-IS13] Biogeochemistry

convener:Keisuke Koba(Center for Ecological Research, Kyoto University), Hideaki Shibata(Field Science Center fot Northern Biosphere, Hokkaido University), Naohiko Ohkouchi(Japan Agency for Marine-Earth Science and Technology), Youhei Yamashita(Faculty of Environmental Earth Science, Hokkaido University), Chairperson:Keisuke Koba(Kyoto University), Yohei Yamashita, Kazuya Nishina, Kazumichi Fujii

Biogeochemistry is an interdisciplinary study field including ecology, geochemistry, oceanography, limnology, hydrology, soil science and environmental sciences. Respective researches have tended to be conducted separately so far. This session aims to provide a common platform for biogeochemists of different disciplines, which facilitates the interactive discussion and information exchanges for further development of biogeochemical studies.

This study aimed to clarify alternations of the quality of dissolved organic matter (DOM) in rainwater moving through temperate forests. For this, we compared the molecular composition of dissolved organic matter (DOM) between bulk deposition (rainfall), throughfall and soil water in Japanese cypress (*Cryptomeria japonica*) and Japanese stone oak (*Lithocarpus edulis*) stands, which were regarded as coniferous and broad-leaved stands, respectively, during a rain event. Analyses of ultrahigh-resolution Fourier transform ion cyclotron resonance mass spectrometry revealed that the number of DOM molecular species detected was significantly greater in throughfall and soil water than in rainfall ($p < 0.05$). In contrast, the number of molecular species did not significantly differ between throughfall and soil water ($p > 0.05$). There were no significant differences in the number of molecular species in both throughfall and soil water between coniferous and broad-leaved stands ($p > 0.05$). These results suggest that a diverse array of DOM molecules are provided from the tree canopies and soils to the rainwater in both stands. Approximately 52%–59% of the total molecular species in throughfall samples ($n = 6$) were unique to throughfall. Additionally, approximately a half of the total molecular species in soil water samples ($n = 5$) were unique to soil water. The classification of molecular species into seven biomolecular classes using a van Krevelen diagram revealed that throughfall samples contained many of lipid and protein molecules compared to rainfall and soil water samples, whereas approximately 70% of the total molecular species in soil water were lignin-like molecules. The analysis of multidimensional scaling revealed that molecular species were significantly differentiated between rainfall, throughfall and soil water ($p < 0.05$). These results indicate that there are diverse molecules unique to throughfall and soil water and that the quality of DOM drastically changes in rainwater as it moves through temperate forests.

Basin-scale transport of allochthonous humic-like fluorescent dissolved organic matter by the North Pacific Intermediate water

*Youhei Yamashita[1], Jun Nishioka[2], Hajime Obata[3], Hiroshi Ogawa[3]

1. Faculty of Environmental and Earth Science, 2. Institute of Low Temperature Science, Hokkaido University, 3. Atmosphere and Ocean Research Institute, The University of Tokyo

The levels of humic-like fluorescent dissolved organic matter (FDOM) in the open ocean generally showed nutrient-type vertical profile. In the surface water, low levels of humic-like FDOM is due to degradation by sunlight. In the dark ocean, linear relationships between levels of humic-like FDOM and apparent oxygen utilization (AOU) have been observed throughout the global ocean, indicating that humic-like FDOM is produced in situ in the ocean interior as organic matter is oxidized by microbes and is resistant to microbial degradation with time scales of thermohaline circulation.

While, it has also been observed that some plots of humic-like FDOM vs AOU in the specific water masses, namely, the North Pacific Intermediate Water (NPIW) and the North Atlantic Deep Water (NADW), seemed to deviate from the general relationship between humic-like FDOM and AOU. The previous studies showed that concentrations of lignin phenols, a unique biomarker of vascular plants, were found to be higher in the NPIW and the NADW compared with other water masses. Thus, the deviations of plots between humic-like FDOM and AOU in the NPIW and the NADW can be considered to be derived from terrestrial (allochthonous) humic-like FDOM.

In this study, we determined a basin-scale distribution of humic-like FDOM from the Sea of Okhotsk to the western subtropical North Pacific. We found the linear relationship between levels of humic-like FDOM and AOU in the deep layer (>1000 m) of the western North Pacific. While, we also found plots in the mesopelagic layer, corresponding to the NPIW, were significantly deviated from the relationship observed in the deep layer. Such distributional pattern implies that allochthonous humic-like FDOM derived from the Sea of Okhotsk is transported widely to the intermediate layer of the North Pacific by the NPIW.

Bacterial contribution to dissolved organic matter in a large monomictic lake (Lake Biwa) indicated by amino acids enantiomers

*Yasuhiko T. Yamaguchi[1], Chikage Yoshimizu[2], Ichiro Tayasu[2], Keisuke Koba[3], Kazuhide Hayakawa[1]

1. Lake Biwa Environmental Research Institute, 2. Research Institute for Humanity and Nature, 3. Center for Ecological Research, Kyoto University

Dissolved organic matter (DOM) plays crucial roles in the biogeochemical cycles in aquatic environments. A number of past studies have strongly indicated that heterotrophic bacteria represent a major source to the ocean DOM pool, suggesting that microbial processes may underlie the mechanisms for DOM preservation ("microbial carbon pump"). In particular, enantiomeric (D/L) analysis of amino acids (AA) in DOM has been used to characterize sources of DOM, and high abundance of specific D-AA bacterial biomarkers have suggested that bacterially-sourced organic matter may be a key in formation of the ocean's recalcitrant DOM pool (e.g., McCarthy et al., 1998; Kaiser & Benner, 2008; Yamaguchi & McCarthy, 2018). In contrast to the marine environments, the distribution of D-AA bacterial biomarkers in DOM has been severely understudied in lacustrine environments. To our knowledge, there has been just one report of D-AA concentration in DOM for a freshwater lake water column (Kawasaki et al., 2013: in eutrophic Lake Kasumigaura, Japan).

Our study explores the use of D-AA bacterial biomarkers as an effective approach to estimate bacterial contribution to the DOM pools in lacustrine environments. First, we have developed a new analytical approach using GC-MS for D-AA concentration in the total DOM pool of lake water. This method can detect unusual D-AA molecules (e.g., D-Val, D-Phe, D-Tyr) together with the major four bacterial biomarkers (D-Ala, D-Glu, D-Asp, and D-Ser) which have been analyzed by the conventional HPLC method. Second, we determined vertical and seasonal variations in the D-AA concentrations of DOM in a large monomictic lake (Lake Biwa, Japan). To our knowledge, this study is the first report of D-AA concentrations of DOM in a meso/oligotrophic lake. Finally, we conducted an incubation experiment using natural microbial community in Lake Biwa to estimate the D-AA yields in freshly-produced bacterial DOM in the lake environment, which are essential for the calculation of bacterial contribution to the natural DOM pools.

From the vertical distribution of D-AA concentration during the stratified period (summer and fall), we estimated that a substantial fraction (30-40%) of the recalcitrant pool of dissolved organic carbon (DOC) is bacterial origin. In contrast, the bacterial contribution was less than 20% to the semi-labile DOC pool which accumulates in the lake epilimnion during summer. These results suggest that the "microbial carbon pump" (production of recalcitrant DOM by heterotrophic bacteria) is an important process in the biogeochemical cycles of lakes.

Ecology of bacterioplankton inhabiting oxygenated hypolimnia of deep freshwater lakes

*Yusuke Okazaki[1]

1. National Institute of Advanced Industrial Science and Technology

In marine and freshwater systems, there are 10^4–10^7 cells mL^{-1} of bacterioplankton in the water column, playing central roles in the microbial food web and biogeochemical cycling. In oligo-mesotrophic deep freshwater lakes, such as Lake Biwa, Baikal and The Laurentian Great Lakes, the hypolimnion is a dark, cold, aerobic water layer below the thermocline that accounts for a majority of the lake volume. Analogous to the deep ocean, the oxygenated hypolimnion is a realm for important biogeochemical processes, such as accumulation and decomposition of semilabile organic matter, nitrification, and methane oxidation. However, our knowledge for the diversity and ecology of the bacterioplankton in the oxygenated hypolimnion is still limited and even poorer than that in the deep ocean. To fill this gap, the present study comprehensively investigated the bacterioplankton community composition in the oxygenated hypolimnia of deep freshwater lakes.

To obtain data from lakes with varying depth, surface area, water temperature, trophic state, pH, lake origin and water retention time, 13 Japanese lakes and 7 European perialpine lakes have been sampled so far. The waters were collected vertically at the deepest point in each lake and the bacterial community composition was determined by 16S rRNA gene amplicon sequencing and catalyzed reporter deposition-fluorescence *in situ* hybridization (CARD-FISH). The result revealed that the oxygenated hypolimnion is inhabited by hypolimnion-specific bacterioplankton lineages that were phylogenetically different by phylum-level from commonly-known freshwater bacterioplankton lineages dominating in epilimnia. While most of the hypolimnion-specific lineages were uncultured and thus their eco-physiology was not well understood, the fact that they commonly predominate in global lakes suggests their importance in the microbial food web and biogeochemical cycling in deep freshwater lakes.

Among the hypolimnion-specific lineages, the CL500-11 lineage (phylum Chloroflexi) is particularly abundant, accounting for more than 10% of bacterioplankton cells in the hypolimnion in many lakes. CARD-FISH analysis revealed their relatively large cell size (1–2 μm), suggesting their contribution in biovolume is even greater. Together with the information collected from literatures and sequence databases, the results demonstrated that CL500-11 inhabit most freshwater lakes with the oxygenated hypolimnion, although their low abundances were observed in lakes with low pH, shallow depth, or short water retention time (<1 year). The results as well as metagenomic and geochemical insights from published studies allowed to hypothesize possible characteristics of substrates supporting CL500-11 growth, most likely nitrogen-rich autochthonous dissolved organic matter (DOM) ubiquitously available in the hypolimnion that may turnover within an annual timescale; for instance, DOM derived from the epilimnion transferred by winter vertical mixing, or DOM secondary produced in the hypolimnion, such as cellular debris from other microbes.

In conclusion, this study revealed that the microbial food web and biogeochemical processes in the oxygenated hypolimnia of deep freshwater lakes are driven by a specific bacterioplankton communities that have eluded previous studies only focusing on the surface waters. Future works should further investigate the ecophysiology of the individual lineages by a metagenomic-based approach or by establishment of their isolated cultures.

Nitrous oxide emission from the drainage and the production processes in oil palm plantation on peatland

*Kazuya Nishina[1], Lulie Melling[2], Ryuichi Hirata[1], Yoshiyuki Takahashi[1], Sakae Toyoda[3], Kotaro Terajima[3], Masayuki Itoh[4]

1. NIES National Institute of Environmental Studies, 2. SARAWAK Tropical Peat Research Institute, 3. Tokyo Institute of Technology, 4. University of Hyogo

In South-East Asia, oil palm plantation has rapidly expanded in the past few decades even in peatland areas. In the light of nitrogen cycling, this land-use change would result in enrichment on the ecosystem N cycling due to the N fertilization for the maintaining oil palm growth and the wastewater emission from the palm mills in the plantation. Oil palm plantations converted from peat swamp forests require the drainage to keep cultivation and thus has unique hydrological characteristics. In such plantation, drainage water surface dominates up to 5% of plantation area and therefore it is important to evaluate the gas exchange between the drainage water and atmosphere.

In this study, we have conducted spatial sampling for dissolved N_2O concentration (dN_2O) in the oil palm plantation on drained peat soil in July 2018, in Sarawak, Malaysia in order to evaluate the indirect N_2O emission from palm oil plantation. We have intensively sampled the water samples from the drainage in the plantation (ca. 120 km^2) and the water samples from Raja river, which is adjacent to the plantation. 90% of samples (N = 84) in the drainage water showed over-saturation in dissolved N_2O concentration (up to 570%), suggesting that the drainage water in the oil palm plantation acts the source of N_2O to the atmosphere. The emission factor for indirect emission (EFr: i.e., dN_2O/nitrate concentration) showed relatively higher than the default EFr in IPCC. However, there were no clear linear relationships between the water qualities (including nitrate) and dN_2O. We have also analyzed the isotopic composition of dN_2O in both drainage and river samples. This analysis suggested the denitrification contributed dN_2O in the drainage water.

[M-IS14] Global climate change driven by the Southern Ocean and the Antarctic Ice Sheet

convener:Osamu Seki(Institute of Low Temperature Science, Hokkaido University), Akira Oka(Atmosphere and Ocean Research Institute, The University of Tokyo), Ryu Uemura(University of the Ryukyus), Ryosuke Makabe(National Institute of Polar Research), Chairperson:Yuji Kato(Kochi University)

The Southern Ocean and Antarctic ice sheet, which are the giant reservoirs of heat, water, and materials, have a potential to play central roles in long-term global climate change. This system is composed of the following sub-systems; ice shelf which is a place of the interaction of ice sheet and ocean, flowing iceberg, seasonal sea ice zone, Antarctic bottom water which drives the thermohaline circulation, active biological production and Antarctic Circumpolar Current. These sub-systems are interacted with each other and have significant impact on changes in the global environmental system. This session aim to summarize recent observational and simulation studies from various fields relating to the past and present changes in the Antarctic Ice sheet and Southern Ocean, which are essential elements for unraveling the changes in the global climate system. Further, future science plans for understanding of the environmental changes of the Antarctic Cryosphere is also discussed.

Mass loss of the Antarctic ice sheet under the influence of ice-ocean interaction

*Shin Sugiyama[1]

1. Institute of Low Temperature Science, Hokkaido University

The Antarctic ice sheet covers 8.3% of the global land surface with a mean ice thickness of 1937 m. The mass of the ice accounts for ~90% of freshwater on the earth and has a potential of 58.3 m sea level rise. Mass change of the ice sheet has a large impact on the Antarctic and global environment since meltwater discharge affects not only sea level, but also ocean circulation and marine ecosystems. Therefore, quantification of ice sheet mass balance and understanding the driving mechanisms are crucially important.

Our understanding of the Antarctic ice sheet mass balance has been greatly improved over the last two decades. Novel satellite measurement techniques enabled us to quantify year to year variations in the mass balance, as well as to investigate key processes such as ice speed, calving and ice shelf basal melting. These new observations have shown a trend of ice sheet mass loss since 1990s. The most significant changes are observed at fast flowing glaciers and ice shelves along the coast in West Antarctica. More detailed studies strongly suggest that the mass loss is due to increasing ice shelf basal melting and ice flow acceleration. To clarify the mechanism of the observed changes, further investigations are in progress on the ice sheet and in the ocean. Study results indicate that the ice sheet is losing mass under the influence of changing ocean, and meltwater discharge is affecting the ocean environment in turn.

In this presentation, we review progress in understanding of the Antarctic ice sheet mass balance and mechanisms driving the recent mass trends. Based on the existing knowledge, we discuss future research directions required for satellite and in-situ measurements as well as numerical investigations.

Accurate chronology and climatic reconstruction around MIS 11 (interglacial period ~400,000 years ago) from Dome Fuji ice core, Antarctica

*Kenji Kawamura[1,2,3], Ikumi Oyabu[1], Shuji Aoki[4], Takakiyo Nakazawa[4], Ayako Abe-Ouchi[5,3], Fuyuki SAITO[3]

1. National Institute of Polar Research, Research Organization of Information and Systems, 2. SOKENDAI (The Graduate University of Advanced Studies), 3. JAMSTEC, 4. Tohoku University, 5. University of Tokyo

Marine Isotope Stage (MIS) 11 is characterized by long duration of glacial termination and interglacial, with higher sea level than today, despite moderate atmospheric CO_2 concentration and small variations in northern summer insolation (due to small orbital eccentricity). To investigate the roles of different forcings (e.g. orbital variations and greenhouse gases) on climate and ice sheets (sea level), paleoclimatic proxy records need to be accurately dated and precisely synchronized with each other. An accurate chronology for the past 360 ky was constructed through orbital tuning of O_2/N_2 ratio of trapped air in the Dome Fuji and Vostok ice cores with local summer insolation (Kawamura et al., 2007), and its improvement has been underway (Oyabu et al., this session). We have also been extending the O_2/N_2 chronology to older periods by analyzing the second Dome Fuji ice core, and constrain the timing and duration of the past interglacial periods.

Marine sediment cores from northern North Atlantic region exhibit millennial-scale variations, including abrupt climatic shifts and bipolar seesaw, during glacial periods and terminations in various proxy records (e.g. sea surface temperature and ice-rafted debris). By correlating the millennial-scale changes recorded in the marine sediment cores with those in the Dome Fuji ice core (CH_4 concentration and d18O of ice), it may be possible to transfer the Dome Fuji chronology to the marine cores from the North Atlantic. We first attempted to correlate planktonic $\delta^{18}O$ and IRD records from the marine core ODP 980 with the Dome Fuji CH_4 around MIS 11 and constrain the durations of interglacial periods recorded in the marine core, with some success. However, the current resolution of the Dome Fuji gas records (~2000 years on average) is not sufficient to undoubtedly identify all millennial-scale events, thus we will start new measurements to improve the resolution. In the presentation, we will show the results of the new measurements and synchronization, and discuss the timing, duration and mechanism of climatic changes over Termination V and MIS 11.

Study on physics and layers of ice cores containing information of climate change over the past 720 k-years, and study on the "oldest ice"

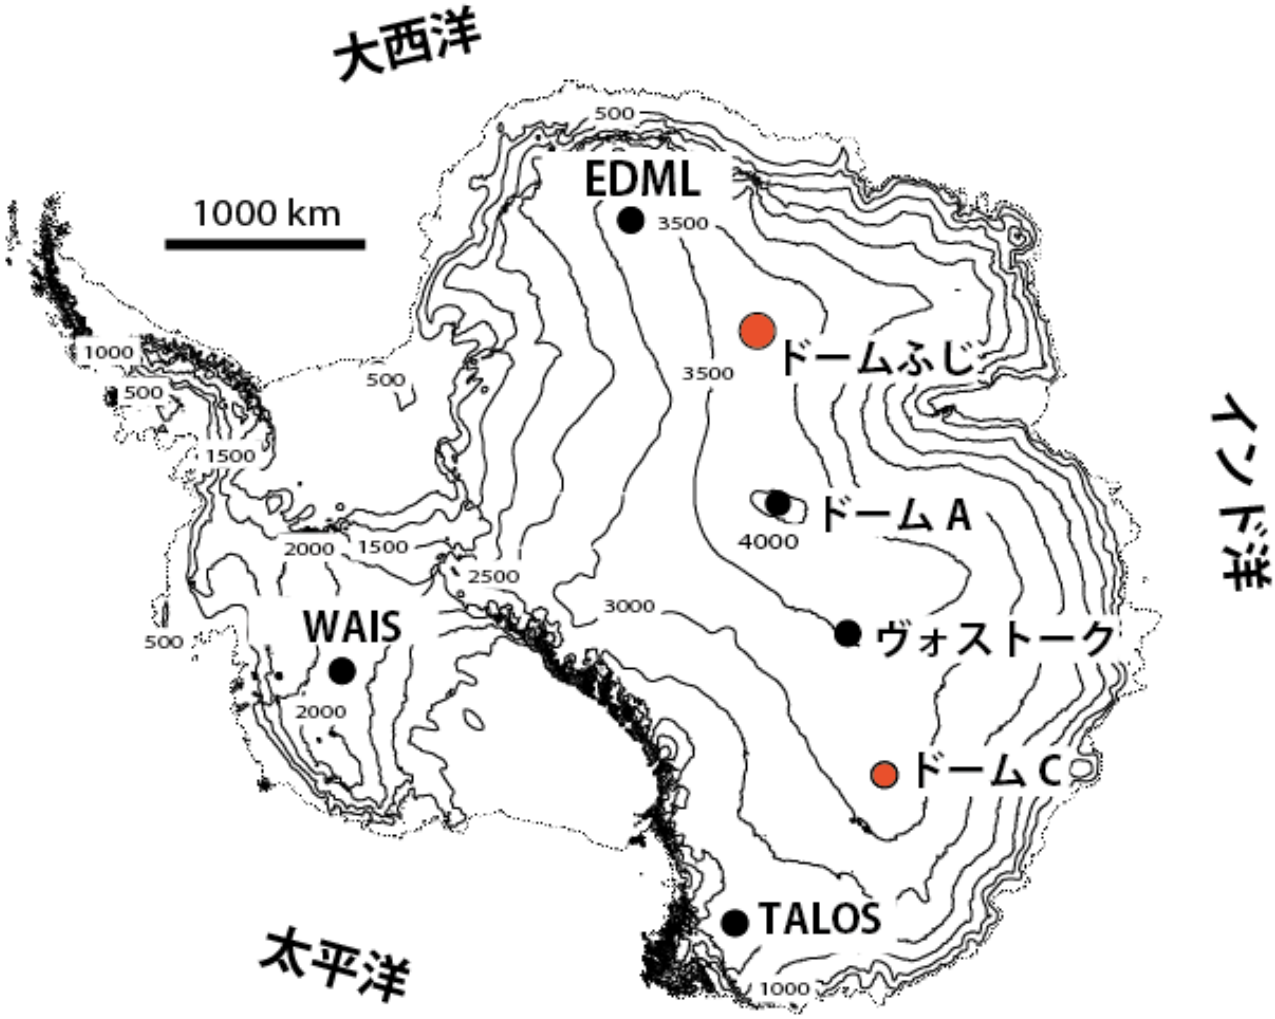
*Shuji Fujita[1,2], Motohiro Hirabayashi[1], Iizuka Yoshinori[3], Hiroshi Ohno[4]

1. National Institute of Polar Research, Research Organization of Information and Systems(ROIS), 2. Department of Polar Science, The Graduate University for Advanced Studies (SOKENDAI), Japan, 3. Institute of Low Temperature Science, Hokkaido University, Japan, 4. Kitami Institute of Technology, Japan

Purpose and Background of the Research

Ice cores collected in inland of Antarctica is one of important information sources for histories of climatic changes that occurred over 1.5 M years. At ice core drilling sites, ice is older in deeper layers; such deep layers are subject to vertical compressions by ice flow. In addition, various time-dependent metamorphic processes undergoes by influences of the geothermal heat flux. If such very deep signals are once resolved with high time resolutions, we can uncover the history of rapid climate changes. Such ice-core-based knowledge will be crucial for building strategies to make sustainable society under global warming. However, current state of our knowledge is based on limited and discrete sampling from ice cores. High resolution continuous methods for analysis has just begun in recent years. In this study, we will use cutting-edge methods for high-resolution and continuous measurements for ice cores, based on crystal physics and continuous flow analysis (CFA); we will analyze layers of ice cores spanning ca. 200,000 years and ca. 720,000 years. Based on it, we will (i) produce valuable information of the climate in the past, (ii) clarify nature of the time-dependent metamorphic processes, (iii) synchronize multiple very deep ice cores, and (iv) predict quality of information from ice cores that cover 1.5 M years.

Research Methods



At an inland site called Dome Fuji in East Antarctica, ice core researchers organized by the National Institute of Polar Research, Japan, collected ice cores covering 720,000 years. We will analyze portions of the ice cores spanning ca. 200,000 years and ca. 720,000 years. Such very old portion constitute deepest ~1000 m span within the ~3000 m-thick ice sheet. Such layers are subject to vertical compressions. In this study, key questions are as follows:
(i) Can we synchronize these very old portions of ice between to major ice cores drilled at Dome Fuji and Dome C?
(ii) How old age of ice back in time, can we clarify detailed histories of rapid changes of climate?
As actions tackling the questions, we will use two major methods to read the layered strata. One of them is to read layers of crystal textures using a method to measure dielectric permittivity tensor with the millimeter wave resonators. Spatial resolutions of this method is ~20mm. Another method is "Continuous Flow Analysis" (CFA) method to read layers of Si, Na and Ca, with a resolutions of ~10 mm.

Expected Research Achievements and Scientific Significance

First, we will produce invaluable ice core data. The data will be used to tackle the key questions. Based on the data, we will synchronize two very old ice cores at Dome Fuji and Dome C, based on collaborations of the European deep ice study community. In addition, we will examine timing difference between the climatic change records between the two ice cores. We aim to accomplish the first reliable and detailed synchronization between very old ice cores up to 720,000 years back in time. we will study change of the climatic mode over the 720,000 years. Furthermore, we will study how very old ice older than 1 M years, can be preserved near the base of the ice sheet.

Reconstructions of the Antarctic Polar Front through the glacial/interglacials

*Hiroki Matsui[1], Yuji Kato[1,2], Itsuki Suto[3], Minoru Ikehara[1]

1. Center for Advanced Marine Core Research, Kochi University, 2. JSPS PD, 3. Graduate School of Environmental Studies, Nagoya University

Understanding the Antarctic Circumpolar Current (i.e., Antarctic Polar Front and Subantarctic front), which connects major three Oceans and major components of the Southern Ocean and Antarctic ice sheets system, is important (from past to present). Modern polar front ranges from 44˚S to 64˚S and is defined by the southern bound of strong SST gradient (>1.5˚ over 100 km) (Freeman et al., 2016). The observed PF position from 2002 to 2014 does not show discernable trend (either northward or southward) in response to the global warming. For the Last Glacial Maximum (LGM), the PF moved northward by 5 degrees (e.g., Gersonde et al., 2005). However, there is difficulty to reconstruct paleo SST gradient because of paucity of surface sediments, and the alternative definition of the PF (e.g., 4 degrees C surface isotherm) was applied (Kohfeld et al., 2013). In this presentation, we summarize current state of knowledge and obstacles of reconstruction of the PF through the glacial/interglacials. We also discuss appropriate methods to certainly track the past PF position.

Integrated observations for marin earth science have been done in the Indian sector of the Southern Ocean during the KH-19-1 cruise by R/V Hakuho-maru in early 2019. Multichannel seismic (MCS) reflection and bathymetric survey were conducted at three sites on the Del Cano Rise and the Conrad Rise, and these site survey for IODP proposal 918 was successfully completed. We also obtained sediment cores from the proposed sites DCR-03A and DCR-02A, and sedimentary archives of a piston core DCR-2PC (at DCR-02A) show obviously glacial-interglacial cycles based on magnetic susceptibility and color reflectance. Various rock samples were collected by dredge observation at the Conrad Rise and the obtained materials to be used for understanding of origin of rise and tectonics in the southwest Indian Ocean. Sediment trap samples were also recovered from a site ECR-1, where is located under the biogenic silica belt south of polar front. Flux of settling particles was increased in summer, suggesting that typical seasonal change was occurred in the Southern Ocean. In addition, multichannel seismic (MCS) reflection and bathymetric survey were also done on the across transect of the deep-sea valleys off Cape Darnley, East Antarctica. By analyzing these materials and data, it is expected to advance the research leading to changes in the sedimentation process accompanying expansion and retreat of the Antarctic ice sheets and elucidation of the history of the Cape Darnley bottom water.

[M-IS14] Global climate change driven by the Southern Ocean and the Antarctic Ice Sheet

convener:Osamu Seki(Institute of Low Temperature Science, Hokkaido University), Akira Oka(Atmosphere and Ocean Research Institute, The University of Tokyo), Ryu Uemura(University of the Ryukyus), Ryosuke Makabe(National Institute of Polar Research), Chairperson:Sam Sherriff-Tadano(University of Tokyo)

The Southern Ocean and Antarctic ice sheet, which are the giant reservoirs of heat, water, and materials, have a potential to play central roles in long-term global climate change. This system is composed of the following sub-systems; ice shelf which is a place of the interaction of ice sheet and ocean, flowing iceberg, seasonal sea ice zone, Antarctic bottom water which drives the thermohaline circulation, active biological production and Antarctic Circumpolar Current. These sub-systems are interacted with each other and have significant impact on changes in the global environmental system. This session aim to summarize recent observational and simulation studies from various fields relating to the past and present changes in the Antarctic Ice sheet and Southern Ocean, which are essential elements for unraveling the changes in the global climate system. Further, future science plans for understanding of the environmental changes of the Antarctic Cryosphere is also discussed.

Institute of Geological Sciences & Oeschger Centre for Climate Change Research, University of Bern, Switzerland

The Southern Ocean (SO) is a place of primordial importance to the understanding of global ocean circulation as it connects the Atlantic, the Pacific and the Indian oceans and thus actively participates in global climate changes. Climate processes and variations in the Indian sector of the SO are not as well understood as processes in the Atlantic sector. This why this project documents climate variations and migrations of the Antarctic Circumpolar Current (ACC) hydrological fronts in the Kerguelen area over the last glacial-interglacial cycle. In this study sea surface temperatures (SST) are reconstructed in two sediment cores, the MD11-3353 (PFZ) and MD12-3396CQ (SAZ), with radiolarian and diatoms microfossil assemblages. By comparing the results given by these two proxies different signals were identified for surface and subsurface waters suggesting a decoupling of these two water masses in the SAZ East of the Kerguelen Plateau. But in the PFZ, both proxies showed similar results. The comparison between these results leads us to think of an influence of lower latitudes warm water in the SAZ whereas this influence is absent in the PFZ in this region.

Present-day crustal motion and gravity change in East Antarctica: implications for the mantle viscosity and Holocene Antarctic Ice Sheet change inferred from GIA modeling

*Jun'ichi Okuno[1,2], Koichiro Doi[1,2], Yuichi Aoyama[1,2], Takeshige Ishiwa[1], Akihisa Hattori[2], Yoichi Fukuda[3]

Geodetic and geomorphological observations in the coastal part of Antarctica indicate the uplift trend associated with the removal mass of the Antarctic Ice Sheet (AIS) in the last deglaciation. The numerical calculations of crustal motion derived from the glacial isostatic adjustment (GIA) modeling have played the role of inferring the ice mass change of AIS from observations related to solid Earth deformation. The deglaciation histories of the AIS inferred from the comparisons between the geomorphological sea-level records, and GIA modeling shows the monotonic Holocene retreat for the AIS (e.g., Whitehouse et al., 2012). However, GNSS observations in some regions in the coastal part of Antarctica cannot be explained the amplitudes of the uplift by only glacial rebound due to the last deglaciation of the AIS. Also, recent studies (e.g., Kingslake et al., 2018) concerning bedrock topography in the margin of AIS inferred that some portions of the ice sheet might have re-advanced after retreating behind the present-day margin in mid-to-late Holocene. Therefore, this re-advance of AIS in Holocene may be caused to arise the mismatch between GNSS observations and numerical predictions. On the other hand, GNSS observations include not only the components of the GIA due to the last deglaciation and also elastic deformation due to present-day surface mass balance (e.g., Hattori et al., 2018). Similarly, this effect could cause a difference between the GNSS observations and the GIA calculations. In this presentation, we will show the crustal deformation rates and gravity changes calculated by the GIA modeling using the previously published deglaciation histories and the comparisons with these observations obtained from East Antarctica. We intend to discuss the influences of AIS mass changes and choice of mantle viscosity profile on the geodetic measurements in East Antarctica.

Reconstructing past variability of the Antarctic ice sheets is essential to understand their stability and to anticipate their contribution to future sea level rise. However, magnitude and timing of ice sheet changes during the last several million years have not been well constrained, especially in central & eastern Droning Maud Land, East Antarctica. Recently, we have carried out several field campaigns in this area to reconstruct changes in thickness, geographical extent, and timing of retreat of the East Antarctic Ice Sheet based on the detailed geomorphological survey, cosmogenic exposure dating, and lake/shallow marine sediment records coupled with glacial isostatic adjustment modeling (GIA). In this presentation, we will introduce these recent achievements from the field campaigns and discuss scientific plans for the next few seasons.

Vertical ice flow motions obtained from year-round GNSS observations on Shirase Glacier, Antarctica

*Yuichi Aoyama[1,2], Koichiro Doi[1,2], Daisuke Hirano[3], Takeshi Tamura[1,2], Shigeru Aoki[3], Kazuo Shibuya[1]

1. National Institute of Polar Research, 2. SOKENDAI, 3. Institute of Low Temperature Science, Hokkaido University

The Antarctic ice sheet is a huge heat sink acting as a feedback controller for adjusting global warming, so a loss of its mass would cause a great impact on the global climate change. It is valuable to evaluate an Antarctic ice mass balance, which is a consequence of competition between an ice discharge and a snow accumulation. With an objective of estimating the ice discharge around Lützow-Holmbukta, East Antarctica, we have measured three-dimensional (3D) ice flow motions around a grounding line of Shirase Glacier, which is fastest and largest ice stream in Lützow-Holmbukta.

We first performed one-month GPS measurement near the calving front of Shirase Glacier in 2011/2012 austral summer. The three-dimensional position of this site was determined by the kinematic precise point positioning (kPPP) method at every 30 seconds with a 4-5-cm precision for 25 days. From the 30-s interval position, we estimated the ice flow velocity vector, the basal melting rate of the iceberg, and ocean tidal variations (Aoyama et al. 2016). Subsequently, a year-round GNSS measurement system was installed six kilometers downstream from the grounding line of Shirase Glacier at the end of Jan. 2015. By maintaining this year-round system (changing SD card and battery) every austral summer season, we have already obtained a three-years continuous data from Jan. 30, 2015 to Dec. 30, 2017.
We analyzed the time series of the three-dimensional position of this system with kPPP method. The time series revealed the ice flow motion downstream from the grounding line of Shirase Glacier during 2015-2017. Focusing on the vertical motion, there is no remarkable ocean tidal variation. And the obtained vertical flow motion shows gradually descent, then rise, again descent slope. In order to clarify whether such vertical change is local or wide area, we compared with a TanDEM-X 90m DEM (Rizzoli et al., 2017). In the presentation, we will show properties of the ice flow motion downstream the grounding line of Shirase Glacier.

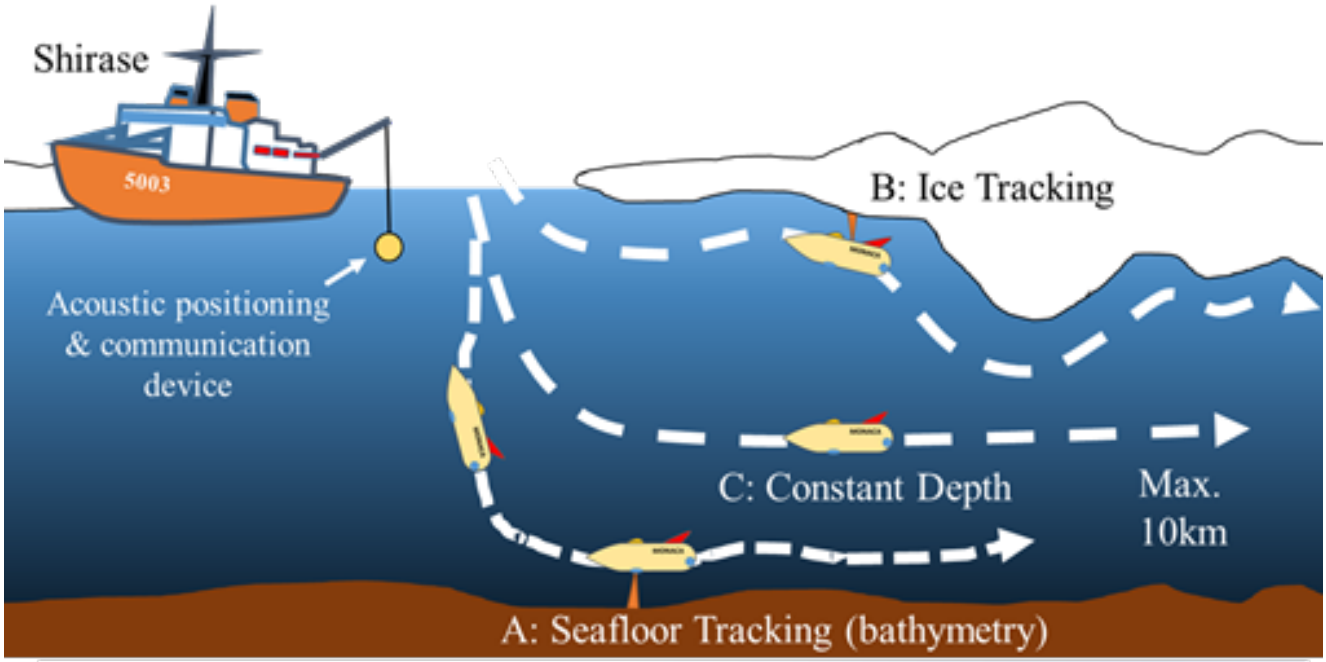
Operation plan and design of the Antarctic exploration AUV "MONACA"

*Hirokazu Yamagata[1], Toshihiro Maki[1], Hiroshi Yoshida[2], Yoshifumi Nogi[3]

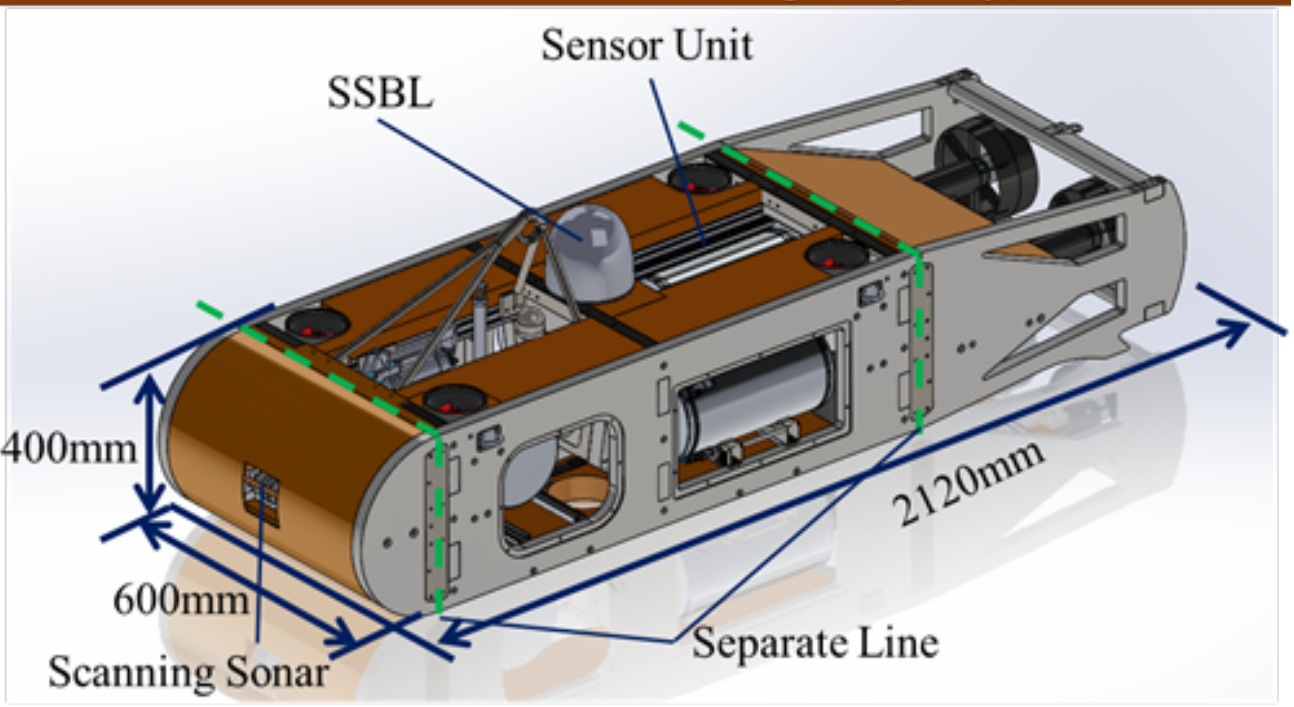
1. Institute of Industrial Science, The University of Tokyo, 2. Japan Marine Science and Technology Center, 3. National Institute of Polar Research

Autonomous Underwater Vehicles (AUVs) have been used for under-ice explorations of the Antarctic Ocean. Most of the current under ice AUVs are large and are used for the long-distance survey. Survey results of these AUVs are extremely precise, but there is a trade-off between precision and running cost and/or risk of losing AUVs.

In this presentation, the authors propose a variable and compact AUV MONACA (Mobility Oriented Nadir AntarctiC Adventurer) which can offer the necessary and sufficient compositions for various survey needs by the modular design. Development of MONACA is supported by JSPS Grant-in-Aid for Scientific Research on Innovative Areas No.4902, to measure the sea ice/shelf ice and ocean floor for research of ice sheet-ocean interaction.



MONACA is 2 m long, 230 kg weight, and it can cruise for about 8 hours. Depth rating is 1500m. The vehicle is designed to go into ice-covered oceans as far as 10 km. The flat body is filled with buoyancy materials at the top so that the battery units and main unit can be accessed from the side. The vehicle has five degrees of freedom (surge, heave, roll, pitch, and yaw) by 4 vertical thrusters and 2 horizontal thrusters. Although the survey range is limited compared with large AUVs, it can conduct a highly precise survey with lower costs.



The three missions are considered as shown in the figure. (A: Seafloor tracking, B: Ice tracking, C: Water survey in constant depth). In the missions A and B, the shape of the seafloor or the ice is mapped by a multi-beam sonar while tracking it by a probabilistic approach using a scanning sonar. The multi-beam sonar measures 480 points in the swath width of 120˚. The vehicle has two set of releasable ballasts for diving and surfacing. The vehicle is designed to follow the seafloor or ice at the reference altitude of 50 m. In the mission C, the vehicle navigates at a constant depth, measuring water quality by a CTD sensor. Resolution of the CTD sensor is Temperature = +/- 0.0001 ˚C, Conductivity = +/- 0.0001 mS / cm, Depth = 0.03 m.

In order to realize these three missions under the size limitation, MONACA has the sensor unit that can be flipped upside down. The sensor unit includes the multi-beam sonar, an INS, and a DVL. Therefore, MONACA can navigate only by the sensor unit in case there are no obstacles in the seafloor.
MONACA is currently under construction, to be launched in 2019.

The seafloor covers more than 70 percent of the solid-earth surface and has been progressively investigated since the 20th century, however most parts have not been explored because of observation difficulties in the ocean. Particularly, the seafloor of the Indian and Southern Oceans are expected to preserve significant records of paleo glacial processes and submarine volcanism as well as continental breakup and seafloor spreading. Here, we show new geophysical dataset just obtained during the R/V *Hakuho-maru*KH-19-1 cruise in early 2019. Underway geophysical mapping as well as multichannel reflection surveys and dredge rock samplings were conducted in this cruse. Specific scientific target area were set to 1) the Southwest Indian Ridge to reveal the seafloor spreading process in the Cenozoic era; 2) Conrad Rise to understand its origin and surrounding magmatism; 3) Del Cano Rise to reveal how it has been formed; 4) off Cape Darnley to reveal relationship between solid-earth processes and presently formed Antarctic bottom water; and 5) Southeast Indian Ridge to reveal the mid-ocean ridge oscillation. Multibeam bathymetry, total and vector magnetic fields, gravity, and sub-bottom profiler data were successfully acquired along the ship tracks which covers Fremantle to Mauritius in leg-1 (2 Jan to 11 Jan 2019) and Mauritius to Fremantle via mentioned target area in leg-2 (16 Jan to 12 Feb 2019). We overview preliminary geophysical results which were combined with previous *Hakuho-maru*cruises of KH-07-04, KH-09-05, KH-10-07, and KH-16-01 and data acquired during Japanese Antarctic Research Expedition by using Japanese icebreaker *Shirase*. Finally, we discuss geophysical insights into tectonic, volcanic, sedimentation, and glacial processes in Indian and Southern Oceans.

[M-IS14] Global climate change driven by the Southern Ocean and the Antarctic Ice Sheet

convener:Osamu Seki(Institute of Low Temperature Science, Hokkaido University), Akira Oka(Atmosphere and Ocean Research Institute, The University of Tokyo), Ryu Uemura(University of the Ryukyus), Ryosuke Makabe(National Institute of Polar Research), Chairperson:Takeshige Ishiwa(National institute of Polar Research)

The Southern Ocean and Antarctic ice sheet, which are the giant reservoirs of heat, water, and materials, have a potential to play central roles in long-term global climate change. This system is composed of the following sub-systems; ice shelf which is a place of the interaction of ice sheet and ocean, flowing iceberg, seasonal sea ice zone, Antarctic bottom water which drives the thermohaline circulation, active biological production and Antarctic Circumpolar Current. These sub-systems are interacted with each other and have significant impact on changes in the global environmental system. This session aim to summarize recent observational and simulation studies from various fields relating to the past and present changes in the Antarctic Ice sheet and Southern Ocean, which are essential elements for unraveling the changes in the global climate system. Further, future science plans for understanding of the environmental changes of the Antarctic Cryosphere is also discussed.

Simulations of glacial ocean carbon cycle with a parameterization of stratification dependence of vertical diffusivity

*Hidetaka Kobayashi[1], Akira Oka[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

Paleo-ocean reconstructions supporting the Southern Ocean hypothesis, in which carbon storage in the deep Southern Ocean increases during the glacial ages, has not been sufficiently reproduced by previous paleoclimate modeling studies. In this study, we apply salinity restoring in the Southern Ocean and a parameterization of stratification dependence of vertical diffusivity to an ocean general circulation model and attempt to reproduce oceanic properties reconstructed from paleo-ocean proxy data at the Last Glacial Maximum (LGM). An LGM simulation including the salinity restoring expresses high bottom-water salinity associated with larger sea ice production at the LGM, and reproduces the reconstructed salinity distribution. Moreover, by considering the stratification dependence of vertical diffusivity in the global ocean, the reduced vertical mixing due to enhanced salinity stratification increases ventilation ages in the intermediate to the deep ocean. As a result, more carbon is stored in the deep ocean and the vertical gradient of dissolved inorganic carbon enlarges. This redistribution of carbon reduces atmospheric carbon dioxide concentration (pCO_2). In addition, the subsequent response of carbonate compensation may amplify the glacial reduction of atmospheric pCO_2. In our presentation, we plan to report the glacial variation of atmospheric pCO_2 explained by the response of the ocean carbon cycle including carbonate compensation in numerical simulations using an ocean general circulation model.

Impacts of precession on the periodicity of climate and AMOC variabilities

*Sam Sherriff-Tadano[1]

1. Atmosphere and Ocean Research Institute, the University of Tokyo

Over the glacial period, climate varied on centennial to millennial time scale between the warm instersadial and the cold staidial. Recent ice core and modelling studies have shown that changes in CO2 and the glacial ice sheet played a critical role in controlling the periodicity of the climate variability through affecting the Atlantic Meridional Overturning Circulation (AMOC). Here, by analysing simulation data from a climate model GFDL, it is shown that changes in insolation pattern due to changes in precession also exert a substantial impact on the periodicity of the climate and AMOC variability. Model results show that a change from a Northern Hemisphere summer solstice perihelion to winter solstice perihelion causes an increase in the periodicity of the AMOC variability from decadal to millennial. Analysis reveals that an increase of sea ice over the Northern Hemisphere and a decrease in sea ice over the Southern Ocean due to insolation changes play a role in increasing the periodicity through stabilising both the vigorous AMOC and weak AMOC. These results may have some implications in interpreting the ice core data.

Warming and climate feedbacks in the southern high latitude driven by obliquity, precession-eccentricity, and atmospheric CO2

*Kanon Kino[1], Ayako Abe-Ouchi[1,2], Ryouta O'ishi[1], Fuyuki SAITO[2], Masakazu Yoshimori[1]

1. Atmosphere and Ocean Research Institute, the University of Tokyo, 2. Japan Agency for Marine-Earth Science and Technology

Polar amplification is widely known as a major characteristic of observed and simulated global warming which induced by increasing atmospheric CO2. In the southern high latitude, a study using GCM investigated climate feedback system to reproduce the warming (Lu and Cai, 2009). A latest study of the Antarctic ice core precisely analyzed phase relationship between temperature changes in the past ages and the periodic changes in the Earth’ s orbital parameters (obliquity, precession and eccentricity (Uemura et al., 2018). In this study, we use MIROC-GCM to investigate the warming in the southern high latitude due to the orbital parameter changes, and climate feedback responses. Results are compared with the doubling CO2 experiment.
We use an AGCM with slab ocean of MIROC-GCM (Hasumi and Emori, 2004) and performed experiments with (1) large obliquity, (2) large precession and the winter solstice (austral summer) at the aphelion (Maximum values in the past ages are used). A seasonal surface feedback analysis method (Lu and Cai, 2009) is also applied.
Results show that warming on the Antarctica (covered by the ice-sheet) due to the orbital parameter change is dominated by short-wave radiation which is not interrupted by cloud, in contrast that the warming due to increasing atmospheric CO2 is dominated by downward long-wave radiation. Results also show that seasonal warming and climate feedback responses on the Southern Ocean are qualitatively common in the insolation and CO2 cases, as well as warming in the Arctic Ocean; little warming in the summer with absorption of energy and large warming in the autumn and winter with releasing of the energy. The strengths of the warming are qualitatively different whether the seasonality, especially spring and early summer, of radiative forcing is favorable for sea ice melt.
We will investigate the changes of the atmospheric circulation, precipitation, and the influence of the oceanic circulation.

Origin of Circumpolar Deep Water intruding onto the Amundsen and Bellingshausen Sea continental shelves

*Yoshihiro Nakayama[1,2], Menemenlis Dimitris[2], Hong Zhang[2], Michael Schodlok[2], Eric Rignot[2,3]

1. Institute of Low Temperature Science, Hokkaido University, 2. NASA's Jet Propulsion Laboratory, 3. Uniersity of California, Irvine

Melting of West Antarctic ice shelves is enhanced by Circumpolar Deep Water (CDW) intruding onto the Amundsen and Bellingshausen Seas (ABS) continental shelves. Despite existing studies of cross-shelf and on-shelf CDW transports, CDW pathways onto the ABS originating from further offshore have never been investigated. Here, we investigate CDW pathways onto the ABS using a regional ocean model. Simulated CDW tracers from a zonal section across 67˚S (S04P) circulate along the Antarctic Circumpolar Current (ACC) and Ross Gyre (RG) and travel into ABS continental shelf after 3–5 years, but source locations are shifted westward by ~900 km along S04P in 2001–2006 compared to 2009–2014. We find that simulated on- and off-shelf CDW is ~0.1–0.2 ˚C warmer in the 2009–2014 case than in the 2001–2006 case together with changes in simulated ocean circulation. These differences are primarily caused by lateral, rather than surface, boundary conditions, implying that large-scale atmospheric and ocean circulations are able to control CDW pathways and thus off- and on-shelf CDW properties.

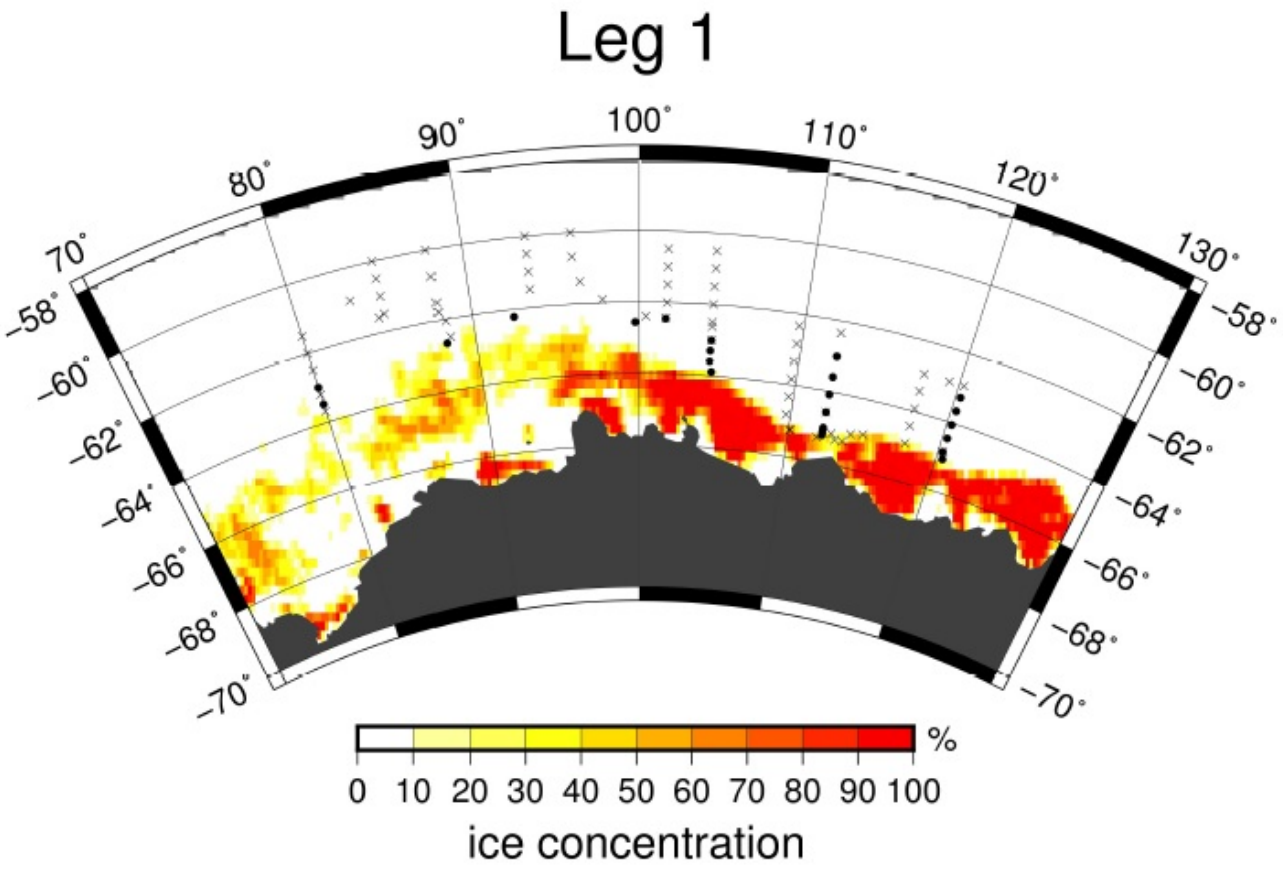
Ocean and material circulation in the southern part of the Australian Antarctic Basin in 2018/2019 summer - preliminary results from Kaiyomaru KY18-04 cruise



*Katsuro Katsumata[1], Daisuke Hirano[2], Daiki Nomura[2], Kaihe Yamazaki[2], Yoichiro Koh[2], Masaaki Kiuchi[2], Shigeru Aoki[2], Hiroto Murase[3]

1. JAMSTEC, 2. Hokkaido Univ., 3. NRI-FSF

The Australian Antarctic Basin collects dense shelf water from the Ross Sea and off Adelie Coast along the westward-flowing Antarctic Slope Current and modifies its property through mixing before initiating the bottom branch of the meridional overturning circulations in the Indian and Pacific oceans. It is necessary to monitor the current status of the near-bottom circulation in the basin in order to understand how the recently-reported volume decrease of the Antarctic Bottom Water and changes in the atmosphere-ocean and cryosphere-ocean interactions are related. It is established that the Southern Ocean, particularly at the north of the Antarctic Circumpolar Current (ACC), acts as a sink of anthropogenic carbon through its low surface pCO2 and mode and intermediate watermass production. Then, is the south of the ACC source or sink of anthropogenic carbon with its dense shelf water production in the face of upwelling of carbon-rich deep water masses? How do these changes in the environment affect the biosphere and ecosystem in the Southern Ocean?
With these questions in mind, R/V Kaiyomaru, Japan Fishery Agency, conducted a research cruise in the basin, in proximity of its seasonal ice edge, from December 2018 to March 2019. This part of the basin has been observed by an Australian team in 1996. At the time of writing, more than 40 stations have been occupied for CTD and LADCP observations and bottle sampling, more than 80 XCTD probes have been deployed. Preliminary analysis shows the changes in the bottom water masses. The Figure below shows the CTD/LADCP/sampling stations (black dots) and XCTD deployments (crosses) for Leg1 (5 Dec 2018 to 16 Jan 2019) with AMSR2 derived ice concentration, which is a combination of west of 90E (observed on 17 Dec 2018), between 90E and 107E (24 Dec 2018) and east of 107E (31 Dec 2018). In the talk, the latest results and its outlook will be discussed.

Mooring observation aiming direct current measurement and quantitative evaluation of Meridional Circulation of Southern Ocean

*Kitade Yujiro[1], Kohei Mizobata[1], Kazuho Watanabe[1], Linquiao Chen[3], Gaopin Guo[3], Shigeru Aoki[2], Shyuki Ushio[4], Keishi Shimada[1], Kay I. Ohshima[2]

The deep Global circulation is a large-scale thermohaline circulation over the Earth and plays an important role in maintaining a stable climate.

In recent years, as rising temperature and freshening of Antarctic bottom water is being observed in various places, in order to quantitatively understand its freshening mechanism and the flow rate and change of Southern Ocean meridional circulation, We are planning to construct a large mooring observation network.

Therefore, as the first attempt, we deployed two moorings (January 2017 - January 2018) by TR/V Umitaka-maru in order to carry out direct current measurement of Meridional circulation. At the time of deployment and recovery of mooring system, we carried out CTD observation up to the sea floor along 110 ˚E line and off Vincennes Bay. At the northern edge of the seasonal sea ice zone, station KMN (60-56 S, 110-07 E, depth of water: 4180 m), we deployed five current meters, one ADP current meter, four MicroCat-CTDs and six RBR soloTs. At KMS (63 - 32 S, 108 - 02 E, depth: 3201 m) in the vicinity of the summer divergence zone, we deployed 10 MicroCats, 3 CTs sensors, 30 soloTs. Because the top buoy of the mooring system at KMN had come up to the sea surface, the two buoys were damaged due to the overhang of the sea ice in winter, but all the sensors were successfully recovered.

Mooring revealed that a flow field suggesting the structure of circulation and periodic fluctuations due to medium-scale eddies and seasonal fluctuations. In this report, we introduce the whole of the observation, the digestive result of the moored observation. The annual averages of current velocitiy [u, v (cm / s)] obtained with 5 current meters are [2.15, -1.26] at 429 db, [1.46, - 0.88] at 859 db, 0.26, -1.26 at 1918 db, [-1.32, -0.78] at 3366 db, and [-1.65, -1.77] at 4080 db. The east-west current structure shows eastward in the upper three layers and westward in the lower two layers, indicating a reasonable zonal current velocity structure. In north - south component, it is slightly larger at the lowest layer, but in other depths it shows southward flow of about 1 cm/s. The 1 cm/s agree well with the current velocity estimated form Sverdrup transport by the wind stress field in this area.

In addition, at around 400 m depth, water masses around 2 degree considered to be the Circumpolar Deep Water were distributed, and it appeared that the temperature rose synchronously with the periodic southward current. We believe that these flow velocity structures and variations are the first approximate features of the circulation of the sea area. In addition, we investigated the fluctuation of Curl of wind stress using WindSat's wind data and found periodic period fluctuations corresponding to some of current fluctuations. In this summary, only the qualitative features which are known from the preliminary report value are described, but at the time of the presentation, other mooring data will be also added and the contents which we entered into more quantitative discussion are introduced.

[M-IS15] Evolution of Pelagic Realm

convener:Atsushi Matsuoka(Department of Geology, Faculty of Science, Niigata University), Katsunori Kimoto(Japan Agency for Marine-Earth Science and Technology), Toshiyuki Kurihara(Graduate School of Science and Technology, Niigata University), Tetsuji Onoue(Earth and Environmental Sciences, Graduate School of Science and Technology, Kumamoto University), Chairperson:Atsushi Matsuoka, Toshiyuki Kurihara

This session focuses on the evolution of ecosystem in the pelagic realms,
including discussions on all aspects of pelagic biota covering biostratigraphy,
biochronology, evolution, and biogeography, which are important to the
reconstruction of the spatio-temporal framework in the pelagic realm.
Reconstructions of plate configuration through time are included in the scope of
 this session. Biological, geochemical, sedimentological approaches to the
pelagic environments are welcomed.

Deep-sea sediment records paleo-environmental changes thorough geologic time. Pelagic clay, one of the most common types of deep-sea sediment, is an important medium recording changes of atmospheric/oceanic circulations and surface ocean productivity that occurred in pelagic realm [1]. Despite its importance, however, less attention has been paid to the pelagic clay than to other sediments, mainly due to the two following reasons: (1) pelagic clay lacks visible features, which hampers clarifying the stratigraphic variations within pelagic clay units, (2) determining the depositional age is very difficult due to lacks of siliceous/calcareous microfossils and difficulties in identifying paleomagnetic reversals.

Our recent studies [2,3] have shown that bulk chemical composition is a very useful tool to characterize apparently homogenous pelagic clay. We previously determined bulk geochemistry of pelagic clay samples obtained from ODP sites 1149 and 1179 in the western North Pacific Ocean [2], and compared with that from LL44-GPC3 in the central North Pacific Ocean [1]. The results indicate that pelagic clay in the North Pacific is composed of common three layers, each having characteristic major- and trace-element composition [2,3]. This suggests that the problem (1) (i.e., difficulty in stratigraphic characterization) can be solved on the basis of geochemistry. Moreover, regarding the problem (2) (i.e., difficulty in age determination), we have applied biostratigraphy of ichthyolith (microfossils of fish teeth) to constraining the depositional ages of pelagic clay at sites 1149 and 1179 [3]. These achievements suggest that the problems in using pelagic clay as a recorder of paleo-environment can be overcome.

Here, we newly determined bulk chemical compositions of pelagic clay cores at DSDP sites 576, 578 and ODP Site 886, whose depositional ages were constrained [4,5]. By combining the results with our previous data, we constructed a dataset of bulk geochemistry and depositional age of pelagic clay covering a broad area in the North Pacific Ocean. The data show that the common chemostratigraphy we have reported [2,3] is truly a general feature of pelagic clay in the North Pacific Ocean. Moreover, the integration of the geochemical features and paleogeographic reconstruction suggests that the common chemostratigraphy in the North Pacific Ocean reflects the global environmental changes through the Cenozoic era.

Reconstruction of oceanic redox conditions in the Lower Jurassic (Pliensbachian–Toarcian) pelagic deep-sea bedded chert sequence of the Mino Belt, central Japan

*Katsuhito Soda[1]

1. Department of Earth and Environmental Sciences, Faculty of Science, Kumamoto University

The Pliensbachian-Toarcian interval in the Early Jurassic is characterized by a second-order marine mass extinction and remarkable worldwide palaeoenvironmental perturbations associated with the early Toarcian oceanic anoxic event (T-OAE). However, oceanic redox conditions and palaeoceanographic processes for redox sensitive elemental accumulation are unclear in the pelagic deep-sea realms of the Panthalassic Ocean. Here we show geochemical and multivariate statistical analyses in the pelagic deep-sea sedimentary rocks of the Panthalassic Ocean during the Pliensbachian-Toarcian. Three principal components (PC1, PC2, and PC3) in the redox sensitive elements explained 88.64% of the total variance. The PC1 represents the comprehensive redox variations, whose stratigraphic variations show euxinic-anoxic conditions across the Pliensbachian/Toarcian (Pl/To) boundary layer and the classical T-OAE. The PC2 depicts the sorption processes of Fe-Mn oxide minerals with transition elements, whose stratigraphic variations suggest few drawdowns of the transition elemental inventory after the Pl/To boundary layer. The PC3 delineates the active particulate shuttles by Fe (-Mn) oxide minerals, whose stratigraphic variations indicate the strong activation between the Pl/To boundary layer and the classical T-OAE. The statistical extraction of both the PC1 and the PC3 support the characteristic phenomena in the pelagic deep-sea realms of the Panthalassic Ocean under the relatively strong reductive conditions.

Conodont biostratigraphy of Anisian pelagic deep-sea sedimentary rocks deposited in the pelagic Panthalassa—Integration with radiolarian biozones—

*Shun Muto[1], Satoshi Takahashi[1], Satoshi Yamakita[2], Katsuhito Soda[3], Tetsuji Onoue[3]

1. Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo, 2. Faculty of Education, University of Miyazaki, 3. Faculty of Advanced Science and Technology

The age of pelagic Panthalassic deep-sea sedimentary rocks such as bedded chert and claystone has been assigned based on radiolarian biozones. However, Middle Triassic radiolarian biozones of pelagic Panthalassic deep-sea strata are not precisely correlated to the standard geological timescale. In order to establish a direct correlation between the pelagic Panthalassic radiolarian biozones and the standard geological timescale, we investigated conodont biostratigraphy in two radiolarian-controlled bedded chert sections of Anisian age: the Ajiro Island section in Oita Prefecture and the Kurusu section in Aichi Prefecture. We recognised six conodont biozones in the studied sections: the upper Olenekian *Novispathodus brevissimus-Icriospathodus collinsoni* and *Triassospathodus homeri* Zones, the lower Anisian *Chiosella timorensis* Zone, the middle Anisian *Paragondolella bulgarica* Zone, the upper Anisian *Paragondolella excelsa* Zone and the uppermost Anisian to lowermost Ladinian *Paragondolella trammeri* Zone. Based on the recognition on these conodont zones, we reassessed the age of the Triassic radiolarian biozones defined by Sugiyama (1997, *Bull. Mizunami Foss. Mus.*, vol. 24, p. 79–193). Sugiyama’ s radiolarian TR 1 Zone, previously considered to be of Olenekian age, extends to the middle Anisian. The TR 2A Zone, the TR 2B Zone and the lower part of the TR 2C Zone are correlated to the middle Anisian, while the upper part of the TR 2C Zone and the lower part of the TR 3A Zone are correlated to the upper Anisian. The upper part of the TR 3A Zone and the lower part of the TR 3B Zone are probably correlative to the uppermost Anisian, but the possibility that they are correlative to the lowermost Ladinian cannot be ruled out.

Pelagic cherts preserved in accretionary complexes represent former seafloor sediment that can retain geochemical evidence of paleoceanographic conditions that predate the oldest extant oceanic crust. The ratio of Os isotopes in seawater, in particular, is of wide interest as a source of insight into notable geologic events such as oceanic anoxic events, rapid global warming episodes, and eruption of large igneous provinces, but marine Os isotope records from before 80 Ma are scarce. We present a record of secular variations of marine Os isotope ratios from a thick, continuous succession of Middle and Upper Triassic pelagic chert in the Sakahogi section of the Mino Belt accretionary complex.

Keywords: Chert, Re-Os isotope, Triassic, Accretionary complex, Mino Belt, Southwest Japan

The preservation of radiolarians across the Jurassic-Cretaceous (J/K) boundary in the Bosso Valley section, Central Italy

*XIN LI[1], Atsushi Matsuoka[2], Angela Bertinelli[3], Marco Chiari[4]

1. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, 2. Niigata University, 3. Università degli Studi di Perugia, 4. Istituto di Geoscienze e Georisorse

The Bosso Valley section is located near the Pianello-Cagli road and follows the Bosso River in the Umbria-Marche area of the Central Italy. The pronounced increase in abundance of *Calpionella alpina* documented at the base of *Calpionella* zone was accepted as the Jurassic–Cretaceous boundary (JKB) indicator in the Bosso Valley section. The magnetostratigraphical record of the JKB has been correlated with the *Calpionella* zone. The JKB is placed between Beds 77 and 78 (Housa et al. 2004). The Maiolica Formation, which crosses the JKB, is characterized by whitish, beige to gray colored, well-bedded limestones with abundant black to gray chert layers and chert nodules and marly intervals. Certain horizons in the Bosso Valley section yield well-preserved radiolarians, significant for the correlation of deep marine sediments. In order to establish radiolarian biostratigraphy across the JKB, detailed study was conducted to elucidate relationship between lithology and preservation of radiolarians in the Bosso Valley section.

Thin sections of 19 samples were observed to elucidate the relationship between lithology and preservation of radiolarians. Three samples of micritic limestone below the JKB (Beds 73, 75, and 77) and two samples above the JKB were collected for analyzing. The limestone samples were immersed in 10% hydrochloric acid for 30 to 60 minutes, then washed, dried and examined under a binocular microscope and a scanning electron microscope.

Radiolarians are abundant both in the chert bands or nodules and in the limestone. Preservation of radiolarians varies in different parts because of the diagenesis. Surfaces of etched limestone are observed and divided into different parts, based on the preservation of radiolarians. Radiolarians are generally calcified in the pure lime beds. Radiolarians are generally bad preserved in the chert bands or nodules. Well-preserved radiolarians are located inside the lime part near the chert bands or nodules. Primary results of radiolarian assemblages near the JKB are proposed. Limestones near chert layers or nodules in the Bosso Valley section enable radiolarian biostratigraphic study across the JKB.

Keywords: preservation, radiolarians, Jurassic-Cretaceous (J/K) boundary

Radiolarian faunas around the Jurassic-Cretaceous boundary in the Bosso Valley section, central Italy

*Atsushi Matsuoka[1], XIN LI[2], Marco Chiari[3], Angela Bertinelli[4]

1. Department of Geology, Faculty of Science, Niigata University, 2. Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciense, 3. C.N.R., Istituto di Geoscienze e Georisorse, sede secondaria di Firenze, 4. Dipartimento di Fisica e Geologia, Università degli Studi di Perugia

The Global Boundary Stratotype Section and Point (GSSP) of the Jurassic–Cretaceous boundary (JKB) is the last among the GSSPs in the Phanerozoic. It is defined as the base of the Berriasian Stage. The formal definition was decided in 2016 to use the base of the *Calpionella alpina* Subzone as the primary marker by the Berriasian Working Group in the International Subcommission on Cretaceous Stratigraphy. The definition is satisfactorily applicable for shallow marine deposits within the western Tethys, north Atlantic and central-south America. Unfortunately, the primary marker taxon cannot be found in the Pacific and circum-Pacific regions because of the limited distribution of *Calpionella*. To determine the base of the Berriasian outside of the *Calpionella* territory, alternative markers are needed.

Radiolarians are good candidates for defining the JKB because they are wide spread and can be found both shallow and deep sedimentary facies. Pelagic sequences across the JKB have been reported in ODP/IODP sites in the western Pacific and land sections in Japan, the Philippines, southern Tibet, Iran and others. Evolutionary lineages of several radiolarian taxa across the JKB are reviewed and suitable bioevents, which are approximate to the JKB, are presented. The *Loopus–Pseudodictyomitra* lineage can be the most important phylogeny for defining the JKB.

The Bosso Valley section in Umbria–Marche, central Italy, is one of potential candidates for GSSP of the JKB. The Maiolica Formation, which crosses the JKB, is characterized by whitish, beige to gray colored, well-bedded micritic limestones with abundant black to gray chert layers and nodules. Calpionellid stratigraphy and magnetostratigraphy have been studied sufficiently in the section. The base of the *Calpionella alpina* Subzone, i.e. the JKB, is placed between Beds 77 and 78. We carried out detailed field observations and careful sample collections in a 4-m interval across the JKB. Acid-etched examination of rock samples revealed that well-preserved radiolarians are recognized inside the lime part near the chert layers or nodules. Several samples of micritic limestone below and above the JKB yield well-preserved radiolarians. The result of radiolarian faunal analysis in the Bosso Valley section is presented.

Mon. May 27, 2019 9:00 AM - 10:30 AM JST | Mon. May 27, 2019 12:00 AM - 1:30 AM UTC | 201B 2F

[M-IS17] History X Earth and Planetary Science

convener:Yasuyuki Kano(Earthquake Research Institute, The University of Tokyo), Kei Yoshimura(Institute of Industrial Science, The University of Tokyo), Hiroaki Isobe(Faculty of Fine Arts, Kyoto City University of Arts), kiyomi iwahashi(National Institute of Japanese Literature), Chairperson:Yasuyuki Kano(東京大学 地震研究所), Kiyomi Iwahashi, Hiroaki Isobe, Kei Yoshimura, Harufumi Tamazawa

The history of modern observation in earth and planetary sciences is often far shorter compared with the timescales of their interests. Investigation of the long-term variations and occurrences of extremely rare events requires effective use of information before modern observations. Historical documents recorded by diverse kinds of authors in various situations are the important sources of such information.

Thus, historical documents have been referred in various fields of earth and planetary sciences such as seismology, climatology, meteorology and astronomy. Sharing their records, methods and experiences will be beneficial for each field and bring new insights. It is also essential to involve experienced scholars in history because one needs to carefully investigate the reliability and the context of each document in order to use it as scientific data. On the other hand, analyzing the record in the historical documents with the eyes of modern science may also bring new insights to the history scholars.

In this session we overview the studies using the historical documents in various fields of the earth and planetary sciences as well as the recent advances in related topics such as digital humanities and historical-data assimilation. The aim is to promote the communication and dialogues among the researchers in various background, and thus foster the new ideas and collaborations in the study of "History X EPS."

Document based reconstruction of environment of forests in the Edo period

*SATOSHI SHIROUZU[1]

1. Chuogakuin University

Edo period is sometimes praised as the people had lived sustainably in harmony with nature. However, the people not necessarily lived sustainably. For example, excess usage of natural resources leaded to exhaustion of the resources.

There is a category of historical document called “O-Hayahi-Kakiage-Cho” or register of official forests. The “O-Hayashi” or the official forest is a forest controlled by Tokugawa shogunate or local feudal government, which could not be used by ordinary people. Maintenance of the forest was assigned to local people, “O-Hayashi-Mori” who made the register. The register contains the data such as kind or name, thickness, highlight, and number of woods. While the register itself is boring document for historians, it is a mine of data for dendrologists. The register describes a condition of the forest over a few hundred years ago, which helps dendrologists to reconstruct the environment of the forests. Dr. Yasuhiro Koyama showed that most of the official forest in northern part of Shinano province, or Nagano Prefecture, were sparse woods with Japanese red pine of 20-30 cm diameter. The official forests in the region were not green nor rich. By contrast, “Sendou-O-Hayashi” in the same region corresponds to Sakae village showed totally different environment. The forest had a spread of 13.5 ha. 70% of the woods were Japanese oak and beech. There were over 56 woods with diameter of 2 m. 1615 of woods had circumference over 3 m which corresponds the definition of “giant tree” by Ministry of the Environment. The forest was the one with a grade of Natural monuments today. It is surprising that there was such a rich forest in Japan only 200 years ago. Natural environment of Japan seemed to foster the rich forests. The rich forests have been lost because of deforestation by human. This is a good example to show the importance of human activities on condition of natural environment.

Rapid deforestation at nonofficial forests leads to exhaustion of useful woods. All the useful woods such as Japanese cedar and arborvitae had been cut down around Akiyama district until late 19 century. A historical document reported that only useless woods such as Japanese beech, oak, or chestnut remained. The people of Akiyama district demanded conifers to make wooden products such as bucket. After difficulty to obtain material, people changed their mind to use broadleaf trees and started to make bowl and plow etc. The useless woods turned to main material for production. Although they overcame the difficulty, they continued deforestation as they wrote on a document that the desire of human was limitless.

Incorrect or false descriptions are found from the close examination of the registers. There are same numbers of woods on registers recorded at different time. The person in charge seemed to alter the number for fear of meeting criticism for insufficient management. This example shows that historical records are product of “human.” The true value of historical science is to reveal the activity and society of human. The examination of historical documents on the assumption of the human nature or the procedure of information evaluation increase the value of the historical documents as data.

Studies of Babylonian Astronomical Diaries: Today and the Future

*Yasuyuki Mitsuma[1]

1. The University of Tokyo

The presenter uses a large group of Akkadian cuneiform texts on clay tablets, the Astronomical Diaries from ancient Babylonia (mainly from Babylon) as the main source of his presentation. The text group is called ADB in this presentation. ADB is a large series of clay tablets recording astronomical and meteorological phenomena, commodity prices, level of the Euphrates, and historical events from the seventh to the first centuries BC. The clay tablets of ADB count up to over 1500, but only about 400 tablets have been published for the use of researchers. The presenter stayed in London for two years and consulted and photographed most of the unpublished tablets of ADB, which are now preserved in the British Museum. He also took photos of a considerable amount of published ADB tablets. Basesd on the photos and additional data of ADB tablets, the presenter will publish the (new and more exact) texts of published and unpublished ADB tablets. The presenter will also colloborate with some researchers and provide them with the astronomical and meteorological data of ADB, which are useful for the restoration of the ancient astronomical phenomena and climate.

Characteristics of the Sunspots that Produce Large Solar Flares and the Possibility to Investigate these Events Utilizing Historical Observational Records

*Shin Toriumi[1]

1. National Astronomical Observatory of Japan

Solar flares are the sudden releasing of magnetic energy and, among them, the energetic ones that occur around the sunspot regions may directly and indirectly affect the Earth through the enhancement of electromagnetic waves, releasing of high energy particles, and coronal mass ejection. While it is accepted that the strongest flare activity ever observed is the "Carrington event" in September 1859, in order to understand the mechanisms and trends of such extreme space-weather events, it is crucial to increase the sample number of the events with enough observational data and conduct statistical investigations. Although often these events do not have observations of sufficient data quality for modern scientific analysis, there are several ways to elucidate how and why the strong events occurred. In this presentation, we first show the morphological and magnetic characteristics of flare-productive sunspots that are revealed by observational data analysis of sunspots in Solar Cycle 24 (especially for six years from 2010) and by magnetohydrodynamic simulations to model these sunspots. Then, we introduce several research attempts to reconstruct magnetic activities by using historical documents such as sunspot drawings. Finally, we discuss the the possibility to investigate extreme space-weather events by applying our modern knowledge of flare-productive sunspots to extreme events in history.

An Approach of Environmental History to the "14th Century Crisis"

*Isahaya Yoichi[1]

1. Slavic-Eurasian Research Center, Hokkaido University

This paper is an introduction to an approach of environmental history to the “14th Century Crisis.” The “14th Century Crisis” is the term for collective peril in the 14th century which is considered to be the time of transition from the Medieval Warm Period (ca. 1000–1300) to the Little Ice Age. The peril consists of cooling, natural disasters, epidemics and political upheaval such as the fall of the Mongol Empire (1206–1368). Our project embarks upon interdisciplinary collaboration between sciences (astronomy, meteorology, and seismology) and humanities (history and archival science) to elucidate an actual phase of the crisis. In the context of world history, the “14th Century Crisis” has attracted scholarly attention as the pivot that closed the multi-centered “13th Century System” across Afro-Eurasia, and paved the way for the European-centered “Modern World-System.” The grand shift, however, could not be calibrated properly without taking account of the environmental transition to the Little Ice Age. This is an introductory remark of our project aiming to shed some new light upon entangled relationships between human development and environment.

In most of the countries in monsoon Asia, the meteorological observations by modern instruments started during their colonial period before the World War II. However, most of these old meteorological data have not been digitized yet, and have not been utilized in the past climatic change researches. Here, we will briefly introduce our recent data rescue activities mainly for the daily precipitation data in the Former British India, China, Philippines, Vietnam, and Japan for the recovery of the past Asian monsoon variations since the late 19th century as one of the activities in the ACRE (Atmospheric Circulation Reconstruction over the Earth) project. Although with the aid of the World Meteorological Organization, the National Oceanic and Atmospheric Administration archived the scanned images of huge data books all over the world, it was sometimes very difficult to read the numerals in the scanned data. The original data books/sheets are needed for the accurate digitization of the old data. Acknowledgments: Part of this study was supported by The JSPS KAKENHI (25282085,26220202,15K16283,18K19951, 18H01681), The GRENE program of the MEXT. Digitization activities of the former British India were supported by Drs. Shoichi Shige (Kyoto Univ.), Masashi Kiguchi (Univ. Tokyo), Hironari Kanamori (Nagoya Univ.), and Nozomi Kamizawa(Tokyo Metrop Univ.). They were also supported from the India Meteorological Department, the Indian Institute of Tropical Meteorology and Indian students in Pune.

Discussion

Historical big data: integrated analysis of the past world by the workflow that bridges data structuring gaps

*Asanobu Kitamoto[1,2,3], Mika Ichino[1,2]

1. National Institute of Informatics, 2. ROIS-DS Center for Open Data in the Humanities, 3. SOKENDAI

1. Introduction

Reconstruct and analyze the past world through the extraction and integration of information from the past books and documents –we call this type of historical research as “historical big data.” This is because this approach has the same structure and purpose with “modern big data” on the current world, and it is meaningful to extend this approach into the past world. A big obstacle, however, is in data structuring. We start from data written in Kuzushiji (cursive scripts) on historical documents to high quality data usable for computaitonal analysis of the past world. For this purpose, we need information infrastructure to support this long data structuring workflow from digitzation to quality control. Because this is difficult to automate, we need efficient data structuring workflow based on human-machine collaboration. We therefore design a workflow to convert non-structured data (e.g. image and text) to structured data (analysis-ready data) and develop information platform for humanities dataset that is reusable and verifiable.

A similar but bigger project has started in EU called “Time Machine Flagship” involving more than 200 organizations. The project is building “time machine” to move freely within spatio-temporal space, especially within the big data of cities such as Venice in Italy and Amsterdam in the Netherlands. This trend has not been incorporated in Japan and Asia, so our platform may also be an entry point for this global initiative.

2. Issues

Many research projects for reconstructing the past have been carried out, but historical big data is a different approach in terms of the following.

First, the type of data is different. For example, paleoclimate research uses any data related to climate; not only books and documents, but also traces in the nature (proxy data such as ice core and growth ring). On the other hand, historical big data limits its scope on records written by human, and focuses on developing new data structuring workflow including the interpretation of textual records.

Second, the target of discipline is different. Research in one discipline had a tendency of focusing only on a limited type of phenomena, and did not pay attention to other phenomena. Even when researchers are studying the same diary, bibliographic data or extracted data were not shared across research groups, and many researchers repeated similar tasks again and again. To solve this problem, historical big data offers data structuring workflow that is effective across disciplines, and enables research that takes advantage of data sharing.

3. Data crossing and re-interpretation

To extend the modern big data into the past, relevant issues are not only the extension of technologies

©2019. Japan Geoscience Union. All Right Reserved.

but also concepts and methodologies.

First, data crossing is a methodology to overlay different data to find unexpected relationship. A typical example is a map. By registering and overlaying data from different sources, we can take actions based on insights obtained from data. Here important challenges include the interoperability of API and sharing of terminology. To solve this challenge, we share future challenges within our research group, take advantage of the strength of each member without overlapping tasks, and develop information infrastructure maximizing the outcome within limited resources.

Second, data re-interpretation is a methodology to find effective reuse of data collected for one purpose into another purpose. A famous example in the modern big data is the case of reusing car probe data for the map showing passed routes after earthquake disasters. A same approach should be effective for historical big data. For example, is it possible to use the change of bureaucrat's directories for evaluating societal impact by climate change? Flexible imagination may lead to the creative usage of data.

4. Beyond “One Bed Multiple Dreams”

Historical big data is a multidisciplinary research. Of course, a big gap exists between humanities and science/technology, but difference within science and technology disciplines are not negligible. How to go beyond these gaps? Our basic idea is to recognize that we are in “one bed multiple dreams” situation in the sense that each member in the research group has a different dream. But at the same time, we recognize the advantages of being in one bed. For example, data and tools can be shared even if we have different dreams. After maximizing the advantages of sharing, an individual researcher tackles the reconstruction of a different part of the past world –this is the concept of historical big data research.

Felt earthquakes in Tokyo (Edo) based on historical daily records and seismic intensity data

*Kenji Satake[1]

1. Earthquake Research Institute, University of Tokyo

There have been three generations of collection and publication of historical materials on earthquakes. They are “Dai-Nihon Jishin Shiryo (Collection of Historical Documents on Earthquakes in Great Japan)” in 1904, “Zotei Dai-Nihon Jishin Shiryo” and “Nihon Jishin Shiryo” in 1941-1951, and “Shinshu Nihon Jishin Shiryo” in 1981-1991. On the basis of these collected materials, annual number of felt earthquakes in Tokyo (formerly Edo) was examined by Usami (1979, CCERP report) and Usami and Watanabe (2005, 2006, Historical Earthquakes). Number of felt earthquakes strongly depends on the available materials. The above collections contains some daily records of clans which documented daily weather and earthquakes, and the recorded earthquakes include small shocks or aftershocks of large damaging earthquakes. In order to discuss temporal changes of seismicity, such homogeneous records should be used. In this study, number of yearly earthquakes in several daily records are counted, and compared with seismic intensity data of Japan Meteorological Agency since 1885.

Among the daily records during the Edo period (1603-1867), “Tsugaru-han On-nikki” recorded the largest number of felt earthquakes; approximately 1550 events during 200 year period between 1668 and 1866. However, there are several years during which no earthquake was documented. The next one is “Sakaki-bara Nikki”, which documented approximately 700 events during 200 year period between 1651 and 1859. This record also contains years without any earthquake, but such years are different from those of the previous record. By merging these two daily records, there are only few years without felt earthquakes. For the earlier Edo period, “Edo-bakufu Nikki” (two different sources) cover more or less continuously from 1631 to 1707 with 680 earthquakes. In addition, several other records such as “Tsushima-han Mainichiki”, “Inaba-shi Eidai Nikki” or “Sakai-ke Shiryo” each documented more than 100 earthquakes. Yearly number of earthquakes were counted for each record, and the largest number for each year was selected. The dataset thus made contain nearly 2500 earthquakes for 241 year period (1628-1868) with annual average of about 10 events. The yearly record has several peaks in 1704 (about 60 events), in 1855 (about 50 events) and in 1649 (about 50 events). These represent aftershocks of the 1703 (31 December) Kanto earthquake, 1855 Edo earthquake and two M7 earthquakes in 1649.

Seismic intensity data since 1885 has been complied by JMA (Ishigaki and Takagi, 2000, Quarterly J. Seismology; Ishigaki, 2007, ibid), which shows that the annual number of earthquakes with intensity 1 or larger, 2 or larger, 3 or larger are 52, 16 and 5, respectively. If we assume that the seismic intensity rate is constant in the last 400 years, then the above merged historical daily data recorded felt earthquakes with intensity 2 or larger. The JMA data show that the largest number of felt earthquakes was recorded in 2011, with 148 events with intensity 2 or larger, representing aftershocks and triggered seismicity by the Tohoku earthquake. Numbers of earthquakes with intensity 2 or larger were 36 and 35 in 1923 and 1924, following the Taisho Kanto earthquake. Combining the historical data from daily records, it is concluded that the number of felt earthquakes was largest in 2011 in the last 400 years.

Climate and social changes in ancient Japan construed by use of high resolution reconstruction of the Climate in Historical Time

*Katsunori IMAZU[1], Takeshi Nakatsuka[2]

1. OKAYAMA University Graduate School of Humanities and Social Sciences, 2. Research Institute for Humanity and Nature

This study focuses on ancient times of Japan, specifically the 8th and 9th Century in an attempt to clarify how the weather impacted societies then. Takeshi Nakatsuka developed per-annum reconstruction of climate for that period of time, which revealed that the 8th Century was, in general, relatively dry but stable, whereas the second half of the 9th Century turned to be unstable and wet, then in the 10th Century the weather changed to dry. Historical literature including Shoku Nihongi (second of the six classical Japanese history texts)、Nihon Kouki (third of the six classical Japanese history texts), Shoku Nihon Kouki (fourth of the six classical Japanese history texts), Nihon Montoku Tenno Jitsuroku (fifth of the six classical Japanese history texts), and Nihon Sandai Jitsuroku (sixth of the six classical Japanese history texts) described history of said period and included the description of the weather then. However, they are very brief and do not provide precise details as to the severity of drought, spells of rain or torrential rain. At long last, high-resolution weather reconstruction helps to bring clarity to the level of extreme dryness and humidity of summer and the damage they brought about, when we review historical documents. Additionally, the deeper understanding of the mid- to long-term weather pattern changes helps to visualize the interrelationship between the climate change and changes in the state and societies.

In this research, our interest, in particular, lies on demographic change and social system transformation in ancient times. In the early 8th Century Taiho Code was enacted and a centralized government established a political system based on the Ritsuryo Codes, which demonstrated their intent to emulate the system in China. The systems set forth by the Ritsuryo-Code-based-nation laid the foundation for the framework of Japan and played an essential role in defining the subsequent development of its history. The population that the state of the Ritsuryo Codes ruled is estimated to be around 4.5 million at the beginning of the 8th Century and approximately 5.5 million at the beginning of the 9th Century, with the average population growth rate from the 8th to 9th Century being 0.2% per annum. The population in the 17th Century, the beginning of the Edo era, is estimated as 12-18 million. The population slightly increased from the ancient times to early modern times. The yearly population increase over a course of 800 years from the mediaeval to early modern times was only 0.1-0.15% at best. Ancient Japan was frequently visited with plague and famine, which kept the nation highly fluid and vulnerable. Despite this situation, yet the population growth was at a higher rate comparing to the middle ages. This is considered due in part to a high functioning reproductive system set forth by the Ritsuryo system in which the central government exercised control over the people's lives and rice paddies and also by a relatively stable weather in the 8th Century.

Changes in Tang dynasty and Shilla, the neighboring countries of Japan, affected the Ritsuryo system in Japan, which collapsed little by little. The Ritsuryo-based-nation considerably changed from the late 9th Century to late 10th Century. These social changes were triggered by the changes in the overseas political landscape in its vicinity as well as the climate change. In the second half of the 9th Century they faced problems of the rise of non-arable rice paddies and flooding of rice fields. We are convinced that the climate change resulting in the humidity level increase of the land was at the root of these problems at that time. The Ritsuryo system started to give up on its exercise of control over its people and rice fields, thereby the reproductive system of the Ritsuryo state broke down. It was exacerbated by frequent

©2019. Japan Geoscience Union. All Right Reserved.

earthquakes, a volcano eruption, famine and pandemic, all of which occurred during the same time frame. It was a time of crisis for ancient Japan as a whole. The nation under the Ritsuryo codes established a centralized government at the beginning of the 8th Century, but in the late 9th Century and onwards it started to collapse and the central government was contracted into a dynastic state in the capital of Heiankyo.

Absolute ages for huge eruptions of Towada Caldera and Baitoushan volcano in the 10th century as seen from dendrochronological studies and historical documents

*Masataka Hakozaki[1], Fusa Miyake[2], Masaki Sano[3], Katsuhiko Kimura[4], Toshio Nakamura[2], Mitsuru Okuno[5], Minoru Sakamoto[1], Takeshi Nakatsuka[6,2]

1. National Museum of Japanese History, 2. Nagoya University, 3. Waseda University, 4. Fukushima University, 5. Fukuoka University, 6. Research Institute for Humanity and Nature

The Towada Caldera (Aomori Prefecture / Akita Prefecture) and Baitoushan volcano (China / North Korea) each caused a huge eruption in the 10th century, respectively. These traces are clearly left behind in the stratum of the northern Japan as To-a tephra and B-Tm tephra. These two eruptions are estimated to be one of the largest in Japan and the world in the past 2000 years, respectively (Hayakawa & Koyama 1998). However, direct document records of these eruptions have not been found from any countries around the volcano. For that reason, these absolute ages had long been unknown. Also, due to uncertain age, the impact on human society and the global environment of these eruptions has not been evaluated.

Recently, the absolute age of the 10th century eruption of Baitoushan volcano was decided in AD946(Oppenheimer et al. 2017, Hakozaki et al. 2018). It was achieved by "^{14}C-spike matching" which is applied a rapidly carbon-14 increase event in AD775 discovered from tree-rings of Japanese trees (Miyake et al. 2012). And this age was also verified by the result of the oxygen isotopic dendrochronology (Kimura et al. 2017). Hayakawa and Koyama (1998) picked up this age (AD946) from descriptions suggesting distant eruptions written in a few old documents of Japan and Korea (ex. "Kofukuji-nendaiki", "Goryeosa") .

On the other hand, due to fixed in AD946 the absolute age of B-Tm, doubts occurred in the age of 10th century eruption of the Towada caldera. The 10th century eruption of Towada caldera had been estimated to be AD915 according to the description on the "Fuso Ryakuki" suggesting the eruption, and the dates of archaeological timbers buried in the lahar at Akita prefecture. Based on this age, the varves at lakes in Akita prefecture counted between To-a and B-Tm to be 14 layers, Kamite et al(2010) estimated the eruption age of Baitoushan volcano to be AD929. However, since the absolute age of B-Tm was AD946, as described above, it became clear that there was a gap of 17 years from Kamite et al's estimates. In other words, there is a possibility that the 10th century eruption of Towada caldera may be AD932. If this is correct, there is a possibility that the description of AD 915 in the "Fuso Ryakuki" indicates the eruption that occurred in volcanoes other than Towada caldera.

Recently, the oxygen isotopic dendrochronology was applied to the timbers of the fence of Tagajo site of Miyagi prefecture, and the absolute age was decided to be AD917 (Saito et al. 2018). In the archaeological survey, this fence has been thought to be built before the ash fall of To-a tephra (AD915) (Miyagi prefectural research institute of the Tagajo site 2018). The fact that the tree-ring of the AD917 was recognized in the timbers of the fence largely contradicts the estimated age (AD915) of To-a tephra. Furthermore, neither bark nor sapwood remained in these timbers, and it is clear that the logging year is later than AD917.

In this presentation, we show how the ages of timbers of Baitoushan volcano and Tagajo site determined

How can we activate collaborations with history and archaeology? –Lesson from Historical Climate Adaptation project

*Takeshi Nakatsuka[1,2]

1. Research Institute for Humanity and Nature, 2. Graduate School of Environmental Studies, Nagoya University

Introduction

Earth and planetary sciences belong to historical sciences dealing with past natural and human phenomena as well as history and archaeology. Although many inter-disciplinary researches have been conducted between them, there are a lot of problems originating from differences of their essential philosophy. Here, I will discuss how to activate collaborations with history and archaeology based on my experiences as the leader of “Historical Climate Adaptation Project” in Research Institute for Humanity and Nature (RIHN) from 2014 to 2018.

Fundamental Strategy of the Project

RIHN is an inter-university research institute, accepting many research proposals aiming to solve a global environmental problem by inter-disciplinary approaches between natural and human sciences. In the framework of RIHN, we created three steps of research strategies. 1) To reconstruct variations in past climate at annual resolution for last several millennia in Japan. 2) To compare paleoclimate data with numerous historical and archaeological archives. 3) To elucidate characteristics of societies resilient or vulnerable to climate changes by comparing many historical cases. Although I initially imaged the unidirectional data provision from paleoclimatology to history and archaeology except for the study of historical climatology, the inter-disciplinary communications actually made unexpected progress in the paleoclimatology, especially in the establishment of super-long chronology of tree-ring cellulose oxygen isotope ratio.

Results of Inter-Disciplinary Collaboration

Tree-ring cellulose oxygen isotope ratio is a novel proxy to reconstruct past summer precipitation precisely even in humid and temperate areas like Japan where traditional dendroclimatology was not very successful. We planned to establish the long-term datasets over Japan. At the beginning, historians and archaeologists were regarded as users of the data, but they actually contributed to the creation and refinement of data by various ways. After receiving the data, they answered to paleoclimatologists as follows. (1) Active provisions of excavated woods and old architectural woods for isotopic analyses. (2) Critical evaluation of the paleoclimate data from the viewpoint of history and archaeology. (3) Request to improve the resolution and extension of paleoclimate data. Paleoclimatologists welcome (1), but it was not easy to answer to (2) and (3) because such criticisms and requests are not usually originating from themselves. However, the request (3) finally made us enable the tree-ring based millennial scales climate reconstruction, by combing the tree-ring oxygen and hydrogen isotope ratios, which were validated by critical evaluations of historians and archaeologists (2). It promoted many studies in paleoclimatology, history and archaeology. However, it was not easy to elucidate “societal systems resilient to climate change” because we had not shared the research purposes between natural and human sciences.

Conclusion

©2019. Japan Geoscience Union. All Right Reserved.

The unprecedented length and precision of paleoclimate data are the results of active inter-disciplinary communications. Although the unidirectional data provision was not successful, the critical interactions improved both the data quantity and quality. On the other hand, the sharing of research philosophy between natural and human sciences was necessary to promote “real inter-disciplinary” research. In the project, I found the fact that historians and archaeologists do not usually study history to solve contemporary problems. Rather, they focus on the difference in people’s sense of values between past and present. Because the future must be different from the present as well as the past, it is very important to promote collaborations between natural scientists who seek the universality in history and human researchers who understand the diversity of history in order to make sustainable society. That was my most important finding in the project.

Discussion

Axisymmetric disturbance on an axisymmetric shallow water vortex

*Toshihisa Itano[1]

1. National Defense Academy

The air in an eye of a typhoon is often considered to be stratospheric origin. Indeed, the region of high equivalent potential temperature invading eyes from stratosphere can be seen in most of tropical cyclones. Therefore, we can recognize tropical cyclones are vortices where the air with low potential temperature revolves around the warm air sucked from stratosphere. Also, elliptical or polygonal deformation of an eye of a tropical cyclone can be attributed to the oscillation of the interface between such two kinds of fluids. Thus, in this study, a tropical cyclone is modeled with two layer fluids where the upper fluid touches the ground surface at the core region of the vortex, and the motion on the interface is investigated with the shallow water equations described in polar coordinate by assuming the upper fluid at rest.
An axisymmetric swirling fluid whose center is completely dried up is adopted as the basic state, where the tangential speed is assumed to be inversely proportional to the α-th power of radius. Perturbations are again set to be axisymmetric. Under these settings, the governing equations are linearized, and an eigenvalue problem is formulated after hypothesizing sinusoidal time variation with the angular frequency ω. The eigenvalues are, at first, obtained numerically by discretizing the variables with a standard staggered grid. Then, in the case of no ambient rotation, the problem is solved analytically, by applying a series expansion to the governing equations.
Results reveal the existence of modes like gravity waves. Since the amplitudes of the modes are non-zero at the inner boundary corresponding to the outer edge of the dry core, they would be responsible for the periodic expansion and contraction of an eye in an actual tropical cyclone. Moreover, quasi-steady modes with no nodes in the radial direction emerge in the case of no ambient rotation. Although numerical and analytic solutions roughly coincide with each other, a definite discrepancy is found near the dry core of the basic vortex: radial cross sections reveal that the numerical solutions tend to swing once more against the analytic solutions around there.

Numerical studies on the classification of flow regimes of the 3-D thermal convection of rotating fluids

*Masanori Kameyama[1,2]

1. Geodynamics Research Center, Ehime University, 2. Japan Agency for Marine-Earth Science and Technology

In this study we made a series of statistical analysis for a thermal convection in a three-dimensional Cartesian box rotating about a vertical axis, aiming at obtaining clues to readily understand the flow regimes of rotating convection. First we conducted numerical calculations of 20 cases where the values of Rayleigh number (Ra), Ekman number (Ek) and Prandtl number are systematically varied in the range of earlier studies. We confirmed that, based on the efficiency of convecting heat transfer, the flow patterns of these cases are classified into three regimes mainly depending on Ra and Ek: (i) no-rotating convection, (ii) the regime with strong effect of rotation, and (iii) that with moderate effect of rotation. In particular, we found that the change between the regimes with strong and moderate effect of rotation is associated with the change in the pattern and occurrence of Ekman pumping near the top and bottom boundaries, which can be clearly seen from the correlation between the vertical components of velocity and vorticity there. In the regime with strong effect of rotation, a strong correlation is observed in the vertical flows both away from and toward the horizontal boundaries. In the regime with moderate effect of rotation, in contrast, it is observed only in the flows departing from the boundaries. Our findings suggest that, from the viewpoint of rotating convection, the flow regime the Earth's outer core can be well identified from the observation of the correlation between the radial components of velocity and vorticity.

Diffusive behavior of columnar vortices in rotating thermal convection

*Daisuke Noto[1], Yuji Tasaka[2], Takatoshi Yanagisawa[3], Yuichi Murai[2]

1. Graduate School of Engineering, Hokkaido University, 2. Faculty of Engineering, Hokkaido University, 3. Japan Agency for Marine-Earth Science and Technology

Rotation effect on thermal convections in a fluid layer driven between two parallel plates with temperature difference, i.e., Rayleigh-Bénard convection (RBC) is a ubiquitous to explain large scale fluid motions observed on the Earth, such as typhoon, tornadoes, and liquid metal convection inside outer core. Various approaches so far have revealed its interesting features, e.g. heat transfer enhancement at moderate rotation rate, rotation dependent flow morphologies, and so on. Especially in them, formation of vertically aligned columnar vortices is one of the most curious phenomenon. Early experimental works mentioned those chaotic behavior like vortex-vortex interactions, however, little is known about this complicated vortex dynamics.

The present study is paying attention to such vortex dynamics observable in rotating RBC. With using encapsulated thermochromic liquid crystals, long-time $O(10^3$ s) experimental visualizations of the vortices on time variations of a temperature field were conducted, and we reached two novel insights. One is horizontal diffusive motion like Brownian motion of the columnar vortices. Statistical analyses on motions of the columnar vortices elucidated various kinds of diffusive motion. Such diffusive motions strongly depend on observation timescale (vortex lifetime) and columnar vortices present anomalous diffusive motion. Another is the effect of centrifugal force even under conditions for empirically negligible small effects of centrifugal force. This is the first found thanks to our long-time observations and might give a new caution to rotating RBC studies.

Liquid metal flows driven by a rotating magnetic field

*Koki Sawada[1], Vladimir Galindo[2], Tobias Vogt[2], Sven Eckert[2], Yuji Tasaka[3], Yuichi Murai[3]

1. Graduate School of Engineering, Hokkaido University , 2. Helmholtz-Zentrum Dresden-Rossendorf, 3. Faculty of Engineering, Hokkaido University,

Doing experimental studies on liquid metal flows under interactions with magnetic fields is of great importance for understanding fluid dynamical phenomena including flows in planetary cores. In this research, liquid metal flows driven by a rotating magnetic field (RMF) were examined experimentally. The RMF generates eddy currents in liquid metal layers, and thus Lorentz force as the results of the interaction between the magnetic field and the current achieves the rotating flows. The fluid motions are dominated by angular velocity and magnetic strength of the RMF. In cases at which the skin effect is negligible small because of moderate angular velocity, modal transitions of the flow occur with increase of magnetic Taylor number (Ta_m), which is a dimensionless number including the angular velocity and the magnetic strength. For sufficiently small Ta_m, a quasi-two-dimensional, axisymmetric steady flow is formed. With increase of Ta_m, then, unsteady flows emerge by collapsing the symmetry. For this transition problem, theory and numerical calculation have been preceded. On the other hand, experimental approaches have essential unknows, even though there are quired to uncover the phenomena especially at higher Ta_m with stronger nonlinearity; namely, how to realize the RMF by experiment, and whether the experiment system can reproduce the flows expected by numerical simulations.

In the present experiment, we tried to produce the RMF by switching electric current in six-pair coils. A square container with aspect ratio 2 filled with eutectic of GaInSn, a liquid metal having low melting point, was arranged at the center of the coil. The GaInSn is an opaque fluid and it is impossible to be optically visualized. Ultrasonic Doppler velocimetry was used to obtain information of the flow fields. The switching frequency of the RMF was set at 50 Hz at which the skin effect did not appear, and Ta_m was modified by changing the magnetic strength. A long these methods, the flow transition depending on Ta_m was observed. As the measurement results, a stationary axial symmetric flow, that is in good agreement with the numerical simulation results, was observed under relatively small Ta_m. The increase in Reynolds number with respect to Ta_m also show reasonable agreement with the numerical simulations. Furthermore, the process of unsteady and turbulent transition in the increase of Ta_m was discussed and was compared with the numerical simulations.

A symmetry-breaking self-regulating dynamo generating Mercury’s anomalous magnetic field

*Futoshi Takahashi[1], Hisayoshi Shimizu[2], Hideo Tsunakawa[3]

1. Faculty of Sciences, Kyushu University, 2. Earthquake Research Institute, University of Tokyo , 3. Department of Earth and Planetary Sciences, School of Science, Tokyo Institute of Technology

The discovery of Mercury’s unusually axisymmetric, anomalously axially offset dipolar magnetic field shows a new regime of planetary magnetic fields. The cause of the offset dipole remains to be resolved, although some exotic models have been proposed. Since the magnetic fields of the terrestrial planets are generated by fluid motions in the liquid iron core through dynamo action, which is inevitably linked to the structure and evolution of planetary interiors, untangling why Mercury has such an anomalous field is not only crucial for understanding the internal dynamics, evolution history and origin of the planet, but also essential for establishing the general theory of planetary magnetic fields by extending our knowledge to small bodies in our solar system such as Ganymede, Moon and asteroids. In this study, we use numerical dynamo models. Convection is driven as thermo-compositional convection. A thermally stably stratified layer is imposed in the outer part of the core. It is found that the magnetic fields similar in morphology as well as strength to that of Mercury are reproduced. Also, the dynamo-generated magnetic fields act on the flow to induce interaction between equatorially symmetric and antisymmetric components, and resultantly to yield north-south asymmetric helicity. Additional runs demonstrate that the offset dipolar field cannot be maintained without the magnetic self-regulating effect. Thus, it is concluded that the symmetry breaking self-regulating effect causes the flow to generate and maintain the Mercury-like offset dipolar field.

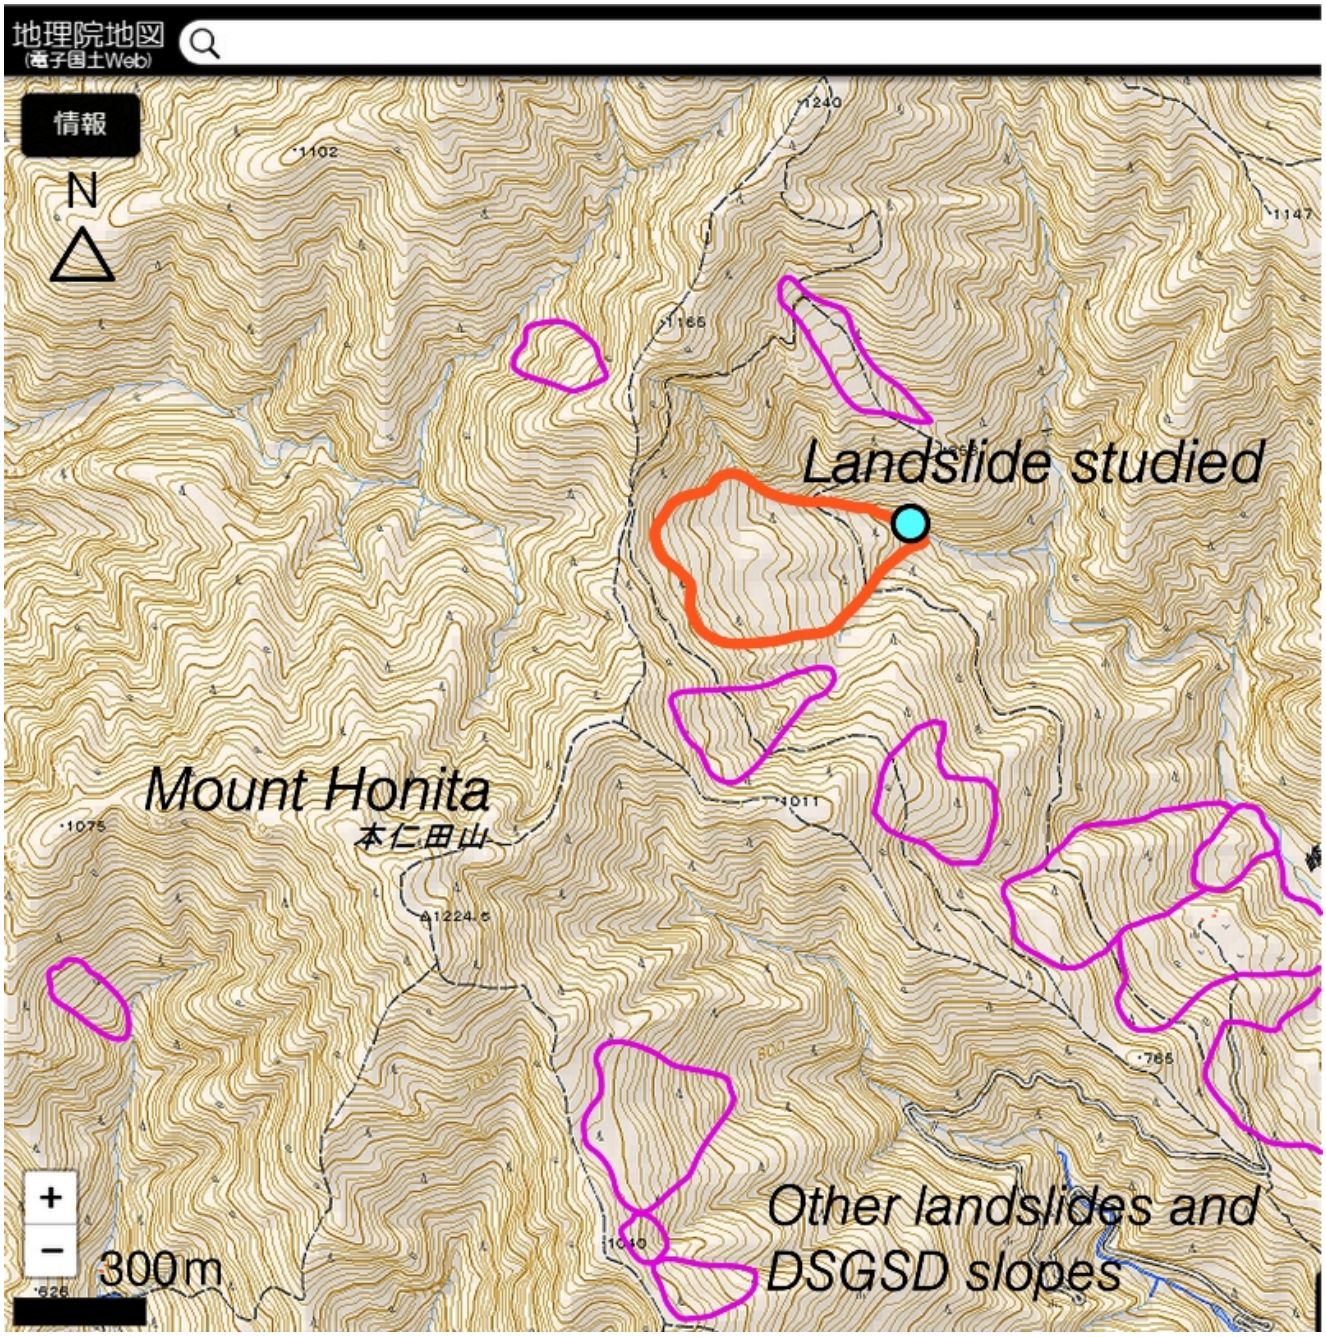
Early Holocene landslide deposits found from Mount Honita, the upper Tama River basin, west of Tokyo



*Yoshihiko Kariya[1], Koichiro Sawabe[2]

1. Department of Environmental Geography, Senshu University, 2. Japan Conservation Engineers

Landslide features are common in the upper Tama River basin west of Tokyo Metropolis where sedimentary rocks derived from Mesozoic accretionary prisms are widespread. We obtained two wood fragments from landslide deposits on the northeast side of Mount Honita (710 m ASL). Radiocarbon ages of those fossils showed 10250-10189 cal BP and 10150-10057/10042-9987/9959-9704 cal BP (2sigma; OxCal4.3 with IntCal13). This result indicates that landslide occurred in the early Holocene when precipitation had increased and the elevation of riverbed had decreased in central Japan due to global changes. This situation would create morphogenetic environments prone to landslide occurrence. Although the Tachikawa Fault zone is close to Mount Honita, the age of latest paleoseismic event revealed by a trenching survey does not coincide with ages of the landslide event shown here.

The effect of understanding of mountainous terrain using 3D maps and solid model

*Jiro Komori[1]

1. Teikyo Heisei University

The topography shows various forms by a background of the formation of the place, i.e history of geology and structural development, weathering, erosion and deposition. However, for a person without an interest and opportunity for geoscience study, it is difficult to understand the relation between the topography and background. On the other hand, it became easy to see a stereoimage of the topography without difficulty using a special relief map, 3D view on the screen and hands-on model by 3D printer. This presentation will introduce practical example and reaction of the students for understanding mountain topography.

Development process of Lake Naganuma in a large-scale landslide on Hachimantai Volcano

*Natsuki Sasaki[1], Toshihiko Sugai[1]

1. Graduate School of Frontier Science, the University of Tokyo

In the Hachimantai volcanic group, landslide is one of the most important origins of wetland, and various types of wetlands, including lakes and peatlands, tend to coexist in a large-scale landslide (Sasaki and Sugai, 2015). Landslide wetlands commonly develop from lakes to peatlands, so the wetland types are considered to reflect their developmental stage. This study analyzed sediment cores to reconstruct the development history of Lake Naganuma formed in a large landslide of the Hachimantai volcanic group, and discussed the difference in the developmental history with Oyachi, a large peatland in the same landslide.

Lake Naganuma, which is formed in the upper part of the Komonomori landslide in the northwest of Hachimantai volcano, has an elliptical shape with a long axis in the north-south direction parallel to the scarp of the landslide, and its southern part is peatland. Drilling surveys were conducted at two sites on the long axis, and each sediment core was designated as NN1 and NN 2 from near to the water area. In NN1 core, we identified two lithostratigraphic units: NN1-Unit 1 (3.40–2.64 m depth) was organic silt; NN1-Unit 2 (2.64–0.00 m depth) was peat. In NN2 core, we recognized three lithostratigraphic units: NN2-Unit 1 (4.50–4.20 m depth) was silt with low organic content showing parallel lamination; NN2-Unit 2 (4.20–1.57 m depth) was organic silt; NN2-Unit 3 (1.57–0.00 m depth) was peat. The boundary between each unit was unclear, and their organic content gradually changed. We visually identified 5 tephra layers in NN1 core and 4 layers in NN2 core. From the result of chemical composition analysis of volcanic glasses, pumice layers at 1.05 m depth in NN1 core and at 1.10 m depth in NN2 core 2 were correlated with the To-a tephra, which is widely distributed over the northern Tohoku region as a result of the 915 AD eruption of Towada volcano. And the chemical composition of volcanic glasses at 2.22 m depth in NN1 core and at 2.87 m depth in NN2 were similar to that of the To-Cu tephra, erupted by Towada volcano at 6.2 ka.

The southern part of Lake Naganuma had developed from lake to peatland, because the organic silt layer changed to the peat layer upward in both sediment cores, and because the lower part of the organic silt layer in NN1 and the silt layer in NN2 showed parallel lamination. The lake changed to peatland before 6.2 ka, since the peat layer of NN1 contained To-Cu tephra. However, in NN2 far from the water area, To-Cu was contained in the organic silt layer below the peat layer. Moreover, the organic silt layer of NN2 was thicker, and the deposition rate between To-a and To-Cu layer was estimated about 0.35 mm/yr for NN2, while that of NN1 was about 0.27 mm/year. These suggest that fine grained soil continuously and slightly flowed into peatland around NN2 from the surrounding slopes even after terrestrialization. From the above, we concluded that Lake Naganuma had gradually filled from the upstream part and then been stable in the present state at least for over a thousand years, while peat layer formed.

Many wetlands are formed in the Komonomori landslide, and the development process of Oyachi peatland in the landslide, located about 800 m southwest of Lake Naganuma, is different from that of Lake Naganuma. Oyachi wetland was in the depression formed by a landslide activity before 8600 cal BP, and its transition from peatland to forest was interrupted at about 5500 cal BP by slope movement leading to the development of a lake that was drained by streams at about 3300 cal BP, after which a peatland environment has persisted until the present (Sasaki and Sugai, 2018). On the other hand, Lake Naganuma is more stable for a long period. These suggested that development processes and rates of wetlands are various even in a same landslide, probably depending on local slope stability rather than regional climatic

Air and ground temperature conditions on alpine and sub-apline zone of Norikura Volcano, Northern Japanese Alps

*Akihiko SASAKI[1], Motoshi NISHIMURA[2], Keisuke Suzuki[3]

1. Department of Geography and Environmental Studies, Kokushikan University, 2. Interdisciplinary Graduate school of Science and Technology, Shinshu University, 3. Faculty of Science, Shinshu University

In Japanese mountains, the alpine zone above the forest limit coincides with the periglacial zone, therefore the position of the forest limit and its genesis are important. The forest limit is thought to control by factors such as thermal conditions, prevailing wind, snow cover, and form and deposit of slope surfaces. We observe the air temperatures on the two sites of forest zone, where are forest limit and under limit of subalpine zone of Norikura volcano. In addition, we also observe the air temperature on an alpine zone of Fujimi-dake in Norikura volcano.
The annual mean air temperatures on the forest limit were 0.1 ℃ in 2014 and -0.3 ℃ in 2017. The warmth index (WI) on the forest limit were 19.7 ℃・months in 2014, 21.8 ℃・months in 2015, and 19.8 ℃・months in 2017, respectively. This WI value exceeds 15℃・months of Kira's WI for the forest line in Japan. This result supports the proposal that the forest line of Norikura volcano is controlled not by thermal conditions but by other factors such as the prevailing wind or snow cover.

Initiation and flow characteristics of debris flows on a sediment deposition zone in a mountain area

*Fumitoshi Imaizumi[1], Yuichi S. Hayakawa[2], Haruka Tsunetaka[3], Norifumi Hotta[4]

1. Faculty of Agriculture, Shizuoka University, 2. Faculty of Environmental Earth Sciences, 3. Forestry and Forest Products Research Institute, 4. Graduate School of Agricultural and Life Sciences

Debris flows is a geomorphic process, which is extremely hazardous as a result of their high velocity, long travel distance, and destructive power. However, debris flow characteristics in the initiation zones, which could possibly be affected by accumulation conditions of the storage (i.e., channel gradient and volume of storage) associated with sediment supply from hillslopes and the evacuation of sediment by debris flows, are poorly understood because of the difficulty in access. Thus, we studied the influence of accumulation condition of the storage on initiation and flow characteristics of debris flow at the Ohya landslide body in Japan by periodical terrestrial laser scanning (TLS) and UAV surveys, and field monitoring. In the Ohya landslide, debris flow occurs frequently (about three or four events per year) due to the mobilization of storage Our study clarified that initiation location of the debris flow is highly affected by depth of the storage and water supply from tributaries. Partly saturated debris flow is an important hydrogeomorphic processes in the initiation zones of debris flow because of the steep terrain. The flow characteristics were affected by the volume of storage and rainfall patterns. Partly saturated flow dominated when total of the storage > 15,000 m^3, while fully saturated flow dominated when total volume of the storage < 10,000 m^3. Transition of the flow type from partly saturated flow to fully saturated flow as the surges flow down was monitored by the time lapse cameras. Therefore, debris flow characteristics in the initiation zone, which is highly affected by accumulation conditions of the storage, are sometimes different from that in the transportation and deposition zones.

Relationships between annual landform changes of the riverbed and vegetation dynamics during recent 10 years in the upper Asusa River in Kamikochi valley in the Japan Alps

*Hiroshi Shimazu[1]

1. Department of Geography, Faculty of Geo-Environmental Science, Rissho University

The Azusa river is originated from Mt. Yarigatake and runs through the Kamikochi valley, whichi has the wide valley bottom instead of the mountain region. The Azusa river forms multi bar with gravelbed braided channel in the Kamikochi valley. There are patchy willow communities of *Salix arbutifolia* and *Salix rorida* in the riverbed. Kamikochi Natural History Research Group has made geomorphological maps more than 25 years, recorded annual landform changes and dynamics of vegetation. This paper discusses the relationships between landform changes and germination and destruction of willow communities.

After 2008 major channel pattern changes occurred in 2009, 2010, 2011, 2013, 2017 and 2018. Except 2009 there were heavy rain event whose daily rain fall was over 110mm in the Baiu rainy season (from June to July). In July 2009 rain observed 29 days and maximum 3 days rainfall was excess 170mm. Based on the overview images taken by interval shooting cameras placed in the study area between July 2011 and October 2016, one or two hours after beginning of rain water level rises and in heave rainfall events occurred not in the Baiu maximum water level was not high as in the event in the Baiu.

Observation of surveyed cross sections of the riverbed and distribution of vegetated area on the gravel bars shows that the channels do not move laterally. Former channels were buried by transported sediments and new channels were excavated. Although the most bars were covered with water and sediments, their surfaces were not eroded. Thus, most vegetation on the bars survived the food event. By slight lateral erosion patchy communities of willow were gradually destructed and reduction of the area. During recent ten years a new willow community germinated in a shallow ditch continues growing. The Height of the community reaches 3 meters. Another willow community germinated in 1998 and more than 20m in height continues growing, reducing its area by lateral erosion in several flood events. Isolated willow trees on the bar in the center of the riverbed survived more than 20 years impact of yearly flood flows. But some of them were washed away in the 2017 and 2018 flood events.

The landform of the riverbed of the Azusa River in Kamikochi region considerably changed by burying former channels and excavating new channels, which occurred in once in several years during heavy rainfall events in the Baiu season. After these flood events *Salix arbutifolia* germinated and form new patchy communities. Although these communities were destructed partly, they have continued growing and some of them form communities of isolated large trees. These processes form the peculiar alpine river landscape in Kamikochi area.

Groundwater age is crucial information for understanding the continuum groundwater flow system from mountain to ocean. Headwaters are origins of the terrestrial hydrological cycle and therefore important areas to understand the water resources management, material cycle, and disaster prevention. After the Fukushima Dai-ichi Nuclear Power Plant accident, concerns of radionuclide contamination of water resources have been elevated. However, the groundwater flow system including age information in radionuclide-contaminated headwaters in Japan has not been well clarified. Therefore, the objective of this study is to investigate the groundwater age and related radionuclide effect on the water resources by using multi-tracer approach in headwater catchments approximately 30 km north-west apart from the Fukushima Dai-ichi Nuclear Power Plant. Periodical field surveys were conducted from May 2011 (2 months after the disaster) to November 2012. Tritium, chlorofluorocarbon (CFCs), and stable isotopes (oxygen and hydrogen) were used as environmental tracers.
Mean groundwater age in the study areas was estimated to be ranging from 10 to 26 years by combined use of multiple CFCs concentrations. The tritium concentration in groundwater was between 1.3 TU and 6.0 TU, which supported the estimated CFCs-based groundwater age. In addition, the governing groundwater flow system was approximated by a piston flow model; however, a modern water fraction was also suggested based on the relationship between CFC-11 and CFC-12. The estimated water age and isotopic signals among the stream water, spring water, and groundwater suggested an indication of the radionuclide intrusion into the groundwater. This is consistent with the monitored ^{137}Cs concentration in the groundwater (Iwagami et al., 2017). Modern water fractions with relatively high radionuclide concentrations into groundwater possibly cause the prolonged contamination of water resources.

Hydraulic adaptation for tree height growth in tall tree species

*Wakana Azuma[1]

1. Kyoto University

Forest ecosystems, one of the major elements of the mountainous area, are characterized by its complicated three-dimensional structure which is 95% occupied by canopy where cannot be reached from the ground, compared to grasslands, deserts and rocky areas (Lowman and Rinker 2004). Various life activities such as photosynthesis, transpiration, breeding, and interaction with various organisms are performed on the canopy. Canopy researches have been progressed rapidly by the development of methods for accessing treetop in recent years (Nakanishi et al. 2018).

The question of why trees can grow up so tall is simple but its discussion has continued for a long time among ecophysiological studies. Among some factors related to tree height growth being pointed out, a main factor is considered that the limitation of water transport from root to leaves at the far end (e.g. Ryan et al. 2006). While this is the beginning of theoretical research, it has not been directly measured how much actual leaves are affected by the water transport limitation in tall trees. Therefore, we accessed to crown for 100 m tall of *Sequoia sempervirens* and 50 m tall *Cryptomeria japonica* by tree climbing, and directly evaluated water relations characteristics of leaves at various heights. As a result, although the supposed influence by water limitation was not observed, the high water capacitance of treetop leaf was revealed. This results suggested that the high water capacitance of treetop leaf would compensate for the physical water transport limit at treetop (Ishii et al. 2014).

How can treetop leaves perform high water capacity? To investigate a relationship between leaf anatomy and water relations, leaves of 50 m tall C. japonica were freeze by liquid nitrogen in situ of crown before dawn and at midday, then took it back to the laboratory and sectioned with cryo-SEM for observations. As a result, it was revealed that the transfusion tissue specific to the gymnosperm, which is located between the vascular bundle and the mesophyll, reversibly stored water and shrink like a sponge. At the treetop, large number of transfusion cells contributed to maintain the physiological function by the tissue structure giving priority to the water limit compensation, and as a result, maximum tree height could be regulated by tradeoff of the resource allocation with photosynthetic structure (Azuma et al. 2016).

To elucidate the mechanism of water retention within leaves focusing on the physicochemical properties, infrared spectroscopy is conducted. By applying it to leaf cross-sections in combination with a microscope, it is possible to quantify and visualize the distribution of water and sugars which were difficult to evaluate by an anatomical method alone. Although water is treated as one kind in the present plant physiology, in actual, physicochemical studies are known that various water components exists due to a difference in hydrogen bonding. In this study, working hypothesis that water with short hydrogen bonding component could be retained to polysaccharides within leaves was discussed. (Azuma et al. 2017).

These results suggest the one of a mechanism for tree height growth in tall conifer species with a new insight that “adaptation” to the water transport limit at treetop. To elucidate the actual ecophysiological characteristics in such huge trees, more comprehensive understanding from multiple perspectives would be necessary.

The molecular phylogenetic structure and biogeographic history of a alpine gravel environment specific plant *Dicentra peregrina* (Papaveraceae) in Japan

*Takahisa Ozaki[1], Hirokazu Matsuda, Koji Tojo[2]

1. Graduate School of Science and Technology, Shinshu University, 2. Biology Department, Faculty of Science, Shinshu University

In determining the distribution area of an organism, meteorology, climate, geography, topography and geology are important factors. In particular plants are more susceptible to climate change by limitations on dispersion compared with animals, thus the relationship between climate change and geographical distributional history in the glacial-interglacial cycles have been discussed a lot. For example, a hypotheses and a pattern have been proposed about the distribution history of alpine plants in the Japanese Archipelago. During the glacial periods, their distribution area was expanded (to the more southern region), on the other hand, the distribution area shrank (to the more northern region) during the interglacial periods and survived only in the alpine areas. Regarding the geological conditions, soil nutrition, size and stability of gravels influence species composition and population dynamics. Not only environmental factors but also biological interactions play an important role. If the weather, geography and geological conditions are severe, it will be a major barrier to plants' lives. However, few cases have established the effects of habitats' environments on their distributional histories. *Dicentra peregrina* inhabiting the alpine gravel lands and represent the alpine desert plants' community. In Japan, *D. peregrina* is also called "queen of alpine plants". Such alpine gravel lands distribute scattered around the volcanoes, and also around the ridgeline areas of high altitude mountains with strong disturbances: harsh weathering and/or unstable lands' surface. Therefore, migration is strongly restricted and highly influenced by weather, geography, topography and geology, compared with other alpine plants. Thus, *D. peregrina* is a suitable targeted alpine plant to investigate the relationship between the habitat environments and the distributional history. In order to estimate their distributional history, we have conducted phylogenetic analyses of *D. peregrina* in the Japanese Archipelago. Additionally, we have also conducted the "Ecological niche modeling" to estimate distributional changes by climate changes. As a result of our phylogenetic analyses, we observed two major genetic lineages within *D. peregrina*: one is endemic to Hokkaido (Group 1), and the other was observed from wide-areas in the Japanese Archipelago (Group 2). The boundary between the two lineages was recognized within the Daisetsu Mountain Range at Central Hokkaido. In Hokkaido, Group 2 was only observed in Mt. Kaundake and Mt. Furanodake. According to some geological studies, both Mt. Kaundake and Mt. Furanodake having comparatively old origin, it is considered that they were formed before 700,000 years ago. In contrast, regarding mountains where observed the Group 1, it is considered that they were formed around 150,000 years ago. Such differences of the mountain formation ages might be affected the population dynamics of *D. peregrina* in the glacial-interglacial climate changes. The Group 2 of *D. peregrina* is highly likely migrated to the Japanese Archipelago during the last glacial period. On the other hand, the Group 1 was dispersed to the Japanese Archipelago in older period and it is considered that their distribution spread more widely in the last glacial period. Thus, these old originated mountains served as refugia during inter-glacial periods. In addition, the genetic structure of *D. peregrina* was largely different from other alpine plants, and such difference suggests the distributional history of *D. peregrina* is strongly related to geological history rather than other alpine plants.

Formation process of small stands of *Abies mariesii* forest in pseudo-alpine zone on Mt. Akita-komagatake, northern Japan

*Asaka Konno[1]

1. International Research Institute of Disaster Science, Tohoku University

The coniferous forest (largely composed of *Abies mariesii*) is presently the typical vegetation of the subalpine zone in Japan. However, around Mt. Akita-komagatake, in northern Japan, the expected predominance of *A. mariesii* is not extensively observed, and the predominant vegetation is instead the dwarf bamboo (Sasa kurilensis) grasslands and broad leaf forests. It' s called Pseudo-Alpine zone. According to pollen analysis, this vegetation is assumed to be attributed to unsatisfactory expansion of *A. mariesii* forest.

Here we clarify the formation process of small stand of the *A. mariesii* forest by its size structure and process of regeneration.

The surveyed area is located in the northern Mt. Akita-komagatake. We classified the vegetation and measured DBH (diameter at breast height) and created frequency histograms of size structure on each vegetation.

The both histograms of *A. mariesii* thick and thin forest display gradual decreasing on the small classes on the *X* axis (DBH). The maximum classes of DBH are the class of 20-30 cm on the both histograms. The decreasing is considered to be brought about by two reasons: the second generation of *A. mariesii* on 20-30 cm DBH class is not enough equipped to propagate, and there is less numbers of first generation. These results are indicated that the small stands of *A. mariesii* forest rapidly formed by second generations.

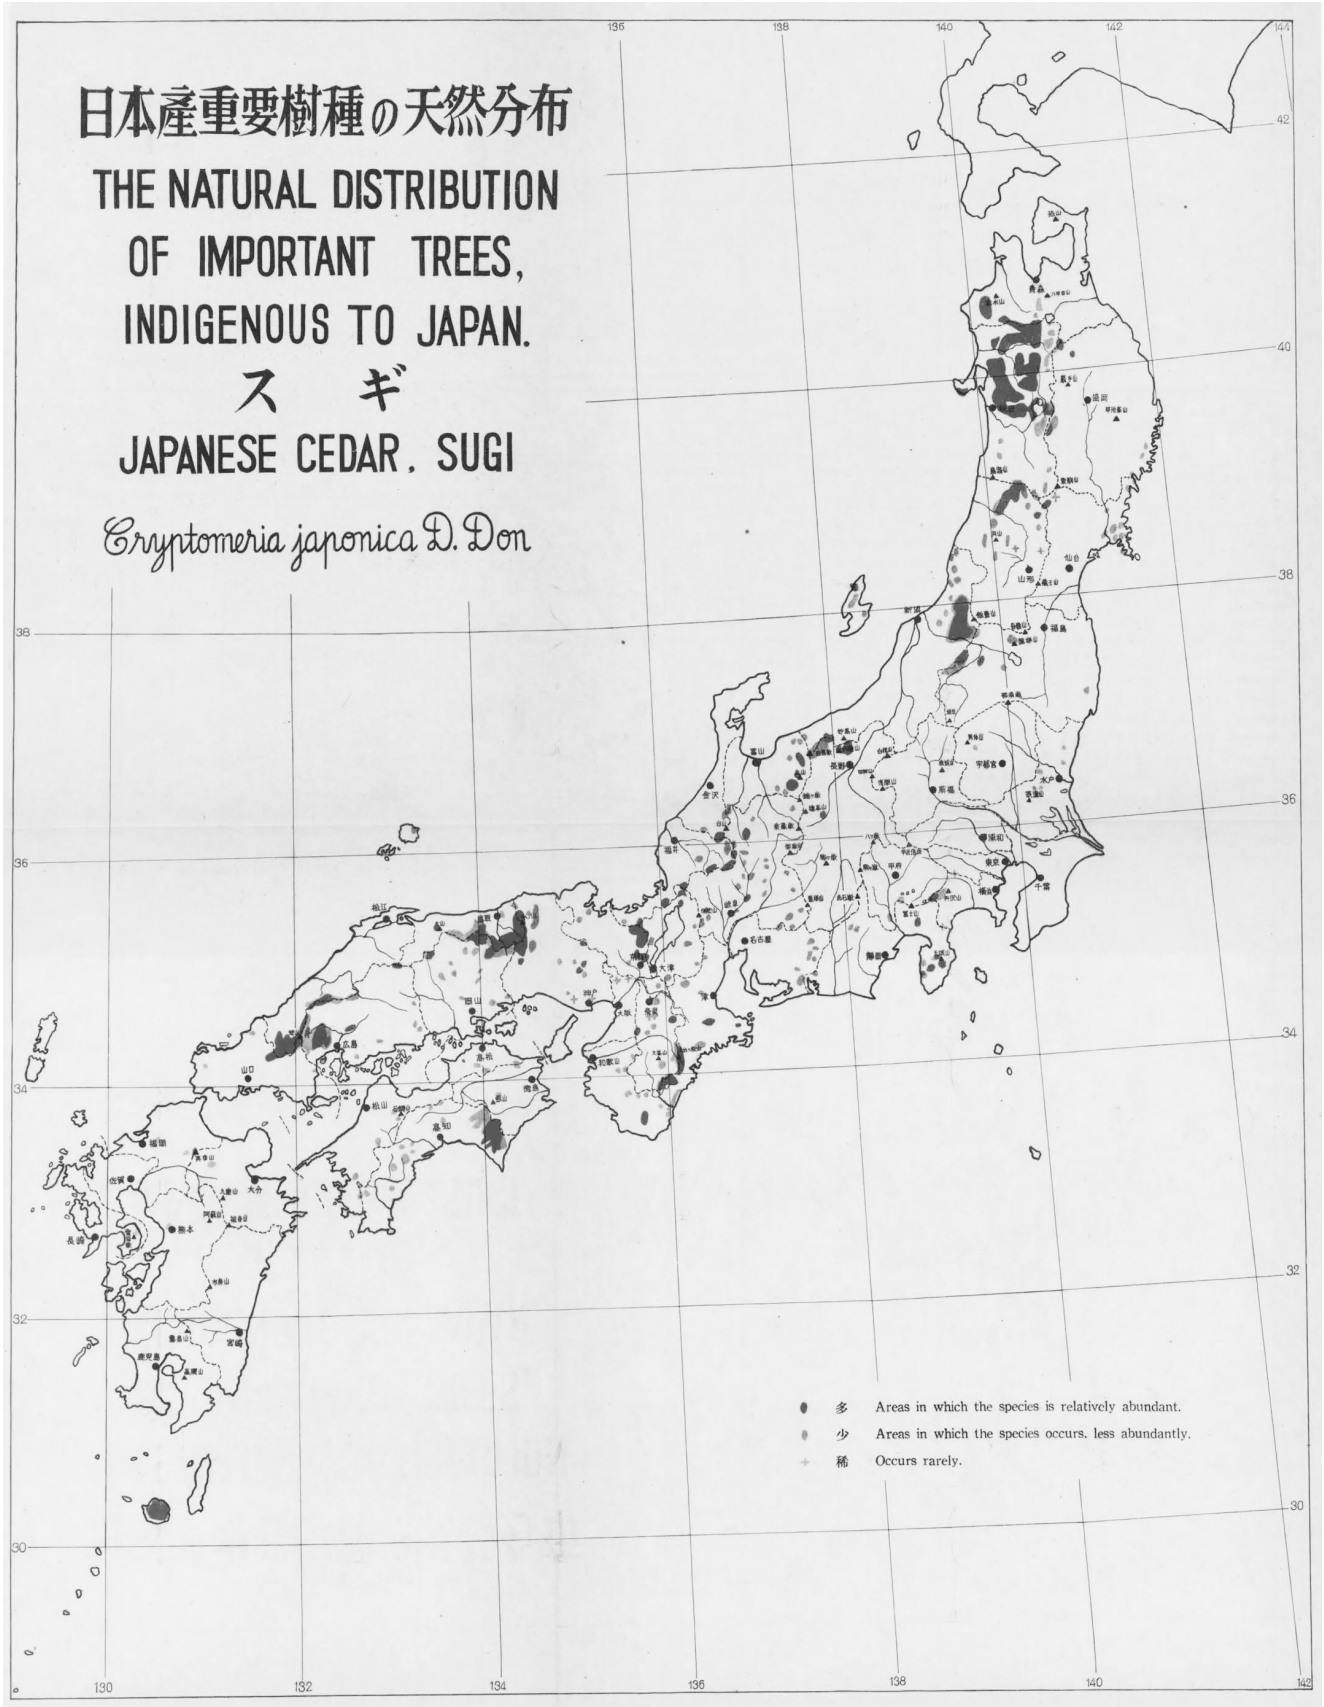
Distribution of the pinas forests including a Cryptomeria japonica and its environmental factors in Echigo mountain range.



*Masatsugu YASUDA[1]

1. Asia Air Survey Co., Ltd.

Natural cedar grows in the area of southeastern part of Aizu area to Higashi Kanbara gun.
This cedar is known as the real name Cryptomeria japonica or Sanjo Sugi, a famous cultivar called Sugi or Sanjo Sugi. On a gentle slope it forms a forest that intermixes with beech and on the ridge it forms a mixed forest with the Chitose or Pinus densiflora.
Forests mixed with sugi and beech are recognized on the Sea of Japan side mainly in Akita prefecture (2018 Echigo valley), whereas forests mixed with sugi and Kitakagoyo or Pinus densiflora are not well recognized in other areas, .
Regarding vegetation in this area Matsuura (2010) says, "The most characteristic of vegetation in this area is avalanche vegetation consisting of shrub forests and grasslands formed by frequent avalanche due to heavy snow.The upper slope of the ridge An avalanche vegetation in a shrub forest from both sides, formed as a result of snow accumulation as a pine forest (Mainly for Kita gobo and Mixed Pinus densiflora in a low altitude) on a Yase ridge remains linear (Mohegan cut) It shows that it is vegetation.
By the way, the author made a survey in this area around the autumn of last year, and found that the pine forest including this cedar has relevance to snow accumulation gradient. In addition, from the viewpoint of the combination of plants, that is, from the viewpoint of plant sociology, it was also found to be strongly related to "Crobe - Kita - gobay Forest" distributed in the sub - alpine region of Japan.
We analyze these relationships, that is, the plant sociological features and the geographical relevance of the environment such as snow cover by using existing vegetation survey database and mesh climate value and report the results.

Roles of glacier microbes in alpine ecosystems of Asian high mountains: effect of cryoconite outflow on soil development in glacier forefields

*Nozomu Takeuchi[1], Masato Shiomuki[1]

1. Chiba University

The Tien Shan Mountains are one of the major mountain systems in Central Asia, extending over 2000 km, from east Uzbekistan to northeast of the Taklamakan Desert in China. The major Tien Shan peaks rise from over 4000 to 7000 m above sea level (a.s.l.). Glaciers presently exist in mountains mainly above 3500 m a.s.l. and most rivers originating from the Tien Shan glaciers flow down through the steppes and deserts surrounding the mountains. Water from the mountains has sustained the local inhabitants and ecosystems of this arid area. Recent studies revealed that there are diverse microbes living on the Tien Shan glaciers and they produce significant amounts of cryoconite, which is a small granular aggregation of microbial organic matter on the glacier ice. We found abundant cryoconite deposit along a river from glaciers, which is likely to contribute development of organic soil in the glacier forefields. Thus, biological communities living on the glaciers also play a role to maintain the alpine ecosystems and regional environments in the Tien Shan Mountains.

Comparison of surface energy balance of seasonal snowcover for three sites in Japanese alpine region

*Motoshi NISHIMURA[1], Akihiko SASAKI[2], Keisuke Suzuki[3]

1. Interdisciplinary Graduate school of Science and Technology, Shinshu University, 2. Department of Geography and environmental Studies, Kokushikan University, 3. Faculty of Science, Shinshu University

Process of snow and glacier ablation is one of the indicator of global climate change, so is of interest as understanding earth system. In the discussion of snow ablation process, calculating surface energy balance (SEB) is one effective method, and it is generally analysed with local meteorological observation data. SEB is sensitive to regional atmospheric conditions, therefore it often reflects in situ regional climate and surrounding environment. This presentation offers the result of regional SEB analysis in central Japanese alpine region, Kamikochi (1490 m a.s.l.), Norikura highland (1590 m a.s.l.) and Nishi-Hodaka (2355 m a.s.l.) to reveal the characteristic of SEB of seasonal snowcover in Japanese sub-alpine region. Three automatic weather stations, operated by Shinshu University, were located each targeted region in snow covered period of 2016/17 (Hydrological year). SEB analysis was conducted using surface energy balance method, and an analysis of turbulent heat flux was done using the bulk aerodynamic method. SEB analysis were conducted only snow covered period from October, 2016 to June, 2017.
The most major energy source was net shortwave radiation and negative energy flux was offered by net longwave radiation and latent heat flux in every site. Those characteristics were often reported in continental regions and high elevation areas, such as alpine region, because atmospheric condition in those regions are often cold and dry so that incoming turbulent enegy flux were restrained. The most atrractive characteristic resulted in SEB comparison is that the behavior of snowmelt energy flux in later ablation period is different in three sites. Snowpack in Nishi-Hodaka is persisted longer (untill June) than other two sites due to a lot of snowfall offered in winter, so that atmospheric condition (e.g. air temperature, specific humidity) and radiation components in later ablation period have been different from other two sites. Threrfore the different SEB properties in each site were also discovered.
Similar and diference SEB properties, which are resulted from regional climate condition and local topographic environment, among the three target sites were revealed. It is interesting that the target sites, relatively near but diferent (or same) elevation band, have each different SEB properties, so more detailed analysis of regional SEB properties are required.Comparison of surface energy balance of seasonal snowcover for three sites in Japanese alpine regionComparison of surface energy balance of seasonal snowcover for three sites in Japanese alpine region

The influence of snow for the local wind system on the east slope of Mt.Norikura

*Genki Uehara[1], Keisuke Suzuki[2]

1. Graduate School of Science and Technology, Shinshu University, 2. Department of Environmental Science, Faculty of Science, Shinshu University

On the east slope of Mt.Norikura (3026 m), there is a unique local wind system, which is thought to be influenced by the snow on the slope. In general, on the mountain regions, the nocturnal flows are down-slope and down-valley wind, while the daytime flow are up-slope and up-valley wind. However, in the Mt.Norikura on the winter-spring, the down-slope wind develop afternoon even though daytime. It is a unique local wind system. The snow on the slope of mountain is possible to play a role in the development of the unique wind system. Because a temperature of a snow surface is always near or below 0 ˚C, a downward sensible heat be formed whenever the air temperature is above 0 ˚C. The air over snow that has been cooled by a downward flux of sensible heat produce the down-slope wind in especially the late afternoon of warm, sunny days (Whiteman, 1999). We consider that the unique wind system is formed with the result of the interaction between “down-slope wind on the snow” and “up-slope wind on the no-snow surface“.

Japanese Alps including the Mt.Norikura is known as a heavy snow region, a lot of snow falls on the mountain region in winter (Suzuki, 2013). The snow surface forms a characteristic thermodynamically structure and plays important roles in the atmospheric environmental of mountain regions. However the atmospheric environment of mountain regions have not been understood sufficiently due to insufficiency of meteorological observation. In this research, We will report the relevance between a local wind system and snow on the mountain region with using the data of meteorological observation.

Mass balance of "Avalanche-accumulation type"glaciers and perennial snow patches in Hida mountain range.

*Kenshiro Arie[1], Chiyuki Narama[2], Kotaro FUKUI[3], Hajime IIDA[3]

1. Graduate School of Science and Technology, Niigata University, 2. Faculty of Science, Niigata University, 3. Tateyama Caldera Sabo Museum

In the Hida mountain range, we clarified mass balance of glaciers and perennial snow patches of ” avalanche-accumulation type" by aerial photos and SfM analysis. Comparing mass balance of the "snowdrift-acumulation type" and "avalanche-accumulation type", "avalanche-accumulation type" was more positive.

Pattern of occurrence of sea of clouds and waterfall cloud near Mt.Nishihotakadake

*Toru Awazawa[1]

1. Faculty of Science, Shinshu University National University, Shinshu University Faculty of Science

The mountain ranges of 3000 m class are connected to the spear ·Mt.Yarigatake-Mt.Hotakadake mountain range, and the mountain ranging from Mt.Nishihotakadake located at the southwest end to Mt.Yakedake, Mt.Norikuradake ridgeline is also over 2000 m. Although it is said that the atmospheric boundary layer is within 1000 meters in the temperate region, situations where the atmosphere boundary layer between Gifu prefecture and Nagano prefecture is divided by continuous mountains often occurs in this area. Under such circumstances, when moist air flows into the lower layer from the Sea of Japan side, it becomes a form that can be stopped at Gifu prefecture side. Furthermore, when an event such as subsidence inversion layer due to high pressure occurs, stratocumulus cover the sky with the reversal layer as the boundary, and a sea of clouds occurs. Analysis of the weather conditions at the time of occurrence revealed that there are some patterns in the inflow of moist air in the lower layer. We also verified the supply of lower layer wetness to maintain the generated cloud sea and the influence of solar radiation at the time of disappearance of the sea of clouds.

In addition, waterfall cloud often occurs near Nishiho Sanso, but this is due to the lowest between Nishiho Maruyama and Mt.Yakedake in the ridgeline leading from Mt.Yarigatake-Mt.Hotakadake mountain range to Mt.Yakedake. It was found that there are two patterns in the waterfall cloud seen in this mountain region. Dynamic things, such as weakening of high pressure and strengthening inflow of moist air in the lower layer, are added at the time of the occurrence of the sea of clouds, the altitude of the sea of clouds rise, and from Nishiho Maruyama - Mt.Yakedake to Nagano Prefecture side It occurs by the cloud overflowing. On a small scale, it is caused by the air rising along the slope like the cap cloud and disappearing when it goes down, but in any case, it will be between Nishiho Maruyama and Mt.Yakutake The low altitude is a major factor in the occurrence.

Keywords: Mt.Yarigatake-Mt.Hotakadake mountain range, sea of clouds, waterfall cloud, inversion layer

Review and prospect of strong local wind “Matsubori-kaze” blowing at the western foot of Mt. Aso.

*Hiroshi Matsuyama[1]

1. Graduate School of Urban Environmental Sciences, Tokyo Metropolitan University

“Matsubori-kaze” (hereafter referred to as MK) is strong local wind blowing at the western foot of Mt. Aso. It is likely to blow when a depression with warm front is located off the southwestern part of Kyushu. In this presentation, we reviewed the studies on MK and their future.

The first study that investigated MK is Hayamizu and Yamashika (1950). They observed wind speed and temperature at Tateno and Ozu from 10th to 21st November, 1949. Strong local wind blew at night when Kyushu was prevailed by an anticyclone. Because Aso-caldera is located at east, they considered cold air pooled at the caldera flew through Tateno Valley. This study was introduced in the textbook of Yoshino (1961). Yoshino (1968) investigated the distribution of wind breaks around Tateno Valley. They were densely distributed around Tateno Valley, and he estimated MK was the strongest there.

Onodera (1975) opposed to the proposed blowing mechanism of MK . He investigated the diaries of Ozu-higashi elementary school, located at the strongest area of MK. He found MK blew more frequently in spring than in autumn-winter. He also found that a depression with warm front was located at 300 km south of Kyushu when strong MK blew. Onodera (1975) concluded that the inversion layer around the top of Mt. Aso, along with the existence of warm front, was important for the occurrence and intensification of MK.

Ozu-higashi elementary school stopped keeping diaries after October 1971. Because meteorological stations were not located there, we could not know when and how MK blew after October 1971. Yoshino (1986) cited Onodera (1975), however, he still explained MK originated from cold air pooled at Aso-caldera as in Yoshino (1961).

Based on long-term meteorological and mobile observations, Kurose et al. (2002a, b) clearly distinguished two types of winds, i.e., “Aso-oroshi” (hereafter referred to as AO) and MK. Kurose et al. (2002a) found AO was outflow of cold air pooled at Aso-caldera that mainly occurred at calm night in autumn-winter. On the other hand, Kurose et al. (2002b) found MK was airflow over Mt. Aso that occurred in the specific weather condition, i.e., stable stratification was formed at lower part of the troposphere, and southeasterly wind over 10 m/s prevailed at 850 hPa level. Under this condition, the airflow over mountains converged at Tateno Valley, and its wind speed exceeded 10 m/s which usually caused damages in agriculture.

It was speculated that unique topography of Mt. Aso certainly affected MK. By using virtual topographies, Inamura et al. (2009) conducted numerical simulation using meso-scale model (RAMS). They clarified MK was composite wind of downslope wind at the southern slope of Tateno Valley as well as the gap wind through it. They also revealed that a critical layer around 850hPa was important for producing well-mixed stagnant layer and generating the strong wind beneath it.

Matsuyama et al. (2014) conducted questionnaire survey to families of the students at Ozu-higashi elementary school. Keywords in the answer sheets were summarized as “strength and mode of MK,

©2019. Japan Geoscience Union. All Right Reserved.

“agricultural damage in areas with strong winds”, and “surrendering to MK". Matsuyama (2014) also analyzed written descriptions of the students’ impressions to MK. As for children, keywords were summarized as “fear”, “outdoor experiences”, and “intellectual interest”.

Sakamoto et al. (2014) caught MK blowing on 5th to 6th April, 2013. They conducted mobile observations and investigated the spatial extent to which MK reached. They also reproduced the phenomena by RAMS. The wind speed around Ozu town was on average 1.5 times as large as that at Nishihara village, closely located south of Ozu town. RAMS revealed that fluctuation of wind speeds depended on the relation between the position of Nishihara village and hydraulic jump caused by airflow over Mt. Aso.

Based on meteorological observations, Sagawa (2017) investigated the spatial extent to which AO reached. He also compared wind speeds at Tateno and Fuketa/Uchimaki where MK is the strongest. Sagawa (2017) clarified that AO blew from Fuketa to the Kikuchi-minami fire station. Wind speeds were significantly lower at Tateno both for AO and MK. It was clearly evident during the blowing of MK.

So far, characteristics of MK have been clarified fairly well. For the occurrence of MK, wind direction and wind speed at 850 hPa (about 1500 m a.s.l.) are important information. At central cone of Mt. Aso, Aso-san Meteorological Observatory (1142.3 m a.s.l.) had been operated whose data were frequently used. However, it stopped observations on 11th December, 2017, i.e., it is impossible to use these data in the future. This is a serious damage in the study of MK.

Two decades of mountain climate monitoring and research: lessons learned and future challenges.

*Luis Duran[1,2,3], Irene Rodríguez-Muñoz[1]

1. interMET Sistemas y Redes S.L.U. Madrid. Spain, 2. Centro de Investigación, Seguimiento y Evaluación del Parque Nacional Sierra de Guadarrama. Madrid. Spain, 3. Departamento de Física de la Tierra y Astrofísica. Facultad de Ciencias Físicas. Universidad Complutense de Madrid. Spain

During the last two decades several efforts have been made in order to have an accurate assessment of climatic conditions in a mountain area in Central Spain (Peñalara Massif). A combination of in-situ measurements, statistical analysis of historical data, use of re-analyses and high resolution modeling has been done in order to overcome the difficulties inherent in such a complex terrain. The first decade has been focused on the design and operation of a mountain observational network. After some efforts, the performance achieved was satisfactory. As a result, long and homogeneous records are now available for the first time. Also, valuable technical and operational information has been gained which helped in the re-design of the network which is now in operation. In the meantime, connections between mountain meteorological phenomena and synoptic forcing has been found using weather typing methods using total column water vapor flux fields from re-analyses. The interaction between regional scale advection of humidity and orography has been identified as the leading phenomena in terms of precipitation. This finally led to the application of an orographic precipitation model giving a high resolution assessment of precipitation at this mountain area which is coherent with in-situ observations. This database opens new horizons of research since it converts point measurements into spatial fields. This comprehensive approach for researching the climate of a mountain area has proven to be effective but also brings future challenges which will be discussed here.

Volcanoes exist on solid planetary surface across the solar system. They tell insight into the interior, and the surface environment when they were formed and subsequent evolution. Recent high-resolution remote sensing data on extraterrestrial body allows us to analyze on outcrop scales. Now we are on the stage to share the research targets beyond fields of general volcanology and planetary science. Because some geomorphological and geological environments
in other planets are similar to those on Earth, research on volcanic geomorphology and geology on Earth will provide good terrestrial analogues to understand planetary volcanology. The aim of this session is to discuss formation history and mechanism of volcanoes across the solar system.

Growth and evolution of isolated volcanic island, Nishinoshima, Ogasawara

*Fukashi Maeno[1]

1. Earthquake Research Institute, University of Tokyo

The process of birth and growth of ocean islands is an interesting phenomenon in the field of geoscience in terms of the creation of new land and the creation of a place for new terrestrial life activities. Nishinoshima is a rare place on the earth that can trace the process of birth, formation and evolution of such ocean islands from various viewpoints of research fields. Meanwhile, since the eruption in the shallow sea can be a factor of maritime hazards, the establishment of investigation/observation method and risk assessment method is also an important subject. Nishinoshima is located in a place deserving to call as an isolated island, 130 km west of Chichijima, Ogasawara Islands. In November 2013, a new island was born by submarine eruption. It gradually covered the preexisted island and increased the land. A series of eruptive activities in Nishinoshima from 2013 to 2018 provided various valuable data on the birth of a new volcanic island and its growth process, and was also important as a place for practical investigation and observation of remote island volcanoes. The eruptive activity of Nishinoshima is divided into November 2013 - December 2015 (first stage), April to August 2017 (second stage), and July 2018 (third stage). Meanwhile, various surveys and observations were conducted to understand the activities of Nishinoshima. Immediately after the beginning of the eruption, the observation data from remote was the only information source, and based on analysis of high-resolution satellite images and direct observation from the airborne, the growth process of Nishinoshima was monitored, focusing on the changes in surface topography and morphology, area, volume, and discharge rate. After that, following the decline in activity at the end of 2015, comprehensive investigation of volcanic activity and biota was carried out in October 2016. In this survey, earth science and ecological scientists collaborated with each other to conduct a landing survey, in order to minimize the risk of bringing invasive species to new Nishinoshima, and lava samples were collected directly for the first time, and the seismometer and the microphone were also installed. In 2017 and 2018, Nishioshima became active again and grew larger, finally its activity ended at the end of July 2018. After 2016, surveys were conducted remotely utilizing drone and unmanned helicopter, taking images and movies of new lavas and craters, sampling eruptive products, installing and collecting loggers for ecological monitoring, magnetic survey and others were carried out, and the result enhancing our understanding of activities and evolution of Nishinoshima is being obtained. Such surveys and observations in Nishinoshima, where it is difficult to access and the perspective of conservation of primitive ecosystem is also necessary, may have common terms with surveys of extraterrestrial body surface. In this presentation, I will introduce the growth and evolution of Nishinoshima, the volcanic activity, and the methods and results of surveys carried out so far, while being conscious of the connection with planetary volcanology.

The style of magmatism on terrestrial planets of various sizes predicted from numerical models of mantle dynamics

*Masaki Ogawa[1]

1. Division of General Systems Studies, Graduate School of Arts and Sciences, University of Tokyo

A series of numerical models of magmatism in the convecting mantle suggest that the vigor and style of mantle magmatism critically depend on the planetary size because of its effects on the elementary processes that exert control over mantle dynamics. On a small planet like the Moon, a mild magmatism continuously occurs for several hundred million years in upwelling limbs of mantle convection and then wanes, because the magmatism extracts heat-producing elements (HPEs) from the mantle. Magmatism, however, often becomes more vigorous and episodic, as observed for the Large Igneous Provinces on Mars and larger planets, because the buoyancy of the generated magma boosts the upwelling flow in the mantle that causes the magmatism itself. The convective stirring enhanced by the MMU feedback keeps the mantle rather homogeneous, despite that the vigorous magmatism due to the feedback differentiates the mantle. The effect of the MMU feedback is particularly important in Venus and the Earth where the lower mantle develops: The solid-solid phase transitions that occur at the top of the lower mantle make mantle upwelling flow pulsating, when the mantle is strongly heated by HPEs and magmatism is vigorous. This pulse or burst of hot materials from the lower mantle causes a vigorous magmatism, especially in the early mantle. Due to this vigorous magmatism, the crust enriched in HPEs recycles back to the mantle to serve as the energy source for the magmatism that continues throughout the history of the mantle. On the Earth, plate tectonics also causes magmatism and recycling of the generated crust. In contrast to Venus, this magmatism differentiates the mantle, because tectonic plates and subducting slabs stir the mantle only mildly.

Lunar and Matian lava tubes and explorations to them through their skylight holes

*Junichi Haruyama[1], Takahiro Iwata[1], Yukio Yamamoto[1], Tetsuya Kaku[2,1], Wataru Miyake[2], Atsushi Kumamoto[3], Ken Ishiyama[1], yokota yasuhiro[4], Takumi Ono[2,1]

1. Japan Aerospace Exploration Agency, 2. Tokai University, 3. Tohoku University, 4. Kochi University

Large and deep hole structures of a few tens to hundreds meter diameter and depth were discovered on Mars in the thermal emission data acquired by Mars Odyssey THEMIS and on the Moon in the SELENE (Kaguya) Terrain Camera visible image data, about 10 years ago. These are probably skylights of underlying caves produced by volcanic activities such as lava tube formation. Later, many hole structures and depression features as "pits" possibly associated to lava tubes have been identified on these celestial bodies in image data of orbiting explores. Intact lava tube existence on the Moon are also suggested by gravity measurements by GRAIL and radar sounding experiments by SELENE (Kaguya).
The role of lava tube on the formation of vast terrains expanding on the Moon and Mars are scientifically interesting, though the study has not been sufficiently done. In addition, lava tubes and their skylight holes offers prominent environments to conduct scientific examination of the history of volcanic activities on the Mars and Moon. Lava tubes on Mars and the Moon are expected to be secure shelters for humans and instruments potentially protecting from micrometeorites bombardments and cosmic ray radiations, In the next decades, therefore, Martian and lunar lava tube exploration will be executed by space agencies of countires and even private companies.
In this presentation, we would introduce recent studies of lava tubes of Mars and the Moon and their explorations.

Jupiter's satellite Io is known as the most active volcanically active body in the solar system. The atmosphere of the satellite consists mainly of volcanic gas composed of sulfur dioxide. The molecular escaped becomes primary source of plasma in the magnetosphere of Jupiter. Here, observations of the volcanic gas escaped from satellite with the extreme ultraviolet telescope satellite, Hisaki, and a groundbased visible telescope, and observations of hot spot of Io's volcano with infrared telescopes are presented. We will discuss the formation of the satellite atmosphere, escape process of the atmospheric gas to the magnetosphere, and their relation to volcano types.

Cryovolcanism, a critical review

*Kei Kurita[1]

1. Earthquake Research Inst.,The University of Tokyo

Volcanoes are surface manifestation of internal activity of planets and satellites. In planetary explorations the primarily available data source would be the surface images so that the volcanoes identified on the surface are unique window into the interior. This argument is particularly significant in icy bodies of the outer solar system because exploration data are so limited except for the surface images. Up to now several types of surface morphology have been considered as a product of cryovolcanism. In this presentation I will focus on the general aspects of the cryovolcanism in comparison to the silicate volcanism and would like to emphasize the significant role of hydrate phase in cryovolcanism.

Similarities and dissimilarities between cryovolcanism and silicate volcanism: There exist a lot of similarities between ice and silicate minerals such as the rheological properties and the melting relationship. The depression of the melting point in the existence of accessary components in both systems should play an important role in promoting differentiation. The critical difference is the pressure dependence of the melting temperature and the density contrast between liquid and solid phase. Since water magma is not buoyant in the icy lithosphere this density reversal requires special mechanism for driving water magma to the surface. This situation is, however similar to the continental basalt volcanism. In the icy satellites the stress field in the outer lithosphere plays an important role. Both exogenetic origin such as tidal forcing and endogenous origin such as thermal stress and volume change driven by phase change would be

Significant role of hydrate phase in cryovolcanism: Hydrate is a common phase in the multicomponent system including H2O. It is stable at higher pressure so that it should be an important constituent phase while it decomposes near surface. This may result in explosive behavior because the decomposition is associated with generation of gas phase. Although a lot of combination of the components form various hydrate phases, there exist two planetologically significant end-members, CO2 hydrate and CH4 hydrate. These two have contrasting nature in terms of the density, which would cause different evolution path in the material differentiation.

Cryovolcanisms on Solar System bodies: Observations, importance, and future perspectives

*Yasuhito Sekine[1]

1. Earth-Life Science Insitute, Tokyo Institute of Technology

Cyrovolcanos are volcanos on icy planetary bodies, erupting liquids and vapors of volatiles (e.g., water, ammonia, methane, and carbon dioxide) from subsurface water reservoirs or oceans. In the Solar System, geologically-active icy moons (e.g., Enceladus, Titan, and potentially Europa) and icy dwarf planets (e.g., Ceres and Pluto) are known to possess cryovolcanisms in the past or even today.

Cryovolcanos are unique windows to reveal the physico-chemical states of the subsurface oceans of the icy bodies, which is essential to understand the thermal evolution and habitability. Morphology of cryovolcanos would be a key to constrain the physical properties (e.g., viscosity and density) of liquids in the subsurface water reservoirs. Chemical compositions of erupting materials would provide information on volatile and salt compositions of the liquids. Eruption of volatiles (e.g., methane and nitrogen) could be also a major source of atmospheric gas species and thus could have affected the surface environments.

Despite such importance, the nature of cryovolcanisms, such as formation mechanisms and eruption styles, is largely unknown. Since pure liquid water is denser than that of ice, dissolved gas species in cryolava would play a key role for its eruption through bubbling and a consequent decline in the bulk density. Dissolved gas/salt in the liquids also controls the viscosity of cryolava. Such importance of dissolved species in cryovolcanisms implies a potential similarity in the role of volatiles in silicate volcanisms on rocky planets, such as Earth. Here we review recent observations of cryovolcanos on the Solar System icy bodies by spacecrafts. We then discuss the possibility of and future perspectives for development of comparative researches between cryo- and silicate-volcanisms in the Solar System.

[M-IS28] Fluid-sediment migration and geo-bio interaction

convener:Robert Jenkins(School of Geosciences and Civil Engineering, College of Science and Engineering, Kanazawa University), Tomohiro Toki(Faculty of Science, University of the Ryukyus), Akira Ijiri(Japan Agency for Marine-Earth Science and Technology), Takami Nobuhara(Science Education (Geology), Faculty of Education, Shizuoka University), Hiromi Kayama WATANABE(Japan Agency for Marine-Earth Science and Technology), Miho Asada(Japan Agency for Marine-Earth Science and Technology), Chairperson:Tomohiro Toki, Robert Jenkins(Kanazawa University)

Chemosynthetic communities are distributed at hydrothermal system and/or cold seep in bathal zone. They gain their energy from chemosynthetic bacteria, a symbiotic life. The chemosynthetic communities have changed in their taxonomic composition and spatial distribution through the Earth history, but the causes and background remain to be unclear.
Mud volcano is one of geological features which derives fluid nd sediment from depth to the Earth's surface and make topographic feature. It plays a role of carbon cycling connecting depth and surface, pipe of life in depth, disaster and civil engineering. Mechanism and activity of mud volcanoes, however, are not enough understood yet. Mud volcano in Japan is mostly active in offshore fields and are frequently accompanying cold seeps at around it.
Here we propose a joint session with Chemosynthetic communities and Mud volcanoes to have cross-cutting discussion between us. Topics relates to mud volcano will help discussion of evolution of communities and chemosynthetic communities will help to understand mud volcano activity along time and space. Study results for usual two sessions, for cross-cutting discussions, and from related settings are absolutely welcome.

Upper Pliocene large lucinid communities with cold-seep carbonates from the Shimajiri Group in the Miyagi-jima Island off the central part of Okinawa-jima Island, Japan

*Takami Nobuhara[1], Robert Jenkins[2], Shin-ichi Nomura[3]

1. Science Education (Geology), Faculty of Education, Shizuoka University, 2. School of Natural System, College of Science and Engineering, Kanazawa University, 3. Chiba Prefectural Kisarazu High School

Fossil chemosynthetic lucinid communities occur with pipe- and burrow-cemented concretions from the Upper Pliocene muddy sand facies of the Shimajiri Group in the Miyagi-jima Island off the central part of Okinawa-jima Island, Japan. The outcrop is a sea-cliff wall along the west coast of Miyagi-jima Island, over 30 m high and 150 m long. The cliff consists of muddy sandstone sporadically yielding outer-shelf to upper-slope molluscan fossils, with intercalation of thin fine-grained sandstone layers. We could directly observe only the lower one-third of the cliff wall, but the fossil-lucinid occurrence seems to be restricted to about a five-meter thick horizon, which is associated with pipe- and burrow-cemented concretions.

Lucioma taiwanensis is dominant and forms shell beds and autochthonous shell clusters in matrix-supported condition. In addition “*Meganodontia*” sp., a gigantic lucinid over 10 cm in diameter, was obtained as floatstones, but all specimens are conjoined valves and maybe fell out from sites with abundant burrow-cemented concretions.

The burrow-cemented concretions look like calianassid nests in shape, irregularly sinuous to vertical to beddings, a few centimeters in diameter and over 1 m long. They amalgamated one another to form network-like clusters. The pipe concretions tend to be recognized below the network clusters of burrow-cemented types. The pipes are cylindrical and straight over 30 cm long, nearly vertical to beddings. They are composed of core calcitic cements (2 cm in diameter, -10 to -15 ‰of δ^{13}C) and surrounding dolomitic coating (4 to 5 cm thick, -20 to lower -40 ‰of δ^{13}C). The δ^{13}C value less than -30 ‰indicates methane seep influence in the sub-bottom of the lucinid community. The pipe concretions are also often recognized 5 m below the fossil lucinid horizons, which suggest that the pipe-like conduits of methane seep supported the lucinid communities.
The fossils of *Lucinoma taiwanensis* often preserve their life positions in matrices apart from the burrows and pipes. Therefore the methane-seep through focused pipe-like conduit were succeeded by into diffusive in sandy surface sediments. But some *Lucinoma* conjoined valves in life position are attached to outer walls of burrow-cemented concretions, which suggests that the burrows made contributions to promoting anaerobic oxidation of methane (AOM) and generating H_2S.

Chemosynthetic fossil community in Early Cretaceous methane seep from Yubari City, Hokkaido

*Nanami Shimazu[1], Robert Jenkins[1]

1. Kanazawa University

Japanese archipelagoes have rich fossil record of the methane-seep communities since the Late Cretaceous, however, the Early Cretaceous record is poorly known. Thus, we have investigated the Early Cretaceous (Albian) carbonate rocks found in Utagoesawa Creek, Yubari City, Hokkaido. The locality was previously mentioned in several papers, but the comprehensive approaches including sedimentary petrological, isotope geochemical and paleontological aspects haven't been done.

Many carbonate boulders were found along the creek and it size distribution along the creek suggest its single origin of outcrop. The carbonate rocks show mosaic textures mainly composed of micritic grayish patchy blocks. Bladed calcite and sparry calcite are filled in void spaces. Detailed observation revealed the micrites and the bladed calcites were precipitated in early diagenetic stages, and its isotopic compositions are -45.8 to -35.8 ‰VPDB for carbon and -25.4 to -17.9 ‰VPDB for oxygen.

The petrological and geochemical features indicate that carbonate rocks were formed under influence anaerobic oxidation of methane(AOM) due to the microbial activity in methane seep.

The carbonate rocks yield many bivalves, such as *Caspiconcha*, lucinids, *Nucinella*, solemyids, and thyasirids, and some hokkaidoconchid species.

Those molluscan species are well known from Cretaceous seeps in the world. No brachiopods were found from the locality. The fossil assemblage indicates that the Utagoesawa seep was fully occupied by chemosynthetic molluscan species whereas the Early Cretaceous seeps in California are characterized to have brachiopods.

Campbell and Bottjer (1995) suggested the faunal composition has been changed mainly from brachiopods to bivalves through transition between Early to Late Cretaceous. The current study indicate the phenomenon occurred only restricted in California.

Marine Snow Hypothesis: What is controling faunal composition of the methane-seep since Mesozoic?

*Robert Jenkins[1]

1. School of Geosciences and Civil Engineering, College of Science and Engineering, Kanazawa University

Fossil record of the methane-seep communities shows several interesting phenomena. One of it is the decreasing of epifaunal bivalve/brachiopod in Late Cretaceous. There are several hypotheses, e.g. “sulfate hypothesis” by Kiel (2015), are proposed to explain the situation. Here, I propose another hypothesis to explain the lacking of epifaunal bivalves/brachiopods in the Late Cretaceous. Occurring pattern of epifaunal bivalves/brachiopods through Paleozoic to Neogene is apparently corresponding to the oil resources in sedimentary rocks in each age. The oil production in the sediments are largely related to the primary production in marine, and the origin of methane is ultimately related to the organic matter in the sediment as almost same as oils. The organic matter, deposited on the sea floor, was subsequently used for the generation of methane in the anoxic condition beneath the sea floor after buried. In the case of increasing organic matter settled onto the sea floor, production of methane would be increasing, and if the organic matter decrease, the production rate of methane would be decrease. These methane is energy source for the chemosynthetic community, thus, the primary production rate at the sea surface level by the photosynthesis may control the presence/absence of epifaunal bivalve/brachiopod in seep environment. I coined this hypothesis as 'Marine Snow Hypothesis', because the particulated organic matter sinking to the sea floor is called marine snow.

In situ Sr isotope analysis of methane-seep carbonates: insight into ancient subseafloor fluid circulation

*Yusuke Miyajima[1], Michał Jakubowicz[2,3], Takafumi Hirata[1]

1. Geochemical Research Center, Graduate School of Science, The University of Tokyo, 2. Institute of Geoecology and Geoinformation, Adam Mickiewicz University, Poland, 3. Isotope Laboratory, Adam Mickiewicz University, Poland

Along continental margins, tectonic activities trigger subseafloor migration and seepage of geofluids enriched in methane, which sustain chemosynthesis-based biological communities on the seafloor. Depending on their source and migration pathway, seeping fluids have various elemental and isotopic signatures that provide insights into subseafloor fluid–rock interactions and material cycling. At the methane seeps, precipitation of carbonate is induced by microbial oxidation of methane and resultant production of HCO_3^- ions. The methane-seep carbonates record elemental and isotopic signals of seeping fluids in the geological past, and several studies have aimed to decode the origin and migration pathways of ancient seeping fluids using geochemical signatures of the carbonates (e.g., Jakubowicz et al., 2015, 2019).

Strontium isotope ratio ($^{87}Sr/^{86}Sr$) is one of the common tracers of fluid circulation and fluid–rock interactions, and has been applied to seep carbonates (Peckmann et al., 2001; Joseph et al., 2012; Jakubowicz et al., 2019). Methane-seep carbonates are often characterized by complex textures composed mainly of clay- or detritus-rich matrix and detritus-free void cements, the latter of which could archive Sr isotope signals of subsurface fluids distinct from near-seafloor sediments. However, millimeter- or smaller-scale cement phases are difficult to sample using the conventional microdrills without contamination from the matrix. In this study, we applied a high spatial-resolution Sr isotope analysis to cement phases of seep carbonates using laser ablation multiple collector inductively coupled plasma mass spectrometry (LA-MC-ICP-MS), in order to detect “pure” isotope signals of ancient seeping fluids. We measured the Sr isotope ratios in isopachous cements of fossil seep carbonates collected from the Hollard Mound (Middle Devonian, Morocco) and Baška (Lower Cretaceous, Czech Carpathians). Results obtained by LA-MC-ICP-MS were consistent with the isotope ratios measured previously by thermal ionization mass spectrometry coupled with microdrill sampling technique (Jakubowicz et al., 2019). We also tested the method using radial calcite cements of Upper Cretaceous seep carbonates in Hokkaido that are hosted by forearc basin sediments (Yezo Group). The Yezo Group is underlain by Jurassic to Lower Cretaceous mafic basement rocks and input of deep-sourced fluids from the basement rocks could be recorded as ^{87}Sr-depleted signals in the carbonates. Pilot results from one of the Hokkaido seep carbonates, Gakkonosawa, yielded Sr isotope ratios less-radiogenic than those for the coeval seawater, implying deep-fluid input. Exploring the ^{87}Sr-depleted signals at other Cretaceous seeps in Hokkaido would provide more insights into the deep subseafloor fluid circulation in the Cretaceous subduction zone at the eastern margin of the Eurasian Continent.

Monitoring CH_4 amounts deep inside deep-water mud volcanoes

*A. Kioka[1], T. Tsuji[2], H. Otsuka[3], J. Ashi[3]

1. Universität Innsbruck, Austria, 2. Kyushu University, Japan, 3. The University of Tokyo, Japan

Mud volcanoes are among the largest geological sources releasing CH_4 gas. Numerous studies have revealed their origins and compositions released from submarine mud volcanoes. Yet, quantification of the amount of gas inside submarine mud volcanoes has been challenging due to the difficulty of in situ measurements, which has hampered better evaluation for their contribution to the global methane budget. Here we provide a coupled geochemical and geophysical model that bridges bulk methane concentrations and seismic wave velocities in the mud conduit of submarine mud volcano. This model is applicable to most submarine mud volcanoes, and is able to estimate methane concentration at greater depths where methane hydrate cannot be present, using downhole logging data or seismic data. Our calculation for submarine mud volcanoes in the Eastern Mediterranean and the Nankai plate subduction zones shows that the weight fractions of gaseous and dissolved methane in total weight of sediment are 1,000--3,500 ppm within their mud conduits, which are much higher than previously expected from pore-water evidence from conventional shallow subsurface sampling. Although more definitive calculations cannot be made until the model parameters are better constrained, our approach provides an opportunity for re-estimating the global methane budget in submarine mud volcanoes, shedding new light upon the impact of submarine mud volcanism on carbon cycle.

Volcanic eruptions often continue for more than a few months or years; the intensity and the style of eruptions remarkably change with time. It is, therefore, desired to forecast such eruption sequences on the basis of field observations during the eruptions. For this purpose, the basic idea of data assimilation is useful. The data assimilation is composed of two mathematical problems: forecasting the system evolution based on forward physical models and determining the model parameters based on inversion analyses of field observations. We are interested in how the mathematical characteristics of the forward models for volcanic eruptions affect those of their inversion problems. In this presentation, we focus on two problems: (1) the estimation of model parameters of magma plumbing system from field observations of magma discharge rate and ground deformation, and (2) the estimation of magma discharge rate of explosive eruptions from tephra-fall deposits.

The inversion problem of magma plumbing system

The eruption sequence is characterized by the evolution of magma discharge rate (Q) and chamber pressure (P) during eruption. To describe the evolution of Q and P, we formulated a model of magma plumbing system composed of a conduit and a magma chamber in elastic rocks. In this model, the effects of gas-exsolution and gas-escape on conduit flow are considered, which leads to complex features of volcanic eruptions such as a transition from a lava-dome forming eruption to an explosive eruption. The eruption style (i.e., evolution of Q and P) is sensitively dependent on model parameters related to geological and petrological conditions (e.g., volume and depth of magma chamber and magma properties). To forecast the eruption sequence, these model parameters need to be estimated from time-varying observations of Q and P through an inverse analysis.

Generally, because of the strong non-linearity of the conduit-flow model, it is mathematically and computationally difficult to investigate the influence of each observation on the estimation of the model parameters. We express the trade-off relationship between the model parameters utilizing analytical solutions of the conduit-flow model (e.g., Koyaguchi, 2005; Kozono and Koyaguchi, 2009), and show that the key parameters that affect the time evolution of P and Q are fundamentally different between explosive and effusive eruptions. Because of this difference, model parameters constrained from the observations of Q and P also depend on whether the eruption is effusive or explosive.

The inversion problem of tephra dispersion

The estimation of magma discharge rate (i.e., Q) is one of the key issues for forecasting volcanic eruption sequence. For explosive eruptions, the value of Q can be estimated from observations of tephra dispersion. The forward model of tephra dispersion is composed of the eruption column dynamics model and the advection-diffusion model. The former describes the supply rate of tephra particles from an eruption column just above the volcano as a function of altitude (referred to as the supply rate function). The latter describes the transportation of tephra particles from the source (i.e., the eruption column just

©2019. Japan Geoscience Union. All Right Reserved.

above the volcano) to the ground surface.
The above two models have distinct features in the inversion problem. The singular value decomposition (SVD) analysis indicate that the inverse problems of the advection-diffusion model is highly ill-conditioned so that the number of basis functions expressing the supply rate function is limited regardless of the number of data of tephra-fall deposits. On the other hand, the eruption column model indicates that the form of the supply rate function is strongly correlated with the eruption conditions such as Q. We, therefore, attempt to develop a method to estimate the value of Q from the supply rate function expressed by the limited number of basis functions. Some preliminary results on this problem will be presented.

Sparse modeling based feature selection of magmatic tectonic settings

*Kenta Ueki[1], Hideitsu Hino[2], Tatsu Kuwatani[1,3]

1. Japan Agency for Marine-Earth Science and Technology, 2. The Institute of Statistical Mathematics, 3. Japan Science and Technology Agency

Understanding the magma generation processes and characteristic end-members in various tectonic settings is fundamental to understand the material circulation and compositional evolution of the solid Earth. Recent studies based on a machine learning approach revealed that volcanic rocks formed in different tectonic settings have unique geochemical signatures, indicating that both volcanic rock geochemistry and magma generation processes are closely connected to the tectonic setting. We present a result of a feature selection where sparse modeling approach is used. Sparse modeling is an approach in which automatically selects the smallest number of essential variables from high-dimensional data and constructs a succinct model. We used 24 elements and five isotopic ratios of igneous rocks formed in eight different tectonic settings for the feature selection of the settings. In addition to the major and trace element concentrations and isotopic ratios, we also considered combinations of elements, i.e., sum or ratio between two different elements, for the feature selection. This study uses sparse multinomial regression (SMR) approaches for feature selection. Multinomial regression is the classical linear discrimination method. Using the multinomial regression with the sparse modeling approach, a small number of essential geochemical information of tectonic settings are extracted. Based on the automatically selected features, we will discuss the geodynamical and geochemical process to derive various magmas and tectonics.

Automatic Detection of Stationary Gravity Waves in the Venus' Atmosphere Using Deep Generative Models

*Minori Narita[1], Daiki Kimura[2], Atsushi Yamazaki[3], Takeshi Imamura[1]

1. The University of Tokyo, 2. IBM Research AI, 3. ISAS/JAXA

Venus is covered with thick clouds of sulfuric acid, and the entire upper atmosphere rotates much faster than the planet itself. Recently, interhemispheric large bow-shaped structures, remaining fixed above the highland in contrast to background wind fields, were observed in long-infrared and ultraviolet images by Venus Orbiter Akatsuki. These bow-shaped structures are said to be the result of atmospheric gravity waves generated in the lower atmosphere and propagate upwards to the cloud top, which has a significant influence on the Venus' atmospheric system. Not a few bow-shaped, stationary features indicative of topographic gravity waves have been reported so far. However, to unravel where and when these structures appear frequently, we need to analyze the phenomena comprehensively, using much more data. Detection of such characteristic cloud features in images has been done by human eye in Venus research, but to detect many more cases efficiently from massive amounts of image data, we need a framework to do it automatically and robustly. Moreover, most of the bow-shaped structures in ultraviolet images are small, which is almost impossible to find out every case by our eyes.

In this study, we propose a novel approach that detects these stationary features using a deep generative model that has deep neural networks (deep learning). There are various types of such deep models nowadays; we used a variational auto-encoder (VAE) because it has reported good results in dimensionality reduction fields and been a well-known method for image reconstruction. The input and the output of VAE are set to be the same, and the network is divided into two parts, which are the encoder that converts an image to latent representation, and the decoder that reconstructs an image from given latent variables. The detection of stationary features can be seen as an anomaly detection task, which treats images that have stationary features as the anomaly class and the normal cloud image as the normal class.

We used ultraviolet (283 nm) images for this analysis. Firstly, we performed photometric correction using Minnaert Law, and averaged several images taken successively in 24 hours to highlight structures that remains still. Then we extracted features that have scales smaller than 6 degrees by high-pass filtering. Lastly, we extracted image patches from these images. Each patch has the size of 24 degrees both in latitude and longitude. We used images taken in 25 days in 2016 and 2017.

The analysis procedure is as follows. First, we train this network using only normal cloud images that do not include stationary features to let it learn its latent features. When testing, we input test images composed of both normal and anomaly (stationary feature) images, and detect anomalies based on the reconstruction loss that is calculated by the sum of the pixel-wise distance between the original image and the reconstructed image that is output from the last layer in the network. The network has five convolutional layers in the encoder and the decoder, respectively. The latent space has 32 dimensions. We used 4,000 normal cloud images as the training data, and 1,000 normal and 255 anomaly images as the test data.

We evaluated our method by calculating the area under the curve (AUC) of the receiver operating characteristic (ROC) curve. As a result, the AUC was 0.93 (maximum is 1.00), which shows that the

©2019. Japan Geoscience Union. All Right Reserved.

proposed method successfully detects stationary features. The reconstruction error of a stationary structure image is large because the network cannot reconstruct such bow-shaped structure properly. Our method can be easily applied not only to Venus but also various planetary images to detect characteristic structures.

From criteria of power output and temporal stability, geothermal is the most promising renewable energy for electrical generation. However, high introduction cost for geothermal power generation, in particular the cost for exploration to identify the geothermal reservoir is a main issue against the plan. Development of more accurate geothermal-resource exploration is necessary for enhancement of geothermal energy use. Detection of geothermal fluids paths including water and steam from geothermal reservoir is a major target in the exploration stage. Topographic analysis is one of the effective methods for the detection. Thus, we have generated a hyper-resolution DEM (HR-DEM) of the Wayang Windu Geothermal Field (WWGF), situated in West Java, Indonesia using UAV. HR-DEM with high spatial resolution (0.5 m) covers an area of 5 km (E–W) by 10 km (N–S) in WWGF. The lineament density map of WWGF was produced by a topographic analysis through HR-DEM. Moreover, spatial distributions of geothermal alteration minerals such as alunite, calcite, and kaolinite were mapped from an image processing of hyperspectral satellite image, Hyperion. A combination of the lineament and mineral distributions specified highly permeable zones in which the fractures and geothermal alteration minerals were concentrated. The location of high igh radon concentration by in-situ measurements correspond well with these estimated permeable zones. Therefore, the integrated analysis is expected to increase the identification accuracy of fluid paths and clarify the geothermal system in WWGF. This research is supported by JST and JICA through Science and Technology Research Partnership for Sustainable Development (SATREPS).

Geochemical characterization of deep-sea sediments in the western North Pacific Ocean by an integrated multivariate statistical technique

*Kazutaka Yasukawa[1,2], Kentaro Nakamura[1], Koichiro Fujinaga[2,1], Hikaru Iwamori[3,4], Yasuhiro Kato[1,2]

1. School of Engineering, The University of Tokyo, 2. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology, 3. Earthquake Research Institute, The University of Tokyo, 4. Department of Earth and Planetary Sciences, Tokyo Institute of Technology

Recently, deep-sea sediments highly enriched in rare-earth elements and yttrium (REY) were discovered within the Japanese exclusive economic zone (EEZ) surrounding Minamitorishima Island [1]. To clarify the distribution of the “extremely REY-rich mud”, eight research cruises (KR13-02, MR13-E02, KR14-02, MR14-E02, MR15-E01 Leg2, MR15-02, MR16-07, and KM17-14C) have collected 71 sediment core samples in total from 2013 to 2018. Now we have constructed a comprehensive dataset of major- and trace-element contents of 1,646 samples by X-ray fluorescence and inductively coupled plasma mass spectrometry analyses [1-8].

Here, in order to depict geochemical features of the deep-sea sediments including the extremely REY-rich mud, we applied an integrated method of k-means cluster analysis (KCA) and independent component analysis (ICA) [9] to the huge (1,646 samples x 41 elements) dataset of the deep-sea sediments in and out of the Minamitorishima EEZ. We demonstrate that the data clusters are distributed not randomly but systematically in the real space; the clusters are vertically aligned from the seafloor to depth in a specific order and thus constitute stratigraphic units defined by geochemical features. In addition, the downhole variation of an extracted independent component (IC) shows a stepwise transition across the extremely REY-enriched layer. This transition is ubiquitous in the studied area of several-hundred-kilometer wide. The geochemical clusters just below the IC transition are variable among the cores, which implies that the IC transition corresponds to an unconformity in the sediment column probably due to erosion [5, 6]. These characteristics of the spatial distributions of the geochemical clusters and ICs support a hypothesis previously proposed by Ohta et al. [10]: an enhanced bottom current caused a physical separation of sedimentary particles, or a winnowing effect, and contributed to form the extremely REY-enriched layer by a selective deposition of relatively coarse and dense grains of biogenic Ca-phosphate that significantly accumulate REY from ambient seawater.

Mon. May 27, 2019 3:30 PM - 5:00 PM JST | Mon. May 27, 2019 6:30 AM - 8:00 AM UTC | A08 TOKYO BAY MAKUHARI HALL

[M-GI33] Data-driven geosciences

convener:Tatsu Kuwatani(Japan Agency for Marine-Earth Science and Technology), Hiromichi Nagao(Earthquake Research Institute, The University of Tokyo), Kenta Ueki(Japan Agency for Marine-Earth Science and Technology), Masayuki Kano(Graduate school of science, Tohoku University), Chairperson:Tatsu Kuwatani(JAMSTEC), Suguru Yabe(JAMSTEC)

It is important to extract essential processes and structures from observed data sets in order to understand and predict the dynamic behavior of the earth and planetary systems. Recently, many powerful methodologies have been proposed to extract useful information from high-dimensional data sets in information sciences. This session aims to provide an opportunity to gather various geoscientists to have a productive discussion for interdisciplinary collaborations.

Markov Chain Monte Carlo: algorithms for multimodal distribution and their applications

*Yukito iba[1]

1. The Institute of Statistical Mathematics

As introduction, history and software of Markov chain Monte Carlo is briefly discussed. Then, replica exchange method (parallel tempering) is explained as a useful tool for sampling multimodal distributions. It is also stressed that applications of Markov chain Monte Carlo are not rescricted to statistical physics or Bayesian computaion; it can deal with a variety of problems related to high dimensional probability, such as counting the number of discrete structures, sampling rare orbits in nonlinear dynamical systems, statistical testing under complicated null hypothesis.

Keywords: Markov Chain Monte Carlo, Replica Exchange Monte Carlo (Parallel Tempering), Bayesian modeling, rare event sampling

Specifying rate constants and reaction path on the water-rock chemical reaction based on exchange Monte Carlo method and sparse modeling

*Ryosuke Oyanagi[1], Tatsu Kuwatani[1], Omori Toshiaki[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Kobe University

Water-rock interaction in surface and subsurface environments occurs in complex multicomponent systems and involves several reactions, including element transfer. Such kinetic information is obtained by fitting a forward model into the temporal evolution of solution chemistry or the spatial pattern recorded in the rock samples, although geochemical and petrological data are essentially sparse and noisy. Therefore, the optimization of kinetic parameters sometimes fails to converge toward the global minimum due to being trapped in a local minimum.

In this study, we present a novel framework to estimate multiple reaction-rate constants from the mineral distribution pattern in a rock by using the exchange Monte Carlo method (Hukushima & Nemoto, 1997; Iba, 2001). We applied the method to the synthetic data, which includes nine unknown parameters to be estimated (Oyanagi et al., 2018). As a result, probabilistic distribution of six unknown parameters among them showed normal distributions and the proposed method could find each true parameter. However, the probabilistic distribution of others showed uniform distributions and the proposed method failed to estimate each true value because these parameters did not contribute to the observed dataset. We suggest that effective reaction paths could be extracted from mineral distribution pattern in a rock, by excluding non-effective rate constant using a sparse Modeling.

Superresolution of X-ray CT images of core samples for understanding the multi-scale structures of water-rock interaction

*Toshiaki Omori[1], Atsushi Okamoto[2], Katsuyoshi Michibayashi[3], Oman Drilling Project Phase 2 Science Party -

1. Kobe Univ., 2. Tohoku Univ., 3. Nagoya Univ.

X-ray computed tomography (CT) has become a common tool of earth sciences for the 3D imaging of various structures (layering, fractures, pores etc) of rocks. Recently, several scientific drilling projects has been carried out, and the X-ray CT of such cores provide us the 100 to 1000 m scale continuous data. However, the resolution of such X-ray CT for the cores (for example, ~0.17 mm by the X-ray CT of Drilling Chikyu) is slightly low compare to reveal the shape and geometry of mineral grains and thin fractures. In contrast, the resolution of X-ray CT in usual laboratories is high (~0.01 mm). Therefore, if we can link the high resolution X-ray CT in the lab of the limited samples to the low resolution drilling core CT data, we can obtain the valuable big data for the analyses of multi-scale structures.

For this purpose, we have tried to apply sparse superresolution techniques to the sample of serpentinezed dunite in the Moho transition zone taken by the Oman Drilling project (CM1A). We took the X-ray CT images of the samples with the voxel size of 10, 20, 40 and 80 micrometers. The X-ray CT image reveals that distribution of magnetite and spinel grains and fractures filled with serpentine. In sparse image representation framework, an image is expressed as a sparse linear combination of basis images. In learning phase, basis images are learned from multiple X-ray CT images. In superresolution phase, high resolution X-ray CT image is estimated from low resolution one through common sparse representation of basis images between high and low resolution images. By applying the sparse superresolution technique to the sample of serpentinezed dunite, we obtained results that 2x and 4x sparse superresolutions provide fine structure from low resolution X-ray image.

Keywords: Oman Drilling Project, superresolution, sparse modeling

3-dimensional Fracture Network Analysis by Persistent Homology

*Miyuki Miyazawa[1], Anna Suzuki[2], Atsushi Okamoto[1], Hiroyuki Shimizu[3], Ippei Obayashi[4], Yasuaki Hiraoka[4,5], Takatoshi Ito[2]

1. Graduate School of Environmental Studies, Tohoku University, 2. Institute of Fluid Science, Tohoku University, 3. Kajima Corporation, 4. The Advanced Institute for Materials Research, Tohoku University, 5. Kyoto University

Persistent homology (PH) based on topology is a method for capturing sizes and shapes of “holes”, that is information of connectivity. Because PH enables to quantify complex structures, automatic pattern recognition of fractures can be carried out.

Fluid flow in rocks is dominated by connectivity between fractures, so it can be expected that the relationship between fracture patterns and fluid flow can be obtained by the PH.

In this study, we quantified the images of the results from crack propagations simulation and natural mesh structures in serpentinites. The PH analysis helps to estimate the flow conditions in which the mesh structures in serpentinites were formed. And we can quantify 3D fracture structure by PH. It can be expected that PH is applied to design for geothermal reservoir by coupling PH analysis result of 3D fracture models with feature of fracture (e.g., surface area, volume, connectivity and permeability).

Characteristic patterns and minimal dynamics of correlated seismicity in Japanese island region

*mitsuhiro toriumi[1]

1. Japan agency of marine science and technology

The seismicity rates in this study are defined as the seismic event numbers of the given volume having one degree of longitude and 2.5 degree of latitude from the surface to 30 km depth and 30 to 660km depth in the Japanese islands region. It shows that the characteristic trends of time series of strongly correlated seismicity are possibly obtained as transformed seismicity rates by SVD; the one shows the long term change, second does the periodic time series with various periodicity involving annual variation, and third does nearly Gaussian noise. The first two types of time series can be mapped as five clusters in the diagram of newly transformed seismicity rate coordinates, suggesting existence of stable nodes with annual oscilation and gaussian noises. From these stable nodes, it concludes that the minimal dynamics of the seismicity of the Japanese island region is approximated as the simple low dimensional nonlinear dynamics with semi-periodic variable as is similar to van del Pol equation.

Keywords: spatio-temporal variation of seismicity, correlated seismicity time series, minimal non-linear dynamics

The future of the journal metrics and new trend of the scholarly publishing

*Yoshiko Tanahashi[1]

1. Clarivate Analytics

The future of the journal metrics and new trend of the scholarly publishing will be discussed.Clarivate Analytics has consistent selection criteria from the 1970s to the present as carefully selecting journals to be included in Web of Science. By looking at the selection criteria, I would like to consider a viewpoint for becoming a globally distinctive journal, managing journals from a global perspective, and seeing the journals originating from Japan to face the global research community with strategy. Furthermore, we summarize statistical data of Web of Science into journals related to JpGU, and present the benchmark which is the basis of grasping the current situation of the journal. I summarize the current status of OA journals, Japan's journal, China's journals on Web of Science as statistics and look at recent trends in the field related to JpGU, and a useful point for strategy formulation to raise the presence of the journal.

Underlying Issues and Problems in Publishing International Scientific Journals in Japan. “DNA Research” As A Case Study.

*Michio Oishi[1]

1. Kazusa DNA Research Institute

In this presentation, I would like to discuss certain issues and problems in regards to publishing scientific journals in Japan. My talk is a reflection of my experience as the Editor-in-Chief of the journal “DNA Research” which was launched at the inauguration of the Kazusa DNA Research Institute in 1994.

Firstly, I would like to introduce the current status of DNA Research, an open access journal, regarding the editorial policy and processes, the scope, the publisher, the geographical distribution of the submitted and published papers, the acceptance rate, the impact factor (IF) and some other aspects.

Secondly, I would like to discuss some of the issues and problems in publishing scientific journals in Japan. One important issue is how to ensure objectivity in reviewing manuscripts; a problem often stemming from the unique cultural, social and academic environment of Japan. Another important issue is how to maintain a consistent editorial policy over the long term, ideally by the same Editor-in-Chief, Executive Editor and majority of associated editors. This may be difficult for some journals of academic societies in which editors selected from their members undergo turnover of their duties every few years. Furthermore, since any of these editorial jobs is quite demanding, few scientists active in research are willing to accept or assume these positions. Regarding the financing of scientific journals, we, DNA Research, decided not to seek financial support from outside; the reason will be presented.

Thirdly, I would like to list our efforts to improve the IF of our journal which now stands at between 5 and 6. Most researchers agree that it may not be correct to evaluate scientific journals by IF alone, but it is also true that there is no other reliable way to evaluate scientific journals objectively and quantitatively. In fact, the IF is now also being utilized for the evaluation of researchers themselves for the purposes of their promotion, job accession and others by taking into consideration the IF of the journals where their papers have appeared. These developments have prompted us to take steps to strive for a higher IF for our journal.

Fourthly, I would like to mention the challenge of dealing with online-publication (e-publication) and open access of scientific journals. Online-publication has virtually eliminated costs for the printing and delivery of journals, thus paving a way to publishing papers at lower cost which benefits scientific journals like ours without outside financial support. The open access movement, which was originally conceived as the result of the demand from the general public and research funders in US and EU countries, has become a mainstream trend in the publication of scientific journals. In an open access world, revenues come from the article processing charge (APC) rather than subscription charges, providing a new incentive for higher IF journals, since the level of APC often reflects the IF of the journal. Because of these trends, the number of journals which employ online only publication and/or open access is rapidly increasing, thus creating more competitions among scientific journals which are vying for higher-grade (IF) rankings.
Finally, I would like to discuss the need and possibility of creating a journal such as Nature or Science in Japan which focuses specifically on emerging research in the natural sciences in Asia.

Review of editorial work for PEPS in 2018-2019 and new strategy for 2019–2020

*Yasufumi Iryu[1]

1. Institute of Geology and Paleontology Graduate School of Science Tohoku University

Progress in Earth and Planetary Science (PEPS) is a peer-reviewed, open-access electric journal published by the Japan Geoscience Union in partnership with Springer. PEPS received its first manuscript at the end of 2013 and we published our first papers in April 2014. By the end of the year 2018 we had published 244 scientific articles. In the first half of the year 2018 PEPS received good news. PEPS received its first Impact Factor of 2.481, which was announced in the June 2018 edition of Clarivate Analytics Journal Citation Reports. PEPS currently ranks 66/189 in the category ‘Geosciences, Multidisciplinary’. Whilst this does not yet make us a Q1 journal we are close.

In addition to being funded by the JpGU, PEPS received a grant-in-aid for scientific research from the Japan Society for the Promotion of Science. As the period covered by this five year grant-in-aid drew to an end we applied for funds for the next five fiscal years (2018-2012). Unfortunately our application has been rejected. Due to this, we were forced to raise article processing charges (APC). Since its inception we have always planned for PEPS to become entirely supported by APCs and therefore completely self financing and we have done some analysis and planning towards this goal. Our analysis shows that the most important thing is that we all focus on maintaining and increasing PEPS’ status as one of the leading journals in our field because this is the surest way of increasing our APC income.

New strategy for 2019-2020 is in preparation and will be introduced in the JpGU meeting 2019.

"Earth, Planets and Space" An Open Access Journal: Past, Present and and Future

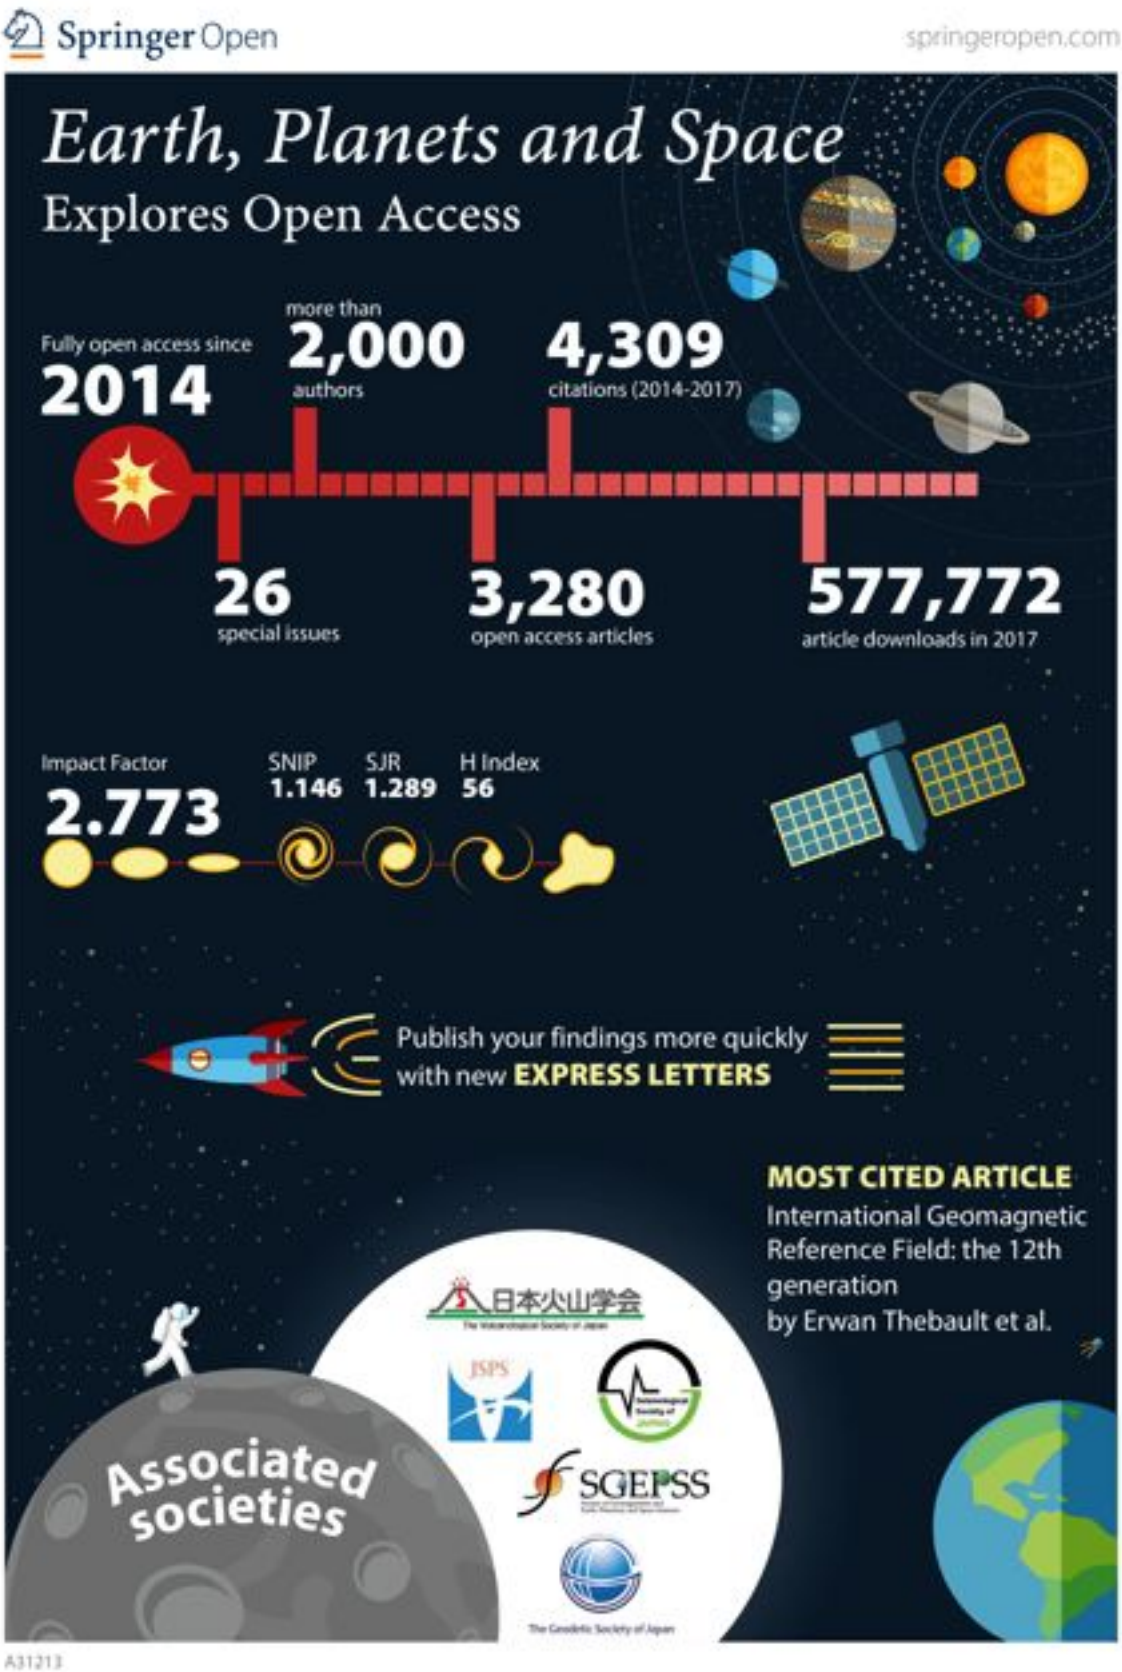
*Yasuo Ogawa[1], Kiyoshi Baba[2]

1. Volcanic Fluid Research Center, School of Science, Tokyo Institute of Technology, 2. Earthquake Research Institute, University of Tokyo

EPS (Earth, Planets and Space) is a peer-reviewed open access journal published on behalf of the following five societies; The Society of Geomagnetism and Earth, Planetary and Space Sciences, The Seismological Society of Japan, The Volcanological Society of Japan, The Geodetic Society of Japan, The Japanese Society for Planetary Sciences. These five societies are all society members of the Japan Geoscience Union.

EPS was established in 1998 as a continuation of the two journals, the Journal of Geomagnetism and Geoelectricity (1949 to 1997) and the Journal of Physics of the Earth (1952 to 1997). In 2014 we started open access publication under the SpringerOpen platform. Open Access publication successfully shortened the publication time, increased visibility of the journal and widened its international readership. We publish average of 190 papers per year and half of the authors are from overseas. One of the qualification indices of the journal, impact factor (IF), is continuously increasing from 1.328 (2014) to 2.773 (2017) and it will also go over 2.6 in 2018. The increasing IF is supported both by increase of highly cited papers and by decrease of uncited papers, suggesting the success of quality control by the editorial board and possibly increasing of the visibility via open access.

The scope of EPS covers Earth and Planetary Sciences, particularly geomagnetism, aeronomy, space science, seismology, volcanology, geodesy, and planetary science. The EPS share common scopes as well as a common journal platform with PEPS (Progress in Earth and Planetary Science). In contrast to PEPS, which emphasizes review papers, EPS is characterized by the following article types: (1) “Express Letter” which aims at fast publications, (2) “Technical reports “, which describe technical developments for scientific researches and (3) “Frontier Letters” for leading edge researches only with the invitation from the editor in chief. EPS promotes topical article collections (what we call special issues) on the first results of geoscientific events (earthquakes and volcanic eruptions) and scientific missions (satellite missions). EPS has been recently successful in attractive special issues.



Aiming at fast and qualified review system, we have expanded editorial board members internationally since 2017. Now we have currently 50 regular editors (including 22 oversea editors). The oversea editors are 10 from Europe, 3 from North America, 5 from Asia, and 3 from Oceania.

As part of the promotion of the journal we have four annual awards to recognize authors and reviewers: (1) EPS Excellent paper awards, (2) EPS Young researcher award, (3) Highlighted Paper Awards and (4) Excellent Paper Awards.

From 2018, EPS has strengthened ties with JpGU. EPS has started collaborative advertisement activities at major domestic and international academic meetings, like JpGU, AGU, EGU and AOGS. EPS has updated the APC (Article Processing Charge) in September 2018 for sustainable operations of the journal.

Enhancing dissemination of research activities to international communities by Japanese Geoscience Union

*Hodaka Kawahata[1]

1. Atmosphere Ocean Research Institute, the University of Tokyo

Progress in Earth and Planetary Science (PEPS) is our official scientific journal established in April 2014 with 51 society members by partnership with Springer. 5 years have passed. This is an English-language peer-reviewed open access e-journal under a collaboration with Springer-Nature. The journal is to be devoted to original articles and reviews (>20%) in the research fields of space and planetary sciences; atmospheric and hydrospheric sciences; human geosciences; solid earth sciences; and bio-geosciences.

In June, 2018, PEPS got the first Impact factor of around 2.48. Now we are taking effective steps (measures) and then hope to get higher IF, around 3, in 2019, hopefully.

JpGU will make an effort to promote the journals which have been published by Japanese Geoscience Societies, taking part in JpGU, including EPS.

The formation process of μm-sized dust grains into km-sized planetesimals in planet formation has several theories such as direct coalescence growth and concentration due to instability and has not yet been unraveled. It is difficult to verify the formation process because we cannot directly observe planetesimals forming in protoplanetary disks. Therefore, we focus on comets which are the most primitive bodies in our solar system and are thought to be leftover planetesimals. Comets are capable of detailed observation by spacecraft. In this work, we focused on the tensile strength of 67P/Churyumov-Gerasimenko, which is one of the comets in our solar system and was observed by the Rosetta mission.

In order to investigate whether or not the formation process of planetesimals can be restricted by their tensile strength, we conducted N-body simulations considering the interaction model of dust particles (Wada et al. 2007, ApJ, 661, 320) and investigated the tensile strength of porous dust aggregates. The initial dust aggregates were isotropically and statically compressed to simulate their formation process (Kataoka et al. 2013, A&A, 554, A4). As a result of our numerical simulations, we found that tensile stress gradually increases as tensile displacement increases, and then the tensile stress takes the maximum value. In other words, the tensile strength was obtained. We also confirmed that cutting of contacts between particles in the dust aggregates begins to occur near the maximum tensile stress. We obtained the relation that the tensile strength of dust aggregates is proportional to the 1.8 power of the initial volume filling factor, inversely proportional to the constituent particle radius, and proportional to the surface energy of the constituent material. Moreover, we succeeded in reproducing numerical simulation results by using a semi-analytical model that the tensile strength is determined by cutting of contacts between particles. It was also revealed that the constituent particle radius of comet 67P has to be about 3.3–220 μm to reproduce its tensile strength using our model. In the conventional planet formation theory, the constituent particle radius is assumed to be 0.1 μm same as the interstellar dust radius and is different from the value obtained from our model. It is necessary to reconsider theories such as the time evolution of the constituent particle radius.

Filling factor dependence of the thermal conductivity understood from the graph structure of dust aggregates

*Sota ARAKAWA[1], Masaki TAKEMOTO[1], Taishi NAKAMOTO[1]

1. Tokyo Institute of Technology

Previous studies (Arakawa *et al*. 2017; 2019) revealed that the thermal conductivity through the solid network of dust aggregates is proportional to the square of the filling factor. However, the reason why the thermal conductivity is given by the power-law function of the filling factor was still unclear. In order to understand the physical reason of this power-law dependence, we need to investigate the geometric structure of highly porous dust aggregates.
In this study, we study the graph structure of fractal aggregates called BCCA aggregates (e.g., Meakin 1991). The fractal dimension of BCCA aggregates is approximately 1.9 (e.g., Okuzumi *et al.* 2009) and the graph structure of BCCA aggregates is classified as a tree. Then the gyration radius r_g and the filling factor ϕ is connected by the following equation, $r_g \simeq \phi^{-1/(3-1.9)}$, and the number of the heat conduction path per unit area, σ, is given by $\sigma \simeq \phi^{2/(3-1.9)}$ for BCCA aggregates. In addition, we calculated the graph-theoretical distances of monomer grains within a BCCA aggregate. We found that the root mean square of the graph-theoretical distance d is given by $d \simeq r_g^{1.2}$. Therefore, the thermal conductivity of BCCA aggregates is proportional to $\sigma r_g / d \simeq \phi^2$.

Collisional disruption of planetesimals: dependence of material strength

*Ryo Suetsugu[1], Hidekazu Tanaka[2], Hiroshi Kobayashi[3], Hidenori Genda[4]

1. University of Occupational and Environmental Health, 2. Tohoku University, 3. Nagoya University, 4. Tokyo Institute of Technology

Collisions are one of the most important processes in planet formation because planetary bodies in the Solar System are thought to have experienced a lot of collisions during the accretion process. Thus, collisional processes have been examined extensively. Roughly speaking, collisional outcomes can be classified into disruptive collisions and erosive collisions by the specific impact energy Q_R. In particular, the specific impact energy required to disperse the largest body such that it has exactly half its total mass after the collision is called the critical specific impact energy Q_{RD}^*. In the case of $Q_R > Q_{RD}^*$, collisions between planetesimals are regarded as disruptive collisions, while they are non-disruptive collisions for $Q_R << Q_{RD}^*$, whose mass ejection is small. The values of Q_{RD}^* have been investigated by laboratory experiments and numerical simulations. When the target is small enough to neglect the effect of the target's gravity, the critical specific impact energy is mainly estimated by laboratory experiments. As target size increases, collision outcomes gradually become dominated by the gravity of the target. However, direct experimental measurements of a large scale collision are difficult to carry out in the laboratory. Thus, the values of Q_{RD}^* for large targets are estimated via shock-physics code calculations, which compute the propagation of the shock wave caused by a high velocity collision: Lagrangian hydrocode such as Smoothed Particle Hydrodynamics (SPH) methods, or a hybrid code of Eulerian hydrocode and N-body. These numerical simulations showed the dependence of the value of Q_{RD}^* on various impact conditions such as target size, impact velocity, material properties, impact angle, and numerical resolution. Recently, we performed impact simulation using the grid-based code (iSALE) in the gravity regime, because almost all high velocity collisions have been examined by the SPH method. We showed that collision outcomes of the iSALE simulation agree well with those of the SPH simulation.
As mentioned above, material properties of the target affect collisional outcomes. However, the dependence of Q_{RD}^* on material properties was not studied in detail. In this study, we perform impact simulations in the gravity regime by using shock-physics code, iSALE. We will discuss the dependence of Q_{RD}^* on material properties and impact conditions for a wide range of specific impact energy, and compare our results with previous studies.

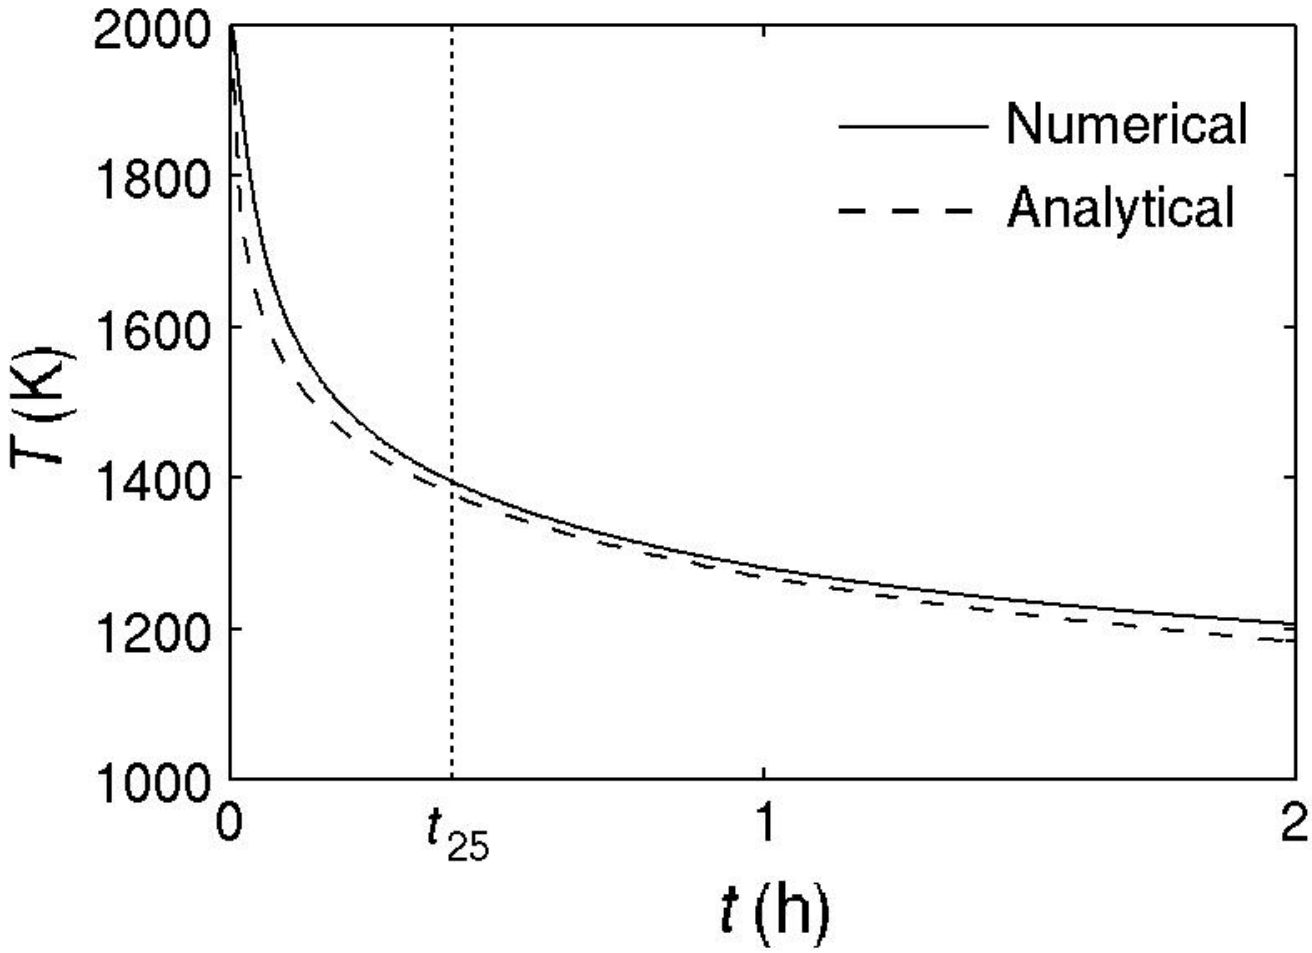
Size and cooling rate of chondrules formed thorough collision between planetesimals containing volatile materials

*Sin-iti Sirono[1]

1. Department of Earth and Planetary Sciences, Nagoya University

Chondrite meteorite contains "chondrules", which are silicate spheres with sizes of 0.1-2 mm. Volume fraction of chondrules exceeds 80% in some chondrites. Its shape and high fraction indicate that chondrules were formed through common heating event in the solar nebula. Cooling rate of chondule has been estimated as 10-1000 K/h from laboratory experiments. The size and cooling rate are the most important quantities which characterize chondrules. Although many models have been proposed, the parameter range suitable for chondrule formation is limited in most models.

Collision of planetesimals has been studied as a chondrule forming mechanism. It requires high velocity collision > km/s which is difficult to attain in the solar nebula. However, the formation of Jupiter can excite the motion of planetesimals. Nagasawa et al. (2019) showed that the impact velocity between planetesimals can exceed 10 km/s due to the exitation. Moreover, the age of chondrules ranges between 1 and 3 Myr after CAI. This is consistent to the timing of Jupiter fomation and duration of excited motion of planetesimals.



In order to form chondrules of 0.1-2mm size, high gas dynamic pressure is necessary. The gas in the solar nebula is too rare to breakup silicate melt down to the size range. If a colliding plantesimal contains volatile materials, they evapolate quickly and expand because of the collisional heating. The velocity difference between silicate melt and gas can lead to breakup of silicate melt. The size of melt droplet is determined by Weber number, which is a ratio between gas dynamic pressure and surface tension. I conducted 1-D numerical simulation of expansion of gas-melt mixture. The simluation parameters are the thickness of the mixture L, mass fraction of volatile materials f, and initial temperature $T_{0.}$ I adopted physical parameters of H_2O, and ideal gas is assumed for simplicity.

Figure shows typical evolution of temperatrure. The temperature of the mixture decreases by the expansion of the gas. In this case, the cooling rate is ~1000 K/h. I conducted simluations with various parameter sets. The range of droplet size is 0.3-2mm. Cooling rate is 100-10000 K/h. These ranges are consistent to those of chondrules.

It is possible that the volatile material is not water but organics. If this is the case, the gas is reducing and Fe becomes Fe metal, not FeO. Then the variation of oxidation condition of Fe can explain by the variation of volatile materials. Moreover, if the inside of a planetesimal is melted due to heating by ^{26}Al, Fe migrates to the center of a planetesimal and avoid collision. Then the variation of Fe content (seen as H, L, LL chondrites) can be explained by the internal melting of a planetesimal.

From Dust to Planet via collisional growth

*Hiroshi Kobayashi[1], Hidekazu Tanaka[2]

1. Department of Physics, Nagoya University, 2. Tohoku University

We investigate collisional evolution from dust to planets in protoplanetary disks. For the collisional growth of dust, the bulk density evolution of dust aggregates is important. On the other hand, the random velocity evolution is needed to be considered for planetesimal growth. We take into account both effects consistently and then carry out the simulation for collisional growth from dust to planets. We show planets are possible to be formed via collisional growth of dust.

Impact Conditions for the Formation of the Extremely Elongated Shape of 1I/’Oumuamua

*Keisuke Sugiura[1], Hiroshi Kobayashi[1], Shu-ichiro Inutsuka[1]

1. NAGOYA UNIVERSITY Graduate School of Science

1I/’Oumuamua is considered to be the first interstellar object observed by the Pan-STARRS telescope on October 2017. The eccentricity of 1I/’Oumuamua is about 1.2, which corresponds to the relative velocity with respect to the sun at infinity of 26 km/s. This relative velocity at infinity is comparable to the relative velocity of solar neighborhoods, and thus we consider that 1I/’Oumuamua came from a nearby planetary system. The absolute magnitude of this object is about 22 magnitude, which corresponds to the size of about 100 m with the albedo of 0.04. This object shows large light curve amplitude of at most 2.5 magnitude, and the shape of 1I/’Oumuamua is estimated to be the extremely elongated one with the ratio of the intermediate to major axis lengths less than 0.3.

To examine whether asteroidal impacts can form the extremely elongated shape of 1I/’Oumuamua or not, we conduct numerical simulations of collisions between asteroids. We use a Smoothed Particle Hydrodynamics code for elastic dynamics with the self gravity, a fracture model for rocky material, and a friction model for completely damaged rocks. We assume that impacting bodies do not have tensile strength of monolith bodies but have frictional forces of granular material. The diameter of target bodies is fixed to 100 m. We conduct impact simulations with various ratios of the masses of two impacting bodies, friction angles, impact angles, and impact velocities, and then we investigate the impact conditions required for the formation of the extremely elongated objects with the ratio of the intermediate to major axis lengths less than 0.3.

As a result of the impact simulations, we find that the formation of the extremely elongated bodies requires the mass ratio larger than 0.5, the friction angle larger than 40 degrees, the impact angle less than 30 degrees, and the impact velocity less than 40 cm/s. The most difficult condition to be realized among these conditions is the impact velocity; the required impact velocity is much smaller than the average impact velocity in the main belt ~ 5 km/s.

The impact velocities less than 40 cm/s require dynamically cold environments in protoplanetary disks. However, turbulent scattering due to gas or gravitational scattering due to larger bodies increase the relative velocities. We estimate required turbulent strength and the size of larger bodies and find that the Shakura-Sunyaev alpha parameter less than $10^{-4}$and the size of larger bodies less than 7 km realize the relative velocities between 100-m sized bodies less than 40 cm/s. This turbulent strength is realized at the places where magnetorotational instability is not active. The size of bodies less than 7 km is realized only in extremely young protoplanetary disks. Therefore,1I/’Oumuamua might have been formed in such an extremely primordial protoplanetary disk, then might have been ejected from the planetary system due to, for example, a stellar encounter, and then visited our solar system.

[P-CG25] Planetary Magnetosphere, Ionosphere, and Atmosphere

convener:Kanako Seki(Graduate School of Science, University of Tokyo), Takeshi Imamura(Graduate School of Frontier Sciences, The University of Tokyo), Hiroyuki Maezawa(Department of Physical Science Osaka Prefecture University), Naoki Terada(Graduate School of Science, Tohoku University), Chairperson:Masaki Nishino(名古屋大学宇宙地球環境研究所), Hiroyuki Maezawa(大阪府立大学大学院理学系研究科)

Exploration of Moon, Venus, Mars, Mercury, Jupiter, Saturn, and beyond together with rapid developments of numerical simulations provides us new view of planetary environment. This session collects general contributions of new findings about planetary magnetosphere, ionosphere, and atmosphere. New methodology and technology development studies for future explorations are also welcome. In order to put the common knowledge at different planets into perspective, this session aims to facilitate discussions on comparative planetary environments.

Titan's atmosphere is characterized by the presence of the number of trace gases such as hydrocarbons and nitriles produced with complex photochemical processes. Cassini spacecraft, which completed its works in 2017, has played an important role to illustrate the dynamic variation of the trace gases. For example, on the high-latitudinal region of the southern hemisphere, both hydrogen cyanide (HCN) and benzene (C_6H_6) exhibited ~1000 times enhancement of their atmospheric abundances from 2011 to 2015 (Coustenis et al. 2016). For the understanding of complicated photochemical processes of Titan, long-term observation of the spatial distribution of such trace gases are crucial.

ALMA is a suitable tool for that purpose. We have constructed a large spectroscopic data-set of Titan's trace gases by converting ALMA's archival data obtained for the calibration purpose into the scientific data known as "FITS cube", which contains calibrated spectra in each 2-D image pixels. Extracted number of Titan's FITS data is more than 3000. Many trace gases such as carbon monoxide (CO), HCN, acetonitrile (CH_3CN), cyanoacetylene (HC_3N) and their isotopologues and other complex molecules are detected clearly. For the illustration of the time distribution, spectral intensity distribution maps of all detected species were produced.

From the analysis of the spectral intensity distribution map, from mid 2015, intensities of HC_3N measured on southern hemisphere is stronger than that of northern hemisphere. In turn, northern hemispheric CH_3CN and HCN intensities are still stronger than that of south in 2015 and 2017, respectively. Newly found difference of the time variation between the nitriles possibly reflects their photochemical production/destruction timescale against the seasonal variation of UV influx and atmospheric circulation. Currently, we are attempting to develop the semi-automated atmospheric retrieval code to reproduce the 3-D distribution of trace species to constrain the photochemical processes.

Transport and energization of planetary ions in the magnetospheric flanks of Mercury

*Sae Aizawa[1], Dominique Delcourt[2], Naoki Terada[1]

1. Graduate School of Science,Tohoku University, 2. LPC2E, CNRS

The transport and energization of planetary ions within Kelvin-Helmholtz (KH) vortices developing in the magnetospheric flanks of Mercury are investigated using both numerical methods and data analysis. Due to the presence of heavy ions of planetary origin (e.g., O^+, Na^+, and K^+) and the complicated field structure present during the KH vortex development, the scale of electric field variations can be comparable to that of the ion gyromotion. Therefore, ions may experience non-adiabatic energization as they drift across the magnetopause. In this study, we focus on the effects of the spatial/temporal variations of the electric field along the ion path. We show that the intensification, rather than the change in orientation, is responsible for large non-adiabatic energization of heavy ions of planetary origin. This energization systematically occurs for ions with low initial energies in the direction perpendicular to the magnetic field. The energy gain is of the order of the energy corresponding to the maximum *ExB* drift speed. It is also found that the ion transport across the magnetopause is controlled by the orientation of the magnetosheath electric field. Analyzing data from MESSENGER allow us to compare the observational facts with our numerical results. We find that the counts of Na^+-group detected by FIPS increase with the existence of KH waves, which is consistent with our numerical results. Although some differences in the energy distribution are expected in our numerical results, the data show no significant differences. This will be the subject of further studies using the newly developed BepiColombo instruments.

Exploring the real-time prediction of Mercury's magnetosphere

*Manabu Yagi[1], Kanako Seki[2], Yosuke Matsumoto[3], Dominique C. Delcourt[4], Francois Leblanc[4]

1. RIKEN Center for Computational Science, 2. Graduate School of Science, University of Tokyo, 3. Graduate School of Science, Chiba University, 4. The National Center for Scientific Research

Observations by MESSENGER found that Mercury's magnetosphere is analogous to the Earth's while there are several differences of the two. Big differences from the Earth's magnetosphere are strong IMF-Bx component and dipole offset which could affect to the global configuration of Mercury's magnetosphere. In this study, first we performed many cases of MHD simulation solving an interaction with solar wind plasma and offset dipole of Mercury. Solar wind densities are given betwenn nominal(35cm^{-3}), high(70cm^{-3}), and extreme(140cm^{-3}), with velocities for 400km/s to 800km/s, which are realistic values in the Mercury's orbit. When solar wind density is nominal and no IMF-Bx, the structure of Mercury’s magnetosphere is not far from ‘miniature’ of Earth’s magnetosphere, while north-south asymmetry is outstanding because of the offset dipole. In the realistic IMF case, global configurations of magnetosphere drastically change and become more complicated structures which include stronger north-south and dawn-dusk asymmetry. IMF-Bx also affects to the intensity ratio of north and south cusp pressure. IMF-By component “twist” the cusp region to longitudinal direction. The heavy ions’ trajectories basically obey the global structure of magnetic field, so that the ions’ precipitation concentrate on the ‘magnetic cusp’ defined from MHD simulations, but the precipitation region is wider and diffusive compared to the MHD cusp. In the presentation, we will discuss more details of heavy ion precipitation pattern. The identification of global structures and ions’ precipitation region especially the cusp is important not only on the understanding of magnetospheric physics itself, but also making a proposal to the observational plan of spacecraft such as Bepi-Colombo.

Model study on the contribution of various physical processes for generation and dissipation of Mercury's exosphere

*Yudai Suzuki[1], Kazuo Yoshioka[1]

1. University of Tokyo

Mercury has tenuous atmosphere (~1e-10 Pa), which escapes into space due to weak gravity and constant exposure to strong solar photo pressure and solar wind.Since exosphere directly connects with ground surface, the amount of generated and dissipated atmosphere drastically variesdepending on the environment.

Exosphere contains several elements such as Na, Mg, H, K, Ca, He. H and He are derived from solar wind, while other species are thought to be supplied owing to desorption from ground surface. For example, thermal desorption, charged particle sputtering (CPS), photon stimulated desorption (PSD) and meteorite impact vaporization (MIV) are suggested as desorption process. The amount of thermal desorption depends on the surface temperature, which is a function of the distance between the Sun and Mercury due to revolution. The amount of CPS changes owing to flares and the intensity of solar wind. Variation of PSD amount is due to fluctuation of solar radiation. MIV is dominated by the amount of dust around Mercury. Therefore, estimating how much each process contributes to generation of atmosphere encourages understanding the environment of inner solar system.

Velocity distribution of emitted particles is different from process to process. Thus, contribution of each process is often presumed by temperature of emitted particles which can be estimated by density profile obtained by the observation of MESSENGER spacecraft. However, the accuracy of estimating the abundance of high-temperature component gas is not enough, and besides it is hard to make an estimate of the dominant process in high latitudes in northern hemisphere and mid-latitudes owing to geometry of the spacecraft’ s orbit.

Thermal desorption dominates the distribution of sodium atoms on ground surface since particles emitted by thermal desorption has small energy and return to the surface only in a short time (~10min). CPS is thought to generate the majority of atmosphere in high latitudes of northern hemisphere and mid latitudes.

In this research, the behavior of neutral sodium particle from generation to escape focused on thermal desorption and CPS is simulated using Monte Carlo method. In addition, the contribution of those processes will be discussed by comparing with the MESSENGER/MASCS/UVVS observation.

The ESA-JAXA joint mission BepiColombo is now on the track to Mercury. Two spacecraft for BepiColombo, "MIO" (Mercury Magnetospheric Orbiter: MMO) and "Bepi" (Mercury Planetary Orbiter: MPO), were launched by Ariane-5 launch vehicle from Kourou in French Guiana on 20 October 2018. During the cruise to Mercury, in addition to two spacecraft MMO Sunshield and Interface Structure (MOSIF) and Mercury Transfer Module (MTM) are all integrated together. The critical phase just after launch and the near Earth commissioning phase were successfully finished in end of 2018, and the first electrical propulsion started from Decemeber 2018. The next activities are delta commissioning of high voltage instruments in mid 2019, and the first flyby around the Earth in April 2020. Here we report the updated status of BepiColombo mission and the overview of its science goals.

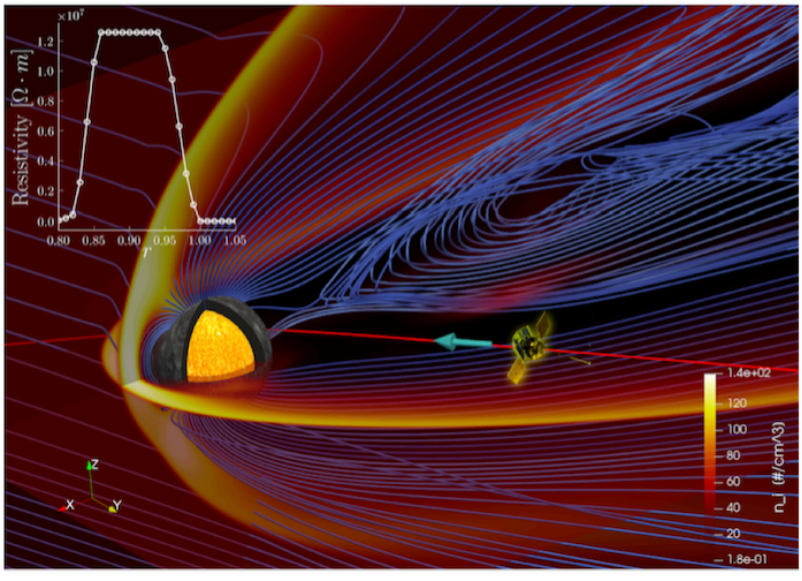
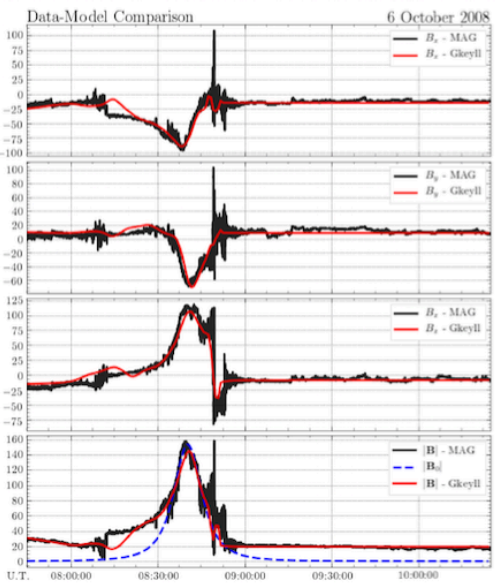
A Novel High-Moment Multifluid Model for Mercury: From the Planetary Conducting Core to the Dynamic Magnetosphere



*Chuanfei Dong[1], Liang Wang[1], Ammar Hakim[1], Amitava Bhattacharjee[1], James A Slavin[2], Gina A DiBraccio[3], Kai Germaschewski[4]



1. Princeton University, 2. University of Michigan, Ann Arbor, 3. NASA Goddard Space Flight Center, 4. University of New Hampshire

We have developed a novel three-dimensional ten-moment multifluid model and applied it to investigate the tightly coupled interior-magnetosphere system of Mercury. This new multifluid model self-consistently solves the continuity, momentum and pressure tensor equations of each species, together with the full Maxwell equations. As a result, non-ideal effects including the Hall effect, inertia, and tensorial pressures are self-consistently embedded without the need for explicitly solving a generalized Ohm's law.

Our simulation results from this new model are in good agreement with observations from MErcury Surface, Space ENvironment, GEochemistry, and Ranging (MESSENGER) spacecraft. The model is able to reproduce the magnetic field vectors, field-aligned currents and cross-tail current sheet asymmetry observed by MESSENGER. We also investigate collisionless magnetic reconnection in Mercury's magnetotail and at dayside magnetopause. In addition, we study the magnetospheric response of Mercury to a hypothetical extreme event with an enhanced solar wind dynamic pressure, which demonstrates the significance of electromagnetic induction effects resulting from the coupled interior. Moreover, two plasmoids (or flux ropes) are formed in Mercury's cross-tail current sheet during this hypothetical extreme event, indicating the extremely dynamic nature of Mercury's magnetotail. Thus, this novel high-moment, multifluid, interior-magnetosphere-coupled model is crucial for understanding Mercury's dynamic magnetosphere and has the potential to enhance the science returns of both the MESSENGER and BepiColombo missions.

DSMC simulation of slow hydrodynamic escape from terrestrial planets

Kaori Terada[1], *Naoki Terada[1], Hitoshi Fujiwara[2]

1. Graduate School of Science, Tohoku University, 2. Faculty of Science and Technology, Seikei University

Slow hydrodynamic escapes of atmospheric components from terrestrial planets subject to intense EUV radiation are investigated by DSMC simulations to understand the long-term evolution of planetary atmospheric composition.

Sun-like stars in earlier stages of their evolution emit intense EUV radiation. For example, the young sun of 4.5 billion years ago may have emitted 100 times stronger EUV radiation than today. After the formation of planets in a protoplanetary disk, planets get their atmospheres from the remnants of the disk gas and the outgassing due to impacts. The atmospheres were subject to the intense EUV radiation from a young central star, which caused significant heating and massive escape of planetary atmospheres.

The energy-limited escape rate is an upper limit of an atmospheric escape rate. The energy-limited escape is a category of the hydrodynamic escape. After an EUV radiation from a central star became weak, a planetary atmosphere was in hydrostatic equilibrium, and an escape rate became equal to the Jeans escape rate. While hydrodynamic escape and Jeans escape are understood well, there is an incomplete understanding of transition from hydrodynamic to Jeans escapes.

The thermal escape processes such as hydrodynamic escape and Jean escape depend on atmospheric composition. A previous study showed that the exobase temperature of Earth exceeded 10000 K and the atmosphere was well within the hydrodynamic regime when exposed to 20 times stronger EUV levels than present-day Earth. The exobase temperature of a CO2 dominated atmosphere like Mars was not heated as much as Earth’ s exobase because of efficient CO2 IR cooling. Nonetheless a previous simulation study using a fluid model showed that the exobase temperature reached about 2500 K and the Martian atmosphere was not in the hydrostatic equilibrium when exposed to 20 times stronger EUV levels.

In this study, escape rates from Earth-like and Mars-like planets for different EUV radiation intensities are estimated by DSMC simulations. Our full-particle upper thermosphere simulation model can solve the escape rates self-consistently. We show the escape rates of each species including the transition from hydrodynamic through slow hydrodynamic to Jeans escapes to understand the long-term evolution of planetary atmospheric composition.

The influence of Martian crustal magnetic fields on atmospheric escape

*Dave A Brain[1,2], Robin Ramstad[1], Yaxue Dong[1], Tristan Weber[1], Shogo Inui[2], Kanako Seki[2], Andrew Poppe[3], Riku Jarvinen[4], Jim McFadden[3], Jasper Halekas[5], Jared Espley[6], David Mitchell[3], Laila Andersson[1], Bruce Jakosky[1]

At present the influence of Martian crustal magnetic fields on atmospheric escape rates is debated. Since Mars lacks a significant global dynamo magnetic field, the presence of strong crustal fields over a significant fraction of the surface could shield portions of the atmosphere from the incident solar wind. The crustal fields could also allow or even enhance atmospheric escape through numerous cusp regions that are magnetically connected to the solar wind. This issue is of interest because the answer has implications for how atmospheric escape has operated on Mars over the history of the planet, including earlier times when Mars was more widely magnetized or even possessed a dynamo field. It is also relevant for assessing whether a global magnetic field is important for atmospheric retention. To this point, both modeling and observational studies appear to disagree on whether crustal fields significantly influence the escape of ions.

We will present the results of a new analysis of ion measurements from the Mars Atmosphere and Volatile EvolutioN (MAVEN) spacecraft mission made over four years. We examine how escape rates vary as Mars rotates and as a function of the solar zenith angle of strong crustal fields, including the dependence on ion energy and species. We also explore whether ion escape rates are larger, in a global sense, above crustal fields compared to non-magnetized regions. Finally, we introduce recent results relevant for evaluating ion escape from individual cusps, including from kinetic models of Martian cusp regions.

Effects of the IMF direction on atmospheric escape under a weak intrinsic magnetic field at Mars

*Shotaro Sakai[1], Kanako Seki[1], Naoki Terada[2], Hiroyuki Shinagawa[3], Ryoya Sakata[1], Takashi Tanaka[3,4], Yusuke Ebihara[5]

International Center for Space Weather Science and Education, Kyushu University, 5. Research Institute for Sustainable Humanosphere, Kyoto University

The planetary intrinsic magnetic field is significantly important in considering the atmospheric escape from planets. The strength of intrinsic field particularly affects the interaction between the solar wind and terrestrial-type planets (e.g., Seki et al., 2001), and it would change the escape mechanism. In contrast, Mars would have kept the warm and wet climate around 4 Ga. However, atmosphere and water are lost by certain processes, resulting in that present Mars only leave thin atmosphere. One candidate of the escape mechanism is the ion outflow from the upper atmosphere associated with the magnetic field. It is expected that ancient Mars had a global intrinsic magnetic field because there exists the crustal magnetic field in present Mars, and thus investigating the effect of intrinsic magnetic field on the ion escape leads to understanding the climate change of Mars from past through present.

Sakai et al. (2018) investigated the effect of an intrinsic magnetic field of 100 nT at the Martian equatorial surface on the escape mechanism. It was shown that the existence of the weak field results in an enhancement of the ion escape rate. A parker-spiral interplanetary magnetic field (IMF) was used in order to obtain the escape rate in this earlier study.

In this study, influences of the IMF direction on the ion escape mechanism under the intrinsic magnetic field of 100 nT at the equatorial surface are investigated based on global multispecies single-fluid magnetohydrodynamics simulations (Terada et al., 2009; Sakai et al., 2018). Ion escape processes from Mars under two IMF conditions, namely, a northward and southward cases, are compared to those of the parker-spiral case. For the parker-spiral case, heavy ions escape through the channel associated with the open field lines and another channel associated with a magnetic reconnection between the planetary and solar wind magnetic fields at the flank magnetopause (Sakai et al., 2018). For the north-IMF case, the heavy ions mainly escape through the open or draped field lines formed by double lobe reconnections. The escape rate of heavy ions is about one order of magnitude smaller than for the parker-spiral IMF case and it is even smaller than for the no-dipole case. On the other hand, the heavy ions escape by the mass loading of draped field lines in the ionosphere for the south-IMF case. The escape rate of heavy ions is about one order of magnitude greater than for the parker-spiral case. For the north-IMF case, the interaction of the weak intrinsic magnetic field and IMF forms the firm magnetosphere, resulting in suppressing the ion escape. In contrast, the erosion of IMF into the deep ionosphere yields the increment of the ion escape rate for the south-IMF case.

Solar disturbances release energetic charged particles that are expected to directly precipitate into the atmospheres of weakly magnetized planets like Mars. However, draped magnetic fields can influence the motion of energetic electrons. Using a test particle model of 1 keV - 100 keV electrons moving in magnetic fields from a multifluid magnetohydrodynamic simulation, we find that energetic electrons with steep pitch angles are affected by gradient drifts over the dayside of Mars. For an interplanetary magnetic field directed in the away sector, electrons will drift southwards, perpendicular to the direction of the draped magnetic field. Gradient drifts at Mars can facilitate increased precipitation by directing electrons towards the magnetized southern hemisphere and into magnetic field cusps. These findings suggest energetic electrons precipitate non-uniformly and are attenuated at low altitudes above the dayside northern hemisphere of Mars.

[P-CG25] Planetary Magnetosphere, Ionosphere, and Atmosphere

convener:Kanako Seki(Graduate School of Science, University of Tokyo), Takeshi Imamura(Graduate School of Frontier Sciences, The University of Tokyo), Hiroyuki Maezawa(Department of Physical Science Osaka Prefecture University), Naoki Terada(Graduate School of Science, Tohoku University), Chairperson:Takeshi Imamura(Graduate School of Frontier Sciences, University of Tokyo), Naoki Terada(School of Science, Tohoku University)

Exploration of Moon, Venus, Mars, Mercury, Jupiter, Saturn, and beyond together with rapid developments of numerical simulations provides us new view of planetary environment. This session collects general contributions of new findings about planetary magnetosphere, ionosphere, and atmosphere. New methodology and technology development studies for future explorations are also welcome. In order to put the common knowledge at different planets into perspective, this session aims to facilitate discussions on comparative planetary environments.

Mars had a thick atmosphere before 4 Ga, but it lost most of them. Ion escape to space could play an important role in the atmosphere loss. The astronomical observations suggest that the solar XUV (X-ray and extreme ultra-violet) flux and the solar mass loss rate were more intense (Ribas et al., 2005; Wood et al., 2002). Previous studies pointed out that the ion loss was several orders of magnitude stronger under such intensified solar conditions (Terada et al., 2009a). On the other hand, the existence of the crustal magnetic field indicates that Mars had an intrinsic magnetic field before 4.1 Ga. The conventional idea is that the intrinsic magnetic field prevents the direct interaction between the solar wind and the atmosphere and thus restrains the ion loss (Lundin et al., 2007). On the contrary, some studies suggested that the existence of an intrinsic magnetic field promotes the ion loss (Sakai et al., 2018). Thus it is important to clarify the effect of the intrinsic magnetic field on the ion loss to understand the atmospheric evolution at Mars.

In this study, we investigated the ion loss processes from Mars under extreme solar conditions and the existence of an intrinsic magnetic field using a 3D multi-species MHD model (Terada et al., 2009b). The solar wind proton density, the solar wind velocity, and the solar XUV flux were assumed to be 1000 /cm^3, 2000 km/s, and 100 times higher than the present-day XUV flux, respectively. The interplanetary magnetic field was assumed to be in Parker spiral and its strength was 60 nT. These parameters are same as those used in Terada et al. (2009a). We conducted four cases of simulations with different intrinsic magnetic field conditions, i.e., dipole fields with the strength of 0 nT, 100 nT, 1000 nT, and 5000 nT on the equatorial surface.

In 0 nT case, there were two major ion loss processes: escape of O^+, O_2^+ and CO_2^+ from the polar region and pickup O^+ carried by the deflected solar wind. In 1000 nT case, O_2^+ and CO_2^+ mainly came from the dayside cusp region through open magnetic field lines. In 5000 nT case, O^+, O_2^+ and CO_2^+ fluxes had almost the same structure and originated from the dayside cusp region. In 0 nT, 100 nT, and 1000 nT cases, the loss rates of O_2^+ and CO_2^+ were higher under the existence of the stronger dipole field, while the O^+ loss rate was nearly the same in these three cases. In 5000 nT case, the loss rates of O_2^+ and CO_2^+ were about three orders of magnitude lower than those of the other weaker dipole cases, while the O^+ loss rate was five times lower. These results suggest that the existence of a weak intrinsic magnetic field facilitates the loss of heavier ions such as O_2^+ and CO_2^+, and there is a threshold strength of the intrinsic magnetic field for this facilitation effect.

Small-scale atmospheric waves, such as internal gravity waves, are recognized as an important part of the terrestrial climate system. They ubiquitously exist on the Earth's upper atmosphere and affect the dynamics, composition, and thermal structure of the terrestrial middle atmosphere and thermosphere. Global characteristics of gravity waves on Earth have been extensively investigated over decades. On Mars, large fluctuations in density and temperature with short vertical wavelengths were first detected in Viking, Opportunity, Spirit, and Mars Pathfinder entry profiles. Wave amplitudes in the Martian atmosphere are larger than those in the terrestrial atmosphere and the important role of gravity waves of tropospheric origin in the middle atmosphere has been appreciated in early modeling studies. Gravity waves strongly affect the large-scale winds, thermal balance, density in the mesosphere and lower thermosphere. Since October 2014, NASA's Mars Atmosphere and Volatile EvolutioN (MAVEN) mission have been performed comprehensive studies of the Martian atmosphere. In-situ measurements of the upper atmosphere, from 300 km down to 130 km, revealed that wavelike perturbations ubiquitously exist in ions and neutrals in the upper thermosphere. Wavelike perturbations have also been detected by remote sensing with the Imaging Ultraviolet Spectrograph (IUVS) onboard MAVEN at altitudes between 20 and 150 km. These IUVS measurements provide opportunities for investigating possible links between waves in the Martian troposphere and thermosphere.
In order to clarify a global characteristic of waves and its upward propagating processes, we use IUVS stellar occultation measurements to characterize a global distribution of waves in the middle atmosphere between 24 March 2015 and 12 April 2018 for two Martian Years. This study first revealed global characteristics of wave perturbations in the night side temperature profiles derived from MAVEN/IUVS stellar occultations at 20 - 160 km altitudes on Mars. The peak amplitudes of waves on Mars exceed 20 % which is larger than those in Earth's mesosphere/thermosphere (~5-13 %). Perturbations were found to be notably large in summer hemisphere at L_s = 0-180. These waves can be interpreted as resulting from superposed harmonics of internal gravity waves and thermal tides. The superposition of thermal-tides and small-scale perturbations generate extensive instability layer around 70 - 100 km, which potentially causes wave-breaking and turbulences. Vertical wavenumber spectral density in the Martian middle atmosphere shows a power-law dependence with the logarithmic spectral slope of -3. This is similar to the features seen in the Earth's atmosphere. The spectral density in southern hemisphere at L_s = 225-315 tends to follow the semi-empirical spectrum of saturated gravity waves on the high-wavenumber side. The spectral power at high-wavenumbers is lower at 80 - 160 km than that at 20 - 80 km. This suggests that the strong radiative damping by CO_2 15-micron could effectively dissipates shorter waves. Instead, the spectral power at low-wavenumbers suggests the amplitude growth with height of unsaturated waves toward upper thermosphere.

Seasonal variation of the dayside N_2/CO_2 at 140 km altitude derived from MAVEN/IUVS

*Nao Yoshida[1], Hiromu Nakagawa[1], Naoki Terada[1], Nicholas Schnider[2], Scott Evans[3], Sonal Jain[2], Hitoshi Fujiwara[4], Takeshi Imamura[5], Justin Deighan[2], Ian Stewart[2], Michael Stivens[6], Roger Yelle[7]

Naval Research Laboratory, Washington, USA, 7. Department of Planetary Sciences, University of Arizona

It is believed that liquid water was abundant on early Mars, despite Mars being too cold today to sustain significant amounts of liquid water. The most likely explanation is that early Mars had a more-effective greenhouse atmosphere and most part of atmosphere and water have lost to space. Mars Atmosphere and Volatile EvolutioN (MAVEN) mission was designed to explore the loss of gas to space at the present. MAVEN spacecraft revealed highly variable nature of upper atmosphere in density, temperature, and atmospheric compounds (e.g. Mahaffy et al., 2015; Elrod et al., 2017; Stone et al., 2018; Slipski et al., 2018). However, the controlling factor of the variations has yet to be fully characterized due to the limited spatial- and temporal- observing geometry by in-situ measurements. In addition to the effects by the external force, such as solar wind and solar EUV on the upper atmosphere, the effect of lower atmospheric phenomena is also required to account for the substantial variations of upper atmosphere. For instance, the homopause (~120 km altitude) influences the upper thermospheric composition, thereby the species escaping to space [Imamura et al., 2016]. The fractionation between the homopause and exobase determines the relative abundance of species to escape to space [Jakosky et al., 2017]. For this purpose, further investigation around atmospheric boundary from the middle atmosphere to lower thermosphere is crucial for understanding regional coupling between lower and upper atmosphere.
We have investigated the seasonal variation of the N_2/CO_2 ratio at 140 km altitude derived from ultraviolet spectroscopy remote-sensing measurements by Imaging Ultraviolet Spectrograph (IUVS) aboard MAVEN. We used the dataset of level 2 version 13 revision 1 data provided by the Planetary Data System, which includes retrieved CO_2 and N_2 number density profiles derived from dayglow emissions. We analyzed N_2 and CO_2 number densities observed from October 2014 to May 2018. Observations cover in the dayside from 7 to 19 hr. The observations covered almost all solar longitudes within the two Martian Years. The retrieved CO_2 density has small uncertainty but the retrieved N_2 density has relatively larger uncertainty in particular above ~170 km due to the dimmer emission intensity. For precise analysis of the N_2/CO_2 ratio, we confine our analysis to the data at 140 km altitude where N_2/CO_2 has uncertainty less than 50%. We found that the N_2/CO_2 ratio at 140 km altitude significantly varies in the range of 0.02 to 0.20, which shows an annual sinusoidal trend. The higher ratio appears during aphelion and the lower ratio appears during perihelion. CO_2 and N_2 number densities also have similar annual variations. It is noted that the CO_2 density varies by a factor of 100, while N_2 density by a factor of 10. This large CO_2 variation affects the N_2/CO_2 ratio at 140 km. The potential sources of the seasonal variation we found are variations (1) of the surface mixing ratio, (2) of the homopause altitude, and (3) of the thermospheric temperature. In this paper, the effect of surface mixing ratio is discussed using Mars Climate Database version 5.3 [Forget et al., 1999; Lewis et al., 1999]. We also address the effects of other sources by considering the seasonal variation of homopause altitude [Slipski et al., 2018] and background temperature [Bougher et al., 2017; Stone et al., 2018].

Automated segmentation of Martian dust storms in MGS/MOC images using a deep learning technique

*Kazunori Ogohara[1], Ryusei Gichu[2]

1. School of Engineering, University of Shiga Prefecture, 2. Graduate School of Engineering, University of Shiga Prefecture

The shape, texture, and size of dust storms and the climatology of these characteristics are important clues to understanding Martian dust storms. The relations between such characteristics and the phases of the variety of atmospheric waves as well as the frequency of textured/curvilinear dust storms and the spatial and seasonal variations of the cumulative area are also worth investigating (Wang 2007; Wang et al. 2011; Guzewich et al. 2015, 2017). However, it is time-consuming to detect all dust storms visually because of the vast number of images taken by just two instruments, the MGS/MOC and MRO/MARCI. It is also difficult to objectively define which features characterize dust storms. Even approximate categorization of dust events into textured dust storms, untextured yet discrete dust storms, and haze depends on the subjective experience of the human observer. For these reasons, visual detection and categorization of the three types of dust storm textures introduced by Kulowski et al. (2017) would not be exactly reproduced by another human viewing and characterizing the images. Furthermore, we perceive a need to update the criteria for detecting dust events, especially obscured ones such as untextured yet discrete dust storms and haze, via visual detection. Therefore, it would be useful to be able to automatically detect dust events, measure their shape, pattern, and size, and improve the objectivity and reproducibility of dust storm detection.
We have developed a novel algorithm for automated segmentation of Martian dust storms using a encoder-decoder type of Convolutional Neural Network. We can separate dust storm areas from the surface and cloud areas in subsets of the global swath images taken by MGS/MOC without any information from other instruments (e.g. MGS/TES). Assuming that segmentation based on authors' experience is the ground truth, 84% of the true dust storm areas in the Arabia Terra is recognized as dust strom. On the other hand, just 69% of the true dust storm areas in the Hellas Basin is correctly recognized as dust storm.

Investigation of variation mechanisms of the Jovian radiation belt using ALMA

*Hajime Kita[1], Hideo Sagawa[2], Takahiro Iino[3], Chihiro Tao[4], Takeshi Kuroda[4], Fuminori Tsuchiya[5], Hiroaki Misawa[5], Yasumasa Kasaba[5], Masaki Fujimoto[1]

1. Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency , 2. Faculty of Science, Kyoto Sangyo University, 3. Nature and Science Museum, Tokyo University of Agriculture and Technology, 4. National Institute of Information and Communications Technology, 5. Tohoku University

Jupiter is now considered as an archetype for gas giants widely exist in extrasolar systems. At the outermost layer of this giant planet, there is a 300 km-depth of the nearly isothermal atmospheric layer (stratosphere) above the massive troposphere. Jupiter is also known to be a fast rotator (with a period of 9.9 h) with an enormous magnetic field. High energy particles trapped in the magnetic field form a radiation belt around the planet, much stronger than the terrestrial Van Allen's belt. In the case of the Earth, the primary control factor of the radiation belt is the solar wind, while the solar wind is difficult to impact the Jovian radiation belt because of the intense magnetic field.

It is theoretically expected that the driving mechanism of Jovian radiation belt is due to the interaction between the radiation belt and the upper atmospheric dynamics: neutral wind perturbations and diurnal wind system control the radial diffusion and spatial distribution of the energetic particles, respectively. Therefore, precise measurements of Jovian wind field are essential for not only the dynamics of the stratosphere but also the magnetosphere.

ALMA's unprecedented high spatial-spectral resolution enables us to extract the limb emission of the trace gasses in the Jovian upper stratosphere with a few tens m/s sensitivity. It is well known that HCN and CS have been injected into Jupiter by the Shoemaker-Levy 9 impact and they distribute only in the upper atmosphere (p ~0.4-1mbar). Therefore, the Doppler shift of those molecular emission lines can be used to investigate the dynamics in the upper atmosphere particularly at the limb of the Jovian disk where the line-of-sight direction is equal to the horizontal direction of the atmosphere. Here we present the sensitivity of ALMA observation to measuring Jovian stratospheric winds, and discuss its capability of constraining the magnetosphere-atmosphere coupling. A test analysis is carried out using JVO ALMA archive data.

Jupiter's radio Riddle arcs observed by LWA and Juno

*Kazumasa Imai[1], Charles A. Higgins[2], Masafumi Imai[3], Tracy Clarke[4]

1. Department of Social Design Engineering, National Institute of Technology, Kochi College, 2. Middle Tennessee State University, 3. University of Iowa, 4. Naval Research Laboratory

The Riddle arcs were found in the dynamic spectrum of Jupiter's decametric radio emissions observed by the Voyager spacecraft [Riddle, 1983]. On a frequency time plot these Riddle arcs have the same slope at the same frequency and System III longitude. (The typical System III longitude is about 260 degrees at 20 MHz.) An isolated Riddle arc can be easily recognized inside of the Io-A arc structures. This emission of Riddle arcs was concluded to be from the instantaneous Io flux tube.

The modulation lane method [Imai et al., 1992,1997,2002] is based on the measurements of the slope of modulation lanes on the dynamic spectrum of Jupiter's decametric radio emissions. We usually measure the slope with a 1 MHz bandwidth and determine the most probable value of the lead angle between activated flux tubes to fit the value of the slope. The lead angle is the longitudinal angle between the instantaneous Io flux tube and the previously energized flux tube (real emitting region). The longitudinal location of the magnetic field line of the radio emitting sources can be calculated by this lead angle.

The Long Wavelength Array (LWA) is a low-frequency radio telescope designed to produce high-sensitivity, high-resolution spectra in the frequency range of 10-88 MHz. The sensitivity of the LWA, combined with the low radio frequency interference environment, allows us to observe wide band modulation lanes of Jupiter's decametric radio emissions [Clarke et al., 2014]. We have analyzed the modulation lane data including the Riddle arcs observed by LWA. We found almost all of the Riddle arcs correspond to a zero degree lead angle. This means that the radio sources related to the Riddle arcs are located along the instantaneous Io flux tube. This result is consistent with Riddle's conclusion.

The Juno spacecraft [Bolton et al., 2017] was inserted into polar orbit around Jupiter on 04 July 2016. Juno's highly eccentric orbits have a period of about 53 days with apojove near 113 Jovian radii and perijove near 1.06 Jovian radii. With the advantage of this unique orbit, Juno's Waves instrument [Kurth et al., 2017] is observing for the first time the polar beaming patterns and geometry of Jupiter's decametric radio emission sources. The dynamic spectra recorded by the Waves instrument show the Riddle arcs very clearly. We are continuing to analyze the Waves data to find the Riddle arcs in each Juno orbit. The Riddle arcs can be used as a reference point to understand the latitudinal beaming patterns of Jupiter's decametric radio emissions and the location of radio sources. We present the preliminary results of this study.

[A-OS17] Kuroshio Large Meander

convener:Toru Miyama(Japan Agency for Marine-Earth Science and Technology, Application Laboratory), Norihisa Usui(Meteorological Research Institute), Takashi Setou(National Research Institute of Fisheries Science, Fisheries Research and Education Agency), Chairperson:Toru Miyama, Takashi Setou, Norihisa Usui

The Kuroshio has taken large meander path since the end of August 2017. Although it is unknown whether it is continuing at the time of the JpGU meeting, this notable event of the coastal area south of Japan after 12 years later from the last one has already attracted societal interests. In this session, behaviors, dynamics, influences, comparisons with past cases, etc. are discussed. Presentations from various perspectives of ocean physics, biology, chemistry, and meteorology are welcome.

1. Japan Meteorological Agency

Office of Marine Prediction (OMP) at Japan Meteorological Agency (JMA) has been routinely operating an ocean data assimilation and prediction system for the western North Pacific (MOVE/MRI.COM-WNP) since March 2008. This system aims to represent ocean characteristics such as the Kuroshio/Oyashio current and meso-scale eddies. Using MOVE/MRI.COM-WNP, OMP provides ocean state information of major currents around Japan (Kuroshio/Oyashio/Tsushima-Warm-Current) and water temperatures in the western North Pacific mainly through the JMA website.
In August 2017, the Kuroshio developed a large meander (LM) for the first time in 12 years. A small meander that developed southeast of Japan’ s Kyushu Island in late March 2017 and propagated eastward to waters off the country’ s Tokai region in August is considered to have induced the Kuroshio LM. In August, MOVE/MRI.COM-WNP successfully forecasted the generation of the Kuroshio LM and JMA published a press release about the probabilityof the Kuroshio LM.
This presentation shows the progress of the Kuroshio LM in and after 2017 as contrasted with the past cases.

Influences of the Kuroshio path variation south of Honshu on summer surface air temperature in Kanto district, Japan

*Shusaku Sugimoto[1]

1. Graduate School of Science, Tohoku University

In the Kuroshio and its extension (KE), the warm surface waters compared to the surrounding waters enhance upward heat release in winter, indicating that the ocean affects the atmosphere. On the other hand, in summer, atmospheric response to the Kuroshio/KE remains unclear because of a small difference between sea surface temperature (SST) and surface air temperature (SAT) over the Kuroshio/KE and of its-associated weak SST gradient. Here we investigated summertime (June-August) SST variations south of Japan, using high spatial resolution satellite-derived measurements of 2003–2018. The result showed that the variation is dominant in the region off Kanto-Tokai district, which was related to the Kuroshio path state; the SST increases off Kanto-Tokai district when the Kuroshio takes the meander path, which would reflect the following two points. In the meander period, (1) the Kuroshio shifted southward around Cape Shionomisaki, moves to the north around the Izu Islands, and then reaches very close to south coast of Kanto district, and (2) westward warm flow, which is a flow on the north edge of the anticlockwise eddy north of the Kuroshio, runs very close to the south coast of Tokai district. To reveal the extent to which the warm surface waters off Kanto-Tokai district influence the atmospheric fields, we conducted regional atmospheric model experiments using the high-resolution Japan Meteorological Agency nonhydrostatic model (JMA-NHM) with 5 km horizontal grid spacing. The experiment showed that, over the warm surface waters, evaporation increased considerably, and the northward water vapor transport by low-level wind caused an increase of moisture in Kanto district. The warm-water-induced moisture increase enhances downward longwave radiation at the surface in Kanto district, leading to the SAT increase. Actually, the SST off Kanto-Tokai district is significantly correlated with the SAT in Kanto district, from the Automated Meteorological Data Acquisition System (AMeDAS) of the Japan Meteorological Agency. Our results indicate that, in summer, the Kuroshio path state (meander or straight path) affect the overlying atmosphere and climate on Japan.

Since 2001, FRA has set up a regular monitoring line, called O-line north and south along 138E off Omaezaki south of Japan and has been conducting the monitoring four or five times a year until now. O-line, the monitoring line was named after Omaezaki City, which is near the starting point of the line. The line has been mainly conducted by the National Research Institute of Fisheries Science and has been carried out for the measure of water temperature, salinity, nutrient, some phytoplankton and zooplankton. In this presentation, the bio-chemical difference on the line between the large meandering case and the non case of the Kuroshio current has been focused on.

The late arrival of 2017-18 Japanese eel recruitment and its links to ocean circulation

*Yu-Lin Eda Chang[1], Yasumasa Miyazawa[1], Michael Miller[2], Katsumi Tsukamoto[2]

1. Application Laboratory, Japan Agency for Marine-Earth Science and Technology, 2. Department of Aquatic Bioscience, The University of Tokyo

In the year 2018, the Japanese eel (*Anguilla japonica*) recruitment almost vanished in Japan in the early recruitment season, and the eel catch peaked up in late recruitment period when the recruitment was usually small. Coincidently, the Kuroshio meander occurring south of Japan was revisiting since the previous event ends in 2005. The role of ocean circulation in 2018 unusual Japanese eel larvae recruitment was investigated using a three-dimensional particle tracking model, in which swimming behaviors of virtue larvae (v-larvae) was included in addition to passively drift by ocean currents. Similar results appeared in the simulation, showing none v-larvae arrival to the south of Japan in early recruitment period and increased substantially in the late recruitment period. The late arrival could be explained by the change of ocean circulation. The southward shifting and weak North Equatorial Current near spawning area, less Subtropical Countercurrent eddies, and weak Kuroshio during the early migration and recruitment period prevented v-larvae transport. In the late recruitment period, the Kuroshio was strengthened and strong near the East China Sea and south of Japan that transported v-larvae downstream efficiently. The maximum eel catch reduction in Tokai region where Kuroshio bifurcated offshore could be related to large meander. The Kuroshio large meander could potentially influence the local eel recruitment, but its actual role remained to be explored.

A probabilistic forecast of the Kuroshio current path variability using an 80-member ensemble simulation.

*Kunihiro Aoki[1], Yasumasa Miyazawa[1], Tsutomu Hihara[1]

1. JAMSTEC

This study aims to describe the probabilistic behavior of the Kuroshio current path variability using an 80-member ensemble simulation in a high-resolution numerical regional ocean model, JCOPE. This simulation provides the outputs for 4 months starting from the initial conditions optimized by the data assimilation (LETKF) for one months. All the members are found to predict the non-large meander path at first 2 months, but some members predict the large meander path after that. We propose a method of quantifying the occurrence/non-occurrence of the branch, the probabilities of each path, and a set of the mean and spread for each path by a machine learning method.

Long-term forecast of the Kuroshio large meander in 2017

*Norihisa Usui[1], Nariaki Hirose[1], Kei Sakamoto[1], Yosuke Fujii[1], Nadao Kohno[1]

1. Meteorological Research Institute

The Kuroshio large meander (KLM) occurred in the end of August 2017 for the first time in 12 years, and has maintained for more than a year. Changes in the oceanic condition south of Japan associated with the KLM have a large impact on various fields such as fisheries, marine transportation, and local weather. The KLM has, therefore, been received much attention. In this presentation, we discuss prospects of the KLM in 2017 on the basis of a long-term forecast experiment using an eddy-resolving ocean model. First, the actual Kuroshio state in the end of August 2018 is reproduced by applying data assimilation. We then conduct ensemble simulations with 40 members, in which atmospheric forcing data are replaced by those on the same day from 1975 to 2014 and the model is integrated for more than three years starting from 28 August 2018. In most cases, the KLM maintains for more than one and a half years (i.e. February 2020). After that, differences in the Kuroshio state among the ensemble members become large. As pointed out be former studies, these behaviors of the Kuroshio path are largely explained by the Sverdrup transport estimated from the wind stress field used in the experiment. In the presentation, we will evaluate the ensemble simulations results using the actual Kuroshio state in May 2019, and will show more detailed results.

Discussion

Real-Time Subsurface Moorings as a Promising Component of Global Ocean Monitoring System

*Jianing Wang[1], Fan Wang[1]

1. Institute of Oceanology, Chinese Academy of Sciences

Subsurface moorings have advantage in providing long term and full-depth ocean monitoring parameters. Traditional moorings normally release data once a year, which put constraints on the mooring data usage in the weather and short-term climate forecasts. Recently, the Institute of Oceanology, Chinese Academy of Sciences (IOCAS) has overcome difficulties in the long-term transmission of real-time data from subsurface moorings. Data from sensors up to 3000 m depth can be transmitted to the surface floating body through wireless acoustic communications and then to the shore through satellite. In 2016, the IOCAS had realized real-time transmission of three dimensional velocities over the upper 1000 m from one mooring for more than 280 days. In 2017, real-time transmission module was equipped on the majority of the moorings, and the depth range of data has been extended from 1000 to 3000 m; this real-time observing network has successfully been conducted for 300 days until now. The aim of this abstract is to make recommendation for Real-Time Subsurface Moorings (RTSMs) as a promising component of global ocean observing systems.

The present prediction skill of ENSO at short lead time still leaves much to be desired. Beyond surface ocean data delivered by moored buoys and satellites in real time, the RTSMs can provide the time-depth variations of temperature and velocity at the subsurface and intermediate layers (e.g., the Equatorial Undercurrent variability), which also play a crucial role in the evolution of ENSO. Assimilation of these data will further improve the ENSO prediction skill. Deep-sea data acquiring in real time are also useful to many marine applications, including shipping, fishing, ocean emergent search and rescue, and pollution monitoring. RTSMs will provide data without the need of the use of a ship. This reduces the cost of ship and the risk of data loss due to mooring damage, making the fixed observation system in a more cost-effective manner.

Seasonal Variation of the Mixed Layer Depth at 60°S and its governing dynamics

*Matheus Ferreira Azevedo[1], Yujiro Kitade[1], Shigeru Aoki[2]

1. Tokyo University of Marine Science and Technology, 2. Institute of Low Temperature Science, Hokkaido University

In this research, data from a yearlong M-TRITON type mooring system deployed in 2012 is used to study the seasonal variability of the dynamics governing the Southern Ocean and its influence on the mixed layer depth by measuring temperature, salinity and current velocity data. GHRSST Satellite data and reanalysis ERA-interim wind data were used to complement the mooring, identifying spatial variation in wind and sea surface temperature (SST). This is relevant in the context of coupling readily available surface information (via satellite) and punctual information from ship CTD casts with corresponding subsurface phenomena.

A major factor of mixing was identified as the work on upper-ocean inertial motions (period T =13.8186 hours) associated with variable wind forcing, corroborating with the work of Alford (2001, 2003), Watanabe & Hibiya (2002) and Furuichi et al. (2008). Strong wind peaks, were observed to break stability, parametrized as the Buoyancy frequency N^2, which varied from an order of 10^{-4} s^{-2} to 0 or negative values in the original mixed layer depth (MLD) at the period, while enhancing stability at deeper layers in the same proportion it decreases at the layer above. As a consequence, the MLD increases by around 25m during these events. Wind forcing was found to influence stability and MLD not only through the work of storm induced near-inertial motion but also through meso-scale meridional transport, modulating the frontal structure of the Antarctic Convergence. During winter, the system response to wind weakened as surface cooling induced large scale convection. In particular a cold front reached the mooring at May 28th, starting the convection process. MLD responded by deepening to as far as 150m, and upward salinity flux could be observed.

Strong shear could be observed, usually bellow the mixed layer and generally agreeing with other reports of momentum penetration beyond the scalar mixed layer (e.g. Johnston & Rudnick, 2009). Shear comparison could not be made throughout the year, however, as the mixed layer goes bellow the ADCP detection range during winter. The strong stratification at the base of the mixed layer was seen to generate a complex internal wave field, where shear instability dissipates through high frequency internal waves of period between 2 and 4 hours. These waves seem to become trapped at the stratified layer and evolve to inertial period oscillations, increasing in amplitude until they break, generating high frequency waves once again. This process was observed to repeat at every mixed layer deepening event, either in summer or winter. The relation between internal waves, mixing and MLD at the Southern Ocean is a step to understand nutrient availability and the formation of important water masses of global influence.

21st-Century Flood Hazards along the U.S. Atlantic Coast: Impacts of Sea Level Rise and Tropical Cyclone Climatology Change

*Reza Marsooli[1], Ning Lin[2], Kerry Emanuel[3]

1. Stevens Institute of Technology, 2. Princeton University, 3. Massachusetts Institute of Technology

Flooding due to tropical cyclones (TC) is among the most destructive coastal hazards along the U.S. Atlantic Coast. TC-induced coastal flooding will worsen under sea level rise (SLR) and climate change. To effectively adapt to these evolving hazards, it is essential to understand potential changes in future flood return levels. The present study investigates the impact of 21st-century sea level and TC climatology on flood return levels along the U.S. East and Gulf Coasts. We use extreme value theory and combine probabilistic estimates of sea level rise and TC storm tides to determine flood return levels for the historical period of 1980-2005 and the future period of 2070-2100 (under the emission scenario RCP8.5). A basin-scale hydrodynamic model is implemented to simulate storm tides for large numbers of synthetic TCs that are generated by a statistical-deterministic TC model under climate conditions observed during the historical period and projected by six climate models for the future period. We present and discuss flood return level projections and the contribution of sea level rise and TC climatology change to the projected changes in the return levels.

The Effect of Ocean Waves on an Explosive Cyclone Development: Investigation with a Coupled Model

*Yuki Kita[1], Takuji Waseda[1]

1. University of Tokyo

Violent ocean waves are generated by the explosive cyclone. Since ocean waves affect the development of tropical cyclones, the impacts of ocean waves on the development of explosive cyclones are expected. Ocean waves have several impacts on the atmospheric surface layer: surface friction, sea spray, and momentum flux. We implemented sensitivity experiments to clarify how much ocean waves affect the development of an explosive cyclone with an atmosphere-ocean-wave coupled model, especially focusing on surface friction affected by ocean waves. The test case is the explosive cyclone emerged in early January 2018 over the Northwestern Atlantic. The atmospheric model is Weather Research and Forecasting Model (WRF), the ocean model is Coastal and Regional Ocean COmmunity model (CROCO), and the ocean wave model is WAVEWATCH III (WW3). We compared the numerical simulation results between the WRF-CROCO model and the WRF-CROCO-WW3 model. In the WRF-CROCO-WW3 coupled model considering ocean wave impacts just on surface friction, it is found that the deepening of the explosive cyclone was intensified by about 2hPa in the central sea level pressure, and the center track slightly shifted. In the fully coupled model, the surface roughness reduced and the wind speed was intensified by and large. Compared with observation data above the ocean, the fully coupled model had more accurate wind speed and sea level pressure than the atmosphere-ocean coupled model. It is also revealed that the boundary surface layer scheme in the atmospheric model is critical for accurate reproduction of surface atmospheric process and ocean waves. To reproduce accurate wind speed and wave height, the YSU (Yonsei University) scheme had a better performance than the MYNN (Mellor-Yamada-Nakanishi-Niino) 3rd scheme. As the next step, it is necessary that a coupled model takes into account the turbulent momentum flux produced by ocean waves to reproduce complete accurate air-sea interactions.

[A-OS20] Global ocean observing systems, obtained results and system optimization: toward OceanObs19

convener:Shigeki Hosoda(Japan Marine-Earth Science and Technology), Shuhei Masuda(Japan Agency for Marine-Earth Science and Technology), Yosuke Fujii(Meteorological Research Institute, Japan Meteorological Agency), Fujiki Tetsuichi(Japan Agency for Marine-Earth Science and Technology), Chairperson:Shigeki Hosoda(Japan Agency for Marine-Earth Science and Technology)

Almost twenty years have been passed since the beginning of Argo programme to construct global ocean observing system. The Argo observing system have been covering the global ocean with more than 3000 Argo floats with collaboration of many countries. The Argo is well known as one of the best practices of ocean observing systems, as lots of scientific results and social/industrial benefits have been gained based on indispensable huge amount of oceanic data which has never obtained before. Recently, the Argo observing system is rapidly expanded to monitor deeper ocean (Deep Argo; >4000m depth) and bio-geochemical parameters (Biogeochemical Argo) in addition to upper layer temperature and salinity (Core Argo; <2000m depth).
On the other hand, sustainability of the Argo is not guaranteed and its observing array is still developing as international infrastructure. For example, Argo float distribution recently tends to be inhomogeneous since a part of float deployment and operation is still conducted by voluntary works. Therefore, improving the observing systems to be more effective and sustainable is a mandatory task in the oceanographic community. In this background, various efforts are forwarded to evaluate impacts of ocean observations by the support of GODAE OceanView which is endorsing the Argo programme. In coming OceanObs19, development, expansion and enhancement of the sustainability of the Argo observing systems will be discussed based on scientific results and application researches.
In this session, current status, recent issues, future works on large-scale ocean observing systems are discussed in related to Argo and other research infrastructures such as GO-SHIP, OceanSITES etc., focusing on the global ocean observing system in coming next decade.

Global Ocean Observing System: The Past, the Present and the Future

*Toshio Suga[1,2]

1. Graduate School of Science, Tohoku University, 2. JAMSTEC

A global ocean observing system with the first letters capitalized is the name of the international program led by the Intergovernmental Oceanography Committee (IOC) of the UNESCO: the Global Ocean Observing System (GOOS). GOOS is responsible for coordinating global ocean observations for three critical themes: climate, operational services, and marine ecosystem health. GOOS was launched in 1991 by the IOC in response to calls from the Second World Climate Congress held in 1990. The ocean research community has been intrinsically involved in the subsequent development of GOOS. The two international conferences, OceanObs '99 and OceanObs' 09, were milestones both for GOOS as the international program and for the global ocean observation system as the system consisting of various observing networks. Focusing on the outcomes and significance of these two conferences, the history of GOOS will be briefly described. At the moment, preparation of OceanObs'19 to be held this coming September is going on. The objective of the conference is to "bring people from all over the planet together to communicate the decadal progress of ocean observing networks and to chart innovative solutions to society’ s growing needs for ocean information in the coming decade." The relevant and background information of OceanObs'19 will be presented and the role of the research community will be discussed.

Observed long-term change and variability in the global upper-ocean stratification

*Ryohei Yamaguchi[1], Toshio Suga[1,2]

1. Graduate School of Science, Tohoku University, 2. Japan Agency for Marine-Earth Science and Technology

With the progress of global warming, enhanced upper-ocean thermal stratification from the 1970s has been reported by IPCC AR5. Many studies on future climate projection using CMIP climate models also point out that upper-ocean stratification will strengthen in this century. The strengthened stratification will reduce vertical nutrient supply from the subsurface by futher stabilizing the upper-ocean water column, and then the primary production of the whole ocean is concerned to decrease.

However, large uncertainties in the observational estimate of the long-term change in the upper-ocean stratification still remain. Strengthening trend of the upper-ocean thermal stratification due to the surface intensification of the warming signals has been detected from estimation using globally-averaged sea surface and subsurface temperature time series. On the other hand, some observational studies focusing on some specific regions or using relatively short time series demonstrate that the upper-ocean stratifications are weakening in recent decades, rather than strengthening associated with global warming.

We investigated globally the long-term change and variability in the upper-ocean stratification defined here as the difference between the surface and subsurface density. To resolve spatial patterns of the trends and superposed decadal variability, we used temperature and salinity observations with as spatial and temporal coverage as wide as possible from World Ocean Database 2013. As a result, strengthening trends of the upper-ocean stratification associated with global warming were detected over the global ocean, except for the Arctic Ocean. In the global average, the increase in density stratification corresponds to a 6.6–11.8% of the mean stratification from the 1960s. In addition to the well-documented cause, that is the surface intensified warming, the subsurface temperature changes and haline stratification changes also have significant impacts on the long-term changes in the upper-ocean stratification. The decadal/interannual variabilities in the upper-ocean stratification associated with each particular climate mode are also detected in some ocean regions: The density stratification is correlated with the Niño 3.4 index in the tropical Pacific, negatively lagged correlated with the North Atlantic Oscillation (NAO) index in the North Atlantic, and shows correspondences with SST variations associated with the Pacific Decadal Oscillation (PDO) in the North Pacific.

Estimation of changes in salinity and dissolved oxygen based on observational networks

*Shinya Kouketsu[1]

1. JAMSTEC Japan Agency for Marine-Earth Science and Technology

Changes in temperature and salinity can be captured by Argo float networks more clearly than before the 2000s. For example, the global changes in ocean heat content can be comparable to the ones in sea surface height and net radiative flux into the earth system. Furthermore, various studies have been focusing on the changes in water masses, especially around surface layers. However, quantitative evaluation of regional changes has not been sufficiently clarified. For example, the salinity changes in the deeper layers cannot be easily captured by a float observation due to measurement uncertainty, and the changes in dissolved materials (ex. dissolved oxygen) remained not to be observed sufficiently. In this study, with the combination of autonomous observations and high accurate ship-based observations, we try to examine the possibility to capture and evaluate more accurately long-term changes with observation network.

As the first step, I will present the results based on the monthly salinity (temperature) distributions on the isopycnal surfaces obtained from Argo float observations. Based on the dataset, the long-term mean circulation with the spatial distribution of diffusivity coefficients was estimated, and the budgets for salinity (and temperature) changes in the recent decade were calculated. Especially, in the deeper layer (below 400m), the diapycnal diffusion effects were relatively large to the salinity (and temperature) increases. The salinity (and temperature) increases on the isopycnal surfaces might be consistent with the temperature increased on iso-depths. As the large-scale patterns of the changes revealed by the datasets were similar to the ones detected by twice occupations of the highest accurate observations, the salinity (and temperature) changes in this study were not so much influenced by biases in autonomous measurements (especially of salinity), and the present observation systems might be able to detect such small changes potentially.

The dissolved oxygen budgets were also estimated in the North Pacific with a long-term climatological distribution of the oxygen. The residuals of the budgets seemed to be consistent with the oxygen utilization estimation in previous studies. However, in some regions, temporal changes in oxygen, which included in temporal changes due to the changes in circulations and biological activities, were in the same order of magnitude of the residuals. Thus, spatial and temporal dense (and relatively high accurate) observation network will be needed to clarify the roles of mean biological activities on oxygen circulations as well as the temporal variabilities.

In the presentation, I will show some results of comparisons with assimilation or numerical models, and the other results (regional changes) appearing in the dataset.

Remotely forced decadal physical and biogeochemical variability of North Pacific Subtropical Mode Water over the last 40 years

*Daisuke Sasano[1], Eitarou Oka[2], Yudai Yamada[2], Enyo Kazutaka[1], Toshiya Nakano[1], Masao Ishii[3]

1. Japan Meteorological Agency, 2. Atmosphere and Ocean Research Institute, The University of Tokyo, 3. Meteorological Research Institute

Half-century-long observations at the 137ºE hydrographic section across the western North Pacific have been analyzed to demonstrate remotely forced decadal physical and biogeochemical variability of Subtropical Mode Water (STMW) over the last 40 years. During unstable periods of the Kuroshio Extension (KE) that lagged the warm phase of the Pacific Decadal Oscillation by 3–4 years, high regional eddy activity reduced the formation rate and salinity of STMW in its main formation region south of the KE. At the 137ºE section south of Japan, decreasing advection of oxygen-rich STMW from the east resulted in decreases of dissolved oxygen and pH and increases of nutrients and dissolved inorganic carbon, accelerating acidification. Such changes reversed and acidification slowed down during stable-KE periods, especially in the current period since 2010 exhibiting a hiatus of acidification. These results indicate a new mechanism by which climate variability affects physical and biogeochemical structure in the ocean interior.

Asessing the impact of the global ocean observing system using ocean data assimilation systems

*Yosuke Fujii[1]

1. Meteorological Research Institute, Japan Meteorological Agency

Ocean and climate prediction systems are one of the important applications of the data observed by the global ocean observing system. In a prediction system, the oceanic field is estimated as accurately as possible through an ocean data assimilation system first, and then forecast integration of a numerical model is started using the estimated field as the oceanic initial condition. Data assimilation systems require ocean observation data for estimating the oceanic field, and the accuracy of the predictions, thus, severely depends on how much oceanic information effective for the predictions are included in the assimilated observation data, as well as the quality of the numerical model and the data assimilation scheme. Therefore, developing observing systems is an important factor of improving the prediction skills. Meanwhile, building up and maintenance of an observing system are conducted by public money or funds by stakeholders, and in order to sustain and to extend the observing system, we need to show that the system brings social benefits that is equivalent to or more than the investigation. Since observation data are exploited in the society mostly through the prediction systems, assessing impact of observation data on the accuracy of analysis and predictions in ocean data assimilation and prediction systems is an effective way to show the value of the observing system in the society.
GODAE OceanView (Its follow-on program “Oceanpredict” will take over the activity from May 2019) has established the Observing System Evaluation Task Team (OS-Eval TT) since the program was started, promotes data-impact assessments and information sharing for that, and builds up international collaboration for the relevant activities. These activities are also supported by CLIVAR Global Synthesis and Observation panel (GSOP). Operational centers, such as JMA and ECMWF, and research institutes, such as JAMSTEC and Scripps Institution of Oceanography, conducted observing system evaluation studies for various observations such as Argo, TAO-TRITON, and satellite altimetry under these supports. Those results are exploited in the evaluation of the TAO-TRIRON array for its reconstruction for example, but they have a limitation due to its system dependency and the importance of multi-system evaluation with common metrics is indicated. Achievements and resent challenges of observing system evaluation studies are summarized in a community white paper for OceanObs’19. This presentation will introduce some achievements of observing system evaluation studies and show a future perspective on this field.

Global ocean state estimation with new float observations

*Shuhei Masuda[1], Satoshi Osafune[1], Tadashi Hemmi[1]

1. Japan Agency for Marine-Earth Science and Technology

Argo floats are successfully contributing to global ocean state estimation. As the important roles of deep ocean to global changes has been recognized, sustainable deep ocean monitoring networks that use autonomous profiling floats have been widely proposed by the ocean observation community. An increasing number of deep-float deployment initiatives around the world. Deployed floats promise to provide unprecedented deep ocean information. Here we applied deep float data deployed by JAMSTEC to a deep ocean state estimation by using a four-dimensional variational approach. The results demonstrate that the available float data enables some corrections of the modeled ocean state locally for each float although the impact of the data on a basin-scale deep ocean state estimation was still limited in this study due to sparseness of used float data. This implies strategic deployments of deep float in the world’s ocean can immediately contribute to improvement of a current global deep ocean state estimation.

[A-CC26] Ice cores and paleoenvironmental modeling

convener:Ryu Uemura(University of the Ryukyus), Kenji Kawamura(National Institute of Polar Research, Research Organization of Information and Systems), Ayako Abe-Ouchi(Atmosphere and Ocean Research Institute, The University of Tokyo), Nozomu Takeuchi(Chiba University), Chairperson:Ryu Uemura(University of the Ryukyus), Ikumi Oyabu(National Institute of Polar Research)

Analyses of ice cores from polar and mountain regions have contributed to the reconstruction and understanding of the past environmental changes on timescales from years to several hundred thousand years. In this session, we welcome paleoenvironmental studies using ice cores and paleoclimatic modeling. Studies on reconstruction methods, recording processes and new paleoenvironmental proxies, technical aspects of paleo-modeling are also welcomed. Studies with marine sediment cores, terrestrial sediment cores and tree-rings on similar timescales are also important and welcomed, in order to discuss past environmental changes from multidisciplinary viewpoints.

Atmospheric aerosols modify the global radiation budget directly through scattering and absorption of solar radiation and indirectly through modification of the microphysical properties of clouds. However, there remain large uncertainties in estimates of aerosol effects on the climate system because of the insufficient prediction of aerosols in the Arctic by previous climate models.
Meteorological Research Institute (MRI) has developed a new version of MRI Earth System Model (MRI-ESM2) for participating in the Coupled Model Intercomparison Project Phase 6 (CMIP6). MRI-ESM2 is an updated version of MRI-ESM1 and consists of four major component models; an atmospheric general circulation model with land processes (a horizontal resolution of approximately 120 km), an ocean-sea-ice general circulation model, an aerosol model (approximately 180 km), and an atmospheric chemistry model (approximately 280 km). The number of vertical levels of MRI-ESM2 is 80 (model top at 0.01 hPa). As MRI-ESM2 shows the improvement of prediction of aerosol variations in the recent Arctic, we estimate effects of aerosols on climate change in the Arctic from the pre-industrial to present conditions.
We conducted the CMIP6 historical experiment (1850-2014) by MRI-ESM2 and compared the model results with the ice core data in Greenland. In the comparisons, we used three types of model calculation results; the MRI-ESM2 calculation with the CMIP6 emission inventory, the MRI-ESM2 calculation with the CMIP5 emission inventory, and the previous MRI-ESM1 calculation with the CMIP5 emission inventory. The comparison with the Greenland SouthEastern Dome (SE-Dome) ice core data shows that the MRI-ESM2 calculations successfully reproduce the temporal variation of deposition flux of sulfate, although the previous MRI-ESM1 calculation largely underestimates the sulfate. The historical experiments by MRI-ESM2 show that sulfate at SE-Dome was mostly originating from anthropogenic sources in winter, but natural sources also played an important role in summer. The comparison with the ice core data at the D4 site shows that the MRI-ESM2 calculation with the CMIP6 emission could not reproduce the enhancement of black carbon concentrations in the early 20th century, but the MRI-ESM2 calculation with the CMIP5 emission could. This result suggests that there still remain large uncertainties in the emission inventory of black carbon. The CMIP6 historical experiments by MRI-ESM2 suggest that the aerosols play an important role for temperature changes in the Arctic. The predictions of the surface air temperature changes by MRI-ESM2 are improved from the previous model both in global and the Arctic. These results indicate the importance of analyses of ice cores for improvement of predictions of climate models and the usefulness of climate models for interpretation of ice core data.

Particles in ice layers of SIGMA-A ice core, northwestern Greenland

*Kaoru Kawakami[1,2], Yoshinori Iizuka[2], Sumito Matoba[2], Teruo Aoki[3], Shin Sugiyama[2], Takuto Ando[4]

1. Graduate School of Environmental Science, Hokkaido University, 2. Institute of Low Temperature Science, Hokkaido University, 3. Graduate School of Natural Science and Technology, Okayama University, 4. Arctic Research Center, Hokkaido University

Arctic atmospheric warming accelerates surface melting on the Greenland ice sheet. In the accumulation areas of the Greenland ice sheet, ice layers are formed by snowmelt and refreezing processes during summer. In the snowmelt water, chemical substances originated from atmospheric soluble aerosols exist as dissolved anion and cation species. After refreezing process, the ions are preserved in the state of acid or salt in the refrozen ice layer. However, the behavior of inclusions in refreezing ice layers is still unclear. In this study, we observed salt inclusions in ice layers of a Greenlandic ice core to understand how and where inclusions were formed along the snowmelt and refreezing process.
During spring 2017, a 60m ice core (hereinafter referred to as SIGMA-A core) was drilled on the northwestern Greenland (78º 03′06″N, 67º 37′42″W, 1490 m a.s.l), which covers the past 100 years. The SIGMA-A core has 243 ice layers (longer than 1mm in thickness), whose mean thickness is 13.8mm.Both the number and the thickness of ice layers have increased in recent 30 years. In a -20℃ cold room of Institute of Low Temperature Science, Hokkaido University, ice layers formed in 2006 and 2014 were selected from the SIGMA-A ice core. The two ice layers were cut to three sections of 40*6.56*25 mm(the 2014 sample), 40*5.45*75 mm(the bottom part of 2006 sample), 40*6*80 mm(the top part of 2006 sample) in the -20℃ cold room. Then, the size and location of inclusions in the sections were observed by a measuring microscope (OLYMPUS, STM-UM) in the cold room. The chemical composition of inclusions were identified by Raman spectroscopy in a cold chamber at -30℃ with the same method described in Ohno et al.[1].
The location of inclusions tends to be the bottom part of the both ice layers. The mean particle size is 17.6μm, which is larger than that in other dry ice cores. For example, the mean size of particles in Greenland NEEM core is about 1-4μm[2], and that in Dome Fuji core is 1-3 μm[1]. Also, inclusions are identified as $Na_2SO_4 \cdot 10H_2O$ and $CaSO_4 \cdot 2H_2O$ by the Raman measurements. The snowmelt and refreezing processes may produce huge salt inclusions at the last stage of refreezing due to ion redistribution.

Information of ice sheet albedo in the past is necessary for improving climatic models and future prediction. Snow grain size is indispensable property for evaluating surface albedo of ice sheets. The large parts of firn/ice core samples, however, have already lost information of initial snow grain size after densification. It is important to develop indicators to evaluate history of snow grain modification from firn/ice core samples. There is a correlation between specific surface area (SSA) and near-infrared reflectance (NIR). Continuous SSA values of core samples can be obtained by near-infrared reflectance analysis. We collected the firn core from SE-Dome, the southeastern Greenland in 2015. The SE-Dome firn core records the seasonal variations over the last 60 years due to their higher accumulation rate (~1m/year). In the present study, we focused on relationship between density and NIR and reconstructed the relationship between climate change and snow grain modification over the last 60 years.
Density and NIR data from the SE-Dome ice core are negatively correlated in the long-term trend. These negative correlations show SSA values basically decrease with snow densification. On the other hand, there is positive correlation between density and NIR data in the short-time trend. Both density and NIR of summer samples particularly tend to be lower value than those of samples deposited during other seasons in same year. Timing and number of the low-SSA and low-density layers are related to those of the periods in which air temperature reaching over -5 ℃ continued. This relationship shows the formation of low-SSA and low-density layers enhanced even though air temperature was less than 0℃. The low-SSA and low-density layers are caused by density reduction due to snow sublimation on the surface of ice sheet.

An ice core retrieved at the SIGMA-D site, Northwest Greenland, in 2014 was analyzed down to the depth of 113 m. Between 6 and 113 m depths, we used a Continuous Flow Analysis (CFA) system developed at the National Institute of Polar Research. The CFA system enabled us to obtain high resolution data of black carbon (BC), stable isotopes of water, microparticles and six elements (Na, K, Mg, Ca, Fe, and Al). The top 6 m of the core was cut at a ca 5 cm interval, melted and analyzed. For BC analysis, we used a recently developed Wide-range SP2 (Single Particle Soot Photometer). We dated the core by annual layer counting using mainly Na and water stable isotopes, with occasional use of other impurities. We divided a year into 12 months and calculated monthly averaged BC concentrations and size distributions.
Here we report the variability of monthly resolved BC concentrations and size distributions over the past 350 years. BC number and mass concentrations started to increase in the 1870s, reached its maximum in the 1920s - 1930s, and decreased again since then. The increases are likely due to anthropogenic input. The increases are most significant in fall and winter months. We find anthropogenic changes in seasonality of BC concentration: annual concentration peak shifted from summer to winter. We also find anthropogenic changes in size distribution of BC: the mode diameter of mass concentration and average mass of BC particles became larger. This suggests that anthropogenic BC particles are larger than natural ones in the snow deposited in Greenland. Apart from anthropogenic BC, BC concentration occasionally showed large spikes in summer. They are likely originated from biomass burnings. We will compare the results from the SIGMA-D core with those from other ice cores drilled in Greenland and discuss spatial variations of BC.

Dust (mineral particles) contained in the ice core has been used as a proxy of past atmospheric circulation or arid climate condition. Most of dust studies have just analyzed dust flux and size distribution, but little study focused the meteorological type and composition of dust. Since the type and composition of dust varies depending on its origin and transport process, they are potential to reveal detailed source of dust and atmospheric circulation fluctuation. In this study, we analyzed mineral composition of dust layers of a shallow ice core drilled in the Pamir Alay Mountains of Central Asia of Kyrgyz Republic in August 2016, using an optical microscope and a scanning electron microscope.
The depth profiles of dust differed between small size ($1<d\leqq15$ μm) and large size ($d>15$ μm). The dust layers consisting mainly of small size dust contained abundant yellow colored minerals, while those with large size dust contained more abundant red colored minerals. Furthermore, the dust layers of large size dust contained calcite originating from limestone, which is an unique geology of Pamir region, indicating they are originate from near the glacier. Results revealed that the mereological type and composition differed significantly among the dust layers of the ice core. In particular, they are possibly originated from two different sources, including a short distance consisting of calcite and red mineral, and a long-distance without them.

Estimation of snow surface patterns from the coast to the inland, Dome-Fuji Station, of Antarctica, using camera images

*Konosuke Sugiura[1], Kengo Watanabe[1], Naohiko Hirasawa[2], Kenji Kawamura[2], Fumio Nakazawa[2], Hiroshi Ohno[3], Shuji Fujita[2], Ikumi Oyabu[2], Takashi Yamanouchi[2], Hideaki Motoyama[2]

1. University of Toyama, 2. National Institute of Polar Research, 3. Kitami Institute of Technology

Snow surface patterns in Antarctica are of practical concern and are important from the standpoint of developing an optimum route in Antarctica. In this study, we estimate snow surface patterns from the coast to the inland of Antarctica using camera images during JARE-59. The interval camera was used to capture the image of snow surface. Snow surface was photographed from November 13, 2017 to December 9, 2017. The number of images from the southern latitude of 69 degrees to 77 degrees was about 14,000 sheets. One sheet was divided into eight zones to distinguish a small-scale snow surface pattern. The pattern of snow surface was classified in three kinds such as 1) deposition, 2) equilibrium, and 3) erosion. We judged the snow surface patterns by sight. When Snow dune/Snow barchan was observed, it was classified as a deposition pattern. When Sastrugi/Glazed surface was observed, it was classified as an erosion pattern. In addition, when snow ripples were observed, it was classified as an equilibrium pattern.
The result of our analysis shows that the frequency of the deposition pattern decreases as latitude rises to 73 degrees south (Katabatic wind region) and then it increases slightly. In contrast, the frequency of the erosion pattern increases as latitude rises to 73 degrees south above which it decreases slightly. On the other hand, there have been no outstanding changes in the equilibrium pattern. The analyzed results of latitude dependence agree with the previous research qualitatively. However, the dominant surface pattern in the inland plateau region was still the erosion pattern. Since we analyzed the data of the outward trip, it is necessary to analyze the data of the return trip from the inland to the coast and to investigate a time scale of the surface pattern changes.

[A-CC26] Ice cores and paleoenvironmental modeling

convener:Ryu Uemura(University of the Ryukyus), Kenji Kawamura(National Institute of Polar Research, Research Organization of Information and Systems), Ayako Abe-Ouchi(Atmosphere and Ocean Research Institute, The University of Tokyo), Nozomu Takeuchi(Chiba University), Chairperson:Nozomu Takeuchi(千葉大学), Kenji Kawamura(国立極地研究所)

Analyses of ice cores from polar and mountain regions have contributed to the reconstruction and understanding of the past environmental changes on timescales from years to several hundred thousand years. In this session, we welcome paleoenvironmental studies using ice cores and paleoclimatic modeling. Studies on reconstruction methods, recording processes and new paleoenvironmental proxies, technical aspects of paleo-modeling are also welcomed. Studies with marine sediment cores, terrestrial sediment cores and tree-rings on similar timescales are also important and welcomed, in order to discuss past environmental changes from multidisciplinary viewpoints.

Isolation of living fungi from Antarctic ice cores

*Masaharu Tsuji[1]

1. National Institute of Polar Research

15 million years ago, the temperature of Antarctica was about 11 ℃ higher than the current temperature [(1)]. Many of fungi reported from Antarctica have also been reported from a variety of extreme, perennial cold environments including the Arctic, Siberia, the Alps, Alaska, Patagonia. Since these fungi have only been reported from the environment like the polar desert, fungi currently inhabited in Antarctica are thought to have come after 15 million years ago. However, the origins of the fungi inhabiting Antarctica are unknown.

In this presentation, to elucidate the origin and evolution of Antarctic fungi, I would like to introduce the isolation of Antarctic fungi from Antarctic ice cores.

1. National Institute of Polar Research, 2. SOKENDAI (The Graduate University of Advanced Studies)

This study attempted to culture ancient fungi preserved in the polar ice cores dated from ~1000 to ~9000 years ago. The samples of several hundred grams of ice collected at depths of 97, 470 and 670 m from Mizuho station (70°42'S, 44°20'E; 2230 m a.s.l.) and at depths of 116, 141 and 169 m from Dome Fuji station (77°19'S, 39°42'E; 3810 m a.s.l.) in Antarctica (Fujii, 1985; Dome-F Deep Coring Group, 1998). The ages of these samples were estimated to be ~1000, ~5500 and ~9000 years for the Mizuho ice core (Nakawo et al., 1989) and ~3000, ~4000 and ~5000 years for the Dome Fuji deep ice core (Dome Fuji Ice Core Project Members, 2017) respectively. In addition, an ice core sample from Åsgardfonna in the northeastern part of Svalbard (79°27'N, 16°43'E; 1140 m a.s.l.) (Uchida et al., 1993) was used for the cultivation. The information on the sample depth and age were unclear. In this study, we successfully cultivated fungi from all the samples. The nucleotide sequences were obtained by DNA analyses of the strains. Many of these sequences showed low homology to those registered in the NCBI DNA database, therefore it was believed that ancient fungi were actually obtained. This suggested that the culture of ancient fungi and its DNA analysis enable to be done over time by using deep ice cores such as the Dome Fuji ice core. This allows to study the physiological ecology of ancient fungi and to use decomposition and fermentation characteristics of ancient fungi for industrial purposes. Also, DNA analyses of the ancient fungi may enable to examine the diversity of fungi with climate and environmental changes and to study the evolutionary history on fungi. In our presentation, we will introduce the results obtained and discuss the prospects and developments of the study using the ancient fungi preserved in the polar ice cores in the future.

We analyzed chemical compositions of dust and sea-salt particles in the EPICA Dome C (EDC) ice core between 26 and 7kyr BP by using an ice sublimation technique, and compared the results with existing data of the Dome Fuji (DF) ice core. Combining the results of non-sea-salt Na and sea-salt Na fractions in total Na from the sublimation measurement and Na^+concentrations from ion measurement, we estimated that sea-salt flux in the two cores are roughly the same, while dust flux in the EDC core is significantly lower than that in the DF core throughout the studied period. Al/Si ratio of dust particles in the EDC core increased since around 16 kyr BP, suggesting that the average mixing ratios of minerals, presumably from different source locations, are different before and after 16 kyr BP. The composition of calcic dust also changed around 16 kyr BP; the fraction of calcium sulfate (calcic dust sulfatized during transport through lower troposphere) decreased and that of calcium nitrate (calcic dust reacted with nitric acid during transport through the middle to upper troposphere) increased. Previous studies on the mineralogy of EDC dust have suggested that dominant dust source area was Patagonia before 16 kyr BP and that multiple dust sources may have contributed thereafter (Siggaard-Andersen et al., 2007; Marino et al., 2008; Vallelonga et al., 2010).On the other hand, atmospheric model simulations have suggested that Patagonian dust is transported via lower troposphere, while Australian dust is transported via middle to upper troposphere (Li et al., 2008; Krinner et al., 2010). Thus, our data collectively confirm the dominance of Patagonian dust during the LGM and support the hypothesis of increased Australian dust contribution during the Termination and Holocene. The Dome Fuji Al/Si ratios were lower than those in the EDC core, and the fraction of calcium sulfate in the DF core are higher than those in the EDC core after around 16 kyr BP. The results suggest that Patagonian dust continued to be the dominant contributor to the Dome Fuji region after 16 kyr BP.

Spatial variation of surface mass balance over the last few millennia in the Dome Fuji area from the analyses of shallow ice cores

*Kenji Kawamura[1], Ikumi Oyabu[1], Fumio Nakazawa[1,2], Shuji Fujita[1,2], Kyohei Yamada[1], Naoyuki Kurita[4], Shun Tsutaki[5], Hiroshi Ohno[6], Konosuke Sugiura[7], Kumiko Goto-Azuma[1,2], Hideaki Motoyama[1,2], Ayako Abe-Ouchi[5,3]

One of the main targets in the current Japanese Antarctic program is to identify the drilling site for the oldest ice around Dome Fuji. The site selection activities (during JARE 59 and 60 summer seasons) include national and international ice-penetrating radar surveys, four shallow ice corings, and firn air sampling at one site. In this presentation, we report the shallow drillings and their analytical results for DEP (dielectric profiling) for deducing spatial differences of accumulation rate among the shallow drill sites.

During the JARE 59 surveys (2017-2018), the first core was drilled at 55 km south of Dome Fuji (New Dome Fuji; NDF) to the depth of 151.9 m, second one was drilled at 40 km southeast of Dome Fuji (DFSE) to 41 m, and third one was drilled at 30 km northwest of Dome Fuji (DFNW) to 41 m. The DEP of these cores were analyzed in summer 2018 at the NIPR cold laboratory, and major volcanic signals were identified back to 13thcentury for all three cores. During the JARE 60 surveys (2018-2019), we set up one base camp 5 km north of NDF (~50 km south of Dome Fuji) (NDFN) and drilled a shallow core to 142 m. The DEP analyses will be conducted for detecting volcanic signals along the core.

We also found a visible 20-mm-thick volcanic ash layer at 118.9 m in the NDF core, and a 10-mm-thick layer at 122.18 m in the NDFN core. Visible ash layers from probably the same origin have also been found in the Dome C (< 1-mm-thick layer at 132.6 m) and Vostok (~30-mm-thick layer at 103.04 m) ice cores. These ash layers were dated at 3500–3600 years before present (Basile et al., 2001; Kohno et al., 2004). On the other hand, volcanic ash layer was not found in the first Dome Fuji deep ice core (Narcisi et al., 2005) but in the second Dome Fuji deep ice core at 133.6 m.

The DEP and in-situ density data are used to date the horizons by comparing the DEP peaks to published volcanic data sets from several ice cores including the WAIS Divide core (Sigl et al., 2014), and to deduce surface mass balance between the volcanic signals for the three cores from JARE 59.

We identified 6 volcanic signals to 40-m depth and 12 signals to ~150-m depth (from the DF and NDF cores). We also use the data from the previously drilled cores (e.g. one from 6-km south of DF drilled in JARE 52, and one from 195-km south of DF in JARE 54) to discuss spatial patterns of accumulation rate from the corings. In the near future, the data will be combined with shallow ice-radar data from the JARE

Sensitivity of global nonhydrostatic atmospheric model to changes in orbital forcing for the early Holocene

*Minoru Chikira[1], Ayako Abe-Ouchi[1], Masaki Satoh[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

Various types of geological records have extensively shown consistent patterns of warmer and moister areas over Asia and Africa during the early to mid-Holocene. Previous sensitivity simulations of many global climate models to the changes in the earth’s orbital parameters during this period have equally shown the enhancement of the Asian and African monsoons, providing a successful interpretation on the qualitative patterns of these records. This study aims to shed a new light on the climate of this period by running sensitivity simulations by a global nonhydrostatic atmospheric model which began to be available for climate studies in recent years. The model used in this study is Nonhydrostatic ICosahedoral Atmospheric Model (NICAM) developed by a Japanese meteorological community: a framework of a cloud resolving model which resolves cumulus convection when used with a proper resolution and does not adopt any cumulus parameterizations. Because of the limit of computational resources, we use NICAM with a horizontal resolution of 56km. Despite not resolving cumulus convection, previous studies confirmed that it behaved similarly to the one with much higher resolution and provided practically reasonable mean-states and variability. The simulations were run with a slab ocean model and orbital parameters of 9000 years B.P. (9kBP). The Integrations were continued for 5 years. The seasonal mean precipitation in the control run is largely overestimated, however, it shows very good spatial distributions in terms of the locations of the ITCZs and peak precipitation. In particular, because of the high resolution enough to represent the steep terrain of the Tibetan Plateau, the model successfully reproduces a narrow rain band along its southern edge. The boreal summer precipitation of the 9kBP simulation shows a well-known northward shift of the African ITCZ, consistent with previous studies. Over Asia, the narrow precipitation band at the south of the Tibetan Plateau is significantly enhanced. The precipitation also increases over the Indian ocean. In between, there is a band-like structure of the suppressed precipitation over the India and Indochinese Peninsula. Although the resolution is not sufficient to resolve cumulus convection, the global nonhydrostatic atmospheric model appears to have a potential to represent small structures of the earth’s topography and evaluate its effect on precipitation which had not been discussed in previous studies. It is expected to be useful in discussing regional scale patterns of the geological records.

Roles of sea ice–surface wind feedback in maintaining contrasting modes of glacial Atlantic meridional overturning circulation and climate

*Sam Sherriff-Tadano[1], Ayako Abe-Ouchi[1]

1. Atmosphere and Ocean Research Institute, the University of Tokyo

During the glacial period, climate varied on millennial-time scale between two contrasting modes. These climate changes are often associated with drastic reorganizations of North Atlantic sea ice and Atlantic meridional overturning circulation (AMOC). However, processes affecting the periodicity of AMOC and climate variability remain unclear. Here, through performing simulations with a comprehensive climate model, we show that sea ice and associated changes in surface winds play a key role in maintaining the contrasting modes of AMOC and climate. Experiments highlights the importance of the suppression of atmosphere-ocean heat exchange by sea ice in inducing a weakening of surface winds. The surface wind anomaly then causes a reduction of salt transport and weakens AMOC, which triggers further expansion of sea ice. Our results show that sea ice–surface wind interactions over the North Atlantic plays an important role in inducing the long periodicity of the climate variability.

During the last termination of ice age cycle (deglaciation), Heinrich event 1 as well as B/A, Antarctic Cold Reversal (ACR) and Younger Dryas occurred as millennial scale climate changes. On the other hand, millennial scale climate changes such as D-O cycles recorded in ice core and deep sea cores in both hemisphere seem to occur more frequently during the mid-glacial state than during the early or late glacial state. Here we ran several sensitivity experiments and deglaciation simulations using a coupled atmosphere and ocean GCM (MIROC4m AOGCM) developed in Japan and analyzed the stability of AMOC and climate. Many model experiments were run for longer than10000 years under many different conditions of constant Greenhouse Gas levels, obliquity with/without glacial ice sheet and with and without freshwater flux into North Atlantic region. The results show large self-sustained oscillation of AMOC and high latitude temperature change similar to D-O cycles, which are consistent with ice core data and deep-sea data in both low and high latitude. Furthurmore, the results imply that both Northern Atlantic ocean-atmosphere-sea ice coupled system and Southern Ocean are important to maintain the oscillation with periodicity longer than 2000 years, for which we propose “Bipolar thermohaline oscillation” as its mechanism. We show that the D-O like oscillation occur with Glacial ice sheets under limited range of CO2, obliquity, and freshwater forcing. Implication on the mechanism and the conditions of the millennial scale climate changes for the past time period is discussed.

Reproduction of the increasing amplitude and period in the glacial cycles using a model incorporating diatomaceous activity.

*Tasuku Akagi[1], Takahiro Hasegawa[2]

1. Department of Earth and Planetary Sciences, Faculty of Science, Kyushu University, 2. Graduate School of Science, Kyushu University

The mode changes in the glacial cycle, smaller amplitudes with 20 kyr periods before 2.7 BP; medium amplitudes with 40 kyr periods between 2.70 and 1 Ma BP; greater amplitudes with around 100 kyr periods after 1 Ma BP, remain unanswered.

Carbon cycling is closely coupled with silicon cycling in the Earth surface. Oceanic silica is supplied from weathering of terrestrial matter, which depends on the atmospheric pCO_2. The atmospheric pCO_2, in turn, is influenced by the diatomaceous biological pump. Silicon can be a crucial driver of the Earth surface environment. Oceanic silica is removed by the burial of amorphous silica produced by diatoms. We have reported that the non-linear dissolution behavior of diatom frustules, where greater diatomaceous production tends to suppress dissolution of dissolved silica forming greater-sized frustule-aggregates.

Here we have developed a numerical model expressing the carbon and silicon cycling in the Earth surface, with diatomaceous biological pump and the non-linear dissolution behavior of diatom frustules being introduced.

The results of the model runs show interesting outcomes: when the amount of circulating carbon is reduced with time, both the amplitude and period of atmospheric pCO_2increase with time. When the insolation changes by Milankovitch forcing were loaded on the model temperature, the mode changes are successfully reproduced.

We propose that the glacial cycles may be understood by the coupling of ice-sheet dynamics and change in the oceanic Si inventory.

Development of an Ice Sheet Model coupled General Circulation Model and application of Energy Balance Model on the estimation of Ice Sheet mass balance

*Ryouta O'ishi[1], Ayako Abe-Ouchi[2,1], Fuyuki SAITO[2], Takashi Obase[1]

1. Atmosphere and Ocean Research Institute, the Universitoy of Tokyo, 2. JAMSTEC

A sea level rise is an important topic in a future climate projection. In the past warm period known as the Last Interglacial (LIG), paleoevidences indicate sea level rise of several meters. Paleoclimate modeling community applies past GCM results on ice sheet models and tries to reproduce past sea level rises.
We designed a coupling procedure between an ice sheet model and a general circulation model and are planning to introduce a surface mass balance of ice sheet not only by a typicall empirical method called PDD (Positive Degree Days) but also surface mass balance on the ice sheet as an upper boundary condition. The PDD only refers the surface atmosphere temperature and snowfall. In the present study, we use a process-based land surface model MATSIRO to estimate surface mas balance forced not only by temperature and snowfall but also by other surface variables including shortwave and longwave radiation. We compare the characteristics of resultant ice melt amount from PDD and MATSIRO to evaluate the inclusion of process-based heat and water balance instead of empirical equation.
We apply this procedure on the estimation of Grennland mass balance in the LIG.

Institute of Low Temperature Science, Hokkaido University

The recovery of a new Antarctic ice core to cover one million years will advance our understandings of the Quaternary climate. Previous ice flow modeling studies indicate that such old ice may exist in inland areas of the Antarctic continent, where horizontal ice flow is slow, the ice is thick, accumulation rate is low, basal temperature is well below the pressure melting point (Pattyn 2010; Fischer et al. 2013). We have been analyzing the field data taken by 59th Japanese Antarctic Research Expedition (JARE 59, 2017-2018) and conducting ice flow modelings as the essential parts of the site selection activities. In the present study, we show results of ice flow modeling to estimate the temperature and age of ice, and age resolution of the ice near the bed at a dome of the ice sheet. We use an one-dimensional ice flow-thermodynamic model, in which the vertical velocity of the ice is parameterized with empirical functions applied to the area near ice sheet domes. At first, the calculated age and temperature profiles of the ice are compared with depth-age profile of the Dome Fuji ice core and borehole temperature at Dome Fuji to assess the model performance for our purposes. Next, we investigate the influence of parameters (ice thickness, accumulation rate, geothermal heat flux, profile of vertical velocity of the ice) on the age of ice especially in the lowest few hundred meters. The results indicate that a fine resolution of oldest ice (~age of 1.0 Ma before present) is expected from a thick ice and a low accumulation, but the thick ice increases the chance of basal melting. The one-dimensional model is applied to the vicinity of Dome Fuji along the transect of JARE 59 surveys, using estimated ice thickness and simplified pattern of surface mass balance and geothermal heat flux. The calculated distribution of the age of ice are compared with internal layers of the ice (isochrone) derived from ground radar surveys. The calculated age of ice roughly follows observed internal layers of ice, and a smaller accumulation near NDF compared to Dome Fuji increases the agreement between calculated age of ice and internal layers of ice.

Climatic histories from about 800 kyr BP up to present have been studied using very deep ice cores drilled at dome summits in East Antarctica at Dome Fuji and Dome C. Knowledge gained from ice cores studies are crucial to understand the past and present climate and to predict the impacts of future climate changes. International Partnership for Ice Core Sciences (IPICS) identified that ice cores covering ages of the mid-Pleistocene Transition are necessary step to better understand climate dynamics. Multiple ice cores older than 1 M yrs BP are necessary. Dome Fuji area in East Antarctica is one of the candidate areas where we may be able to find very old ice core near the bottom of the ice sheet. Japanese Antarctic Research Expedition (JARE) has conducted deep ice coring at Dome Fuji twice in the past decade. They recovered ice cores covering ages up to about 720 kyr BP. At the same time, they have accumulated radar sounding data in this area. Alfred Wegener Institute (AWI), Germany, made an extensive airborne radar survey in 2016/2017 season covering Dom Fuji with a basic survey line spacing of 10 km. In the following season of 2017/2018, JARE also made ground-based radar surveys over a distance of 2950 km with a line spacing of 5 km or less. Based on results of these surveys, we conducted a more detailed radar surveys at Dome Fuji in 2018/2019 season as a collaborative research between University of Alabama, the University of Kansas, National Institute of Polar Research under Research Organization of Information and Systems (Japan), and Norwegian Polar Institute. Norwegian Polar Institute joined also collaborating on these efforts with the European framework of Beyond EPICA - Oldest Ice (BE-OI). We used two state-of-the-art radars: A wideband radar ice sounder developed by CReSIS, University of Kansas and ultra-wideband radar developed by University of Alabama. In addition, we used a classical pulse-modulated VHF radar of JARE with high gain antennas. Using a traverse team of JARE and its snow vehicles, we investigated along 2,700 km in an area of about 1,000 km^2. Final spacing between survey lines varied between 0.5 km and 0.25 km. The surveys were completed by the end of December, 2018. We will present preliminary results from these surveys. Preliminary quick-look results indicate that we collected an excellent radar data set with very good layering information including the bottom 10% of the ice. The data will be examined to identify candidate locations to drill very old ice.

Deformation mechanism of coarse-grained polycrystalline ice is well investigated by various experiments. However, the deformation of ice-sheet ice is complicated by various factors such as local distributions of impurities and mechanical anisotropies. Detailed analyses of ice cores have revealed that ice from glacial periods (ice-age ice) that has highly-concentrated impurities and small grains deforms rapidly compared with ice from Holocene. Although the causes of the rapid deformation in ice-age ice have been discussed in various studies, the detailed mechanism remains unclear.
The deformation rate in ice sheets is extremely slow; therefore, ice-sheet ice deforms under low dislocation density state. To replicate such deformation mechanism in laboratory experiments, we prepared fine-grained ice which has much grain boundaries. Since grain boundaries can act as sinks of dislocations, a low dislocation density state is kept during deformation like ice sheets.
To investigate the cause of rapid deformation of ice-age ice, we conducted deformation experiments and microstructural observations using artificial ice, with focusing on the influences of microparticles and grain size (grain boundaries). We made pure ice, and silica-dispersed ice with particle diameters of 0.3 μm and mass concentrations of 0.1 and 0.01 %. For the investigation of grain-size-sensitivity of deformation, various-sized ice (mean grain size with 30 μm –2 mm) was prepared.
Our experimental results revealed different trends for softening and hardening effect due to microparticles dispersion, grain-size-sensitivity, and microstructural evolutions during deformation in fine- and coarse-grained ice. Silica-dispersed ice with coarse grains indicated a hardening trend compared with pure ice, while little direct effect on the deformation in fine-grained ice. Grain-size-sensitivity was appeared only in fine-grained ice: the strain rates become larger at finer grains.
In this presentation, we discuss the possible cause for the rapid deformation of ice-age ice based on systematic deformation experiments and microstructural observations.

[A-GE30] Conservation and Restoration of Soil Environment at Terrestrial Surface

convener:Yasushi Mori(Graduate School of Environmental and Life Science, Okayama University), Chairperson:Yasushi Mori(Okayama University)

Soil is the largest store of carbon of all terrestrial media. Soils also have important functions such as water storage and plant support roles. However, at present, these characteristics do not fully function, because of mismanagement of the field or climate-change-induced heavy rainfall would wash away the organic-rich surface soils. In this session, soil environment research, from soil conservation to restoration technique for degraded soils are welcomed.

Soil Organic Cabon Contents Estimation using Neural Network System

Ikumi Kaida[1], *Yasushi Mori[1], Takayuki Shuku[1]

1. Graduate School of Environmental and Life Science, Okayama University

Dynamics of organic matter in soil greatly affects the material circulation of the outermost layer of the earth and since it has the largest storage capacity in the terrestrial area, its accumulation and disappearance attracts high attention on global warming. Previous studies showed some achievements on the estimation of soil organic matter. However, since natural process is very complicated, the parameters are extracted from the accumulation of individual research, and are not estimated while considering mutual relationships based on a sufficient amount of data. Therefore, it is going to be waste of time or not realistic to tackle the problem for relating huge sets of soil parameters without understanding functional relationship. With the development of computers in recent years, machine learning and neural networks, which are rapidly becoming to be applied to realistic tasks, read huge amounts of data and learn individual relationships while estimating the target value.

Therefore, in this study, we tried to find deeply related soil parameters using 11000 sets of 16 parameters (limited only in Europe) obtained from Harmonized World Soil Database (FAO, IIASA). Recursive Feature Elimination (RFE method) eliminated the weakly related parameters, and then the deeply related parameters are used to estimate organic carbon using neural network. Among the verifications, the neural network showed the best performance when the parameter selection was set to seven. Clay content, dry bulk density, clay CEC, total CEC, base saturation, exchangeable base, and ESP are evaluated as having high relevance. Interestingly, uncommon parameters were also included in the selection. 70% of the models constructed with these seven parameters estimated the amount of soil organic matter very well, 30% resulted in extremely bad results. In addition, although the selected parameter is deeply related to soil organic matter contents, it is not clear whether each parameter works positive or negative for estimation in the non-linear function. Since the derived relation is nonlinear and very complicated, it is difficult to understand the calculation process. But since the model function is obtained without giving a functional system from the human side, it is going to be a powerful tool in extracting necessary parameters from huge data sets which seems to have unknown relationships. In addition, the research will be more effective, and will greatly contribute to elucidation of environmental dynamics involving complex factors.

The effects of trenching and insertion of crop residue on infiltration and soil erosion in a farmland

1. Utsunomiya University, 2. Graduate school of Environmental and Life Science, Okayama University

It has been recognized that dynamics of water and the associated materials such as sediment and nutrients are important to conserve ecosystem existing in a watershed. Among others, excess soil and nutrients transports toward the coastal zones and deposition on corals are one of the major environmental problems in Okinawa, Japan, in which agricultural area is the major source of sediment yield. In this study, we focused on effects of trenching and insertion of crop residue on infiltration and soil erosion in a sugarcane field.

In the term of fallow period, water discharge in the trenching plot was 69% smaller than that in the control plot because the rainwater was infiltrated at the trenches on the surface. However, sediment yield in the trenching plot increased 57% over that in the control prot because soil surface was distubed by subsoiler to make trenches.

In the term of cropping period, water discharge in the plot of trenching and insertion of crop residue was 39% smaller than that in the control plot. The effect of increasing infiltration was continued because trenches did not fill with soil due to insertion of crop residue. Sediment yield in the plot of trenching and insertion of crop residue decreased 64% over that in the control prot. Then, from the view of preventing soil erosion, trenching and insertion of crop residue are effective practice during cropping period.

Measuring wide-range soil water content using GPS signals

*Kosuke Noborio[1], Natsumi Naganuma[1]

1. Meiji University

For prediction of the amount of irrigation water during a crop growing period, estimation of groundwater recharge amount, landslide forecast, and others, measurement of a wide range of soil moisture content is indispensable. Since the introduction of TDR moisture meter by Topp et al. in 1980, measurement of soil water content at a certain point has become possible with high precision, and remote automatic data acquisition. However, when measuring a wide range of soil moisture content as conventional measurements using satellites or cosmic rays, there are concerns on resolution and measurement accuracy so that it has not been applied to routine observation. In 2008 Larson and colleagues reported that there is a significant relationship between the ground reflected wave intensity contained in the GPS signal and the soil moisture content around the GPS antenna. Since GPS satellites are operated to be observed at any location on the earth for 24 hours a day, if we could measure soil moisture content using GPS signals, applicability of this method would be immeasurable. In this report, we outline the principle and examples of wide area soil moisture content measurement using GPS signals.

Life search on Mars by Life Detection Microscope (LDM)

*Yoshitaka Yoshimura[1]

1. College of Agriculture, Tamagawa University

Recent findings on Mars tend to support the possible presence of living microbes near the surface of Mars. MSL Curiosity has found organic compounds [1], the temporal increase of methane concentration in Martian atmosphere [2] and reduced sulfur compounds such as pyrite in Martian soil [3]. Methane and reduced sulfur compounds can be energy sources to support the growth of chemoautotrophic microbes [4]. The detection of hydrated salts suggested the possible presence of liquid water at Recurring Slope Lineae [5]. Although present Martian environments are hostile to life, terrestrial microorganisms inhabit a wide range of environmental conditions, suggesting some microorganisms may survive near the surface [4]. Though UV radiation is harmful, it would be shielded by thin layers (less than a millimeter) of dust or regolith [6]. A depth of several centimeters from the surface, therefore, could provide sufficient covering for microorganisms to survive.

The Viking mission in 1970’ s did not find evidence for life [7], however, the sensitivity of the GC-MS (mass spectrometer) onboard the Viking mission was found not to be very high, and it was not able to detect 10^6 microbial cells in 1 gram soil [8, 9], indicating that another life detection program is necessary.

The Life Detection Microscope (LDM) that we have proposed [6, 10] has the potential sensitivity much higher than the Viking instrument. Microscopes directly image life forms and identify their shapes, sizes, and other morphological structures and have the potential to detect a single cell in field of view. Therefore, the sensitivity can be as high as desired just by increasing the volume of sample to be scanned in a reasonable duration of experiment. LDM scans about 1 mm^3 and detects less than 10^4 cells in 1 gram soil at a spatial resolution of 1 μm [10]. LDM differentiates among organic compounds surrounded by membranes or with enzyme activity by staining the samples with fluorescent pigments. This technique is especially useful for the detection of living microorganisms.

Our investigation goals are the followings. 1) Identify cell-like structure in which organic compounds are enveloped by membrane, which may represent Martian life. 2) Search for organic compounds in Mars surface samples. The compounds include cells, other biological materials, and abiotic polycyclic aromatic hydrocarbon (PAH). 3) High-resolution characterization of regolith and dust particles. The search for living microorganisms is important not only for scientific interest but for planetary protection. Before future human missions begin, surveys investigating the presence of living microorganisms should be conducted to mitigate the risk of human contact with Martian microorganisms, which may be harmful to human health. The LDM would be also an effective tool for this purpose.

Moisture movement in sand during evaporation under reduced pressure

*Masaru Mizoguchi[1]

1. Graduate school of Agricultural and Life Sciences, The University of Tokyo

In order to investigate the mechanism of moisture transfer in the basement of Mars, experiments were conducted to measure the moisture, temperature, and salt distribution in the sand column during the vacuum evaporation process. As a result, it was found that the sample freezes at low salt concentration while it does not freeze at high concentration. In addition, we found that the salt moves to the surface layer with liquid water movement, and that the higher the salt concentration, the higher the evaporation amount. These results may relate to phenomena such as drying accompanied by evaporation under reduced pressure, freezing due to latent heat loss, crust formation due to salt concentration and freezing point depression.

In recent years, evidence of the existence of water has been found on the moon and Mars. The water resources on the moon or Mars are expected to be utilized as an in situ resource for future manned exploration. It is necessary to elucidate how the water exists in the porous media and how we can extract it. Under the 1G condition, water flow in porous media is expressed by Richards' equation. According to Richards' equation, water moves by a matric potential gradient and a gravity gradient. It was reported that water movement by a matric potential gradient, however, changed under microgravity. Therefore, water movement under low gravity might be different from estimation by conventional water movement theory. In this study, we observed water movement in porous media made of glass beads under microgravity and evaluated the effects of gravity on liquid behavior in porous media. We conducted infiltration experiments using porous media of 0.4 mm grass beads under microgravity conditions created by parabolic flight. The advances of the gas-liquid interface were captured by a video camera and the infiltration rate was calculated. We also conducted a horizontal infiltration experiment under 1G and compared the infiltration rate under each gravity conditions. The infiltration rate under microgravity was slightly lower than the horizontal infiltration rate under 1G. The decrease of infiltration rate, however, was smaller than the decrease in the previous study using 1.5 mm glass beads.

Effects of changes in viscosity under low gravity on infiltration rate

*Kento Nogawa[1], Naoto Sato[2], Yuichi Maruo[1], Natsumi Naganuma[1], Kosuke Noborio[2]

1. Graduate School of Agriculture, Meiji University, 2. School of Agriculture, Meiji University

It is important to clarify water behavior in the porous media to realize cultivation of crops in spacecraft, on Mars or on the Moon. However, Jones et al. (1999) revealed that infiltration rate in porous media under microgravity (μG) is lower than that under 1G. In addition, Maruo (2018) revealed that infiltration rate in the capillary tube under μG is lower than that under 1G. Infiltration in porous media under μG depends on capillary force, so that the decrease infiltration rate in the capillary tube might be a cause of the decrease in infiltration rate in the porous media under μG. It is thought that the decrease of infiltration rate in capillary tube under μG was caused by a decrease in surface tension, an increase in contact angle, and/or an increase in viscosity. Naganuma et al. (2019) reported that the surface tension of water does not vary with gravity. In addition, it was revealed that the contact angle of water droplets under μG does not change compared to under 1G (Naganuma et al., 2018). However, there are few studies that evaluated the gravitational dependence of the viscosity of water. In this research, we evaluated the gravity dependence of the viscosity of water and estimated the influence of viscosity change on infiltration rate. In this experiment, low gravity experiment using parabolic flight was carried out for 2 days using MU-300 (Diamond Air Service Inc., Nagoya, Japan) as an aircraft. The gravity condition was μG (1st day: 3 times, 2nd day: 3 times), 1/6G (1st day: 3 times, 2nd day: 6 times), 1/3G (1st day: 5 times, 2nd: 3 times), and each low gravity duration was 20 to 30 seconds. Changes in gravity were acquired from the accelerometer installed in the aircraft. For the acrylic column with an inner diameter of 64 mm and a height of 41 mm used for the experiment, water repellent treatment was performed on the upper 14 mm of the inner wall of the column, and the water level was adjusted so that the boundary between the processed part and the unprocessed part became the water surface. Degassed water was used as the sample to be filled in the column. For measurement of viscosity, a viscometer (Tuning Fork Vibro Viscometers SV-10, A & D Co., Ltd.) was used. The water temperature was measured by a temperature sensor built in the viscometer. The measurement interval of viscosity and temperature was 2 seconds on the 1st day and 1 second at the 2nd day. I photographed the state of the surface with a video camera (GoPro Hero 4, GoPro Inc.). Experimental results showed a negative correlation between viscosity and gravity in the range of 0G to 1G (Fig. 1). In the range of 1 G to 2 G, the measured values varied due to vibration, and reliable data could not be obtained. Since it is known that the surface tension and the contact angle do not change under μG, it is considered that the decrease infiltration rate in the capillary tube was brought about only by the increase in viscosity. From this, we consider the effect of increase in viscosity under μG on decrease of capillary invasion rate. Maruo (2018) defines the rate of change of infiltration rate in the capillary tube under μG compared to under 1G as a coefficient of delay α and is expressed by equation (1) (Fig. 2). Postulate that values other than viscosity do not change with 1G and μG in equation (1), it is considered that equation (2) holds. Therefore, $1/\alpha^2$ in capillary infiltration experiment by Maruo (2018) is compared with $\eta_{\mu G}/\eta_{1G}$ in this experiment. $1/\alpha^2$ is 2.49 at the capillary diameter of 0.8 mm, 2.78 at 2.37 mm, 3.19 at 5.5 mm, $\eta_{\mu G}/\eta_{1G}$ is at 2.66 on the 1st day and 2.70 on the 2nd day, $1/\alpha^2$ and $\eta_{\mu G}/\eta_{1G}$ are nearly the same value. From this, it is considered that the decrease infiltration rate in the capillary tube under μG was caused by the increase in viscosity.

Differences in infiltration process on the planets under different gravity.

*Yasushi Mori[1]

1. Graduate School of Environmental and Life Science, Okayama University

These days, we are trying to conduct the long-term stay in the space station, the various experiments under microgravity by the parabolic flight, and the research to explore the possibility of our stay on the other planets. In addition, we are exploring the existence of water and traces of living things on the other planets and satellites. If such an approach has become realistic, the next approach would be the earth, soil or regolith, where we need to consider how liquid flows and behaves. Here we consider the penetration phenomenon of solution when gravity is different. In the parabolic flight, they report that water in a vessel is sucked into noodles when it becomes zero gravity. When the influence of gravity becomes small, the influence of the capillary force by the porous body becomes relatively large, and the downward movement by the inertial force is restricted. Indeed, preliminary experiments showed that the downward reach of the solution increased as pseudo gravity increased. When we are trying to use regolith as planting on a planet with small gravity, the solution such as water might not move downward as we are estimating.

[A-CG38] Multi-scale ocean-atmosphere interaction in the tropical Indo-Pacific region

convener:Ayako Seiki(Japan Agency for Marine-Earth Science and Technology), Tomoki Tozuka(Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo), Motoki Nagura(Japan Agency for Marine-Earth Science and Technology), Youichi Kamae(Faculty of Life and Environmental Sciences, University of Tsukuba), Chairperson:Ayako Seiki(Japan Agency for Marine-Earth Science and Technology), Motoki Nagura(Japan Agency for Marine-Earth Science and Technology)

Multi-scale ocean-atmosphere interaction in the tropics exerts a significant imprint on the global climate via atmospheric teleconnection. Since the 1980s, anchored by in-situ and satellite observations, improvements in modeling and theoretical understanding, various aspects of dominant modes of interannual (e.g., ENSO and IOD), intraseasonal (e.g., MJO) variabilities and their impacts on tropical (e.g., monsoons) and extra-tropical (e.g., North America) climate variations have received wide attention. Recent satellite-based salinity measurements indicate for an active role of salinity in the tropical ocean-atmosphere interaction. While recent studies suggest a possible link between interdecadal Pacific oscillation and global warming hiatus in 2000s, changes (if any) in the tropical ocean-atmosphere interaction are yet to be understood. Due to interactions between different time scales, between different ocean basins, and with the extratropics, the tropical ocean and atmosphere play a key role in shaping climate, its variability and change. To better understand and examine these challenging issues from various perspectives, this session offers a forum to discuss recent progress in observational, modeling and theoretical studies of multi-scale tropical ocean-atmosphere interaction.

Various aspects of climate system variability associated with ENSO

*Shuhei Maeda[1]

1. Climate Prediction Division, Japan Meteorological Agency

The El Niño-Southern Oscillation (ENSO) is the most dominant interannual climate variability in the Earth’ s climate system, and its pattern is characterized as zonal east-west see-saw of oceanic and atmospheric conditions in the tropical Pacific, and their associated teleconnections in the atmosphere to the extra-tropics. In addition, various aspects of climate system variability associated with ENSO are observed. For example, (1)vertical distribution of sea sub-surface temperature, (2)global average temperature, (3)energy budget at the top of atmosphere, (4)available potential energy in the atmosphere, (5)atmospheric meridional circulation such as Hadley and Ferrel circulations, (6) sub-tropical jet streams, (7)wave activities in the extra-tropics, and (8) polar vortex. In the presentation, I will review these aspects of climate system variability associated with ENSO, and discuss related mechanisms.

Influence and mechanism of the tropical Pacific variability on the Arctic and its seasonality

*Tsubasa Takigawa[1], Yu Kosaka[1], Bunmei Taguchi[1], Lea Svendsen[2]

1. Research Center for Advanced Science and Technology, University of Tokyo, 2. Bjerknes Centre for Climate Research, University of Bergen

Arctic temperature has increased about twice as fast as global mean surface temperature in recent decades. While anthropogenic influence on this Arctic warming is evident, potential contributions from internal climate variability remains to be examined. Svendsen et al. (2018) showed that Pacific decadal variability played a key role in the early twentieth century Arctic warming through a coupled model pacemaker experiments with historical forcing. It is still unclear, however, how much influence the Pacific internal variability induces on the Arctic and how this remote influence is conveyed.
This study investigates the relationship between Arctic climate and tropical Pacific variability (TPV) by using a pre-industrial control experiment with GFDL CM2.1, with the primary aim to quantify the effect of TPV in different timescales. The result shows that the surface temperature response at high latitudes is amplified at multi-decadal timescales compared to sub-decadal one. The Arctic temperature anomalies peak near surface and diminishes with height. Moreover, Arctic temperature and sea ice responses feature strong seasonality with peak in late winter, despite weak seasonality of the tropical SST anomalies associated with decadal TPV. These features bear similarity to radiatively induced Arctic warming, and suggest importance of local feedbacks in Arctic climate variability driven remotely by the TPV.

Subsurface nonlinear dynamical heating and ENSO asymmetry in CMIP5: Implications for anthropogenic tropical-warming uncertainties

*Michiya Hayashi[1], Fei-Fei Jin[1]

1. Department of Atmospheric Sciences, University of Hawaii at Manoa

El Niño-Southern Oscillation (ENSO) is a dominant interannual tropical variability, playing a key role in worldwide climate. Most climate models participating in CMIP5 (Coupled Model Intercomparison Project phase 5) can produce ENSO amplitude close to observations, but the asymmetry between its warm and cold phases is still poorly simulated in general. Here, using 25 CMIP5 historical simulations and multiple ocean reanalysis datasets, it is shown that the model-to-model diversity of ENSO asymmetry is mostly explained by the representation of nonlinear dynamical heating (NDH) in the subsurface ocean along the equatorial Pacific thermocline. The skewness of sea-surface temperature (SST) anomalies in the Niño-3 region linearly increases with respect to the variability of the subsurface NDH among the CMIP5 models (correlation of 0.8). The NDH variability in most CMIP5 models is under-simulated due to weak Equatorial Undercurrent variability.

Using a small subset of the models having the NDH variability greater than the CMIP5 average, the influence of ENSO amplitude change in CMIP5 anthropogenic warming scenarios is further assessed. The future change in ENSO amplitude still shows a large spread even within this subset. Nevertheless, the long-term change in climatological NDH mean follows the ENSO amplitude change, which is absent in the rest of the CMIP5 models having weak NDH variability. Hence, increasing the rectification effect of the subsurface NDH that deepens the mean-state thermocline to warm the SST can enhance the so-called "El Niño-like" global-warming pattern that exhibits the faster eastern-Pacific surface warming. In contrast, suppressing the subsurface rectification effect can cause a more "La Niña-like" warming pattern. These results suggest that properly simulating ENSO asymmetry and subsurface NDH in climate models is critical on projecting future climate.

Uncertainty in the projections of ENSO amplitude change under global warming: Role of the response of atmospheric circulation to SST anomalies

*Jun Ying[1]

1. Second institute of Oceanography, Ministry of Natural Resources

The study investigates the mechanism of the large inter-model uncertainty in the change of ENSO’s amplitude under global warming, based on 31 CMIP5 models. We find that the uncertainty in ENSO’s amplitude is significantly correlated to that of the change in the response of atmospheric circulation to SST anomalies (SSTAs) in the eastern equatorial Pacific Niño3 region. This effect of the atmospheric response to SSTAs mainly influences the uncertainty in ENSO’s amplitude during El Niño (EN) phases, but not during La Niña (LN) phases, showing pronounced nonlinearity. The effect of the relative SST warming and the present-day response of atmospheric circulation to SSTAs are the two major contributors to the inter-model spread of the change in the atmospheric response to SSTAs, of which the latter is more important. On the one hand, models with a stronger (weaker) mean-state SST warming in the eastern equatorial Pacific, relative to the tropical-mean warming, favor a larger (smaller) increase in the change in the response of atmospheric circulation to SSTAs in the eastern equatorial Pacific during EN. On the other hand, models with a weaker (stronger) present-day response of atmospheric circulation to SSTAs during EN tend to exhibit a larger (smaller) increase in the change under global warming. The result implies that an improved simulation of the present-day response of atmospheric circulation to SSTAs will be effective in lowering the uncertainty in ENSO’s amplitude change under global warming.

Impact of atmospheric variability on Indian Ocean Dipole mode

*Yuya Baba[1]

1. JAMSTEC Japan Agency for Marine-Earth Science and Technology

Some preceding studies investigated tropical atmospheric internal variability such as Madden-Julian oscillation on the formation of Indian Ocean Dipole mode (IOD), but still number of the studies remains few, and their relationship remains unknown. In this study, we focused on the impact of atmospheric variability especially intraseasonal variability. To reveal the impact, we conducted sensitivity experiments for the IOD during 1980-2009, using an ocean general circulation model and difference atmospheric forcing data, such as (1) climatological forcing, (2) same as (1) but with yearly anomalies, (3) same as (1) but with seasonal anomalies, (4) same as (1) but with monthly anomalies, (5) 90-day low-pass filtered forcing. The simulated Dipole mode index (DMI) indicates that the sensitivity case of (1) could not reproduced realistic DMI at all, (2) and (3) reproduced decreased DMI amplitudes, and (4) and (5) reproduced similar DMI which was simulated with daily forcing data. In this presentation, possible mechanisms that caused different features of simulated IODs will be explained, focusing on the relationship between the variabilities of ocean and atmosphere.

Do salinity anomalies matter for the evolution of the IOD? –Experimental assessments using a regional ocean model-

*Shoichiro Kido[1], Tomoki Tozuka[1], Weiqing Han[2]

1. Graduate School of Science, The University of Tokyo, 2. Department of Atmospheric and Oceanic Sciences, University of Colorado Boulder

The Indian Ocean Dipole (IOD), which is a dominant climate mode in the tropical Indian Ocean, is accompanied by significant surface and subsurface salinity anomalies. These salinity anomalies alter density field and stratification in the upper ocean, and thereby have potentials to affect the evolution of the IOD itself. Though many previous studies have attempted to estimate the impacts of the IOD-related salinity anomalies, no comprehensive assessments have been conducted. To this end, a series of sensitivity experiments using a regional ocean model is conducted with a novel experimental strategy. Results from these sensitivity experiments show that interannual salinity anomalies associated with the positive IOD tend to suppress the cooling in the eastern equatorial Indian Ocean by about 1.0˚C. Through an on-line heat budget analysis of each experiment, it is shown that weakening of the upwelling in the eastern Indian Ocean, which originates from the upward shift of the Equatorial Undercurrent, is the primary cause of the suppressed cooling there. These changes are induced by enhanced stratification in the eastern equatorial Indian Ocean associated with negative (positive) salinity anomalies near the surface (pycnocline). Momentum budget analysis and additional sensitivity experiments using a linear continuously stratified ocean model further support these ideas. Therefore, salinity plays an active role in the evolution of the IOD, rather than being passively influenced by atmospheric anomalies.

Mechanisms of future changes in equatorial upwelling: CMIP5 inter-model analysis

*Shoshiro Minobe[1,2], Mio Terada[2], Curtis Deutsch[3]

1. Earth and Planetary Sciences, Faculty of Science, Hokkaido University, 2. Graduate School of Science, Hokkaido University, 3. School of Oceanography, University of Washington

The future change in equatorial upwelling is investigated for the Pacific and Atlantic Oceans using data from 24 Coupled *Model* Intercomparison Project Phase 5 (CMIP5) models for the Representative Concentration Pathway 8.5 scenario until 2100. Three-dimensional velocity components of CMIP5 multi-models are used for the first time in an upwelling study, and allow to divide upwelling velocities into diapycnal and isopycnal velocities. This analysis, combined with inter-model regression, revealed that both the multi-model ensemble (MME) mean and the inter-model variability in the upwelling change in the eastern equatorial Pacific, where strong upwelling change occurs, are explained by two mechanisms. One is that the diapycnal upwelling decreases near the surface, which is associated with a weakened Ekman divergence. The other is that the isopycnal upwelling decreases at depths of 75–200 m around the core of the equatorial undercurrent (EUC) due to EUC flattening. Both the weakened Ekman divergence and the EUC flattening are induced by the locally weakened trade wind over the eastern Pacific basin. In the equatorial Atlantic, both the change in MME mean and the inter-model variability of upwellings are significantly related to the weakened trade wind and enhanced stratification, although these drivers are not independent. The results for the Pacific Ocean imply that future reduction in upwelling may impact the sea surface temperature and marine ecosystem by different mechanisms. The rapid warming of sea surface temperature in the eastern Pacific basin may be related to the near-surface diapycnal upwelling reduction, while the decrease in net community production, which is often measured by marine export production at a depth of 100 m, may be related to the isopycnal upwelling reduction.

The Indo-Pacific cross-basin interaction of the decadal climate variability under the progress of the global warming

*Yuma Miyaji[1], Youichi Tanimoto[2]

1. Hokkaido University, Graduate School of Environmental Science, 2. Hokkaido University, Faculty of Environmental Earth Science

We investigate a relationship of the decadal sea surface temperature (SST) variability between over the Indian Ocean and over the tropical Pacific based on the observed data sets and the multi-model climate simulations. In the present study, by subtracting the multi-model ensemble mean rather than the observed linear trend, we attempt to retain the decadal signals without the effect of the radiative forcing, in the observed long-term records of the ocean and atmosphere.
While several observational studies indicated that the simultaneous correlation coefficient of the long-term SST variability over the two basins changed from positive before 1985 into negative after 1985, our analysis always shows the positive correlation regardless of the selected decades, indicating that the internal dynamics of the Indo-Pacific ocean-atmosphere system for this cross-basin interaction. While the decadal variations of the surface winds over the Indian Ocean are influenced by the SST variability over the tropical Pacific, the SST formation processes by those surface winds are different among the regions north and south of 10˚S, respectively. The effect of the climatological meridional gradient in the thermocline depth on the different formation processes is discussed.

Air-sea flux observation by unmanned autonomous sea surface vehicle in the Tropics - Application of the Wave Glider -

*Iwao Ueki[1]

1. JAMSTEC Japan Agency for Marine-Earth Science and Technology

Air-sea fluxes of heat and momentum are fundamental variables for the ocean and atmosphere interaction, which influence weather and climate. The air-sea flux measurements; actually measurements of air temperature, humidity, sea surface temperature, winds, and radiations, are mainly conducted by research vessels, mooring buoys, and satellites. Based on these measurements, many types of global air-sea flux products are produced. However, these products still remain large biases and uncertainties in the global fields. Reducing inaccuracies in air-sea fluxes is important for improving long-term weather and climate predictions. For that purpose, we should consider about intensification of *in situ* measurements, which contribute to improve bulk algorithms, to understand mechanisms of flux variability, and to validate the products as proposed in Community White Papers of air-sea fluxes with a focus on heat and momentum in OceanObs’19. Due to the relatively high cost of research vessel and mooring buoy operations, number of in situ measurements is limited. The sparsity of the *in situ* measurement in present situation is one of obstacles to improve satellite algorithm development and product validation. Because of recent progress of unmanned autonomous ocean surface vehicles (UAVs) development, we can use these vehicles as a platform for air-sea flux observation. In this study, several field tests and evaluations of the acquired data through comparison with mooring buoys have been conducted especially in the tropical region. The present status of these activities will be introduced in the presentation.

Radar-derived Fresh water flux and its possible impact to the oceanic stratification observed during the Years of the Maritime Continent (YMC)

*Masaki Katsumata[1], Biao Geng[1], Satoru Yokoi[1], Shuichi Mori[1], Iwao Ueki[1]

1. Japan Agency for Marine-Earth Science and Technology

To investigate the air-land-sea interaction in the Maritime Continent (the world's largest archipelago bridging tropical Indian Ocean and tropical western Pacific), a series of the field campaign “YMC-Sumatra” was conducted as part of the project "Years of the Maritime Continent (YMC)". In “YMC-Sumatra 2017”, we deploy the research vessel "Mirai" at one station near the west coast of Sumatra Island to obtain time series.

The continuous dataset from C-band polarimetric radar is converted to the rainrate (i.e. fresh water flux) by utilizing the data from disdrometers and raingauges. The estimated fresh water flux is compared to the oceanic near-surface stratifications measured by the unmanned surface vehicle “wave glider”. The observed salinity at 0.2m and 6m depths differ under a precipitating event with weak wind (< 5 m/s). The event was followed by the strong wind (>10 m/s) precipitation. After the event, low salinity layer was captured down to 30~40 m depth for more than half days.

Driving Mechanism of Inter-Annual Precipitation Variability during Monsoon Season over the Northern Part of Sumatra Island, Indonesia

*Yahya Darmawan[1,2,3], Huang-Hsiung Hsu[2]

1. Taiwan International Graduation Program, Academia Sinica, 2. Research Center for Environmental Changes, Academia Sinica, 3. Indonesian Agency for Meteorology, Climatology and Geophysics (BMKG)

The precipitation variability of the Northern part of Sumatra Island in Indonesia has been driven by the complex tropical climate systems along with the local factors. The aim of this study is to investigate the driving mechanism of precipitation variability during the JJA-periods (June, July, and August) over the northern part of Sumatra. Moist Static Energy (MSE) budget analysis was used to model the source of energy which supports the precipitation anomalies. Composite analysis and statistical methods were used for confirming the result of MSE budget. By using 36 years of ERA-interim data, precipitation anomalies of JJA periods were classified into two categories, namely: wet years and dry years. Positive precipitation anomalies are found during the wet years which are supported by the upward motion of vertical velocity. During the wet years, the weaker easterly wind of Indian Summer Monsoon (ISM) associated with the westerly winds of a negative El Niño–Southern Oscillation (ENSO), a positive Indian Ocean Dipole (IOD), and a strong Western North Pacific Subtropical High (WNPSH). As a consequence, these anomalous circulations trigger a moisture flux convergence and positive precipitation anomaly. In the dry years, the downward of vertical velocity leads to negative precipitation anomaly. Generally, a stronger easterly wind of ISM was found during the dry years which is associated with a positive ENSO, a negative IOD, and a weak WNPSH. Even though the precipitation anomalies occur due to the collaboration of those winds, a new finding shows that WNSPH has a stronger impact to the precipitation anomalies than ENSO and IOD in the Northern part of Sumatra Island. In addition to those circulations, higher topography of the Barisan Mountains supports the ascending motion to moisten the lower troposphere and induces a positive precipitation anomaly in this maritime continent.

The impact of diurnal precipitation over the maritime continent on synoptic disturbances and its relation to the MJO

*Ayako Seiki[1], Satoru Yokoi[1], Masaki Katsumata[1], Kunio Yoneyama[1]

1. Japan Agency for Marine-Earth Science and Technology

Diurnal cycle has been known to contribute to a significant amount of precipitation over the maritime continent. In this study, the impact of diurnal precipitation over Sumatra Island, the Indonesian maritime continent, on synoptic disturbances over the surrounding ocean, especially the eastern Indian Ocean, is examined using the Global Satellite Mapping of Precipitation (GSMaP) data. High precipitation area observed over Sumatra in afternoon migrates offshore during night-time and reaches 500 km off the coast in average. Synoptic disturbances represented by eddy kinetic energy are enhanced south of the equator off Sumatra when the diurnal precipitation is strong, then they migrate poleward with cyclonic structures over the eastern Indian Ocean. These results suggest that the diurnal precipitation over Sumatra can excite synoptic disturbances over the eastern Indian Ocean.

[A-CG39] Biogeochemical cycles in Land Ecosystem

convener:Tomomichi Kato(Research Faculty of Agriculture, Hokkaido University), Kazuhito Ichii(Chiba University), Takeshi Ise(FSERC, Kyoto University), Munemasa Teramoto(National Institute for Environmental Studies), Chairperson:Tomomichi Kato(Hokkaido University)

Terrestrial ecosystem influences global climate through cycles of water, carbon, and nitrogen between land surface and atmosphere. For better understanding of those behaviors, a great effort has been paid for developing varieties of approaches and techniques such as biometric survey, eddy and chamber methods, near and satellite remote sensing, biosphere modeling and so on.
 In particular, the JapanFlux, founded in 2006 as a researchers network of CO2, H2O and other trace gas flux measurement, has promoted the multi-disciplinal studies not only for flux measurement community, but also for remote sensing and biosphere modeling communities. Moreover, the Research-Group-on-Integrated-Land-Processes, which was founded in 2006, also has contributed to build networks between Japanese researchers to better understanding of physical and biological processes on interactions between terrestrial surface and atmosphere.
 This session unites those multi-disciplinal activities, and promotes the oral and poster presentations on the role of terrestrial ecosystem in material circulations of water, carbon, nitrogen, energy and other substances by any approaches and technics. This session takes over the former session in last year: A-CG40.

Global warming will alter the precipitation pattern, resulting in the increase in seasonal fluctuation of soil water conditions. Both environmental factors of soil temperature and water fundamentally affect soil CO_2 release, a major carbon flux in terrestrial ecosystems. However, our understandings of soil CO_2 release under the increased temperature and fluctuated water conditions are still insufficient to infer the feedback of terrestrial carbon cycling in future worlds. In the present study, we are conducting laboratory incubation experiments for examining the combined effects of temperature rising and soil water fluctuation on CO_2 release from volcanic ash soils. Volcanic ash soil is the major soil type in Japan and is expected to have great ability to stabilize carbon as soil organic matter. We incubated volcanic ash soils under four combinatorial conditions of two temperatures (20 and 30 ˚C) and two water conditions (a continuously constant water and a fluctuated water conditions). The rate of CO_2 release was periodically measured during the incubation. Then, the ratio of CO_2 release at 20 ˚C to that at 30 ˚C, namely Q_{10}, was expressed as the temperature sensitivity of soil CO_2 release. The fluctuated water condition was maintained with multiple dry-wet cycles to achieve an average water content of 40% of water holding capacity which was equivalent to that under the continuously constant water condition. For the incubation at 20 ˚C, soil CO_2 release under the fluctuated water condition was up to 50% greater than that under the constant water condition. The excess of soil CO_2 release under the fluctuated water condition was, however, reduced to less than 10% for the incubation at 30 ˚C. Thus, Q_{10} under the fluctuated water condition (1.3 to 1.5) was equivalent to or lower than that under the continuously constant water condition (around 1.5). These preliminary results offer the needs of modifying basal CO_2 release extent and Q_{10} value for inferring the soil CO_2 release under increased temperature and fluctuated water conditions. The experiments are still ongoing and results and further insights will be presented at the meeting.

1. Introduction

Intense land-use change in tropical Asia has a significant influence on greenhouse gases (GHGs) budget in the region. Conversion of tropical peat swamp forest to both acacia and oil palm plantation is a typical land-use change in the region. To evaluate impact of the conversion on GHGs budget, we have to quantify many related processes, for example, enhanced decomposition of peat soil, N_2O emission from fertilization, biogas emission from palm oil mill effluent (POME) treatment ponds, etc. Oil mill facility is built adjacent to oil palm field because fresh oil palm fruit needs to be processed immediately after harvest. Oil palm plantation forms a stationary material cycle system as an integration of palm oil field and mill facility. POME treatment ponds is typical waste water treatment system in an oil palm plantation. Biogas contains high concentration of methane, because methane fermentation is an essential process in waste water purification in the ponds. Measured values of GHGs emission from POME treatment ponds is limited. We conducted field observation of GHGs emission from a POME treatment ponds in an oil palm plantation in tropical peatland as a joint research of National Institute for Environmental Studies and Sarawak Tropical Peat Research Institute.

2. Methods

We conducted field measurement of GHGs emissions from POME treatment ponds in an oil palm plantation on tropical peatland near Sibu Town, Sarawak, Malaysia. The life of the sampling equipment was assumed considerably short in POME treatment ponds due to the exposure to high concentration of corrosive hydrogen sulfide and pollution by oily scum. To quantify GHGs emission from the ponds, we had developed floating chamber system specialized to the POME ponds. The low cost and program controlled system made it possible to perform multi-point simultaneous sampling automatically in a short period of time. We collected biogas from the ponds into balloons of gas-barrier film using the chambers. We measured total amount of biogas in the balloons with modified water replacement method firstly, consequently measured concentration of gases (CH_4, CO_2, O_2, H_2, and H_2S) with portable gas monitor (BIOGAS 5000, Gastech, U.K.). We calculated gas fluxes from covered area, sampling duration, gas volume and gas concentrations. The gas fluxes measurements were conducted in eight ponds in upstream side of whole ten ponds during dry season (June 2018).

3. Results and discussions

Biogas from POME treatment ponds were mainly CO_2 and CH_4. Markedly large biogas flux was found in fourth pond from upper stream. About 65% of the biogas from the fourth pond was CH_4. This might be due to neutral pH and moderate temperature were suitable for methane fermentation in the pond. In the three upper-stream ponds, the pond water was acidic in which CO_2 dominated about 60% of biogas. Biogas flux was small in the ponds in lower-stream of the forth pond.

4. Summary

©2019. Japan Geoscience Union. All Right Reserved.

In the POME treatment ponds, decomposition process of organic matter in POME would be different in each stage because of differences in the various environmental factors such as pH, temperature, organic matter content, etc. It was successful in the integration of data in severe environmental condition in the POME treatment ponds despite various technical challenge. Oil palm plantation is a continuous and stationary material flow system as a whole including plant field, mill facility and POME treatment ponds. To fully understand the impact of land-use change on GHGs budget, it is very important to quantify the relationship between GHGs budget and material cycle in the whole plantation system. Besides field measurements, we also do interviews on material flow in the plantation with the cooperation of business entity of the plantation.
We will introduce the result of wet season (January 2019) during this presentation.

Soil CO_2 efflux dynamics with land-use changes in Southeast Asia

*HAJIME TOMIMATSU[1], NAISHEN LIANG[1], MUNEMASA TERAMOTO[1], JIYE ZENG[1], ZHAO XIN[1]

1. National Institute for Environmental Studies

Land use changes greatly affect carbon cycle of forest ecosystem. Since the 1970s, about 35% of tropical primary forests were lost due to disorderly commercial logging, plantation development such as oil palm and rubber in Southeast Asia. These rapid land use changes cause serious environmental problems such as soil erosion, decrease in soil fertility, and decrease in productivity. As a result, there will be a major change in the regional biochemical cycles.

Soil is an important source of information on the global carbon budget and it is a carbon sink, and soil respiration (R_s) is one of the most important elements of the carbon cycle in terrestrial ecosystems. Land use changes influence the dynamics of R_s. However, most studies on the effects of land use change on R_s focused on the boreal, temperate and subtropical ecosystems. In Southeast Asia, we have addressed the response of R_s to the land use changes, but mostly it is a short period with little spatial or temporal repetition, especially there are few long-term observations in lowland rainforests with no seasonal changes in temperature.

To examine the long-term response of R_s to land use change in Southeast Asia, we selected 4 research sites of different land use type, primary forest (PF), secondary forest (SF), oil palm plantation (OP), and rubber plantation (RP). In 2010, we installed total 30 soil collars (diameter 32 cm) in each site. The 30 collars were distributed in two rows, each with 15 collars and at 5 m intervals. R_s was measured every two weeks using a portable automatic opening and closing chamber system developed by the National Institute for Environmental Studies.

R_s showed synchronicity seasonal change among all sites, suggesting that it is controlled by both soil temperature and moisture. The apparent temperature sensitivity of R_s (Q_{10}) decreased from 4.86 in NF to 2.09 in SF, 2.14 in OP, 3.79 in GP. In addition, the annual average soil respiration rate decreased about 38% in SF, about 33% in OP and about 40% in GP compared with NF. Our results indicate that logging and/or conversions of primary forests to plantations lead severe soil degradation.

Individual-based analyses of the carry-over effects from recent climatic conditions on the interannual variability of LAI of an evergreen conifer stand

*Akihiro Sumida[1], Tsutomu Watanabe[1], Tomiyasu Miyaura[2]

1. Institute of Low Temperature Science, Hokkaido University, 2. Faculty of Science and Technology, Ryukoku University

The leaf area index (LAI) of a forest stand has been known to remain within a specific range after a peak at relatively young stand ages. For evergreen stands, however, little has been known about interannual variability of LAI and its effects on biomass increase. In this paper we introduce a series of studies ([1], [2]) in which interannual variability of the LAI and the growth rates of stem biomass were investigated with biological and climatic factors affecting them in an evergreen hinoki cypress (*Chamaecyparis obtusa*) stand between 21 and 40 years of stand age. In this long-term investigation, the stem diameter at the crown base (D_{CB}) was recorded for all living trees each year. This allowed us to estimate the leaf area of a tree (tree LA) using an allometric equation, which is known to be little affected by the difference in stand ages. Given the tapered shape of a tree stem within the crown, a rapid rise of the crown base height can lead to a decrease in D_{CB}, or a decrease in the tree LA. The other measurements also allowed us to estimate the stem dry mass for each tree in each year, and then the stand LAI and the stand stem biomass. The prediction intervals of LAI and stand stem biomass were evaluated for each year by propagating errors of those individual-based estimates. Monthly meteorological data were obtained using the climatic measurements recorded at the nearest weather station (AMeDAS).

The LAI varied between 7.1–8.8, with a relatively long fluctuation cycles over the observation period. This LAI range was maintained such that the gradual increase in the LA of the largest trees counterbalanced the gradual loss in LA of the smallest trees. The decrease in LA of the smallest trees resulted in their gradual death. Just before their death year, their tree LA had decreased to ~1% of the LAI of that year. Hence their death did not affect the LAI. These smallest trees were able to survive for many years even as their LA was decreasing, which would be important for LAI to be maintained without a sudden decrease. The total basal area decreased twice during the 20 years, whereas the stand stem biomass never decreased despite the death of trees. This was because the portion of the stem within the crown maintained a certain level of radial growth even in the trees with almost no stem radial growth at breast height.

There was a weak but significant positive relationship (r=0.40) between the LAI and the current-year mean summer temperature (July and August). This indicates that LAI tended to increase in the year with warm summer during which new leaves are produced. Further, we found that the moving average of the summer temperatures of 6 years (the current year and the previous 5 years) indicated a much stronger relationship (r=0.93) with the current-year LAI. According to a previous study in the same forest, the mean turnover time of the canopy leaves was estimated to be 4.3–6.3 years, suggesting that the summer temperature of the past years when the leaves in the current-year canopy accumulated was strongly influential in the LAI of the current year.

As canopy photosynthesis would generally be proportional to LAI, we had expected that the annual stem biomass increase rate (dB_{STEM}) would be greater in a year with a high LAI. However, the relationship

©2019. Japan Geoscience Union. All Right Reserved.

between them was not significant (r=0.09). Instead, dB_{STEM} had a positive significant relationship with the sum of precipitation of early summer (May-July) of the current year. Preceding studies of tree physiology have pointed out that a considerable portion of non-structural carbohydrates (NSC) from photosynthesis are used for purposes other than growth (e.g., maintenance of physiological homeostasis), and that the priority of the NSC to be allotted to growth would be lower than any other uses. This partly explains why dB_{STEM} was not correlated with LAI.

Carbon dioxide balance of an oil palm plantation on tropical peat

*Takashi Hirano[1], Frankie Kiew[2], Ryuichi Hirata[3], Guan Xhuan Wong[2], Edward Baran Aries[2], Kevin Kemudang[2], Joseph Wenceslaus[2], Lo Kim San[2], Lulie Melling[2]

1. Research Faculty of Agriculture, Hokkaido University, 2. Sarawak Tropical Peat Research Institute, 3. CGER, National Institute for Environmental Studies

Oil palm plantations have been expanding rapidly over recent decades especially in Indonesia and Malaysia, the two largest oil palm producers in the world. The greatest concern associated with such expansion is its environmental impact. Carbon rich tropical peat swamp forest is also not excluded from such expansion, because it is accessible for developers. Carbon dioxide (CO_2) release through accelerated oxidative peat decomposition is one of the main environmental concerns in the land conversion from peat swamp forest into oil palm plantations, which were drained and compacted to increase yield. Changes in aboveground biomass also might significantly alter the CO_2 exchange dynamics of the ecosystems. Despite the possible significant changes in the CO_2 balance through the land conversion, there is still no study on the ecosystem-scale CO_2 balance of oil palm plantations established on tropical peat. Thus, we have monitored CO_2 flux above an oil palm plantation established on tropical peatland in Sarawak, Malaysia by the eddy covariance technique since 2011. We quantify the annual CO_2 balance of the oil palm plantation and compare it with that of a secondary peat swamp forest in the same region.

The effect of heat wave in the summer of 2018 on carbon and water fluxes in an open black spruce forest in an interior Alaska

*Hideki Kobayashi[1], Robert Busey[2], Yongwon Kim[2], Sigrid Dengel[3], Stephen Chan[3]

1. Japan Agency for Marine-Earch Science and Technology, 2. International Arctic Research Center, University of Alaska, Fairbanks, 3. Lawrence Berkeley National Laboratory

Temperatures have been increasing at higher rate in the northern high latitudes than any other regions of the globe, especially over the land areas, and are projected to continue to do so during this century. In interior Alaska, where the majority of landscape is covered with evergreen needleleaf forest, an exceptionally hot dry summer heat wave was observed in July 2018. In this study, we investigated the eddy covariance carbon and water fluxes under the hot dry period in July 2018. The study was performed in an open black spruce forest site located in the Poker Flat Research Range in interior Alaska. Three eddy covariance systems (two enclosed path and one open path eddy covariance systems) were utilized in the study period. We found the significant down regulation of net ecosystem exchanges (NEE) during a high temperature period during DOY 201-206, 2018. We will introduce the results from the carbon and water fluxes with meteorological and spectral measurements in order to understand how the environmental conditions regulated the carbon and water fluxes and how these fluxes are related with the continuous spectral measurements.

[A-CG39] Biogeochemical cycles in Land Ecosystem

convener:Tomomichi Kato(Research Faculty of Agriculture, Hokkaido University), Kazuhito Ichii(Chiba University), Takeshi Ise(FSERC, Kyoto University), Munemasa Teramoto(National Institute for Environmental Studies), Chairperson:Tomomichi Kato(Hokkaido University)

Terrestrial ecosystem influences global climate through cycles of water, carbon, and nitrogen between land surface and atmosphere. For better understanding of those behaviors, a great effort has been paid for developing varieties of approaches and techniques such as biometric survey, eddy and chamber methods, near and satellite remote sensing, biosphere modeling and so on.
 In particular, the JapanFlux, founded in 2006 as a researchers network of CO2, H2O and other trace gas flux measurement, has promoted the multi-disciplinal studies not only for flux measurement community, but also for remote sensing and biosphere modeling communities. Moreover, the Research-Group-on-Integrated-Land-Processes, which was founded in 2006, also has contributed to build networks between Japanese researchers to better understanding of physical and biological processes on interactions between terrestrial surface and atmosphere.
 This session unites those multi-disciplinal activities, and promotes the oral and poster presentations on the role of terrestrial ecosystem in material circulations of water, carbon, nitrogen, energy and other substances by any approaches and technics. This session takes over the former session in last year: A-CG40.

Evaluation of feasibility of continental vegetation monitoring using Himawari-8.

*Kodai Hayashi[1], Kazuhito Ichii[1], Hiroki Yoshioka[2], Kazutaka Murakami[3], Reiko Ide[3], Kenlo Nasahara[4], Tomoko Akitsu[4], Tomoaki Miura[5]

1. Chiba Univ., 2. Aichi Prefectural Univ., 3. NIES, 4. Tsukuba Univ., 5. Univ. Hawaii

A new generation geostationary meteorological satellite, Himawari-8, began operation in July 2015. Due to newly attached multiple bands in the visible and near infrared wavelength ranges and improved observation frequency of onboard sensor, AHI (Advanced Himawari Imager), application to terrestrial monitoring is expected.
Himawari-8/AHI data are provided as the radiance or the reflectance at the top of atmosphere (TOA) level. In order to monitor terrestrial vegetation, conversion to surface reflectance (TOC: Top of canopy reflectance) is necessary. However, the methods to estimate and verify TOC reflectance of Himawari-8/AHI data has not yet been established. Furthermore, the TOC reflectance data of Himawari-8/AHI requires careful interpretation due to observational geometric conditions unique to geostationary orbit.
In order to understand the feature of the TOC reflectance and the normalized index by Himawari-8/AHI data and to evaluate the usefulness for terrestrial vegetation monitoring, first, we estimated the TOC reflectance from Himawari-8/AHI data with 6SV. The estimated TOC reflectance from Himawari-8/AHI was further evaluated using independent observations such as Terra, Aqua MODIS data and ground observations (HemiSpherical Spectro-Radiometer (HSSR) at Phenological Eyes Network (PEN) sites).
We compared the Himawari-8 TOA/TOC reflectances with the MODIS TOA/TOC reflectances from Terra and Aqua. In particular, in the shorter wavelengths such as blue and green, the R^2 was greatly improved by atmospheric correction. Furthermore, if we selected data only with similar illumination and geometric condition of AHI and MODIS, both TOC reflectances were very close to each other in all wavelength bands. Then, we checked the monthly variation in the TOC reflectances of AHI, MODIS, and HSSR. We found that the three TOC reflectances are similar in the first half of the year (spring and summer). However, after summer, the TOC reflectances of AHI were higher than those of MODIS and HSSR. It can be explained by the dominant backward scattering component in AHI in Japan. In particular, the difference in intensity between the backward scattering and the forward scattering increases toward winter seasons. Meanwhile normalized index such as NDVI could effectively reduce the anisotropic effect on the TOC reflectance and it can capture vegetation phenology similar to MODIS. As a result of cross-validation, Himawri-8 TOC reflectance estimated in this study was generally consistent with other data. However it is necessary to consider the observation conditions of the Himawari-8 TOC reflectance. In the next step, we will demonstrate how the high temporal resolution of Himawari-8 improve our understandings of terrestrial vegetation dynamics.

Estimation of global carbon dioxide emissions by fires

*Tomohiro Shiraishi[1], Ryuichi Hirata[1]

1. National Institute for Environmental Studies

Global warming accelerates snow melting and drying which cause forest fires. The forest fire gives positive feedback in global warming because large greenhouse gases are emitted into the atmosphere by the forest fire. The purpose of this study is to estimate carbon emissions caused by forest fire with high spatial and temporal resolution, which are 500 m and daily base.
In this study, we used several satellite observation data to estimate global carbon dioxide emissions by fires from 2001 to 2018. We used MODIS MOD14A 1 product for fire detection, MODIS MCD12Q1 product as land cover classification map, and above ground biomass map created by (Avitabile et al., 2016) in Wageningen university. Carbon dioxide emissions were estimated from burned area, biomass densities, burning efficiencies and emission factors for each land cover categories. The estimated carbon dioxide emissions through 18 years were 6159.77 [Tg/year] on yearly average and 607.26 [Tg/year] on standard deviation. These results underestimated to approximately 11% for GFED4.1s and FINN1.0, 8%, 36% for GFAS 1.0 and G-G (Shi et al., 2015), respectively.

Interactions between topography, permafrost, and vegetation in Siberian larch forest: a simulation study

*Hisashi Sato[1]

1. Institute of Arctic Climate and Environment Research, Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

In eastern Siberia, larches (Larix spp.) often exist in pure stands, constructing the world's largest coniferous forest, of which changes can significantly affect the earth's albedo and the global carbon balance. Siberian larch area locates on the environmental edge of existence of forest ecosystem, and hence small difference in environmental condition alters existence of larch trees.

Indeed, there is a quantitative pattern that topographic properties controls the abundance of larch forest via both drought and flooding stresses in this region; larch abundance appears to be controlled by drought stress in mountainous regions, while controlled by flooding stresses in plain areas (Sato& Kobayashi 2018). Besides, this region is underlaid by permafrost, vegetation productivity is constraint by depth of active layer; plant productivity becomes lower for shallower active layer by reducing liquid-state-water holding capacity (Beers et al. 2007). At the same time, active layer depth is a function of soil wetness, because wetland soil has larger ice content in active layer, which facilitates downward heat conduction to the permafrost, resulting in shallow thaw for the active layers (Woo & Xia 1996).

To reconstruct such complicated interactions between topography, permafrost, and vegetation in Siberian larch forest, the TOPMODEL, which is a physically based streamflow and water-table-depth computation scheme was implemented to a dynamic vegetation model SEIB-DGVM (Sato et al. 2016), which works with a thermohydrology model. In this presentation, I will talk how this integrated model reasonably works, and how it can be employed for future projection of environmental conditions of the Siberian larch region.

Data assimilation experiments with MODIS LAI observation and the dynamic global vegetation model SEIB-DGVM in Japan

*Hazuki Arakida[1], Shunji Kotsuki[1], Shigenori Otsuka[1], Takemasa Miyoshi[1]

1. RIKEN Center for Computational Science

In the previous study, Arakida et al. (2017) developed a data assimilation system with the SEIB-DGVM (Spatially Explicit Individual-Based Dynamic Global Vegetation Model), and assimilated satellite-observed Leaf Area Index (LAI) successfully over Siberia. In this study, we extend the experiment to a Japanese forest at the Takayama flux site and investigate the performance of the data assimilation system. We estimate the vegetation functions and structures, and model parameters related to the phenology of the deciduous broad-leaved tree and the undergrowth. For the climate forcing data, we used the global reanalysis dataset known as the ERA5. The original data assimilation system developed for Siberia turned out not to be suitable for the Japanese forest because of different LAI variabilities between Siberia and Japan. Namely, LAI stays at the saturated level for an extended period in Japan, while in Siberia, the LAI starts to drop soon after it reaches to the maximum value. Therefore, a model parameter which controls the saturated LAI level was considered for additional parameter estimation. In addition, the undergrowth was changed from deciduous to evergreen. The results show that the DA system performs generally well in Japan with the additional parameter estimation and the modification to the undergrowth.

Obtaining ecological data by field observation has been labor intensive. In this study, we present several approaches to obtain ecological bid data, using information technology. First, introduction to data-driven science and big-data science will be presented. As an example of these new approaches, deep learning with neural networks has various applications in ecological studies. In fact, digital images from satellite, UAV, or even smartphone can be the big data. We show how these big data are used to identify specific features of organisms and vegetation. Moreover, deep neural networks can be applied to analyze time-series data and project the future conditions.

[A-CG40] Coastal Ecosystems - 1. Water Cycle and Land-Ocean Interactions

convener:Masahiko Fujii(Faculty of Environmental Earth Science), Makoto Yamada(Faculty of Economics, Ryukoku University), Jun Shoji(The University of Tokyo), Ryo Sugimoto(Faculty of Marine Biosciences, Fukui Prefectural University), Chairperson:Masahiko Fujii, Makoto Yamada

Substances from land which are brought by river and/or submarine groundwater discharge are important for the process of biological production in coastal areas. This session focuses on land-ocean interactions through water cycle. The aim of this session is to create interdisciplinary discussions on the research of connectivity of ecosystems, water cycles in terrestrial and coastal areas, fishery resources and biodiversity. Comprehensive discussion on the mechanisms that promote productivity and biodiversity in coastal ecosystems will be made from the viewpoint of land-ocean interactions. Presentations on water-material cycle in terrestrial and coastal areas, fishery resources, biodiversity and connectivity of the ecosystems are encouraged.
A companion session proposed as "Coastal Ecosystems - 2. Coral reefs, seagrass meadows, and mangroves" focuses on benthic communities in shallow-water ecosystems such as coral reefs, seagrass meadows and mangroves and is dedicated to promote researches on comprehensive assessment and monitoring of ecosystem functions and development of effective means for conservation and restoration. Main focuses of these two sessions are different. However, there are much of information that covers both sessions. Scientists who work on the related field will be able to obtain information and share them with other scientists if they attend to both of these sessions.

Discussion

Submarine groundwater discharge from Mt. Fuji in Suruga Bay(VI)

*Yasuhide Muranaka[1], Takafumi Kamitani[1], Noriaki Fushimi[1], Tomoya Oka[1], Masahiko Ono[2], Atsunao Marui[2]

1. Shizuoka Institute of Environment and Hygiene, 2. National Institute of Advanced Industrial Science and Technology

Around the foot of Mt. Fuji, the main flow passages of groundwater are thought to be in the Younger Fuji volcano, which consists of the pervious basaltic lavas in new volcanic stage. Most of rainfall and melted snow have been considered to be percolating into underground, turning to groundwater, flowing down in the layers of the Younger Fuji volcano and partly discharging from seabed in Suruga Bay. Especially, the Fujikawa-kako fault zone, which stretches south to north in the southwestern side of Mt. Fuji, has a potentially effect on the local groundwater flow system into Suruga Bay. Therefore, precipitation at Mt. Fuji have been considered to be discharging partly from seabed in Suruga Bayand making a impact on the biological production at the coastal sea area.

For the purpose of contribution to make sense of the rich coastal ecosystem in Suruga Bay, we conducted a survey for submarine groundwater discharge (SGD) in Oku-Suruga Bay: from the mouth of the Fuji River, at which the fault is found, to Tagonoura, where the lavas of the Younger Fuji volcano are distributed from 100 to 200 m below sea level. We detected SGD in the top of the cliff in the west of Tagonoura usinga remotelyoperatedvehicle(ROV), sampled seawater containing a high percentage of sea bottom spring water and conducted water quality analyses. In this presentation, we introduce our works noted above.

Relationship between the distribution of freshwater groundwater under the seabed at Obama Bay and the surrounding terrain of the land

*Makoto Yamada[1], Ryo Sugimoto[2], Toshimi Nakajima[3]

1. Faculty of Economics, Ryukoku University, 2. Fuculty of Marine Biosciences, Fukui Prefectural University, 3. Fukui Prefectural University

In Obama bay at north side of Obama City, Fukui Prefecture, research on submarine groundwater discharge (SGD) has been actively carried out so far, and it is clear that the SGD are discharging in Obama Bay. However, there are still many unclear points about the situation of SGD, that is, the distribution of freshwater groundwater under the seabed. Therefore, in this research, in order to clarify the distribution of freshwater groundwater under the seabed, we conducted the survey of resistivity distribution under the seabed by using a towing electric exploration system (SuperSting: Advanced Geosciences, Inc.). We discussed about relationship between the distribution of freshwater groundwater under the seabed and the surrounding terrain of the land from the results and the surrounding land topography.

The range indicated by the resistivity value under the seabed was approximately 0.1 to 6.2 Ohm-m. The place where the relatively high resistivity value of 1 Ohm-m or more was seen was mainly the place close to the land of the alluvial fan. At the north survey area, Observation towards the offshore direction revealed that the high resistivity area extended towards the offshore area. However, further offshore there was no place of high resistivity. These facts suggest that there is a possibility that freshwater groundwater is present in the high resistivity area extending about 500 m from the shoreline to the offshore.

At the estuary of the Kita-river in the south survey area, a high resistivity area was found at a distance of 1 km from the shoreline, suggesting the possibility that freshwater groundwater is present there. According to the bathymetric chart of Obama bay, the slope of the seabed at the offshore of Kita-river is gentle from estuary towards the ocean, which is considered to be covered with sediments derived from Kita-river. The place where high resistivity was observed corresponds to that part. In other words, it is considered that freshwater groundwater is present in the fan-shaped sediment. The above suggests that the groundwater flowing through the basement of the fan in land area may flow through the alluvial fan sediment under the seabed and supply freshwater groundwater under the seabed.
As a result, it was suggested that the distribution of freshwater groundwater under the seabed in Obama Bay was influenced by the spread of the alluvial sediment at the seabed and related to the shape of the alluvial fan in land area.

Influence of recirculated submarine groundwater discharge on phytoplankton dynamics in Moune Bay, Kesennuma

*Toshimi Nakajima[1], Takahiro Kusunoki[1], Yoshitake Takao[1], Ryo Sugimoto[1]

1. Fukui Prefectural University

Riverine inputs are often considered as the main terrestrial source of dissolved inorganic nitrogen (DIN), phosphorus (DIP), and silicon (DSi) in coastal seas. However, the fluxes of nutrients through submarine groundwater discharge (SGD) often exceed riverine inputs in different local and regional scale settings. Although the combined effects of riverine and SGD-derived nutrient inputs are crucial for sustaining marine productivity, a difference of nutrient composition in each source may result in a different response of phytoplankton dynamics in coastal seas. In this study, we evaluated the influence of each nutrient source on phytoplankton dynamics in the head of Kesennuma Bay in June, September and November 2018. Using the short-lived radium and radon isotopes, we quantified the contribution rates of four nutrient sources (river water, fresh SGD, recirculated SGD and offshore waters) on surface waters. Simultaneously, we evaluated productivity, biomass, apparent growth rates and species composition of phytoplankton. In brief results, DIP-enriched recirculated SGD affect significant impacts on phytoplankton dynamics. In the presentation, we will discuss more detailed results.

Estimation of contribution rate of Submarine Groundwater Discharge to *Ulva pertusa* using nitrogen stable isotope ratio analysis

*Tatsuhiro Ishida[1], Masaru Takeuchi[1], Toshimi Nakajima[1], Ryo Sugimoto[1], Shiho Kobayashi[2], Keisuke Koba[3], Keitaro Fukushima[3], Osamu Tominaga[1]

1. Fukui Prefectural University, 2. Kyoto University, 3. Center for Ecological Research,Kyoto Univrsity

In recent years, the influence of Submarine groundwater discharge (SGD) has attracted attention as a source of nutrient that supports biological production in the coastal area. However, the information about the direct influence of SGD on biological production is poor. In this study, in order to examine how much the groundwater contributes to primary production, we collected the primary producer *Ulva pertusa* in Yuza, Yamagata Prefecture, where the groundwater is abundant. On August 27, 2018, we collected sea water, ground water and ambient water around *Ulva* at five sites in the Yuza Coast and simultaneously measured salinity, water temperature, ^{222}Rn concentration which is the indicator of undergroundwater. We also analyzed the nutrient concentration, of sampled water and of *Ulva*. Finally, we estimated the contribution of groundwater to Ulva using two source Bayesian Mixing model. The value of nitrate nitrogen derived from SGD was low. In the high SGD sites (^{222}Rn concentration 427 ~ 22000 Bq/m^3) and the low SGD sites (^{222}Rn concentration 38.1 to 210.6 Bq/m^3), the of *Ulva* was 2.1 to 3.6 and 5.4 to 6.9, respectively. It was suggested that nutrient derived from SGD contributed to the production of *Ulva* in Yuza.

Evaluation of the environmental condition of Submarine Groundwater Discharge (SGD) using carbon and oxygen stable isotope ratio of the sessile bivalve *Crassostrea nippona* shell

*Osamu Tominaga[1], Takeuchi Masaru[1], Ryo Sugimoto[1], Ishida Tatsuhiro[1], Takeru Hirai[1], Toshimi Nakajima[1], Jun Shoji[2], Hisami Honda[4], Makoto Taniguchi[3]

1. Fukui Prefectural University, 2. Tokyo Univ. AORI, 3. RIHN, 4. Fukui Pref Gov

Submarine Groundwater Discharge (SGD) results in various biogeochemical changes in the coastal environments, such as coastal primary production, eutrophication, and benthic production. The SGD condition of 6 sites along volcanic mountain coast in northern Japan was evaluated by using carbon and oxygen stable isotope ratio ($\delta^{13}C$ and $\delta^{18}O$) in the shell of sessile bivalves *Crassostrea nippona*. In order to estimate the proportion of fresh water flow rate in SGD (FR) from the respective $\delta^{13}C$ and $\delta^{18}O$ of *C. nippona* shell, we used the three end member (sea water, riverine water and fresh underground water) bayesian stable isotope mixing model. The significant positive correlation was found between $\delta^{13}C$ and $\delta^{18}O$ of the shell and those of ambient water, respectively. FRs estimated from three source model were 3.1 -8.6% at low ^{222}Rn sites and 21.9-28.5% at high ^{222}Rn sites. At the site (Nishihama) of river mouth, the $\delta^{13}C$ and $\delta^{18}O$ of the shell collected were low (estimated FR 10.6-25.0%) and ^{222}Rn concentration was also low. The contribution of DIC in SGD and riverine water for shell formation was estimated to be 19.8 % and 7.8%, respectively. In the present study, we demonstrated the effectiveness of $\delta^{13}C$ and $\delta^{18}O$ of *C. nippona* shell as the tool for estimating FR.

[A-CG40] Coastal Ecosystems - 1. Water Cycle and Land-Ocean Interactions

convener:Masahiko Fujii(Faculty of Environmental Earth Science), Makoto Yamada(Faculty of Economics, Ryukoku University), Jun Shoji(The University of Tokyo), Ryo Sugimoto(Faculty of Marine Biosciences, Fukui Prefectural University), Chairperson:Masahiko Fujii, Makoto Yamada

Substances from land which are brought by river and/or submarine groundwater discharge are important for the process of biological production in coastal areas. This session focuses on land-ocean interactions through water cycle. The aim of this session is to create interdisciplinary discussions on the research of connectivity of ecosystems, water cycles in terrestrial and coastal areas, fishery resources and biodiversity. Comprehensive discussion on the mechanisms that promote productivity and biodiversity in coastal ecosystems will be made from the viewpoint of land-ocean interactions. Presentations on water-material cycle in terrestrial and coastal areas, fishery resources, biodiversity and connectivity of the ecosystems are encouraged.
A companion session proposed as "Coastal Ecosystems - 2. Coral reefs, seagrass meadows, and mangroves" focuses on benthic communities in shallow-water ecosystems such as coral reefs, seagrass meadows and mangroves and is dedicated to promote researches on comprehensive assessment and monitoring of ecosystem functions and development of effective means for conservation and restoration. Main focuses of these two sessions are different. However, there are much of information that covers both sessions. Scientists who work on the related field will be able to obtain information and share them with other scientists if they attend to both of these sessions.

Discussion

Influence of climate change on river and submarine groundwater discharge for three decades and the change of nutrient fluxes from the land to the coastal area

*Saki KATAZAKAI[1], Jing ZHANG[2], Kota NOJIMA[3]

1. Graduate School of Science and Engineer, University of Toyama, 2. Graduate School of Science and Engineering for Science, University of Toyama, 3. University of Toyama

In Toyama prefecture, 10 billion tons of river and submarine groundwater discharge annually flows in to Toyama Bay containing nutrients (Hatta et al., 2005) . Urasawa et al. (2016) shows that 20-40% of nitrate originated on land contributes to the coastal ecosystems. So it is important to evaluate the state of nutrient transport of from the land to the coastal area. However, global warming has caused an increase in rainfall and a decrease in snowfall in Hokuriku area and it is possible that the states of water and material fluxes has changed over the past years. The aim of this study is to clarify the change of nutrient fluxes via river and submarine groundwater discharge into the coastal area, analyzing hydrogen and oxygen stable isotopes as well as chemical composition.
Results of my analysis, should be, data in my study show that the stable isotopes decreased due to increasing rainfall and decreasing snowfall for three decades. Nitrate and phosphate fluxes are shown to have dramatically decreased as forest and paddy field decreased and the water treatment facilities increased over the years.
These results suggest that nutrient fluxes from the land to coastal zone in this region may continue to decrease due to ongoing climate change and the impact of human activities.

The assessment of human impacts on the distribution patterns of mangroves: a comparative study between the Rewa and Ba delta, Fiji

*Masahiko Fujii[1], Jone Ravuci Sassen[2]

1. Faculty of Environmental Earth Science, 2. Graduate School of Environmental Science

Mangrove ecosystems are among the most productive ecosystems on this planet. They are sources of livelihood to many people, the first walls of protection from storm waves, and nursery grounds for some marine organisms. Unfortunately, mangroves in Fiji are observed to have decreased over the years due to human (induced) activities. Moreover, apart from human impacts, there are several other natural impacts like tropical cyclones that may influence the distribution patterns of mangroves. The aims of this study are: (1) to elucidate changes of the distribution patterns of mangroves and the causes, and based on the results, and (2) to provide practical suggestions for sustainable use of mangroves and saving the ecosystems in Fiji.

To estimate changes in the area of mangroves, satellite imagery data from Landsat 7 and 8 were acquired and analyzed by using Geographic Information System (GIS) to produce land use classification maps for the Rewa delta (in 2002, 2005, 2016 and 2017) and Ba delta (in 2004, 2007, 2010 and 2017) in Fiji. A total of five land cover classes, i.e. mangrove, non-mangrove, urban, barren land, and water were used to classify the land cover. To elucidate causes of the changes in the area of mangroves, social survey was conducted in three villages of Kiuva, Muana I ra and Kinoya in the Rewa delta and three villages of Natutu, Nawaqarua and Votua of the Ba delta, respectively.

The trend in distribution patterns of mangroves was different between the study sites. In the Rewa delta, the area of mangroves has increased from 2002 to 2016 and decreased by 5 km² from 2016 to 2017. In Ba delta, on the other hand, the area decreased from 2004 to 2007, increased from 2007 to 2010, and again decreased from 2010 to 2017. The difference is considered to be caused by the difference in the dependency of people on mangrove ecosystems in the two sites, i.e. higher dependency on mangrove ecosystems for livelihood in the Ba delta with less access to urban centers than in the Rewa delta. Impacts of tropical cyclones and subsequent floods to mangrove ecosystems were also examined as possible climate change stressors, but the impacts were not found clearly in this study.

This study suggests that anthropogenic factors have continuously been major causes of mangrove degradation in Fiji. Mangrove protection in Fiji can be improved firstly by raising people’s awareness on the importance of mangroves to their lives. Secondly, amendment of current legislation might administer the protection of mangrove ecosystems by broadening its scope to monitor the domestic use as well as the commercial use of mangroves. Furthermore, mangrove areas are also required to be designated as “protected areas”, which can be an effective way to guard mangrove ecosystems from human impacts.

Landscape factors affect persistence and accumulation of organic carbon in sediment of secondary mangrove forests: A preliminary study

*Toshihiro Miyajima[1], Rempei Suwa[2], Keith Limuel C. Bejasa[3], Rene N. Rollon[3], Maria Lourdes San Diego-McGlone[3], Caroline M.B. Jaraula[3], Fernando P. Siringan[3], Kenji Ono[4], Yasmin H. Primavera Tirol[5], Yosuke Miyairi[1], Yusuke Yokoyama[1]

Mangroves are swamp forest ecosystem that predominates in low-energy brackish environment of subtropical and tropical coastal systems. Mangroves have a remarkable capacity to capture CO_2 by primary production and sequester organic carbon (OC) in the sediment, thereby contributing to climate change mitigation. Typical carbon sequestration rate and OC stock in top 1 m of mangrove sediment have been estimated to be 1030 kg C ha^{-1} $year^{-1}$ and 723 Mg C ha^{-1}, respectively (median values of available data; Alongi 2018). Mangroves have been vastly degraded by human activities and reclaimed and/or converted to aquacultures and agricultural fields for past a few centuries. Current global loss rate of mangroves has been estimated to be up to 2% per year, which corresponds to an emission of 0.27 to 0.59 Pg CO_2 $year^{-1}$ at the maximum, if OC in top 1 m of sediment is assumed to be entirely reoxidized after reclamation and conversion (Alongi 2018, Atwood et al. 2017). However, the degree to which and the rate at which sediment OC is returned to the atmosphere as CO_2 after degradation of mangroves are still uncertain, and presumably depend on land use pattern and hydrodynamic conditions after conversion. Some part of sediment OC may be reoxidized shortly after conversion, while other parts may remain unoxidized in the soil for long term or be flushed out to the ocean by tidal exchange. To estimate the rate of OC loss after degradation and conversion of mangroves and evaluate how the sediment OC stock may be recovered by reforestation, we are now conducting a multidisciplinary research project in coastal areas of Panay Island, Philippines, where various types of habitats typical to once degraded and converted mangroves are found, such as naturally recovered secondary mangroves, artificially reforested mangroves, artificial mangroves planted on originally seagrass-dominated habitats, and tidal marshes and shrubs growing on abandoned aquaculture plots. Here, we introduce first preliminary results on OC characteristics in sediment cores collected from a naturally-recovered secondary mangrove in an estuarine delta (Ibajay) and a replanted mangrove in a well-protected embayment (Batan Bay). Estimated OC stocks in top 1 m of sediment ranged from 40 Mg C ha^{-1} in lower estuary of Ibajay to 420 Mg C ha^{-1} in Batan Bay, which are significantly lower than the world-median OC stock for natural mangroves mentioned above. Radiocarbon dating showed that the cores from the lower estuarine secondary mangrove were predominated by modern carbon down to a depth of 1 m, which suggests that old OC originally stored in the primary mangrove had been reoxidized and/or washed out to the sea soon after the conversion. In contrast, sediment OC in the upper estuarine secondary mangrove showed a radiocarbon age of 400 –1200 yBP throughout the cores, suggesting that old OC stored in original mangroves persisted at least partially through conversion and subsequent regrowth of the forest. The OC loading, i.e. the amount of OC per unit surface area of sediment grains, seemed to be constrained by the hydrodynamic stability of sediment. This implies that detrital particles derived from mangrove litter was stored at the higher concentrations in sediment of the more protected environment. The curvilinear correlation of stable carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) isotope ratios to the OC loading suggests that

©2019. Japan Geoscience Union. All Right Reserved.

mangrove-derived detritus typically exhibits the $\delta^{13}C$ of −28‰ vs. VPDB and the $\delta^{15}N$ of +0.5‰ vs. atmospheric N_2. The other endmember of sediment OC, putatively marine seston, is represented by the $\delta^{13}C$ of around −25‰ and the $\delta^{15}N$ of +3‰ and tended to decrease with increasing sediment depth. Our results overall showed that both the persistence of old sediment OC and the accumulation of newly supplied detrital OC in secondary mangroves are strongly constrained by the hydrodynamic setting of habitat.

Multiple benefits of blue carbon ecosystems in promoting blue economy and reinforcing resilience in coastal communities

*Atsushi Watanabe[1]

1. The ocean policy research institute, The Sasakawa peace foundation

Blue carbon ecosystems (hereafter BCEs) such as seagrass beds and mangrove forests have recently been paid international attention due to their capability in effectively absorbing and storing carbon dioxide and thus mitigating climate change impacts when they are managed properly. BCEs could also be beneficial to the coastal communities in terms of preventing or minimizing climate change impacts, offering better environmental settings for aquaculture and fisheries, and in turn reinforcing their resilience. For instance ecosystem-based disaster risk reduction (Eco-DRR), sustainable food production through fisheries and aquacultures, and sustainable tourism could enhance adaptation capacity of the coastal community to climate change. The properly managed coastal ecosystems are thus the basis for the secure, safe, and circular coastal society, which is one of the main targets of the sustainable blue economy.
In this presentation, the definition and characteristics of BCEs such as mangrove forests, seagrass beds, coral reefs, and their interlinkages will be introduced first. Then some good examples and lessons learned from coastal communities in Japan as well as Palau will be introduced. Restoration of seagrass beds and coral reefs has involved multi-stakeholders and strengthened socioecological systems in Japanese coastal communities with some innovative ideas or continuing efforts of locals. In Palau, beautiful, unique marine ecosystems have attracted tourists from overseas and environmental fees paid by these tourists have contributed to the conservation and monitoring of these ecosystems in return. Through cataloguing and networking of these good examples from world coastal areas with similar natural or socioeconomic backgrounds, sustainable use of BCEs could be mainstreamed for promoting the blue economy and combating loss of these important ecosystems globally.

Significant storage of organic carbon in mineral matrix in both land and ocean and the role of Fe

*Rota Wagai[1]

1. NARO, Institute for Agro-Environmental Sciences

Land-ocean linkage is one of the least understood aspects in biogeochemistry and carbon (C) cycle, which presumably results from insufficient collaboration between land and ocean scientists as well as the inherent complexity of land-to-ocean processes. At a global scale, the largest C reservoir on land is soil (1500-2400 Pg C) in which major portions of C is stored as organic C (OC) in association with soil mineral particles. In ocean, sediment holds similar amounts of OC. Thus, OC stability and reactivity in soils and sediments have been a great concern as their strong impacts on global C cycle and climate change.

In this talk, I focus on the interaction of organic C with minerals (e.g., aluminosilicate clays, hydrous iron oxides) and discuss the similarity and difference in their interaction between soil and sediment based on my own studies and the literature. I also discuss mechanistic reasons why OC is stabilized in mineral matrix in both systems. An emphasis is given to iron-C interaction due to their high reactivity and ecological importance in both terrestrial and aquatic systems. For instance, OC cycle is linked to N and P cycling as many organic compounds contain N and P. Iron can control P cycle due to strong sorption of phosphate to Fe oxides.

I plan to end my talk by emphasizing that basic understanding of soil formation and biogeochemistry would greatly help when tackling C and nutrient-related questions in river and coastal water.

[A-CG41] Promotion of Application and Utilization of Aircrafts for Earth sciences

convener:Nobuhiro Takahashi(Institute for Space-Earth Environmental Research, Nagoya University), Makoto Koike(Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo), Toshinobu Machida(National Institute for Environmental Studies), Taro Shinoda(Institute for Space-Earth Environmental Research, Nagoya University), Chairperson:Nobuhiro Takahashi(Institute for Space-Earth Environmental Research, Nagoya University)

The problem of global environmental change such as global warming is a problem throughout the Earth and planetary sciences. To confront this problem, progresses of the observations that are dedicated for the monitoring Earth and for the process studies as well as the progresses of numerical prediction models. Aircraft observation has the great advantages of immediate and direct (in-situ) observations which cannot be achieved by Earth observing satellites or ground-based observations. Recently, the importance of aircraft observation is increasing in "in-situ measurements" such as concentration of greenhouse gases, aerosol and cloud particle size distribution, and chemical composition, and "remote sensing" such as three dimensional typhoon observation and observation on forests and vegetation. In addition, the application of aircraft observation to geodesy, study on earthquakes and volcanos are also progressing. However, steady and extensive aircraft observations to fulfill the requirements in Japan are not realized at the present time. Meanwhile, it is also a fact that the aircraft observations which have been carried out has cited the world leading results. In order to realize the effective research by using aircraft, it is necessary to have a close collaborations among researchers to promote aircraft observations, and it is also necessary to carry out as the master plan of national academic council of Japan. In this session, we will discuss the future aircraft observation through the latest research results with aircraft observations.

After the US aircraft reconnaissance in the western North Pacific was terminated in 1987, typhoon intensity is estimated by the Dvorak technique using satellite cloud pattern. Consequently, uncertainty of intensity estimation became large for very intense typhoons. Accurate intensity estimations are essential for prevention and mitigation of typhoon disaster. They are also important information for a study of long-term change of typhoon with the climate change. To improve this problem, the T-PARCII (Tropical cyclone-Pacific Asian Research Campaign for Improvement of Intensity estimations/forecasts) project performs an in situ observation of typhoons. In this project, Nagoya University and Meisei Electric Co., Ltd developed a new dropsonde and a four-channel dropsonde receiver. Using these systems on a jet aircraft, the T-PARCII project performed aircraft observations of very intense typhoons in 2017 and 2018. Typhoon Lan (2017) was the most intense typhoon in 2017 and was categorized as a supertyphoon by JTWC. It moved northeastward in the east of the Okinawa main island at 23 N on 21 October and at 28 N on October 22, 2017. In these two days, we made dropsonde observations inside of the eye and in the surrounding area of the eyewall. The T-PARCII team also made aircraft observations of Typhoon Trami (2018) during the period from 25 to 28 September 2018 in collaboration with the SATREPS ULAT group as well as Taiwan DOTSTAR. The observed dropsonde data were transmitted to GTS (Global Telecommunication System) in real time and were used for typhoon forecasts in 2018.

Because the height of dropsonde is derived from GPS, error of height data becomes large just before the dropsonde reaches to the sea surface. As a result, the sea level pressure is uncertain. Typhoon intensity is represented by the central sea level pressure. Accurate estimation of sea level pressure is necessary for a typhoon intensity information. We, therefore, developed two schemes to estimate the sea level pressure from dropsonde data. Temperature, humidity and pressure are measured by sensors of dropsonde. We assume that the accuracy of these data is sufficiently high and height is also accurate above ~500 m in height. In the scheme I, the sea level pressure is calculated by a pressure correction method from 50~100 observed points in 900~750 hPa. The final result is the average of these calculated sea level pressure values. In the scheme II, heights of observed pressure levels below 800 hPa are calculated by the hydrostatic equation using virtual temperature. The sea level pressure is corrected from the lowest grid point.

These schemes were examined by special observations around Minami-Daitojima comparing dropsonde observations with balloon sonde observations launched from Minami-Daitojima Island as well as the JMA surface observation. The maximum difference of sea level pressure is less than 3 hPa. The central sea level pressures of typhoons Lan and Trami were calculated by the schemes I and II. The results by these two schemes agreed well each other. We consider that the sea level pressures were estimated with a sufficient accuracy. They were compared with the JMA best track data. The difference of central pressure of typhoon Trami was about 5 hPa on September 25 when the typhoon was most intense. It was about 10 hPa on September 28 when the typhoon was weakened in the south of the Okinawa main island.

New observation strategies for typhoon intensity over the western North Pacific

*Hiroyuki Yamada[1], Kazuhisa Tsuboki[2], Taro Shinoda[2], Hisayuki Kubota[3], Yukihiro Takahashi[3], Norio Nagahama[4], Kensaku Shimizu[4], Tadayasu Ohigashi[5], Kosuke Ito[1], Munehiko Yamaguchi[6], Tetsuo Nakazawa[6]

Recent activities on typhoon intensity observation/estimation using aircraft reconnaissance and ground-based Doppler radars in the western North Pacific are introduced. Since aircraft reconnaissance by the US military was ceased in 1987, new techniques of intensity estimation using microwave radiometer and a geostationary satellite are used in this basin without enough verification. The major obstacle of aircraft reconnaissance is the difficulty of having a specially-designed propeller aircraft that withstands strong turbulence. Since wind speed in a typhoon is stronger in the lower troposphere, it takes a great deal of labor and expense to measure the center position and the central pressure of a typhoon through low-altitude flight with slow speed. On the other hand, since the winds become weaker in the upper troposphere, it is possible to fly into the typhoon center if the risks of heavy icing and severe turbulence in a convective burst can be avoided by using an airborne weather radar. During T-PARCII (Tropical Cyclone-Pacific Asian Research Campaign for Improvement of Intensity Estimations / Forecasts), we succeeded in observing the central pressure of two intense typhoons, Lan (2017) and Trami (2018), by using a commercial jet aircraft (Gulfstream-II) with a newly-developed GPS dropsonde system. These flight missions were made in the upper troposphere (43,000ft, approximately 13.7 km) and were marked by very weak turbulence during eyewall penetration. These flights demonstrated a possibility of typhoon intensity observation using a civil aircraft. In the Pacific coast of Japan and Philippines, Doppler radars became available in this decade. The combination of aircraft reconnaissance off the coast with the ground-based velocity track display (GBVTD) analysis near the coast will provide accurate information on typhoon intensity.

Airborne typhoon observations were conducted for Typhoon Trami (2018) under Tropical cyclones-Pacific Asian Research Campaign for Improvement of Intensity estimations/forecasts (T-PARCII). Using the dropsonde data (zonal and meridional winds, temperature, and relative humidity) and the Japan Meteorological Agency Global Spectral Model (JMA/GSM, TL959L100) and 4 Dimensional Variational data assimilation (4DVAR, TL319L100), we performed Observing System Experiment (OSE) to see the impact of the newly available observational date on the track/intensity predictions by the JMA/GSM.

Three sets of numerical experiments, CNTL, EXP1 and EXP2, were performed. All the T-PARCII dropsonde and typhoon bogus data were used in the data assimilation in CNTL while T-PARCII dropsonde (typhoon bogus) data only were assimilated in the 4DVAR in EXP1 (EXP2). The period of the experiments is from 2018.09.25 00UTC to 2018.09.28 18UTC with a 6-hour data assimilation and forecasting cycle.

The error of the track predictions of EXP1 and EXP2 is smaller than that of CNTL. For example, the 3-day track prediction error of CNTL, EXP1 and EXP2 is 232, 201 and 218 km, respectively. A possible reason of the degradation of the track predictions by CNTL is that some dropsonde data were assimilated at the almost same locations as typhoon bogus data, which might deteriorate the initial structure of the typhoon.

In the operational configuration of the 4DVAR, all dropsonde data were assimilated irrespective of the existence of the typhoon bogus data. The results of a series of these numerical experiments may lead to improvement in the operational setting of dropsonde assimilation.

In this presentation, we will talk about the basic behaviors, microphysical and associated optical properties, and transport-and-removal processes of the tropospheric black carbon and iron oxide aerosol which have been elucidated mostly from aircraft measurements. We will clarify the scientific significance and contribution of these findings in the context of the related international research activities on atmospheric aerosols and climate change. In addition, we will suggest some related open problems which need to be investigated through in-situ aircraft measurements in future research.

Aerosol measurements around the ridge of East Antarctica using a Rogallo wing UAV

*Ryohei Haraguchi[1], Masahiko Hayashi[1], Keiichiro Hara[1], Naohiko Hirasawa[2], Koki Nakata[3], Kei-ichi Ozuka[4,1]

1. Fukuoka University, 2. National Institute of Polar Research, 3. kkt Inovate Co., Ltd, 4. Nippon Tungsten Co., Ltd

Meteorological observations using a UAV in the Antarctica have been carried out at S17 Air Base (69° 02’ S, 40° 06’ E, 606m a.s.l.), near Syowa Base by the 48th, 54th, and 56th Japanese Antarctic Research Expedition, (JARE). The JARE 58th planned to perform meteorological observations including snow, water vapor and aerosols budgets at S17 during December 22nd, 2016 and February 4th, 2017. One of main mission of the observation focused on aerosol processes using automated UAVs with a Rogallo wing, called Kite Planes. Two types of Kite Planes were used for different type observations. One is engine powered Kite Plane for horizontal observations with a condensation particle counter, an optical particle counter, and an aerosol sampler for SEM/EDX analyses. Another is a glider KitePlane supported by electric motor with an optical particle counter for vertical distribution observations. 22 flights were successfully carried out during the campaign of JARE 58th and obtained following results.

1. Uniformity in CN and Mie particle concentrations is very high during January in 2017.
2. Low CN concentrations were sometimes observed near surface.
3. High CN event with low Mie particle concentration from free troposphere was observed on January 23rd, suggesting caused by new particle formation.
4. High CN event with high Mie particle concentration from ocean area was observed on January 27th, 2017, suggesting hygroscopic growth of aerosols from marin boundary layer.

Un-manned Aerial Vehicles have been developing rapidly and performance as observation platform are increasing. Our group have used Rogallo wing UAV, called KitePlane for aerosol measurement about 20 years ago. In-situ wind measurements have tested, becuase of importance for meteorological analyses and technical requirements for safety flight operations. There are two typical methods for atmospheric wind measurements based on in-situ data by in-flight airplane. One is direct calculation method by difference between gound speed and true air speed. The other is that drift of center of hodograph circle for ground speed coinsident with wind vector during flight.
Time and spatial resolutions for the direct calculations are around 1 second and 10 m respectively, and require high accuracy for true wind vectors. On the other hand, those for the hodograph methods are around 1 minuite and several hundreds meters, respectively, however the method only require position and time for calculations.
It will be presented based on actual flight by KitePlane that accuracies of wind speeds and directions are around 0.1m/sec and several degrees for both methods with recently developed small and precision sensors.

[A-CG44] Coastal Ecosystems 2 Coral reefs, seagrass and macroalgal beds, and mangrove

convener:Yu Umezawa(Tokyo University of Agriculture and Technology), Toshihiro Miyajima(Marine Biogeochemistry Group, Division of Ocean-Earth System Science, Atmosphere and Ocean Research Institute, The University of Tokyo), Atsushi Watanabe(The ocean policy research institute, The Sasakawa peace foundation), Tomihiko Higuchi(Atmosphere and Ocean Research Institute, The University of Tokyo), Chairperson:Yu Umezawa(Tokyo University of Agriculture and Technology), Toshihiro Miyajima(The University of Tokyo), Tomihiko Higuchi(Atmosphere and Ocean Research Institute, The University of Tokyo), Atsushi Watanabe(Tokyo Institute of Technology)

Coastal marine ecosystems are complex open system interacting with surrounding watersheds, outer ocean, and the atmosphere, providing a wealth of various ecosystem services to human life. Simultaneously, they are also influenced strongly and often negatively by human activities. This session, together with a companion session dedicated for the water cycle and land-ocean interactions, aims to provide a platform for interdisciplinary discussion covering various aspects of frontiers in coastal ecosystem sciences. This session particularly focuses shallow-water benthic communities ranging from temperate to tropical regions, such as coral reefs, seagrass and macroalgal beds, and mangroves. All these communities are characterized by intrinsically high primary production, active material cycling, and biodiversity hot spots. However, increasing human demand for coastal marine resources and industrial development concentrating on coastal regions incur the risk of rapid degradation and diminishment. Comprehensive assessment and monitoring of ecosystem functions and development of effective means for conservation and restoration are urgently needed for such communities. This session is dedicated to organizing and promoting such research and management activities by sharing state-of-the-art science and technology among ecologists, geologists, geochemists, biogeographers, etc. Field-based and modeling studies concerning the following topics are especially welcome: material cycling and ecosystem functions; community connectivity; environmental changes such as global warming, ocean acidification, and sea-level rise; ecosystem services such as carbon sequestration, nutrient regulation, and fisheries production; broad-scale comparison; long-term ecological researches.

Evaluation of mangrove ecosystems as a dissolved iron supplying system to tropical coastal waters

*Yasuhiro Nakanishi[1], Ko Hinokidani[1]

1. Tokyo University of Agriculture

Iron, one of the essential micro elements for plants, is normally contained in the insoluble forms in sea water, content of the dissolved forms greatly affects propagations of marine phytoplankton which are origins of the marine food chain and absorb CO_2 in sea water.

As one of the studies on natural systems for dissolved forms of iron from land to sea, we focused on mangrove ecosystems located at boundary between the land and sea in the tropical regions. To clarify the dissolved iron supplying systems, we have conducted studies on polyphenols content in leaves of some mangrove species and elution of dissolved iron generated in reactions between the polyphenols and mangrove floor soils. Additionally, we surveyed dissolved iron elution from the floor soils mixed with fecal materials of benthos, such as *Neosarmatium smith* and *Telebralia palustris* which feed on mangrove leaves.

Among different wetland habitats, mangroves are key source of dissolved organic matter (DOM) for the estuarine and coastal waters. However, the quantity and quality of DOM from both natural and rehabilitated mangroves sustained under contrasting hydro-climatological settings of tropical and subtropical regions have not been examined comprehensively. The present study was carried out in areas of such regions in the tropics (Panay and Palawan, Philippines) and sub-tropics (Ishigaki and Iriomote, Japan). Surface water sampling was performed along the salinity gradient of mangrove dominated rivers and estuaries in 2018, aiming to investigate the distribution, mixing and fate of dissolved organic carbon (DOC), δ^{13}C-DOC and optical properties such as chromophoric dissolved organic matter (as CDOM). Preliminary results showed that mean DOC concentration was ~2-fold higher in Ishigaki and Iriomote than Panay and Palawan mangroves (225±111 μM and 103±52 μM, respectively) due to dilution effect by increased rain water flux from the typhoon event during sampling in Panay and Palawan. Strong correlation between DOC and CDOM absorption coefficient at 412 nm was only evident for the Ishigaki and Iriomote mangroves, indicative of dominance of predominantly allochthonous DOM. In the Philippines, there were no significant variations of DOM properties observed between natural (Palawan) and rehabilitated (Panay) mangroves but their mixing pattern along the salinity transect differed significantly. Property-salinity relationship revealed regions of non-linear mixing of DOC for both sites demonstrating dynamic source-sink reaction processes within the river estuaries. During the course of transport to the sea, DOC was added to the waters in Palawan in contrast to the recruited mangroves of Panay reflecting higher mangrove material input for the former site. Other optical descriptors (like spectra slope between 275 nm and 295 nm, and slope ratio in the ranges of 275-295 nm and 350-400 nm) confirmed the shift in DOM origin from terrigenous to marine sources along the salinity transects of the river estuaries. The linear decreasing trend of specific UV absorption at 254 nm ($SUVA_{254}$) further indicated the loss of DOM aromaticity downstream to the sea. Further attempt will be made to better characterize the DOM molecular compositions and fluorescence properties from the same tropical and sub-tropical mangrove sites.

Modeling coral polyp-scale bleaching phenomenon and upscaling to reef-scale

*Takashi Nakamura[1], Tomihiko Higuchi[2], Toshihiro Miyajima[2], Lawrence Patrick Cases Bernardo[1], Kazuo Nadaoka[1], Atsushi Watanabe[1,3], Hiroyuki Fujimura[4]

1. School of Environment and Society, Tokyo Institute of Technology, 2. AORI, The University of Tokyo, 3. The ocean policy research institute, The Sasakawa peace foundation, 4. University of the Ryukyus

To elucidate the mechanism responsible for coral bleaching and to project the status of coral communities in the near future, a coral bleaching model was developed based on a reef-scale three-dimensional hydrodynamic–biogeochemical model coupled with a polyp-scale coral bleaching model.

The polyp-scale bleaching model was developed by incorporating the dynamics of photoinhibition, reactive oxygen species (ROS), and zooxanthella abundance based on a previously developed coral polyp model by Nakamura et al. (2013). The polyp-scale model assumes that ROS are produced by zooxanthellae and that corals expel zooxanthellae when the concentration of ROS in their tissues exceeds tolerable levels. When temperature increases, corals release more zooxanthellae because the ROS production rate per zooxanthella cell increases with increasing temperature. This mechanism accounts for coral bleaching at high temperatures. The model assumes that ROS are produced from excess electrons transferred from photosystem II (PSII) that are not used in the downstream photosynthetic process. Photoinhibition, which is a key factor in the transfer of electrons from PSII, was included in the model, and the temperature dependence of Rubisco activity was introduced as a blocking factor in the downstream photosynthetic process. The ROS dynamics include detoxification of ROS by antioxidant substances, and the zooxanthella population dynamics include reproduction, mortality, and the rate of zooxanthellae release, which depends on the ROS damage of the coral cell. Results of simulated incubation experiments under different temperature conditions by the bleaching model reproduced the temperature dependence of the coral bleaching phenomenon. Moreover, recovery process after bleaching was also reproduced, and the ability of the model to describe the recovery process is a unique feature. The model also reproduced the phenomenon that coral bleaching is effectively reduced by light shading. A comparison between photoinhibition and its absence revealed that photoinhibition effectively reduced electron transport from PSII and consequently reduced the production of excess electrons that form ROS. Photoinhibition therefore protects the photosystem and tissues from oxidative damage by ROS. A temperature-dependent repair delay from photoinhibition also reduces ROS production and thereby prevents coral bleaching. The delay may be strategically controlled by zooxanthellae.

The polyp-scale bleaching model was coupled with reef-scale hydrodynamic-biogeochemical model based on the model framework by Nakamura et al. (2018). The model was applied to both the Shiraho coral reef based on Nakamura et al. (2018), and Sekisei Lagoon based on Bernardo et al. (2017). The results of the model simulation confirmed that the model accurately reproduced the spatiotemporal variations of bottom water temperatures on the reef. In particular, the temperatures during the daytime were significantly higher on the reef crest and in shallow nearshore areas than in the offshore seawater. The model confirmed that the spatial pattern of zooxanthella density coincided with the spatial pattern of water temperature on the reef. The model can use the internal condition of the corals to output the parameters that characterize coral population dynamics, such as coral growth rates and mortality rates. The coupled model therefore has the potential to simulate long-term spatiotemporal changes in coral

©2019. Japan Geoscience Union. All Right Reserved.

coverage. Although the model still needs some improvement, incorporation of additional modules and improvement of the model will make it a useful tool for evaluating how corals respond to multiple environmental stresses on the reef-scale.

Reversal of surface ocean acidification and recovery potential of calcification: ecology of proton concentration control

*Kazuhiko Ichikawa[1]

1. (post) Graduate School of Environmental Earth Science, Hokkaido University

Surface ocean ecology is open system under anthropogenic effect on atmosphere. Coral reefs and individual coral polyps are interacting with surrounding watersheds. They are influenced strongly and often negatively by human activities. All the coordinates pointed out by atmospheric PCO2 and surface ocean pH were irregularly scattered at PCO2 > 290ppm under anthropogenic effect on surface ocean. The calcifying organism habitats of surface ocean are controlled by the proton dynamics and chemical physics of comprehensive global-environment. The surface oceans of calcifying organism habitats showed the proper base of ~8.0 < pH < ~8.3 at ~200ppm < P_{CO2} < ~290ppm under no anthropogenic effect on P_{CO2}. The calcifying organism habitats of surface ocean are controlled by the proton dynamics and chemical physics of comprehensive global-environment.Surface ocean ecology is open system under anthropogenic effect on atmosphere. Revisit of massive *Porites* coral growth under the outbreak of crown-of-thorns starfish and thermal stress in Sekisei Lagoon, Japan

*Kohki Sowa[1]

1. Japan Agency for Marine-Earth Science and Technology

Recently, shallow water coral reefs have come under high pressure because of the changes in climate due to global warming and water quality due to pollution. Coral reefs, which are distributed from the tropical to the temperate areas, consist of calcareous biotas such as scleractinian corals. As the coral skeletal growth is one of the candidate proxies for representing the whole coral reef health, it can provide vital information for developing effective conservation strategies for coral reefs. However, there are only a few studies on the long-term and *in-situ* verification of the relationships among coral skeletal growth, and changes in coral ecology and climate information.

Sekisei area is located between the Yaeyama Islands and the largest coral reef lagoon in Japan (approximately 400 km^2). Continual monitoring of coral and crown-of-thorns starfish (COTS) started in 1983, and the results revealed the negative effects of the outbreak of COTS and the thermal stress-induced severe damage to coral reef ecology. Massive *Porites* coral is one of the key species in the framework of coral reefs in North-West Pacific. The coral continuously precipitates carbonate skeleton over its previous frame, which provides us an opportunity to hindcast the skeletal growth for the long term. Therefore, massive *Porites* coral skeleton in Sekisei Lagoon offers an opportunity to verify whether their skeletal growth is an indicator of coral reef health.

This study shows the revisit of long-term massive *Porites* coral growth (extension rate) estimated from the coral cores in Sekisei Lagoon from 1965 to 2000 reported by Omata *et al.* (2002). Eighty-two coral cores were collected from 12 areas, including reef fronts and patch reefs in Sekisei Lagoon. This study then selected seventy-four coral cores. The average growth anomaly decreased from the 1980s to 1990, which corresponded to decreasing coral coverage. The results imply that the growth of *Porites* coral would be an indicator of the changes in coral coverage by biodisturbance in this area. On the contrary, there were several reductions in extension anomaly, but it did not entirely correspond to the coral bleaching events in 1983 and 1998. These results imply that the growth of *Porites* coral does not represent the coral bleaching events in this area.

[A-CG44] Coastal Ecosystems 2 Coral reefs, seagrass and macroalgal beds, and mangrove

convener:Yu Umezawa(Tokyo University of Agriculture and Technology), Toshihiro Miyajima(Marine Biogeochemistry Group, Division of Ocean-Earth System Science, Atmosphere and Ocean Research Institute, The University of Tokyo), Atsushi Watanabe(The ocean policy research institute, The Sasakawa peace foundation), Tomihiko Higuchi(Atmosphere and Ocean Research Institute, The University of Tokyo), Chairperson:Yu Umezawa(Tokyo University of Agriculture and Technology), Toshihiro Miyajima(The University of Tokyo), Atsushi Watanabe(Tokyo Institute of Technology), Tomihiko Higuchi(Atmosphere and Ocean Research Institute, The University of Tokyo)

Coastal marine ecosystems are complex open system interacting with surrounding watersheds, outer ocean, and the atmosphere, providing a wealth of various ecosystem services to human life. Simultaneously, they are also influenced strongly and often negatively by human activities. This session, together with a companion session dedicated for the water cycle and land-ocean interactions, aims to provide a platform for interdisciplinary discussion covering various aspects of frontiers in coastal ecosystem sciences. This session particularly focuses shallow-water benthic communities ranging from temperate to tropical regions, such as coral reefs, seagrass and macroalgal beds, and mangroves. All these communities are characterized by intrinsically high primary production, active material cycling, and biodiversity hot spots. However, increasing human demand for coastal marine resources and industrial development concentrating on coastal regions incur the risk of rapid degradation and diminishment. Comprehensive assessment and monitoring of ecosystem functions and development of effective means for conservation and restoration are urgently needed for such communities. This session is dedicated to organizing and promoting such research and management activities by sharing state-of-the-art science and technology among ecologists, geologists, geochemists, biogeographers, etc. Field-based and modeling studies concerning the following topics are especially welcome: material cycling and ecosystem functions; community connectivity; environmental changes such as global warming, ocean acidification, and sea-level rise; ecosystem services such as carbon sequestration, nutrient regulation, and fisheries production; broad-scale comparison; long-term ecological researches.

Discussion

Reconstructing sedimentation process of lagoon sediment in the Eastern Kume Island, Ryukyus

*Wataru Sano[1], Shoko Hirabayashi[2], Yusuke Yokoyama[3], Yosuke Miyairi[3], Kazuhiko Fujita[4], Hironobu Kan[2], Lauren T. Toth[5], Richard B. Aronson[6]

Florida Institute of Technology

This study aims to reveal the sedimentation process of the barrier reef lagoon in the Eastern Kume Island. We drilled at two sites (the south of Ooha island and the east of Eef beach)in Kume Island and obtained 4 cores. The penetration depth of cores were from 2.4 to 4.2 m. Unlithified sediments in coral reef lagoons in Kume Island were mainly composed of bioclast such as branching coral pebbles, foraminifera, shell, algae and lime mud.
We measured radiocarbon dating of 28 samples (18 coral pebbles and 10 foraminifera) in the cores and estimated their sedimentation rates. The results showed that the sedimentation rate was slow at the south of Ooha Island, but rapid at Eef beach. The timing of rapid sediment accumulation at Ooha Island coincided with the timing of relative sea-level rise around 6.7 ka and reached its highest level at Tonaki Island (Kan et al.,1997) locating next to Kume Island. The sediment accumulation at Eef Beach was from 4.1 to 3.2 ka and it lagged behind Ooha Island. It may be because the coastal plain was developed with three beach ridges behind Eef Beach (Kawana,1990) and the coring sites were located at the front of the coastal plain formation.
This study was supported by JSPS and the U.S. National Science Foundation.

Addressing challenges in long-term coral reef monitoring: Statistical tools to address the effect of new methods

*Iwao Fujii[1,2], Jennifer Selgrath[3,2], Amanda Vincent[2]

1. The Ocean Policy Research Institute of the Sasakawa Peace Foundation, 2. Project Seahorse, Institute of the Oceans and Fisheries, The University of British Columbia, 3. Hopkins Marine Station, Stanford University

Tracking how coral responds to marine protected areas (MPA) is critical for the effective coral reef management. Ideally, one method would be employed consistently throughout monitoring, but such longitudinal sampling can pose problems of methodology. Some possible reasons include a possibility of a current method found inappropriate in the course of monitoring or development of new preferred approaches over time. What happens when procedures are suboptimal and must be changed? Our project evaluated how data from two reef survey methods, line intercept transect (LIT) and photoquadrat (PQ), estimated coral cover. We then explored a way of combining data from different sources as one time-series dataset.

Data used in this study were collected in a three-year period of 18-year monitoring, where both LIT and PQ were executed. Monitoring surveys were conducted between 1998 and 2016 in dry and wet seasons (March ~ April, and September ~ October, respectively) at eight MPAs. LIT was used in the first half of monitoring (1998 ~ 2010) and PQ in the later half (2008 ~ 2016). Both methods were used between 2008 and 2010 as a transition period. In LIT, two 20 m transects were set up as fixed transects in each MPA; however, this method was replaced with PQ due to difficulties in maintaining the transects as fixed. In PQ, ten 23 m transects were placed haphazardly at each MPA. The surveys were conducted at the depth shallower than 5 m. LIT data were also sampled from areas between 5 and 10 m, but data from the deep areas were not included in this study.

In a comparison of data from the transition period, LIT showed higher mean percent coral cover than PQ (LIT mean: 40.5 %, PQ mean: 31.1 %). However, a difference between the two methods became insignificant after increasing sample sizes of LIT data by resampling (LIT mean after resampling: 39.0 %). In resampling, two 20 m LIT transects were subsetted by 1 m and thus, 40 samples were generated. In an analysis of coral cover change over time, PQ showed significant results (5.8 % decrease / year) whereas LIT exhibited insignificant results (1.8 % increase / year). This difference can be attributed to characteristics of PQ, where larger sample sizes were collected from wider areas. Although temporal patterns of LIT did not significantly change even after resampling, a comparability between the two methods can increase by adding deep LIT data, given there is no depth effect. These results confirmed that a difference in sample sizes and areas need to be carefully considered when data form different sources are analyzed. In addition, they indicated that resampling can be effective to improve comparability of different datasets. The results from this study can help improve the quality of monitoring data and thus, contributed to more powerful coral reef conservation.

Ocean currents and herbivory drive macroalgae-to-coral community shift under climate warming

*Naoki H. Kumagai[1], Jorge García Molinos[2], Hiroya Yamano[1], Shintaro Takao[1], Masahiko Fujii[2], Yasuhiro Yamanaka[2]

1. National Institute for Environmental Studies, 2. Hokkaido University

Range shifts in foundation species induced by global warming are likely to have ecosystem-wide implications for biodiversity, ecological functioning, biogeochemical cycling and resources used by humans. Corals and macroalgae are habitat-forming species in coastal ecosystems that co-occur and compete for space, and thus global degradation of coral reefs and macroalgal beds can have ecosystem-wide implications. However, recent studies in warm temperate zones have documented community shifts from macroalgae to corals, signaling a potential mechanism for coral conservation under climate warming at the expense of macroalgae under climate warming. Although such community shifts are expanding geographically, our understanding of the driving processes is still limited. Here, we reconstruct long-term climate-driven range shifts in 30 species of macroalgae (8 kelp and 22 fucoid species), 12 species of corals and three species of herbivorous fishes (records of overgrazing) from over 60 years records (mainly 1950–2015) stretching across 3,000 km of the Japanese archipelago from tropical to subarctic zones.

The direction and rate of the observed range shifts calculated for each species and coast during the study period showed considerable variation in both distribution centroids and range edges. Expansions were scarcer than contractions in macroalgae, whereas fishes and corals experienced expansions much more frequently than contractions. Expansions were fastest in fishes, followed by corals, fucoids and kelps, whereas macroalgae contracted their range faster than corals and fishes. Based on a revised coastal version of climate velocity trajectories and a Bayesian inference, we found that prediction models combining the effects of climate and ocean currents consistently explained observed community shifts significantly better than those relying on climate alone. Corals and herbivorous fishes performed better at exploiting opportunities offered by this interaction.

The contrasting range dynamics for these taxa suggest that ocean warming is promoting macroalgal-to-coral shifts both directly by increased competition from the expansion of tropical corals into the contracting temperate macroalgae, and indirectly via deforestation by the expansion of tropical herbivorous fish. Beyond individual species' effects, our results provide novel evidence on the important role that the interaction between climate warming and external forces conditioning the dispersal of organisms, such as ocean currents, can have in shaping community-level responses, with concomitant changes to ecosystem structure and functioning. Further, we found that community shifts from macroalgae to corals might accelerate with future climate warming, highlighting the complexity of managing these evolving communities under future climate change. Nevertheless, and although expansion rates are faster than contraction rates overall, we found that not only macroalgae but even corals might be unable to keep pace with climate change. This may suggest that the apparent expansion in overall range might be a transient effect potentially masking risk of metapopulation collapse with decreasing connectivity among local populations and future range collapses. Thus, future conservation of these communities might require of a more proactive management towards climate adaptation including abundance control of herbivorous fishes, artificial assistance for thermal adaptation through selection of thermal-tolerant lineages, or relocation and translocation into cooler areas.

Estimation of temperature of seaweed bed vegetation boundary in the Western Seto Inland Sea using satellite SST

*Naoki Yoshie[1], Anri Kabe[1], Hiromori Shimabukuro[2], Goro Yoshida[2]

1. Center for Marine Environmental Studies, Ehime University, 2. Japan Fisheries Research and Education Agency

Seaweed bed is algal community in the coastal region, and important for the coastal fishing. It provides various ecosystem services to human society. However, it has been changing seriously, especially in the species and composition and habitat. Therefore, vegetation and distribution of seaweed in the near future is regarded as uneasiness by fisher men. Although several studies had reported the changes associated with the warming of sea surface temperature due to the climate change, they have some problems, such as low spatial-temporal resolution for the coastal region. Moreover, the boundary temperatures of the seaweed vegetation are not clear. In this study, I investigated the boundary temperature of seaweed vegetation in the Bungo Channel by using a satellite sea surface temperature data set (NOAA/AVHRR Pathfinder version5.3 level 3 collated global 4km sea surface temperature) which had enough resolution for the coastal region. The Bungo Channel has large gradient of sea surface temperature and various seaweed vegetation. First, I analyzed the accuracy of the satellite temperature in this region by comparing with ship board observation. The result shows that the accuracy of the satellite temperature in winter is enough high (RMSE<0.74℃), while the accuracy in summer is relative low (RMSE<1.25℃) compared with those in winter. Secondly, I analyzed the time series of the temperatures of three boundaries of seaweed vegetation both winter and summer. One is the restrictive temperature of the southern limit of temperate kelps habitat. Second is the restrictive temperature of the southern limit of the other temperate seaweeds habitat. Third is the restrictive temperature of the southern limit of the transition region between temperate and subtropical seaweeds (i.e., the northern limit of subtropical seaweeds). I found that the restrictive temperatures in winter were 14.5℃, 15.0℃, 16.0℃, and also the restrictive temperatures in summer were 26.0℃, 26.5℃, 27.0℃, respectively. The restrictive temperature of the southern limit of temperate kelps moved northward from 1989 when the winter temperature have been over 14.5℃. It was also affected by warm summer temperature changing in the 2000s. The restrictive temperature of the southern limit of the other temperate seaweed habitat was considered to be strongly affected by the warm winter temperature over 15.0℃ after the 1990s. Invasion of the subtropical seaweed seemed to be related with the disappearance of the temperate seaweed which lived in there after the 1990s.

Fate of macroalgal organic matter and its effects on in and outside of algal bed

*Shigeki Wada[1], Yuko Omori[1], Takeo Hama[1,2]

1. University of Tsukuba, 2. Dokkyo University

Macroalgal bed is known as one of the most productive biome on the earth’ s surface. Their habitat is limited to shallow coastal region, but the coastal environments are linked with the open oceans. A part of organic matter derived from macroalgae would be exported, and it contributes to ecosystem outside of algal bed. Dislodgement of algal body from their base provide drifting algae which would be partly utilized by organisms in offshore. Another fate of organic matter which is exported would be dissolved organic matter (DOM). DOM is exuded to body surface of macroalgae, and transported with mixing of water mass. Based on quantitative estimates of these fate of macroalgal products, we have tried to evaluate the ecological roles of macroalgae in large special scale.

Dislodgement of macroalgae

Dislodgement of macroalgal body would often happen due to wave action. In order to quantitatively estimate the amount of dislodgement, we labeled the body of *Ecklonia cava* which is dominant species in kelp forest around Shimoda, Izu Peninsula, Shizuoka, Japan. A part of labels was disappeared due to dislodgement, and it accounted for about 20-30% of fixed carbon by *E. cava*. In addition, we collected benthic organisms in offshore region with/without drifting algae, showing settlement of drifting algae increases species diversity of fauna on the seafloor.

Macroalgal DOM

Release rate of DOM is estimated by covering bag on blades of *E. cava*, and approximately 40% of fixed carbon is released as DOM. Horizontal distribution of DOM across algal bed to offshore showed a gradient of macroalgal DOM, being consistent with the fact that *E. cava* releases large amount of DOM in coastal region. We additionally examined the microbial and photochemical decomposition processes of the macroalgal DOM. Macroalgal DOM has a resistance for bacterial mineralization, while it was degraded by exposure to sunlight. Therefore, macroalgal DOM would be exported with mixing of water mass, and it is partly decomposed in surface layer. On the other hand, the fraction transported to deeper layer has resistance for bacterial decomposition, and contributes to carbon sequestration.

[A-CG45] Visible Remote Sensing of Hydrospheric Science and Its Application

convener:Joji Ishizaka(Institute for Space-Earth Environmental Research, Nagoya University), Mitsuhiro Toratani(School of Engineering, Tokai University), Yuji Sakuno(Graduate School of Engineering, Hiroshima University), Toru Hirawake(Faculty of Fisheries Sciences, Hokkaido University), Chairperson:Yuji Sakuno(広島大学大学院工学研究科)

Variety of visible remote sensing data for hydrospheric science is now available. For example, it is known that 20 years of long time series of 1 km resolution ocean color data from OCTS-SeaWiFS-MODIS is available. At the end of 2017, 250 m resolution SGLI (Shikisai) was launched by JAXA, and with 300 m resolution European OLSI it became possible to use high resolution and high frequency data. Furthermore, geostationary satellite data from Korean GOCI is also useful. Not only the satellite variety, diversity of products is also increasing from just phytoplankton pigment, chlorophyll-a, to primary production, phytoplankton community structure and even non-phytoplankton materials and optical properties. Those ocean color satellite data should be useful for various fields of hydrospheric science, combining with higher resolution LANDSAT as well as high frequency Himawari data. In this section, we will discuss the variety of new observations and applications of visible remote sensing in hydrospheric science.

Further information in the coastal areas from 250-m resolution multiple bands of GCOM-C “SHIKISAI”

*Hiroshi Murakami[1], Manabu Shimizu[2], Goh Onizuka[3]

1. Earth Observation Research Center, Japan Aerospace Exploration Agency, 2. Japan Fisheries Research and Education Agency, 3. National Research Institute of Fisheries and Environment of Inland Sea, Japan Fisheries Research and Education Agency

Generally, since the optical characteristics of a coastal area is more complicated than an open ocean, it is necessary to take into consideration the regionality of the in-water optical properties (absorption and scattering, and their spectral characteristics) in order to estimate biological variables like a chlorophyll-a concentration from satellite observations. On the other hand, the optical properties may be useful as new environment information if they can be derived correctly.

The Second-generation Global Imager (SGLI) boarded on Global Change Observation Mission - Climate (GCOM-C) has launched in Dec. 2017. Since SGLI has 19 observation channels with 250-m spatial resolution in the visible - infrared wavelengths, applications near the coastal areas are expected to be improved. The SGLI channels (380, 412, 443, 490, 530, 565, 672, and 867 nm) include a near-ultraviolet band (380 nm) and a pair of an absorption and a baseline in comparatively longer wavelengths (530 nm and 565 nm) which can improve estimate of high chlorophyll-a concentration since the absorption is not saturated with the high concentration in the wavelengths.

GCOM-C captured patches where water-leaving reflectance (r_w) of 565-nm, which is derived by the atmospheric radiative transfer code, Pstar-4 (Ota et al., 2010), were especially higher compared with r_w at 530 nm in the central part of the Seto Inland Sea on August 1, 5, and 13 2018. High a_ph/(a_ph+a_dg) ratio areas were captured (Fig. 1) through the in-water optical property model (Lyon and Hoge, 2006; Murakami, 2018) using average spectra of a_ph or a_dg in NOMAD dataset (Werdell, and Bailey, 2005). Generally, difference between absorption coefficients of phytoplankton at 530 nm and 565 nm (a_ph(530nm) - a_ph(565nm)) is larger than difference between absorption coefficient of CDOM + detritus at 530 nm and 565 nm (a_dg(530nm) - a_dg(565nm)). It may correspond to the redtide which has been reported around the area by Fisheries Agency (Fisheries Agency, 2018).

We will continue to make more precise water-leaving spectra to be used for useful information of coastal environment through improvement of correction aerosol absorption and so on.

Features of GCOM-C/SGLI standard atmospheric correction scheme and its processing results

*Mitsuhiro Toratani[1], Kazunori Ogata[2], Hajime Fukushima[3]

1. School of Engineering, Tokai University, 2. Japan Aerospace Exploration Agency/Earth Observation Research Center, 3. Tokai University

On December 23, 2017, the Second-generation Global Imager (SGLI) aboard the Global Climate Observation Mission-C (GCOM-C) satellite "Shikisai" was launched. SGLI has 11 observation bands in the visible and near-infrared region (380-870 nm), designed to detect slight change in water color (spectral water reflectance) with 250m spatial resolution. In order to retrieve accurate water reflectance, the correction of atmospheric absorption and scattering effects (atmospheric correction) is of vital importance. One feature of the JAXA standard atmospheric correction for SGLI is to combined use of the conventional atmospheric correction method for open ocean with the method that utilize the short wavelength infrared bands for coastal high suspended matter concentration waters. We demonstrate the processing results in comparison with MODIS results, and discuss the remaining issues.

Verification of GCOM-C/SGLI-derived chlorophyll *a* data in the western North Pacific during May 2018 aboard the R/V *Shinsei Maru*

*Koji Suzuki[1], Stanford B. Hooker[2], Tomonori Isada[1], Kazunori Ogata[3], Mitsuhiro Toratani[4], Hiroshi Murakami[3]

1. Hokkaido University, 2. NASA, 3. JAXA, 4. Tokai University

The Second-generation Global Imager (SGLI) aboard the JAXA GCOM-C satellite was successfully launched on 23 December 2017. We conducted the first GCOM-C field campaign for the western North Pacific during 20–30 May 2018 aboard the R/V *Shinsei Maru*. During this expedition, in situ apparent optical property (AOP) measurements were made using a Compact-Optical Profiling System (C-OPS, Biospherical Instruments Inc.) in order to match up with SGLI data. Also, phytoplankton pigment samples were concomitantly collected from surface waters. A significant linear correlation (R^2 = 0.99, n = 6) was found between ultra-high performance liquid chromatography (UHPLC)-determined chlorophyll (Chl) *a* levels and those derived from C-OPS with the in-water algorithm OC3M6. However, the C-OPS values were underestimated by 32% as compared with the UHPLC data. This could be partly due to the higher pigment extraction efficiency of *N*,*N*-dimethylformamide (DMF) than other organic solvents such as methanol and acetone which are generally used in the world. During the field campaign, SGLI data were successfully matched up with in situ data at a station off Iwate Prefecture, Japan on 21 May. The SGLI-, C-OPS-, UHPLC- and Turner fluorometry-determined surface Chl *a* values were 0.546, 0.709, 0.847 and 1.21 mg m^{-3}, respectively. Other results obtained from the GCOM-C field campaign will also be shown in our presentation.

Toward a global retrieval of in-water optical properties using Deep Neural Network

*Salem Ibrahim Salem[1], Hiroto Higa[2], Kazuo Oki[1], Taikan Oki[1]

1. The University of Tokyo, 2. Yokohama National University

Reflected sunlight from water bodies, which records by ocean color sensors, contains information of optical properties of water bodies (e.g., chlorophyll-a concentrations, absorption and backscattering coefficients). During the last few decades, researches have been proposed many approaches for monitoring water bodies by retrieving their optical properties. These approaches include bands ratio, semi-analytical algorithms, and spectrum matching. However, there is no accurate continuous monitoring on a global scale, particularly over inland lakes and coastal regions. This is mainly due to the nonlinear complexity of water environment. In additions, there are a few studies that used the synthetic simulated reflectance to train artificial neural network (ANN) models to be applied on a global scale. However, the recent revaluation of these ANN models over the Japanese and European lakes revealed their limitation to provide accurate monitoring of these water bodies. These results could be attributed to two main reasons; (1) inappropriate ANN architecture with one hidden layer which could not be suitable to represent the complex situation of water bodies. (2) the limitation of the synthetic simulated reflectance that used to train these models. The deep neural network (DNN) with multiple hidden layers could provide a promising approach to overcome these complexities. Up to 2006, there is no way to accurately train a DNN due to a Vanishing gradient problem. the recent advances of DNN enable researchers to efficiently use the DNN models with low cost. During the current research, the performance of a DNN model with three-, five- and seven-hidden layers under different architecture conditions will be presented. These conditions include different activation functions (i.e., sigmoid, Relu and TanH), different optimization technique (i.e, Adam optimizer and stochastic gradient descent) and with/without applying dropout technique. The DNN model was designed to receive water leaving reflectance of several ocean color satellites (e.g., Global Change Observation Mission –Climate (GCOM-C)). Nine water quality parameters are generating from the DNN model. Two independent simulated datasets comprising 100,000 water leaving reflectance spectra each were generated for training and testing the DNN models. The two simulated datasets cover wide ranges of Chla (0.01–250 $mg{\cdot}m^{-3}$), NAP (0.01–250 $g{\cdot}m^{-3}$), and CDOM (0.001–10 m^{-1}) concentrations, representing the open ocean, coastal areas, and inland lakes. The proposed technique was also validated using in-situ datasets (e.g., NOMAD dataset, and many Japanese lakes and coastal bodies) that represent various trophic statuses. The results reveal the ability of proposed technique to provide accurate retrieval of in-water optical properties as will be discussed.

Reflected sunlight from water bodies, which records by ocean color sensors, contains information of optical properties of water bodies (e.g., chlorophyll-a concentrations, absorption and backscattering coefficients). During the last few decades, researches have been proposed many approaches for monitoring water bodies by retrieving their optical properties. These approaches include bands ratio, semi-analytical algorithms, and spectrum matching. However, there is no accurate continuous monitoring on a global scale, particularly over inland lakes and coastal regions. This is mainly due to the nonlinear complexity of water environment. In additions, there are a few studies that used the synthetic simulated reflectance to train artificial neural network (ANN) models to be applied on a global scale. However, the recent revaluation of these ANN models over the Japanese and European lakes revealed their limitation to provide accurate monitoring of these water bodies. These results could be attributed to two main reasons; (1) inappropriate ANN architecture with one hidden layer which could not be suitable to represent the complex situation of water bodies. (2) the limitation of the synthetic simulated reflectance that used to train these models. The deep neural network (DNN) with multiple hidden layers could provide a promising approach to overcome these complexities. Up to 2006, there is no way to accurately train a DNN due to a Vanishing gradient problem. the recent advances of DNN enable researchers to efficiently use the DNN models with low cost. During the current research, the performance of a DNN model with three-, five- and seven-hidden layers under different architecture conditions will be presented. These conditions include different activation functions (i.e., sigmoid, Relu and TanH), different optimization technique (i.e, Adam optimizer and stochastic gradient descent) and with/without applying dropout technique. Development of atmosphere and in-water combining algorithm using GCOM-C/SGLI in Tokyo Bay

*Taiga Nakayama[1], HIROTO HIGA[1], Kazuki Ogata[2]

1. Yokohama National University, 2. Japan Aerospace eXploration Agency

GCOM-C / SGLI launched at the end of December 2017, has an excellent spatiotemporal resolution such as one time observation every two or three days at a resolution of 250 m on coastal area, is expected to monitor coastal areas where water environment change is siginificantly large and water area is comparatively small. However, high accuracy of water estimation is exceedingly difficult because coastal light environment in water changes complexly. In the traditional ocean color atmospheric correction algorithm, it is assumed that the water leaving radiance in the near infrared region is 0 and radiance due to air in the visible region is calcuration after estimating the radiance of atmospheric scattering. However, as in the coastal region, in the case of organic matter and inorganic matter increasing significantly, the water leaving radiance in the near infrared region increases and the assumption does not hold. Because of this, an aerosol reflectance is over estimated and an error occurs in the estimation of the water leaving reflectance in the visible region band. To improve this, there is a method of estimating aerosol reflectance while estimating water leaving reflectance in the near infrared region by the iterative method, and if the in-water model is suitable for the water area, highly accurate water leaving reflectance estimation Is possible. SGLI uses this iterative method in a low turbidity water such as the case1 water, and estimates atmospheric reflectance from a short-wavelength infrared channel without using an in-water model in a coastal area or other high turbidity water area, However, its accuracy is not as good as the high turbidity area.

In this study, we tried to develop a combination algorithm of atmospheric correction model, and in-water model which is adequate for coastal areas as a target of Tokyo Bay where organic matter is dominant. This is a modification of the in-water model used at the atmospheric correction stage to the Bio-Optical model created based on the measured SIOPs(Specific inherent optical properties) in Tokyo Bay, an selection aerosol model and estimation of reflectance at each wavelength are conducted by iterative calculation based on three parameters of Chl-a(Chlorophyll-a), CDOM(Color dissolvedorganic matter) and NAP(Non-algal particles). As a result, the suggested model became possible to estimate Chl-a and Rrs with high accuracy compared to normal SGLI atmospheric correction.

Analysis of the uncertainty of backscattering coefficient by radiative transfer simulation in coastal areas and lakes

*Hidehito Taki[1], Hiroto Higa[1], Yoshiyuki Nakamura[1], Takayuki Suzuki[1]

1. Graduate School of Urban Innovation, Yokohama National University

In coastal areas and lakes, the ocean color change is greatly complicated because of various substances which are derived from terrestrial and internal production coexist in the water. Therefore, in radiative transfer simulation in the water, the inherent optical properties per substance concentration, which is the basic parameter change greatly in spatiotemporal, resulting in errors in calculation accuracy. In particular, it has been pointed out that the uncertainty of the backscattering coefficient is one of the major error factors in radiative transfer simulation. (Lain et al., (2017)). In this study, we have conducted field observations to measure water quality, apparent optical properties and inherent optical properties which are basic parameters in radiative transfer simulation in coastal areas and lakes having different optical characteristics such as Tokyo Bay, Kasumigaura Lake, Thailand Bay, and Seto Inland Sea respectively. Furthermore, we tried to conduct radiative transfer simulation by using Hydrolight 4.1 (Mobley et al., (2000)) based on in-situ specific light absorption coefficient and specific backscattering coefficient in each water areas. As a result, it was found that the simulated remote sensing reflectance: R_{rs} (/str) is remarkably variable due to the fluctuation of backscattering probability expressing the particle scattering form in the water.
It was suggested that this result is because of not considering properly the variations of scattering form related to particle characteristics.

[A-CG45] Visible Remote Sensing of Hydrospheric Science and Its Application

convener:Joji Ishizaka(Institute for Space-Earth Environmental Research, Nagoya University), Mitsuhiro Toratani(School of Engineering, Tokai University), Yuji Sakuno(Graduate School of Engineering, Hiroshima University), Toru Hirawake(Faculty of Fisheries Sciences, Hokkaido University), Chairperson:Joji Ishizaka(名古屋大学宇宙地球環境研究所)

Variety of visible remote sensing data for hydrospheric science is now available. For example, it is known that 20 years of long time series of 1 km resolution ocean color data from OCTS-SeaWiFS-MODIS is available. At the end of 2017, 250 m resolution SGLI (Shikisai) was launched by JAXA, and with 300 m resolution European OLSI it became possible to use high resolution and high frequency data. Furthermore, geostationary satellite data from Korean GOCI is also useful. Not only the satellite variety, diversity of products is also increasing from just phytoplankton pigment, chlorophyll-a, to primary production, phytoplankton community structure and even non-phytoplankton materials and optical properties. Those ocean color satellite data should be useful for various fields of hydrospheric science, combining with higher resolution LANDSAT as well as high frequency Himawari data. In this section, we will discuss the variety of new observations and applications of visible remote sensing in hydrospheric science.

Discussion

Development of a blue tide estimation method based on the optical properties of sulfur colloid particles by geostationary ocean color satellite

*HIROTO HIGA[1], WATARU NAKAMURA[1]

1. Yokohama National University

Blue tides occurs every year from the summer to the fall in Tokyo Bay or Mikawa Bay, Japan. The blue tides occurs by upwelling sulfur colloid particles, which is generated by reacting oxygen with hydrogen sulfide in the hypoxic water at the bottom. The sulfur colloid particles scatter the light strongly at the surface and the ocean color changes to blue-white, therefore, it is called blue tide. When the magnitude of the blue tide is huge, mass mortality of shell and fish occurs and sometimes it is connected to damage of fisheries. Hence, the blue tides are recognized as an important water environment problem. Because the blue tide is short time scale phenomenon, it is difficult to monitor the spatial behavior adequately. Hence, the blue tide monitoring is expected by using geostationary ocean color satellite which spatio-temporal resolution is superior.
In the previous study, simple method of sulfur estimation method based on simple band of Rrs(Remote sensing reflectance) at 660 nm have been suggested(Higa et al., (2017)). However, it is impossible to separate the backscattering of sulfur and other detritus, respectively. In this study, we developed a bio-optical model, which is specialized in blue tide, based on the measured IOPs(Inherent optical properties) of Sulfur colloid particles. Furthermore, a sulfur estimation method was developed to separate the backscattering of sulfur and other detritus based on the QAA(Quasi-Analytical Algorithm).

Characteristics of water quality and red tide distribution in the Seto Inland Sea immediately after heavy rain in the western Japan by GCOM-C SGLI data

*Yuji Sakuno[1], Hiroto Higa[2], Hiroshi Kobayashi[3], Mitsuhiro Toratani[4]

1. Hiroshima University, 2. Yokohama National University, 3. Yamanashi University, 4. Tokai University

The heavy rain in western Japan disaster occurred in early July 2018. After this heavy rain, a large amount of sediment discharge from the river and damage of red tide occurred in the Seto Inland Sea. Meanwhile, Chla (Chlorophyll-a), TSM (Total Suspended Matter), CDOM (Color Dissolved Organic Matter), SST (Sea Surface Temperature), Rrs (Remote Sensing Reflectance) of GCOM-C SGLI launched at the end of December 2017 Standard product data with 250 m spatial resolution will be provided once every 2-3 days from JAXA (The Japan Aerospace Exploration Agency). In this research, the results of accuracy verification of these product data (Level 2) officially released in December 2018 will be reported. Secondly, a method for estimating the distribution of harmful red tides (mainly *Chattonella* and *Karenia*) occurred in the Seto Inland Sea from Rrs products will be examined. The study period is mainly from June to August 2018. As a result, the SGLI product satisfies the target accuracy even in this water area, and the characteristics of the water quality and red tide distributions in the Seto Inland Sea about one month after the heavy rainfall became clear.

Application of Satellite Remote Sensing to Monitor Eutrophication Status of Inland Lakes

*Wei Yang[1], Bunkei Matsushita[2]

1. Chiba University, 2. University of Tsukuba

Eutrophication of inland lakes is becoming a severe environmental issue all over the world. Routine monitoring of eutrophication status of inland lakes is essential for guaranteeing sustainable development of freshwater resources. The coupled spatial and temporal heterogeneity of water bodies often result in inadequate monitoring and characterization of water quality by using conventional sampling methods. On contrast, satellite remote sensing is quite flexible for monitoring the eutrophication status of inland lakes in terms of being able to cover large spatial areas at very frequent intervals. However, remote sensing of inland lakes has been far less successful than that of open oceans, due mainly to the complex interactions among optically active substances in the lake waters, as well as the difficulties in atmospheric correction. In this presentation, we will introduce our state-of-the-art remote sensing algorithms for estimating Chlorophyll-a concentrations (Chl-*a*) and Secchi disk depth (SDD), which have been widely used to evaluate the eutrophication status of lakes. These algorithms have been extensively validated using extensive in situ collected data sets, yielding satisfactory performances in overcoming the difficulties in remote sensing of turbid inland lakes. Application studies on satellite-based operational monitoring of Chl-*a* and SDD in several lakes of Japan will also be presented. Assessment results demonstrated that the proposed algorithms have the potential of being applied to operationally monitor water quality of inland lakes.

Exploring the Potentials of Google Earth Engine for Global Assessment of Coastal Eutrophication Based on Chlorophyll-*a* concentration

*Eligio de Raus Maure[1], Genki Terauchi[1], Joji Ishizaka[2]

1. Northwest Pacific Region Environmental Cooperation Center, 2. Institute for Space-Earth Environmental Research, Nagoya University

Eutrophication is either emerging or growing environmental issue in many parts of the global marine systems in the ocean. This deterioration in water quality in the coastal regions may at times result in the appearance of harmful algal blooms or hypoxic conditions that affects large spatial and temporal scales with serious damages to the environment and economy, and the marine ecosystem itself. To assess the coastal eutrophication the Special Monitoring and Coastal Environment Assessment Regional Activity Centre (of the Action Plan for the Protection, Management and Development of the Marine and Coastal Environment of the Northwest Pacific Region of the United Nations Environmental Programme) developed a screening procedure to detect symptoms of eutrophication based on satellite observations of chlorophyll-a concentration. The methodology was originally developed for the Toyama Bay, Japan and later applied to the whole Northwest Pacific region. In this presentation, we introduced the method and its applicability to the global ocean. Furthermore, we also introduce the potentials of the Google Earth Engine (GEE)—a cloud-based tool with planetary-scale analysis capability—for future coastal eutrophication assessment based on recent higher resolution ocean colour sensors such as SGLI on GCOM-C with 250 m or Sentinel-3 with 300 m spatial resolutions. Once the GEE is proven useful, it will be an important tool in providing rapid assessment of the status of marine systems in many regions where the information on the status and extent of coastal eutrophication is very limited.

Seasonal and interannual variability of seagrass distribution detected by Landsat TM, ETM+ and OLI images in western Nanao Bay

*Genki Terauchi[1]

1. Northwest Pacific Region Environmental Cooperation Center

Western Nanao Bay is known for being a home to massive seagrass beds. A massive die-off of seagrass was reported in 2012 in this area, possibly due to high water temperature in summer. Archive images of Landsat Thematic Mapper (TM), Enhanced Thematic Mapper Plus (ETM+) and Operational Land Imager (OLI) were obtained from USGS to detect seasonal and interannual variability of seagrass distribution. Ground truthing survey with an underwater video camera were carried out from a small boat to study sea floor substrates on June 1, 2 and 16 in 2016. Still photos were also taken from a Stand Up Paddleboard on June 1, 2016 to study seagrass species in a very shallow (< 1m) water area. Information of sea floor substrates obtained from the field survey was then used to classify sea floor types. Six classes of training data were then prepared for classifying the Landsat OLI image observed on June 1, 2016 namely: (1) dense seagrass, (2) dense seagrass with *Sargassum*, (3) *Sargassum*, (4) sandy bottom, (5) mud and (6) exposed sand. Supervised classification of the bottom substrates was carried out by the maximum likelihood method using bands of Red, Green and Blue or ratios of Green/Blue, Green/Red, Blue/Red and Green/Coastal bands corrected with the Depth Invariant Index (DII) method. Accuracy assessment showed better results in the DII corrected band ratios: overall accuracy of 0.73 and tau coefficient of 0.66.

To study seasonal and interannual variability for seagrass, past Landsat archive images were analyzed to detect seagrass distribution. Since past field data of seagrass distribution were not sufficient, the K means unsupervised classification technique with the six classes was applied for mapping the seagrass distribution from past Landsat archive images. The classification result of the Landsat OLI image on June 1, 2015 was used as a reference to determine seagrass distributions as it had a good compliance with the ground truth data. Since two out of the six classes obtained from the unsupervised classification corresponded to a distribution pattern of (1) the dense seagrass and (2) the dense seagrass with *Sargassum* classes from the June 1, 2015, these two classes were merged into one class to represent seagrass distribution in Western Nanao Bay. A comparison of seasonal patterns of seagrass distribution estimated by the unsupervised classification of the Landsat archive data from November 22, 1991 to June 1, 1992 and from November 21, 2014 to June 1, 2015 showed consistent similar seasonal pattern; indicating seagrass recovery between late fall to early summer, which corresponds to seagrass seed germination periods. The Landsat archive data during the seagrass seed germination periods were also obtained to study interannual variability of seagrass distribution. The obtained results showed that there are fewer seagrass years (1994, 1996 and 1999) and more seagrass years (2000, 2004, 2007 and 2008) during the seagrass seed germination periods, indicating the survival rate of seagrass varied depending on the year.

Today’s Japan has conducted immediate, wide-area tsunami forecasts using the quantitative tsunami forecasting system that databases results of numerous preliminary tsunami simulations. In the future, in order to conduct more accurate tsunami forecasts, it is necessary to verify the accuracy of the tsunami run-up calculation. However, there were few studies about the variation of run-up tsunami force by calculating on-site. In this study, we conducted the on-site tsunami run-up calculation using the two-dimensional simulator and analyzed the variation of run-up tsunami force.

We focused on the earthquake near Palu, Indonesia on September 28, 2018. We set some tsunami sources based on the results of the field study, (by Arikawa *et al.*) and conducted the 300 cases of two-dimensional tsunami run-up simulations by changing the fault parameters. Next, we investigated statistically the variation of the maximum inundation depth and Froude number at the maximum inundation depth. Using the calculation results of all cases we conducted, we made groups every 0.2m from the small inundation depth and made histograms of the maximum inundation depth and Froude number for each group.
As a result, the average of Froude number increased monotonically as the maximum inundation depth increased, and the variance of Froude number tended to increase about 4 times as the maximum inundation depth increased. This corresponds to a value of Froude number of 1.5 to 2.0 times. This indicates that even if the inundation depth is the same, there is a possibility that there is a difference in tsunami force, so it is necessary to investigate the variance of the Tsunami force in the area where the inundation depth is large. In addition, it is also necessary to further study the variance of the flow velocity in numerical calculation.

Tsunami Source of the 2018 Sulawesi Earthquake Estimated from Tsunami and InSAR Data

*Tungcheng Ho[1], Kenji Satake[1], Shingo Watada[1], Ray Y Chuang[2], Chih-Heng Lu[2]

1. Earthquake Research Institute,The University of Tokyo, 2. Department of Geography, National Taiwan University

An unexpected destructive tsunami struck Palu Bay after the Mw 7.5 strike-slip faulting earthquake in Sulawesi, Indonesia, on 28 September 2018. This tsunami impacted Palu city with 5 m to 10 m runup. The combined effects of the earthquake and tsunami caused a few thousand casualties. The tsunami waves were observed by two tide gauges in Sulawesi. One tide gauge at Pantoloan port in the bay recorded tsunami waves starting at about 5 minutes after the earthquake with amplitudes of up to 2 m. The other tide gauge at Mamuju port recorded tsunami waves after about 20 minutes with peaks of about 10 cm. To understand the mechanism of this unusual tsunami, we jointly utilized the tsunami records and InSAR data to analyze the source of this earthquake. The InSAR data observed by Sentinel-1 well resolved the offset of horizontal ground movement in the direction of the orbit azimuth along the fault strike. The data show a strike of about 358˚ in the north of the bay and about 352˚ in the south of the bay. The magnitude of the offsets varied from about 1 m in the north to up to 5 m in the south. Our simple modeling result suggests a slip of about 5 m at the north and a slip up to 8 m at the south to reproduce the observed tsunami waveform at Pantoloan. The southern asperity extended about 40 km from the bay with a width of about 16 km. Tsunami travel time analysis showed that the main tsunami arrived at the Mamuju station after about 45 minutes which means the first tsunami wave at this station was triggered by another source.

Keywords: Palu, tsunami, InSAR, Sulawesi Earthquake, source inversion

Source Models of the Two September and December 2018 Indonesia Tsunamis Based on Spectral Analyses and Numerical Modeling

*Mohammad Heidarzadeh[1], Abdul Muhari[2], Tomoya HARADA[3], Takeo Ishibe[4], Antonius Wijanarto[5]

1. Brunel University London, 2. Ministry of Marine Affairs and Fisheries, Jakarta 10110, Indonesia, 3. Earthquake Research Institute, The University of Tokyo, Japan, 4. Association for the Development of Earthquake Prediction, Tokyo, 101-0064, Japan, 5. Badan Informasi Geospasial, Cibinong, Indonesia

Indonesia was struck by two tsunamis in September and December 2018 in Sulawesi and Sunda strait, respectively. The combined fatalities from the two events were ~2500 people which made 2018 as one of the deadliest year for Indonesia in terms of natural disasters. The 2018 twin tsunamis were unique because both events were not generated by typical earthquake-generated seafloor deformation. The Sulawesi tsunami in September 2018 was most likely associated with a large submarine landslide (Heidarzadeh et al., 2018, Pure & Appl. Geophys. 176) and the Sunda event was of volcanic origin. Therefore, there have been intense speculations in the scientific community about the origins and mechanisms of these twin tsunamis without any clear clues about the source mechanisms so far (February 2019). Our methodology here to address the puzzle of the 2018 twin tsunamis is analyzing the observed tide gauges records of both events and then applying numerical simulations. For the Sulawesi tsunami, two tide gauge records were analyzed belonging to Pantoloan (inside the Palu Bay) and Mamuju (outside the Palu Bay). Maximum tsunami trough-to-crest heights of 380 and 24 cm, were measured in Pantoloan and Mamuju, respectively. Spectral analyses of the tide gauge records revealed dominating wave periods of 3.6–4.4 and 10 min at the aforesaid stations, respectively. Spectral results indicate that the tsunami source dimensions should have been most likely in the range of 3.4–4.1 km and 32.5 km, for inside and outside of the Palu Bay, respectively. We were able to reproduce the two observed tide gauge records using numerical simulations. However, the maximum simulated runup was approximately 2 m which was less than the observed runup of 11 m. It is likely that a secondary source, i.e. submarine landslide(s), has contributed to the tectonic source of the tsunami. We identify the southern part of the Palu Bay, around the latitude of -0.82°S, as the most likely location of a potential landslide based on our backward tsunami ray tracing analysis. For the Sunda tsunami, four tide gauges were analyzed revealing wave amplitudes in the range of 44-139 cm. The dominating period of the waves were ~7 min which are shorter than tsunamis generated by earthquakes. We have considered several landslide scenarios and conducted numerical modeling in order to reproduce the observed tsunami waves on the tide gauges and propose a source model for this tsunami.

Abrupt Large Uplift Caused by Volcanic Tsunami Earthquakes near the Kermadec Islands, New Zealand

*Osamu Sandanbata[1], Shingo Watada[1], Kenji Satake[1]

1. Earthquake Research Institute, the University of Tokyo

Abnormal non-double-couple (NDC) earthquakes are sometimes observed near volcanic or geothermal areas [e.g. Shuler et al., 2013, JGR], some of which generate large tsunamis despite their moderate seismic magnitudes, M5-6. The Torishima earthquakes are ones of the few examples and were attributed to a large crustal uplift associated with some volcanic activity at a submarine caldera edifice on Izu-Bonin Ridge [Fukao et al., 2018, Sci. Adv.; Sandanbata et al., 2018, PAGEOPH]. This type of earthquakes therefore can be regarded as "volcanic tsunami earthquakes."

Another series of volcanic tsunami earthquake were observed near the Curtis and Cheeseman Islands, parts of the Kermadec Islands, north of New Zealand, on 17 Feb 2009 and 8 Dec 2017 (UTC). Tsunamis were recorded at tide gauges and ocean bottom pressure gauges with a maximum amplitude of ~40 cm. The two earthquakes are remarkably similar in seismic magnitudes (M~6.0), focal mechanisms (dominant NDC components), centroid locations (gap of ~10 km) and observed tsunami waves.

In order to investigate their tsunami sources, we numerically solved two-dimensional Boussinesq-like equations with the simulation code, JAGURS [Baba et al., 2015, PAGEOPH]. We first located their source region in the vicinity of the Curtis and Cheeseman Islands, by assuming Gaussian-shaped sea-surface uplifts at 9 locations. We then conducted the tsunami waveform inversion with Green’s functions computed from cosine-tapered uplift distributed around the islands. The estimated tsunami source has a large sea-surface uplift concentrated just over a bathymetric depression that is a characteristic structure of calderas. This suggests a large uplift on seafloor was caused by the earthquakes associated with a volcanic activity of the submarine caldera.

Large uplift events called “resurgence” have been observed at calderas in nature and experiments, which are often attributed to reactivation of ring faults due to overpressure of a magma reservoir [e.g. Acocella et al., 2001, JVGR]. We modeled crustal deformation of a caldera with an interacted system of a ring-fault structure and a shallow sill-like magma reservoir [Liu et al., 2017, AGU Fall Meeting]. Our modeling suggests that the system can cause a large uplift concentrated just over the caldera. The uplift also reproduced tsunami waves similar to the observations, while the gap between seismic and tsunami magnitudes can be explained qualitatively. We therefore suggest that a ring-fault reactivation due to overpressure in a sill-like magma reservoir as a possible mechanism of the earthquakes and their resultant tsunamis.

Adaptive tsunami waveform inversion for estimating coseismic vertical displacements and slip distribution

*Iyan E. Mulia[1], Aditya Riadi Gusman[2], M. Jakir Hossen[3], Kenji Satake[1]

1. Earthquake Research Institute, The University of Tokyo, 2. GNS Science, 3. BRAC University

We developed an advanced two-step tsunami source inversion method with adaptive Green's functions by applying an optimization and a reciprocity principle (Mulia et al., 2018 JGR). In the first step, the method reconstructs the sea surface displacement from observed tsunami waveforms based on a superposition of Gaussian-shaped unit sources. Here, we optimize the unit source locations that give the best fit of waveforms to observations. This leads to non-equidistantly distributed unit sources, in which the synthetic waveforms from such sources to the observation points are generated using the reciprocity principle to save computational efforts of Green's functions. In the second step, the reconstructed sea surface displacement is used to estimate the slip on a finite fault plane. We also optimize the fault parameters that produce the closest displacement pattern to the first step result. Therefore, our method provides best fitting of waveforms and optimum fault parameters with automation for the process. The current method improves our previous studies, in terms of the construction of tsunami Green's functions using the reciprocity principle and determination of fault parameters through the optimizations.

We tested the proposed method using tsunami data of the 2004 Kii Peninsula, Japan event generated by an M_w 7.4 intraplate earthquake. Our result revealed a maximum initial displacement of approximately 0.5 m with the uplift region extended northwest to the epicenter. This value is slightly higher than that of most source models by the previous studies (e.g. Baba et al., 2005 EPS, Satake et al., 2005 EPS), but yields more accurate tsunami waveforms, particularly at the later phase of waveform recorded at a Global Positioning System buoy station off Cape Muroto. In terms of fault slip distribution, our model produced a maximum slip of 2.1 m, located at the uplift region of the coseismic displacement. Furthermore, the shallow fault depth resulted from our simulation is consistent with the more reliably relocated aftershock distribution by Bai et al. (2006 EPS).

Real-time tsunami prediction in a coastal zone, using a superposition of Green’ s function

*Seiji Tsuno[1], Norihiko Hashimoto[2]

1. Railway Technical Research Institute, 2. ITOCHU Techno-Solutions Corporation

Recently, S-net (Seafloor observation network for earthquakes and tsunamis along the Japan Trench) and DONET 1 & 2 (Dense Oceanfloor Network system for Earthquakes and Tsunamis) are installed off the Pacific Ocean, Japan by NIED (National Research Institute for Earth Science and Disaster Resilience) and JAMSTEC (Japan Agency for Marine-Earth Science and Technology); therefore, real-time tsunami forecasting methods using directly tsunami data observed in oceanfloor are proposed (e.g. Yamamoto, 2016; Tanioka, 2018). In this study, focusing on the immediacy and the robustness of tsunami forecasting, we investigated real-time tsunami prediction method in a coastal zone, using a superposition of previously calculated Green’ s function.

In this method, we divide the entire source area of tsunami into element sources (for example, 50 km x 50 km), and we, in advance, calculate the Green’ s function to a coastal point for the unit tsunami water level (1 m) in the element source. Assuming that the tsunami water level is the same within the element source when a tsunami occurs, we the Green’ s function to the element source –the coastal point for the maximum value of the tsunami water level observed at one point in the element source. By applying this to all the divided element sources and superimposing these Green’ s functions, we can obtain the tsunami water level in a coastal zone for the entire source area. Comparing the result predicted by this method to a tsunami simulation result simulated from source model proposed by the Cabinet Office, Government of Japan, for the 2011 off the Pacific coast of Tohoku earthquake, we confirmed that two results are in good agreements.

Moreover, to use the amount of tsunami water level in the source area due to heterogeneous fault rupture, we investigated the possibility to replace the time series of tsunami data observed at a point in the element source with the amount of tsunami water level within the element source area. We confirmed that the time series of tsunami data can be used for real-time tsunami prediction using a superposition of Green’ s functions by appropriately estimating the time when the tsunami propagates within the element source.

[H-RE17] Application of earth science data towards the renewable energy field

convener:Hideaki Ohtake(National Institute of Advanced Industrial Science and Technology), Fumichika Uno(National Institute of Advanced Industrial Science and Technology), Teruhisa Shimada(Graduate School of Science and Technology, Hirosaki University), Daisuke Nohara(Central Research Institute of Electric Power Industry), Chairperson:Hideaki Ohtake(National Institute of Advanced Industrial Science and Technology (AIST))

Renewable energy (RE) penetration is increasing dramatically in the world. RE power generations have made their presence felt in an electric power system. However, it is a challenge for RE to be stable power sources due in part to natural variability of RE and the distributed resources. For effective use of RE, a combination between power resources and energy storage technologies (e.g., pumped-storage power generation, storage battery system and electric vehicle) is required to provide power and energy flexibility. Therefore, we need to understand the amount of REs, causes of variation, and the predictability of power output. Then, enormous and diverse observation data sets and modeling technologies from earth science field should be analyzed and applied to power energy field to achieve easy use of earth science databases.
 This proposed session needs your presentation from the whole of RE fields (solar power, wind power, geothermal power, tidal power, wave power and biomass power generations). Our goal of this session is to exchange views with various researchers between RE field and earth science field (e.g., usage-trends of earth science datasets for RE field, the subjects in hand, earth science datasets availability, and cooperation between RE and earth science fields, and so on).

Discussion

Application of geological dara to ground source heat pump systems with special reference to thermal conductivity of geological materials

*Masakatsu SASADA[1]

1. Geo-Heat Promotion Association of Japan

Ground source heat pump systems are getting popular in Japan. Ground source means low temperature energy in geological units shallower than 200 meters below the surface. A geothermal heat pump system is much more efficient than a conventional air source heat pump system. A ground source heat pump system also contributes to mitigating a heat island phenomenon in large urban areas like Tokyo, because it does not emit exhaust heat outside in summer.
Effective thermal conductivity is one of the most important parameters to design ground source heat pump systems. Thermal response tests result in effective thermal conductivity of geological units under the building site. The reference values of thermal conductivity for several geological units are also available to building designers.
The regulation of Energy Conservation Standards came into effect in April 2016. Under the regulation annual primary energy consumption for every type of building is standardized. An owner of building has to submit building certification application with data of annual energy consumption calculated by Web Program of Building Research Institute. When ground source heat pump systems are installed in the building, the thermal conductivity of the building site must be input the Web Program for calculation of annual primary energy consumption.
Thermal response test is the best method to estimate the thermal conductivity of the geological units under the building site. However, it is not always applied to residential houses and small size buildings. The reference data of thermal conductivity are usually applied to them. Since geological units are so diverse in the Japanese Islands that much more measured data of thermal conductivity are required for reference database.

Use of groundwater in the Nishi-Osaka Area and its activities.

*Naoko Kitada[1], Hiroko Ito[1], Tomoo Echigo[1], Teruyuki Fujiwara[1], Makoto Nishigaki[2]

1. Geo-Research Institute, 2. Okayama University

On the west side of Osaka plain, several clay layers accompanying repeated sea level change accumulate in layers, and the gravel layer between the clay layers forms a submerged aquifer where abundant underground water resides. On the other hand, due to the severe ground subsidence caused by the massive pumping up of factory water in the 1960s, pumping is currently strictly regulated. However, in recent years, especially in Osaka city, consideration is being made on effective utilization of groundwater, such as the promotion of underground water use project as regenerative thermal energy.

Therefore, we conducted survey of water level, water temperature, and water quality using existing observation holes near Nakanoshima from around Osaka Station for the purpose of acquiring background data on the properties of groundwater at the present time. The aquifer covered in this study is a sand gravel layer (1st aqueduct layer: Dg1) distributed beneath the clay layer (Ma13) of the Holocene, and the gravel layer (the second caught aquifer: Dg 2) distributed under the clay layer (Ma12). Regarding the water quality, we analyzed the composition of the principal components etc. for groundwater sampled 4 times in total in June, September, November 2016 and January 2017. As a result, it was revealed that both Dg 1 and Dg 2 were reductive and showed a Na - Cl type water quality composition, especially Dg 1 had a higher salt concentration.

Improvement of prediction of wind power ramp by using monitoring data

*Shinji Kadokura[1], Daisuke Nohara[1], Masamichi Ohba[1], Atsushi Hashimoto[1], Keisuke Nakao[1], Yasuo Hattori[1], Takeshi Watanabe[1], Hiromaru Hirakuchi[1]

1. Central Research Institute of Electric Power Industry

Introduction of power generation by renewable energy such as photovoltaics(PV) and wind power (WT) is worldwidely progressing. Since PV and WT power generation are markedly fluctuated due to the change of the wheather, there is concern about the stability of the electric power system. Therefore, we have been developing a prediction method of wind power generation output to contribute for the stabilization of electric power system. In this method, the numerical forecast value provided by the Japan Meteorological Agency is downscaled using the weather model WRF and CFD model to predict the wind speed at the wind turbine, and the power output is predicted using the power curve. By adding the generated power output for each wind turbine obtained, the total output of the area is obtained. In this study, we have improved the prediction of wind speed and power generation output by using the monitoring data for each wind turbine, by making correction based on multiple regression and by using empirical power curve. Furthermore, we have corrected the accuracy of the area total power output by sequentially correcting the windfarms where data for each windmill is not acquired. In addition, by performing multiple regression on the amplitude of the output change, we have improved the supplementation rate of the wind power generation rapid change henomenon, ramp.

A study of the use of meteorological data for energy management

*Hideaki Ohtake[1], Takashi Oozeki[1], Junichi Imura[2]

1. National Institute of Advanced Industrial Science and Technology, 2. Tokyo institute of technology

Recently, a large amount of photovoltaics (PV) power systems (approximately 45 GW as of June 2018) have been connected to a power grid in Japan. Electric power supply with PV power generation exceed electric power demand in a power grid. For safety control of an energy manage system (EMS) with variable PV power generation, optimal use of other power plants (thermal power plants etc) and battery systems will be required in a future energy network (Fig.1). PV power monitoring and forecasts based on a meteorological data can be useful information for an optimal control of other power systems. In our research group (referred as a HARPS in a JST CREST project), we developed a communication tool between meteorology and EMS research fields. Impacts of meteorological data have been also investigated in an EMS (e.g., optimal control of electrical power systems and battery systems) under large PV installations. Furthermore, real time monitoring of regional PV power estimation have been also tried using a new geostationary satellite, Himawari 8/9. In this presentation, we will introduce research topic of meteorological data in the EMS field.

[H-TT22] New Developments in Shallow Geophysics

convener:Kyosuke Onishi(Public Works Research Institute), Kunio Aoike(Oyo corporation), Keisuke Inoue(National Agriculture and Food Research Organization), Tishiyuki Yokota(National Institute of Advanced Industrial Science and Technology), Chairperson:Toshiyuki Yokota, Keisuke Inoue

The session of shallow geophysics calls many research contributions on geophysical exploration techniques for the near surface. Our target depth is strictly restricted in the depth zone from 5 cm to 30 m (or from 2 in to 100 ft) below the surface of the ground. It may be the closest unknown territory for human society and advanced societies cannot have controlled yet to avoid disasters caused by dynamics in the shallow near surface. Peoples require techniques to manage levee, landslide and earth constructions also knowledge to control groundwater, liquefaction and soil pollution. The near surface has many geotechnical, environmental and hydrogeologic problems.
Major survey techniques are surface wave method, electric exploration, ground-penetrating radar and land streamer, but any methods will be discussed if your target is located in the specified depths. This session welcomes to discuss laboratory tests and rock physics for unconsolidated porous media in the vadose zone. Also, we will welcome not only cutting-edge technologies but also classic theory, if the knowledge is useful for human living.

High-frequency seismic reflection measurements for imaging internal structure of a sabo dam damaged by a huge debris flow

*Tomio INAZAKI[1], Hiroshi Kisanuki[2], Takanori Ogahara[1], Takeshi Shimizu[1], Naoki Fujimura[1]

1. Public Works Research Institute, Tsukuba Central Institute, 2. PWRI (Present address: OYO Corporation)

We conducted high-frequency, high-resolution seismic reflection measurements on the rear face of a sabo dam which had been damaged by a huge debris flow attack in July 9, 2014. The debris flow swept away the top 5 m part of the dam and segmented the dam body into several blocks associated with horizontal cracks. Estimated surface dislocation was at most 20 cm.
iezoelectric type high-frequency accelerometers were pasted on the surface at 10 cm intervals, and manual hit using a rock hammer was employed for generating high-frequency signals. High-performance data acquisition systems were also employed to obtain high-resolution and high sampling seismic data. Minimum sampling rate was set to 2 microseconds. We set 5 horizontal lines and 1 vertical line on the rear surface during December 2014 to April 2016. Relative height was about 5 m between the first and the last horizontal line. Assuming the RMS velocity to the constant value to 2,500 m/s, which was the typical S-wave velocity of concrete, we processed the dataset to reconstruct migrated depth sections. Clear flat reflection events appeared at 10 m and 7 to 5 meters. The former or deeper reflection event was correlated to the frontal face of the dam. The latter events were possible to be correlated to a horizontal joint which had dislocated the dam body caused by the debris flow attack. A gently dipping reflector, which started from the point just the survey line intersected a vertical fracture, was recognized in the lowest depth section.
In conclusion, field measurements demonstrated that high-frequency and high-resolution seismic reflection surveying was helpful to image the internal fracture distributions in a damaged concrete dam body.

Development and applications of 3D ambient noise tomography

*Chisato Konishi[1], Koichi Hayashi[1]

1. OYO Corporation

In a microtremor array measurement, receivers are usually placed on a center and the circumference of a circle or a center and the vertexes of a triangle to observe ambient noise from omni-directions for 1D S-wave velocity delineation. We developed 2D/3D ambient noise tomography as an extension of the normal microtremor array method, and we have conducted several field experiments. Cable-less seismographs including GPS clock, AD converter, battery, and SD card memory are used for the survey, and that makes a receiver array deployment flexible. Additionally, the estimated phase velocity is not affected by a specific direction of the ambient noise because several tens of receivers are deployed in X and Y directions on the ground surface. Furthermore, high quality data can be obtained due to a stacking of the multiple receiver pairs even if the observation time is limited.
CMP-SPAC analysis that is a modification of the CMPCC analysis in the 2D surface wave method is used in the 3D ambient noise tomography. SPAC coefficients are calculated for all possible pairs of the receiver arrays, and these are stacked and sorted by receiver separations at each CMP bin to make CMP-SPAC gathers. The frequency versus phase velocity image is obtained by comparing the CMP-SPAC gather with Bessel function. Dispersion curve is obtained from the frequency versus phase velocity image at all CMPs. By the same procedure to the 2D surface wave method, 1D S-wave velocity structure can be estimated by an inversion based on the non-linear least square method. And then 3D S-wave velocity is created by interpolating the 1D velocity structure at all CMPs. The computation time for this analysis is comparable to the 2D surface wave method, so we can easily obtain the 3D S-wave velocity.
Several field experiments have been conducted and the results almost agree with the existing geological information and other geophysical survey results. We found that the accuracy of the estimated S-wave velocity structure is lower around the edge of the survey area, and the estimated phase velocity around the edge might be affected by the direction of the ambient noise due to the limited receiver pairs. Nevertheless, we can eliminate this issue by extending the survey area, which is a usual countermeasure in most of geophysical surveys. Another finding is that even if the ambient noise does not include high frequency or short-wave length, we can investigate the shallow subsurface by adding a manmade vibration around the receiver array easily.

An Attempt to Estimate the Level of Non-confind Groundwater by Earthing Resistance (I) - Outline of Theory -

*Kunihiro Ryoki[1]

1. Polytechnic University

1. Introduction

In the Musashino district of the Kanto plain, some loam layers for several meters with good permeability cover the Musashino gravel layer. The groundwater under no pressure here uses the Musashino gravel layer as the main aquifer. However, the seasonal recharge may raise the water level to the upper loam layer. The impermeable layer, which has a clay-rich lens shape, is often present in the loam layer (Kakuda, 2017). As the perchied water level rises to near the surface of the earth, flood damage is brought about occasionally (for example, Tokyo Metropolitan Geological Survey Association, 2000). Therefore, observation of such groundwater level fluctuation at many points is required to prepare for flood damage. Ohshima *et al*. (2015) examined the stability of these earthing resistances, in order to use the housing foundation as the earthing electrode to ensure safety for the electrical equipment, using a small model foundation of about 2 m ×2 m or the building foundation of a real scale housing. According to this, it was shown that there is a seasonal fluctuation in earthing resistance of about 200% in the small model or about 20% to 30% in the real scale. It is thought that this fluctuation is caused by the characteristic accompanying the temperature change. On the other hand, the observations of groundwater level at the wells around Inokashira pond, from the beginning of December 1988 until March 2001, showed that the peak-to-peak annual change of 2 m to 3 m (Kokubu, 2005). These variation in the groundwater level makes to change the earthing resistivity, and it becomes a factor of changing the earthing resistance of the electrode (Ryoki, 2019). In this memoir, the conseption is introduced, and then, it has been proposed that a method for estimating the level, based on the contribution of the variation of the groundwater level to the earthing resistance.

2. Theory

Consider the point current I flowing from the origin O to the ground of the semi-infinite medium with the resistivity ρ, the potential V_r, that is created on the surface of the distance r, is $V_r=\rho I/2\pi r$. When the hemispherical metal electrode of the radius a, which instead of the point current source, is grounded, the potential in the metal becomes equal to the potential $V_a=\rho I/2\pi a$ on the surface. Therefore, R, as the resistance of the origin O (*eq*. the resistance value of the hemispherical metal electrode) viewed from infinity, is expressed as follows; $R=V_a/I=\rho/2\pi a$. This is the earthing resistance of the hemispherical metal electrode.

Next, let us consider the ground potential when the earth is regarded as a horizontal two-layers structure. According to the mirror image method (Figure 1) shown by Hagiwara (1951), the potential $V_{0(r,\,z=0)}$ on the ground surface, z=0, at the distance r made by the point current source is as follows; $V_{0(r,\,z=0)}=\rho_1 I(1/r+2\Sigma^{\infty}_{k=1}(Q^k/(r^2+(2kd)^2)^{1/2}))/2\pi$. Where Q is the reflection coefficient with respect to the current density; $Q=(\rho_2-\rho_1)/(\rho_2+\rho_1)$. ρ_1 and ρ_2 are the resistivities of the first layer and the second layer, respectively. d is the layer thickness of the first layer. Now, consider R_a, the earthing resistance of the earth electrode on the two-layer structure, as in the case of Wenner's method which is a vertical electrical prospecting, letting $r=a$; $R_a=V_a/I=\rho_1(1/a+2\Sigma^{\infty}_{k=1}(Q^k/(a^2+(2kd)^2)^{1/2}))/2\pi$. This is able to call the equivalent earthing resistance. Consider the ratio of R_a to the earthing resistance R_1 which is in the semi-infinite medium consisting only of the first layer of resistivity ρ_1; $R_a/R_1=1+2\Sigma^{\infty}_{k=1}(Q^k/(1+4k^2(d/a)^2)^{1/2})$. This is able to call the apparent resistivity with respect to the equivalent earthing resistance.

©2019. Japan Geoscience Union. All Right Reserved.

Fig. 2 shows the relationship between d/a and R_a/R_1, here, d: thickness of the first layer, a: radius of the hemispherical conductive electrode. Shown in Fig. 2, it is able to understand that the equivalent earthing resistance takes a change when the groundwater level varies. Therefore, it is able to expect that variations in groundwater level is sensed by monitoring fluctuation of earthing resistance.

3. Future plans

In order to verify the method introduced here, the observation well will be drilled, and the fluctuation of the groundwater level *etc.* will be measured there. Then, the earthing resistance of the earth electrode for safety of electrical equipment will be continuously measured. The planned observations are (1) the groundwater level, (2) also the temperature, (3) also the electrical conductivity, (4) the apparent resistivity of the earth, and (5) the earthing resistance. Preliminary measurement results will be shown at the JpGU meeting.

Experimental and Theoretical Studies for Seafloor Survey by Ground Penetrating Radar

*Jun Sonoda[1], Tomoyuki Kimoto[2]

1. National Institute of Technology, Sendai College, 2. National Institute of Technology, Oita College

The electromagnetic wave (EM) do not propagate in the seawater because of high conductivity. In recent, the ultrasonic wave is widely used in the sea, such as the fish-finder, the side-scan sonar, and so on. We have used the ground penetrating radar (GPR) by several hundred MHz to search missing persons and rubbers in the sea after the tsunami caused by the Great East Japan earthquake. In this study, we have studied the under seawater prospecting using 350/400 MHz GPR in Hiroura Bay, Natori city, in Isohama fisher port, and off the coast of Sakamoto, Yamamoto town, Miyagi prefecture. At first, frequency characteristics of complex permittivity of several seawater samples by the time domain reflectometry (TDR), and conductivity in the depth of seawater by the conductivity temperature depth profiler (CTD) have been shown. Also, it is shown that the reflected wave from several objects at the about 10 meters depth has been observed using the 350 MHz GPR. Finally, the EM wave propagation in the seawater has been analyzed using the FDTD method with the graphics processing unit (GPU).

Evaluation of the 3-D Distribution of Fractures in a Rock Mass using Directional Borehole Radar Data from a Horizontal Borehole

*Kazuhiko Masumoto[1], Tomoaki Matsushita[2], Suguru Shirasagi[1], Takashi Ueki[3], Shinsuke Karasawa[3], Daiki Makino[3], Kazushige Wada[4]

1. Kajima Technical Research Institute, 2. Kajima Corporation, 3. Matsunaga Geo-Survey Co., Ltd., 4. Mitsui Mineral Development Engineering Co., Ltd.

Evaluation of the distribution of fractures in a rock mass ahead of a tunnel face is required for safe and reasonable tunnel excavation. To evaluate not only the position of fractures, but also their inclination before tunnel excavation, a directional borehole radar may be a suitable technique. A directional borehole radar can determine the inclination of fractures with a single pilot boring because it can estimate the arrival direction of the waves reflected by fractures, which are measured by a dipole array antenna with multiple elements. This study first examined the application of a directional borehole radar to investigate within a horizontal pilot boring. Next, field test using the directional borehole radar was conducted in a horizontal borehole drilled in the sidewall of a tunnel in order to confirm the applicability of the directional borehole radar for evaluating the three-dimensional distributions of fractures.

To apply the borehole radar for horizontal pilot boring in a tunnel, a casing is needed to prevent collapse of the borehole. Because the steel casing pipe which is typically used for pilot borings cannot be used for radar measurements, the applicability of a glass fiber reinforced plastic (GFRP) tube was verified as the borehole casing in this study. As the results of the experimental study, it could be concluded that GFRP tubes with steel joint couplers can be used as a borehole casing for measurements with radar.

Next, a directional borehole radar was applied to the survey of fractures in granite in a horizontal borehole drilled in the sidewall of a tunnel in order to confirm its applicability for evaluating the three-dimensional distribution of fractures. The results indicated that the strike and dip of each reflector estimated by the directional borehole radar measurements approximately corresponded to the fractures observed with a borehole scanner. Therefore, it was concluded that a survey with a directional borehole radar in a horizontal borehole could evaluate the three-dimensional distribution of fractures surrounding the borehole.

Automatic Detection of Deteriorated Concrete Bridge Deck using 2 GHz Horn Antennae

*Kunio Aoike[1], Shogo Tanaka[2], Naoto Takase[1], Akio Matsuyama[1], Masaya Yamauchi[1], Yoshinori Uno[1]

1. OYO Corporation, 2. Professor Emeritus of Yamaguchi Univ.

In 10 years, about 40% road bridges in Japan will become over 50 years old after the construction. Although many inspections have been conducted to the aged road bridges, the upper part of the bridge deck is impossible to inspect visually because of the asphalt concrete layer covering the bridge decks. It is becoming an important problem that slab deterioration is often generated in the upper part of the aged concrete bridge deck. Thus, it is becoming urgently necessary for the deterioration of the aged concrete bridge deck to be detected and repaired to elongate the life of the bridge. Ground penetrating radar (GPR) mounted on a vehicle is one of the effective non-destructive methods, which enables us to inspect the deterioration under no traffic control. A high pulse resolution is required to the GPR to detect anomalies beneath the asphalt concrete layer of the thickness of about 8cm. Adding to it, both a high scan rate in data acquisition and a safe mounting way of the GPR on vehicle are required to achieve the accurate and high-resolution inspection with a high speed traveling of the inspection cars. We adopted the horn antenna, produced by GSSI, whose central frequency is 2 GHz. The antenna can detect reflection waves from the boundary between the asphalt layer and the concrete bridge deck, and also can distinguish them from the surface reflection wave of the asphalt surface. SIR-30 type radar system having 8 channels enables us to realize 989 scans per second with 512 samples, thus it can realize the inspection under the vehicle speed up to 80km/h. We also mount the GPR antennae to the height of 45cm (i.e., lift off) from the road surface. This mounting is important for safe traveling of the inspection vehicle. 8 antennae are mounted on a boat trailer towed by vehicle and aligned in the transverse line to the moving direction. It allows us to scan about 1.7m width at one time. For the inspection of the deterioration of the concrete bridge deck, we developed an automatic processing system. This method predicts a received signal by using two empirical reflection waveforms. We acquired in advance surface reflection waveform and asphalt bottom reflection waveform from an experiment using a real size physical model. We determined the arrival time and the amplitude for each empirical waveform by matching the linear combination of the two empirical waveforms and the actual received signal. To visualize the anomaly distribution of the concrete bridge deck and to inspect the deterioration, we made three types of 2 dimensional maps on thickness of asphalt layer, relative reflectivity at the asphalt bottom, and the fitness between the received and the predicted waveforms. As the results, we could successfully detect the anomalies and delineate their extents. Fig. 1 shows an example of the processing results on a concrete bridge deck model which simulated slab deterioration. We have a plan to continue to modify and update the proposed method by applying the method to real road bridges as a future work.

Seasonal variation of gravity values at the Ishioka Geodetic Observing Station

*Akira Tomiyama[1], Tokuro Kodama[1], Shuichi Oomori[1], Yoshifumi Hiraoka[1], Toshihiro Yahagi[1]

1. GSI of Japan

Conventionally consistency between absolute gravimeters has been confirmed through the International Comparison of Absolute Gravimeters (ICAG) which is offered by the Comité International des Poids et Mesures (CIPM) with supports of the International Association of Geodesy (IAG). In order to extent the consistency to inside Japan, the Domestic Comparison of Absolute Gravimeters (DCAG) has been conducted by the Geospatial Information Authority of Japan (GSI) since 2002. Thanks to the opening of a new facility of GSI, named the Ishioka Geodetic Observing Station, the DCAG has been held there with inviting several domestic organizations which own absolute gravimeters. In order to evaluate validity of obtained data, it is necessary to collect data inside the Ishioka station and to examine influences of external factors. Therefore, we carried out periodic measurements using one of our FG5 absolute gravimeters for about one week every month throughout one year at the fundamental gravity point, “Ishioka FGS”, which is installed inside the Ishioka station. In this presentation, we will report the seasonal variation of gravity values obtained from our verification work.

Mount Fuji is an active volcano, the difficult situation is that we can’ t tell where the vent will open. Moreover, the eruption is thought to occur rapidly after the precursors such as grand deformations or increase of the seismic activities, because of its low viscosity magma. As a part of the volcano monitoring system, we are now constructing the gravity monitoring network. We are planning to install multiple continuous gravity monitoring stations. We installed the First Gravity Station in Mount Fuji Research Institute (MFRI) last year, where the absolute gravity value is measured by GSI. We are going to start the continuous observation in this station. Although low frequency events or tremors are observed sporadically, Mount Fuji is quiet at this point of time. So, the purpose of our observation at the beginning is to comprehend the precipitation and ground water effect, including snow melting effect in the spring time.

There is another interesting point for the gravity observation in Mount Fuji. The gravity difference between MFRI and the fifth station of the Yoshida trail is about 320 mGal, and the travel time between two points is about 30 minutes. It means that this is a good observation line for the verification of the gravimeters. Now we suggest the "phase-free" gravity measurement (https://phasefree.org/). The idea of "phase-free" is to eliminate the social phases (time, state) of normal times and disasters, so that goods or services normally used can be appropriately used at the time of disaster. If we continuously use the gravity observation line for the verification by various gravimeters in the normal time, that will be the important data for the volcano monitoring when the Mount Fuji is starting to prepare the eruption.

Absolute gravity and GNSS measurements on bedrock outcrops in Dronning Maud Land, East Antarctica

*Takahito Kazama[1], Yuichi Aoyama[2], Yoichi Fukuda[1], Koichiro Doi[2]

1. Graduate School of Science, Kyoto University, 2. National Institute of Polar Research

The Antarctic ice sheet plays a significant role in the long-term global climate change, so the spatiotemporal variations in the Antarctic ice sheet should be precisely monitored to forecast future climate changes. The ice sheet variations can be detected as loading deformations of the solid Earth, which are composed of the elastic deformation due to the present-day ice melting and the viscoelastic deformation due to the past ice melting. These effects can be separated by measuring both of the crustal deformation and land gravity variation, but enough gravity data has not been collected in the Antarctic region as of now. In order to understand more about the ice sheet variations in terms of solid-earth geophysics, land gravity data should be repeatedly measured at more sites in the Antarctic region.
We therefore collected new absolute gravity data using the FG5-210 absolute gravimeter at two stations located on bedrock outcrops in Dronning Maud Land, East Antarctica in November-December 2018. We first stayed at the Norwegian station, Troll (72.01S, 2.53E) from November 13 to 26, and installed the gravimeter on the benchmark (Troll AA) of the gravity hut. We needed to take more time to vacuum the dropping chamber of the gravimeter during the installation, because vacuuming pumps did not work normally, mainly associated with the cold weather in Troll Station. We started to measure absolute gravity values on November 18, and obtained the average gravity value of 982,360,741.41 +/- 1.16 +/- 1.82 microGal from the 178 sets of the gravity data collected for 5 days. We also stayed at the Indian station, Maitri (70.77S, 11.73E) from November 26 to December 4, and started to measure gravity values on the benchmark (Maitri AB) of the gravity hut on November 28. We obtained the 112 sets of the gravity data for 4 days, and determined the average gravity value of 982,576,883.10 +/- 1.23 +/- 1.83 microGal.
Our absolute gravity values collected in November-December 2018 was found to be smaller than those obtained in January-February 2012 (Dr. Jaakko Mäkinen, personal communication) by -4.4 and -4.2 microGal at Troll and Maitri stations, respectively. The gravity decrease may be caused by ground subsidence and/or ice mass decrease around the stations. The cause of the gravity decrease will be investigated in detail by analyzing the GNSS data which was collected simultaneously with the absolute gravity data at two stations.

Capability of ICA Method for separating GIA and Ice Mass Signals in Antarctica

*SHI TIANYAN[1], Yoichi Fukuda[1]

1. Graduate School of Science, Kyoto University

The Gravity Recovery and Climate Experiment (GRACE) mission provided global gravity change data with a spatial resolution of a few hundred kilometers and a temporal resolution of 30 days. The GRACE data revealed the total mass changes in Antarctica and contributed to Antarctic Ice Sheet (AIS) mass balance researches. However, there are large uncertainties in Glacial Isostatic Adjustment (GIA) effects, which should be removed from the GRACE data, for estimating the AIS mass balance. While many studies have been conducted for estimating or removing the GIA effects thus far, we try to use a statistical analysis method called Independent Component Analysis (ICA) and investigated its capability of separating GIA and AIS mass signals.

We primarily employed GRACE RL05 mascon data provided by NASA Jet Propulsion Laboratory (JPL) of all the GRACE available period from January 2002 to June 2017 with the spatial coverage of all Antarctica. And we used three ICA methods, namely, spatial ICA (sICA), temporal ICA (tICA), and spatio-temporal ICA (stICA), for testing the characteristics and/or the capabilities of the methods.

The results showed that the GIA like signal can be recovered successfully with sICA which separated GIA signals and AIS mass change signals into two statistical independent components. On the other hand, tICA decomposed the GIA signal into two independent components. This suggested that tICA could not solve the signals mixing problem completely. Nevertheless, tICA detected an extra anomaly snow-fall signal around 2010. This shows that tICA may have the potential to separate long-term trend signals with different time scales. The results of stICA suggested that its characteristics could be seen as a combination of the above two methods. Thus, an appropriate combination of the methods should be examined.

We also tested other datasets and revealed the different datasets and/or pre-processing of the datasets largely affected the obtained results. It is impossible to assess the validity of the results only using the GRACE data. Therefore, additional information should be necessary to validate and interpret the results.

Preliminary result of continuous observation with an iGrav superconducting gravimeter at the Teshikaga observatory, eastern Hokkaido, Japan

*Kazunari Nawa[1], Hiroaki Takahashi[2], Mako Ohzono[2], Kazumi Okada[2], Teruhiro Yamaguchi[2], Daisuke Oka[3], Noritoshi Okazaki[3], Ryo Honda[4], Hiroshi Ikeda[5]

1. National Institute of Advanced Industrial Science and Technology, 2. Hokkaido University, 3. Geological Survey of Hokkaido, 4. Mount Fuji Research Institute, 5. University of Tsukuba

In November, 2018, continuous observation with the iGrav type superconducting gravimeter (# 017) was started at the Teshikaga Observatory of the Hokkaido University in order to carry out high spatiotemporal resolution gravity monitoring in the caldera / volcanic area in eastern Hokkaido. The gravity meter used in CCS project of Tomakomai site was temporarily relocated to the Minami-shinkawa Observatory in September of the same year and then moved to the Teshikaga Observatory from Minami-shinkawa at the timing before entering the snowy season . We report what kind of record is obtained by the superconducting gravimeter at each observatory in wide frequency band from the seismic to the geodetic band. The observation data will be registered in the Crustal Deformation Database of Hokkaido University for the purpose of archive, distribution and comparative analysis with other principle data.

On the anomalous temporal gravity change between VERA and F-net stations at Ishigakijima, Japan

*Kazunari Nawa[1], Yuichi Imanishi[2], Yoshiaki Tamura[3], Hiroshi Ikeda[4], Takeshi Kimura[5]

1. National Institute of Advanced Industrial Science and Technology, 2. Earthquake Research Institute, The University of Tokyo, 3. National Astronomical Observatory of Japan, 4. University of Tsukuba, 5. National Research Institute for Earth Science and Disaster Resilience

Continuous gravity and hydrological observations at Ishigakijima revealed that the gravity difference between the F-net station (gPhone) and the VERA station (superconducting gravimeter) is closely related with the change in the soil water content near the F-net station. It was also noted, however, that the gravity difference did not indicate significant changes on some occasions of heavy rainfall. In addition, our precipitation response model did not predict the observed gravity change well for a particular period expanding a few tens of days. Here we reexamine our data of precipitation, soil moisture, and underground water level as well as gravity, to refine our model of the hydrological effects on gravity at Ishigakijima.

Discussion

Absolute gravity signals at the Sakurajima volcano since 2009 through 2018

*Shuhei Okubo[1], Keigo Yamamoto[2], Masato Iguchi[2], Yoshiyuki Tanaka[3], Yuichi Imanishi[1], Ryuichi Nishiyama[1], Miwako Ando[1], Atsushi Watanabe[1]

1. Earthquake Research Institute, The University of Tokyo, 2. Disaster Prevention Research Institute, Kyoto University, 3. Graduate School of Science, The University of Tokyo

In this paper, we present gravity signals based on continuous absolute gravity measurements since 2009 through 2018. During this period, several hundreds to a thousand eruptions/explosions were observed every year during 2009 through 2015 (phase 1). Significant seismicity and crustal deformations were observed on Aug. 15, 2015 (phase 2), followed by unusual quiescence since August 2015 (phase 3). Gravity signal after eliminating groundwater disturbance showed remarkable features according to the phase of volcanic activity as described below. During the phase 1 characterized by frequent vulcanian eruptions from the Showa crater, gravity fluctuated about a mean with rather small amplitude of 10 microgals, suggesting dynamic equilibrium is achieved at the magma chamber; magma supply from deeper interior is balanced with mass loss through eruptions. The phase 2 is interpreted as a dyke intrusion event, which causes elastic deformation and short-term gravity change almost simultaneously. In the current phase 3 (2016-2018), gravity shows monotonous increase of 10 microgal/yr, suggesting deflation of magma.

Detection of Earthquake-induced Prompt Gravity Signals in Multi-channel Data

*Masaya Kimura[1], Nobuki Kame[1], Shingo Watada[1], Makiko Ohtani[2], Akito Araya[1], Yuichi Imanishi[1], Masaki Ando[3], Takashi Kunugi[4]

1. Earthquake Research Institute,The University of Tokyo, 2. National Institute of Advanced Industrial Science and Technology, 3. Department of Physics, The University of Tokyo, 4. National Research Institute for Earth Science and Disaster Resilience

Seismic waves radiating from an earthquake rupture induce density perturbations of the medium, which in turn generate widespread transient gravity perturbations before the arrival of P-waves. Recently, signal detections of such prompt gravity perturbations from the 2011 Tohoku-Oki earthquake were reported. However, the data used for the detections were only a small subset of the available data, and the statistical significance of the signals were not sufficient nor discussed. In this study, we optimized multi-channel data recorded by several instruments and searched for the signals from the 2011 event. Though the single-trace records did not show any signal, the stacked trace of the broadband seismometer array data in Japan showed a signal clearly standing above the noise level, and this detection was confirmed with a sufficient statistical significance. This result provides the first constraint on the amplitude of prompt gravity signals by observation and will work as a reference for future detections.

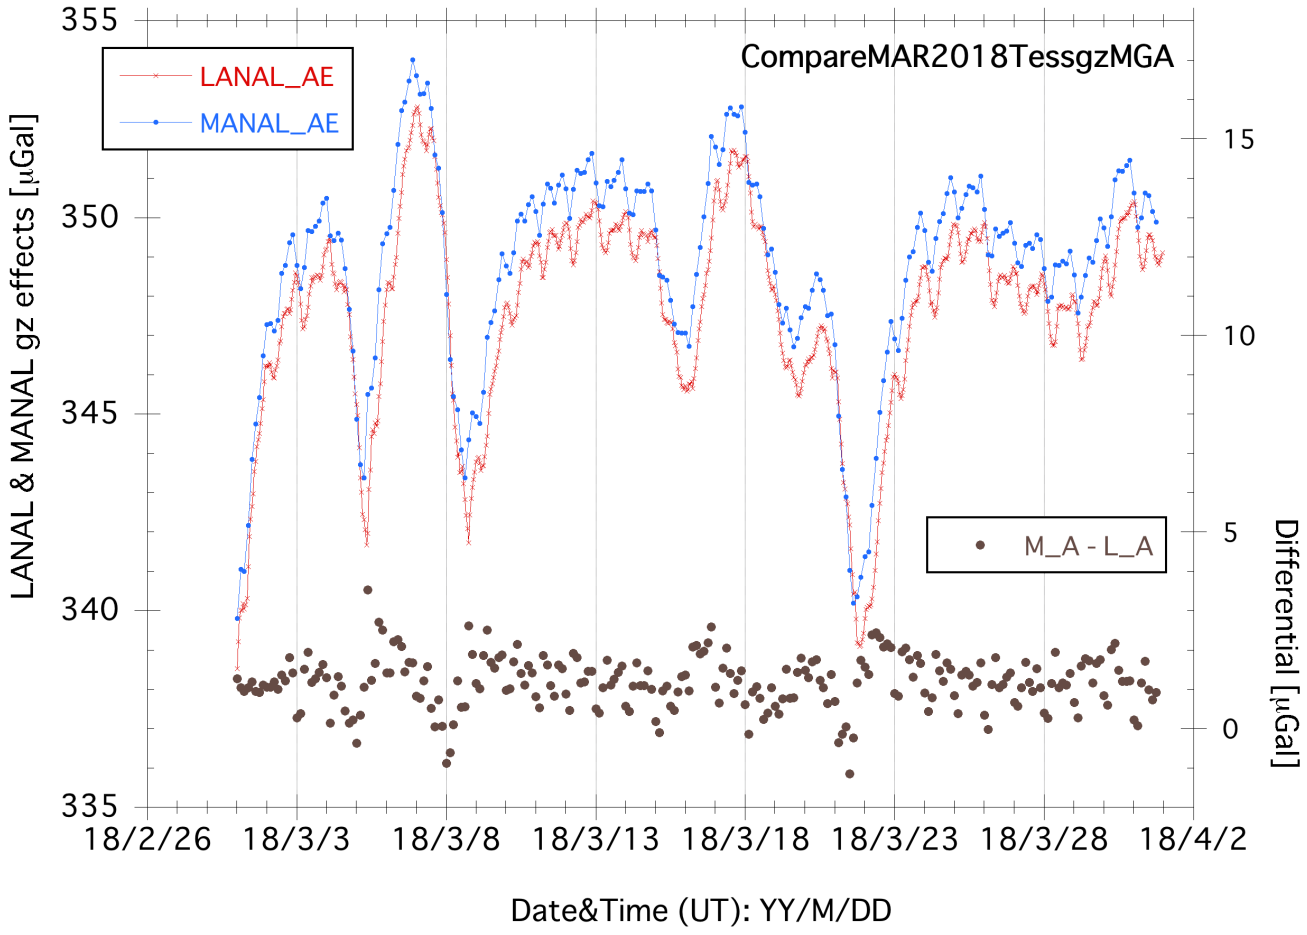
Evaluation of atmospheric attraction effect using local-scale objective analysis (LANAL)



*Toshiyuki Tanaka[1]

1. Tono Research Institute of Earthquake Science, Association for the Development of Earthquake Prediction

Tono Research Institute of Earthquake Science (TRIES) has been conducting continuous gravity observations both above the ground and below the ground of Mizunami Underground Research Institute in order to monitor the underground mass fluctuation including groundwater (Tanaka and Honda, 2018, doi: 10.1002 / 2017EA000311). The mass fluctuation between these two gravimeters can be evaluated from the difference between the two gravimeter values. Also, the sum of the two gravimeter values reflects the gravitational effects both from above the ground gravimeter position and from the below the underground gravimeter position. In order to extract the gravity fluctuation related to earthquake phenomena, that is, the gravitational effect only from below the subsurface gravimeter position, it is necessary to correct the atmospheric attraction effects above the ground gravimeter. Here, for the sake of simplicity, it is assumed that the atmospheric loading deformation effects and the existence of high altitude near the observation point are negligible. TRIES has been used the meso-scale objective analysis (MANAL) to calculate the atmospheric attraction effect in the range of 10 ˚×10 ˚×100 hPa–surf (approximately, 900 km in latitudinal direction ×1100 km in longitudinal direction ×16 km in altitudinal direction) centered on a gravity observation point before now. This attraction effect accounts for approximately 60% of the time-variating amplitude of the global summation. Local-scale objective analysis (LANAL) began publishing since 2018. The lattice spacing was 5 km, the same as MANAL, but LANAL increased the number of isobaric surfaces by 1 (975 hPa surface) from MANAL. This increase improved the spatial resolution of the altitude close to the observation point. Moreover, the time resolution improved as time interval changed from three hours of MANAL to one hour. Therefore, the updating from MANAL to LANAL to calculate the atmospheric attraction effect have to been evaluated quantitatively. Like other objective analysis data, LANAL is also offered in GRIB 2 format. We accessed LANAL using the GrADS software (http://cola.gmu.edu/grads/), but as it was seen in MANAL, it was not possible to display correctly with the control file generated by the g2clt or alt_g2ctl commands. In the PDEF line of the control file, you need to change the jref variable set to 1 to the value of the jsize variable. Also, from the necessity both of atmospheric density calculation on the topographic surface and comparison between isobaric surfaces and a topographic altitude, we use the enclosed terrain data (4-byte real binary). This feature is also the same specification as MANAL, and the GrADS draws the North-South direction reversed figure. In order to correct this problem, the data stored with the northwest end as the starting point was restored as the start point at the southwest end (byte swapping is necessary depending on the processing system). After that, the atmospheric attraction effect was calculated according to the procedure developed for MANAL. At the time of this writing, it was an evaluation for only one month in March 2018. The standard deviation of the difference of simultaneous numerical values between MANAL and LANAL was 0.66 microGal, and the maximum difference of instantaneous values was 2.4 microGal. It turned out that there was a significant difference. In the future, we would like to evaluate the difference from using MANAL by applying to gravity observation data.

Airborne gravity survey for establishment of a new precise gravimetric geoid model

*Tokuro Kodama[1], Akira Tomiyama[1], Shuichi Oomori[1], Erika Wada[1], Toshihiro Yahagi[1], Yoshifumi Hiraoka[1], Hiroshi Kawawa[1]

1. GSI of Japan

The vertical datum of Japan has been maintained by the Geospatial Information Authority of Japan (GSI) since more than 130 years ago. Basically it has been realized by conducting periodical leveling surveys in order to determine orthometric height of benchmarks, which are installed at approximately 2 km intervals along main national highways, based on the mean sea level of the Tokyo Bay. However, since this method takes much time and costs a lot, it is quite difficult to reflect vertical land movements quickly caused by such as plate motions and big earthquakes.

In order to tackle this situation, the GSI established a geoid model, called GSIGEO2011+2000, in April 2013 and also implemented a new manual for utilizing the model for public surveys in order to obtain orthometric height from GNSS data. It in fact played a certain role in improving the efficiency of surveying. Geoid models released by the GSI so far are all hybrid, which are constructed of a gravimetric geoid model and geoid heights directly measured by GNSS/leveling surveys, in order to compensate the lack of precision of the gravimetric geoid model. However, since the GNSS/leveling data are based on results of the leveling surveys, they are unavailable once crustal deformation occurs until the leveling surveys are conducted again. In order to improve the precision of the gravimetric geoid model, it is necessary to prepare high quality gravity data all over Japan. But current gravity data contain some problems such as blank areas in both mountainous areas and coastal waters , age of data and inaccuracy of location information decided by topographic map.

In order to solve these problems and make it possible to measure precise orthometric height more quickly, the GSI has been carrying out a new airborne gravity survey project since FY2018. First, we will collect high quality nationwide gravity data using aircraft, then calculate a new precise gravimetric geoid model combined the airborne gravity data with other ones such as terrestrial, marine and satellite gravity data. We are planning to introduce a new height system based on this new geoid model and ellipsoidal heights obtained from GEONET by 2014. Since the geoid model is basically very stable against the crustal deformation, it is expected to update the orthometric height immediately by GNSS data even if crustal deformation occurs.

In this presentation, we will review our future vision of the new height system and report the progress of GSI’ s airborne gravity survey project.

Gravimetric geoid modeling using airborne gravity data : a case study in Colorado, U.S.A.

*Koji Matsuo[1], Rene Forsberg[2]

1. GSI of Japan, 2. Denmark Technical University

We present the conputational results of gravimetric geoid over Colorado using airborne gravity data. The gravity data and degital elevation model were provided by IAG JWG2.2.2 with the colaboration of National Geodetic Survey. Here we show the gravimetric geoid based on the two Stokes-Helmert approaches, i.e. the classical approach (Moritz, 1980) and UNB approach (Vanicek et al., 2013).

[S-GD02] Engineering Application of Space Geodesy

convener:Seiichi Shimada(Graduate School of Frontier Sciences, University of Tokyo Nippo Co. Ltd.), Shuichi Rokugawa(The University of Tokyo), Basara Miyahara(GSI of Japan), Toshiaki Tsujii(Department of Aerospace Engineering, Osaka Prefecture University), Chairperson:Masaatsu Aichi, Kazuki Sakai

In the space geodetic community in Japan, geoscience and other scientific researches, such as seismology, volcanology and meteorology, are predominant. However, engineering application researches are also actively conducted in academic societies abroad. Recent advances in GNSS and InSAR measurement techniques are progressing towards widely engineering usage of space geodetic measurements even in domestic Japan. In addition, the Geospatial Information Authority of Japan (GSI) is about to shift from conventional leveling survey to space geodetic surveying such as GNSS levelling, and the space geodetic method could spread rapidly even in many engineering fields using conventional leveling survey. In this session, we introduce advanced engineering research using space geodetic measurements such as ground measurement / self-driving in particular to young earth scientists. We will also welcome a wide range of general presentations on measurements/research in engineering fields using space geodetic technology.

1. GSI of Japan

Global Navigation Satellite System (GNSS) are conventionally used for determining reference positions in Japan by static survey activities following a uniform standard based on the survey low. In recent years, thanks to improvement of satellite positioning techniques, the utilization of GNSS positioning has been expanded to various real-time positioning services such as autonomous driving system, intelligent construction, smart agriculture and drone delivery. This trend would accelerate in the future due to new services like Centimeter Level Augmentation Service (CLAS) offered by Quasi-Zenith Satellite System (QZSS) or Precise Point Positioning (PPP) provided by private companies. Basically those kind of real-time positioning data give us ‘current’ location though most geospatial information, represented by maps, are built based on the certain ‘past’ epoch. The difference between them becomes larger year by year because of active crustal deformation in Japan. The more precise the real-time position are decided, the more careful we should treat this difference.

Therefore GSI has been developing a new system for correcting this difference in order to fully utilize the real-time positioning data by keeping consistency between existed geospatial information. The prototype of the system was offered to public from January to March in 2019 to collect feedbacks from stakeholders. We plan to launch this system officially until 2020.

It is also important to obtain precise elevation for three dimensional positioning. Historically the height system in Japan has been maintained by conducting nationwide split leveling surveys for more than 130 years. However, since it needs a lot of time and cost, it is necessary to prepare a precise geoid model for determining an orthometric height directly from an ellipsoidal height obtained by GNSS data. Hence GSI launched a new airborne gravity survey project in 2018 to collect high quality gravity data all over Japan, which is necessary to construct a new precise gravimetric geoid model within several centimeters precision. It is expected to introduce a new height system based on the new geoid model and GNSS data up to 2014. It will enable users to determine reasonable elevation data by GNSS without leveling surveys.

Through these efforts, GSI will contribute to realize the future society which fully utilize precise three dimensional position data for various geospatial information services. In this presentation, we will review the current actions of GSI and share a future vision derived from them.

Preliminary study on the application of satelite-based monitoring for land surface displacement to inverse analyses of groundater flow/land subsidence modeling

*Masaatsu Aichi[1]

1. Graduate School of Frontier Sciences, The University of Tokyo

Incerasing land subsidence monitoring data with InSAR and GNSS techniques are expected to improve a calibration process of groundwater flow/land subsidence model. However, the observed data possibly includes the displacement caused not only by known groundwater abstraction but also natural displacements such as seismic/post-seismic crustal motion. Then, it is not straight forward to use the observed data for inverse analysis. It is important to separate known and unknown components from monitoring data with a simultaneous
calibration of land subsidence model.
This study presents a new method based on the prior assumption that the crustal deformation is smooth in space relative to land subsidence cone caused by groundwater abstraction. It consists of the iteration of the following three steps. In the first step, the map of difference between the observed data and the calculated result of the land subsidence model with assumed parameters. In the next step, the spatial roughness of difference map is evaluated from the rotational energy. In the final step, the model parameters are modified to minimize the spatial roughness of unknown components.
This method was tested by a synthetic data composed of land subsidence from the assumed groundwater abstraction, the assumed sudden and long-term displacement like earthquake and post seismic motion. The proposed method successfully separated the land subsidence caused by groundwater abstraction and other components, and exactly found the model parameters. The results suggest that the porposed method has the possibility to enhance the application of satellite-based land subsidence monitoring data to the calibration of land subsidence models.

Monitoring of ground deformation all over Japan by InSAR and utilizing 2.5-D analysis

*Kazuki Sakai[1], Kyonosuke Hayahsi[1], Masaki Kuwahara[1], Tatsuya Yamashita[1], Masaki Honda[1], Hiroshi Munekane[1]

1. GSI of Japan

GSI (Geospatial Information Authority of Japan) has been conducting SAR interferometry (InSAR) analysis with ALOS-2 data to monitor ground deformation all over JAPAN. In addition, we have conducted InSAR urgent analyses once natural disasters such as volcanic crisis or large earthquakes occur. We provide InSAR-derived deformation data to the Earthquake Research Committee, the Coordinating Committee for Prediction of Volcanic Eruptions and others. Furthermore, we publish those data on GSI website for general users.

InSAR analysis with a pair of observation data can reveal only line-of-sight (LOS) deformation. However, quasi-up-down and quasi-east-west component deformation may be calculated by combining LOS deformations observed from both east and west direction. This analysis method is called 2.5-D analysis (Fujiwara et al., 2000). “Quasi” means that the directions of obtained deformation by 2.5-D analysis are slightly different from up-down and east-west.

LOS deformation from InSAR analysis is usually represented in rainbow color, and is difficult to understand intuitively. Furthermore, deformation direction can’t be identified from such InSAR image. On the other hand, 2.5-D analysis image is easier to understand and deformation direction can be identified. GSI has been considering a way to make InSAR image more understandable to general public, and 2.5-D analysis is one of the candidates. The 2018 Hokkaido Eastern Iburi Earthquake is an example of utilizing 2.5-D analysis. The quasi-up-down component deformation was utilized in setting a recovery survey area.

In this presentation, we will introduce ground deformations detected by InSAR analysis and some examples of 2.5-D analysis derived from earthquakes and volcanic activities.

*Acknowledgment

ALOS-2 data were provided based on the joint research agreement with JAXA (Japan Aerospace Exploration Agency). The ownership of ALOS-2 data belongs to JAXA.

Resource Exploration using Interferometric Synthetic Aperture Radar Measurement Technology

*Shuichi Rokugawa[1], Takako Nakamura[1]

1. The University of Tokyo

InSAR using synthetic aperture radar (SAR) is a technology that enables the detection of the earth surface deformation without any observation points on the ground. The L-band SAR mounted on ALOS / PALSAR-2 is effective even in the vegetated areas because of relatively long wavelength of the sensor. InSAR has the potential to be used in the various technical applications. This technique has been primarily used to analyze fluctuations due to natural disasters and large-scale deformations such as crustal movement caused by earthquakes and volcanic eruptions. However, the extraction of the small deformation is also possible by continuously monitoring the ground deformation. Compared with the leveling and global navigation satellite system, InSAR provides the advantage of wide range observation capability. However, accumulating a certain amount of data is required for this kind of analysis. In this study, the second largest oil filed in Kuwait and East Kanto gas field in the Chiba prefecture, were analyzed as case study fields. InSAR data from 2004 to 2010 are applied to derive the surface deformation. The results of the detailed analysis confirmed remarkable ground deformation mainly at four locations in Kuwait. It was confirmed that each of these four points coincided with the positions of the Burgan, Minagishu, Umm Gudair and the Wafra oil fields, respectively. Therefore, it was discovered that InSAR can accurately grasp the ground deformation near the oil production wells. Moreover, these results reveal that there was a linear correlation between the influence range of the oil and the production amount of the oil field. A high correlation was also observed between the subsidence amount of the oil field and the actual production amount. Therefore, it is established that the InSAR analysis results can be applicable in production management, as well. Similarly, in Chiba prefecture, the InSAR time series analysis was conducted to grasp the spatial distribution of the ground change in time series. It also demonstrate the possibility of the tools for monitoring and management of the actual oil/gas fields.

The application example of GNSS for natural gas development together with PDCA Management Method

*Yoshiyuki Muramoto[1], Susumu Hayatsu[1], Michiharu Hiyama[1], Daisuke Murai[1], Shoji Kunisue[1]

1. KANTO NATURAL GAS DEVELOPMENT CO., LTD

[Background]
We have been developing the Southern Kanto gas field for many years. This field which contains natural gas dissolved in water is located primarily under Chiba prefecture, and it extends across a wide area of the Kanto region, including Ibaraki, Saitama and Kanagawa prefectures as well as Tokyo Metropolis. This field's recoverable reserves are estimated 368.5 billion cubic meters, making it the largest field of gas dissolved in water in Japan. The gas is dissolved in formation water which is called brine, so it is produced together with brine. Commercial production of natural gas has been conducted in Chiba prefecture since 1931 and has contributed to the growth in the region. Formerly, it was mainly used for industrial gas, but now most common usage is for city gas. On the other hand, land subsidence has been confirmed in Kujukuri area, east of Chiba prefecture. Brine production is considered as one of possible causes of it. Companies producing natural gas in this area including our company have made a land subsidence prevention agreement with the Chiba prefectural government to prevent and control land subsidence. Also, from the technical point of view, we conduct joint study on environmental issues with other gas production companies as a member of "Environmental Technology Research Association for Natural Gas Dissolved in Water".

[Observation of land subsidence]
The Chiba prefectural government has conducted leveling every year. We also have conducted it, but it takes a lot of time to get the survey result because we have to revise the observation data based on the leveling result conducted by local government. On the other hand, GNSS observation which is one of the surface level observation techniques has been prevailed recently. The advantage of GNSS is that continuous observation is possible at the place where it is installed. In Japan, the Geographical Survey Institute has established GEONET (GNSS Earth Observation Network System) throughout the country. We installed GNSS stations in our operating area and analyze these data together with GEONET's since 2013 to get circumstance of land subsidence quickly.

[Application example of GNSS for natural gas production]
We installed GNSS station to monitor the land subsidence in a certain area where natural gas is newly developed. The reason for that is because we need to adjust the brine production rate based on land subsidence. We use GNSS data in "PDCA Management for Land Subsidence Control", one method for controlling land subsidence systematically. This method consists of four elements. "P", Plan, means making of production plan based on the simulation result. "D", Do, means production of natural gas based on the production plan. "C", Check, means observation and evaluation of land subsidence by GNSS and leveling. "A", Act, means update of simulation model. By repeating this method every year, we will improve the way of subsidence management.
In the presentation, we will introduce the application example of GNSS for natural gas development together with PDCA Management Method.

New threats and countermeasures in the aviation field where the use of GNSS satellite navigation expands

*Takeshi Fujiwara[1], Toshiaki Tsujii[2]

1. Japan Aerospace Exploration Agency, 2. Osaka Prefecture University

To contribute to the realization of the next-generation air transportation system, JAXA is promoting the research and development project named DREAMS (Distributed and Revolutionary Efficient Air-safety Management System). Research and development of high precision and reliable navigation system is one of the most important targets of this project. In this paper, the impact of the plasma bubble, a kind of ionospheric anomalies, on the availability of GBAS precision approach is investigated based on the collected data under the actual plasma bubbles and the mathematical models of the plasma bubbles are introduced to be used in the Monte-Carlo simulations to estimate the availability.

Seasonal variations in crustal seismicity in San-in district, southwest Japan

*Taku Ueda[1], Aitaro Kato[1]

1. Earthquake Research Institute, the University of Tokyo

A growing body of evidence suggests that seismicity is seasonally modulated in a variety of tectonic environments (e.g., Gao et al., 2000; Heki, 2003; Bettinelli et al., 2008; Ben-Zion & Allam, 2013; Amos et al., 2014; Johnson et al., 2017). Identifying cyclic variations in seismicity leads to an improvement of our understanding about the physics of earthquake triggering.

San-in district, southwest Japan, is an active seismicity zone characterized as high shear strain rate by geodetic measurement (Nishimura and Takada, 2017). Moreover, Ogata (1983) has pointed out a possibility of seasonal variations in seismicity rate in the Inner Zone of southwest Japan. We here focus on seasonal variations in crustal seismicity in San-in district.

We used the JMA catalog (constructed by Japan Meteorological Agency) from 1975 through 2017 (magnitude M >= 3.0 and depth <= 20 km). We applied space-time Epidemic Type Aftershock Sequence (ETAS) model (e.g., Ogata, 1998; Zhuang et al., 2004) to the catalog and used a probability-based declustering procedure based on the work of Zhuang et al. (2002) to evaluate the significance of the seasonal variations, adopting uncertainties derived from the declustering scheme.

We demonstrated that semiannual variations in background seismicity rate, which increases in spring and autumn, are statistically significant from 1980 through 2017. The distribution of large historic and modern earthquakes (from 1850 through 2017, magnitude M >= 6.2, constructed by Chronological Scientific Tables) shows a similar pattern to recent background seismicity, suggesting that seismicity in San-in district has shown seasonal variations for over 150 years. There is some correlation between the monthly averaged background rate shifted backward 2 months and monthly averaged rain amount in the studied region. These results infer that seasonal variations in seismicity in San-in district can be explained by increasing pore pressure within fault zones, caused by infiltration of rainfall in autumn and decreasing surface mass due to snow melting in spring. Some correlation between seismicity and precipitation suggests that modulation of precipitation may be a key ingredient to produce time-dependence of background seismicity.

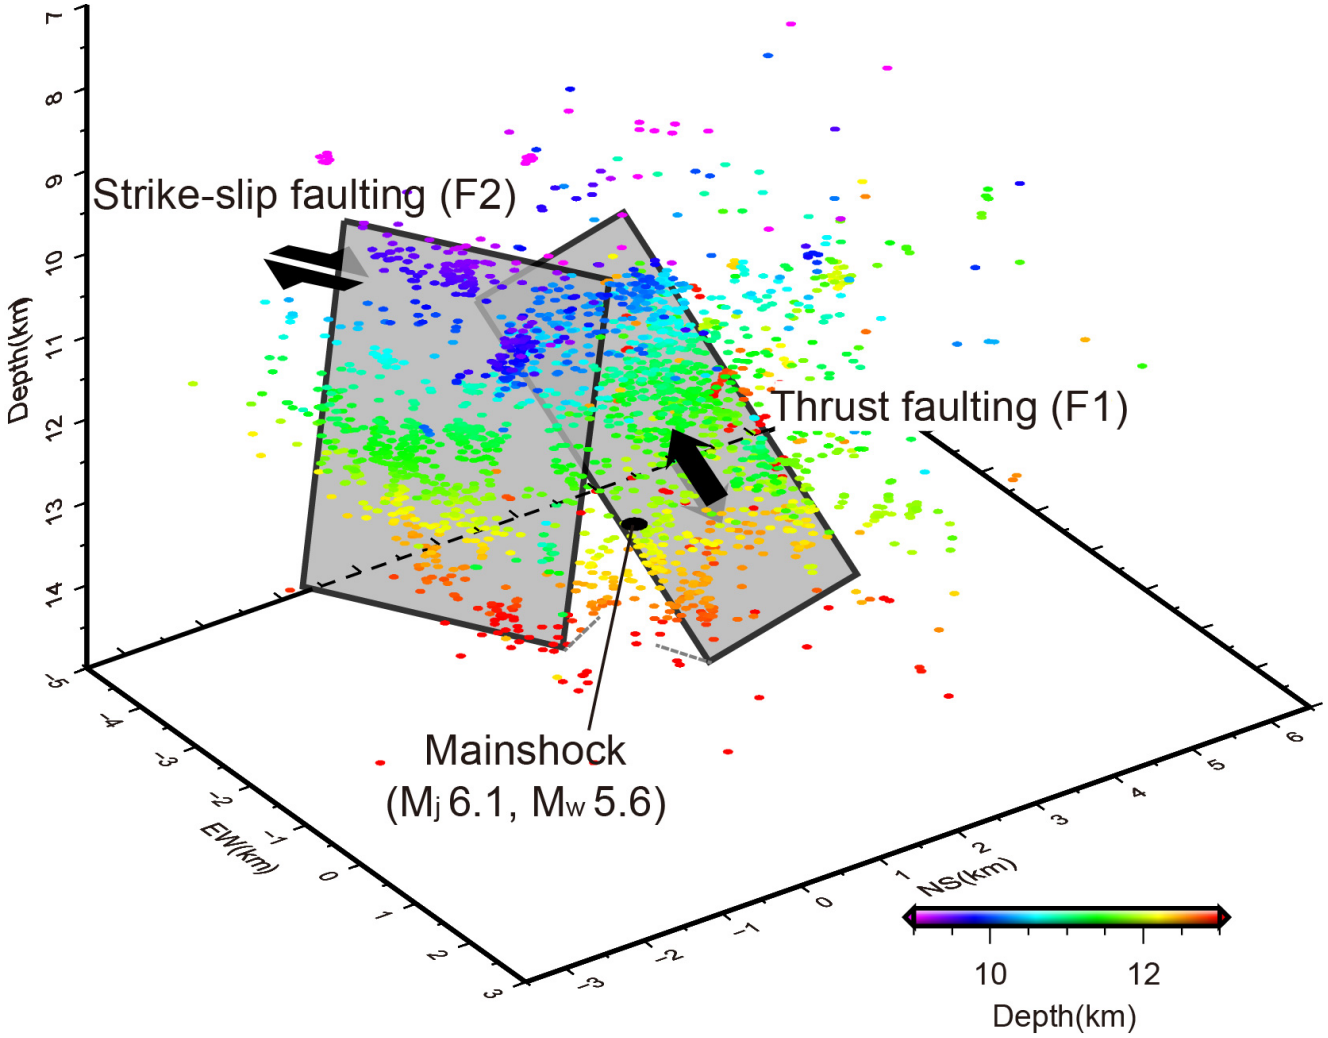
Source fault model of the 2018 M_w 5.6 northern Osaka earthquake, Japan, inferred from the aftershock sequence



*Aitaro Kato[1], Taku Ueda[1]

1. Earthquake Research Institute, the University of Tokyo

We reconstructed the spatiotemporal evolution of seismicity associated with the 2018 M_w 5.6 northern Osaka earthquake, Japan, to discuss the source fault model of the mainshock rupture, the possible link between this rupture and known active faults, and subsequent crustal deformation. We first relocated the hypocenters listed in the earthquake catalog determined by the Japan Meteorological Agency using a double-difference relocation algorithm. We then searched for the earthquake waveforms that closely resembled those of the relocated hypocenters by applying a matched filtering technique to the continuous waveform data. The relocated hypocenters revealed two distinct planar alignments with different fault geometries. A combination of the relocated hypocenters and focal mechanisms suggests that the mainshock rupture initiated on a NNW–SSE-striking thrust fault, dipping ~45° to the east, with the rupture propagating to an adjacent sub-vertical ENE–WSW-striking strike-slip fault ~0.3 s after the initial mainshock rupture, resulting in the simultaneous propagation of dynamic rupture along the two faults. The strike-slip fault is oblique to the strike of the Arima-Takatsuki Fault, indicating that blind strike-slip faulting occurred. While the east-dipping thrust fault is located deeper than the modeled extent of the Uemachi Fault, a simple extrapolation of the near-surface geometry of the Uemachi fault partially overlaps the mainshock rupture area. Although it is unclear as to whether a blind thrust fault or a deep portion of the Uemachi Fault ruptured during this mainshock–aftershock sequence, a mainshock rupture would have transferred a static stress change of >0.1 MPa to a portion of the east-dipping thrust fault system. Intensive aftershocks have persisted along the northern and southern edges of the source area, including moderate-magnitude events, whereas the seismicity in the central part of the source area has shown a rapid decay over time. Delayed triggered aftershocks were clearly identified along the northern extension of the rupture area. Because the background seismicity is predominant in this northern area, we interpret that aseismic deformation, such as cataclastic flow lubricated by crustal fluids, triggered this off-fault seismicity.

National Research Institute for Earth Science and Disaster Prevention

The Hokkaido Eastern Iburi earthquake (M_{JMA} = 6.7) occurred on 6 September 2018 in the Hokkaido-corner region where the Kurile and the northeastern Japan island arcs meet. We relocated aftershocks of this intraplate event immediately after the mainshock by using data from a permanent local seismic network and found that the aftershocks concentrated in depths from 20 to 40 km, which is extraordinarily deep when comparing with other shallow intraplate earthquakes in the inland area of Honshu and Kyushu, Japan. Moreover, we found that the aftershock area consists of three segments. The first one is located in the northern part of the aftershock area, the second one is located in the southern part, and the third one is located in a stepover segment between the first one and the second one. The hypocenter of the mainshock, which is a rupture initiation point, is located in the stepover segment. The centroid moment tensor solution for the mainshock indicates a reverse faulting, whereas the focal mechanism solution determined by using a first motion polarity of *P* wave indicates a strike-slip faulting. To explain this mismatch qualitatively, we present a model that the rupture started as a small strike-slip faulting in the stepover segment of the aftershock area and it is followed by the large rupture of two reverse faulting in the northern and the southern segments.

Layered structure of the upper mantle and the crust revealed in the time series analyses of the aftershocks of the 2018 Hokkaido Eastern Iburi Earthquake

*Takayuki Kawabe[1]

1. Faculty of Education, Arts and Sciences, Yamagata University

The 2018 Hokkaido Eastern Iburi Earthquake, occurred at September 6, 2018 03:07:57 am. Many aftershocks occurred along a plane which is striking north-northeastward and is dipping to the east at an inclination of 70 ˚. The depth of the upper limit at which aftershocks occurred has been becoming shallow over time.
According to time series analyses of the aftershocks, four depth zones are recognized. They are as follows;
Depth zone of 45 to 30 km deep: Many aftershocks occurred in the zone just after the main shock.
Depth zone of 30 to 20 km deep: Less aftershocks occur. However the magnitude of many of them are larger.
Depth zone of 20 to 10 km deep: Many small aftershocks were active. They distribute not uniformly but on multiple radial lines, and they occurred line by line.
Depth zone of 10 to 5 km deep: less aftershocks occur. However the dip of the plane on which aftershocks occurred is gentle as 45 ˚
These recognized zones seems to show the difference in physical properties of the underground geology. According to the slow development of aftershock and distribution form of epicenters suggest strongly the involvement of the deep hot water flow along the fault plane.

Aftershock sequence of the 1847 Zenkoji earthquake: Temporal decay presented in four historical materials and best fit values of paramaters for Omori-Utsu law

*Kentaro Hattori[1], Ichiro Nakanishi[1]

1. Kyoto Univ.

Seismic intensities estimated from damage caused by earthquakes have been most commonly used to locate earthquake epicentral area since Irish seismologist Mallet used degree of damage by the great Napoli earthquake of 1857 to locate earthquake source area. However, the scales of seismic intensity are different among countries. The seismic intensities are somewhat subjective and are affected by ground conditions.

Matsui and Oike (1997) proposed the use of the numbers of felt aftershocks right after large historical earthquakes to locate source area. A problem in their approach is that it is usually difficult to count the number of aftershocks in epicentral area or places close to the area.

We attempt to fit Omori-Utsu law (Utsu, 1961) to aftershock sequences of a historical large earthquake to overcome the above mentioned problem of the location of epicentral area. The value from counting aftershocks is integer, and seems to be more robust than the estimation of ground motion from the description in historical materials. The temporal decay of the number of aftershocks n(t) is described by the empirical Omori-Utsu law as $n(t) = K (t+c)^{-p}$, where t is the lapse time after the mainshock, p is an exponent showing the decay rate, c is a time scale, and K is a parameter showing aftershock activity.

We use aftershock sequence data of the 1847 Zenkoji earthquake presented in four historical materials owned in Matsushiro, Suwa, Fujinomiya, Gifu, in order of the distance from the epicentral area. We assume c=0.1 and p is common in four data, and obtain the best fitting p and four K. The result is shown in Fig.1. In the figure, it is clear that Omori-Utsu law does not fit the time range right after the earthquake occurrence for Matsushiro, Gifu, Suwa data, but fits Fujinomiya data. Another clear feature in Fig.1 is that the parameter K for Gifu data is 300. This value is much larger than those for Suwa (K=80) and Fujinomiya (K=6), both places are located closer to epicental area than Gifu. Fig.1 may suggest that the data preserved in Gifu were not written in Gifu, but in a place much closer to epicentral area.

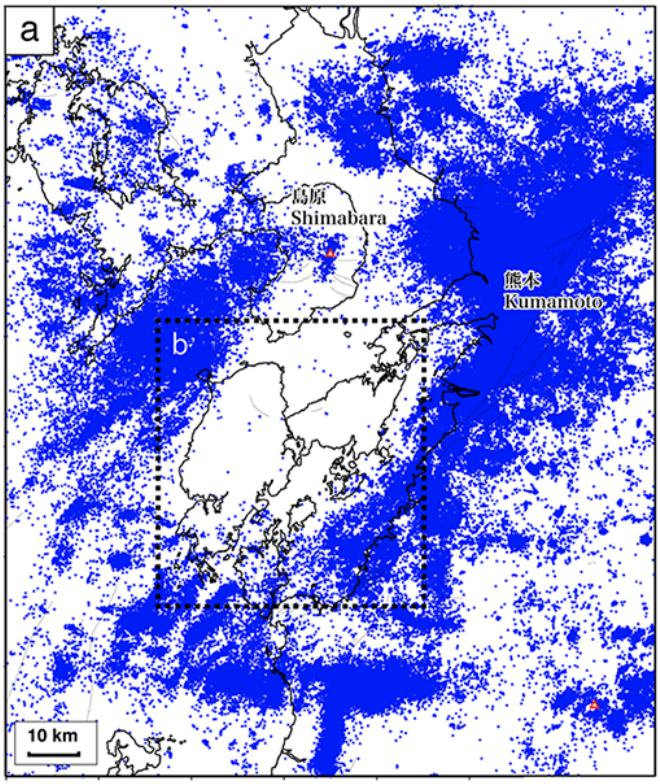
The aseismic islands, Amakusa-Kamishima and Shimoshima, Kumamoto Prefecture, southwest Japan: What persistently shuts off regional seismicity



*Shinji Toda[1]

1. International Research Institute of Disaster Science, Tohoku University

Is there any inland region in Japan totally aseismic? This is a simple question against the frequently releasing comment by seismologists to the general public “none of the region in Japan can be avoided from strong ground motion.” To strictly check if this is true, we simply examined the Japan Meteorological Agency (JMA) earthquake catalog of 1923-January 2019, and then found one of the significantly aseismic regions in Kumamoto Prefecture, Amakusa-Kamishima and Shimoshima islands that extend about an area of 2,000 km^2 (hereinafter AAR). Neither historical destructive earthquake is documented in the AAR (Usami et al, 2013). Instead the AAR is surrounded by tectonically and seismically active zones of the Beppu-Shimabara graben to the north, Amakusa-nada graben to the west, the Futagawa-Hinagu fault system that caused the 2016 Kumamoto earthquake to the east, and highly seismic zone to the south. The AAR is characterized by high-Bouguer gravity anomaly possibly related to the underlying metamorphic rocks, while the most of the area exposes upper Cretaceous to Paleogene sedimentary rocks folded along NNE-trending axes (Takai and Sato, 1982). Numerous WNW-trending strike-slip faults, transverse these anticlines and synclines, are thought to have developed in the Miocene period but not been active during the late Quaternary period. Although the coastal geomorphologic features suggest uplifted marine terraces to the north and rias-type subsidence to the south formed during the late Quaternary, we infer long-term very gradual crustal uplift has been lasting since late Miocene due to the lack of sediments. Since the recent GNSS observation indicates a very low rate of strain in the AAR (GSI, 2018), we believe the AAR behaves as a rigid block enclosed by active tectonic zones mentioned above, those condition brings long-term stress shadow to bear such a persistent aseismic region.

[S-SS10] Seismicity

convener:Kei Katsumata(Institute of Seismology and Volcanology, Hokkaido University), Chairperson:Akio Katsumata(気象研究所地震津波研究部第一研究室), Yasushi Harada(東海大学)

This session aims to improve our understanding on seismicity. Any contribution on behavior of earthquakes as a cluster, such as regional seismicity and aftershocks, are welcomed. We also welcome contribution on temporal and spatial interactions that control seismicity, and tectonic processes, and geological and thermal structures that regulate seismicity.

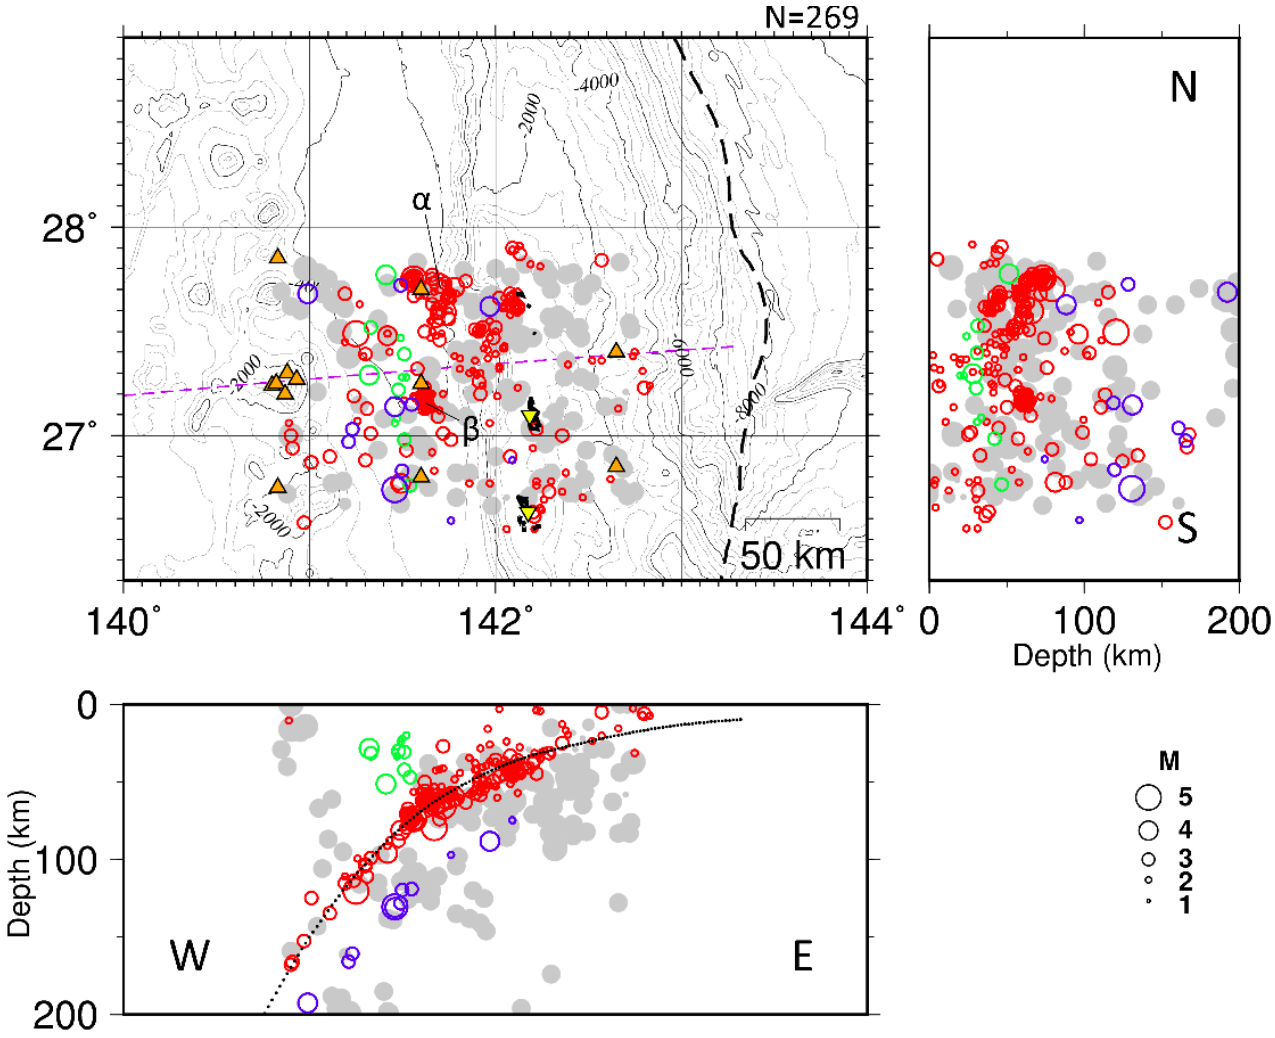
Seismicity in the matle wedge around Ogasawara Islands and Lesser Antilles



*Akio Katsumata[1], Kenji Nakata[1], Akio Kobayashi[1], Fuyuki Hirose[1], Takahito Nishimiya[1]

1. Meteorological Research Institute, Japan Meteorological Agency

Nakata et al. (2018) deployed ocean bottom seismometers around Ogasawara Islands from July to October in 2015, and observed seismicity of the area. Double seismic zone and seismicity in the mantle wedge (green circles in the figure) were identified. Some hypocenters were distributed in the 20-50 km depth range inside the mantle wedge. These earthquakes are located beneath the Ogasawara Trough without forming any clusters. Ogasawara Trough is a forearc basin between the the current volcanic arc and the Ogasawara ridge.
Seismic activity is usually low in the mantle wedge in areas without complex plate interactions. However, seismicities in the mantle wedge have been reported for other regions. Uchida et al. (2010) found supraslab seismicity off Sanriku coast. Davey and Ristau (2011) reported seismicity observed in the mantle wedge beneath northeast New Zealand. Laigle et al. (2013) reported seismicity in the mantle wedge along the Lesser Antilles subduction zone. The seismicity in the mantle wedge beneath Lesser Antilles is distributed over trench-normal distance more than 50 km, which is wider than that seen in the figure.
Supraslab earthquakes offshore Sanriku (Uchida et al. 2010) are distributed mainly near the toe of the mantle wedge, and form clusters. Earthquakes in the mantle wedge beneath northeast New Zealand form clusters near the boundary of subducting slab. The seismicity around Ogasawara Islands looks like that of Lesser Antilles rather than those offshore Sanriku and beneath northeast New Zealand.
The tectonic features of the forearc basins in the Lesser Antilles and Ogasawara Island regions are similar. Ogasawara ridge was formed with volcanic activities in 41-48 Ma related to beginning of the Pacific plate subduction in this area (Ishizuka et al. 2006). The backarc and forearc basins of the Lesser Antilles were formed as a single structure, and the Lesser Antilles were formed by volcanic activities with dividing the single basin into the two (Aitken et al. 2011). The volcanic activity started at about 40 Ma (Briden et al. 1979) due to the rollback of the Atlantic oceanic slab subduction (Aitken et al. 2011). Both forearc basins around Ogasawara Islands and Lesser Antilles are related to beginning of oceanic slab subduction. The seismic activity in mantle wedge may be related to dehydration of minerals which were formed at the time of subduction onset.

Improvement of the accuracy of the unified Japan Earthquake Catalog using ocean bottom seismographs

*Hiroshi UENO[1], Mitsuharu Ueda[1], Hiromi Misu[1], Hirofumi Yokoyama[1], Yuriko Iwasaki[1], Iwakiri Kazuhiro[1]

1. Seismology and Volcanology Department, Japan Meteorological Agency

The Unified Earthquake catalog for Japan has already been made available to the public by the Japan Meteorological Agency (JMA). In this catalog, hypocenters are determined using high-density seismic data collected by Japanese institutes and universities.

Recently, many ocean bottom seismographs(OBS) were installed around Japan Trench and Nankai trough.

In order to utilize many OBS data, we will optimize the hypocenter determination method of JMA from the following viewpoints.
1. Applications of the correction travel times of OBS for sedimentary beneath OBS.
2. Applications of velocity structures for OBS stations estimated from some velocity structure investigations.
3. Applications of the correction values of OBS for calculating magnitude with velocity amplitudes.

Spatial distribution of seismic activity and stress field in the source region after the 2011 Tohoku-Oki earthquake

Tomoya Nishimori[1], *Ryota Hino[1], Masanao Shinohara[2]

1. Graduate School of Science, Tohoku University, 2. Earthquake Research Institute, The University of Tokyo

The 2011 Tohoku-Oki earthquake changed the stress field around its source region. Significant coseismic rotation of the principal stress axes was observed and it was suggested that almost all the accumulated shear stress was released on the ruptured plate boundary (e.g. Hasegawa et al. 2011). Therefore, it is important to study the spatial variation of the stress state after the Tohoku-Oki earthquake in detail to understand not only the coseismic stress change but also the stress state before the occurrence of the earthquake. Since previous studies used the focal mechanism solutions to estimate stress field inversion are based on the data of the onshore seismic networks, it has been difficult to discuss detailed features of the spatial variation of the stress state, especially of the depth variation, because accuracies of focal depths (centroid depths) of offshore earthquakes are not sufficient. In this study, we relocated the hypocenters by using arrival time data of ocean bottom seismic stations deployed in the central part of the Japan trench where the coseismic slip was large to improve three-dimensional distribution of the focal mechanism solutions of the earthquakes in the area occurred before and after the Tohoku-Oki earthquake. As a result of stress field estimation based on the improved focal mechanism catalogue, it was shown that the stress field after the Tohoku-Oki earthquake shows clear difference between the overring and the subducting plates in the west side of the coseismic slip region. This sharp change in the stress field across the plate boundary suggests that the shear stress along the plate interface is extremely small. The area corresponds to the region with extensive afterslip estimated from the postseismic deformation data. A remarkable intraplate seismicity extending upward from the plate interface by ~ 25 km was identified after the Tohoku-Oki earthquake at the western rim of the large coseismic slip area. By applying a moment tensor inversion to these earthquakes, we investigated the depth variation of the stress field in the upper plate above the large coseismic slip zone. As a result, the minimum principal stress axis was found to orient almost in the direction of the coseismic slip just above the plate boundary, whereas its direction changed to the along-strike direction in the shallow depth range. The change can be interpreted by the decrease of the tensional stress associated with the coseismic slip with the increasing distance from the rupture plane.

Assessment for a large earthquake occurrence on the northern side of the focal region of the 2011 off-Tohoku mega-thrust earthquake

*Kazuyoshi Nanjo[1], Kazuki Miyaoka[2], Akio Yoshida[3]

1. University of Shizuoka, 2. Japan Meteorological Agency, 3. Shizuoka University

Eight years have passed since the occurrence of the 2011 off-Tohoku mega-thrust earthquake (off-Tohoku earthquake). Seismic activity in the central part of the focal region has settled down. However, magnitude (*M*) 5 to 6 earthquakes occur occasionally along the coast and inland areas of Tohoku and Kanto. Therefore, it can be said that seismic activity in a wide area is still in a higher level than that before the off-Tohoku earthquake.
Soon after the off-Tohoku earthquake, it was worried that a large earthquake might occur in the northern or southern adjacent regions, for it is not rare that a mega-thrust earthquake was succeeded by an occurrence of another large shock within several years. Last year, Matsu’ura (2018) warned impendence of a large earthquake occurrence in east-off Hokkaido, based on analysis of seismicity changes as well as historical records about great earthquake occurrence in the concerned area. Here, we report results of a detailed investigation about changes in the seismicity and the *b* value in the sea area on the northern side of the focal region of the east-off Tohoku earthquake.
Based on a *b* value analysis using data in three years after the off-Tohoku earthquake, Tormann et al. (2015) inferred that stress level in the focal region had already returned to the state before the earthquake, and presented an idea that a large earthquake may not repeat at an interval of a characteristic period, but rather occur at random. On the other hand, Nanjo and Yoshida (2017) showed, by re-analyzing data of a longer time period, that such a feature of the notable lowering of the *b* value as was observed before the off-Tohoku earthquake in the large-slip area was not seen. However, it was found that the *b* value in the northern adjacent area, far-east off Aomori Prefecture, is notably low. The area covers the focal region of the 1994 far-off Sanriku earthquake partly and extends further north. Further, it was seen that seismicity there has been decreasing in recent years.
Based on seismicity in the study region covering from off Aomori Prefecture to east-off Hokkaido, we found, in this study, spatiotemporal variability in *b* value. In particular, the 2003 *M*8.0 Tokachi earthquake did not show a transition of *b* value to normal levels but further lowered *b* value and expanded zones of low *b* values. The result obtained here is consistent with that by our previous work (Nanjo and Yoshida, 2017). From these observations, we think that a large earthquake may occur in the northern adjacent area of the focal region of the off-Tohoku earthquake in the near future.
Seismicity along the coast of Tohoku on the down-dip side of the coupling region is still high. A seismic quiescence as well as lowering of the *b* value is often observed before occurrence of an *M*5~6-class earthquake in the area around their foci. Although effectiveness of the observation of seismic quiescence and lowering of the *b* value in the prediction of a large-earthquake occurrence is still a problem under debate, we would like to propose here that extent of the low-*b* value area and the *b* value at the center of the area may be useful indices in evaluating results of the *b* value analysis. This is an analogy of a typhoon where their magnitude and intensity are evaluated by an extent of the storm area and air pressure at the central point. We expect further that imminence of a large earthquake occurrence may be assessed by noting tendency of the lowering of the *b* value.

Spatial and temporal distributions of *b*-values related to long-term slow-slip and low-frequency earthquakes in the Bungo Channel and Hyuga-nada regions, Japan

*Keita Chiba[1]

1. Institute of Seismology and Volcanology, Faculty of Science, Kyushu University

Long-term slow-slip events (SSEs) and low-frequency earthquakes (LFEs) repeatedly occur in the area encompassing the Bungo Channel and Hyuga-nada region in Japan (e.g., Shelly et al., 2006; Ide et al., 2007; Ozawa et al., 2013; Ozawa, 2017). SSEs are slow earthquake events with a duration of months to years, characterized by a type of slip that is considered transitional between the fast rupture of regular earthquakes and stable sliding along a plate interface, and have characteristics sensitive to stress states near the plate interface (e.g., Obara and Kato, 2016). In addition, since LFEs are also thought to occur at the plate interface, it would be useful to infer the stress state in this region. This study focuses on the stress-dependent characteristics of the *b*-value of regular earthquakes, SSEs, and LFEs, as well as the spatio-temporal relationships between *b*-values and these events in this area, using the Japan Unified high-resolution relocated Catalog for Earthquakes (JUICE) (Yano et al., 2017). The *b*-value, which represents the relative proportion of large to small earthquakes (Gutenberg and Richter, 1944), is inversely related to differential stress or effective stress (e.g., Scholz, 1968, 2015; Wyss, 1973; Urbancic, 1992). As a result, the *b*-values are moderate to low (b = 0.6–1.1) in regions with a high incidence of long-term SSEs. This spatial anomaly in *b*-values is attributed to a partial release of the accumulated stress in regions with relatively high differential stress that are characterized by SSEs. In addition, the *b*-values in the Bungo Channel region are relatively higher than those in the Hyuga-nada region. It was also found that the difference of the *b*-values in the vertical direction within the plate for the Bungo Channel region is larger than that for the Hyuga-nada region. These findings support a generation model of LFEs by Nakajima and Hasegawa (2016), in which undrained conditions in the overlying plate are a key factor for generating LFEs. On the other hand, the *b*-values increase and decrease before and during periods of enhanced LFE activity in the Bungo Channel, respectively. The increase and following decrease in *b* -values are thought to reflect episodes of low and high shear strength along the plate interface, which were caused by the presence of abundant fluids supplied from the subducting slab under undrained conditions above the plate interface and the decreased pore pressure related to fluid consumptions by the generation of the LFEs, respectively.

4D b-Value Mapping for Japan

*Yasushi Harada[1], Yuichi Akamine[1], Masayoshi Anzai[1]

1. School of Marine Science and Technology, Tokai University

b-value is considered as an index for seismicity, and smaller b-value means relatively more earthquakes of large magnetude, larger b-value means relatively less earthquakes of large magnetude. We tied to produce 4D b-value map for Japan to examine the difference of seismicity before and after the M9-class 2011 Tohoku quake. Dr. Kazuki Nanjo kindly provided us his code for calculating b-value and the standard deviation(SD). We created not only 4D b-value maps of Japan but also maps of the SD of b-value. Since large SD may mean a failure of Gutenberg–Richter law. Also from the map of b-value around Japan, we noticed a tendency of smaller b-value at distant area from the coastline. The tendency can be explained by the fact that seismometers cannot detect small distant earthqukes. Therefore we constructed a correction formula for b-values. With this formula, the most of the effect of smaller b-value around the M9-class 2011 Tohoku quake are disappeared. However the current formula is not good enough and it have to be improved in future studies.

Tue. May 28, 2019 9:00 AM - 10:30 AM JST | Tue. May 28, 2019 12:00 AM - 1:30 AM UTC | A09 TOKYO BAY MAKUHARI HALL

[S-SS11] Seismic wave propagation: Theory and Application

convener:Kiwamu Nishida(Earthquake Research Institute, University of Tokyo), Kazuya Shiraishi(Japan Agency for Marine-Earth Science and Technology), Takao Nibe(JAPEX), Kaoru Sawazaki(National Research Institute for Earth Science and Disaster Resilience), Chairperson:Shunsuke Takemura(防災科研)

Seismic wave propagation provides rich information of earth's heterogeneities and the excitation sources. In order to extract the information, integrated studies are needed among mathematical/numerical studies based on the wave theory, miniature physical experiments using rock specimens, and practical data analyses. Furthermore, it is greatly beneficial to conduct comparative studies of various kinds of waves, such as elastic, acoustic, traveling ionospheric disturbances, and oceanic waves. This session widely invites presentations about the theories and applications related to seismic and other geophysical waves.

Fluid flows inferred from microseismic events associated with injection test in Okuaizu Geothermal Field

*Kyosuke Okamoto[1], Li Yi[2], Hiroshi Asanuma[1], Takashi Okabe[3], Yasuyuki Abe[4], Masatoshi Tsuzuki[5]

1. National Institute of Advanced Industrial Science and Technology, 2. Osaka University, 3. Geothermal Energy Research and Development Co., Ltd., 4. Okuaizu Geothermal Co., Ltd., 5. Japan Oil, Gas and Metals National Corporation

In the Okuaizu geothermal field (Yanaizu, Fukushima Prefecture), a recharge water injection test has been carried out to stabilize the steam production since 2015. In order to avoid cooling of the geothermal reservoir by the water injection and to obtain a larger recharge effect, it is important to grasp and anticipate the flows of the injected water. On the other hand, subsurface structures are generally complicated, especially within the brittle region. Therefore, it is difficult to predict the flows with a simple homogeneous model because the following phenomena are expected in real cases; selective flows passing through a highly permeable region such as a fracture zone as well as creation of a new flow path by shearing. In the shearing, the mechanism of its creation (e.g., reduction of effective stress due to in-flow into fractures, propagation of stress change, stress accumulation due to thermal change) is hard to identify, which is essential information to expect new flow paths.

In the Okuaizu geothermal field, a microseismic monitoring network has been established as part of the JOGMEC project named "Geothermal Reservoir Evaluation and Management Technology" since fiscal year 2015. In this study, we use the seismic record to estimate the subsurface fluid flows associated with the injection test. We investigate factors of the creation of microseismicity associated with the injection test by using elastic wave velocity changes in fractures estimated by seismic scattering analysis as well as pressure and temperature information.

3D distribution of intrinsic attenuation factors and random velocity fluctuations in southwestern Japan inferred from seismogram envelopes

*Masashi Ogiso[1]

1. Meteorological Research Institute, Japan Meteorological Agency

Hi-frequency (> 1 Hz) seismogram envelopes show various envelope shapes due to the influence of seismic scattering as well as intrinsic attenuation of the medium. Intrinsic and scattering attenuation structures inferred from seismogram envelopes are important for precise strong ground motion prediction as well as understanding the Earth structure. Ogiso (2019) have proposed a two-step approach to estimate the 3D distribution of intrinsic attenuation factors and scattering coefficients using envelope fitting method and sensitivity kernels proposed by Takeuchi (2016). In this study, we propose the method to estimate 3D distribution of intrinsic attenuation factors and random velocity fluctuations, which is the improved version of Ogiso (2019).

The same as Ogiso (2019), the proposed method consists of two steps. First, we estimate appropriate attenuation parameters (intrinsic attenuation factor and strength of random velocity fluctuation) for each observed envelope. Second, we map the estimated attenuation parameters in step 1 into 3D space using sensitivity kernels. Radiative transfer theory with non-isotropic scattering coefficients based on the Born approximation is used to model seismogram envelopes. The effect of depth-dependent velocity structure is also considered for modeling envelopes.

The proposed method is applied in southwestern Japan. The estimated structure has three main features: (1) both intrinsic attenuation factors and random velocity fluctuations are stronger in the Kyushu than the other regions, (2) both intrinsic attenuation factors and random velocity fluctuations are smaller in the lower crust than the upper crust, which is clearly found in the Chugoku region, and (3) horizontal heterogeneity in intrinsic attenuation factors at the depth of 10-50 km of the Shikoku region. These features, probably reflecting the tectonic settings of southwestern Japan, seem to be consistent with previous studies.

Regional to teleseismic strong ground motions from a 610 km deep 24 May 2013 Sea of Okhotsk earthquake

*Takashi Furumura[1], Brian LN Kennett[2]

1. Earthquake Research Institute The University of Tokyo, 2. Research School of Earth Sciences, The Australian National University

A very large deep earthquake (Mw8.3, 610 km depth) occurred in the Sea of Okhotsk near Kamchatka on 24 May 2013 producing a large shocks across the Japanese Islands. The maximum shaking intensity reached 3 on the JMA scale at Sarufutsu, Hokkaido and Akita, and the felt area spread to Kagoshima, 3000 km from the hypocenter. According to USGS, the shake was also reported in Northern India, California, and Dubai 6000 km away; also CNN reported that people in Moscow were evacuated from the buildings. Kuge (2015) analyzed teleseismic records and claimed that shaking at large distance is consistent with the radiation pattern of P wave, similar to the 1994 Bolivia Mw8.3 earthquake (Anderson et al., 2015). In this study we aim to understand the cause of large ground motion at regional to teleseismic distances from this very deep event using dense F-net, Hi-net, and IRIS DMC observations, complemented by 3D FDM simulation of seismic wave propagation.

Observed strong ground motion in Japanese Islands

The observed pattern of peak ground velocity (PGV) over Japan demonstrates large motions in Sea of Japan side, opposite to the large shake on the Pacific Ocean side as is usually seen in deep earthquakes. The PGV does not attenuate monotonically with distance, and a second PGV peak was seen at distance of about 2000 km.

At shorter distances (<2000 km) upward travelling waves arrive from the 610 km deep source, waves emitted downwards overlap somewhat and dominate beyond 2000 km. The large PGV is associated with successive arrivals of upgoing and downgoing S waves (near a caustic). S waves incident on the surface at the critical angle generates large sP conversions, which propagate in the crust and uppermost mantle to sustain PGV. Furthermore, a third PGV peak occurs at distances around 3000 km created by the SS wave traveling through deep mantle and reflected twice on the surface. Similar anomalous PGV attenuation is found for other deep earthquakes e.g. near Sakhalin in 2012 (Mw7.7; 600 km).

Strong motion simulation of deep earthquake

FDM simulations using ak135 model demonstrate the ways in which the S wave caustics and sP conversion create the second large PGV peak at regional distances, which moves from 1500 to 3000 km as the source depth increases from 200 to 610 km. The efficiency of sP and SS conversion and reflection is very sensitive to the thickness of the crust; SS is large and sP is weak by reflection from thick continental crust, and thin oceanic crust gives the reverse. The large SS observed over Japanese Island is due to the reflection of S wave at the thicker crust (20-30 km) in the Sea of Okhotsk, and large sP phase at Izu-Ogasawara Islands and the Northwest Pacific, corresponds well with the simulation results.

With a Pacific slab model (Yokota et al., 2017) in the 3D FDM simulation model, we find that S waves traveling through the High-V plate are refracted into the Low-V mantle, making large ground motions on the Sea of Japan side. This anti-waveguide effect differs from the stochastic waveguide effects in the plate at high-frequency (>1-2 Hz) waveguide effect, which is weak for the long-period wave of this distant earthquake with oblique transmission.

Shaking at thousands of kilometers due to long-period ground motion?

©2019. Japan Geoscience Union. All Right Reserved.

The IRIS DMC records show that the PGV has large peak at distance of about 3500 km due to the arrival of the SS wave. Then, PGV attenuate gently until the next large PGV peak around 7000 km with the arrival of the SSS phase. Shaking in the distance range 4000-6000 km from the Sea of Okhotsk earthquake comes from long-period SS and SSS waves. At Obinisk (OBN; 6050 km) near Moscow long-period S and SS produce 0.7 cm/s ground velocity at a period of 3.5 s. With amplification of long-period ground motions in sedimentary basins, the ground motion can grow to the JMA’s long-period intensity scale 1 (> 5 cm/s).

Trial estimation of eclogitization depths within subducting oceanic crust of the Philippine Sea slab inferred from head wave propagating along the oceanic Moho

*Shunsuke Takemura[1], Takashi Tonegawa[2], Junichi Nakajima[3], Katsuhiko Shiomi[1]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Japan Agency for Marine-Earth Science and Technology , 3. Tokyo Institute of Technology

To investigate structural properties within the subducting oceanic crust of the Philippine Sea slab, we analyzed head wave propagating along the oceanic Moho (P_{PHS}). In the case of offshore earthquakes occurred at depths shallower than oceanic Moho, P_{PHS} is first arrival at onshore seismic stations (e.g., Takemura et al., 2016 EPS). During southeast off Mie earthquake, observed Hi-net seismograms illustrated first arrivals with an apparent velocity of 7.2 km/s, which correspond to apparent velocity of P_{PHS}, at epicentral distances of 70-200 km. At distances greater than approximately 200 km, apparent velocity of first arrivals was increased. Such distance change of apparent velocities is related with velocity structure at depths below the continental Moho.

We conducted two-dimensional (2D) finite-difference method (FDM) simulations of seismic wave propagation using the realistic slab model (Hirose et al., 2008 JGR). Thickness of subducting oceanic crust was assumed to be 7 km. Crust and mantle structures were referred from the F-net 1D model (Kubo et al., 2002 Tectonophys.). Although P_{PHS} was clearly found in simulated seismograms, the simulation result with oceanic crust at deeper (> 70 km) depths did not reproduced observed first arrivals at greater (>200 km) distances. By replacing structural properties of the oceanic crust with ones of the oceanic mantle at depths of 40-60 km, simulated first arrivals were changed depending on structural change depth. A structural change depth of 52 km is the optimal model for explaining observed first arrivals. This depth well corresponds to an eclogitization depth of the subducting oceanic crust beneath the Kii Peninsula (Kato et al., 2014 EPS).

We consider that estimated structural change depth within the oceanic crust is linked with transformation to anhydrous eclogitic oceanic crust (Fukao et al., 1983 Nature; Abers et al., 2003 GRL; Hacker et al., 2003 JGR). Our analysis using head wave propagating along the oceanic Moho may provide depth of eclogitization within the oceanic crust.

Acknowledgement
NIED F-net MT catalog and Hi-net velocity seismograms were used. Finite-different method simulations were conducted on the Earth Simulator at the JAMSTEC.

Transient gravity perturbations due to a buried gravitational source in a homogeneous elastic half space

*Aditya Nitin Deshmukh[1], Pratik Laxman Borate[1], Abhishek Venkatesh Chitgopkar[1], Nobuki Kame[2], Ranjith Kunnath[1]

Earthquake ruptures induce transient deformations which result in changes in the gravity field (Harms, *et. al* (2015)). Prompt elastogravity signals due to the earthquake source arrive before any seismic wave from the source and it has been proposed that these signals could be used for earthquake early warning systems. In this work, we study the model of a buried gravitational load in an isotropic, homogenous elastic half-plane or half-space. The response at the surface is determined for a suddenly applied gravitational line-load in an elastic half-plane. Also, the response at the surface is calculated for a suddenly applied gravitational point-load in an elastic half-space. Due to the gravitational field induced by a suddenly applied line-mass, every point in the half-plane acts as a source by itself. The elastic response due to each point in the half-plane is calculated using the solution of Garvin (1956) for a buried line blast load in an elastic half-plane. The total response at the receiver point on the surface of the half-plane is determined numerically by the convolution of Garvin’ s solution with the gravitational force. Similarly, the elastogravitational response to a suddenly applied point mass in a half-space is determined using the solution of Johnson (1974) to Lamb’ s problem of a source buried in a half-space. We show that in both these models, prompt gravity signals are obtained.Earlier, Kame and Kimura (2018) had considered the elastic response to a suddenly applied point mass in an unbounded medium. They showed that the ground acceleration at any receiver point is exactly cancelled by the gravity perturbation during the entire duration of the prompt period so that a gravimeter at the receiver will not detect any prompt signals. This appears to be a peculiarity of the model of an unbounded medium.

[S-SS14] Fault Rheology and Earthquake Physics

convener:Keishi Okazaki(Japan Agency for Marine-Earth Science and Technology), Hideki Mukoyoshi(Department of Geoscience Interdisciplinary Graduate School of Science and Engineering, Shimane University), Hiroyuki Noda(Kyoto University, Disaster Prevention Research Institute), Keisuke Yoshida(Tohoku University), Chairperson:Keisuke Yoshida(東北大学大学院理学研究科 地球物理学専攻), Keishi Okazaki(JAMSTEC)

The goal of this session is to integrate theoretical, experimental, observational, and numerical perspectives from various fields such as seismology, geodesy, geology, mineralogy, and so on, to define what is known about earthquake source processes and the physical and chemical elementary processes of faulting. This session welcomes studies that address such issues as pre-, co-, and post-seismic processes, the rheology of seismogenic faults and fault rocks, laboratory experiments on elementary processes, numerical models based on frictional laws, and estimates of the stress field in the seismogenic zones. We also welcome studies on fault-zone drilling projects and in situ stress measurements.

To deepen fundamental understanding of earthquake faulting, it is of crucial importance to image fine scale structure of fault zone. We installed a thousand of seismic stations in the source area, which covers an entire aftershock zone of the 2000 Western-Tottori earthquake (Mw 6.7) from March 2017 to March 2018. The spatial interval of each seismic station ranges from 1 to 2 km. We initially detected ~3000 earthquakes from the continuous waveforms, using automatic arrival time picking technique. Applying a double-difference algorithm to the arrival data-set, we relocated more precise hypocenters in the studied region. The completeness magnitude of the catalog is around -0.7.

From the center to the southeast part, the relocated hypocenters are aligned along sharp fault planes, which are dipping almost vertically. In contrast, at the northwest area, the hypocenter distributions are complex, including several fault planes which are conjugate to the main NW-SE aftershock trend.

We focus on a tiny seismic cluster associated with Mj 1.7 event (main event) in the aftershock zone, which took place on 24th Dec., 2017. Following this event, a total of ~80 micro-earthquakes were detected by automatic-processng and matched filter technique. We visually picked up P-wave arrival times for each micro-earthquake. Using differential travel times derived from waveform cross-correlation technique, we succeeded to relocate them very precicely. The relative hypocenter acuuray appears to be less than 5 m. The relocated micro-earthquakes are sharply aligned along vertically NNW-SSE-striking fault. The length and dip-width of the fault dimension is about 200 m, respectively. This hypoenter alignment is well consisten with a focal mechanism of the main event. Based on the distribution of the earthquakes, the fault zone width is estimated to be ~10 m. The ratio of the fault (process) zone width to the fault length is ~0.01, which fairly matches with that geological observation of fault exposure.

In addition, we identify spatial-temporal evolution of the micro-earthquakes after the main Mj 1.7 event. Interestingly, these migrating events occurred so that they did not overlap events that occurred earlier, like complementary manner. The migration speed is estimated to be < ~0.1 km/day, which is quite lower than that slow slip events observed typically along subduction. This slow migration is similar to fluid migration speeds inferred from seismic observation of induced seismicities following the 2011 Tohoku-Oki earthquake. These results indicate a growth of fault network on a scale of tens of meters.

Estimation of fault model of the 2017 Pohang, South Korea earthquake using seismic and geodetic analyses

*Sun-Cheon Park[1], Won-Jin Lee[2], Geunyoung Song[1], Duk Kee Lee[1]

1. Korea Meteorological Administration, 2. National Institute of Environmental Research

After the 2017 Pohang, South Korea earthquake with magnitude (ML) 5.4, surface deformation was observed using Interferometric Synthetic Aperture Radar (InSAR) technique. This observation of surface deformation can be a constraint to estimate the fault model in addition to aftershock distribution and other seismic information. As the result of InSAR processing using X-band Cosmo-Sky-Med and C-band Sentinel-1 data, we observed the maximum deformation of about 4 cm in Line-Of-Sight (LOS) direction. Considering this observation, we estimated the fault model of the 2017 Pohang earthquake. We determined hypocenters of the earthquake sequence and carried out moment tensor inversion. Then we estimated the dimension and depth of the fault plane using aftershock distribution and displacement on the fault using the seismic moment. Surface deformation was calculated using the formula of Okada (1985) and assuming several models of slip distribution on the fault and was compared with the surface deformation pattern in LOS direction. Larger surface deformation toward the satellite was observed to the northeast from the epicenter and this pattern was well explained by fault models having the slip on the shallow fault plane. During the presentation, we will discuss more about the fault model comparing surface deformation and the aftershock distribution.

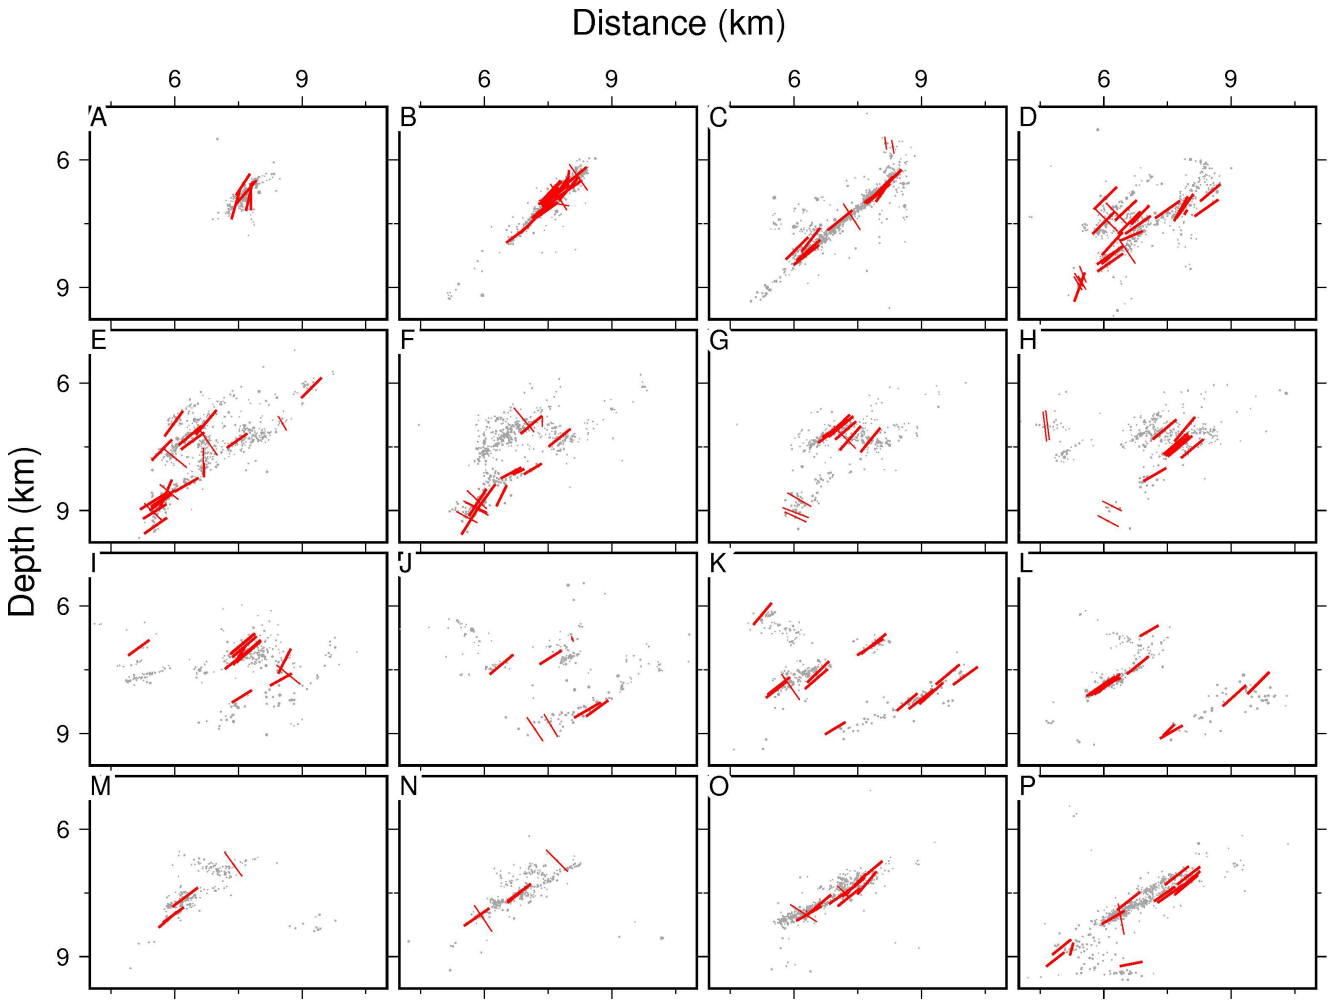
Estimation of rupture directivity, fault plane, and stress drop of small earthquakes in inland areas of Japan

*Keisuke Yoshida[1], Tatsuhiko Saito[2], Kentaro Emoto[1], Yumi Urata[2]

1. Tohoku University, 2. NIED

Dominant frequency or duration of seismic waves is considered to reflect the fault size. Some studies used the dominant frequency for the estimation of fault size and stress drop for small earthquakes assuming simple fault models (e.g., Brune, 1970; Sato & Hirasawa, 1973; Madariaga, 1976) without estimating heterogeneous slip distribution on the fault. Some of the simple source models are based on a symmetrical circular fault model (Madariaga & Ruiz, 2016). The assumption of the isotropic rupture evolution on a symmetrical circular fault can lead to a large estimation error of the fault size and thus the stress drops if the real source process is asymmetrical or exhibits a significant directivity effect (e.g., Kaneko & Shearer, 2015). We should carefully check if we can assume a symmetrical source model when we apply it in analyzing seismograms of small earthquakes.

We investigated the rupture directivities of small and moderate-sized earthquakes (M_JMA>2) in the Yamagata-Fukushima border earthquake swarm which was estimated to be triggered by the upward fluid movement after the 2011 Tohoku-Oki earthquake. We utilized the dense nationwide seismic network in Japan to estimate the rupture directivity. Apparent source time functions were calculated at each station for 1,782 earthquakes based on the waveform deconvolution technique with nearby (< 300 m) small earthquakes to remove the propagation- and site-effects. We found clear directional dependences of the peak amplitude and the pulse width in the apparent source time functions, suggesting the earthquake rupture directivity, for 904 of 1,782 events.



Based on the unilateral rupture model, we estimated the direction, duration, and velocity of rupture for each earthquake. Rupture directions of most earthquakes tend to be different from those of the hypocenter migration. This difference between the microscopic and macroscopic propagations of rupture might be explained by the spatial variation of the frictional strength; ruptures of each earthquake are hindered to develop toward shallower part due to higher frictional strength ahead of the pore-pressure front (shallower part) than behind (deeper part). It suggests the importance of the knowledge of frictional strength on fault to understand fracture dynamics of small earthquakes.

Besides, we estimated fault planes of small and moderate-sized earthquakes based on focal mechanism and rupture directivity (Fig.). Most of fault planes are parallel to the macroscopic planar structures, which suggests that they were triggered by fluid intrusions along those common planar structures. By taking the limitation of the resolution of hypocenter relocation, information from the rupture directivity can be unique data to reliably determine the fault planes of small and moderate-sized earthquakes.

By considering the estimated fault planes and areas of small earthquakes, we confirmed the temporal increase in stress drop reported by Yoshida et al. (2017, JGR). The systematic temporal changes in frictional strength, stress drop, background seismicity rate, b-values, the upward hypocenter migration along the planar structures, and the rupture directivity rather opposite to the hypocenter migration can be explained in a consistent manner by the effects of the upward fluid flow along several pre-existing planes after the 2011 M9 Tohoku-Oki earthquake.

Possible aseismic phenomena causing the hypocenter migration in the precursory activity and aftershocks of the 2017 M 5.3 Kagoshima Bay earthquake, Kyusyu, SW Japan

*Yoshiaki Matsumoto[1], Keisuke Yoshida[1], Toru Matsuzawa[1], Akira Hasegawa[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Tohoku University

An earthquake occurs when the shear stress acting on the fault plane reaches the frictional strength. It has been suggested that an increase in pore pressure plays an important role in earthquake occurrence (e.g. Hasegawa, 2017; Hubbert & Rubey, 1959; Nur & Booker, 1972; Sibson, 1992). Migration behavior of earthquake hypocenters is considered to be caused by aseismic processes such as fluid movements or aseismic slip propagations. It is expected that information on aseismic processes in the crust can be obtained by examining the hypocenter migration in detail.

On 11 July 2017, an M 5.3 earthquake occurred at approximately 10 km depth in Kagoshima Bay, Kyusyu, SW Japan. Near the main shock hypocenter, seismicity had been activated since December 2016. In order to investigate the generation mechanism of this seismic sequence, we improved relative locations of hypocenters of the precursory activity and aftershocks by using waveform cross correlations.

First, precise differential arrival times were obtained by calculating cross correlations of a pair of waveforms out of the earthquakes that occurred after January 2010 in the Southern Kagoshima Bay region. We used waveform data observed at 20 stations located around the main shock hypocenter. Calculations of cross correlations of waveforms were performed in the same way as Yoshida & Hasegawa (2018). Then, we applied the double-difference relocation method (Waldhauser and Ellsworth, 2000) to the differential arrival time data thus obtained by cross correlations and those listed in the JMA (Japan Meteorological Agency) unified catalog. We used hypocenters listed in the JMA unified hypocenter catalog as the initial hypocenters in the relocation.

The relocated hypocenters are concentrated forming several thin “planes”. The dominant orientations of the planes agree with the eithers of nodal planes of focal mechanisms of the main shock and aftershocks.

Hypocenters of the precursory activity are neatly concentrated along one of the planes and exhibit distinct migration behavior. Hypocenter distribution of the precursory activity along that plane shows a clear seismic gap located adjacent to the main shock hypocenter. Most of aftershock hypocenters are distributed along the same plane but did not fill this seismic gap. We calculated the corner frequency of the mainshock source spectrum using the spectral ratio method and estimated the mainshock fault size. The estimated fault size is consistent with the size of the seismic gap. It suggests that the seismic gap reflects the main shock rupture area (e.g. Wetzler et al., 2018).

Aftershocks tend to move upward with time along several thin planes. This spatiotemporal feature of earthquake hypocenters is similar to those observed in the earthquake swarms in central Tohoku that were triggered by the 2011 M9 Tohoku-Oki earthquake probably due to the upward movement of fluids (Yoshida & Hasegawa, 2018)

©2019. Japan Geoscience Union. All Right Reserved.

We explain the characteristics of the precursory activity, main shock and aftershocks as follows. (1) Prior to the occurrence of the main shock, crustal fluids penetrated into an existing weak plane from below and reduced the frictional strength, which caused the precursory seismic activity along the plane and the migration of hypocenters. Aseismic slip might also contribute to the hypocenter migration. (2) Then the seismic gap, which had not been ruptured by the precursory activity, was finally ruptured by the main shock. (3) Due to the stress change associated with the main shock, aftershocks were triggered in the region surrounding the main shock hypocenter. Aftershock hypocenters moved upward due to the upward fluid movements after the main shock.

Stress and pore fluid pressure changes in fault zone preceding the earthquake occurrence

*Teruo Yamashita

I theoretically study stress and fluid pressure changes in fluid-saturated fault zone that deforms elasto-plastically. Such study will be useful to gain an insight into the process leading to the earthquake occurrence. I employ poro-elasto-plasticity theory (Coussy,2006) and assume a Capped Drucker-Prager model as the yield criterion (Figure 1). The line segment (A) is described by the equation $f= \tau_J + f_m \sigma_{eff} + \kappa = 0$, where f_m and κ are the internal friction coefficient and a function of the hardening variable; $(\tau_J)^2$ and σ_{eff} denote the second deviatoric stress invariant and the effective mean stress. The point I represents the initial state in the elastic region and the yield criterion is satisfied first at point P on A; relatively low effective normal stress is assumed. The stresses τ_J and σ_{eff} move in a direction indicated by the arrow along the line segment A with the increase in the remotely applied stresses. I assume a non-associated flow law; the plastic potential corresponding to the line segment A is given by the equation $g= \tau_J + f_d \sigma_{eff} + \kappa$, where f_d is the dilatancy factor. It is known that the plastic component of volumetric strain is positive on the line segment A, so that the fluid pressure change will be negative there. It is known that f_m is larger for larger values of porosity (Chang et al.,2006). It is also known for low porosity rocks that permeability is higher at locations closer to the fault core, so that it will be allowed to assume that f_m is smaller at locations closer to the fault core. I therefore assume a 1D model such that f_m takes a minimum value just outside the fault core ($|y|=c+0$) and it increases linearly with the distance and attains a constant value (Figure 2). The f_m-increase zone is defined as the fault damage zone. Since the porosity is sufficiently low in the fault core, the value of f_m in the fault core is assumed to be equal to that at $y=\infty$; the boundary at $|y|=c$ is assumed to be impermeable. I also assume the absolute values of the remotely applied principal stresses ($\sigma_1 < \sigma_2 < \sigma_3 < 0$) increase quasi-statically with time. Hence, the yield criterion is first satisfied at $|y|=c+0$; the plastic zone expands with further stress accumulation. The plastic deformation never occurs in the fault core during the calculation. In this model, the time scale is governed by the magnitude of permeability. I assume that the increase rate of the maximum principal stress σ_1 that is remotely applied is 0.2MPa/year. Figure 3 shows examples of fluid pressure change at $|y|=c+0$ for the permeability$10^{-18}m^2$. The curve A is the case of plastic hardening. While both B and C are the cases of perfect plasticity, the damage zone width for C is twice as large as that for B. The figure shows that the fluid pressure decrease is larger for smaller degree of plastic hardening or for larger damage zone width. However, the elastic component of fluid pressure change (elevation) is estimated to be about 10MPa at time t/dt=10,000. Hence, the plastic decrease of fluid pressure is almost negligible. The calculation also shows that the values of $|\sigma_1 - \sigma_3|$ and $|\sigma_1 + \sigma_3|$ in the plastic zone are, respectively, smaller and larger than those in the elastic zone; the difference grows with the expansion of plastic zone. This suggests that the fault damage zone become more stable with the expansion of plastic zone, while the sudden stress and fluid pressure changes formed at $|y|=c$ may damage the impermeable boundary there. However, such stable situation never lasts indefinitely. The yield criterion such as represented by the curve B in Figure 1 seems to be satisfied once stresses exceeds a critical threshold. The plastic component of volumetric strain turns negative on the curve B, so that the damage zone may become unstable. Hence, the stress point is required to move onto the curve B for the occurrence of earthquake. I will show numerical examples of the whole process leading to the earthquake occurrence in the presentation.

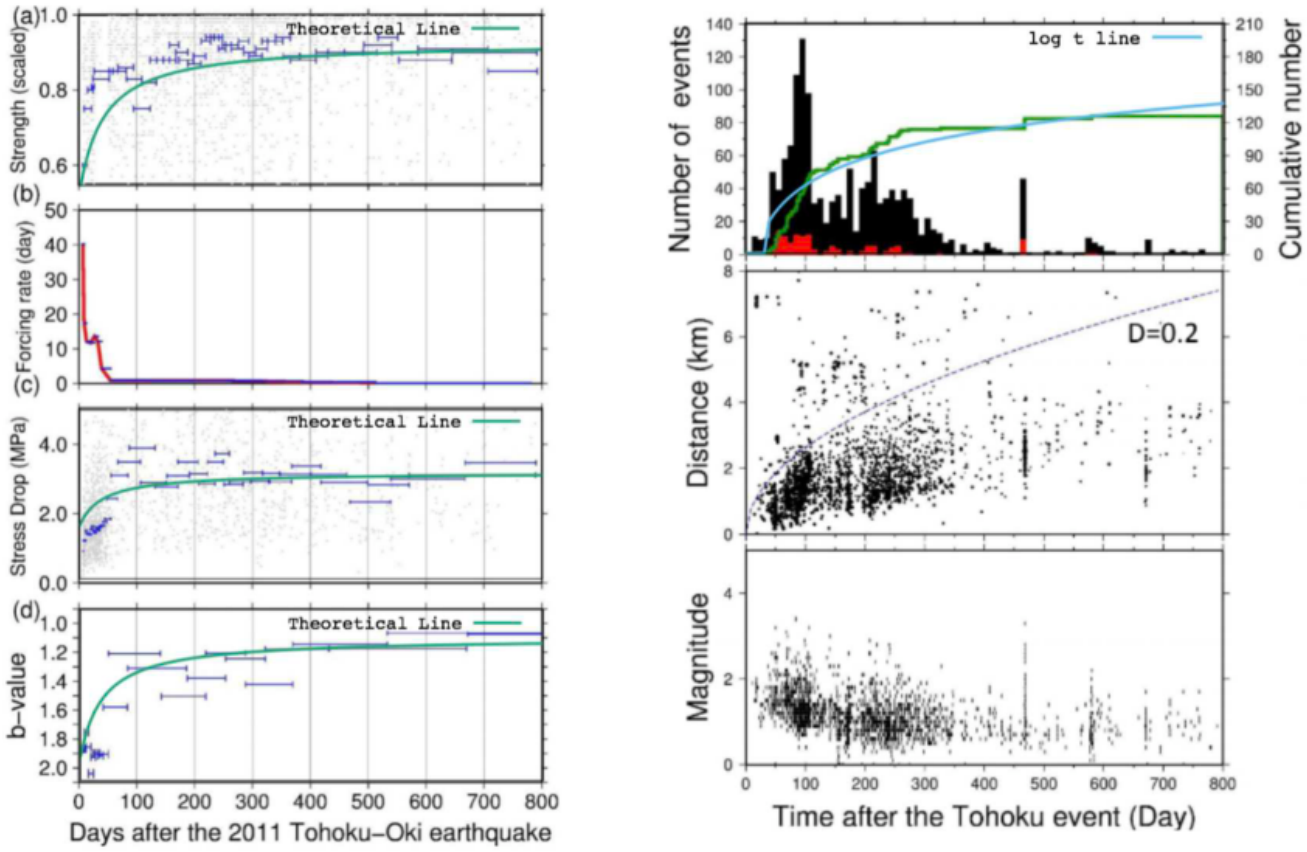
Micromechanical model of fluid-induced seismicity to reproduce observed spatiotemporal changes in source parameters and on-fault fluid diffusion

*Daisuke Sato[1], Keisuke Yoshida[2]



1. Disaster Prevention Research Institute, Kyoto University, 2. Tohoku University

Fluid and seisimicity are considered to be related, as suggested from earthquake swams of natural earthquakes and man-made earhtquakes induced by fluid injection. Some data analysis with relocation techniques of earthquake sources showed that the earthquake activities propagete facially (e.g., Yukutake et al., 2010), and that some source parameters (such as stres drops, strength, b-value, seismicity rate) are functions of elapsed time from fluid injection (Bachmann et al., 2012) or sudden increase of (possibly fluid-induced) seisimicity rate not following mainshocks (Yoshida et al., 2017). In this research, by considering strength heterogeneity of faults expected from experimentally verified physics, we provide the micromechanical model of such seismicity induced by on-fault fluid diffusion, and explain the results of the above data-driven analysis.

Presentation contains following four contents. First, the micromechanical model is proposed. In the model, many patches are distributed randomly on a fault so that the patches are sufficiently small (or distant) to interact with each other; those patches rupture when the effective strength becomes smaller than applied shear stress due to the fluid diffusion. Second, the spatiotemporal changes of the source parameters are obtained as the solutions of the model. Consequently, multiple source parameters are parametrized by injected pressure, diffusion raidus of fluid, normal stress on the fault, and the fluctuation of the exess strength; after the parametrization, those source parameters are shown to follow the common master curve. Third, the observed data is fitted, and the consistency between the theory and the observation is suggested. Fourth, the thoretical prediction for the temporal transience in the moment release rate is checked by the data of Yoshida et al. (2017), and the result strongly supports the theory.

Discussion

Historical documents and oral transmissions on historical tsunamis in the Paciffic coast of Tohoku

*ebina yuichi[1]

1. International Research Institute of Disaster Science

I analyzed historical tsunamis which attacked the Pacific coast of Tohoku, especially on the AD 1611 Keicho Oshu earthquake and tsunami (commonly called as the Keicho Sanriku earthquake and tsunami), based on historical documents, oral transmissions, and formation process of them.

After the AD 2011 Great East Japan Earthquake, huge historical tsunamis which damaged in the Pacific coast of Tohoku district have received attention. Some people consider the AD 869 Jogan earthquake as the precursor of AD 2011 earthquake and believe huge tsunamis occur once a thousand years. People also recognize the importance of oral transmission and the place name comes from past disasters. Previous studies pointed out the underestimation of the AD 1611 Keicho Oshu earthquake and tsunami but reinvestigated the earthquake and tsunami based on historical documents (Ebina and Imai 2014). Recently, some studies considered the AD 1454 Kyotoku earthquake as a similar event to AD 1611 Keicho oshu earthquake (Namegaya and Yata 2014; Sawai et al., 2015). Furthermore, the tsunami deposit can be correlated with this event have been found in Miyagi and Iwate Prefectures (e.g., Sawai et al., 2012; Takada et al., 2016).

According to “Sunpu Seiji Roku” and “Sunpu Ki", a vassal of the Date family said that another vassal of that encountered the tsunami on the boat during fishing and the boat was driven to the top of the mountain “Senganmatsu”. This event was estimated to occur near the mouth of Abukumagawa River in Iwanuma City. Watanabe (1998) considered this story was not true because Senganmatsu area is too high to be inundated. However, the pictorial map around Iwanuma created in Edo period indicates that Abukumagawa River was located inland from the present position of the river in that time, where a fishing village has been located since the middle ages (Ebina, 2014). Therefore, it is likely that the tsunami actually attacked the area although the story has a little exaggeration.
It is important to restore old geographical features for constraining the sizes of earthquakes and tsunamis. For instance, Fukuhara and Tanioka (2018) estimated that the magnitude of the Keicho earthquake is similar to or large than that of AD 2011 earthquake based on the data of tsunami height inferred from historical documents and oral transmissions in Miyako City, Iwate Prefecture compiled by Ebina and Imai (2014). However, the restored geographical features show that places inundated by the Keicho tsunami were located near the old channel. Therefore, the inundation in Miyako can be interpreted as the result of river run-up.

The knowledge of historical earthquakes and tsunamis along the Pacific coast of Tohoku have not been known by local residents before AD 2011 earthquake and tsunami. According to “Zishigaku Oyobi Chirigaku Kenkyu Zairyo Hokoku”, when the Imperial Science University of Tokyo (present the University of Tokyo) carried out a questionnaire about the existence of "Kaisyo" to municipal corporations all over the country in the 1890s, those in the coastal regions of Iwate answered that there are no historical records and oral transmissions on the historical earthquakes and tsunamis before AD 1856 Ansei Hachinohe-oki earthquake tsunami (Ebina and Satake 2018). This report shows that the coastal residents did not recognize that tsunamis frequently attack the Pacific coast of Tohoku in those days. Shoshin Yamana reevaluated the historical records and oral transmissions still remained in the coastal area. He

carried out the survey after the AD 1896 Meiji Sanriku earthquake tsunami and wrote “Sanriku Engan Daikaisyo Torisirabe Syo”. This book includes that the description of the damage in many areas and Keicho Oshu earthquake tsunami hand-copied from the reference books of "Muto Rokuemon Syozo Komonzyo" and “Miyako Yurai Ki. These materials are obtained by the survey for influential local persons in various places. Yamana also studied the place name may be coming from driftage by past tsunamis through the interview survey to the local residents and compiled those as “Iwate Engan Kochimei Ko”. Among those 40 place names, half of them still exist (Muranaka et al., 2017). However, it is difficult to consider that many of those places were inundated by tsunamis. The possibility that some oral transmissions of those place names newly generated under the confusion by the Meiji Sanriku earthquake and tsunami.
Considering the historical viewpoint on formation processes of historical documents and oral transmissions will be useful for studies on paleo earthquakes and tsunamis.

Co-seismic crustal movements along reverse faults which subsidence component is larger than uplifting component

*Taku Komatsubara[1]

1. Institute of Geology and Geoinformation, Advanced Industrial Science and Technology

Introduction

Reverse faulting should cause crustal movement which uplifting component is larger than subsidence component. There are many reverse faults which subsidence component is larger than uplifting one in the Niigata-Kobe and eastern margin of Japan Sea tectonic zones during geological era, Presenter gathered examples of historical co-seismic crustal movement along such faults.

Example 1. Kuwana fault and AD 1586 Tensho Earthquake, Mie Pref., central Japan

Height of the MIS5e shoreline in the uplift area of the Kuwana fault is +63m, it of the upper surface of MIS5e marine deposits in the subsidence area is -92 to -72m.

This fault is one of the source of the 1586 Tensho Earthquake, however a house built on AD 1576 is existing in the subsidence area near the coast at that time. Almost all medieval structural remain surfaces in the subsidence area are less than 1m beneath ground in depth.

Example 2. Hyuuga fault and AD 1662 Kambun Ohmi-Wakasa Earthquake, Fukui Pref., central Japan

Height of the MIS5e shoreline in the uplift area of the Hyuuga fault is +15 to +16m, and it of the upper surface of the MIS5 lacustrine sediments in the subsidence area is -90 to -80 m.

Ahistorical document reported 2.4 m uplift on the north eastern side of Lake Mikata (Suga) and 1.5 m subsidence on the south western side of it occurred during the 1662 Kambun Ohmi-Wakasa Earthquake.

Example 3. Noshiro fault zone and AD1694 Genroku Noshiro Earthquake, Akita Pref., north eastern Japan

Height of the MIS5e shoreline in the uplift area of the Noshiro fault is +30 to 60m, it of the upper surface of the MIS5e marine deposits in the subsidence area is -85m. The 1694 Genroku Noshiro Earthquake induced uplifting of northern bank of the Hachiro-gata lagoon, but no reports describes subsidence in the footwall side of it.

Conclusion

These three historical co-seismic crustal movement along the subsidence prevailing reverse fault did not go with distinct subsidence. This suggests aseismic subsidence in the footwall side of these faults have occurred in the geological era.

The Iyo-Bungo, southwest Japan, earthquake on September 1st, 1596 as deduced from contemporary historical records

*Katsuhiko Ishibashi[1]

1. Emeritus Professor, Kobe University

In leap July of the 5th year of the Bunroku era (in the old Japanese lunar calendar; September, 1596 in the Gregorian calendar) Bungo province (present-day Oita Prefecture) in Kyushu, southwest Japan, suffered from severe earthquake and tsunami disasters. Concerning the occurrence date of the causative earthquake, currently prevailing idea is that a large earthquake took place on leap July 9 in Iyo province (present-day Ehime Prefecture) in Shikoku, on the eastward opposite shore of Bungo, and another large earthquake occurred on leap July 12 around Bungo. Against this idea I claim that a single event which could be called "the Iyo-Bungo earthquake" occurred around seven p.m. on leap July 9 in the Iyo-Bungo region based on reliable contemporary historical records.

There are more than 70 documents on this (these) earthquake(s) printed in the existing collections of historical earthquake materials, but their values as historical records vary considerably. Since the essential principle of historiographical seismology is to utilize only reliable first-grade documents, I performed historical source criticism to select 16 contemporary materials. I referred to their original or best texts, not using texts printed in the collections.

According to the contemporary records, in Bungo, violent earthquake ground motion collapsed shrines around seven to nine p.m. on leap July 9 and a large tsunami hit Fuchu (Oita) in the twilight (*"Yusuhara-no-miya Nendai Ryakki"*). *"Kodo-ji Daihan'nyakyo Okugaki"* and *"Shibayama Kanbei Ki"* also describe strong earthquake shaking and large tsunami around Fuchu on that day. In Kyoto, roughly 430 km east-northeast of Bungo, earthquake ground motion was felt around seven to nine p.m. on leap July 9 (*"Kotokuni-kyo Ki"*), or around seven p.m. on the same day rather strongly (*"Ozuki-Takasuke-Sukune Ki"*). In Hiroshima Prefecture, at Hatsuka-ichi and Itsukushima strong ground motions were felt at night on leap July 9 without damages (*"Hoida Motokiyo's letter"*), and at Mihara strong earthquake tremors continued from leap July 9 till 12 (*"Buttsu-zenji Juji Ki"*). In Iyo, *"Yakushi-ji Daihan'nyakyo Okugaki"* says a severe earthquake tremor occurred on leap July 9 and the whole Iyo province had trouble, suggesting earthquake disaster in a wide area. In Satsuma and Osumi provinces (present-day Kagoshima Prefecture), *"Kabayama Shoken Jiki"* writes a strong earthquake on leap July 9, and *"Nanko Nikki Zankan"* also writes an earthquake on the same day. *"Chosa Yachi's letter"* written on leap July 29 describes that since leap July 8 earthquake tremors had continued.

As a fundamental methodology of historiographical seismology, these tremors and tsunami in Bungo, Iyo, Kyoto, Hiroshima and Kagoshima on leap July 9 are considered to have been produced by an identical earthquake unless there is any counter-evidence. Leap July 12, the other proposed date of the Bungo earthquake, comes from historical materials written after 1698, which probably mistook the great Kyoto earthquake in the midnight of leap July 12 for the Bungo event. The seismic intensities are evaluated to be stronger 6 in some places in Bungo and Iyo, 4 in Hiroshima, stronger 3 in Kyoto, and about 3 in Kagoshima on the JMA scale. The most simple and reasonable interpretation is that a large earthquake with the source region from around Oita to the midst of Iyo took place around seven p.m. on leap July 9, whose magnitude being around 7.5, and the tsunami on the Bungo coast followed. The rupture of the Kawakami fault in the MTL fault zone during this earthquake suggested by Tsutsumi *et al.* (2000) may have

Geologically recorded historical and prehistoric tsunamis in the Tonankai region

*Shigehiro Fujino[1], Haruo Kimura[2], Junko Komatsubara[3], Dan Matsumoto[3], Yuichi Namegaya[3], Yuki Sawai[3], Masanobu Shishikura[3]

1. Faculty of Life and Environmental Sciences, University of Tsukuba, 2. Civil Engineering Research Laboratory, Central Research Institute of Electric Power Industry, 3. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST)

A coring survey at a coastal lowland in Mie Prefecture exposed 10 sand layers deposited from about 4500 to 500 years ago. The layers are interpreted as tsunami deposits because of the presence of abundant bioclasts of marine organisms such as foraminifers and gastropods, and sedimentary structures common in modern tsunami deposits. At the study site, no substantial seawater inundations and sand depositions have been recorded even for the largest typhoons to ever hit the region. On the other hand, written document tells that the Ansei-Tokai earthquake tsunami (1854 CE) inundated the study site and deposited substantial sand layer. Estimated ages of the youngest three sand layers overlap well with tsunamis in 1498, 1096, and 684 CE. Our results support the hypothesis suggested by archaeological studies that the 684 CE rupture extended farther eastward than the historical record indicates or that another tsunami occurred at some time close to 684 CE. We did not find any sand layers that were definitely correlated with the tsunamis of 1361 and 887 CE, which are thought to have occurred by multi-segment ruptures of the Nankai Trough that includes the segment directly offshore from the study site. If the sand layers found at the study site were deposited by the tsunamis of 1498, 1096, and 684 CE, and if the tsunamis of 1361 and 887 CE did not inundate the study site, the tsunami recurrence interval during the relevant time period was about 400 years. This finding does not support the widely believed hypothesis that earthquakes and tsunamis occur at regular intervals of approximately 100 years in this area. In addition, similar to the historical tsunamis, intervals of geologically recorded prehistoric tsunamis at the study site vary from about 100 to 600 years. The hypothesis of variable recurrence of earthquakes and tsunamis along the Nankai Trough should be tested by future geological and historical studies in unbiased way.

[S-VC38] Active Volcanism

convener:Yuta Maeda(Nagoya University), Takahiro Miwa(National research institute for earth science and disaster prevention), Takeshi Nishimura(Department of Geophysics, Graduate School of Science, Tohoku University), Chairperson:Fukashi Maeno, Yosuke Aoki

This session discusses various aspects of active volcanisms including, but not limited to, recent and historical eruptions, various phenomena associated with the volcanic activities, underground structures of the volcanoes, and developments of new instruments based on geophysical, geochemical, geological, and multidiscipline approaches. We also welcome studies on understanding and predicting the transitions of the eruptive activities from observational, theoretical, and experimental approaches.

A sequence of volcanic flank collapse and tsunami event on 22 December 2018 at Anak Krakatau volcano, Indonesia

*Fukashi Maeno[1], Takayuki Kaneko[1]

1. Earthquake Research Institute, University of Tokyo

Tsunamis were generated at the Sunda Strait, Indonesia, on 22 December 2018 (~21:00 local time), and a disaster (>430 victims) occurred along the coastal area close to Krakatau. As it became clear that the southwest side of Anak Krakatau Island that has continued eruptive activity in recent years had collapsed, the tsunamis are thought to have occurred with the edifice collapse of this volcanic island (PVMBG, 2018). The volume of collapsed material, the process of the collapse event, the tsunami generation and propagation processes, and the relationship between these and the eruption activity are still unclear. Therefore we investigated the sequence of the eruption and tsunami event at Anak Krakatau on 22 Dec 2018 based on satellite images and tsunami numerical simulation. Infrared data of Himawari-8 showed that thermal anomaly has continued since the middle of June 2018 but no specific anomaly signals were detected before the collapse-tsunami event. Then the data showed that the eruptive plume occurred from ~13:50 UTC on 22 December 2018. This time was 40-70 min before tsunami arrival at the coastal areas around Sunda Strait (~14:30-15:00 UTC). The first eruptive plume developed after ~13:50 but soon declined within an hour, then the second eruptive plume developed from ~15:20. It became much higher than the first one and sustained in the next couple of days. Numerical simulation of tsunami and volcanic flank collapse was carried out with the two-layer shallow water model based on non-linear long wave theory that has been developed for the tsunamis generated by gravity flows (pyroclastic flows, debris avalanche, etc.) flowing into the water. It was solved with a finite difference method. Bathymetry data is the same as that used in Maeno and Imamura (2011). The bottom friction coefficient of the gravity current was set to be 0.01 for subaerial condition and 0.06-0.12 for submarine condition. The interfacial drag coefficients between the gravity current and seawater were set to be 0.2. The four cases with different collapsed volumes (0.16, 0.21, 0.26, 0.31 km^3) were examined. The computed tsunami waveforms were compared with tide gauge records (PVMBG, 2018) at representative locations. The most likely initial condition to explain the tide gauge records was the initial collapse volume of 0.21-0.26 km^3. Other parameters don't significantly affect the results. Numerical results also showed that, for all cases, the maximum wave height (>3 m) in the SW coast of Java became higher than other areas. This tendency is consistent with the observational records that the SW coast of Java was more heavily damaged by tsunamis. This is probably because the direction of the collapse was southwestward but the direction of tsunami propagation was gradually changed from SW to S-SE by the effect of bathymetry. We also calculated tsunami travel times and estimated the occurrence time at the source, comparing with tsunami arrival times recorded in the tide gauges. As a result it seems that the tsunamis were caused by 13:54±2 min. We conclude that the collapse occurred almost simultaneously with the small eruption from ~13:50 UTC then followed by the main sustained eruption from ~15:20. In order to determine the timing and mechanism of the collapse event more precisely, it is necessary to further evaluate initial conditions and models as well as to compare with other geological and geophysical data.

The 2018 eddifice collapse event of Anak Krakatau, Indonesia: Telseismic waveform analysis and tsunami simulation

*Shingo Watada[1], Iyan E. Mulia[1], Masumi Yamada[2], Dimas Sianipar[3]

1. Earthquake Research Institute, University of Tokyo, 2. Disaster Prevention Research Institute, Kyoto University, 3. TIGP-ESS Academia Sinica, National Central University, Taiwan

On December 22, 2018 at around 14:30 UT, a tsunami hit the coast of Java and Sumatra islands near the Sunda Strait, Indonesia and claimed more than 400 lives. The Anak Krakatau volcano island in the Sunda Strait erupted coeval with the tsunami and the summit elevation decreased from 300 m before the eruption to 100 m after the eruption, suggesting that the tsunami was generated by the subaerial or submarine edifice collapse of Anak Krakatau. SAR images show that the edifice including the summit collapsed toward southwest and disappeared into the sea. Tide gauge records around the strait suggest that the tsunami was generated at around 13:58. There were no report of a strong seismic event in Indonesia before the tsunami event, although broadband seismic networks in and around Indonesia clearly recorded unusual seismic waves (S-waves and Rayleigh waves) dominated by the long-period (50-100 sec) components. S-waves arrived at the Ryukyu islands at 14:11 and Hokkaido at 14:16. Rayleigh waves arrived at Hokkaido at 14:27. All seismic waveforms indicate occurrence of a long-period seismic event at around 13:56 near Anak Krakatau. Teleseismic body waves hint that the source duration is less than 100 sec (about 1min). Three-component broadband seismic records from four stations near the Sunda Strait can be explained by a near horizontal slightly upward force of $5x10^{11}$ N acting toward northeast for the first 20 sec followed by a near horizontal slightly dipping force of the similar magnitude acting toward southwest for about 50 sec. The force direction and angle is consistent with a collapse model predicted by Giachetti et al. (2012, Geol. Soc. London) in which a resurgent volcano Anak Krakatau collapses into the bottom of submarine Krakatau caldera at 250 m deep along a sliding slope with a dip of 8 deg. The estimated total mass of the edifice collapse is $3x10^{11}$ kg based on the empirical formula between the maximum force and the total mass of landslides (Ekström and Stark 2013, Science). Assuming the soil density 2 g/cm^3 the volume is about 0.15 km^3, roughly consistent with the submarine landslide volume 0.2 km^3 estimated from our numerical tsunami simulation for tide gauge records. Based on the routine seismic monitoring no large earthquake enough to cause tsunami was registered. On the other hand, long-period seismic waves from the seismic event at Anak Krakatau coeval with the tsunamis arrived at Jakarta 40 sec after the event. If long-period seismic events were routinely monitored in Indonesia, we could have detect the edifice collapse of the Anak Krakatau volcano and were aware of the possibility of tsunami generation prior to the arrivals of disastrous tsunamis to the coasts.

The 2018 edifice collapse event of Anak Krakatau, Indonesia: Landslide movement history estimated from seismic waveforms

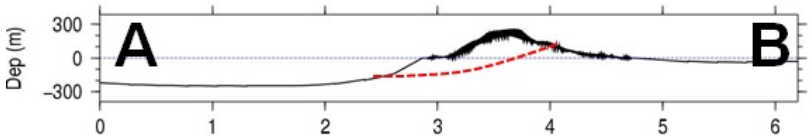
*Masumi Yamada[1], Shingo Watada[2], Haruhisa Nakamichi[1], Iyan Mulia[2], Karyono Dr.[3]

1. Disaster Prevention Research Institute, Kyoto University, 2. Earthquake Research Institute, University of Tokyo, 3. Center for Earthquake and Tsunami, BMKG

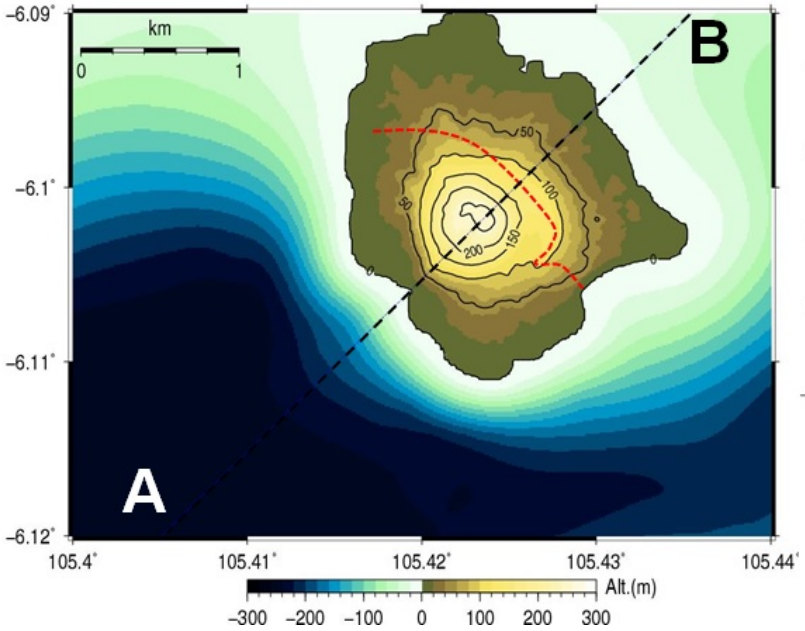
On December 22, 2018, a huge Tsunami occurred at the Sunda strait in Indonesia, and more than 400 people were killed. There was no large earthquake at that time and the tsunami was associated with the volcanic eruption and edifice collapse in Anak Krakatau island.

The seismic signals due to this event are recorded by the broadband seismic network in Indonesia. There are about 170 broadband stations all over Indonesia, with a spacing 50-100 km. We performed the seismic waveform inversion using long-period component (20-100 s) at the near-field distance (60-200 km), assuming a single force mechanism. We also performed a grid search with 10 km spacing to estimate the location of the source.

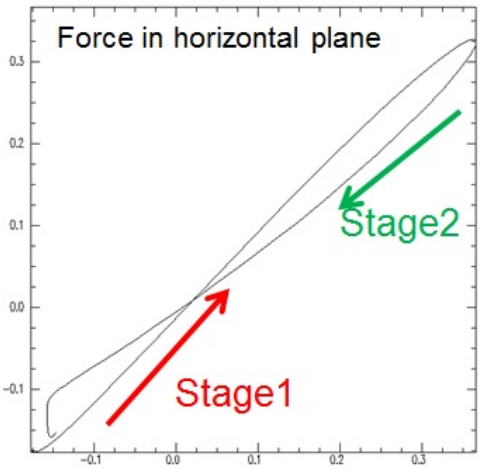
Our result shows that the onset of the event was about 14:55:50 (UTC), December 22, 2018. The duration of the source time function is about 1 min with a large amplitude, followed by a smaller signal about a few min. The particle motion of the source time function suggests the event was occurred from northeast to southwest direction with very low dipping angle (about 10 degree). The location of the event was estimated at the Anak Krakatau.



This seismic event was most likely caused by the edifice collapse of the Anak Krakatau. The satellite image shows that the southwest half of the island was subsided after the collapse, and there is a oceanic basin at the depth of 200 m in the southwest of the island, which was the old crater created by the eruption in 1883. These geometries are consistent with the movement history estimated by the seismic waveform inversion.



Based on the scaling relationship between single force amplitude vs mass of the landslide (Ekström and Sterk, 2013), the mass was estimated as 0.2-0.4 * 10^12 kg. This number is consistent with the volume estimated by the tsunami waveform simulation (Maeno and Kaneko 2019; Watada et al., 2019). We think that the edifice collapse was very low-dipping and moved like a landslide, and the mass sliding into the ocean caused the huge tsunami.



The relationship between this landslide and volcanic eruption is still debating, but Center for Volcanology and Geological Disaster Mitigation in Indonesia officially reported the timing of the eruption was 15:03 (UTC). Since the occurrence of the landslide was estimated as 14:55:50, the eruption may be triggered by the landslide, such as the 1980 eruption of Mount St. Helens triggered by the massive landslide.

Intense Swarm Activity in the Vicinity of Yake-dake Volcano, Central Japan, Started in November 2018

*Shiro Ohmi[1]

1. Earthquake Hazards Division, Disaster Prevention Research Institute, Kyoto University

An intense seismic swarm activity started in November, 2018 in the vicinity of the Yakedake volcano, Hida mountain range, central Japan. It started on November 22 and lasted for about 10 days (hereafter sited as Series A) . Hypocenters are located at the western flank of the Yakedake volcano in the depth range from 3 km to 4 km below sea level. On December 4, a small swarm activity occurred in the Kamikochi area, where is the eastern flank of Yake-dake volvano, that lasted for two days (Series B). Other small activities took place at the end of January 2019 (Series C) to the western area of the activity of Series A, as well as an activity just beneath the ridge of Hida mountain range where is several kilometers south to the summit of the Yake-dake volcano in the beginning of February 2019 (Series D).

Earthquakes in Series A exhibit ordinary characteristics of tectonic earthquakes with NW-SE compressional stress field and neither significant hypocenter migration nor change in source mechanism were observed during the activity. Earthquakes in Series B, however, some exhibit normal fault type stress field which is not coincide with the regional stress field.

The maximum intensity reported by JMA was less or equal to level 2 for all the events during the activity, however, instrumental seismic intensity observed nearby hypocentral area by DPRI recorded as large as level 4 for some earthquakes. Monitoring data of Yakedake volcano, that include crustal movement by GNSS and tiltmeter, geomagnetic total intensity by proton magnetometer, and ground temperature nearby summit, did not show the anomalous behavior during the swarm activity.

Change of the volcanic activity at Kuju volcano.

*Mori Takehiko[1], Muga Yaguchi[1], Yasushi Kawamura[2], Hideyuki Hiramatsu[3], Keiji Ikeda[2], Sugai Akira[2], Michitomo Sugahara[2], Kenichi Takata[2], Kyo Matsumoto[2], Fukuoka Regional Headquarters Japan Meteorological Agency, Oita Meteorological Office Japan Meteorological Agency

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Fukuoka Regional Headquarters, Japan Meteorological Agency, 3. Oita Meteorological Office, Japan Meteorological Agency

In Kuju volcano, after an eruption occurs at the east-hillside of Mt. Hossyo (near Mt. Iwo) in October 1995 and January 1996, the eruption has not occurred. The continuous volcanological observation by a research institution and Japan Meteorological Agency started after the eruption in 1995. Although the active seismicity which has the hypocenter in the shallow zone under Mt. Iwo was observed, the activity became calm after 2005. Moreover, after 1995, continued cooling in the shallow zone under Mt. Iwo was obtained by the geomagnetic observation, and the trend for fumarolic activity to decline gradually was seen. In this way, the declining volcanic activity was captured by various observation data.
Changes in volcanic activity of Kuju volcano began to appear around 2012. First, the GNSS observation showed that the length of the base line between the two points crossing Kuju volcano began to grow slightly. Next, the geomagnetic observation began showing the heat-reserve trend in the shallow region of Mt. Iwo from 2014. The gradual increase in fumarolic activity starts around 2015, and the slight increase in seismic activity also started around 2016.
Before the 1995 eruption, continuous volcano observation at Kuju volcano was not done, so the change of various phenomena preceding the eruption was not sufficiently obtained. We have not been able to judge whether the current volcanic activity change is an activity suggesting future eruptive activity. However, we believe that accumulation of observational data will help predict future volcanic activity. Then, by continuous observation of multiple items not only including geophysical observations but a volcano chemistry observation, the character of the volcanic activity in Kuju Volcano is grasped, and change of volcanic activity is monitored.

Posteruptive Thermoelastic Deflation of Intruded Magma in Usu Volcano, Japan, 1992–2017

*Yosuke Aoki[1], Xiaowen Wang[1]

1. Earthquake Research Institute, University of Tokyo

Secular ground subsidence at Usu volcano (Japan) has been reported around the eruption vents following the four eruptions in 1910, 1943, 1977, and 2000. However, the mechanisms accounting for the subsidence have not been well understood. In this study, we systematically investigated the posteruptive deformation at Usu volcano using interferometric synthetic aperture radar based on 111 JERS, ALOS-1, and ALOS-2 images acquired from 1992 to 2017. We also calculated quasi east-west and vertical ground displacements between 2006 and 2017. Our results show three localized deformation regions from west to east of Usu volcano with their locations corresponding to the 2000, 1977, and 1943 eruption vents, respectively. All the deformation sites show patterns of east-west contraction and subsidence. The extent and rate of posteruptive subsidence declined dramatically at the vent of the 2000 eruption site from 2006 to 2017, decreased gradually at the 1977 vent, and show a steady pattern for the 1943 site during 1992-2017. We ascribed the observed posteruptive subsidence to thermoelastic contraction of a sphere intruded at the time of the eruptions to constrain locations, depths, and volumes of heat sources with the assumption of the spherical source shapes. Thermoelastic modeling reveals that the heat sources are embedded at shallow depths not deeper than 400 m below sea level with volumes of about (8.72 ±0.19) $\times 10^6$, (132.18 ±5.21) $\times 10^6$, and (49.51 ±2.02) $\times 10^6$ m^3 for the 2000, 1977, and 1943 eruption sites, respectively. The modeling also highlights the importance of underground water in assessing the thermal diffusion process and the associated posteruptive deformation.

[S-VC38] Active Volcanism

convener:Yuta Maeda(Nagoya University), Takahiro Miwa(National research institute for earth science and disaster prevention), Takeshi Nishimura(Department of Geophysics, Graduate School of Science, Tohoku University), Chairperson:Jun Oikawa, Takeshi Tameguri

This session discusses various aspects of active volcanisms including, but not limited to, recent and historical eruptions, various phenomena associated with the volcanic activities, underground structures of the volcanoes, and developments of new instruments based on geophysical, geochemical, geological, and multidiscipline approaches. We also welcome studies on understanding and predicting the transitions of the eruptive activities from observational, theoretical, and experimental approaches.

Volcanic tremors and ash fall volumes associated with the 2018 vulcanian eruptions of Shinmoe-dake

*Jun Oikawa[1], Yasuhisa Tajima[2]

1. Earthquake Research Institute, University of Tokyo, 2. NIPPON KOEI CO.,LTD.

Kirishima volcanic chain is one of the active volcanoes in southern Kyushu, Japan and is categorized into a composite volcano whose active vents are Shinmoe-dake and Ohachi. The latest eruptive activity of Shinmoe-dake started on August 22, 2008. Subsequently, it erupted on March 30, April 17, May 27, June 27 and 28, and July 5 and 10, 2010. In 2011, the eruption started on January 19 included subplinian and vulcanian explosions. and was followed by sub-Pulinian eruption on 27 January. Eruptive activity gradually ceased since February 2, and moved to Vulcanian activities. It erupted on October in 2017 and on March in 2018. Eruptions continued until June 27. Tajima et. al (JpGU 2019) show volcanic ashfall volumes for each eruption in 2018 and we discuss the relation of ashfall volumes and durations of eruptions that is characterized by the power law: ashfall volume is proportional to durations to the second power.

Crustal deformation around the Kirishima Volcano Group detected by GNSS and SAR observation after 2018 eruption.

*Hiroshi Yarai[1], Tomokazu Kobayashi[1], Satoshi Fujiwara[1], Tomokazu Kobayashi[1], Hiroshi Munekane[1], Masaki Honda[1], Kyonosuke Hayahsi[1], Satoshi Kawamoto[1], Atsuko Oowaki[1]

1. GSI of Japan

Since July 2017, GNSS Earth Observation Network (GEONET) maintained by Geospatial Information Authority of Japan (GSI) has observed elongation at the baseline surrounding the Kirishima volcano group. Sharp shortening occurred at the eruption of Shinmoedake volcano in March, 2018, after which elongation was observed again. Similar crustal deformations are also observed during the Shinmoedake eruption in 2011, and at that time expansion and contraction of magma reservoir of about 6 to 7 km northwest of Shinmoedake is presumed (for example, Kobayashi et al., 2012) . In addition, in the Iwo-yama located in the northwest of Kirishima-yama, expansive crustal deformation centered the Iwo-yama was captured by analysis of Daichi 2 (ALOS-2) SAR data. In April 2018, an eruption took place in Iwooyama for the first time in 250 years.

Detailed investigation of crustal deformation of the Kirishima volcano group is important in grasping the situation of volcanic activity. In this research, we investigated the crustal deformation of the Kirishima volcano group including Shinmoe-dake and Iwo-yama after the eruption of Shinmoedake and Iwozan in 2018, using GNSS observation and ALOS-2 (Daichi 2) SAR data analysis.

Harmonic tremor during 2011 eruption at Shinmoedake, Japan

*Minoru Takeo[1]

1. Earthquake Research Institute, University of Tokyo

Volcanic tremor is a continuous seismic signal that is observed near active volcanoes and is often accompanied by evidence of subterranean movement or pressure fluctuation due to a physical or chemical process inside the volcano. However, the source of volcanic tremor is still poorly understood. Most existing tremor’ s models, except for Julian’ s nonlinear channel flow model (Julian, 1994), consider an acoustic resonance in the magma channels, but mechanism to excite this resonance has not been identified until now.

During 2011 eruption at Shinmoedake, Japan, we observed a series of volcanic tremors including harmonic tremor which exhibits a set of narrow, evenly spaced frequency peaks. Natsume *et al.*(2018) perform non-linear time-series analysis on a harmonic tremor recorded near the crater. They found that the stable oscillation of the harmonic tremor is predominantly a limit cycle, implying that the harmonic tremor is generated by self-sustained oscillation. In this paper, I propose a new model of harmonic tremor and reproduce the topological characteristics of observed harmonic tremor using the new model. I formulate a lumped-parameter model of incompressible viscous fluid flow through a partially constrictive path, which seems to be realistic modeling in a shallow part of conduit. I consider inertias and resistances in the upstream and in downstream pipes. The upstream pipe is connected to a large chamber with pressure of Po. Lengths and radiuses of the pipes and the constrictive path could be set flexibly in this model. This model leads to a third-order system of nonlinear ordinary differential equations with functions of area of throat, fluid velocities in upper stream and in downstream. The equations of the model are as follows:
Mass conservations in upstream and in downstream of the constricting path; Conservation of momentum in upstream and in downstream of the constricting path; Equations of motion in upstream pipe and in downstream pipe; Elastic law of the constrictive path;
Typical frequency of the harmonic tremor is 1~2Hz and the wavelength seems to be hundreds meter, so these signals were recorded within a distance of one wavelength, being little affected by wave propagation. Therefore, assuming that these observed signals represent only linear transformations of one parametric function of the nonlinear tremor model, we can compare topological characteristics of observed and simulated signals to evaluate validity of the new model. When the resistance of downstream is larger than that of upstream, a self-sustained oscillation starts in a suitable parameter range. For different driving pressure (Po), numerical solutions exhibit steady flow, simple limit-cycle oscillation, limit-cycle oscillation with double-loops or with quadruple-loops, and a chaotic oscillation. Changing Po in time, I succeed in simulating a harmonic tremor which has same topological characteristics with the observed harmonic tremor in several portions of time series (see Figure 1).

Forecasting Volcanic Eruption of Sakurajima Volcano Based on Magma Intrusion Rate

*Masato Iguchi[1], Takeshi Tameguri[1], Jun-ichi Hirabayashi, Haruhisa Nakamichi[1]

1. Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University

In order to find an empirical event branch logic from abnormal phenomena to following volcanic activity for forecasting scale and type of eruption, the magma intrusion rate prior to eruptions of Sakurajima volcano is examined using ground deformation mostly from observation data and partially based on legends, for eruptions after the 20th century: the 1914 eruption starting with plinian eruption followed by effusion of lava, the 1946 eruptions with lava effusion, eruptions at the summit crater of Minamidake during the period from 1955 to 2005, and vulcanian eruptions at Showa crater east of the summit from 2006 to 2017. Prior to the 1914 eruption, it is estimated that the magma intrusion rate attained a level of approximately 10^8 m^3/day and was on the order of 10^6 m^3/day during the effusion of lava in the 1946 eruption. During the eruptive period of Minamidake summit crater, three types of eruption occurred: vulcanian eruption, strombolian/lava fountain and continuous emission of volcanic ash. In cases of intrusion of magma forming a new conduit, the intrusion rate immediately before the 1914 eruption exceeded 10^8 m^3/day, but only 10^6m^3/day in the dyke-forming event of August 15, 2015. Magma intrusion rate into a pre-existing conduit prior to eruptions at Minamidake summit crater are ordered as follows: vulcanian eruption ($1x10^5$ to $8x10^5$ m^3/day) > continuous emission of volcanic ash (approximately $1x10^5$m^3/day) > strombolian/lava fountain ($0.2x10^5$ to $2x10^5$ m^3/day). The magma intrusion rate prior to vulcanian eruptions at Showa crater is smaller (approximately 10^4m^3/day) than for eruptions at Minamidake summit crater. However, the rate reached an order of 10^5m^3/day prior to lava fountain on August 22, 2017. Magma intrusion rates well correspond to the scale and type of eruption. In the case of magma intrusion under detection, the change of volcanic gas and increase in the heat discharge rate are available for the empirical event branch logic.

Tilt and strain change before and after the explosion at Minami-dake, Sakurajima, in 2017

*Kohei Hotta[1], Masato Iguchi[2]

1. University of Toyama, 2. Disaster Prevention Research Institute, Kyoto University

A deformation source associated with each eruption at Sakurajima have been estimated beneath Minami-dake [Ishihara, 1990; Iguchi et al., 2013]. Deformation sources for mid-long-term magma intrusion event were estimated beneath Aira caldera, Kita-dake and Minami-dake; and the deformation source beneath Kita-dake was found to act as a buffer of mid-long eruptive activity at Sakurajima [Hotta et al., 2016].

On November 13, 2017, an explosion with an infrasound occurred at Minami-dake at 22:07. Ground deformation was accompanied and kept for approximately five hours. For the period of 22:07–22:10 (period I), a large strain change at Arimura observation tunnel, which is the nearest tilt/strain station from Minami-dake crater and operated by Ministry of Land Infrastructure, Transport and Tourism, was detected whereas no significant change in tilt/strain was detected at other tilt/strain stations. For the period of 22:10–22:50 (period II), tilt/strain change was detected at all tilt/strain stations associated with violent eruptive activity. At around 23:00, style of eruption shifted from Vulcanian to Strombolian. For the period of 22:50–3:00 of the next day (period III), a pattern of tilt change at Japan Meteoritical Agency (JMA)-A station, which located on western area of Sakurajima, and tilt/strain gradually stopped.

We modeled the detected tilt/strain change using a finite spherical source model [McTigue, 1987]. Because of the poor constraint of the radius of the source, we assumed the radius of the source as 20 m for period I and 200 m for periods II and III. A shallow deflation source was located at a depth of 0.1 km above sea level beneath Minami-dake for period I. A deeper deflation source was located at a depth of 5.9 km below sea level beneath Minami-dake for period II. Then, a deflation source was located at a depth of 5.9 km below sea level beneath Kita-dake for period III. Deformation sources beneath Minami-dake for periods I and II are corresponding to the deformation sources previously found for each eruption at Sakurajima. Meanwhile, the deformation source beneath Kita-dake for period III is corresponding to the deformation source beneath Kita-dake which was found during mid-long eruptive activity. Each eruption at Sakurajima revealed to cause deflation of not only Minami-dake source but also Kita-dake one, which considered to repeat inflation/deflation during mid-long eruptive activity at Sakurajima. Temporal development of deflation accompanied by the eruption on November 13, 2017, will be revealed in our future study.

Pyroclastic Flow Accompanied with an Eruption on June 16, 2018 at Sakurajima Volcano

*Takeshi Tameguri[1], Masato Iguchi[1], Masayuki Maki[2], Haruhisa Nakamichi[1], Daisuke Miki[1]

1. Sakurajima Volcano Research Center,Disaster Prevention Research Institute, Kyoto University, 2. Research Field in Integrated Studies,Kagoshima University

At Sakurajima volcano, the explosive eruption has repeated at the summit crater since 1955. The eruption resumed for the first time in 58 years in the Showa crater on the eastern flank of the mountain, and the eruption activity was particularly active from 2009. The eruption activity has been transitioning again from the Showa crater to Minamidake summit crater since 2018. Characteristics of the explosive eruption include ejection of volcanic bombs, generation of shock waves, the release of sudden volcanic ash and gases. Besides, although the frequency is small, the explosive eruption of the Minamidake summit crater and Showa crater produces small pyroclastic flows. The pyroclastic flow is one of the most dangerous phenomena of volcanic eruption, with pyroclastic flow of high temperature and volcanic gas flowing down the flank at high speed, prediction of the pyroclastic flow occurrence is important for volcanic disaster prevention.
Seven pyroclastic flows have been confirmed with the eruption at Minamidake summit crater between 1967 and 1985 (Kamo and Ishihara, 1986). Furthermore, 37 pyroclastic flows have been reported to occur in the Showa crater from 2006 to 2014 with the eruption by the Japan Meteorological Agency. Travel distance of the pyroclastic flows from the Minamidake and Showa craters were less than 2 km. Although it is Sakurajima which continues active eruption activity, pyroclastic flow is minor phenomenon and the mechanism of pyroclastic flow generation in Sakurajima has not been elucidated. In the future, when the eruption activity becomes active, it is necessary to consider the occurrence of a large pyroclastic flow, and it is important to understand the occurrence mechanism of the pyroclastic flow. In this study, we will clarify the characteristics of precursory seismic activity and ground deformation data on the pyroclastic flow occurred in the Mimamidake and Showa craters between 2012 and 2018. In addition, we investigate whether it is possible to predict the scale and travel distance of the pyroclastic flow from the data of the precursory earthquakes and ground deformation.
In the explosive eruption at Minamidake summit crater that occurred on June 16, the volcanic ash reached to 4700 m and the pyroclastic flow went down 1.3 km from the crater in the southwest direction. The expansion of the ground deformation was observed about 18 hours before the occurrence of the eruption. The precursory earthquake sporadically occurred about 1 hour before the eruption, but it was not a clear activity compared to the eruption of the Showa crater. The pictures of the pyroclastic flow shows that the ejected material dropped from the plume flowed down the slope about 1 minute after the eruption started to rise. The pyroclastic flow does not occur simultaneously with the eruption, which has the same characteristics as the pyroclastic flow that occurred during the Minamidake activity period (Kamo and Ishihara, 1986). Amount of ejecta by the eruption is estimated to be 280,000 m3 from the ground deformation data. Not all of the ejecta will be pyroclastic flow. It is necessary to estimate the amount of pyroclastic flow out of the ejecta in order to predict the flow down distance. Estimate the amount of ejecta that became a pyroclastic flow from the calculation of fall volcanic ash using weather radar.

Tokachidake is an active volcano that repeated magmatic eruptions in 1926, 1962 and 1988. Prior to these eruptions, phreatic eruptions had been confirmed from several years ago. Although there has been no magmatic eruption in the last 30 years, long-term expansion centered around the 62-2 crater has been observed since around 2006. One of the GNSS stations near the crater moved more than 50 cm in total till the end of 2017. Coinciding with this expansive crustal deformation, long-term demagnetization under the 62-2 crater has also been observed.

Repetitive GNSS observations around the crater for more than 10 years suggested the fluctuation of deformation area centered around 62-2 crater and Taisho crater. Analysis of the temporal change of the motion vector assuming an isotropic deformation source at these two places revealed that the two inflation sources expanded at a substantially constant rate as a whole while changing the rate complementarily. Since the assumed fluctuation source is extremely shallow and flowing out of hot muddy water at the bottom of the 62-2 crater has occasionally been observed, we consider that this long-term deformation reflects the mechanical response of the shallow hydrothermal system.

Geodetic observation revealed that the long-term expansive deformation turned into stagnation in the period from the end of 2017 to the beginning of 2018. Almost at the same time, the total magnetic force data showed change in its trend of demagnetization. Also, in the Furikozawa fumaroles, an expansion of the geothermal area and an increase in fumarolic activity have been reported since around 2017.

Under such circumstances, number of volcanic earthquakes and tremors temporarily increased from late May 2018. A volcanic tremor on May 29th which activated seismicity was accompanied by a tilt motion showing a stepwise subsidence in the crater direction. Therefore, we visually examined the tiltmeter record from January 2018 which were obtained at the station MTKW (about 650 m west of the crater). Although there were few tilt events until around the end of March, occurrence frequency of such event increased thereafter, and it further increased on May 29th. A total of 117 events were identified by the end of August, 10 events by the end of March, 30 events in April and May and 77 events by August. Tilt events generally show a stepwise subsidence in the crater direction, but careful examination of each event revealed that there are various types of events: tilt change following a small preceding phase, inflation –deflation pattern, gradual change more than a few minutes, and events associated with VLP-like seismic signals, etc. Examining the direction of the tilt motion vector at MTKW about these 117 events, almost 90 % shows subsidence in the crater direction of N120 –135°E. For the event on May 29th, a preliminary analysis using tilt data around the crater showed that the tilt motion can be roughly explained by an isotropic deflation source of 130 m^3 located at 1300 m above sea level slightly south of the 62-2 crater.

Summarizing the shallow activities of Tokachidake volcano, expansion of the geothermal area and increase in fumarolic activity appeared almost at the same time with the latest stagnation of long-term expansive deformation and demagnetization for over 10 years. Volcanic earthquakes and tremors

©2019. Japan Geoscience Union. All Right Reserved.

accompanying stepwise subsidence in the crater direction increased around the same time with the deflation of the crater area. We can roughly consider two hypotheses for the latest deflation: one is a decrease in the amount of hot water supplied from the deep part, and the other is a change in supply / release balance due to an increase in discharge amount from fumaroles. Expansion of the fumarolic area, increase of the fumarolic activity, and increase of the tilt event strongly suggest the possibility of the latter hypothesis, although it is difficult to discuss the amount supplied from the deep part.

Moment tensor inversion of very-long-period seismicity at Stromboli volcano based on a very-near-field observation

*Shunsuke Sugimura[1,2], Maurizio Ripepe[2], Giorgio Lacanna[2], Denis Legrand[3], Sébastien Valade[4], Takeshi Nishimura[1]

1. Department of Geophysics, Graduate School of Science, Tohoku University, 2. Department of Earth Sciences, University of Florence, Italy, 3. UNAM University, Mexico, 4. GFZ-German Research Centre for Geosciences, Potsdam, Germany

In recent decades, moment tensor inversion of very-long-period (VLP, 2-100 s) earthquakes associated with explosive/non-explosive activities has been applied to estimate the optimal source location and mechanism. Source mechanism of VLP associated with explosions at Stromboli volcano has been interpreted as the pressure source of opening/closing cracks embedded in the volcanic medium (Chouet et al., 2003). However, the nearest temporal station is 300 m away from the craters so that the source mechanism might have not been constrained well to discuss the detail processes of the magma motion in the conduit. In this study, we analyze broadband seismic data observed in the very-near-field condition, only 100-300 m away from the active craters, to obtain a more precise source mechanism solution.

We use the seismic data recorded at eight broadband seismic stations including temporary and permanent networks. Infrasonic array analyses show that the explosive eruptions mostly occurred at the north-east (NE) crater during the observation period in the end of September 2016. We apply a moment tensor inversion method to VLP (0.05-0.2 Hz) signals associated with the largest explosion occurring at the NE crater. The result shows that the optimal centroid is located at 200 m southwest of, 160 m beneath the NE crater. The source mechanism is greatly dominated by the vertical component of the moment tensor (Mzz), although the polarity inverts with other two diagonal components (Mxx, Myy). The squared error between the observed and synthetic waves (Ohminato et al. 1998) is only 11%.

We note that the squared errors less than 20 % are widely distributed around the optimal location: 300 m ×300 m in horizontal distances and 250 m in the vertical direction. For example, the solution obtained at a depth of 160 m beneath the NE crater shows the error of 18 %, which is within the confidence interval 95 % range of the residual at the optimal location. At this location, the inverted source mechanism is dominated by three diagonal components with a same polarity. This is much different from the best solution.

To examine why such different source mechanisms are obtained for nearby source locations, we calculate a model resolution matrix using the Green’ s functions computed from a point source at the optimal location and investigate how well the moment tensors can be resolved. The minimum singular value in the model resolution matrix is assumed to be 2.1 % of the maximum. We replace this value with zero and consider the pseudoinverse. The model resolution matrix for the pseudoinverse shows that the resolution of the diagonal components of moment tensors is lower than deviatoric ones. This suggests that the amplitudes of diagonal components are not well constrained from the moment tensor inversion even using near-by stations in our temporal observations. These results will be indispensable for discussing the spatial distribution of the volumetric change in the conduit or magma chamber accompanying the explosions.

Pressure source estimation of tilt changes associated with small explosions at Stromboli volcano

*Ayumu Ishikawa[1], Takeshi Nishimura[1], Hiroshi Aoyama[2], Ryohei Kawaguchi[3], Eisuke Fujita[4], Takahiro Miwa[4], Taishi Yamada[4], Maurizio Ripepe[5], Riccardo Genco[5]

1. Graduate school of science, Tohoku university, 2. Faculty of science, Hokkaido university, 3. Meteorological Research Institute, 4. National Research Institute for Earth Science and Disaster Resilience, 5. University of Florence

Stromboli volcano is characterized by continuous activities of Strombolian explosions (small explosions) at summit craters. A lot of studies have investigated volcanic processes by multi-parameter observations. However, pressure source determination by geodetic measurements, which is indispensable to understand shallow magma reservoir which is a key for understanding magma dynamics, have not yet been well conducted because of insufficient geodetic observation network. In the present study, we analyze tilt records at 3 temporal and 2 permanent stations located closely to the summit craters to determine the locations and size of pressure source by comparing the observed tilt vectors with the theoretical ones that are calculated by using finite element method.
Temporal stations CPL, PZZ, RFR were equipped with Applied Geomechanics 701-2A, and installed at a distance of <500 m from the active craters. Continuous stations LFS, OHO, LSC, operated by University of Florence, were equipped with Pinnacle 5000T. We analyze continuous tilt records of 5 stations during July 1 to July 15 when small explosion activity was high. We extract uplift and subsidence tilt signals associated with each of small explosion and classify them in 4 stages: (A) Gradual uplift prior to small explosions, (B) Rapid uplift just before small explosions, (C) Rapid subsidence after small explosions, (D) Small uplift after (C). Tilt azimuths and amplitudes are almost same for the stages of (A) –(C), although LFS show about 30 degrees difference. We use the tilt vectors averaged for 680 events in the following analyses. We suppose that the pressure source is represented by an ellipsoidal cavity at (1) beneath the summit craters or (2) VLP source (Chouet et al., 2003; 200 m NW from the summit craters). We searched optimal source model which could explain the observed tilt vectors by changing the size and shape of the ellipsoidal cavity. The results show that simple shape sources such as a sphere cannot explain the observed tilts both for the locations of (1) and (2). A spheroidal source that is modeled from the VLP source mechanism do not explain the observed tilts, either. By changing the size and directions of ellipsoidal cavity, we find that the ellipsoidal cavity with a size of 300×150×600 m at 400 m depth beneath the summit craters can well explain the observed tilts. The pressure applied during the episode (A) is estimated to be about 1 kPa.
The size and position of the estimated ellipsoid is basically consistent with the picture of shallow magma reservoir inferred from an analysis of temporal evolution of flank lava effusion in 2007(Ripepe et al., 2015). The mass and volume of magma supplied for conduit during a small explosion that are estimated from the obtained pressure change, appropriate conduit radius and magma density is comparable to the ejected mass and volume of one small explosion estimated from the observations of surface phenomena.

Seismic and acoustic waves excited by volcanic explosion: analyses of energy ratio and source spectra

*Mohammad Hasib[1], Takeshi Nishimura[1], Hisashi Nakahara[1]

1. Department of Geophysics, Graduate School of Science, Tohoku University

Volcanic eruptions generally accompany both seismic and acoustic signals, and these signals are used to understand volcanic fluid motions in the conduit and/or its effusion process from active vents. In the present study, we compare these two kinds of signals observed at three volcanoes in Japan, systematically examining the temporal changes of radiated energy. We further examine the basic spectral characteristics of seismic and acoustic signal radiations during large and small Vulcanian explosions at Sakurajima volcano. We use seismic and acoustic records at seismic-acoustic stations operated by Japan Meteorological Agency (JMA).

We first examine the energy ratio between seismic and acoustic signals of volcanic explosions at Sakurajima, Kirishima, and Kuchinoerabu-jima volcanoes. We calculate the time series of energy ratio of acoustic signals to three-component seismic signals by calculating their envelopes at the frequency band of 1-5 Hz. To obtain averaged characteristics, we stack the energy ratios of seismic and acoustic signals of about 900 explosions at Sakurajima and 8 explosions Shinmoe-dake (Kirishima) volcanoes, respectively. We analyze only one eruption at Kuchinoerabu-jima. The results at Sakurajima and Shinmoedake (Kirishima) show the following characteristics in the temporal changes: the ratio of seismic energies to acoustic energies rapidly decreases at the beginning and reaches the minimum in about 10 s -20 s; then the ratio gradually increases for 20 s - 40 s; the seismic signals continue after the acoustic energy decreases down to the noise level. Although we can analyze one eruption data for Kuchinoerabu-jima volcano (18 December 2018), similar characteristics are recognized. These results suggest that the volcanic fluid motions are strong in the shallow parts in the beginning, and the active zone gradually becomes deep.

Next, we investigate the source spectra of acoustic signals of volcanic explosions. Applying the spectral ratio method that has been often used for seismic signals, we clarify the difference of source spectra between large and small acoustic signals. We stack the spectral ratios of acoustic signals according to their maximum amplitudes, and classify them into Classes IV, III, II, and I from the largest to the smallest. The maximum amplitude of the largest event is about 10 Pa, while the smallest is about 2.5 Pa. Since the wind around the volcano may disturb the wave propagations, we only select the acoustic signals excited by volcanic explosions occurring during a low wind speed (< 3.3 m/s) condition, using the assimilation wind data recorded by ECMWF (European Centre for Medium-Range Weather Forecasts). We observe that the spectral ratios of acoustic signals are similar among different stations both for direct and coda waves. This means that the spectral ratio method is applicable for the acoustic signals of volcanic explosions during low wind speeds. All pair of the observed source spectral ratios of acoustic signals (Class IV/I, III/I, II/I) are characterized by almost flat amplitudes at the frequency range of about 0.2 -10 Hz. The difference between the classes is the amplitude. This characteristic is much different from the seismic signals excited by Vulcanian explosions (Hasib et al., 2018), in which a flat amplitude at low frequency range (about 0.5 - 2 Hz), a gradual decrease with frequency at an intermediate frequency range (about 2–3.5 Hz), and a flat amplitude at high frequency range (about 3.5 –10 Hz). These differences suggest the differences in the generation mechanisms between seismic and acoustic signals, which may reflect the difference of excitation region: the seismic waves are in the volcanic conduit beneath the vent, while the

©2019. Japan Geoscience Union. All Right Reserved.

acoustic waves are at the orifice of the conduit.

Field survey report on Zao Volcano (2012–2018)

*Akio Goto[1], Noriyoshi Tsuchiya[2], Nobuo Hirano[2], Miwa Kuri[3], Tetsuya Matsunaka[4], Kengo Sawayama[2]

1. Center for Northeast Asian Studies, Tohoku University, 2. Graduate School of Environmental Studies, Tohoku University, 3. International Research Institute of Disaster Science, Tohoku University, 4. Institute of Nature and Environmental Technology, Kanazawa University

We have been conducting field surveys on Zao volcano since 2012, such as temperature monitoring and water sampling on Maruyama-sawa geothermal area, ruin of Niizeki hotspring and Okama crater lake, based on the expectation that Zao volcano may be activated by 2011 Great East Japan Earthquake. Geophysical observation network by Japan Meteorological Agency, which has started 24-hour monitoring in September 2010, detected volcanic tremor in January 2013 for the first time, and a tremor and preceding tilting occurred in April (JMA, 2013). Since then Zao volcano sustains its higher activity than usual. Volcanic warning, Level 2: Do not approach the crater, were issued in April 2015 due to the increase in volcanic earthquake and in January 2018 due to the occurrence of volcanic tremor with largest-ever amplitude and continuous tilt motion. In harmony with these activities our field surveys also detect some changes in surface activities. Here we review our field survey results since 2012, especially focusing on the 2017-2018 results which has not reported yet.

Temperature of over 20 fumaroles has been measured repeatedly on Maruyama-sawa geothermal area, where small phreatic explosion occurred in 1940 (Toraishi and Tominaga, 1940; Anzai, 1941). The highest temperature exceeded 102 ˚C in 2012, but decreased over 7 ˚C within four months in 2013; fumarole temperature overall fell lower than 95 ˚C by 2014. After the first volcanic warning in 2015, the highest fumarole temperature reached nearly 100 ˚C temporarily, and then overall temperature rise occurred in 2016. In 2018, after volcanic warning was issued for the second time in January, the highest fumarole temperature exceeded 100 ˚C in June and reached 104 ˚C in July, which is the highest record in our survey since 2012.

We have paid attention to ruin of Niizeki hotspring, where high temperature and high concentration hotsprings gushed as a result of activization in the past, but no activity was recognized between 2012 and 2014. In September 2015, five months later from the first volcanic warning, we found that Niizeki hotspring resumed welling up with multiple hotsprings at around 32˚C. But in 2016 surveys, Niizeki hotspring had only a few weak cold-water springs, and no remarkable activity was recognized after the second volcanic warning in 2018.

In contrast with Maruyama-sawa and ruin of Niizeki hotspring, no thermal activity has been recognized on Okama crater lake thus far. The bottom temperature was around 4 ˚C in late May and early June (2014 and 2016), and around 7 ˚C in early September (2014, 2015, 2017 and 2018). We installed thermocouples in 2017 and 2018 on the bottom of Okama crater lake to record the temperature change one hour interval. We found that 3-4 ˚C temperature rise occurred in early October in 2017 and 2018, which is probably not be the results of thermal activity of Zao volcano but seasonal variation, because the degree of temperature change and the time of the year were identical. In 2018 other research group conducted topography survey of Okama crater lake bottom using a multiple-frequency sonar system and detected vertically extending reflection over a small mound on the center of the lake bottom, which may be caused by a chain of rising volcanic gas bubbles or hot water plume (Yamasaki et al., 2018). One of our

thermocouple is set within 10 m from the reflection source. Our thermocouple may catch the temperature change if thermal activity occurs there.

Inflation Event of Zao Volcano in 2015

*Satoshi Miura[1], Mare Yamamoto[1], Masahiro Ichiki[1], Tomotsugu Demachi[1]

1. Graduate School of Science, Tohoku University

Volcanic earthquakes and tremors have been occurring beneath Zao volcano located in the northern Honshu, Japan since 2013, following the increase in the number of deep low frequency earthquakes from around 2012. Tohoku University has deployed some new seismological, geodetic, and geomagnetic stations to enhance rather poor observation network prior to the activity. On account of a burst of volcanic earthquakes initiated in April 2015, the Japan Meteorological Agency announced a warning of eruption, however, the number of events gradually decreased for the next two months and the warning was canceled in June 2015. In the same time period, minor expansive deformation was observed by GNSS. Small-scale volcanic earthquakes and tremors are occasionally occurring, and long-period earthquakes have taken place sometimes accompanied by static tilt changes. In this talk, We report the outcome obtained from the five-year observational research to monitor the preparatory process going under the volcano for evaluation of the eruption potential.

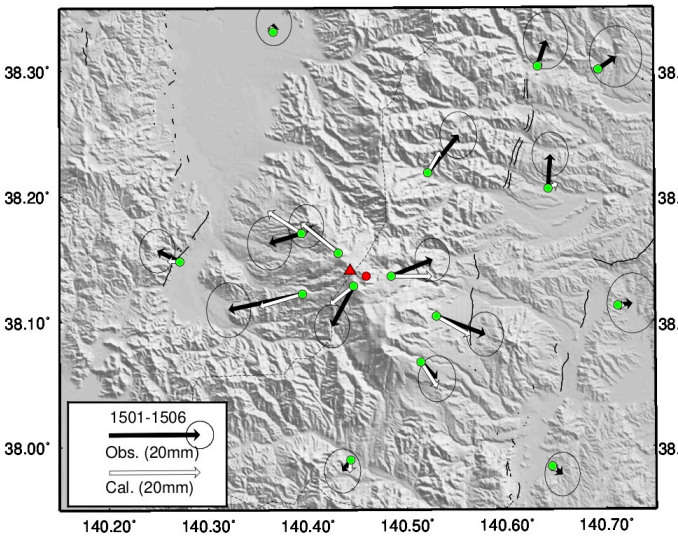

Figure 1 demonstrate the horizontal and vertical movement around Zao, respectively, from Jan. to Jun. of 2015. The black arrows show the observed ground movement. The radial pattern of movement around the summit of the volcano is clearly seen and the upheaval indicated by the black bars also centered around the summit. These characteristics of deformation can be modeled by a infinitesimal pressure source underground (so called Mogi model). We tried inversion analyses to find its location and magnitude. It is located about 0.8 km east of the crater lake with depth of about 5.6 km, and the volumetric change equivalent to the pressure change is $3.8 \times 10^{6} m^{3}$. The calculated displacements are shown in the figure by white arrows and bars.

Comparing the hypocenter map, the pressure source is located just above the deep low frequency earthquakes cluster. This suggests that the pressure source might be activated by geothermal heat supplied by magma or fluid. Ogawa et al. (2014) found a conductive zone beneath Zao volcano deeper than about 5km and this may support our result.

[S-VC38] Active Volcanism

convener:Yuta Maeda(Nagoya University), Takahiro Miwa(National research institute for earth science and disaster prevention), Takeshi Nishimura(Department of Geophysics, Graduate School of Science, Tohoku University), Chairperson:Mare Yamamoto, Yuta Maeda(Nagoya University)

This session discusses various aspects of active volcanisms including, but not limited to, recent and historical eruptions, various phenomena associated with the volcanic activities, underground structures of the volcanoes, and developments of new instruments based on geophysical, geochemical, geological, and multidiscipline approaches. We also welcome studies on understanding and predicting the transitions of the eruptive activities from observational, theoretical, and experimental approaches.

A machine-learning-based estimation of large amplitude regions for monitoring volcano seismicity

*Yuta Maeda[1]

1. Nagoya University

The seismic network of Mt. Ontake has improved after the 2014 eruption, producing one of the most dense observational networks in the world composed of 9 stations within 1 km of the summit, 17 within 4 km, and 29 within 10 km. This network has recorded long-period (LP) events and tremors which had been considered quite rare at Mt. Ontake (Maeda et al., 2018, JPGU). These signals are attributed to movements and volume changes of shallow volcanic fluids according to studies of similar signals at other volcanoes; thus they are important markers to understand the state and behavior of the fluids. However, despite finding several events, the entire activity of them are not known at Mt. Ontake; it is not easy to manually create an event catalog because of abundance of spurious events (i.e., local wind noise) and difficulty of distinguishing them from real volcano-seismic signals. This is partly related to a difficulty of comparing the records at many stations with a sufficient temporal resolution using a small number of figures. A new strategy to extract useful information from the large number of stations is thus needed.

In this study, we developed a method to investigate a spatiotemporal distribution of large amplitude regions to easily monitor the activities of earthquakes and tremors. The amplitudes could be a measure to monitor the seismicity including those without clear initial motions, but could be affected by local structures beneath the stations. To reduce this effect, we used information of whether the amplitudes are significantly larger than the normal level. We determined a threshold to distinguish significantly large and normal amplitudes from every 5-min-long window of each data trace, based on an idea that Gaussian and non-Gaussian portions of the frequency distribution of the amplitudes are normal and significantly large parts, respectively. This idea is implemented by creating a cumulative frequency distribution of absolute amplitudes in the 5-min-long window using only the smallest N data samples; calculating the fitting error between this distribution and an error function; and searching for an optimal N which minimizes the fitting error. The amplitude corresponding to this optimal N was regarded as the threshold. We then computed the ratio of large amplitude samples in every 1-sec-long window of each trace. We used the spatial distribution of this ratio as the input to a machine learning of a neural network model to investigate the large amplitude region for the 1-sec window. In this way, the spatial distribution of the large amplitude region is investigated for every 1-sec window, which could be used to distinguish true volcano-seismic signals from spurious ones.

We applied this method to the continuous records in November and December 2017 at Mt. Ontake. For most earthquakes occurred in the analysis domain, the large amplitude region distributed within a narrow area around the epicenter or spread with time from the epicentral area to a wider region. For distant earthquakes and local noise, the large amplitude region extended over the entire analysis domain with a small probability. These different patterns of the large amplitude regions were useful to distinguish the true volcano-seismic signals from spurious ones, although there were some missing detections of small earthquakes and tremors. Using the large amplitude region, only one figure is needed for each second, enabling a seismicity monitoring easier than detailed evaluations of continuous waveform records. We are now trying the 2nd stage of the machine learning to automatically detect earthquakes and tremors, which uses the spatiotemporal distribution of the large amplitude as the input, giving 93% success as a preliminary result.

Development of a technique for automatic determination of volcanic earthquakes with unclear onsets - Application to Mt. Asama -

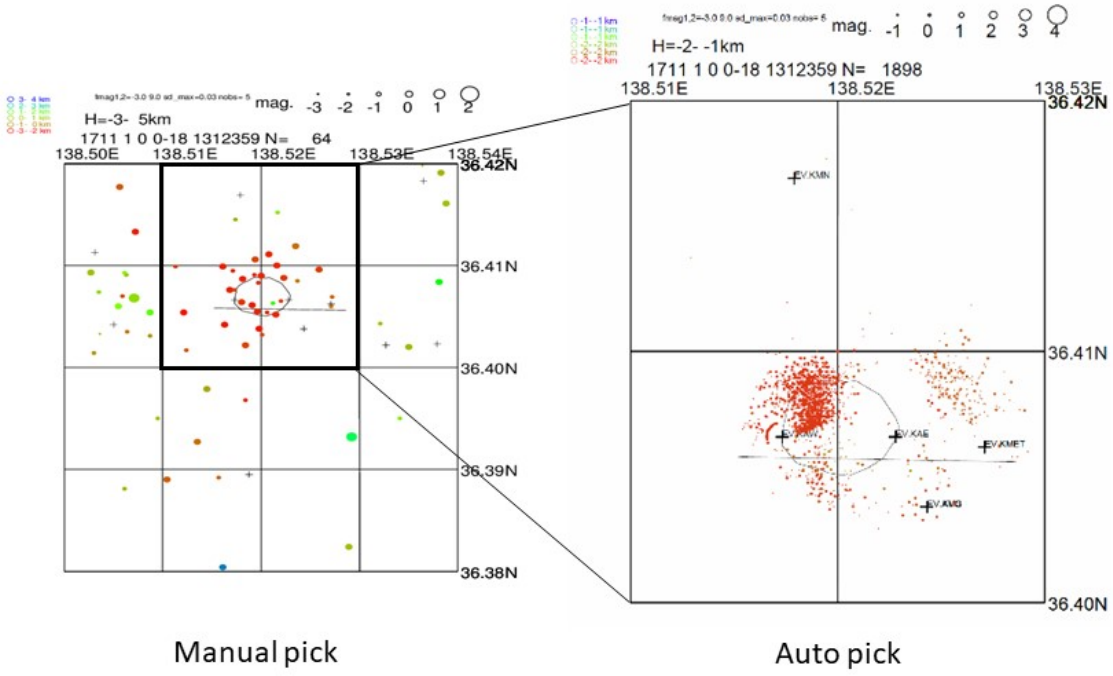
*Takao Ohminato[1], Shigeki Horiuchi[2]

1. Earthquake Research Institute, Tokyo University, 2. Home Seismometer Corporation

Some of volcanic earthquakes have clear P and S-wave onsets, and other has unclear onsets. In the traditional classification of volcanic earthquakes, the former is called A-type, VT, or HF earthquakes, and the latter is called B-type, LP, or LF earthquakes. The source process of the former is thought to be the rock rupture due to the stress changes in the volcanic edifice. For the latter, various source processes involving volcanic fluids such as gas, hot water or magma, have been proposed.

Numerous B-type earthquakes are often detected by the seismic network near the active volcanic vent of a volcano even if the activity level of the volcano is not high. In addition, a sharp increase in the number of B-type earthquakes is often observed when volcanic activity increases. Because shallow B-type earthquakes reflect the state of the magma plumbing system or the shallow hydrothermal system, constant monitoring of their activity is important. However, since B-type earthquakes are numerous and it is difficult to read their onset by human eyes, manual processing is not easy. Therefore, it is necessary to develop a automatic method to detect the event and to determine the hypocenter location. For events with unclear onsets, various methods, such as obtaining travel time differences by using waveform correlation, using particle motion, using spatial distribution of amplitude, etc., have been proposed so far. In particular, methods using waveform amplitude are widely used for hypocenter determination of B-type earthquakes due to their excellent performance.

In this study, we first examine how effective the Horiuchi et al. (2010)'s method for hypocenter determination of volcanic earthquakes with unclear onset. This method has been used in hypocenter determination of non-volcanic earthquakes. The basic idea of this method is, first, to define an evaluation function that imitates the comprehensive judgment of experienced human beings, then, to optimize the parameters of the evaluation function automatically so that the results of automatic readings approach the human readings. Furthermore, the influence of noise is reduced by giving a higher score values to observation stations where the difference between the theoretical and the observed travel times is smaller and by choosing a solution with the sum of the score values of all observation stations is maximum. In order to further improve signal-to-noise ratio, S-waveforms are appropriately rotated before reading S-arrival.



When we applied the method in its original form to Mt. Asama data, the accuracy of the result was poor. Possible reasons would be, in addition to difficulty in onset reading itself, the influence of various factors such as poor human readings which are the basis of parameter optimization, and high noise level of the data. In order to improve the performance of the method, we have tried various remedy such as improving onset reading, utilizing amplitude, reducing noise, etc. and have finally reached the stage where automatic determination is satisfactory. The measures we have taken and their results are as follows.
1) If the conventional automatic reading method is applied as it is, the accuracy of S-reading is not good enough. We examined a method in which an approximate hypocenter location is determined first using the waveform amplitude, then the S-wave arrival is read using the correlation. In order for improving the accuracy of S-reading, we used the correlation of the S-waveform envelope. We then computed the hypocenter location by using both the amplitude and the travel time. But the high accuracy of the

©2019. Japan Geoscience Union. All Right Reserved.

S-reading was not reached. We abandoned this approach.
2) The hypocenters were determined by using both the automatic reading of S-arrival and amplitude, but accuracy was not satisfactory.
3) We performed following four remedy first: "To avoid reading noisy waveforms", "To discriminate between distant earthquakes and local volcanic earthquakes", "Not to use readings with low signal-to-noise ratio", "To remove amplitude data with inconsistent S-arrival". We then carried out hypocenter determination by using waveform amplitude alone. The results obtained by this procedure were most satisfactory.

When we apply above-mentioned improved method to the data for three months from November 2017 to January 2018, we could determine hypocenters of about 1900 events near the summit of Mt. Asama. The number of events that was determined manually during the same period was less than 100 events. Although we need to investigate more about the accuracy of the obtained hypocenter location, we believe that the improved version of this method is fairly promising.

Amplitude source location method with depth-dependent scattering and attenuation structures for volcano-seismic signals

*Hiroyuki Kumagai[1], John Makario Londono[2], Alvaro Esteban Acevedo Rivas[2], Yuta Maeda[1]

1. Graduate School of Environmental Studies, Nagoya University, 2. Colombian Geological Survey

The amplitude source location (ASL) method has been used to locate seismic events and tremor at various volcanoes. It has been indicated that the far-field and isotropic radiation equation for *S* waves used in the ASL method is valid in highly scattering wavefields. A constant *Q* value in the far-field and isotropic radiation equation has been commonly used in previous studies. This implicitly assumes homogenous distributions of scattering characteristics represented by the mean free path (l_0) and intrinsic attenuation (Q_i) beneath volcanoes. Wegler (JGR, 2004) and Kumagai et al. (JGR, 2018) showed that highly heterogeneous structures at volcanoes only exist in a surface thin layer with a thickness of about 1 km, below which less heterogeneous layers comparable to those in the normal crust exist. To evaluate the effects of such layered structures for ASL determinations, we performed synthetic tests using envelope waveforms simulated with the Monte Carlo method of Yoshimoto (JGR, 2000) for a two layer model based on the l_0 and Q_i structures at Nevado del Ruiz volcano (NRV) estimated by Kumagai et al. (2018). Our results indicated that the input source locations were estimated by the ASL method when appropriate values of *Q* values for the two layered model were used in the far-field and isotropic radiation equation. When a constant *Q* value was used, the estimated locations were largely deviated from the input locations especially in the depth direction. We then determined ASLs of volcano-tectonic (VT) earthquakes at NRV, which were compared with their hypocenters determined by the onset arrival times. Our results indicated that the differences between the ASLs and hypocenters of VT earthquakes became smaller when using a two layer *Q* model than those using a constant *Q* model. Our estimated ASLs of long-period (LP) events and tremor at NRV using the two layer *Q* model were more sharply clustered beneath the SW flank compared to those using the constant *Q* model. These locations corresponded to high *P*-wave to *S*-wave velocity ratio regions (Londono and Kumagai, JVGR, 2018), suggesting that the LP events and tremor were generated by fragmentation processes in a shallow magma storage region. These results indicate that use of appropriate *Q* values in the ASL method accommodating a thin surface heterogeneous layer is important to estimate precise source locations.

Seismic interferometry at active volcanoes in Japan: Analyses of seismic records of JMA for the period from 2012 to 2018

*Takeshi Nishimura[1], Tomoya Takano[1], Takashi Hirose[1], Hisashi Nakahara[1]

1. Department of Geophysics, Graduate School of Science, Tohoku University

We analyze the seismic records of JMA stations deployed at active volcanoes in Japan, to examine the basic characteristics of daily variations of seismic velocity changes in the shallow medium. About 20 active volcanoes are systematically analyzed at the frequency range of 0.5-4 Hz. Temporal changes of the seismic velocity changes calculated from comparison of 7 years averaged cross-correlations and 5-days ones show long-period changes with periods of a year and/or a few months. The frequency distributions of seismic velocity changes at each station pairs roughly follow the normal distributions with a standard deviation of about 0.2 to 1 percents. Several phreatic eruptions occurred at Kuchinoerabu-jima, Ontake, Hakone and Aso volcanoes during the observation period, but no significant change is observed in the seismic velocity changes. On the other hand, seismic velocity changes due to the strain changes by volcanic pressure sources, moderate and large earthquakes, and/or dike intrusion are observed at, for example, Sakurajima, Miyakejima, Izu-Ohshima, Azuma and Tarumae volcanoes.

Empirical relation for *Q* factors of crack resonances and its use to estimate source properties of volcanic LP events

*Kimiko Taguchi[1], Hiroyuki Kumagai[1], Yuta Maeda[1], Roberto Torres[2]

1. Nagoya University Environmental Studies, 2. Colombian Geological Survey

Long-period (LP) seismic events are thought to arise from the oscillations of a fluid-filled resonator. The resonator geometry and fluid properties of LP sources have been estimated by comparing observed frequencies and *Q* factors to those calculated from a crack model (Chouet, *J. Geophys. Res.*, 1986). Taguchi et al. (*J. Geophys. Res.*, 2018) developed a method based on an analytical formula for the crack resonance frequencies proposed by Maeda and Kumagai (*Geophys. J. Int.*, 2017). This method enables us to estimate all the parameters of crack geometry and fluid properties. But the comparison of *Q* factors was conducted by numerical simulations of the crack model, which took extensive computational time, especially for LP events with large *Q* factors. So we systematically investigated the relation between *Q* factors and the crack model parameters by numerical simulations. It is known that *Q* factors of the crack resonances are proportional to α/a, where α is the *P* wave velocity of the solid and *a* is the sound speed of the fluid in the crack (Kumagai and Chouet, *J. Geophys. Res.*, 2000). We additionally found an empirical relation, indicating that the proportional constant depends on $\log(W/L)$, where *L* and *W* are crack length and width, respectively. To test the applicability of this empirical relation, we used it to analyze LP events at Galeras volcano, Colombia, in January 1993. These LP events have been thought to be generated by resonances of the crack filled with dusty gas. Our estimates of the crack model parameters displayed decreasing trends in both crack volume (*V*) and gas-weight fraction of water vapor (*n*) in the crack. These trends are similar to those shown by Taguchi et al. (2018). We further analyzed LP events at Galeras in May 1993 and December 2006 with the empirical relation for *Q* factors assuming dusty gas as the fluid in the crack. Because of their large *Q* factors, the determinations of crack geometry and fluid properties for these LP events with numerical simulations of the crack model were computationally expensive. The empirical relation for *Q* factors enables us to estimate all the crack model parameters for these LP events easily, and we found similar decreasing trends in both *V* and *n* to those in January 1993. This similarity implies that these variations during the individual periods of LP events were caused by the similar processes at this volcano.

These results demonstrate that the empirical relation obtained in this study is applicable to estimate all the parameters of LP sources, and may contribute to improved monitoring of fluid states under volcanoes and better understanding of LP source processes.

A study on the radiation pattern for resonating fluid-filled crack

*Mare Yamamoto[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

Volcanic earthquakes observed around active volcanoes often exhibit harmonic characteristics having multiple spectral peaks, and thus the oscillation of fluid inclusions beneath volcanoes have been considered as one of the most plausible source models of these signals. As examples of such resonator model, the resonance of fluid inclusions whose shapes are sphere, cylinder, and crack have been proposed and successfully applied to the analyses of observed signals to explain the spectral characteristics of volcanic earthquakes. In recent years, it becomes more common that we have dense seismic observation close to the source of volcanic earthquakes, and we often observe varieties of spectral shapes showing different amplitude pattern between spectral peaks and between stations. To utilize the amplitude information of observed spectral peaks, in this study, I model the radiation pattern for a resonating fluid-filled crack, and discuss about the possibility to estimate the orientation and size of the fluid-filled crack.

In this study, the radiation of elastic waves from a resonating thin fluid-filled crack in 3-D infinite medium is considered. First, I compute the oscillation of fluid-filled crack, and compute the wave radiation from the crack by numerically integrating the elastic waves generated by the tensile dislocation on the crack surface. By computing the energy at each direction, the radiation pattern is then obtained as a function of distance from the crack. Because Yamamoto and Kawakatsu (2008) showed that the distribution of the tensile dislocation on the crack surface can be described by small numbers of Chebyshev polynomials as far as we consider the low-frequency oscillation of the crack, for the sake of comparison, I also calculate the wave propagation using this analytical expression. If we consider only far-field compressional wave, the model setting is same as that discussed in Chouet (1986). In contrast, in this study, I use analytical Green’s function including both near- and far-field terms for P and S waves to study the radiation pattern for the resonating fluid-filled crack.

In the case of the crack containing hydrothermal fluids, which have rather large acoustic velocity contrast between inside and outside of the crack, the radiation pattern of each resonant mode becomes almost comparable to that obtained only with far-field compressional term at distance larger than about 50 times of the crack size. On the other hand, the radiation pattern in short distance range is severely distorted due to the contribution of near-field term and the interference of waves emitted from different point of the crack. In addition, there exists the difference between even- and odd-modes of the resonant mode. These results can be explained by considering the following mainly two points: the wavelength of radiated elastic waves is same order of the crack size, and thus the distant range in which the contribution of near-field term dominates is proportional to the wavelength of each resonant mode; the distribution of tensile dislocation have different symmetry for odd/even modes, and thus the effect of the interference of waves emitted from different point of crack surface depends on the direction, as already pointed out by Kumagai et al. (2002). It also becomes clear that there exists the distant dependency of amplitude ratio between resonant modes.

These results indicate the possibility to estimate the orientation and size of fluid-filled crack beneath volcanoes by observing amplitude ratio between stations and between spectral peaks. Because the

spectral amplitude ignoring phase information is less affected by the wave scattering caused by small-scale heterogeneity in shallow volcanic edifice compared to the waveform itself, the methodology has an advantage in practical data analyses. These results also suggest the importance of near-field dense observation to understand the detailed source mechanism and source process of volcanic earthquakes.

Rheology of granular materials near the jamming transition under oscillatory shear

*Michio Otsuki[1], Hisao Hayakawa[2]

1. Graduate School of Engineering Science, Osaka University, 2. Yukawa Institute for Theoretical Physics, Kyoto University

Amorphous materials consisting of repulsive and dissipative particles such as granular materials, colloidal suspensions, foams, and emulsions behave like liquids below a critical value of the packing fraction, while they behave like solids above that value. This sudden change is known as a jamming transition [1]. In this talk, we present our recent numerical results on the rheological properties of granular materials near the jamming transition under oscillatory shear. It is confirmed that the shear modulus depends on the amplitude of the initial oscillatory shear before the measurement [2]. Even at densities below the transition point, where isotropic jamming occurs without shear, the initial oscillatory shear can induce the finite shear modulus. This behavior is consistent with a transition known as shear jamming. We also discuss the yielding transition above the jamming point under sufficiently large strain.

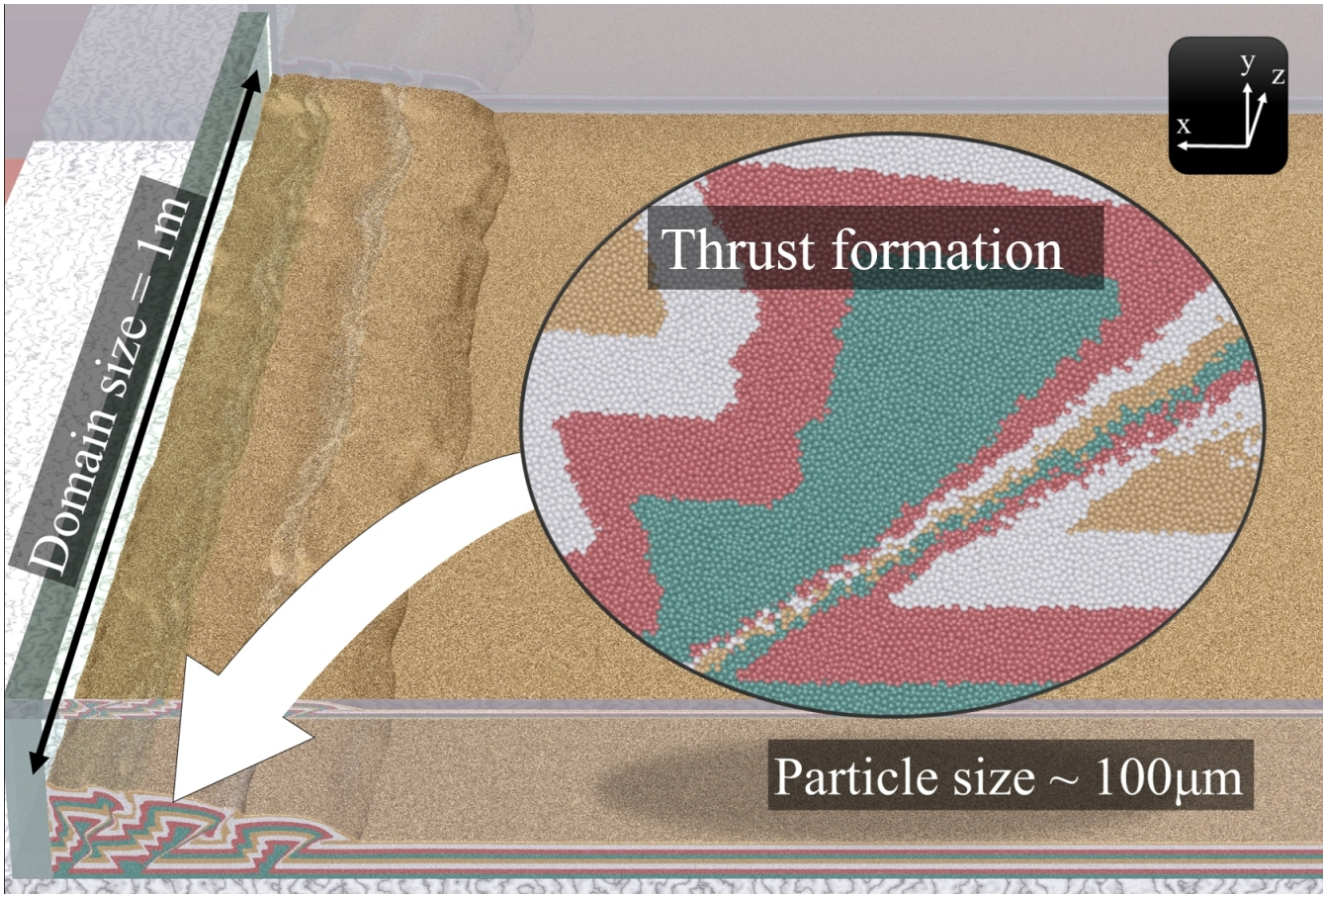
The real-scale numerical sandbox experiments for understanding stress state in accretionary prisms

*Mikito Furuichi[1], Arthur Bauville[1], Daisuke Nishiura[1], Takane Hori[1], Osamu Kuwano[1]

1. Japan Agency for Marine-Earth Science and Technology



The sandbox experiment is known as a scaled physical analog model of accretionary prisms. Thus, understanding the stress state inside the sand layer is the interesting challenge of the geology. However, measuring stress states in laboratory sandbox experiments is still practically infeasible. Here we performed real-scale numerical sandbox experiments using the Discrete Element Method (DEM) to understand the 3D stress state in the accretionary prism. The critical bottleneck of DEM was the limited number of particles acceptable for practical computation time and it was difficult to simulate a system with a huge number of particles required by such as our target sandbox test with realistic particle size. We had overcome this issue by developing the dynamic load balancing technique for the DEM codes and run the real-scale numerical sandbox simulation using up to 2.4 billion particles [Furuichi et.al. 2017]. We also performed the large-scale stress chain analysis. One of the interesting findings was that the simulation of the horizontal shortening of the granular layer showed undulated margins similar to those observed in accretionary prism, despite the nearly uniform initial conditions. The 3D stress chain analysis that is practically infeasible for the laboratory experiment studies, revealed that arcuate faults emerge from micro-scale perturbations owing to the formation of the stress arch [Furuichi et.al. 2018]. Furthermore, analyses demonstrate that the in-situ stress orientation from borehole data can be a signal of either the regional direction of plate convergence or the local stress orientation associated with such a stress arch. The results may greatly enhance the outcome of long-term monitoring in areas, such as the Nankai Trough. In this contribution, we also investigated the stress state associated with a seamount (indenter) entering the accretionary prisms. The role of indenter was significant as a frictional heterogeneity to control the tomography (taper angle), material transport and stress chain distribution. Especially, amount of sediment covering the indenter was transported inward without deformation. This mechanism potentially constructs the thick low-velocity zone into the plate boundary, the subduction channel. In this presentation, we discuss the detail mechanism of these observed compressional events inside the sand layers.

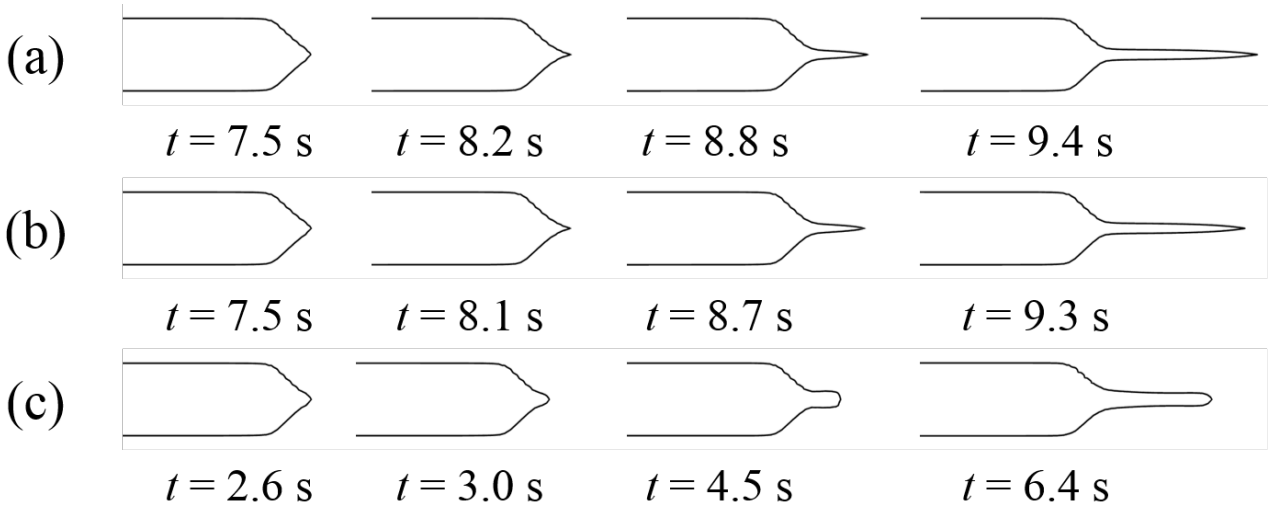
Numerical analysis on the fracture of Maxwell fluid by phase field models

*Masaharu Kameda[1], Keita Yamanishi[1], Akinori Yamanaka[1], Mie Ichihara[2]

1. Department of Mechanical Systems Engineering, Tokyo University of Agriculture and Technology, 2. Earthquake Research Institute, The University of Tokyo

Brittle fragmentation of vesicular magma is a key process in explosive eruption. Recent estimation on the decompression time in real explosive events indicates that the style of fragmentation is to be “brittle-like fragmentation” (Kameda et al. JVGR 2013). The solid-like fracture of the material occurs even if the bulk rheological properties is close to fluid state. We also found the fact that the spatial inhomogeneity of bubble distribution is a major source of crack development that lead to brittle-like fragmentation (Kameda et al. Sci. Rep. 2017).



In order to model our findings by numerical approach, we propose a continuum description of fracture in viscoelastic fluid using the phase field fracture model developed by Kuhn et al. (Comput. Mat. Sci. 2015). The phase-field modes with sharp interfaces consist in incorporating a continuous field variable so-called “order parameter,” by which the magma and the bubbles (or the cracks) are distinguished. The evolution of fracture is obtained implicitly by solving the coupled mathematical models formed by the phase field fracture model and the dynamics of the material. A commercial multiphysics solver (COMSOL) is used as the platform of numerical simulation. The phase field fracture model is solved using PDE solver of COMSOL. The dynamics of the material is calculated using conventional finite element analysis (FEM) prepared in the solver, in which the rheology of unbroken magma is assumed to be a linear Maxwell fluid.

First, we simulated crack propagation in a two-dimensional notched plate in a tensile test at a constant extension rate. We obtained the extension of crack with a sharp tip in pure elastic body (Fig. 1(a)) or viscoelastic body with sufficiently high viscosity (Fig. 1(b)). On the contrary, in the viscoelastic liquid with moderate viscosity the blunted tip occurs after the crack extension starts (Fig. 1(c)). Subsequently, the crack propagates again due to further extension.

Second, we simulated crack initiation and propagation in a porous material, which is a sphere including a large bubble at the center. Additionally, we placed two satellite bubbles nearby the large bubble. The pressure at the outer surface of the material was reduced to generate the non-uniform stress field in the material. As a result, the plane crack was generated between the satellite bubbles. The crack reached outer boundary, then a sharp crack was opened. The computed time scale in the crack propagation was equivalent to the scale observed in the experiment (Kameda et al. Sci. Rep. 2017). This time scale is much smaller than the scale simulated with another phase field fracture model proposed by Karma et al. (Phys. Rev. Lett. 2001).

Diagenesis- and earthquake-driven transformations of carbonaceous materials and their implication for frictional strength and earthquake rupture dynamics in carbon-bearing plate-subduction faults

*Shunya Kaneki[1], Tetsuro Hirono[1]

1. Graduate School of Science, Osaka University

Various physicochemical reactions on fault-forming materials, such as illitization of smectite and crystallization of amorphous silica, have been suggested as possible controls on frictional strength of rocks and thus on earthquake dynamics in plate-subduction zones. Carbonaceous material is one of the universal materials that exist in and around both active plate-boundary and inland faults, and previous studies suggest that transformation of carbonaceous material may affect its frictional strength during frictional slip. However, there is currently no systematic study attempting to investigate the relationship of maturity of carbonaceous material to its frictional strength, and thus how diagenesis- and earthquake-driven transformations of carbonaceous material can affect frictional strength and rupture dynamics of carbon-bearing faults, still remains unknown. We conducted high-velocity friction experiments together with elemental analysis, transmission electron microscope observation, X-ray diffraction analysis, and infrared and Raman spectroscopies, on four grades of carbonaceous material in the form of lignite, bituminous coal, anthracite, and graphite. Our experimental results clearly show that an increase in maturity and crystallinity of carbonaceous material results in a decrease in the peak friction coefficient at the initial stage of slip, from 0.5 (lignite) to 0.2 (graphite). We also infer from our results of spectroscopic analyses that low- (lignite and bituminous coal) and intermediate-grade carbonaceous material (anthracite) increases its maturity by high-velocity frictional slip, but friction applied to high-grade carbonaceous material (graphite) induces an opposite trend. Furthermore, by considering systematic decrease and increase in fracture energy and stress ratio with increasing maturity of carbonaceous material, both of which strongly affect rupture propagation process during earthquake, both diagenesis- and earthquake-driven transformations of carbonaceous material can strongly affect the frictional strength of carbon-bearing faults, potentially affecting the depth-dependences of not only frictional strength but also rupture dynamics on plate-subduction faults.

Viscous behavior of chert during frictional melting

*Ginta Motohashi[1], Kiyokazu Oohashi[2], Kohtaro Ujiie[1]

1. University of Tsukuba, 2. Yamaguchi University

Pelagic chert is one of the major lithology in accretionary complexes. Thus, frictional properties of chert at seismic slip rates are important for understanding of earthquake faulting in subduction zones. Here, we conducted high-velocity friction experiments on chert collected from the Jurassic accretionary complex in central Japan at a slip rate of 1.3 m/s and normal stresses of 5–13 MPa under room humidity conditions. The results show that initial slip weakening was followed by slip strengthening and subsequent second slip weakening toward a steady-state shear strength. Slip strengthening resulted from the formation of a silica-rich melt layer (experimentally generated pseudotachylyte) at lower melting temperatures than expected. The chemical composition of the pseudotachylyte matrix suggests the frictional melting of quartz with a small amount of illite, which may contribute to reduce melting temperatures. The second slip weakening occurred despite an increasing shear strain rate because of the thinning of the melt layer, implying that the viscosity of the melt layer decreased with slip. The estimated temperatures before and after the second slip weakening and microstructural and chemical features of experimentally generated pseudotachylytes suggest that the viscosity decrease during the second slip weakening is not due to a change in the chemical composition of melt layer, but rather a temperature increase in the melt layer.

Effect of friction and comminution on the optically-stimulated luminescence of quartz grains

*Kiyokazu Oohashi[1], Koji Akasegawa[2], Yuki Minomo[1], Noriko Hasebe[3], Kazumasa Miura[4]

Optically-stimulated luminescence(OSL) dating is considered to be applicable for fault dating owing to its instability even for short-time heating such as frictional heating. However, fault zone material may experience not only heat but also friction and comminution with coseismic faulting. If the OSL signal becomes small or disappear due to friction and comminution that is also accompanied by stable sliding (fault creep), OSL signal zeroing in natural fault zone can not be simply attributed to earthquake event. Here we report an increment of OSL signal of quartz during a low- to intermediate-velocity frictional sliding. The increments of OSL signal intensities were found from finely ground recovered sample (<75 μm). We also recognized an increment of fast to medium component of OSL with increasing sliding velocity. These results can be explained by (1) trapping of electron on newly-formed mineral surface, (2) rate-dependent emission of electron, such as triboemission, at asperity contact.

Frictional behaviors of smectite clay: constraints for the mobility of slow-moving landslides in the cold season

*Tatsuya Shibasaki[1], Sumio Matsuura[2]

1. Japan Conservation Engineers and Co., Ltd, 2. DPRI, Kyoto University

In Japan, reactivated landslides are distributed on gentle clayey slopes in specific geological settings, such as Neogene soft sedimentary rock areas and hydrothermally altered rock areas around active and inactive volcanoes. These strata are typically composed of smectite-bearing high-plasticity soils. Of all the clay minerals, smectite shows an extremely low residual friction angle. Therefore, landslides consisting of these soils can easily become unstable and be reactivated on very gentle slopes. In many cases, such landslides are likely to be reactivated during certain seasons every year, moving slowly with typical velocities ranging from 0.01 to 0.1 mm/min. According to behavioral data of landslides in the Niigata Prefecture, a well-known landslide-prone area in Japan, some landslides begin to move during the early cold season (late autumn or early winter). Some landslides are activated during the winter, and display continuous movement, while others are activated predominantly during the snow-melting period. These various behaviors cannot be explained solely by fluctuations in pore-water pressure (ground water levels), and this therefore raises the question of what the key controlling mechanisms are. Shallow landslides, less than 10 m deep, are sometimes activated in the early cold season. We inferred that the change in ground temperature may play a key role in activating landslides. In order to verify this, we investigated the effect of temperature on residual shear strength of various clayey soils. Reversal box shear experiments and ring shear experiments were performed on undisturbed slip-surface soils and reconstituted soil samples, respectively. The test results revealed that the shear strength of smectite-rich soils decreases with decreasing temperatures under slow shearing rates of lower than 0.1 mm/min. This finding implies that seasonal fluctuation in ground temperature can influence slope instability, especially for shallow, slow-moving landslides. It is also evident that the effect of temperature on residual strength changes with the shearing rate. We infer that the velocity-dependent characteristic is strongly regulated by the fabric of smectite particles along the shearing plane.

Strength of a deep fault zone along the Median Tectonic Line: Influence of chrolite friction

*Ichiko Shimizu[1], Ayumi S. Okamoto, Andre R. Niemeijer[2], Christopher J. Spiers[2], Shun Arai[3], Toru Takeshita[4]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, 2. Faculty of Geosciences, Utrecht University, 3. Tohoku University, 4. Hokkaido University

To explore the fault strength at the middle crustal levels, we conducted high-pressure hydrothermal experiments using natural fault rocks exposed along the Median Tectonic Line (MTL), focusing on the role of chlorite in fault weakening. Chlorite is a hydrous mineral commonly observed in basic metamorphic rocks and fault zones, and is known to have low friction coefficients around 0.3–0.4 at room temperature water saturated conditions (Behnsen and Faulkner, 2012), and about 0.3 at hydrothermal conditions (Okamoto et al., *in review*).

The experiments were performed on powdered samples of cataclasite and protomylonite, which are originated from tonalite or basic rocks in the Ryoke belt on the northern side of MTL. Cataclasites contain ~30 wt.% mica and clay minerals. Among them, chlorite-rich cataclasite (Chl-cataclasite) contains ~14 wt.% chlorite, and mica-rich cataclasite (Ms-cataclasite) contains ~14 wt.% white mica. Chlorite geothermometer (Bourdelle *et al*., 2013, CMP) yields a bimodal distribution (230–240˚C and 290–340˚C) for the protomylonite sample. The low-temperature chlorite occurs as blobs with the diameter of ~1–2 mm, which contain lamella of white mica. These chlorite grains are considered as pseudomorphs of biotite. The high-temperature chlorite filled fractures and interstice of grains. We therefore interpreted that brittle deformation first occurred at a temperature around 300˚C and subsequent hydrothermal alteration occurred at 230–240˚C. Chl-cataclasite also shows a bimodal temperature distribution (180–220˚C and 240–300˚C), although no clear relationships between temperatures and microstructures were found.

To simulate the deformation conditions at depth, friction experiments were conducted at temperature of 300˚C, normal stress of 300 MPa, and pore fluid pressures of 120 MPa and 240 MPa, using the hydrothermal ring shear apparatus at Utrecht University. Sliding velocities were varied from 0.001 mm/s to 0.1 mm/s. The steady-state friction coefficients obtained for protomylonite were ~0.68, whereas those for Ms- and Chl-cataclasites were ~0.65 and ~0.56 at 120 MPa, and ~0.87 and ~0.66 at 240 MPa, respectively. Velocity stepping tests yielded velocity-weakening or neutral behaviours, although existing laboratory data for pure chlorite gouges mostly show velocity-strengthening behaviours. Our results indicate that fault strengths and sliding behaviours in the middle crusts are not drastically changed by the presence of phyllosilicates even if chlorite contents in fault zones are relatively high (<14 wt.%).

Changes in seismic wave velocity during brittle deformation of gabbro and peridotite

*Yuya Akamatsu[1], Ikuo Katayama[1]

1. Hiroshima University

The Moho is defined as a discontinuity of seismic wave velocity and often interpreted to be the crust-mantle boundary. The oceanic crust is continuously created by magma system at the mid ocean ridge; consequently, the discontinuity of seismic wave velocity and/or sharp seismic reflection at the Moho is expected to be laterally uniform. However, recent seismic observations reported regional variations of the Moho reflectivity (e.g., Mutter and Carton, 2013; Ohira et al., 2018). As seismic wave velocity is greatly influenced by nucleation and growth of microcracks, such seismic anomaly at the Moho can be influenced by microcracks. We found that minor amounts of dilatancy in peridotite relative to mafic rocks based on strain measurements during triaxial deformation tests using these rocks (Akamatsu et al., 2019). This contrasting dilatant behaviors possibly lead to different evolution of seismic wave velocity between crust and mantle, and potentially cause the regional seismic anomaly in the oceanic plate. In this study, we measured elastic wave velocities of gabbro and peridotite during triaxial deformation experiments, and discussed how brittle deformation influences on the seismic velocity and reflectivity.

We used gabbro collected from the Oman ophiolite, and peridotite collected from the Horoman Complex. Triaxial deformation experiments were performed with intra-vessel deformation and fluid flow apparatus at room temperature, a constant strain rate of ~10^{-6} s^{-1}, and a constant confining pressure of 20 MPa. Compressional and shear waves traveling in a direction normal to the loading axis were measured during deformation, where shear waves were polarized normal and parallel to the loading axis. Seismic wave velocities were determined by a pulse transmission method, in which travel times of seismic waves through the sample were measured.

In gabbros, both Vp and Vs markedly decreased (Vp: ~40%, Vs: ~30%) as the samples approache failure. Crack density inverted from the velocities showed anisotropic crack orientation, where microcracks parallel to the loading axis (axial microcracks) were dominantly created. These results correspond to strain data and microstructural observation of recovered samples after deformation (Akamatsu et al., 2019). On the other hand, in peridotites, a small decrease in Vp and Vs (<20%) were observed up to the maximum stress, and inverted crack density showed no significant increase in axial microcracks. This indicates that microcracks developed in peridotites were mainly “mode II” shear microcracks, corresponding to strain data and microstructural observation. These contrasting evolutions of seismic wave velocity and crack density between gabbro and peridotite during brittle deformation can modify the seismic discontinuity and reflectivity at the Moho, and contribute to the variation of the Moho in the oceanic plate.

Dislocation textures in shock-compressed MgO and their formation mechanisms

*Kiyoshi Fujino[1], Xun Liu[2], Tsutomu Mashimo[2]

1. Geodynamics Research Center, Ehime University, 2. Institute of Pulsed Power Science, Kumamoto University

Deformation phenomena under high-pressure in Earth and planetary science occur under the shock compression as well as under the static or quasi-static compression. However, the studies on dislocation textures of materials under the shock compression are very limited, compared to those under the static or quasi-static compression. To fill such gap, the shock compression experiments on MgO were carried out and the dislocation textures of the recovered samples were examined under TEM to consider the formation mechanisms of those dislocation textures.

The shock compression experiments of single-crystal MgO were performed with a powder gun at the Institute of Pulsed Power Science, Kumamoto Univ. The shock compression experiments were done along the <100> and <110> directions. The recovered MgO samples were examined under 200 kV TEM at the Geodynamics Research Center, Ehime University.

In the previous studies, the Burgers vector of MgO is always $(\boldsymbol{a}_1 + \boldsymbol{a}_2)/2$ and the slip planes are mostly {110} and {100}. The present TEM examination showed that the sample under the <100> compression has dislocations of only the {110} slip plane, while under the <110> compression the sample has dislocations of only the {110} slip plane at low pressure but has dislocations of both {110} and {100} slip planes at higher pressure, indicating that the slip plane changes from {110} to {100} with increasing pressure. In addition to these results the dislocation textures which are usually not observed in the static or quasi-static compression, were also observed. In the presentation, the formation mechanisms of the observed dislocation textures are also discussed.

Development of rotational diamond anvil cell and large strain deformation experiments of lower-mantle materials

*Shintaro Azuma[1,2], Ryuichi Nomura[3,4], Kentaro Uesugi[5], Yu Nishihara[4], Doi Shunta[4], Takeshi Arimoto[4], Tetsuo Irifune[4]

1. Tokyo Tech., 2. Kyushu Univ., 3. Kyoto Univ., 4. Ehime Univ., 5. Japan Synchrotron Radiation Research Institute (JASRI)

The rheological properties of lower-mantle materials are key to understanding the dynamics and evolution in the Earth’ s interior. However, the pressure range of deformation apparatuses which can achieve large strain is limited to ~30–40 GPa due to a technical reason. We developed the rotational diamond anvil cell (rDAC) which can conduct deformation experiments with large strain under ultra-high pressure conditions, corresponding to those of core-mantle boundary [Nomura et al., 2017]. The rDAC can apply the torsional deformation to sample with constant strain rate by a gearbox and diamond anvils with grooves [Azuma et al., 2018]. However, the stress measurement and high temperature conditions has not been achieved in rDAC. To solve these problems, the vacuum chamber newly designed for rDAC was installed and the stress measurements using X-ray Diffraction (XRD) were applied to deformation experiments in rDAC at SPring-8 (Japan). In this presentation, we will present the preliminary results of stress measurements, high temperature techniques in rDAC, and the results of deformation experiments of lower-mantle materials.

In this study, the mixture of bridgmanite $(Mg,Fe)SiO_3$ and ferropericlase (Mg,Fe)O, which was synthesized from San Carlos olivine, was deformed under torsion geometry using the rDAC. The experimental conditions are ranging 26–130 GPa, 300–673 K. Starting material was grooved by FIB and the groove was deposited by Pt as a strain-marker. Recovered samples were cut by FIB to observe the deformation microstructures in each cross-section. Deformation experiments were conducted at BL47XU, SPring-8 (Japan) and 3D visualization of strain marker within samples was performed every rotation angle of upper anvil of 5–30 degree using X-ray laminography technique [Nomura and Uesugi, 2016]. Stress was measured by collecting X-ray diffraction pattern at twelve different azimuthal angles, Ψ= 0º, ±30º, ±60º, ± 90º, ±120º, ±150º, and 180º. Testing of the new vacuum chamber was also performed at SPring-8. The vacuum chamber has a removable Kapton window for incident and diffracted X-ray, and can keep the vacuum state (<~10 Pa) to prevent the diamond anvils from oxidation during high-temperature deformation experiments. Platinum wires were used as a resistance heater surrounding the sample and Rhenium gasket.

The geometry of strain-marker in cross-section of deformed samples show nearly simple shear (or general shear). Deformed microstructure of recovered samples was observed using FE-SEM and we determined the 2D surface area of ferropericlase and aspect ratio of bridgmanite. The deformation microstructures of the recovered samples showed that ferropericlase highly deformed and formed an interconnected weak layer. On the other hand, the aspect ratio of bridgmanite did not change with the strain, indicating that bridgmanite has high viscosity compared with ferropericlase. These results imply that ferropericlase dominates the deformation in the regions where large shear strain occurs under relatively low-temperature conditions in the lower mantle (e.g., mantle portion in subducted slabs).

Stress in bridgmanite was estimated by using diffraction peaks (110) and (112) at P = 50 GPa and T= 673 K. Shear stress in bridgmanite was relatively constant values, whereas uniaxial stress changed during

deformation experiments. This preliminary experiment was performed under low-temperature and high-pressure conditions, thus the equivalent stress in bridgmanite was about three times higher than that in previous studies [Girard et al., 2016].

In heating experiments using new vacuum chamber, temperature was monitored by Pt/Rh thermocouple placed close to the sample and and we succeeded in increasing temperature up to ~1000 K. However, the resistance heater (Pt) was unstable in vacuum. In the future, high-temperature deformation experiments using rDAC will be conducted in reducing atmosphere produced by inactive gas or internal heating system should be developed for rDAC.

Rheology of hcp-iron

*Yu Nishihara[1], Doi Shunta[1], Noriyoshi Tsujino[2], Daisuke Yamazaki[2], Yuji Higo[3]

1. Geodynamics Research Center, Ehime University, 2. Institute of Planetary Materials, Okayama University, 3. Japan Synchrotron Radiation Research Institute

Seismic observations have revealed presence of axi-symmetric anisotropy with respect to polar direction in the Earth’ s inner core which consists of solid metal, where a P- wave propagating along the polar direction is ~3% faster than that along the equatorial direction. Although many hypotheses have been proposed for origin of seismic anisotropy in the inner core, there is no general consensus for its origin. Lasbleis and Deguen (2015) discussed that dominant mechanism of the inner core dynamics depends on the inner core age and viscosity, and there are several candidate mechanisms which includes anisotropic growth model (Yoshida et al., 1996) and thermal convection model (Jeanloz and Wenk, 1988). Since the inner core is considered to consist of hexagonal close-packed iron(hcp-iron), information of viscosity of hcp-iron is a key for the understanding of the inner core dynamics. In this study, we have studied rheology of hcp-iron based on high-pressure and high-temperature deformation experiments.
Uniaxial deformation experiments were carried out using a D111-type apparatus installed on a beamline NE7A at PF-AR, KEK and a deformation-DIA apparatus installed on a beamline BL04B1 at SPring-8. Using polycrystalline bcc-iron as a starting material, deformation experiments were carried out at pressure of 16.9-22.6 GPa, temperature of 423-873 K, and strain rate of $0.2–5.2\times10^{-5}$ s^{-1}. Stress and strain during deformation were determined based on two-dimensional X-ray diffraction and X-radiography, respectively, using monochromatized synchrotron X-ray with energy of 60 keV.
A preliminary analysis of the observed data suggests that power-law dislocation creep with stress exponent of ~5 is dominant at >700 K whereas power-law breakdown occurs at lower temperatures. Extrapolation of the data based on homologous temperature scaling suggests that viscosity of hcp-iron at the inner core conditions is ~10^{21} Pa s or higher.

[S-CG61] Dynamics in mobile belts

convener:Yukitoshi Fukahata(Disaster Prevention Research Institute, Kyoto University), Toru Takeshita(Department of Natural History Sciences, Graduate School of Science, Hokkaido University), Hikaru Iwamori(Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology), Chairperson:Keisuke Yoshida(東北大学大学院理学研究科 地球物理学専攻), Masaoki Uno(東北大学)

The dynamic behaviours of mobile belts are expressed across a wide range of time scales, from the seismic and volcanic events that impact society during our lifetimes, to orogeny and the formation of large-scale fault systems which can take place over millions of years. Deformation occurs on length scales from microscopic fracture and flow to macroscopic deformation to plate-scale tectonics. To gain a physical understanding of the dynamics of mobile belts, we must determine the relationships between deformation and the driving stresses due to plate motion and other causes, which are connected through the rheological properties of the materials. To understand the full physical system, an integration of geophysics, geomorphology, and geology is necessary, as is the integration of observational, theoretical and experimental approaches. In addition, because rheological properties are greatly affected by fluids in the crust and fluid chemical reactions, petrological and geochemical approaches are also important. After the 2011 great Tohoku-oki earthquake, large-scale changes in seismic activity and regional scale crustal deformation were observed, making present-day Japan a unique natural laboratory for the study of the dynamics of mobile belts. This session welcomes presentations from different disciplines, such as seismology, geodesy, tectonic geomorphology, structural geology, petrology, and hydrology, as well as interdisciplinary studies, that relate to the dynamic behaviours of mobile belts.

Deciphering dynamics of thermal events at lithosphere-asthenosphere boundary from peridotite xenoliths of Ichinomegata maar, NE Japan

*Yuto Sato[1], Kazuhito Ozawa[1]

1. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo

Mantle xenoliths are fragments of mantle materials almost instantaneously transported to the surface by alkali basalt or kimberlite magmas (Nixon, 1987). They are unique in that they record temporal changes of mantle processes in chemical zonings and microstructures of constituent minerals. Thus, such information can potentially constrain time-dependent dynamic processes occurring in the lithosphere-asthenosphere boundary (LAB) zone, where mechanisms of heat and material transfer drastically change (Sleep, 2005, 2006). In this regard, Takahashi (1980) and Koyaguchi (1986) achieved key contributions. They examined chemical zonings of olivine and pyroxenes in spinel peridotite xenoliths from Ichinomegata, a latest Pleistocene andesitic-dacitic maar located in the back-arc side of NE Japan arc (Katsui et al., 1979). They clarified a variety of thermal history that the xenoliths underwent, but processes responsible for the diversity is not resolved yet because the derivation depth was not constrained. We have conducted very careful geothermobarometry of spinel peridotite xenoliths from Ichinomegata maar and successfully reconstructed the thermal, chemical, and rheological structures of the LAB zone beneath NE Japan arc at the time of Ichinomegata maar formation (80-60 ka) (Sato and Ozawa, 2017, 2018, JpGU meeting; Sato and Ozawa, 2016, 2017, AGU fall meeting; see our companion presentation in this meeting). We examined temporal changes of the structures through analyses of chemical zonings of pyroxenes in 9 plagioclase and spinel peridotite xenoliths from Ichinomegata.

In our previous study, the depths and temperatures of 8 of the 9 xenoliths just before the xenolith extraction are estimated to range 28-55 km and 828-1081 ˚C. The mantle beneath Ichinomegata consists of shallow (28-32 km), low temperature, granular (less strained), and amphibole-bearing zone and deep (41-55 km), high temperature, porphyroclastic (strained), and amphibole-free and melt-bearing zone. We identified the shallower zone as lithospheric mantle, the deeper zone as LAB zone, and that their boundary was controlled by wet solidus.

We obtained Ca, Al, Cr, and Ti zonings of large clinopyroxene and orthopyroxene using EPMA at the University of Tokyo and analyzed them with a diffusion model. The zoning patterns of Ca, Al, and Cr of pyroxenes allow us to identify 4 different thermal histories from 4 types of chemical zonings for orthopyroxene (O1-O4) and 3 types for clinopyroxene (C1-C3) as summarized in Table 1. They are (1) continuous cooling at a cooling rate of ~$1x10^{-4}$ ˚C/y over the time scale of ~1-10 million years from ~1000 to ~830 ˚C (constrained from O1 and C1), (2) cooling followed by weak heating at ~900 ˚C over the time scale of ~10-100 thousand years (from O2 and C1), (3) cooling followed by strong heating at ~1050 ˚C over the time scale of ~1-100 thousand years (from O3 and C2), and (4) prolonged cooling and heating at ~1000 ˚C (from O4 and C3). There is a systematic depth variation of thermal histories as summarized in Table 2. It is notable that the shallow lithospheric mantle is characterized by simple cooling or cooling followed by weak heating and the deep LAB zone by cooling followed by strong heating. This systematic depth variation requires a thermal perturbation of asthenospheric mantle beneath the deeper LAB zone, most plausibly asthenospheric upwelling.

The age of the Japan Sea opening is comparable to the time scale of cooling estimated from O1 and C1, and the continuous cooling at the shallow lithospheric mantle is attributable to the cooling of the

©2019. Japan Geoscience Union. All Right Reserved.

back-arc basin lithosphere, The timescale of the heating event in the deep LAB zone is too short to be explained by LAB-fixed heat conduction model. Effective heat transportation mechanisms are necessary, either partial crystallization of melt generated in the asthenosphere that passed through the LAB zone as advocated by Takahashi (1980) or extensive lithosphere thinning.

Experimental investigation of reaction-induced stress and permeability evolution in MgO–H_2O system

*Masaoki Uno[1], Hisamu Kasahara[1], Atsushi Okamoto[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies, Tohoku University

Crustal and mantle hydration reactions at subduction zones accompany large solid volume change as much as several vol.% to several tens of vol.%. Such large solid volume change can generate stress and fractures, accelerate reactions and fluid migrations (e.g., Kelemen and Hirth, 2012), and potentially influence the fluid transport in the crust and mantle (e.g., Jamtveit et al., 2000). Field observations of serpentinization and peridotite carbonation suggest fracture generation and permeability enhancement by such “reaction-induced stress” (e.g., Jamtveit et al., 2008; Plumer et al., 2012). However, the permeability enhancement during hydration reaction have not been reproduced by experiments, and the mechanisms and conditions of permeability enhancement by volume-increasing reactions remain largely unknown.

To understand the controlling mechanisms of fluid flow during hydration reactions, we show one of the first experimental trial to measure the permeability evolution during hydration reactions. We use MgO–H_2O system, where periclase (MgO) react with H_2O to produce brucite ($Mg(OH)_2$). The reaction involves solid volume increase of as much as +119%. Our earlier experiments have revealed that the reaction-induced stress in this system are controlled by the competition of reaction rate and stress-dependent deformation rate, and exceeds 40 MPa in this system which well exceeds the tensile strength of crustal rocks.

In this presentation, we have conducted flow thorough experiments to reveal the permeability evolution during hydration reactions. Experiments were conducted with sintered MgO with 4–14 vol.% porosity, under 100–300˚C with 5–50 MPa confining pressure and 5–15 fluid pressures. Preliminary experiments showed rapid permeability decrease in 2–3 orders, and finally the stainless sleeve broke by the reaction-induced expansion. The rate of permeability decrease is a function of the confining pressure, suggesting that the deformation of the reactant (brucite) has significant control over the permeability evolution during hydration reactions. We will present further experiments with various reaction rate/deformation rate ratios, and discuss the controlling factors of permeability enhancement/reduction during hydration reactions.

Fluid-Flow, Resistivity and Elastic Wave Velocity Simulation of Digital Rock Fracture and Comparison with Experimental Data

*Kazuki Sawayama[1], Fei Jiang[2], Takuya ISHIBASHI[3], Takeshi Tsuji[4], Yasuhiro Fujimitsu[4]

1. Department of Earth Resources Engineering, Graduate school of engineering, Kyushu University, 2. Department of Mechanical Engineering, Faculty of Engineering, Yamaguchi University, 3. Fukushima Renewable Energy Institute, National Institute of Advanced Industrial Science and Technology, 4. Department of Earth Resources Engineering, Faculty of engineering, Kyushu University

Fluid-flow in the fracture plays a key role to evaluate the mechanism of earthquake and fractured reservoirs (e.g., geothermal and shale) since fracture flow constrains the fluid-flow behavior and rock strength under the ground. To predict the fluid-flow and its distribution under the ground, geophysical explorations (seismic and electromagnetic methods) have been broadly applied. However, there is no established rock physical model to estimate the fluid-flow properties (e.g., permeability) in the fracture from resistivity or elastic wave velocity, and thereby fluid-flow behavior in the fracture are difficult to be precisely interpreted by geophysical explorations. For the better interpretation of these exploration data, more detailed investigation about the effect of fluid-flow behavior on resistivity and elastic wave velocity of fractured rocks is required. In this study, in order to discuss this effect, we measured and calculated them by using fractured rock samples which have different apertures.

We conducted laboratory fluid-flow testby using fractured Inada granite (50 mm in a diameter, 80 mm in a length) which have single tensile fracture with different aperture. For the numerical model, we digitalized this real rock fracture (0.1 mm grid resolution) to calculate fluid-flow, resistivity and elastic wave velocity under the same condition with experiment. Three dimensional fracture flow was simulated by using Lattice Boltzmann Method and we applied Finite Element Analysis to calculate resistivity and elastic wave velocity after this fluid-flow simulation.

As a result, permeability decreases with pressure increase under laboratory experiment and calculated permeability also shows the decrease as the aperture increases. This agreement suggests that fracture permeability is constrained by aperture closure due to the pressure effect. From the permeability matching approach, we found that permeability dramatically decreases after the fracture contact area exceeds ~80%. At this threshold value, fluid-flow path, resistivity and elastic wave velocity show inflections. Our results suggest that permeability change caused by aperture closure could be estimated by seismic and electromagnetic explorations.

Fluid distribution in the crust –inference from seismic velocity and electrical conductivity

*Tohru Watanabe[1], Kenta Yoshida[2]

1. Gradudate School of Science and Engineering, University of Toyama, 2. Research and Development Center for Ocean Drilling Science, Japan Agency for Marine-earth Science and Technology

Aqueous fluids must play important roles in crustal dynamics including seismicity. Geophysical mapping of fluids will thus give us insights into crustal dynamics. Electrical conductivity profiles have suggested that fluids exist pervasively in the crust. However, the fluid distribution has not been quantitatively constrained. It must be due to our poor understanding of pores that govern seismic velocity and electrical conductivity under high pressures.

In order to understand pores governing physical properties under pressures, simultaneous measurements of elastic wave velocities and electrical conductivity were conducted on a brine saturated granitic rock (Aji granite) under pressures up to 150 MPa and microstructure of pores was observed by X-ray micro CT and SEM with ion-milling and FIB. X-ray micro CT images show that many grain boundaries are open at atmospheric pressure. Elastic wave velocity increases and electrical conductivity decreases with increasing confining pressure. Most of grain bouundary cracks are closed under high pressures (>100 MPa). The electrical conductivity is, however, still much higher than that of the solid phase. The brine must be interconnected under high pressures. SEM images suggest that wide aperture parts in grain boundaries are open even at high pressures and form conduction paths.

There should be cracks with various sizes in the crust: from grain boundaries to large faults. Though cracks are closed under pressure, there must be a variation in the aperture. Wide aperture parts may form conduction paths even under high pressures. The influence of wide aperture parts on physical properties can be evaluated by tube model. Electrical conductivity is proportional to the fluid volume fraction. A change in conductivity by 4 orders of magnitude requires a change in fluid volume fraction by 4 orders of magnitude. However, seismic velocity for tube model is insenstive to fluid volume fraction. Seismic velocity will thus show relatively small decrease for a large change in fluid fraction. Observed large variation in conductivity and relatively small variation in seismic velocity (e.g., Ogawa et al., 2001; Matsubara et al., 2004) are consistent with tube model. The variation in fluid fraction must reflect that in the amount of wide aperture parts, which is attributed to the variation the amount of cracks.

The seismological structure about fault zone extending to the lower crust in the northern Kinki district, southwestern Japan

*Shinya Kato[1], Yoshihisa Iio[1], Takuo Shibutani[1], Hiroshi Katao[1], Masayo Sawada[1], Kazuhide Tomisaka[1]

1. Disater Prevention Research Institute, Kyoto University

The “water-weakened lower crust model” has been proposed to explain the mechanism of stress concentration on faults of inland earthquakes (Iio et al. 2002). According to this model, it is necessary that heterogeneous structure caused by the fluid exists locally in the deeper part of fault zones in the lower crust, but it has not been clearly confirmed in previous researches. This is because we do not resolve the heterogeneous structure due to fluid in the deeper part of fault zones in the lower crust. In order to solve this problem, in this study, we tried to image the heterogeneous structure in the lower crust in detail.

We conducted S-wave reflection analysis to detect the horizontal distribution of the heterogeneous structure (reflector), and receiver function analysis to estimate the structure beneath the reflector, in the northern Kinki district, southwestern Japan. As a result of the S-wave reflection analysis, it is found that the reflector exists on the north side of the Arima-Takatsuki fault zone and does not exist on the south side of it. We consider that the distribution of the reflector is related to the Arima-Takatsuki fault zone. From a result of the receiver function analysis, it is found that reflector is a thin layer with low S-wave velocity.

It is concluded that the thin layer with low S-wave velocity exists in the lower crust of the northern Kinki region. As the origin of it, it is possible to consider fluid dehydrated from the Philippine Sea slab subducting beneath the Arima-Takatsuki fault zone. In the vicinity of the Arima-Takatsuki fault zone, it is known that fluid that seems to originate in the mantle springs out (Kazahaya et al. (2014)). In the lower crust, pores between minerals exist independently (Yoshino et al. 2002), and fractures caused by faulting is thought to be necessary for fluid movement (Mibe et al. (2000)). Furthermore, since the spatial distribution of the reflector is related to the Arima-Takatsuki fault zone, we consider that the reflector in the lower crust indicates that fluid exists in fractures caused by faulting. This result supports the water-weakened lower crust model.

Inland repeating earthquakes in the vicinity of low frequency earthquakes around Hakodate, Hokkaido

*Keisuke Yoshida[1], Akira Hasegawa[1], Shinako Noguchi[2], Keiji Kasahara[2]

1. Tohoku University, 2. Association for the Development of Earthquake Prediction

Strength reduction due to pore pressure increase plays an important role for the generation of earthquakes. Earthquake swarms in central Tohoku activated after the 2011 Tohoku-Oki earthquake are examples of this; they are estimated to be caused by the upward fluid migration due to the decrease of WNW-ESE compressional stress after the earthquake (Yoshida & Hasegawa, 2018a and b). Inland deep low frequency earthquakes are also considered to be closely related to the fluids (e.g., Hasegawa & Yamamoto, 1994), but their detailed mechanism is poorly understood. In this presentation, we introduce our recent study on earthquakes occurring in Hakodate, Hokkdaido, which are covered by a dense seismic network installed by the Association for the Development of Earthquake Prediction (ADEP) (Noguchi et al., 2017). In this area many low frequency earthquakes are occurring, shallow ones of which occur in the immediate vicinity of ordinary earthquakes. This provides a unique opportunity to investigate the relationship between the diversity of fault motions and the fluid behavior.

We start by relocating hypocenters of ordinary earthquakes and low frequency earthquakes by applying the double-difference location method (Waldhauser & Ellsworth, 2002). We used precise differential arrival time data of P- and S-waves obtained by the waveform cross-correlation following Yoshida & Hasegawa (2018), which largely improved the accuracy of relative hypocenter locations. We relocated hypocenters of 198 earthquakes for the period from 2003 to Oct. 2018, which are listed in the JMA unified catalog or in the ADEP catalog; 22 of them are ordinary earthquakes and 176 are low frequency earthquakes. Relative locations of ordinary earthquakes are very precisely determined due to the similarity of waveform, but those of low frequency earthquakes are almost controlled by the manually picked arrival time data because of the diversity of their waveforms.

Relocated hypocenters show that low frequency earthquakes are distributed in a plate shape dipping eastward with focal depths from 5 to 35 km, which are confirmed by the S-P times obtained at the stations just above their epicenters. Low frequency earthquakes occurring in the shallow part of the crust are located in the immediate vicinity of ordinary earthquakes. We found that the initial parts of P- and S-waves of these low frequency earthquakes have similar waveform characteristics with those of the nearby ordinary earthquakes. Furthermore, ordinary earthquakes occurring near the low frequency earthquakes have very similar waveforms themselves. They turned out to be inland repeating earthquakes based on the hypocenter relocations using precise differential arrival times obtained by the waveform cross-correlation. Other repeating earthquake sequences were also found based on the template matching method (Shelly et al., 2013). Some earthquakes in one of those repeating earthquake sequences occur with a time interval of about ten minutes or so. Similar repeating earthquake occurrences with such a short time interval have been found in an induced seismicity of a recent fluid-injection experiment (Lengline et al., 2014), which suggests that natural repeating earthquakes are also caused by a similar mechanism to the fluid injection induced seismicity; slips are repeatedly caused in the same locations due to successive reduction in frictional strength by the pore pressure increase.

[S-CG61] Dynamics in mobile belts

convener:Yukitoshi Fukahata(Disaster Prevention Research Institute, Kyoto University), Toru Takeshita(Department of Natural History Sciences, Graduate School of Science, Hokkaido University), Hikaru Iwamori(Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology), Chairperson:Bunichiro Shibazaki, Daisuke Sato

The dynamic behaviours of mobile belts are expressed across a wide range of time scales, from the seismic and volcanic events that impact society during our lifetimes, to orogeny and the formation of large-scale fault systems which can take place over millions of years. Deformation occurs on length scales from microscopic fracture and flow to macroscopic deformation to plate-scale tectonics. To gain a physical understanding of the dynamics of mobile belts, we must determine the relationships between deformation and the driving stresses due to plate motion and other causes, which are connected through the rheological properties of the materials. To understand the full physical system, an integration of geophysics, geomorphology, and geology is necessary, as is the integration of observational, theoretical and experimental approaches. In addition, because rheological properties are greatly affected by fluids in the crust and fluid chemical reactions, petrological and geochemical approaches are also important. After the 2011 great Tohoku-oki earthquake, large-scale changes in seismic activity and regional scale crustal deformation were observed, making present-day Japan a unique natural laboratory for the study of the dynamics of mobile belts. This session welcomes presentations from different disciplines, such as seismology, geodesy, tectonic geomorphology, structural geology, petrology, and hydrology, as well as interdisciplinary studies, that relate to the dynamic behaviours of mobile belts.

Modeling strain concentration and mountain building processes in central Japan considering heterogeneous rheological structure

*Bunichiro Shibazaki[1]

1. International Institute of Seismology and Earthquake Engineering, Building Research Institute

Recent analysis of crustal deformation using GEONET data has revealed the existence of several strain concentration zones in the Niigata–Kobe Tectonic Zone (Sagiya, et al., 2000), in the Ou backbone range (Miura et al., 2004), in Kyushu, and San-in (Nishimura et al., 2018), etc. Many large inland earthquakes have occurred in the strain concentration zones. Elucidating the mechanism of strain concentration leads to understanding generation processes of large inland earthquakes. We develop a model of strain concentration and mountain building in the island-arc crust of central Japan, where several high mountain ranges have been formed by active crustal deformation. We use the finite element code with nonlinear viscoelasticity and plasticity based on Mohr-Coulomb criterion (e.g. Shibazaki et al., 2016). We consider gravitational force as a body force because the plasticity and the flow law depend on absolute stress.

Based on dense geothermal gradient data from Hi-net (Matsumoto et al., 2007) and the Geological Survey of Japan (Tanaka et al., 2004), we develop a thermal structure. We also consider a thick sedimentary layer where the friction coefficient is low based on the J-SHIS deep subsurface structure (NIED). Numerical results show that under the compressional tectonic setting, mountains are reproduced along high geothermal gradient regions. We can reproduce the Hida mountain range, Chikuma mountain, Echigo mountain range, and others, where a geothermal anomaly exists. Our model can also reproduce strain concentration in the Hida region. Furthermore, we can reproduce a strain concentration zone by setting the frictional coefficient to be low in the basement of the Niigata region.

However, the model cannot reproduce the strain concentration zone in the Atotsugawa and Kinki regions where strike slip faulting is dominant; therefore, we consider the boundary condition that yields the stress state of the strike-slip faulting and the effect of water distribution or rheology of partial melting based on seismic velocity anomalies (Nakajima and Hasegawa, 2007). We can reproduce strain concentration along the seismic velocity anomalies. Our results suggest that the Niigata-Kobe strain concentration zone is developed by several factors: thermal anomaly, pre-existing rift structure, and the presence of fluid and partial melting in the crust and the upper mantle.

Aso Volcanological Laboratory, Institute for Geothermal Sciences, Graduate School of Science, Kyoto University

An earthquake is a phenomenon that differential stress loading on the Earth’ s crust is released. Thus, we need to know state of stress in the crust to understand the earthquake generation mechanism. The state in the crust has been investigated in many studies, based on data of the focal mechanisms and seismic moment tensors (e.g., Michael 1984; Horiuchi et al. 1995; Terakawa & Matsu’ ura 2008). However, information on the stress fields in non-active seismic areas is insufficient because accurate stress estimation requires the data from a number of earthquakes. A key factor for acquiring knowledge of the stress field in an aseismic zone is the inelastic strain, which is related to the deviatoric stress based on the flow rule in plasticity theory (Matsumoto 2016). Thus, the strain rate due to inelastic deformation source needs to be separated from the total strain rate measured via geodetic observation. Here, we propose a new method for estimation of the deviatoric stress field through inelastic strain analysis that combines the seismic moment tensor and geodetic data. In this method, the deformation source of inelastic strain in the upper crust is estimated from short wavelength component of the observed total strain rate field, and the inelastic source tensor yields tensor shape of deviatoric stress field based on the flow rule. This method is applied to data for a region in and around the aseismic zone of Amakusa located at west part of Kyushu Island, Japan. It was found that the inelastic deformation in the seismic gap exhibits either normal-fault or strike-slip type. Furthermore, the deviatoric stress field estimated from the inelastic deformation has same trend as the surroundings. In addition, the estimated stress explained slip vectors of event rarely occurring there. These results might provide us with important information regarding the origin of the seismic gap and stress concentration on the surrounding fault.

Persistent and time-dependent crustal deformation in northern Fossa Magna and its tectonic implications

*Takeshi Sagiya[1], Koki Kumagai[2], Angela Meneses-Gutierrez[3], Nobuhisa Matsuta[4], Daisuke Hirouchi[5], Kenjiro Matsuhiro[2], Takashi OKUDA[2]

In the northern Fossa Magna of the northern Nagano Prefecture, GNSS observations over last two decades identified a rapid E-W contraction around the northern Itoigawa-Shizuoka Tectonic Line (ISTL) and the Western Nagano Basin Fault (WNBF). After the 2011 Tohoku-oki earthquake, postseismic deformation with a large E-W extension occurred throughout northeast Japan. However, the northern Nagano area has been still under contraction, implying that the local contraction is a persistent deformation feature. Similar persistent deformation was identified in the Niigata area by Meneses-Gutierrez and Sagiya (2016) and around other active faults in central Japan. These observations illustrate that there exists persistent localized deformation in the lower crust beneath active faults, driven by the regional stress field. This localized deformation in the lower crust is the driving force for faults in the upper crust. The persistent local crustal deformation around active faults suggests that the long-term inland deformation and resultant inland seismic activity are steady over a longer time scale than that of an earthquake cycle at subduction zones. On the other hand, after the 2014 Northern Nagano Earthquake (Mw6.3) along the northern ISTL, an acceleration of contraction along the WNBF was identified. This observation implies that the northern ISTL and WNBF are not independent but mechanically interact each other, forming an active deformation system that accommodates regional deformation. Such a complicated behavior of the fault system implies that the long-term activity of each fault in the system is not steady but time-dependent. Such a time-dependence may be a cause of irregular activity of inland faults and such a possibility should be considered for evaluation of seismic hazard.

Unexpected relationship between ΔCFF and the strain-rate paradox: separation of plastic strain from inelastic strain

*Yukitoshi Fukahata[1], Angela Meneses-Gutierrez[1], Takeshi Sagiya[2]

1. Disaster Prevention Research Institute, Kyoto University, 2. Disaster Mitigation Research Center, Nagoya University

In the field of seismic activity, the phenomena of stress shadow is well known, that is to say, the area with negative ΔCFF after an large earthquake tends to have fewer aftershocks (e.g., Toda et al. 2011, GRL). The concept of ΔCFF is also usful to understand earthquake activity for longer time scales as exemplified by Shikakura et al. (2014, JGR), which shows that large inland earthquakes that happened in western Japan recent 500 years can be very well exlpained by the change history of ΔCFF, which is mainly controled by the repeated occurrences of the Nankai earthquakes and secular increase of east-west compression.

Meneses-Gutierrez and Sagiya (2016, EPSL) have successfully separated the component of inelastic strain from the analysis of pre- and post-seismic GNSS data of the 2011 Tohoku-oki earthquake in the area around the Niigata prefecture. However, when we examine the observed GNSS data in detail, the separated inelastic strain rate is slightly but clearly faster before the Tohoku-oki earthquake. If the inelastic strain is due to viscous flow that depends only on the absolute stress, it is difficult to explain the observed GNSS data, because the stress change due to the 2011 Tohoku-oki earthquake in this area is less than 1 MPa, which is likely to be much smaller than the absolute stress.

Therefore, we consider that the concept of ΔCFF could be applicable not only to seismic activity but also to crustal deformation. In other words, we consider that the change of the inelastic strain rate is caused by plastic strain, which was active before the 2011 Tohoku-oki earthquake but ceased after the earthquake, because the stress level is dropped due to the occurrence of the 2011 Tohoku-oki earthquake, although inelastic strain due to viscous flow occurs essentially in the same manner before and after the 2011 Tohoku-oki earthquake.

If we accept this concept, the strain rate paradox of Japan is viewed differently, that is, the strain rate was exceptionally faster before the 2011 Tohoku-oki earthquake. It might also be possible to issue more effective warnings of large inland earthquakes in western Japan from detailed analyses of crustal deformation data.

Active period of inland earthquakes based on numerical simulation of megathrust earthquake cycle incorporating viscoelasticity

*Tsukasa MITOGAWA[1], Takuya NISHIMURA[2]

1. Graduate School of Science, Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University

In the subduction zone, megathrust earthquakes may modulate shallow crustal seismicity in the overriding plate. Historical documents demonstrate that large inland earthquakes frequently occurred for 50 years before and 10 years after megathrust earthquakes along the Nankai trough, southwest Japan. Previous studies suggest that inland earthquakes cannot occur until recovering the stress reduced by a megathrust earthquake on the fault. In this study, we modeled megathrust earthquake cycle in a simple oblique subduction zone and calculated temporal evolution of the Coulomb’ s Failure Stress changes (ΔCFS) on inland right-lateral strike-slip faults. And we examined the influence of megathrust earthquake cycle on the activity tune of inland earthquake.

Sources for loading inland faults are assumed to be interseismic locking and coseismic slip on the megathrust fault, stress changes due to inland earthquake and interaction between inland earthquake, and creep on a deeper extension of the inland faults. The stress change due to the megathrust fault was computed with numerical code by Fukahata and Matsu'ura (2006), assuming a medium composed of an elastic layer overlying a Maxwell viscoelastic half-space. We focus on ΔCFS depending on the distance from the megathrust fault, not its along-strike variation. In other words, only two-dimensional stress change at the center of a sufficiently long thrust fault plane (length 2000 km) is calculated. The megathrust fault is represented by a single rectangular fault whose depth, width, strike, dip, and rake are 11 km, 108 km, 270˚, 10˚, and 117˚, respectively. We assigned 6 m of coseismic slip at an interval of 100 years and 6 cm/year of back-slip during the interseismic period on the megathrust fault.The inland faults are located at 150 km (hereafter fault A) and 300 km (hereafter fault B) away from the upper edge of the megathrust fault and their depth, length, width, strike, dip, and rake are 4 km, 30 km, 6 km, 110˚, 90˚, and 180˚, respectively. Coseismic slip of 2 m was assigned when ΔCFS at the center of the inland faults exceeded 4.4 MPa.Becuase the code of Fukahata and Matsu'ura (2006) approximates a rectangular fault by numbers of point sources, a stress change on the fault plane can’ t be calculated. Therefore, we calculated a coseismic stress change on the fault plane assuming a semi-infinite elastic medium (Okada, 1992). In addition, stress loading by creep on a deeper extension of the inland faults was given to each inland fault at a constant rate.

ΔCFS on both inland faults is negative at the megathrust earthquake. When the stress loading rate is 5 kPa/year, the inland earthquake does not occur for 42 years on fault A and 15 years on fault B after the megathrust earthquake. Our interpretation is that viscoelastic effects of megathrust earthquakes makes these quiescence periods shorter and longer for faults A and B, respectively. Also, when the stress loading rate is 0.5 kPa/year, the quiescence period is 83 and 71 years for faults A and B. It is interesting that the quiescence period is not much dependent on the distance from the megathrust fault if the stress loading rate is small, though ΔCFS on both inland faults is highly dependent on the distance at the megathrust earthquake.

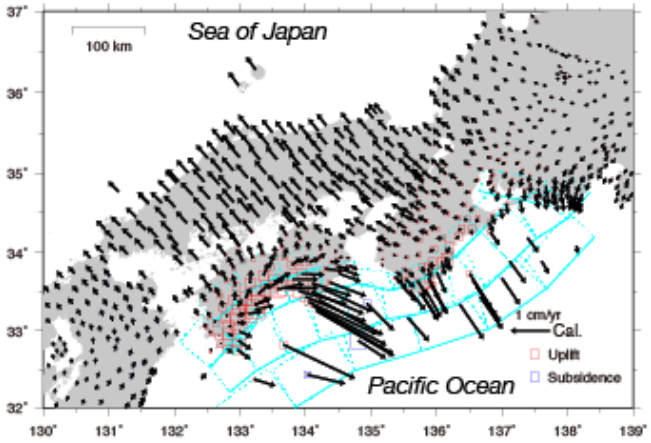
Influence of viscoelastic relaxation on estimated interplate coupling along the Nankai Trough, southwest Japan

*Takuya NISHIMURA[1], Fred F Pollitz[2]

1. Disaster Prevention Research Institute, Kyoto University, 2. U.S. Geological Survey

Viscoelastic relaxation in asthenosphere is an important factor for understanding crustal deformation in the subduction zone. Although interplate coupling on subduction interface has often been estimated from geodetic data using a purely elastic dislocation model, several recent studies (e.g., Li et al., 2015) pointed out that ignoring viscoelasticity in the medium made estimated coupling distribution biased. Pollitz and Evans (2017) developed viscoelastic block models introducing a viscoelastic correction term for earthquake cycles to estimate both interplate coupling and rigid rotation of microplates in western US. Once you subtracted the viscoelastic correction velocities from observed ones, the corrected velocities can be inverted by conventional elastic block models. The viscoelastic correction term consists of two components. One (hereafter, 1st component) is viscoelastic velocities due to interplate locking in the past, which is constant over the interseismic period. The other (hereafter, 2nd component) is total postseismic velocities of past earthquakes repeated with a certain recurrence interval, which is dependent on a time from the last earthquake. Here we examine these viscoelastic correction components for megathrust earthquake cycles along the Nankai trough.



We calculated viscoelastic deformation using VISCO1D (Pollitz, 1997) and assumed a 35 km thick elastic plate overriding a Maxwell viscoelastic half-space with a viscosity of 10^{19} Pa s. Coseismic fault model for the 1944 Tonankai and 1946 Nankai earthquakes estimated by Sagiya and Thatcher (1999) is used for viscoelastic calculation. A recurrence interval of megathrust earthquakes is 117 years and slip deficit accumulated for the interseismic period is completely released by the megathrust earthquakes. Figs. A-C show 1st and 2nd components as well as the sum of them as of 2007. 1st component represent a difference between elastic and viscoelastic responses of locking that has continued since the infinite past. It reaches 2 cm/yr along the Pacific coast and several mm/yr even along the coast of Sea of Japan (Fig. A). 2nd component is generally reverse to 1st component and decays with time from the last earthquake. Amplitude of 2nd component is roughly equal to that of 1st component 30 years after the last earthquake. Therefore, total viscoelastic correction is minimized 30 years after the last earthquakes during the interseismic period. Even after 61 years of the last earthquakes, velocities of 2nd component is still comparable to those of 1st component (Fig. B). Total correction velocities, therefore, exceed 2 mm/yr only near peninsulas along the Pacific Ocean (Fig. C). 2nd component reaches several mm/yr in the last years of the interseismic period for the Nankai subduction zone and cannot be ignored for better viscoelastic correction.

We present a result of applying viscoelastic correction to the block model of Nishimura et al.(2018) which models onshore GNSS and offshore GNSS-Acoustic velocities in southwest Japan.

Revisiting the Forearc Sliver Scenario Along the Southern Kurile Trench to Reconcile Interdisciplinary Observations

*Yuji ITOH[1], Kelin WANG[2], Takuya NISHIMURA[3]

1. Graduate School of Science, Kyoto University, 2. Pacific Geoscience Centre, Geological Survey of Canada, 3. Disaster Prevention Research Institute, Kyoto University

Forearc sliver has been proposed as a mechanism to accommodate margin-parallel component of oblique plate convergence along the southern Kurile trench. The sliver scenario was established based mostly on the presence of the margin-perpendicular Hidaka Mountain Range (HMR), graben at Bussol Strait, en echelon Kurile Islands and high temperature metamorphic and intrusive rocks exposed at HMR. Along the volcanic front, geological faults including Kamishi-Yubetsu tectonic zone with 50 km right-lateral displacement was reported. Seismic velocity tomography and refraction/reflection experiments beneath HMR show the heterogeneous crustal structure relating to collision of the Kurile forearc and Northeast Japan arc, indicating upwelling of upper mantle, sinking of crustal material and delamination of upper mantle beneath HMR, and shortening in the foreland of HMR. Anomalous deep crustal earthquakes beneath HMR such as the 1970 M6.7 Hidaka and 1982 M7.1 Urakawa-oki earthquakes show active margin-parallel compression. However, other observations cast doubt on the forearc sliver being presently active. Although some active faults are reported along the volcanic front, they are not right-lateral faults. Interseismic GNSS velocities do not show localized right-lateral shear deformation along the volcanic front, although they show active margin-normal shortening in the foreland of HMR consistent with active collision. In this study, we propose a new scenario of forearc kinematics and strain partitioning along the southern Kurile trench to reconcile these seemingly discordant observations.

A mountain like HMR pushes sideways because of gravity and acts as a buttress of the forearc sliver to impede its migration. We compared the stress field inferred from CMT solution with that predicted from a buttressed sliver model. The comparison suggests that (1) the forearc sliver is buttressed at HMR and (2) resistance to right-lateral shear along the volcanic front is very large. Therefore, we propose a scenario as follows. The forearc sliver had been increasingly buttressed as HMR rose, so that the rate of strain partitioning diminished with time. Eventually, the forearc migration became too slow to cause recurring large earthquakes and to maintain a mature active fault zone along the volcanic front. As a result, the fault zone healed with time. At present, the forearc and backarc deform together without active faulting and localized shear along the volcanic front.

We also compared Kurile with other oblique subduction zones and found that margin (trench) curvature appears to principal control forearc kinematics. At Cascadia and Nankai where the margin is concave seaward, interseismic GNSS velocities do not show discernable localized shear to define the forearc sliver but strong margin-parallel shortening towards the area of maximum margin curvature. In contrast, in southernmost Chile where the trench is approximately straight, there is little margin-parallel shortening but significant forearc sliver migration. However, at Kamchatka, although the margin is concave off-Kamchatka Peninsula, significant margin-parallel migration of Aleutian Islands is still occurring, which we speculate is due to the extreme obliquity of plate convergence here. Even in this case, significant shortening is observed at the leading edge of the forearc sliver. The concave margin has buttressed the forearc sliver and caused shortening in the area of maximum curvature in the geological time scale as well because the tectonic setting itself, such as the margin curvature and the obliquity of plate convergence, is the controlling factor of the forearc kinematics.

Segmentation of crustal deformation area within the Sanriku coast, northeast Japan, on the basis of spatial distribution of millennial-scale crustal movements

*Yuichi Niwa[1]

1. Faculty of Science and Engineering, Chuo University

Along the Sanriku coast, northeast Japan, discrepancies in crustal movement have been reported between uplift on a timescale of 10^5 years (Koike and Machida, 2001) and subsidence on a timescale of 10^1 –10^2 years (Kato, 1983; Ozawa et al., 2011). Some hypothetical models, which explain these discrepancies, are proposed in relation to megathrust earthquake cycle (e.g., Ikeda et al., 2012; Nishimura, 2014). These models assume that crustal movement style is same within whole part of the Sanriku coast, and show that amount of accumulation of uplift exceeds that of subsidence during one earthquake cycle. However, because of lack of age data of marine terrace except for Hachinohe to Kuji (Miyazaki and Ishimura, 2018) and of putative marine terrace along the southern part of the Sanriku coast (Koike and Machida, 2001), spatial distribution of crustal movement cannot be estimated on the basis of only feature of Pleistocene marine terrace. On the other hand, sedimentary successions in alluvial plains distributed along the Sanriku coast may offer records of millennial-scale crustal movements during the Holocene.

Recent sediment core analyses and radiocarbon dating shows sedimentary succession influenced by sea-level changes during the past 10,000 years. In the Rikuzen-takata plain, Kesennuma Okawa plain, and Onuma, on the southern Sanriku coast, a millennial-scale subsidence is inferred on the basis of height distribution of intertidal sediments which is lower than non-tectonic relative sea-level (Niwa et al., 2014, 2015; Ishimura and Miyauchi, 2017). Depositional environment estimated from a sediment core of the Tsuya plain, between Kesennuma plain and Onuma, also support a millennial-scale subsidence (Niwa et al., 2016). In the Tsugaruishi plain, on the central coast, height distribution of intertidal sediments and aggradation of delta sediments since ca. 7500 cal BP indicates subsidence on a millennial-scale (Niwa et al., 2017). On the other hand, sedimentary feature typical of subsidence area is not identified in sediment cores obtained from Omoto plain, northern Sanriku coast, suggesting no noticeable subsidence on a millennial-scale (Niwa et al., in press).

Inferred millennial-scale crustal movements shows subsidence trend on central to southern Sanriku coast and relatively uplifting trend on northern part of the coast. This spatial distribution of millennial-scale crustal movements is consistent with geodetically estimated subsidence rate on a timescale of 10^1 –10^2 years (Kato, 1983) and the amount of subsidence at 2011 Tohoku-oki earthquake (Ozawa et al., 2011), indicating that the Sanriku coast presents a variety of crustal movement styles. These results suggest that the northern and the central to southern parts of the Sanriku coast should be considered separately when assessing crustal deformation related to subduction.

Shear wave splitting east off NE Japan based on the S-net data

*Naoki Uchida[1], Junichi Nakajima[2], Ryota Takagi[1], Keisuke Yoshida[1], Takashi NAKAYAMA[1], Ryota Hino[1], Tomomi Okada[1], Youichi Asano[3], Sachiko Tanaka[3]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions Graduate School of Science, Tohoku University, 2. Department of Earth and Planetary Sciences, Graduate School of Science and Engineering, Tokyo Institute of Technology, Tokyo, 3. National Research Institute for Earth Science and Disaster Resilience

We estimated the anisotropy of seismic wave speed by using shear wave splitting data in the offshore area of NE Japan. The analysis was made possible by the deployment of the Seafloor Observation Network for Earthquakes and Tsunamis along the Japan Trench (S-net) by National Research Institute for Earth Science and Disaster Resilience (NIED). We used the waveforms of 421 interplate earthquakes from August 2016 to October 2018 which are selected based on the focal mechanisms of Full Range Seismograph Network of Japan (F-net) operated by NIED and located under the S-net stations (within 35 degree from the vertical). We determined the fast polarization directions and delay times between fast- and slow-shear waves by the cross-correlation method.

The results show that the shear wave splitting tends to have trench parallel fast polarization direction for the region east off Chiba to Hokkaido which is the same with the observations in the land area of the forearc. Since we used earthquakes on the plate boundary, the anisotropy must be located in mantle wedge or forearc crust. The interpretation of the polarization includes the flow-normal fast direction of B-type olivine fabric in the forearc mantle-wedge and cracks aligned in the trench parallel direction due to the present forearc stress-field or fossil structures developed during the formation of the forearc.

Acknowledgements: We used S-net data which is deployed and maintained by NIED.

Gravity anomaly due to active faults and crustal rheology in the northeastern Japan arc inferred by fault dislocation model

*Mitsuhiro Hirano[1], Hiroyuki Nagahama[1], Jun Muto[1]

1. tohoku university

Short-wavelength Bouguer gravity anomaly reflects crustal structures including effective elastic thickness distribution in the northeastern (NE) Japan arc [1-3]. Moreover, earthquake epicenters and active faults tend to be located in the region of the negative gravity anomaly or high gradient in the anomaly in the NE Japan arc [1-3]. Following the relationship between gravity anomaly and active fault distributions, Yamazaki and Nagahama [4] derive an equation of static gravity change by volumetric strain due to fault dislocation, and argue that active faults contribute to Bouguer gravity anomaly in the NE Japan arc. On the other hand, seismicity and active fault distribution tend to be located in the region with high gradient of thermal gradients or along the boundary between high and low seismic wave velocity [5-7]. Thermal gradient and seismic wave velocity reflect mechanical behaviors (viscosity and elasticity) and they are indices of crustal rheology. However, relationship between gravity anomaly and the influence of the inhomogeneity in crustal rheological structures including active fault distributions have been not unknown yet. In addition, although large positive gravity anomaly is expected along the Ou-backbone Range by its pop-up structure, negative or small positive gravity anomaly zone exists along the Ou-backbone Range. So, we study relationship between gravity anomaly and rheological properties in the NE Japan arc. First, we calculated gravity anomaly due to volumetric strain by fault dislocation model in a homogeneous elastic half space. In this case, considering compressive stress field that has continued since 3 Ma in the NE Japan arc, we give total fault displacements in the 3 million years to active faults. This model calculation generates negative gravity anomaly less than 15 mGal around active faults and these generally agree with some negative areas of short-wavelength Bouguer gravity anomaly (such as the Ou-backbone Range, Yamagata Basin and the Niigata Plain). Next, we compare short-wavelength Bouguer gravity anomaly with three available datasets in the NE Japan (thermal gradient, crustal strain rate and P-wave velocity) along the two transects created normal to the arc. This comparison reveals the correlation between negative peak in the gravity anomaly and the peaks of thermal gradient and contraction, and negative peak of P-wave velocity around the Ou-backbone Range. The comparisons suggest the relationship between gravity anomaly and crustal rheology, and that contraction along the Ou Backbone Range produces negative gravity anomaly. The result also explains the relationship between gravity anomaly and seismicity and active fault distributions since both of them distribute to transitional areas of crustal rheological structures. Hasegawa et al. [8] pointed out that reverse faults and large contraction along the Ou Backbone Range reflects the heterogeneity in rheological properties in the NE Japan arc. Therefore, those comparisons imply that reverse faults and anelastic contraction produce continuous negative gravity anomaly along the Ou-backbone Range. Finally, we propose that the gravity anomaly can be an index of the heterogeneity in crustal rheology.

On the temporal decay of the localized strain rate in the Tohoku region after the Tohoku-Oki earthquake

*Youichiro Takada[1], Tomomi Inamatsu[2]

1. Faculty of Science, Hokkaido University, 2. Dept. Natural History Sciences, Hokkaido University

The 2011 Tohoku-Oki earthquake (Mw9.0) provides us the first opportunity to examine the responses of strain concentration zones and active faults to megathrust earthquakes with dense permanent GNSS network. Along the Backbone range in the Tohoku region, strain rate localization has been found before and after the Tohoku-Oki earthquake (e.g., Miura et al., 2004; Takada and Inamatsu, 2018). In this study, we focused on the post-seismic strain rate localization along the Backbone range, and examined its driving mechanism with GNSS data and simple FEM simulation.
We used daily coordinates obtained at GEONET stations operated by GSI. We estimated surface velocity field before and after the earthquake by removing annual and semi-annual perturbations. For post-seismic period, we estimated the velocity field for every two years to use linear approximation. From the velocities thus obtained, we calculated the strain rates following the method of Shen et al (1996). Next, we approximated the long wavelength components, which reflects the afterslip and/or the viscoelastic relaxation of Asthenosphere following the Tohoku-Oki earthquake, by polynomial function for each component, and removed it to extract the short wavelength component. Then, we found patchy distribution of localized contraction (negative dilatation rate) areas along the Backbone range with these amplitudes rapidly decreasing with time.
To examine the mechanism of rapidly decreasing strain rate, we conducted a simple numerical simulation with a finite element software COMSOL Multiphysics. There are thermally active regions with many calderas along the Backbone range (e.g., Yoshida, 2001; Takada and Fukushima, 2013). On the other hand, the thermal activity of surrounding area is not very high. Considering these points, we set a rectangular elastic body and located several ellipsoids in north-south direction that consist of low viscosity Maxwell viscoelastic medium. Then we applied gravitational body force to all the model region, and supported it from a lateral boundary. In addition, we also applied a step-wise 1 MPa stress change which represents coseismic stress perturbation due to the Tohoku-Oki earthquake. From the calculated results, we removed the long wave-length component. Then, we successfully extracted the short wave-length dilatation rate around the viscoelastic ellipsoids. Just after the step-wise stress change, whole medium responded as an elastic body. Soon after that, viscous flow starts in the ellipsoids. As differential stress decreases with time in the ellipsoids due to viscous relaxation, the surrounding elastic region becomes important to support the differential stress. Thus, the localized strain rates can be large only during the viscous relaxation in the ellipsoid. After the completion of viscous relaxation, all the differential stress is supported solely by elastic region, and the localized strain rates vanish. Thus, three dimensional connectivity of low viscosity regions play an important role when considering crustal response to an externally applied stress change.

Revisiting the Coseismic Slip Distribution of the 2011 Tohoku-oki Earthquake Considering Early Postseismic Deformation, Non-linear Viscoelasticity, and Heterogeneous Structure

*Takeshi Iinuma[1], Ryoichiro Agata[1], Yusaku Ohta[2], Ryota Hino[2], Takane Hori[1]

1. Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 2. Graduate School of Science, Tohoku University

The 2011 Tohoku-oki earthquake produced large coseismic displacements that were detected by terrestrial and seafloor geodetic observations, namely, global navigation satellite systems (GNSS), GNSS-Acoustic (GNSS-A), and ocean bottom pressure (OBP) measurements. Previous studies constructed coseismic slip distribution models of the Tohoku-oki earthquake using the daily GNSS site coordinate time series, seafloor GNSS-A, and/or OBP data to estimate the coseismic displacements [e.g., Ito et al., 2011; Koketsu et al., 2011; Ozawa et al., 2011; Iinuma et al., 2012]. However, studies for these several years suggested that the coseismic displacements must include early postseismic deformation due to a low-viscosity zone beneath the Pacific plate that is necessary to explain terrestrial and seafloor postseismic crustal deformations [Sun et al., 2014; Freed et al., 2017; Suito, 2017]. This low-viscosity zone may not be persistent but could result in huge changes in stress resulting from the coseismic slip with reflecting non-linear rheology [Muto et al., 2018; Agata et al., 2019]. The effect of non-linear rheology is great immediately after a main shock. Therefore, coseismic displacements based on the daily site coordinate time series and GNSS-A measurements inevitably must include early postseismic deformation.

Thus, we derived “pure” coseismic displacements based on 1-Hz site coordinate time series at GNSS sites of the Geospatial Information Authority of Japan estimated by utilizing kinematic PPP (precise point positioning) analysis and based on 1-min average seafloor level time series at OBP sites. The residual displacements were obtained by subtracting the pure coseismic displacement from that based on the daily site coordinate time series. The data showed subsidence and trenchward motions in the entire Tohoku district. These broad deformations could not be explained solely by aftershocks nor by afterslip on the plate interface. Viscoelastic deformation that occurs immediately after the main shock is required to explain the displacement field. We present the results of our investigations into coseismic slip distribution and early postseismic deformation by applying Green’s function, which is calculated by considering the shapes of surface terrain and subducting slabs as well as heterogeneous thermal structures and power-law rheology.

Life on Earth is based on a diversity of physical and chemical dynamics and processes throughout the history of the Earth. It can essentially be regarded as the history of interrelation between Life, Water, Mineral (Solid Earth) and Atmosphere. To solve this kind of complex systems problems, interdisciplinary approach, a way of thinking and communication, is necessary. This session will be a cradle for such interdisciplinary researches.

The hydrothermal vent shrimp *Rimicaris* dominates the megafaunal community in many hydrothermal vent ecosystems in the globe, including Mid Atlantic Ridge, the Central Indian Ridge (CIR), and the Caribbean Mid-Cayman Rise. *Rimicaris* harbors numerous strains of episymbiotic bacteria in its gill chamber and depends on them for most of the nutrition as adults. Probably due to the metabolism of this symbiotic bacteria, the tissues in the gill chamber were found to be encrusted with brown or black iron precipitates. The precipitates are removed by molting, but in a few days after molting, *Rimicaris* will be covered with precipitates again. Although *Rimicaris* relies on episymbiotic bacteria nutritionally, it is thought that the precipitates originated from episymbiotic bacteria disturb their swimming activity, nutrient uptake by the host. Thus, the relationship between *Rimicaris* and its epibionts seems to be different from general mutualistic relationship. To understand this symbiotic relationship correctly, it is necessary to clarify the relationship among the host, episymbiotic bacteria, and the precipitates. In this study, iron chemical speciation analysis based on XAFS were performed to black and brown precipitates in the gill chamber of *Rimicaris kairei* in order to clarify the chemical environment in the gill chamber.
Specimens of *Rimicaris kairei* were collected during the YK16-E02 cruise at two hydrothermal vent site, Edmond and Kairei on the CIR. Each tissues were fixed in 99.5 % ethanol, and embedded in Epoxy resin(Epofix, Struers), and both sides polished thin section with a thickness of about 50 μm were obtained. Thin section was subjected to μ-XRF element analysis and Fe K-edge XANES analysis at KEK PF BL-4A to investigate the element distribution and the speciation of iron around the bacteria. Fitting was carried out using a software REX 2000 (Rigaku) using ferrihydrite, goethite, magnetite, $FePO_4$, pyrite, pyrrhotite as reference materials.
By observing the freeze-dried samples by scanning electron microscope (JSM-6100, JEOL) and thin section samples by polarized microscopy, it was observed that the brown precipitates forms crusts of about 50 μm in thickness and covers entirely the inside of the branchiostegite, where black precipitates occur as submicron size microparticles in organic filmy tissues around filamentous bacteria. From the XANES fitting, it was suggested that the brown precipitates contain ferrihydrite, goethite, $FePO_4$, while the black precipitates contain ferrihydrite, goethite, $FePO_4$, and pyrrhotite. It was revealed that iron exists as Fe^{3+} in the brown precipitate, but in the black precipitate, iron exist as a mixture of Fe^{2+} and Fe^{3+}. It is estimated that the brown precipitates were formed in the aerobic environment and the black precipitates were formed in the relatively anaerobic environment. Overall, our suggested that the gill chamber environment was diverse even among the same species. We will perform next-generation sequencing of microbes in the gill chamber, and we need to investigate in detail the precipitation conditions of each mineral and the environment in which the host can grow.

Experimental study on hydrogen generation during low temperature serpentinization by using natural samples

*Shunta Higashino[1], Ryohei Kawakita[1], Tsubasa Otake[2], Tsutomu Sato[2]

1. Graduate School of Engineering, Hokkaido University, 2. Faculty of Engineering, Hokkaido University

Low temperature serpentinization, a reaction between ultramafic rocks and water under ambient conditions, generates hydrogen near Earth’ s surface environments. This reaction has been considered to play important roles in the origin of life since hydrogen may have been an important reducing gas for building blocks of life as well as early metabolisms. Furthermore, this process may be applicable for industrial hydrogen production that does not emit carbon dioxide during its production or consumption whereas the conventional method for hydrogen production essentially relies on fossil fuels. During serpentinization, hydrogen is generated by the reduction of water accompanied with oxidation of ferrous ion to ferric ion in the primary minerals of ultramafic rocks such as olivine or pyroxene. However, the amount of hydrogen produced during low temperature serpentinization is controlled by various factors, which have not been well understood, particularly, the effect of the formation of secondary minerals (Mayhew et al., 2018). Therefore, we conducted a series of experiments for hydrogen production using 10 ultramafic rock samples (dunites and harzburgites), from Japan (Horoman and Wakamatsu), Oman and Indonesia, showing various lithological features and degrees of serpentinization subjected during obduction. Mineralogical and geochemical characterizations were conducted using XRD, XRF and SEM-EDS. Experiments were then conducted by reacting the samples with water under anaerobic conditions at 90℃, for 2 weeks. After the experiments, gas, solid, and solution obtained from the experiments were analyzed by GC-RGD, XRD, and ICP-AES, respectively.

The results of experiments show that samples with lower degrees of serpentinization tend to generate larger amounts of hydrogen, and that harzburgites tend to generate more hydrogen than dunite when they are at the same degree of serpentinization. However, some highly serpentinized samples also generated large amounts of hydrogen though these results werepooly reproduced. This may have stemmed from the oxidation of trace minerals (e.g., Ni-Fe alloy) or their catalytic effects, in addition to the dissolution of Fe^{2+}-bearing primary minerals, because these minerals were heterogeneously observed by microscopy in the serpentinites. Experiments were also conducted with some additives (e.g., MgO, SiO_2, and magnetite) to investigate the effect of solution chemistry and formation of secondary minerals on hydrogen generation. The results show that hydrogen was generated the most under Si-rich conditions. Solution chemistry suggests that, olivine and pyroxene were likely dissolved more rapidly with Si-rich solutions. This is consistent with the trend that harzburgites generate hydrogen more than dunite because harzburgite contains pyroxene, which dissolved much Si compared to olivine. Moreover, thermodynamic calculations suggest that the precipitation of amorphous Mg-silicate minerals (e.g., M-S-H), which are commonly precursors of serpentine controls the solution chemistry including decreasing pH. Because the dissolution rate of the primary minerals is greater at lower pH, the precipitation of Mg-silicate minerals may have promoted the dissolution cycle of the primary minerals and therefore generation of hydrogen, especially under Si-rich conditions.

Constraint on the origin of methane from Hakuba Happo serpentinite-hosted hot spring by using $^{14}CH_4$ and noble gas isotope

*Konomi Suda[1], Takahiro AZE[2], Yosuke Miyairi[2], Yusuke Yokoyama[2], Yohei Matsui[3,2], Hisahiro Ueda[3], Takuya Saito[3], Tomohiko Sato[4], Yusuke Sawaki[2], Ryosuke Nakai[1], Hideyuki Tamaki[1], Hiroshi A Takahashi[1], Noritoshi Morikawa[1]

1. National Institute of Advanced Industrial Science and Technology, 2. The University of Tokyo, 3. Japan Agency for Marine-Earth Science and Technology, 4. Tokyo Institute of Technology

Ultramafic rock-water interaction systems attract more interest from the perspective of study for origin of life since the discovery of the hyperalkaline hydrothermal system in the Atlantic Ocean in 2001 (Kelley et al., 2001). These serpentinite-hosted systems are generally characterized by high concentrations of methane (CH_4) and higher hydrocarbons (C^{2+}) regardless of seafloor or on-land (e.g., Schrenk et al., 2013; Etiope and Sherwood-Lollar, 2013). Previous stable carbon and hydrogen isotopic studies have suggested that hydrocarbons could be formed abiotically via polymerization process (Proskurowski et al., 2008; Suda et al., 2017). However, the following is still poorly constrained; when and where hydrocarbons are produced. In this study, to constrain the origin of methane, we determined the radiocarbon (^{14}C) content in CH_4 and the helium isotope obtained from serpentinite-hosted hot spring in Hakuba Happo.
Hakuba Happo hot spring lies on a serpentinized ultramafic rock body in the Shiroumadake area, which belongs to the Hida Marginal Tectonic Belt in central Japan. The hyperalkaline waters (pH>10), with temperatures of approximately 50˚C, are pumped from two borehole wells (Happo #1 and Happo #3). N_2, H_2 and CH_4 are main gas components (Homma and Tsukahara, 2008; Suda et al., 2014). Water chemistry and volatile component are controlled primarily by serpentinization reaction.
Sample collection was conducted in 2015-2018. Hot spring gas samples were collected by a displacement method in water from two borehole wells (Happo #1 and Happo #3). For radiocarbon (^{14}C) analysis of methane, firstly, CH_4 in gas samples was converted to CO_2 by using the custom-built flow-through vacuum line system (similar to Pack et al., 2015) at JAMSTEC. Secondly, the purified CO_2 gas was reduced to graphite by using the graphitization reactor with Fe powder and hydrogen gas, and then the ^{14}C content was determined by using an accelerator mass spectrometry (AMS) at AORI, the University of Tokyo. Noble gas isotope abundances were measured with a noble gas mass spectrometer at GSJ, AIST. The concentrations of CO and CO_2 in gas phase were determined by using a GC-methanizer-FID method, which was suitable for detection of trace amounts of CO and CO_2 (Kaminski et al., 2003). The concentration of dissolved inorganic carbon (DIC) in spring water was measured by using GasBench/IRMS system at GSJ, AIST.
In Hakuba Happo hot spring, CO and CO_2 were below detection limit (<0.0005 vol.%). DIC concentration was <28 μmol/L (upper values because of suspicion of air contamination during sampling), which was lower than dissolved methane concentration (124-664 μmol/L; Suda et al., 2014). Methane is the most abundant carbon compound in Hakuba Happo hot spring. If methane production occurs under on-site condition, the inorganic carbon compounds (CO, CO_2 and DIC) are not likely to be a carbon source for CH_4. The high helium isotope ratio ($^3He/^4He$) was observed in both well sites. The $^3He/^4He$ ratios for Happo #1 and Happo #3 were 4.10 R_{atm} and 4.47 R_{atm}, respectively (where R_{atm} is the atmospheric $^3He/^4He$ ratio of 1.4×10^{-6}). For Happo #1 site, relative contribution of air, mantle and crustal components are estimated to be 47%, 31% and 22%, respectively. For Happo #3 site, 69%, 24% and 8%, respectively. The result of AMS measurements on two CH_4 samples from Hakuba Happo reveals that ^{14}C contents are near the detectable limit, i.e., the ^{14}C ages of CH_4 is at least approximately 50,000 years before present. Radiocarbon evidence rules out a modern carbon compound (e.g., atmospheric CO_2, organics in surface

©2019. Japan Geoscience Union. All Right Reserved.

soil) as the carbon source of CH_4 at Hakuba Happo hot spring system. The helium isotope and $^{14}CH_4$ data could be consistent with deep-derived carbon source of the Hakuba Happo CH_4. Therefore, it will be important to consider a relation between surface reaction system and deep mantle/crustal system.

Inhibition of calcium silicate hydrate formation by lignosulfonate and lignin

*Kanako Toda[1], Tsubasa Otake[1], Tsutomu Sato[1]

1. Laboratory of Environmental Geology, Faculty of Engineering, Hokkaido University

Dams and harbors have frequently dredged in order to secure the water storage capacity and shipping routes. Dredged soils are mostly treated as waste, though utilization of dredged soils for construction resources are economically and environmentally desired. Only a part of the dredged soils has been used for construction materials after mixing with steel slags due to their low physical strength. Mixture's strength development has been known to depend on utilized dredged soil. However, even under the same mixing conditions, some combinations may not be hardened. Soil composition is generally complex as it reflects the result of mineral-water-organic matter-microbe interactions occurred onto components from diverse origin. In solidification of the dredged soils to form construction materials, alkaline activators, steels slags in this case, are added, which triggers the formation of secondary phases such as calcium silicate hydrate (C-S-H). Factors affecting C-S-H formation have been reported previously (e.g., Tremblay et al., 2002; Zhu et al., 2007; Toda et al., 2018). However, inhibition mechanism of authentic organic matter in the soils and the quantitative effects of their functional groups on C-S-H formation are not fully understood.

In this context, the effects of 1) lignosulfonate and 2) lignin that contain carboxylic, sulfonic and thiol functional groups that have similar structures to soil organic matter and 3) simple organic molecule with one of carboxylic, sulfonic and thiol functional groups on C-S-H formation were investigated in this study. C-S-H was synthesized from $Ca(OH)_2$ and amorphous silica in coexistence of multiple addition ratio of lignosulfonate and lignin to expecting amount of C-S-H formed, in 100 rpm shaker at 50℃ for 10 days. After the syntheses, C-S-H were characterized by X-ray diffraction and FT-IR analysis, and chemical composition of the remaining solutions were analyzed by ICP-AES and TOC analyzer. After syntheses, solution pH were all above 12. The threshold quantity of lignosulfonate and lignin was evaluated to suppress the formation of C-S-H. Above the threshold, XRD peaks assigned to $Ca(OH)_2$ and amorphous silica could still be obtained after synthesis, without C-S-H peaks. Furthermore, below the threshold, the broad diffraction peak assigned to (001) reflection of C-S-H decreased with increasing the added amount of lignosulfonate and lignin. This suggests that lignosulfonate and lignin may suppress the dissolution of initial phases but also C-S-H crystal growth. Both of the indicated inhibition factors could occur due to the surface coverage by negatively charged functional groups in the organic matter under alkaline condition, which may be interacting with positively charged sites such as $Ca(OH)_2$ surface and CaO layer in C-S-H. C-S-H synthesis with simple organic molecule with various functional groups were also conducted to further discuss how the difference in soil organic matter structure in terms of functional group can inhibit C-S-H formation.

Calcium carbonate formation processes on cyanobacterial surface

*Fumito Shiraishi[1], Takeru Omori[1], Naotaka Tomioka[2], Satoko Motai[2], Hiroki Suga[3], Yoshio Takahashi[3]

1. Hiroshima University, 2. JAMSTEC, 3. The University of Tokyo

Cyanobacteria is oxygenic phototroph known to calcify under optimum ambient water chemistry. Fossils of calcified cyanobacteria are widely spread especially during the Phanerozoic, and the fluctuation in their abundance is crucial for reconstructing paleo-ocean chemistry (e.g., pH). Two major mechanisms are suggested for cyanobacterial calcification: 1) the photosynthetic increase in $CaCO_3$ saturation state, and 2) the crystal nucleation sites supplied by acidic groups of extracellular polymeric substances (EPS). Previous study based on natural samples demonstrated that acidic EPS is crucial for controlling the degree and the style of calcification. However, the influence of EPS on crystal morphology, crystal arrangement, and precursor (amorphous calcium carbonate: ACC) formation are still not well understood. The present study, therefore, examined the relationship between physical/chemical characteristics of EPS and calcification styles by using cultivated cyanobacteria.
Four cyanobacteria having different EPS characteristics (*Spirulina*, *Phormidium*, *Scytonema*, and *Leptolyngbya*) were cultivated. Acid-base titrations and lectin binding analysis indicated that all investigated cyanobacteria secreted EPS containing acidic groups. These cyanobacterial cultures were incubated in an aquarium (pH = ca. 8.5, $[Ca^{2+}]$ = 2 mM, DIC = 2 mM) with light supply to cause calcification. Microelectrode measurements (pH, O_2, and Ca^{2+}) showed that all cyanobacterial cultures induced $CaCO_3$ precipitation by photosynthesis, although the degree of precipitation was different. Observations by transmission electron microscopy (TEM) and scanning transmission X-ray microscopy (STXM) revealed that the characteristics of precipitated $CaCO_3$ were significantly different among the investigated cyanobacteria. Especially, calcite formed around *Spirulina*, *Phormidium*, *Scytonema* exhibited specific features including ACC, sub-micron-sized calcite polycrystals, and superstructures, suggesting that the nucleation occurred on acidic EPS via ACC nanoparticles. In contrast, such features were rarely observed in calcite formed around *Leptolyngbya* producing only a few amounts of EPS. From these results, $CaCO_3$ formation processes on cyanobacterial surface is suggested as follows: 1) ACC nanoparticles are formed on acidic EPS, 2) crystallization takes place inside of grown ACC particles to form submicron-sized calcite polycrystals, and 3) these polycrystals grow into calcite single crystal while ACC and polycrystals remain partly.

Mineralogical and geochemical study on sedimentary rock containing microfossils from 1.9 billion years ago(Ga) Gunflint Formation, Canada

*kouhei Sasaki[1], Akizumi Ishida[1], Takeshi Kakegawa[1]

1. Graduate School of Science, Tohoku University

The ca. 1.9 Ga Gunflint microfossils are well studied by previous investigators. On the other hand, no agreements exist for primary producers indicated by microfossils, and their living environments. In this study, we performed geological, mineralogical and geochemical studies on samples from Schreiber and Mink Mountain regions. In addition, detailed morphologies of microfossils in stromatolite were observed. In Schreiber region, we discovered the novel microfossils of cyanobacteria colony, akinete, and endospore. Undiscovered microfossil type with radial wall ornamentation is found, indicating eukaryotic affinities. In particular, in situ analysis of microfossils by NanoSIMS discovered multilayered microstructure of cell wall and heterogeneous distribution of carbon, nitrogen and sulfur possibly associated with biological incorporation of those elements followed by later diagenetic modification. At Mink Mountain region, detailed observations and chemical analyses suggest that iron-oxidizing bacteria were dominant around stromatolites. Fe^{2+} and clays were supplied by local and shallow hydrothermal systems along the paleo-coastal lines. Such hydrothermal environments created local anoxic environments, allowing accumulation of Fe^{2+} followed by microbial oxidation. In summary, microbial life at the Gunflint age was more diverse and evolved than previously thought, cyanobacteria were primary producers in most places, but structure of microbial ecosystems in the Gunflint ocean dynamically changed with environments.

[B-BC03] Interrelation between Life, Water, Mineral, and Atmosphere

convener:Takeshi Kakegawa(Graduate School of Science, Tohoku University), Tadashi Yokoyama(Graduate School of Integrated Arts and Sciences, Hiroshima University), Keisuke Fukushi(Institute of Nature & Environmental Technology, Kanazawa University), Fumito Shiraishi(Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University), Chairperson:Takeshi Kakegawa, Fumito Shiraishi(Hiroshima Univ.)

Life on Earth is based on a diversity of physical and chemical dynamics and processes throughout the history of the Earth. It can essentially be regarded as the history of interrelation between Life, Water, Mineral (Solid Earth) and Atmosphere. To solve this kind of complex systems problems, interdisciplinary approach, a way of thinking and communication, is necessary. This session will be a cradle for such interdisciplinary researches.

Secular variation of multiple sulfur isotopic compositions of sulfate and sulfide during long term incubation of *Desulfovibrio desulfuricans*

*Fumihiro Matsuura[1], Hiroko Makita[2], Ken Takai[3], Yuichiro Ueno[1,3]

1. Tokyo Institute of Technology, 2. Tokyo University of Marine Science and Technology, 3. Japan Agency for Marine-Earth Science & Technology (JAMSTEC)

Incubation experiments of sulfate reducing microbes have been carried out since 1950s to quantify sulfur isotope fractionation. Sulfur isotope fractionation models are constructed from the results of these experiments. These models are applicable only when steady state is accomplished in the cells; thus, most of incubation experiments targeted cells exponential growth phase. We aimed to quantify the isotope fractionation in stationary to death phase of the cells and carried out two series of incubation experiment of sulfate reducing bacteria, *Desulfovibrio desulfuricans* (DSM-642), until c.a. 2000 hours. In addition, we used glucose as electron donor to make cell specific sulfate reduction rate low. Cells grew linearly rather than exponentially until cell concentration became c.a. 2×10^7 cells/mL in the early stage of incubation. Calculated sulfur isotope fractionation increased from 13.5±3.7‰ at the earliest stage of linear growth phase to 70.5±21.0‰ at the middle of linear growth phase. The cell specific sulfate reduction rate was 1.0±0.3 fmol/cell/day when sulfur isotope fractionation became 70.5±21.0‰, consistent with the results of a previous study. In the stationary to death phase, sulfide concentration started decreasing on the contrary to our expectation. Besides, $\delta^{34}S_{sulfide}$ value increased concomitant with the decrease of $\Delta^{33}S'_{sulfide}$ value. The $\delta^{34}S'_{sulfide}$ and $\Delta^{33}S'_{sulfide}$ have good linear correlation, and that indicate a sulfide originated reaction in a closed system with a unique fractionation factor dominates sulfur cycle during stationary to death phase. The calculated enrichment factors of the reaction in the two series experiments are 10.5‰ and 30‰. These enrichment factors are large compared to those of biotic or abiotic sulfide oxidation experiments of previous studies. We checked the reaction occur without cells and infer that the reaction is caused from sulfide oxidation by oxidants containing in the medium or sulfurization of organic matter containing in the medium.

Origins of volcanic SO_2 on Earth

*Hiroshi Ohmoto[1]

1. The Pennsylvania State University

SO_2 is a principal volcanic gas today. The two important questions to be addressed are: (i). the origin of S atoms in volcanic SO_2; and (ii) whether or not SO_2 was an important volcanic gas of early Earth. I have approached these questions from: (a) thermodynamic- and kinetic analyses of various reactions involving S-bearing species in silicate melts, fluids, rocks, minerals, and aqueous solutions at T = 0-1500 ˚C and P = 1-10 kb, and (b) examinations of the chemical and S-isotopic characteristics of volcanic gases and rocks in various tectonic settings on modern Earth. Here are some of the important suggestions from these investigations:

1. All of the S-bearing species from submarine volcanic eruptions have been nearly completely trapped in oceans through reactions such as: $H_2S_{(g)} = H_2S_{(aq)}$; $4SO_{2(g)} + 4H_2O = 3HSO_4^- + H_2S_{(aq)} + 3H^+$; $S_{8(g)} = 8S_{(s)}$; and $7H_2S_{(aq)} + HSO_4^- + 4Fe^{2+} = 4FeS_{2(py)} + 7H^+ + 4H_2O$. S-bearing volcanic gases have only been emitted into the atmospheres by subaerial eruptions. Therefore, on the ocean-covered planets, possibly including the pre-3.0 Ga Earth, S-bearing gases have not been emitted into the atmospheres.

2. The fluids that originated from normal-mantle-derived-magmas (i.e., $\log fO_2$ = FMQ-2 to FMQ+0.5) were initially H_2S-rich and SO_2-poor, whereas those from subduction-related arc magmas (i.e., $\log fO_2$ = FMQ+0.5 to FMQ+3) were initially SO_2- and/or H_2S-rich.

3. H_2S-rich magmatic fluids may become SO_2-rich gas, if: (i) the fluids were derived from high fO_2 magmas (i.e., $\log fO_2$ > FMQ) and ascended slowly through conduits (i.e., diffusive eruptions) and re-equilibrated with wall-rocks at P_{H2O}<10 bars, or (ii) the fluids are oxidized by reactions with an O_2-rich atmosphere, -groundwater and/or high-fO_2 wall-rocks during and/or after the ascent through conduits. In the absence of (i) and (ii), such as the Earth prior to the oxygenation of the atmosphere, H_2S-rich magmatic fluids were not transformed to SO_2 during eruptions.

4. SO_2-rich fluids from arc magmas would remain SO_2-rich during explosive or diffusive eruptions. However, if the fluids cool down to <~700˚C, SO_2 transforms to H_2S.

5. Volcanic SO_2 from arc magmas was transformed from seawater sulfate through the following processes: (i) formation of pyrite, hematite and anhydrite by reactions between SO_4^{2-}-rich seawater and hot basalts on MORs; (ii) devolatilization of H_2O- and SO_2-rich fluids from the subducting oceanic crust; (iii) formation of oxidized- and SO_4^{2-}-rich magmas by partial melting of peridotite in the mantle wedges, and (iv) degassing of SO_2-rich fluids from these magmas. If the oceans were SO_4^{2-}-poor, volcanic gases from arc magmas would be SO_2-poor.

6. Oceanic SO_4^{2-} has been produced mostly by the oxidative weathering of pyrite on land. Therefore, subaerial volcanic gases on planets with O_2-poor atmospheres would be SO_2-poor and H_2S-rich. Then, the current paradigm concerning the origin of mass-independent-fractionations of sulfur isotopes (MIF-S) in Archean-aged sedimentary rocks (i.e., the UV photolysis of volcanic SO_2 in an O_2-poor atmosphere) becomes invalid. Consequently, the MIF-S record in sedimentary rocks is not supportive evidence for the “Great Oxidation Event” at ~2.5 Ga ago. Furthermore, the current atmospheric O_2-evolution models,

©2019. Japan Geoscience Union. All Right Reserved.

which are based on the premise of SO_2-rich volcanic gases throughout geologic time, become invalid.

(7). The MIF-S in the Archean- and younger sedimentary rocks may have been created by the chemisorption isotope effects during thermochemical reductions of seawater sulfates by hydrothermally-generated, very reactive organic matter.

Volcanism, sedimentation, and development of life in a Mesoarchaean intracratonic setting: the Dominion Group, South Africa

*Andrea Agangi[1,2], Axel Hofmann[2], Dora Paprika[2], Andrey Bekker[2,3], Frantz Ossa-Ossa[2,4]

1. Akita University, 2. University of Johannesburg, 3. University of California, 4. University of Tuebingen

The ca. 3 billion-years-old Dominion Group of the Kaapvaal craton, South Africa is a >2 km-thick volcano-sedimentary succession emplaced in an intracontinental setting shortly after craton consolidation. As such, it represents one of the oldest examples of volcanism and sedimentation on stable continental crust. Deposition of the Dominion Group is interpreted to have occurred largely subaerially in a failed rift. In contrast to other Palaeo- to Mesoarchaean successions of the Kaapvaal craton, the Dominion Group is little deformed and was metamorphosed at greenschist facies grade, allowing excellent preservation of rock textures and chemical composition. The succession includes a thin basal conglomerate that marks a major, craton-scale nonconformity, and is overlain by sandstone. Volcanic rocks include intercalated massive to amygdaloidal mafic lavas of tholeiitic affinity, felsic lavas, and ignimbrites with high Fe/Mg.

In the area around the town of Ottosdal, the Dominion Group is represented by felsic volcanic rocks with intercalated, thin sedimentary layers that crop out discontinuously for several km along the strike. The presence of shallow, porphyritic intrusions that developed peperitic contacts with the sediments and the intense alteration developed in sediments underlying (but not in overlying) volcanic rocks indicate deposition of these sediments in a volcanically and hydrothermally active environment, such as volcanic lakes. These sediments are composed of carbonaceous and variably sulfidic shale and minor arenite and have a distinctive aluminium-rich composition (Al_2O_3 up to 36 wt.%) and very low contents of alkaline elements, Ca, and Fe (Na_2O content from below detection limit to 0.3 wt%; Fe_2O_3 = 0.1 to 1.6 wt%). The main mineral components of these sediments are pyrophyllite, diaspore, K-mica, rutile, and pyrite. No carbonate was found.

The total organic carbon content) is up to 1.5 wt%, and bulk-sample isotope analyses indicate strongly ^{13}C-depleted composition ($\delta^{13}C_{VPDB}$ = -45 to -29‰). These isotopic values are diagnostic of biogenic carbon fixation and the lowest, best-preserved values are indicative of methanogenesis and methanotrophy in a redox and chemically stratified shallow basin. Modern examples of volcanic environments hosting methane-producing Archaea, even under low pH and high temperature conditions, are known from Kamchatka, Russia and Argentina.

Our results indicate that restricted and ephemeral lakes that developed in Mesoarchaean volcanic environments shortly after the large-scale emergence of the Kaapvaal craton fostered life and were likely niches for life diversification. This ancient environment might be a better Mars analogue than modern caldera environments on Earth where the impact of advanced biosphere is more pronounced.

New microbial ecology results from genome centered metagenomics studies of iron carbonate and sulfidic hot springs

*Shawn E McGlynn[1], Lewis Ward[2], Takeshi Kakegawa[3], Yuichiro Ueno[1], Mayuko Nakagawa[1]

1. Earth-Life Science Institute, Tokyo Institute of Technology, 2. Harvard University, 3. Tohoku University

The ability to recover microbial genomes from metagenomic datasets has revolutionized how we understand microbial inhabitants in the environment, and is a powerful way to develop detailed hypotheses of community function and evolution. In this talk, I will discuss recent genomes we have recovered from two iron rich, carbonate hot springs in Japan, and contrast these to observations in low iron, sulfidic springs. Surprisingly, despite the different chemistry, some overall trends in phylogeny and physiology are observed, however water chemistry differences such as salinity and the availability of ferrous iron does alter the observed microbial inhabitants and physiologies.
These overall results will be discussed within the context of the possible ability to recognize microbial inhabitation on Earth through time.

Superhabitability in ultradeep rocky environments

*Yohey Suzuki[1]

1. Graduate School of Science, The University of Tokyo

It is challenging for life to proliferate in cold rocky habitats deeply isolated from photosynthetic organic matter. Although fluid circulation is previously considered to be necessary for supplying energy sources and oxidants, it is also considered that substrates available within the rocky environment are diluted by fluid circulation. As the abundance of microbial life within the rock matrix is largely unknown, I developed nanoscale analytical procedures to unveil the distributions of microbial cells, organic matters and low-temperature minerals. As a result of applying the analytical procedures to various deep-sea and subsurface rocky environments such as deep-sea hydrothermal vents, deep-sea ferromanganese crusts and deep subseafloor basaltic rocks, it is unexpectedly unveiled that the rocky habitats are superhabitalble with cell densities locally exceeding 10^{10}cells/cm^3. The superhabitablity might be explained by the coexistence of solid silicate phases such smectite clays that play roles in concentrating nutrients from the ambient fluid.In this presentation, I will introduce the analytical procedures and main results obtained from the ultradeep rocky habitats.

Exploring planetary habitability beneath the oceans

*Fumio Inagaki[1]

1. Japan Agency for Marine-Earth Science and Technology

Since Ocean Drilling Program (ODP) Leg 201 in 2002 off Peru and eastern equatorial Pacific, numerous geochemists and microbiologists have participated in multiple expeditions of scientific ocean drilling to explore subseafloor life and the deep biosphere beneath the oceans. The discovery of diverse microbial life in marine sediments and oceanic crusts worldwide points to a notion that subseafloor microbial ecosystems may have uniquely co-evolved with Earth's dynamics and this inevitable interrelationship has shaped environemnts for more than 3 billion years. Expanding our knowledge of the comprehensive ocean-Earth-life system through scientific ocean drilling inspires new insights into the essence of "planetary habitability"—down to the Earth’s upper mantle, which with today’s drilling technology provides the deepest yet accessible limit. The deep ocean offers windows into thick piles of ocean sediment and the Earth’s interior that has vast potentials for the development of sustainable ocean-Earth-life system in the past but also into the future, yet there is still a large insufficiency in our knowledge of the habitability extent of our own planet. Such explorations towards deep frontiers will lead us to an understanding of how and why life emerged on our planet, as well as an estimation (prediction) of the possible trajectories of life on Earth, and finally, will provide hints as to whether life persists in the other celestial bodies, and which ones are the most likely to be habitable and even inhabited.

[B-CG08] Phanerozoic biodiversity change: Extinction and diversification

convener:Yukio Isozaki(Department of Earth Science and Astronomy, Multi-disciplinary Sciences - General Systems Studies, Graduate School of Arts and Sciences, The University of Tokyo), Yusuke Sawaki(The University of Tokyo), Chairperson:Yukio Isozaki(Department of Earth Science and Astronomy, The University of Tokyo), Yusuke Sawaki(The University of Tokyo)

Phanerozoic biodiversity is the consequence of repeated extinctions and following diversifications in the past, which were caused by large-scale environmental changes, in particular, by extremely rapid and drastic forcing that changed the environments of the biosphere. Irreversible and episodic changes in material cycling on the planet and influences of severe galactic cosmic radiation enhanced by encounter with dark cloud are nominated as major driving mechanisms for the alleged rapid, large-scale environmental perturbations. The biodiversity change in the fossiliferous Phanerozoic record is characterized by 5 major mass extinctions within the long-term trend of diversity increase. Nonetheless, each extinction event has been explained rather in ad hoc manner, without any universal explanation. Therefore, ultimate triggers that caused the Phanerozoic biodiversity still remain as unsolved issues. This session discusses the ancient environmental changes related to Phanerozoic biodiversity under a new light of the recent progress in geology.

Discussion

The Ediacaran-Cambrian transition of North China

*Xingliang Zhang[1]

1. State Key Laboratory of Continental Dynamics, Shaanxi Key Laboratory of Early Life and Environments, and Department of Geology, Northwest University

The central mountain range, known as the backbone of China, separates the country into North China and South China, which are different from each other in geology, geography, climate, and culture. The Precambrian-Cambrian transition of South China has received much attention of world scientists for beautiful sections and numerous fantastic fossil-Lagerstätten. However, the Ediacaran-Cambrian sequences of North China have some attractive points as well. The lowermost Cambrian of North China, the Xinji Formation, unconformably overlies Precambrian rocks of various ages, from Archean to late Ediacaran. The Xinji Formation is rich in SSFs of Cambrian Epoch 2 aspects and thus the Terreneuvian is absent throughout North China. The Xinji SSF assemblage is taxonomically dominated by molluscs and hyoliths, which are represented by 26 and 12 species, respectively. A number of molluscan taxa are conspecific with Australia, Antarctic and Laurentia, and thus have biostratigraphical and paleobiogeographical values. Remarkably, shell microstructures are well preserved in molluscs and hyoliths, which demonstrate how these Cambrian animals use minute mineral crystals to build their shells. Additionally, shell microstructures shed new light on the phylogenic links between the groups. Ediacaran rocks developed in marginal regions and cratonic basins. Along the south and west margins of North China, the Dongpo/Tuerkeng Shale/Slate immediately underlies the unconformity and overlies the Luoquan/Zhengmuguan Diamictite which is poorly constrained in age. The shale/slate unit above the diamictite yields a diverse form of macroscopic, soft-bodied fossils, e.g. the annulated tubular form *Shaanxilithes*, the form of a string of beads *Horodyskia*, the WiFi symbol-like form *Palaeopascichnus*, an unnamed form resembling a string of rings (which might be a segmented organism composed of many repetitive units), and small clew-like fossils of unknown affinities. Algal fossils are abundant but simple in complexity and poor in diversity. The presence of *Shaanxilithes* and *Palaeopascichnus* suggests an age of late Ediacaran. New specimens demonstrate that *Shaanxilithes* is composed of a cone-in-cone internal tube encased in a flexible external tube with irregular cross annulations. Such a morphological reconstruction is analogous to the contemporary *Cloudina* and other tubular organisms. New findings in North China would provide new insights into the biotic evolution of the Ediacaran-Cambrian transition.

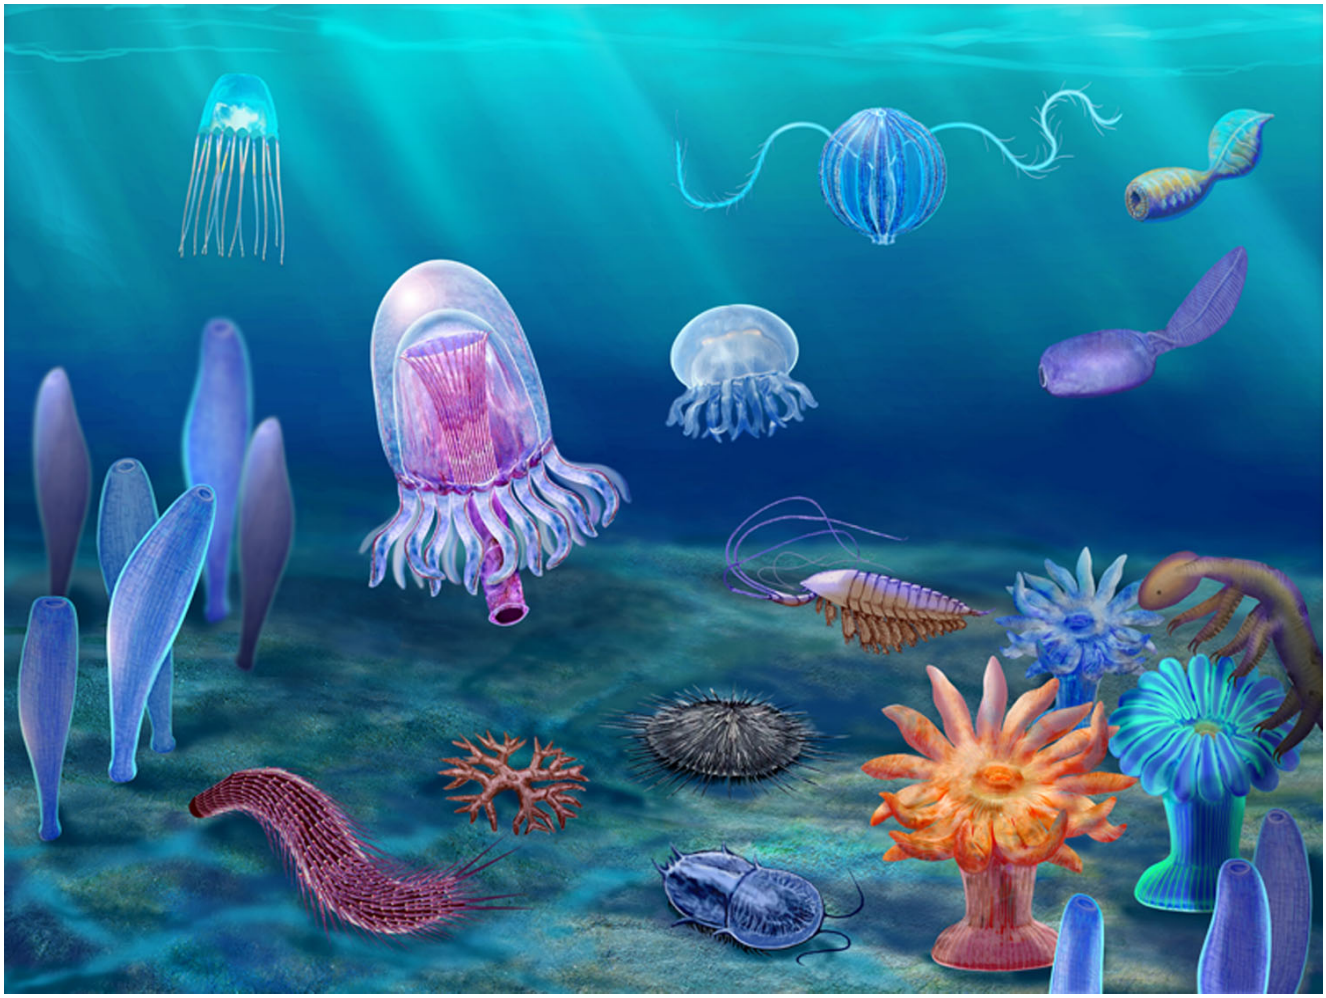
The Qingjiang biota –An extraordinary new Burgess Shale-type fossil Lagerstätte from the early Cambrian of South China



*Dongjing Fu[1], Xingliang Zhang[1], Robert R. Gains[2]

1. State Key Laboratory of the Continental Dynamics, Shaanxi Key Laboratory of Early Life and Environment, Department of Geology, Northwest University, Xi' an 710069, PR China, 2. Department of Geology, Pomona College, Claremont, CA 91711, USA

Our understanding of the Cambrian explosion and of the fundamental structure of the tree of animal life rests in large part on evidence from a dramatically enhanced fossil record, characterized by the preservation of entire assemblages of soft-bodied fossils. In the one hundred years since Walcott' s original discovery of the Burgess Shale, exceptionally preserved fossil assemblages have been reported from Cambrian strata of almost every paleocontinent. Nevertheless, only the early Cambrian Chengjiang biota of Yunnan Province has matched the Burgess Shale in total diversity of soft-bodied taxa and fidelity of exceptional preservation. Here, we report the discovery of an extraordinary new early Cambrian Burgess Shale-type (BST) fossil Lagerstätte from the Changyang area of South China, which is characterized by high taxonomic diversity (101 metazoan taxa plus 8 algal forms), an unexpectedly large proportion of new taxa (53.2%), and exquisite preservation of fine aspects of labile tissue anatomy. The taxonomic richness of soft-bodied taxa (85%) approaches the top tier of BST deposits, presently occupied only by the Burgess Shale and Chengjiang biotas. Rarefaction analyses suggest that diversity may surpass all other BST biotas. Novel aspects include high abundance of cnidarians, including both medusoid and polypoid forms, new taxa resembling extant kinorhynchs, and abundant larval or juvenile forms. While approximately coeval to the Chengjiang biota, the Qingjiang biota (518 Ma) appears to have occupied a more distal environmental setting, in which a different early Cambrian ecosystem flourished. The uniqueness of the Qingjiang biota in the taxon composition and preservation quality holds special potential to provide new insights into the evolution of early metazoans and the structuring of Cambrian ecosystems across environmental gradients.

Enhanced flux of extraterrestrial ^{3}He across the Permian–Triassic boundary

*Tetsuji Onoue[1], Naoto Takahata[2], Honami Sato[4], Akira Ishikawa[3], Katsuhito Soda[1], Yuji Sano[2], Yukio Isozaki[2]

1. Kumamoto Univ., 2. Univ. Tokyo, 3. Tokyo Inst. Tech., 4. Chiba Inst. Tech.

The Solar System contains abundant submillimetre interplanetary dust particles (IDPs) that are enriched in ^{3}He. ^{3}He concentrations in ancient deep-sea sediments have been used to constrain the flux of IDPs onto the Earth for at least the last 100 Myr. However, the use of ^{3}He in detecting IDP flux is often compromised by the diffusional loss of ^{3}He in sedimentary rocks, with the exception of some Ordovician samples that record a period of unusually high extraterrestrial^{3}He ($^{3}He_{ET}$) flux. In this study, we report for the first time the preservation of extra-terrestrial ^{3}Hein deep-sea bedded chertfrom a continuous Permian-Triassic boundary (PTB) section at Waidani in Japan, which was deposited in the Panthalassa superocean.

High ^{3}He/^{4}He ratios (up to 150 Ra; 1Ra = the atmospheric ratio) were detected from acid-insoluble residues fromthe uppermost Permian deposits, which suggeststhe existence of extraterrestrial He hosted mainly in IDPs. The estimated extraterrestrial fraction of ^{3}He across the PTB revealsthat$^{3}He_{ET}$ concentrations are higher in the topmost ~1.5 m ofthe studied Permian deposits, which is 4–5 times greater than that measured in the overlying Triassic unit. Based on the $^{3}He_{ET}$ concentration and sedimentary mass accumulation rate of the PTB section at Waidani, we calculated $^{3}He_{ET}$ fluxacross the PTB.The data document the presence of an up to 4-fold increase in IDP flux for the last 500 kyr interval of the Permian.This unusual signal suggests a significant increase in the influx of interplanetary dust particles, likely related to an asteroid showerin the inner Solar System. High-resolution stratigraphy indicates that peak IDP flux occurred during the final 500 kyr of the Permian, concurrent with a pre-extinction decline in radiolarian diversity.

End-Triassic Mass Extinction: Causes and Consequences

*Wataru Fujisaki[1]

1. Japan Agency for Marine-Earth Science and Technology

The biodiversity crisis across the Triassic-Jurassic boundary (TJB; *ca.* 201 Ma) is characterized by one of the largest mass extinctions in the Phanerozoic. Significant increases in the extinction rate of marine fauna, and major turnovers in terrestrial vegetation and vertebrate groups, have been well documented across the TJB. In addition to the extinction, several unique geological episodes around the TJB were recognized; i.e., the emplacement of the Central Atlantic Magmatic Provinces (CAMP) which is associated with the breakup of Pangea, carbon cycle perturbations, and widespread ocean anoxia and associated deficits of nutrients. In the last decade, based on of the numerous data-set obtained from the shallow-marine shelf sequences around the Pangea, major advances have been made in our understanding of the TJB biotic crisis, related environmental changes, and the CAMP volcanism. However, the casual relationships between the CAMP volcanism and extinction-related environmental changes of global context still remain unclear. Therefore, the deep mid-Panthalassa, which occupied major portion of the global ocean during the Triassic-Jurassic transition, is indispensable for reconstructing the global environmental changes related to the TJB biotic crisis.

Deep-sea bedded cherts in the Mino-Tanba belt in SW Japan provide critical constraints for reconstructing paleo-environmental changes because they preserve extinction-related intervals from the Middle Permian to the Early Jurassic deposited in the deep mid-Panthalassa. Most recently, the stratigraphic $\delta^{13}C_{org}$ variation using Rhaetian (Late Triassic) to Hettangian (Early Jurassic) shales interbedded within deep-sea cherts was established in the Katsuyama section in the Mino-Tanba belt. By obtaining high-resolution Rhaetian to Hettangian $\delta^{13}C_{org}$ values, three negative carbon isotopic excursions (NCIEs) were newly detected before and across the TJB. The mid-Panthalassic NCIEs are well correlated with those in many shallow-marine regions including the base Jurassic GSSP of TJB at Kuhjoch in Austria, suggesting that three NCIEs in the Tethys and mid-Panthalassa likely reflected global perturbations of the carbon cycle, rather than local phenomena. Based on the Os isotopic records correlated with $\delta^{13}C_{org}$ stratigraphic profiles, the mid-Panthalassic NCIEs can be interpreted as the consequences of the multiple emplacements of CAMP volcanism.

On the other hand, despite the oxic deep mid-Panthalassa, widespread ocean anoxia and associated deficits of nutrients around the TJB were recently identified in the Eastern Panthalassa. Since the redox conditions were quite different between shallow-marine regions and mid-Panthalassic sites, information regarding nutrient concentrations in the mid-Panthalassa is required. Oceanic fixed nitrogen is a bio-limiting component in the modern ocean, and total nitrogen isotopic composition ($\delta^{15}N_{TN}$) of sedimentary rocks is a useful tool for the reconstruction of ancient nitrogen cycles. To advance our understanding on the global nitrogen cycle, this study for the first time provides Rhaetian to Hettangian $\delta^{15}N_{TN}$ records in combined with Mo and U concentrations from the shales in the Katsuyama section. Based on the newly obtained data-set, I comprehensively discuss relative concentrations of biologically available nitrogen compounds in the mid-Panthalassa, their possible association with the redox condition, and biodiversity during the Triassic-Jurassic transition.

[B-CG08] Phanerozoic biodiversity change: Extinction and diversification

convener:Yukio Isozaki(Department of Earth Science and Astronomy, Multi-disciplinary Sciences - General Systems Studies, Graduate School of Arts and Sciences, The University of Tokyo), Yusuke Sawaki(The University of Tokyo), Chairperson:Wataru Fujisaki(Japan Agency for Marine-Earth Science and Technology)

Phanerozoic biodiversity is the consequence of repeated extinctions and following diversifications in the past, which were caused by large-scale environmental changes, in particular, by extremely rapid and drastic forcing that changed the environments of the biosphere. Irreversible and episodic changes in material cycling on the planet and influences of severe galactic cosmic radiation enhanced by encounter with dark cloud are nominated as major driving mechanisms for the alleged rapid, large-scale environmental perturbations. The biodiversity change in the fossiliferous Phanerozoic record is characterized by 5 major mass extinctions within the long-term trend of diversity increase. Nonetheless, each extinction event has been explained rather in ad hoc manner, without any universal explanation. Therefore, ultimate triggers that caused the Phanerozoic biodiversity still remain as unsolved issues. This session discusses the ancient environmental changes related to Phanerozoic biodiversity under a new light of the recent progress in geology.

Transition of biodiversity in mobile populations and the small world in local subpopulations

*Kota Imaoka[1], Kazuhito Yamasaki[1]

1. Kobe University Graduate school of Science

Speciation is one of the factors that influences ecological biodiversity on the geological time scale (Gould 1989, Kawata, 2000). So its mechanism is the important paleontological theme that leads to learn evolution. The basic mechanism is reproductive isolation. Allopatric speciation needs geographical barriers that divide the population into two subpopulations and block the genetic flow between them of individuals (Hubbell, 2001). These isolated groups accumulate incompatible genes leading to reproductive. Sympatric speciation happens with ecological interactions in the same niche. Difference of resources and habits leads to disruptive selection and ultimately to speciation (Gavrilets, 2003). Recently, a neutral theory of speciation, without geographical barriers or ecological interactions, has been shown to predict many patterns consistent with the behaviors observed in nature, e.g. species abundance distributions and species-area relationships. This neutral speciation is driven by physical and genetic distances which are essential for assortative mating. As the condition is restricted, speciation is promoted. Such a speciation model is named 'topopatric speciation'. In addition, another factor that influences ecological biodiversity on the geological time scale is radiation (Yamasaki et al., 1999). However, many studies of topopatric speciation consider standing still populations. So we considered mobile populations and the effect of them on speciation and ecological system. Our study may show that mechanism of speciation and how populations increased their biodiversity in the past. Moreover, we considered the spatial structure of each species with networks and quantitatively showed the distribution of populations on the process of speciation. This study uses a multi agent system to simulate the neutral stochastic evolution without natural selection. We consider an initial population of diploid and genetically identical individuals. In reproduction, we extend the Dobzhansky-Muller model to the most general form contains multiple alleles. A species is defined as the concept of ring species (Irwin et al., 2001, 2005). In the simulations, we found not only the number of species in the space, but also species diversity (species abundance distributions) and genetic diversity (heterozygosity). Furthermore, we calculated average path lengths and clustering coefficients by considering individuals as nodes and linking between them which can reproduce. Our simulations showed that the number of species and species diversity, genetic diversity changed depending on the mobile speed in populations. Accordingly, the difference of mobile speed in populations influences on biodiversity. In addition, from our results we predict species abundance distributions and species-area relationships. The highest species richness was found at minimum mobile speed, then average path length is smaller and clustering coefficient is larger. So this shows that the populations have a feature of 'small world' on the network. In the small world, we can communicate quickly each other and have many strong connections. In other words, individuals can exchange genomes quickly each other and have many mates. Thus, speciation is promoted by dividing the population into local subpopulations that form the small world and accumulating genetic variation. Consequently, in mobile population, assortative mate based on isolation by physical and genetic distance without geographical barriers and ecological interactions leads to divide population and speciation.

Rivision of the lowermost Cambrian SSF stratigraphy

*KONO SENA[1], Yukio Isozaki[1], Tomohiko Sato[2], Xingliang Zhang[3], Wei Liu[3]

1. The University of Tokyo School of Arts &Sciences, 2. Earth-Life Science Institute, Tokyo Institute of Technology, 3. Northwest university, China

The earliest Cambrian evolution of animals is marked by the appearance and rapid diversification of small shelly fossils (SSFs). We examined the litho- and bio stratigraphy of the lowermost Cambrian at the Xiaolantian and Hongjiachong sections in the Chengjiang area, eastern Yunnan, South China. By analyzing both outcrop and drilled core samples, we picked up many SSFs from the ca. 30 m-thick phosphorites (Zhongyicun Mb), and obtained the following results.1) the Zhongyicun Mb comprises 6 lithostratigraphic units, which include Unit 3 with characteristic black mudstone beds for a significant key for the mid-Zhongyicun Mb.2)SSFs were found from 26 horizons out of 83 in the Zhongyicun Mb and the overlying Dahai Mb. Five zones were discriminated. Interval 1 with*Acanthocasis orthocanthus, Spirellus* sp., *Protohertzina unguloformis* and*Protohertzina anabarica*(from uppermost of Unit 1 to lower part of Unit 2); Interval 2 with *Ocruranus finial, Purella*sp.and*Yunnanopleura biformis*(from upper part of Unit 2). This marks the first occurrence of cap-shaped SSFs. Interval 3 with *Helcionella*sp.and*Oelandiella korobkovi*(from Unit 3). Interval 4 with *Obtusoconus*sp.,*Conopoconis*sp. and*Erongia acculatus*(from lower part of Unit 6). Interval 5 with*Igorella* sp., *Bemella simplelx*and*Paragloborilus subglobosus*(from upper part of Unit 6). 3) In addition, at the Hongjiachong section, a unique interval with *Halkieria* sp.*,Pteromus* sp.and*Sinosachites delicatus*occurs between Interval 1 and 2.

These results from the Xiaolantian and Hongjiachong sections, the following 6 SSF zones are proposed here. Namely, 1)*Acanthocasis orthocanthus- Protohertzina anabarica*Zone, 2) *Halkieria- Pteromus*Zone, 3) *Ocruranus finial-Yunnanopleura biformis*Zone, 4)*Paracarinachites sinensis-Oelandiella korobkovi*Zone, 5) *Obtusoconus-Conopoconis*Zone, and 6) *Igorella -Bemella simplelx*Zone.Previously the Zhongyicun Mb was divided into two SSF assemblage zones (Steiner et al., 2007); however, the present study offers 6 zones. It is noteworthy that the key bed in the mid-Zhongyicun Mb, restricted within the*Paracarinachites sinensis-Oelandiella korobkovi*Zone,appears useful for regional correlation.

δ^{88}Sr and ^{87}Sr/^{86}Srrecords of the Middle-Late Permian seawater: mass extinction-relevant change in ocean Sr budget

*Tomomi Kani[1], Yukio Isozaki[2], Keiji Misawa[3], Akira Ishikawa[4], Shigekazu Yoneda[5]

1. Kumamoto University, 2. The University of Tokyo, 3. National Institute of Polar Research, 4. Tokyo Tech, School of Science, 5. National Museum of Nature and Science

As Sr isotope compositions in seawater are globally homogeneous, these proxies are useful in checking marine Sr budget change in direct link to global calcium cycle. ^{87}Sr/^{86}Sr valueis mainlydriven by two input fluxes to seawater; riverine flux connected with weathering of time-integrated radiogenic old continent and hydrothermal input flux derived from less radiogenic mantle. δ^{88}Sr in seawaterreflects marine calcium carbonate input/output flux. The marine Sr budget changed dramatically, in particular, during the Guadalupian (Middle Pemian), with the lowest value of seawater ^{87}Sr/^{86}Sr in the Phanerozoic, i.e., “the Capitanian minimum”. This likely reflected a major global environmental change associated with the end-Guadalupian mass extinction. Likewise, the δ^{88}Sr started to decrease in the Early Permian, and reached the Phanerozoic lowest value at the end of Capitanian (late Guadalupian). We measured δ^{88}Sr values of the Middle-Upper Permian marine carbonates with detailed biostratigraphy by TRITONTIMS, with correction of isotope fractionation during mass spectrometry with ^{87}Sr-^{84}Sr double spike. Analyzed samples were from various localities in the world, e.g., the Akasaka paleo-atoll limestone (Japan), and shelf carbonates in S. China. These results confirmed that both in stable δ^{88}Sr and radiogenic ^{87}Sr/^{86}Sr ratios, low values remained throughout the Guadalupian, whereas they increased in the Wuchiapingian. The extremely low δ^{88}Sr value in seawater may reflect the increased dissolution of carbonates and/or reduced carbonate burial, i.e., enhanced carbonate weathering or suppression of reef building on shelf settings according to the coeval global sea-level drop.

Formation of stratiform manganese deposits during the Carnian (Late Triassic) “pluvial event” in the pelagic Panthalassa

*Yuki Tomimatsu[1], Tetsuji Onoue[2], Daisuke Yamashita[3], Tatsuo Nozaki[4,5,6,7], Yutaro Takaya[8]

1. Graduate school of Science and Technology, Kumamoto University, 2. Faculty of Advanced Science and Technology, Kumamoto University , 3. Satsumasendai City Office, 4. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology, 8. Department of Resources and Environmental Engineering School of Creative Science and Enginerring, Waseda University

Stratiform manganese deposits have been reported from the Triassic bedded chert sequences in the Japanese accretionary complexes, which are considered to have accumulated in a mid–oceanic basin of the Panthalassa Ocean.However, their precise mineralization age and depositional environment remain poorly understood. In the present study, we investigated lithostratigraphy, conodont and radiolarian ages, and geochemistry of bedded cherts and chert-hosted manganese deposits from the Jurassic accretionary complexes (Chichibu, Mino–Tamba, and Northern Kitakami Belts) in Japan.
The studied sequences are classified into three to four lithostratigraphical units; lower bedded chert, massive chert, manganese ore (30-150 cm thick), and upper bedded chert units in ascending order. Radiolarian fossils from the lower bedded chert unit indicate the Early Carnian age, based on the occurrence of *Capnuchosphaera deweveri*and *C. triassica*, whereas the upper bedded chert unit contains Late Carnian radioralian species, including *Poulpus carcharus*and *Trialatus megacornutus*. Conodonts extracted from the upper bedded chert unit also include Late Carnian species, such as *Paragondolella praelindae*and*Metapolygnathus praecommunisti*. These occurrences of microfossils suggest that the sedimentary age of the manganese ores can be constrained from the late Early Carnian to early Late Carnian. Chemical compositions of the manganese ore are characterized by the enrichments in Mn and low concentrations of Co, Ni, and Zn. These geochemical features are similar to those in modern submarine hydrothermal manganese deposits. On the other hand, highly enrichments in V, Ni, Zn, U, and high U/Th ratio were recognized in the massive chert unit below the manganese ores, which indicate deposition under a reducing depositional environment.
Our biostratigraphic and geochemical analyses indicate that a redox state change from anoxic to oxic environments occurred in a pelagic deep seafloor in the late Early to early Late Carnian. This interval is known as a period of increased rainfall, named the Carnian Pluvial Event (CPE) in the western Tethys. CPE is characterized by the increased continental weathering which led to the increased nutrient flux and triggered the development of anoxia. It is likely that the Upper Triassic manganese deposits may have been formed during recovery from the reducing environment associated with the CPE.

Enrichment of chalcophile elements in Cretaceous–Paleogene boundary clays

*Teruyuki Maruoka[1], Yoshiro Nishio[2]

1. Faculty of Life and Environmental Sciences, University of Tsukuba, 2. Research and Education Faculty, Kochi University

Cretaceous-Paleogene (K-Pg) boundary clays are enriched in chalcophile elements along with siderophile elements [1]. As elemental ratios of siderophile elements in the K-Pg boundary clays are very similar to chondritic values, the enrichment of siderophile elements in the K-Pg boundary clays results from the incorporation of meteorite condensates. On the other hand, it cannot be assumed that the chalcophile elements in the K-Pg boundary clays were supplied by meteorite condensates, because the ratios of chalcophile and siderophile elements in the K-Pg boundary clays, such as Zn/Ir, As/Ir, and Sb/Ir, are one to two orders of magnitude higher than those in chondrites. In this study, to elucidate the processes that could have contributed to the enrichment of chalcophile elements in the K-Pg boundary clays, we analyzed the chemical compositions of major and trace elements in the K-Pg boundary clays from Stevns Klint in Denmark.

The concentrations of major and trace elements in the K-Pg boundary clays varied among the collected samples even from neighboring outcrops. Cross plots of the concentrations of these elements suggested the mixing of three materials with different chemical compositions. The first component was enriched in all chalcophile elements and iron. The second component was depleted in chalcophile elements and enriched in calcium. The third component was enriched particularly in copper, silver, and lead. The first and third components included iridium that was obviously supplied at the K-Pg meteorite impact. Therefore, these two components were produced by phenomena related to the K-Pg meteorite impact. We propose that chalcophile elements were supplied to the K-Pg boundary clays by a combination of impact heating of the target rocks and intense acid rain following the impact.

Iron oxide/hydroxide grains with sizes of one to several tens of nanometers have been previously observed in the K-Pg boundary clays [2]. These likely condensed from the vapor plume that formed by impact heating at the K-Pg meteorite impact. These iron oxides/hydroxides could absorb chalcophile and siderophile elements from seawater. Such materials would have been converted to pyrites incorporating chalcophile elements under the reductive conditions on the seafloor. In addition, the correlations between the concentrations of chalcophile elements and soot have been observed in the K-Pg boundary clays [3]. This soot could have been produced by the impact heating of hydrocarbons in the target rocks. Bacterial sulfate reduction and subsequent pyrite production occur in reducing environments where hydrocarbon deposition occurs, thus resulting in the simultaneous accumulation of pyrite and hydrocarbons. Therefore, chalcophile elements accompanied by soot may have been released by impact heating of pyrite in the target rocks. Both chalcophile elements and iron, which were enriched in the first component, could have been provided by the impact heating of the target rocks.

Copper, silver, and lead, which were concentrated in the third component, are generally concentrated in acid soluble sulfides such as sphalerite and galena. Therefore, the third component was possibly supplied by intense acid rain after the K-Pg impact.

In summary, chalcophile elements in the K-Pg boundary clays comprises two components, one that is enriched in all chalcophile elements and another that is enriched particularly in copper, silver, and lead. These components were likely supplied by phenomena associated with the meteorite impact at the K-Pg boundary, such as the impact heating of the target rocks and intense acid rain.

Mass extinctions: hierarchy of causes and cosmoclimatological perspective

*Yukio Isozaki[1]

1. Department of Earth Science and Astronomy, Multi-disciplinary Sciences - General Systems Studies, Graduate School of Arts and Sciences, The University of Tokyo

This paper reviews possible causes proposed for the double-stepped extinction in regard of the current status of mass extinction studies. Causes of extinction can be grouped into four categories; from small to large scale, Caterogry 1 to Category 4. Category 1 –direct kill mechanism, Category 2 –global environmental change, Category 3 –trigger on the planet’ s surface, and Category 4 –ultimate cause. Among the Big-5 mass extinctions of the Phanerozic, two events in the Paleozoic, i.e.,the Hirnantian (Ordovician) and end-Guadalupian (Permian) events, show significant similarities in various aspects. Biological and non-biological aspects unique to these two distinct events include changes in biodiversity, isotope ratios (C, Sr *etc.*) of seawater, sea level, ocean redox state, episodic volcanism, and geomagnetism. In particular, the similar appearance of global cooling (Category 2) suggests the same cause and processes were likely responsible for the biodiversity drop. In addition to the most prevalent scenario of mantle plume-generated large igneous provinces (LIPs) (Category 3) for the end-Permian extinction, an emerging perspective of cosmoclimatology is introduced with respect to astrobiology. Galactic cosmic radiation (GCR) and solar/terrestrial responses in magnetism (Category 4) could have had a profound impact on Earth’ s climate, in particular, on extensive cloud coverage (irradiance shutdown). Furthermore, the star-burst events detected in the Milky Way Galaxy apparently coincide in timing with the cooling-associated major extinctions of the Phanerozoic and also with the Proterozoic snowball Earth episode. As an ultimate cause (Category 4) for major extinction, the episodic increase in GCR flux from the source (dark clouds derived from star-burst) against the geomagnetic shield likely determined the major climate changes, particularly global cooling in the past. The study of mass extinctions on Earth is entering a new stage with a new astrobiological perspective.

[M-IS10] Interface- and nano-phenomena on crystal growth and dissolution

convener:Yuki Kimura(Institute of Low Temperature Science, Hokkaido University), Hitoshi Miura(Graduate School of Natural Sciences, Department of Information and Basic Science, Nagoya City University), Hisao Satoh(Naka Energy Research Laboratory, Mitsubishi Materials Corporation), Katsuo Tsukamoto(Graduate School of Engineering, Osaka University), Chairperson:Yuki Kimura (Institute of Low Temperature Science, Hokkaido University)

Recent developments of observations in nano-scale opened a detail discussion concerning mechanisms of crystal growth and dissolution based on interface phenomena including dynamics. In this session, growth and dissolution mechanisms of crystals will be discussed focusing on interface phenomena of minerals in the fields of biological origin, global environment, planets and space in addition to general minerals.

Fabrication of octacalcium phosphate block through a dissolutionprecipitation reaction and its biological evaluation

*Yuki Sugiura[1], Munar L Melvin[2], Kunio Ishikawa[2]

1. National Institute of Advanced Industrial Science and Technology, 2. Kyushu University

Although octacalcium phosphate (OCP) powder and a collagen/gelatin composite demonstrate good potential as bone substitutes, an OCP block has not been fabricated to date. In this study, the feasibility of fabricating an OCP block was evaluated through a dissolution-precipitation reaction using a calcium sulfate hemihydrate (CSH) block as a precursor. When the block was immersed in a phosphate salt solution, its composition changed to that of OCP, while its structure was maintained. The diametral tensile strength (DTS) of the OCP block was 1.0 ±0.2 MPa. The macroporosity and microporosity of the OCP block were 33.4 ±4.5% and, 69.0 ±1.6%, respectively. New bone attached well to the OCP block, and this block was partially replaced by bone 2 weeks after implantation. Four weeks after implantation, the surface of the OCP block was nearly covered with new bone and ~30% of the block was replaced by new bone, while no replacement by bone was observed in the case of a hydroxyapatite (HAp) block used as a control. It is concluded that OCP blocks are potentially suitable for their use as artificial bone substitutes.

Development of optimized incineration process of fisheries waste for synthesizing a functional heat storage material

*Hidekazu Kobatake[1], SHinji Kirihara[1]

1. Hirosaki University Institute of Regional Innovation

A part of fishery waste, such as scallops or oyster shells, are utilized for fertilizer, feed, soil conditioner, or fishing ground preparations, and most of the shells from aquaculture residue are incinerated as general waste at or above 1273 K using a huge amount of fuels and cost. And the most of the incineration products are used for a landfill disposal. For the establishing the sustainable fisheries industry and local community, the reduction of the incineration cost and utilization of the incineration products are indispensable. In this research, the incineration temperature of fisheries waste was examined for lowering incineration temperature. Addition to the investigation on the incineration temperature of fisheries waste, the properties of the calcium oxide derived from the fisheries waste as heat storage material was also evaluated based on the thermal analysis.

The samples used for thermal decomposition kinetics investigation are 2 species of shells (Scallop *Mizuhopecten yessoensis*, Oyster *Crassostrea gigas*), a spines of a sea urchin *Mesocentrotus nudus*, and calcite reagent (purity 99.95%). The surface deposits on these shells and spines are removed using a wire brush or tweezers, then washed by tap water. The cleaned samples were crushed in a porcelain mortar, then dried in an oven at 383 K. The dried powder particles were allied by their size using a sieve to sort in size in the range between 63 and 125 micron meter. The thermal incineration temperature was investigated using these samples.

Calcite reagent (purity 99.95%) the sorted, shells (Scallop, Oyster, Myoida *Hiatella orietalis*, and Tube worms *Dexiospira foraminosus*), and spines of Sea urchin were thermally decomposed for 1 hour at 1273 K to be converted to calcium oxide and then reacted with distilled water to prepare $Ca(OH)_2$. The thermal decomposition temperature of the $Ca(OH)_2$ of these samples was experimentally investigated for the evaluation of the incineration product as a heat storage material.

The prepared powder samples were put in a platinum container covered with Pt disk and then installed in a Differential Scanning Calorimetry. The samples were heated up with the temperature increasing rate from 5 K /min to 40 K /min in Ar atmosphere (99.9999%).

The thermal decomposition complete temperature is depending on the temperature increasing rate. As increase of the temperature increasing rate, thermal decomposition temperature of each samples became higher. The activation energy and frequency factor of the thermal decomposition were determined from the relation between thermal decomposition complete temperature and the temperature increasing rate. However, there is only 8% difference in the activation energies of thermal decomposition among the all samples. This result implies that the thermal decomposition kinetics is mainly controlled by the frequency factor.

Meanwhile the thermal decomposition temperature of the $Ca(OH)_2$ differs each other depending on the derived specimens. There is a weak positive correlation between the thermal decomposition temperature of calcite and calcium hydroxide. The shells and spines having lower thermal decomposition temperature have lower thermal decomposition temperature of calcium hydroxide. The incineration products from shells and spines have also better reaction property than that of derived from the calcite reagent.

These differences could be caused by the microstructures of the reagent, shells and spines. The adjustment of the particle size of shells during the firing can further reduce the reaction temperature and fuels and control the reaction property as a heat storage material.

Spatiotemporal control of crystallization from a solution is often required for detailed exploration on mechanism of early stage of crystallization because the stochastic nature of nucleation process hinders us to chase its early stage. Recently, laser trapping-induced crystallization technique has received increasing attention as a possible candidate to realize spatiotemporally controllable crystallization.[1] In the technique, the crystallization is induced by trapping molecular clusters in a solution with optical tweezers, in which dielectric tiny particles are captured by electrical field gradient force generated by tightly focusing laser light by optical lens. This technique has actually demonstrated forced nucleation of various organic molecules from an unsaturated mother solution at the focal spot. Although recent progress of nanoscience including research on nucleation dynamics demands precise manipulation of nanoscopic objects, the conventional optical tweezers, electrical field gradient force of which relies on the focusing the laser by optical lens, has a limitation of diffraction limit on focusing the light. To overcome the limit, the use of near-field generated by localized surface plasmon resonance, which is collective oscillation of free electrons on surfaces of metal nanoparticles when light impinges on the nanoparticle, has been proposed. [2] Because the near-field is confined in nanoscale, the light focusing beyond the diffraction limit can be achieved consequently, allowing us to capture the smaller particles much tightly than the conventional method. However, the plasmonic optical tweezers has never been applied to crystallization. Here we applied plasmonic optical tweezers to crystallization of acetaminophen molecule from an aqueous solution.

Figure 1 shows schematic illustration of experimental setup. Periodic Au nanolattice the unit structure of which is gammadion with the size of 500 nm was fabricated on a cover glass by electron beam lithography. An aqueous solution of acetaminophen saturated at room temperature (24^{o}C) was dropped on the Au nanolattice, and then solution thin layer supported by the nanolattice was formed by capillarity. Near-infrared continuous-wave left-handed circularly polarized laser (1064 nm, 6.4×10^{9} W/m^{2}) was focused to the nanolattice supporting the solution thin layer by passing through an objective lens equipped on an inverted polarized-light optical microscope. In-situ microscopic observation for the vicinity of the focal spot was also performed simultaneous with the laser irradiation.

Figure 2 shows time-lapse micrographs of the in-situ observation in the vicinity of the focal spot. After the laser irradiation, crystals with the size of 1000 ~ 2000 nm were precipitated 19 mm away from the focal spot in annular pattern. The position of the annular pattern moved while following the change of in-plane position of the focal spot via dissolution/precipitation process, indicating that position of the crystal is manipulatable. When the plasmon excitation by laser irradiation was stopped, the crystals were disappeared via two-step dissolution process; the crystals first transformed to dense liquid droplets, and then the dense droplet disappeared through molecular diffusion.

Generally, large temperature gradient generates in the vicinity of the focal spot when localized surface plasmon resonance was excited, because of the heat generation through electron-phonon scattering. Thus, the large temperature gradient exerts thermophoretic force outward from the focal spot on acetaminophen molecules. Since the electrical field gradient force attracts the molecules towards the focal spot, the annular-patterned precipitation can be interpreted as the consequence of the balancing the electrical field gradient force as attractive force and the thermophoretic force as repulsive force. Therefore, our observation strongly suggested that plasmonic optical tweezers can precisely control crystallization.

Investigation of liquid cell transmission electron microscopy combined with antisolvent crystallization

*Tomoya Yamazaki[1], Yuki Kimura[1]

1. Institute of Low Temperature Science Hokkkaido University

Crystallization of salts in solutions is a quite common phenomenon in the earth and is important not only for production of materials but also for understanding geochemical processes. However, initial stage of crystallization, called nucleation, is not fully understood and numerous studies to understand the process have been reported. Recently, multistep nucleation pathway, which formations of one or more metastable phases are required on the route to a formation of a crystalline phase, have been proposed. Liquid cell transmission electron microscopy (TEM) is a promising method for observing the nucleation process directly because the spatial resolution of this method is under nanometer scale. More recently, multistep nucleation pathways of the crystals of calcium carbonate [1] and lysozyme protein [2] have been revealed by liquid cell TEM. However, capturing a moment of a nucleation event is quite difficult because the observable area of the method is small ($< 100\ \mu m^2$) and a nucleation event is typically very rare in the tiny volume within the area. In order to observe nucleation events efficiently, a supersaturation of a sample solution should be increased with observing the solution. To create the situation, we applied the anti-solvent crystallization technique, which crystallize the solute to add the solvent with the extremely low solubility of the solute (anti-solvent), to liquid cell TEM and tried to observe the nucleation event of a salt crystal.

We used the TEM holder (Poseidon 300, Protochips Inc.) and the liquid cells of silicon chips equipped with thin silicon nitride windows. Aqueous solution of sodium chlorate under equilibrium at room temperature was enclosed in the liquid cell. The TEM holder has two injection ports of liquid, and one of the ports was filled by acetone as the anti-solvent of sodium chlorate. After starting the observation of the sample solution, acetone was injected by syringe pump for mixing the aqueous solution in the liquid cell.

Using the methods, we succeeded in observing the nucleation events of crystals. In this presentation, we will report the detailed analysis of crystals and the nucleation processes.

DNA-guided crystallization of nanoparticles: optimization of crystallization conditions and structure analysis

*Miho Tagawa[1], Shoko Kojima[1], Hayato Sumi[1], Arisa Nishibu[1], Takumi Isogai[1], Maasa Yokomori[2], Shunta Harada[1], Toru Ujihara[1], Katsuo Tsukamoto[1]

Due to the programmability and self-assembly characteristic, DNA is a powerful tool for guiding the assembly of nanometer-sized particles into large-scale ordered structures. Recently, DNA-guided nanoparticle crystallization has been demonstrated and many types of crystal structures have been created[1-3]. By changing particle size ratio, DNA length and complementarity, particles assemble into different types of crystals. By TEM imaging after silica encapsulations, Mirkin et al. confirmed that some of DNA-guided nanoparticle crystals assembled into wulff polyhedra in solution[3]. However, it is crucially difficult to grow large-scale wulff polyhedral single crystal of DNA-functionalized nanoparticles (DNA-NPs) with size up to several microns. Herein, we demonstrate the optimization of solution composition on DNA-NP crystal growth, specifically the effect of sodium chloride concentration and polyethylene glycol (PEG) addition into DNA-NP colloidal solution.

Au nanoparticles of diameter 7 nm were functionalized with two different sequenced thiolated-DNA strands (DNAa and DNAb), respectively. These DNA-functionalized nanoparticles, DNA-NPa and DNA-NPb, were combined with linker DNA strands, which hybridize to complementary sequences of DNAa and DNAb (Figure 1). The mixed solutions were adjusted under different sodium chloride concentration (100, 300, 500, 700 and 900 mM) and by adding PEG with different molecular weights (1000, 4000 and 8000) and subsequently heated to 65 ºC and then slowly cooled back to 25 ºC. The crystal structure of assembled DNA-NP superlattices were analyzed by small angle x-ray scattering (SAXS) and imaged by scanning electron microscope (SEM).

We confirmed the crystal structure of assembled DNA-NP aggregates was bcc by analyzing peak positions of SAXS 1D curves. The differences were seen in SAXS and SEM data with different samples under different sodium chloride concentrations. Relatively large wulff polyhedral single crystals of DNA-NP superlattices were assembled in buffer solution under 500 mM NaCl. The significant differences were seen in SAXS and SEM data with different samples by adding PEG with different molecular weights. DNA-NP superlattices assembled in the buffer solution with PEG 1000 showed a clear SAXS 1D curve which indicates bcc structure (Figure 2) and a significant increase in average crystal size were confirmed by SEM (Figure 3).

We will also present the recent progress on the formation of lattice using DNA-NPs linked by DNA polyhedral constructs. DNA polyhedron has symmetrical connecting bonds and plays a determining role in the inter-particle bonding; that allows for control of particles coordination. DNA nanostructure-directed crystallization has a power of the proposed approach for assembly of complex nanoparticle lattices[4].

Discussion

Growth mechanism of binary colloidal crystals

*Jun Nozawa[1], Suxia Guo[1], Hiromasa Niinomi[1], Junpei Okada[1], Satoshi Uda[1]

1. Tohoku University

Colloidal crystals have been attracted great attention from wide application fields owing to their unique optical properties. Now, varieties structures of the colloidal crystal, e.g. non-closed packed structure, are significantly demanded for diverse applications. For this ends, to grow binary colloidal crystal is promising method since it displays rich structural diversity. However, in contrast to single component system, growth mechanism of binary system of colloidal crystals is poorly understood. Also, to grow large size of binary colloidal crystals with high crystallinity is still difficult. In this study, in-situ observation is conducted to reveal detailed growth process of binary colloidal crystals. Then, growth mechanism is discussed.
Polystyrene particles are employed in the experiment. Green fluorescent particles with 500 nm and red with 700 nm are employed. Crystallization of colloidal crystals is induced by depletion attraction.
We have found several features on the growth of binary colloidal crystals. First, it grows on substrate. The AB_2 structure (A: 700 nm, B: 500 nm) is found to be grown by utilizing crystals composed only of 700 nm particles. The AB_2 crystals also grow on crystals of 500 nm. The specific crystallographic orientations between those crystals are recognized. Combination of orientations between AB_2 and substrate are classified into four types. Heteroepitaxial growth is found to occur for growth of AB2 structure. Second, growth rate of binary colloidal crystals is quite small compare to that of single component system under the same particle concentration. We think this is attributed to complex structure of the crystals, which requires each particle incorporating to their own site. This process is not required for crystals composed of single component. Third, cluster formation at the interface is recognized. The ordered structure composed only of 500 nm is formed at growing interface. Particles of 700 nm is incorporated into the ordered structure generates AB_2 structure.
These observations provide great hints to reveal overall growth mechanism of binary colloidal crystals, which will lead to establish sophisticated growth technique to grow large and high quality crystals.

1. Graduate School of Engineering, Hokkaido University, 2. Faculty of Engineering, Hokkaido University

INTRODUCTION

Magnesium silicate formation at low temperature (25-200℃) is receiving a lot of attention in various research fields. Sepiolite and serpentine, crystalline Mg-clay minerals, are known to be formed in MgO-SiO_2-H_2O systems at low temperature. However, some studies have been suggesting that low-crystalline magnesium silicate recently should be formed in this low-temperature condition. These kinds of low-crystalline silicates have actively been studied by many reaserchers and engineers. For instance, calsium and alminium silicates are known as C-S-H (calcium silicate hydrate) and allophane/imogolite, respectively. These are studied for both natural minerals and synthesized materials. On the other hand, studies of the low-crystalline magnesium silicate are still in their infancy and little is known. Therefore, the nature of the low-crystalline magnesium silicate has not been clear yet. Since the magnesium silicate can be utilized in various engineering fields (e.g., improved oil recovery, CO_2 geological storage, geothermal power generation, concrete degradation, mineral clogging in radioactive waste disposal, treatment of environmental pollutions, etc.), the current reserch gaps in the understanding of the low-crystallline magnesium silicate formation need to be addresed so as to contribute positively to the above engineering technologies. Moreover, this study can also be applied to the field of planetary science because low-crystalline magnesium silicate should be observed even on surface of Mars and in interstellar silicate dusts.

ANALYSES OF NATURAL PRODUCTS

Firstly, this study confirmed that low-crystalline magnesium silicate forms in nature. Samples of precipitates were collected from the surface where fluid flows out from serpentinite rocks around Kamuikotan metamorphic belts, Hokkaido, Japan. Although a clear XRD pattern from the bulk samples was not observed, electron microscopy (Field emission scanning electron microscope and Transmission electron microscope; TEM) clearly identified the phase. TEM-energy dispersive X-ray spectrometry indicated that the low-crystalline phase was composed of Mg, Si, and O. Moreover, electron diffraction with TEM showed diffuse halo rings from some particles in the samples, showing the formation of low-crystalline phase. Furthermore, the fluid samples participating in formation of the precipitates were collected and analyzed. From the results, the fluid samples were alkaline ($9.50 < pH < 10.67$) and saturated with low-crystalline magnesium silicate phase (magnesium silicate hydrate reported by Lothernbach et al., 2018).

FLOW-THROUGH EXPERIMENTS

Secondly, to demonstrate the above formation, flow-through experiments in open system were conducted. Alkaline solution with 1.5 mM of dissolved silica was flowed into MgO powder in the reaction cell. TEM observation revealed the low-crystalline magnesium silicate formation as well. Moreover,

©2019. Japan Geoscience Union. All Right Reserved.

dissolution rate of Mg-bearing mineral and formation rate of magnesium silicate were obtained from dissolved silica and magnesium concentrations in the output solutions. These suggested that the magnesium silicate formation was extremely rapid under the oversaturated condition, and that the dissolution of Mg-bearing mineral is the rate-determining step during formation of the low-crystalline magnesium silicate. Although the flow-through experiments used only MgO as a Mg-bearing mineral, the above discussion can be applied to all of Mg-bearing minerals such as olivine and pyroxene because dissolution rate of MgO is greater than any other Mg-bearing minerals. Therefore, the flow-through experiments broaden the kinetical understanding of low-crystalline magnesium silicate formation not only at the Kamuikotan metamorphic belts, but also to other areas where the magnesium silicate is formed from the supply of Mg-bearing minerals in rocks/soil.

Homogeneous Nucleation from Vapor in Al-O Binary System

*Shinnosuke Ishizuka[1], Jun Kawano[2], Tomoya Yamazaki[3], Tetsuya Hama[3], Yuki Kimura[3]

1. National Institute for Environmental Studies, 2. Faculty of Science, Hokkaido University, 3. Institute of Low Temperature Science, Hokkaido University

A gaseous molecule can have a chemical formula that is inconsistent with its ability to act as a building block for crystals; for example, hot AlO and AlO_2 vapors cannot solidify directly to crystals. The contributions of such gases to homogeneous nucleation processes are unknown. Using in situ IR spectroscopy on nucleating nanoparticles, we show that a liquid-like behavior of nucleating nanoparticles in the Al–O system induces immiscible phase segregation. In an oxygen-deficient atmosphere, aluminum oxide nanoparticles formed with a unique shape composed of an Al metal head and an anisotropic Al_2O_3 crystalline tail. The anisotropic nanoparticles are larger than Al_2O_3 nanoparticles formed in a sufficient oxygen condition. Fewer nuclei may be available in the supersaturated gas, indicating that homogeneous nucleation is initiated by oxygen-bearing species. The nuclei grow by incorporation of Al-bearing species, changing the composition of the particle as a whole toward an Al-rich material. In situ IR measurements revealed that the degree of anisotropy continues to increase, suggesting that oxygen-bearing species also formed by oxidation on the surface of the molten Al-rich head. The scenario is supported by quantum-chemical calculations indicating that oxygen-deficient $(AlO)_n$ clusters as few as 16 molecules induce aggregation of Al atoms. Because Al metal has a significantly lower melting temperature than Al_2O_3, the immiscibility of the nucleating nanoparticles leads to vapor–liquid–solid growth. Astronomical implication will be given in the presentation.

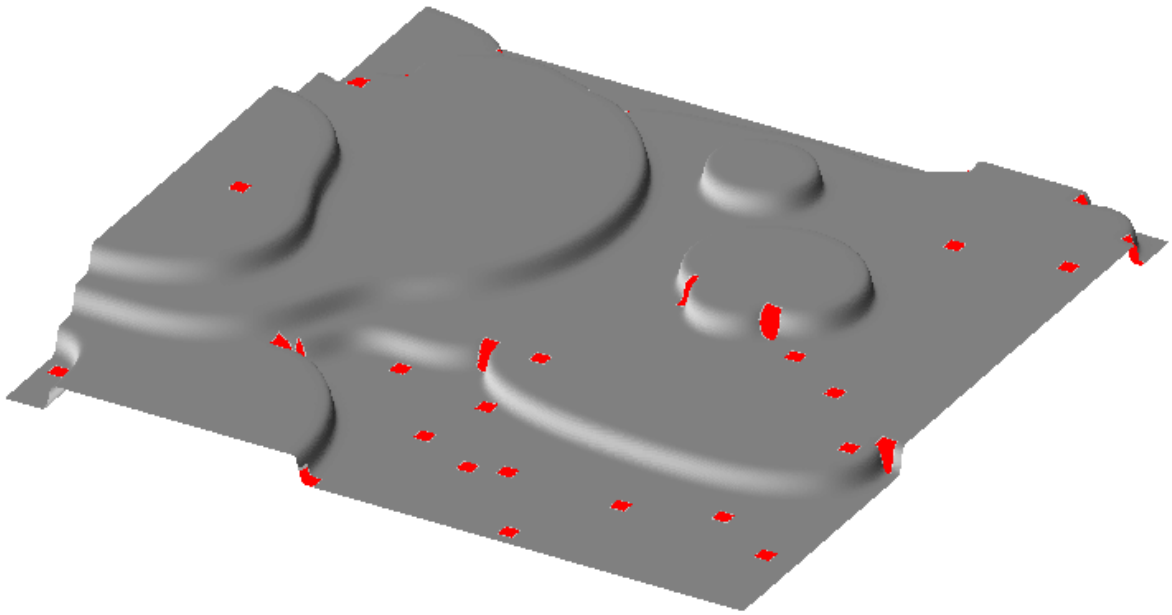
Crystal growth hysteresis in birth-and-spread mechanism

*Hitoshi Miura[1]

1. Graduate School of Natural Sciences, Department of Information and Basic Science, Nagoya City University

Crystal growth hysteresis is a remarkable phenomenon induced by impurities: the crystal growth velocity when the driving force (supersaturation or supercooling) is increased is different from that when it is decreased. It has been considered that the growth hysteresis is caused by slow adsorption of impurities onto the crystal surface. On the surface, there are steps in atomic scale that advance independently due to continuous incorporations of growth units, therefore the surface is grown layer by layer (layer-by-layer growth mechanism). The step advancement is inhibited by impurities adsorbed on the surface. However, the amount of the adsorbed impurities is also affected by the step passages: frequent step passages reduce the amount of adsorbed impurities. The competition between two timescales —impurity adsorption timescale and time interval of surface-updating (terrace exposure time)— causes complex nonlinear phenomena such as crystal growth hysteresis.



The mechanism of the crystal growth hysteresis was elucidated by a mean field theory. Punin & Artamonova [1] and Miura & Tsukamoto [2] formulated the following two effects —inhibition of step advancement by adsorbed impurities (pinning effect) and removal of adsorbed impurities by step passages (impurity sweeping)— to clarify the existence of multiple steady solutions that satisfies both of two formulas at a certain range of supersaturation. In the case of constant step interval, numerical simulations based on a phase-field method demonstrated that the growth hysteresis emerges as predicted by the mean field theory even when the physical quantities are fluctuated around these averages [3]. The phase-field simulations also confirmed the emergence of hysteresis in the case that the surface is grown by a screw dislocation [4]. However, the growth hysteresis has not been investigated in the case that the surface is grown by two-dimensional nucleation (birth-and-spread mechanism), which is another mechanism to generate new steps on the surface. The birth-and-spread growth dominates the spiral growth at high supersaturation, so it is important to elucidate the impurity-induced effect for that. In this study, we theoretically investigate the growth hysteresis in the birth-and-spread growth mechanism.

At first, we formulated the interdependence between the step velocity and the amount of adsorbed impurities based on the mean field theory, in the same way in the case of the spiral growth. As the result, we found that multiple steady solutions exist at a certain range of supersaturation. This suggests that the growth hysteresis can emerge even in the birth-and-spread growth in principle. At second, we carried out the phase-field calculation with the equivalent condition of the mean field theory. We confirmed the emergence of growth hysteresis in down-and-up cycles of supersaturation. In addition, we found that the range in supersaturation at which the growth hysteresis is observed depends on the rate of supersaturation variation: slow change in supersaturation makes the hysteresis behavior unclear.

The mineral assemblages on asteroids are useful to constrain the aqueous environments, the temperature (T), pressure (P), water to rock ratio (W/R), and bulk chemical composition, existed in them or in their parent bodies. Near- to mid-infrared (IR) reflectance spectroscopy of asteroids contains the information of the surficial minerals in their characteristic absorption features, spectral slopes, and overall brightness or darkness. Recent remote-sensing of asteroids by Hayabusa2, OSIRIS-Rex, and Dawn spacecrafts as well as telescopic observations by AKARI infrared space telescope provided detailed IR reflectance spectra of many types of asteroids. These observations would allow us to discuss the diversity of asteroids in their principle parameter space of paleo-aqueous environments: T, P, W/R, and the bulk chemical compositions. This study aims to connect the observed IR spectra of asteroids to the original bulk compositions and T-Pconditions of them or their parent bodies. We performed a series of chemical equilibrium calculations to obtain the mineral compositions. We computed the model IR reflectance spectra from the obtained mineral compositions. The chemical equilibrium calculations assumed the rocky bulk compositions of CV chondrites. We treated W/R as a parameter (0.2-10). We fixed the relative abundance of volatiles to water. The model IR reflectance spectra were calculated by adopting the radiative transfer theory for granular surfaces. The reflectance of a model mineral assemblage was computed from the weighted average of the single scattering albedos (SSAs) of endmembers. We found that the model reflectance spectra vary according to the equilibrium mineral compositions. Reducing W/R led to the darkening in overall reflectance as the dominant minerals change from bright carbonate to serpentine, gibbsite, and dark phases: pyrite, troilite, magnetite, and organics. The change in the dominant phase is visible in the characteristic absorption features: carbonate at 3.5 micro m and 4.0 micro m and serpentine at 2.7-2.8 micro m. We note that, though carbonate has a broad absorption from 2.7 to 3.2 micro m, the absorption feature of serpentine is sharp and distinguishable.Ammonia-bearing saponite more than a few wt.% shows its characteristic absorption feature at 3.1micro m in the reflectance of mixture. In this presentation, we discuss the implications for Haybusa2 and AKARI observation results.

Estimation of formation mechanism and morphological condition in calcite concretion

*Takayuki Ihara[1], Sin-iti Sirono[1]

1. Nagoya University

Iron oxide concretions were discovered on Meridiani plain by Mars explorer opportunity. The concretion found on Mars is called blueberry, it is spherical and the composition is mainly iron oxide. Concretions similar to them are found on the Navajo sandstone stratum in the United States of Utah , and is Gobi Desert, Mongolia. They are called Fe-oxide concretion. Both Fe-oxide concretion and blueberry have a spherical shell structure of iron oxide. [1] performed field work and analyzed element maps to investigate the mechanism of formation of Fe-oxide concretion of Utah and Gobi. As a result, [1] showed the formation mechanism of spherical Fe-oxide concretion as follows. In an eolian layer spherical calcite concretions were formed as a precursor. Second, acidic groundwater containing iron ions flows into it and reacts with $CaCO_3$ and iron precipitates in a spherical shell shape. Furthermore, [1] indicated that the iron contraction of Mars is a similar mechanism. However, the formation mechanism of spherical calcite concretion as a precursor is not known. If we can clarify the formation mechanism, we can restrict the ancient environment of Earth and Mars.

In this study, we focused on calcite concretion produced in an eolian layer. Calcite concretion of the eolian layer is produced in three forms, spherical, plate-like, fish egg (globular gathering state). It is aimed to clarify the forming mechanism and the forming conditions in indoor experiments. We will report the current experiment status. $CaCO_3$ is precipitated by evaporation in Utah's sand. In order to increase the solubility of the $CaCO_3$ aqueous solution, CO_2 is blown into the solvent. $Ca(HCO_3)_2$ is made in the solvent. By evaporating it $CaCO_3$ is precipitated in the layer of sand to generate a concretion. Then $Ca(HCO_3)_2$ is made in the solvent. It evaporates to precipitate $CaCO_3$ in the layer of sand.Utah's sand has an average particle diameter of 150 μm (Kawakami 2015). The minimum size of calcite concretion and Fe-oxide concretion discovered on Earth is several mm in diameter [2] and experiments are conducted with the aim of creating the size. $CaCO_3$ concentration and evaporation rate are changed as parameters. X-ray CT is used to analyze $CaCO_3$ in the experimental layer. In order to investigate whether $CaCO_3$ and sand can be distinguished from X-ray CT images, a experiment was conducted when $CaCO_3$ precipitated in the sand layer. The simulated sample was prepared by mixing sand from Navajo sandstone and a few mg of $CaCO_3$. As a result of the X-ray CT experiment, it was confirmed that a $CaCO_3$ having a size of 0.50 mm can be discriminated at a resolution of 0.019mm/pixel. It was also found that $CaCO_3$ and sand are close in density, so it can not be determined that $CaCO_3$ is not sufficiently larger than the average particle diameter of sand 150μm.

In the future, we will analyze the samples prepared in the experiment and try experiments under various conditions by adding experimental parameters as well as $CaCO_3$ concentration, evaporation rate and sand filling rate. Then we will clarify the formation mechanism and the morphological condition of calcite concretion in the eolian layer.

Reconstructing groundwater hydrology and water-rock reactions around Gale Crater on early Mars

*Natsumi Noda[1,2], Yasuhito Sekine[1], Shuya Tan[1,2], Takazo Shibuya[3], Hidenori Genda[1]

1. Earth-Life Science Institute, Tokyo Institute of Technology, 2. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, 3. Department of Subsurface Geobiological Analysis and Research, Japan Agency for Marine-Earth Science and Technology

NASA's Mars Science Laboratory Rover, Curiosity, has provided key information on geochemistry and mineralogy of the lacustrine sediments deposited within Gale Crater on early Mars(e.g. Grotzinger et al. 2015, Rampe et al. 2017). Gale's lacustrine mudstones of Murray Formation are characterized by authigenic depositions of high levels of silica (e.g., opal CT and amorphous silica) together with iron oxides (e.g., magnetite and hematite), suggesting inputs of dissolved SiO_2 and Fe^{2+} into the early Gale lake (Hurowitz et al. 2017). One possible source of dissolved SiO_2 and Fe^{2+} is upwelling groundwater. However, little is known about the conditions of both climate and water table capable of upwelling groundwater into Gale Crater. Additionally, the chemical compositions of groundwater on early Mars, particularly the determining factors of concentrations of dissolved SiO_2 and Fe^{2+}, have been poorly constrained.

Here, we perform both hydrological modeling and hydrothermal experiments to interpret the observations. Based on the simulation and experimental results, we discuss the climate, groundwater hydrology, and input fluxes of dissolved SiO_2 and Fe^{2+} of Gale lakes.

In the hydrological modeling, we perform three-dimensional hydrological simulations for the area surrounding Gale Crater using GETFLOWS, which deals with fully-coupled surface and subsurface flows based on the hydro-geophysical equations. We find two modes of the lake distribution and groundwater flow around Gale. One is the high-evaporation mode where multiple shallow lakes can appear at local topographic lows owing to vigorous upwelling of groundwater under (semi-)arid climate conditions. The other is the low-evaporation mode where lake(s) exists only at the lowest place(s) under relatively humid climate conditions. To explain both a closed-basin lake within Gale Crater and some lakes around Gale, the high-evaporation mode is most likely to have occurred on early Mars. Our results suggest (semi-)arid climate conditions around Gale with a shallow water table. Under the arid climate conditions, evaporation of lake water would have caused effective upwelling of groundwater. Given thermal gradient within the crust, such upwelled groundwater would have experienced hydrothermal reactions with the crustal rocks.

In the hydrothermal experiments, we simulate high-temperature water-rock reactions between groundwater and Martian crustal rocks. Hydrothermal reactions at 200ºC between a synthesized Martian rock analog and fluids are performed using a Dickson-type apparatus. Various secondary minerals, such as analcime, quartz, albite, Fe(Mg-)saponite, Fe(Mg-)serpentine, and trace carbonates are also formed via the hydrothermal reactions. We find that dissolved SiO_2 concentration (1–10 mM) is buffered by dissolution of quartz; whereas, that of Fe^{2+} (~10^{-3} mM) is likely controlled by dissolution of Fe-carbonate (siderite).

Combining these simulation and experimental results, we estimate the input fluxes of dissolved SiO_2 and Fe^{2+} contained in upwelled groundwater into Gale lakes. The flux of dissolved SiO_2 corresponds to ~0.02–0.2 mm/year of the deposition rate of silica, implying that the parallel laminae of the lacustrine

©2019. Japan Geoscience Union. All Right Reserved.

mudstone(Grotzinger et al. 2015) may be varve. This further suggests ~10^5 years of warming periods to explain the thickness of Murray Formation. Upwelling groundwater might have also provided Fe^{2+} into the lake, leading to formations of Fe oxides and H_2. Our results suggest that low-latitude deep craters, including Gale, would have played key roles in upwelling deep groundwater at arid climates in the global hydrological cycles, providing reductants and greenhouse effect gas to the surface of early Mars.

Habitable zone for a land planet

*Takanori Kodama[1], Hidenori Genda[2], Ryouta O'ishi[3], Ayako Abe-Ouchi[3]

Most of the studies for habitable planets have focused on Earth-like planets with globally abundant water on the planetary surface. Liquid water vaporizes entirely when planets receive the insolation above a certain critical value, which is called runaway greenhouse threshold. On the other hand, the planetary climate state lapses into a snowball state when planets receive insolation below a certain value, which is called the complete freezing threshold. The habitable zone, in which planets can maintain liquid water on their surface for a long term, is determined by these thresholds.

Abe et al. (2011) focused on so-called land planets with a very small amount of water, and investigated these thresholds using a three-dimensional general circulation model. As results, they found that land planets have a wider habitable zone than Earth-like planets have. However, it is not enough to understand the relationship between the distribution of water and the climate because their range of the amount of water is extremely narrow, leading the almost same distribution of liquid water on the planetary surface.

We assumed various types of the surface water distribution, and investigated the effect of those on both the runaway greenhouse threshold and the complete freezing threshold for Earth-sized planets using a three-dimensional general circulation model. We consider the surface water distributions as longitudinally uniform water distribution and a 1-bar atmosphere whose composition is similar to the current Earth’s atmosphere. As results, both thresholds change gradually depending on the distribution of surface water. Additionally, they are dominated by the atmospheric circulation which determines the surface condition.

A study on the dependence of ocean planet climate on solar constant: influence of oceanic heat transport in the case of large absorption coefficients of gray atmosphere

*Yuta Kawai[1,2], Yoshiyuki O. Takahashi[1], Masaki Ishiwatari[5], Kensuke Nakajima[3], Shin-ichi Takehiro[4], Hiroki Kashimura[1,6], Seiya Nishizawa[2], Hirofumi Tomita[2], Yoshi-Yuki Hayashi[1,6]

1. Introduction

In order to reveal the diversity of climate realized on planets with water and climate stability, our research group has been exploring climates on idealized planets. Ishiwatari et al. (2007) (INTH07) investigated solar constant dependence of climates on swamp ocean planet using a 3-dimensional atmospheric general circulation model, although oceanic heat transport is not considered. Since oceanic heat transport also affects planetary climates, for example, Rose (2015) (R15) explored climates on a planet globally covered with ocean (referred to as “ ocean planet”, here) with a coupled atmosphere-ocean-sea ice model, and showed the importance of oceanic heat transport for the climates. Recently, as an extension of INTH07, we also have investigated solar constant dependence of ocean planet climates with our coupled model. Representing ocean general circulation obviously changes atmospheric fields. However, the displacement of ice-line is small and there is no qualitative change of climate regime diagram which represents the relation between solar constant and ice-line latitude. We imagine the reason is that the variation of temperature with solar constant in partially ice-covered states obtained from gray radiation setting of INTH07 is quite smaller than that in R15. Therefore, we perform further experiments in the case of large absorb coefficients. In this presentation, the experimental results will be shown.

2. Model and Experimental setup

The model used here is our constructing coupled atmosphere-ocean-sea ice model. The atmosphere model is DCPAM, in which the 3-dimensional primitive equations are solved. Most of the atmospheric setting is same as that in INTH07, except absorb coefficients of water vapor and dry air in the gray radiation scheme are replaced with larger values, 1×10^{-1} and 1×10^{-5} [m^2/kg], respectively. The ocean and sea-ice model are zonally averaged 2-dimensional models. In the ocean model, the hydrostatic Boussinesq equations are solved, and mixing due to mesoscale eddies and convection is parameterized. The sea-ice model is a vertically 1-dimensional thermodynamics model, and the transport is represented by horizontal diffusion. The value of surface albedo is 0.5 if surface temperature is lower than 263 K, otherwise 0, but the value on grid-point is given considered the sub-grid distribution of surface temperature. In addition to experiments with the coupled model, in order to evaluate the effect of oceanic heat transport, we also perform experiments in which dynamic ocean is replaced with slab ocean. The number of atmosphere model grid is 64x32x16. The number of grid points on the ocean and sea ice models is 64x60 and 64, respectively. For most cases, the initial condition is a rest atmosphere and ocean with 280 K, but various solutions are also used. The temporal integration for slab ocean cases is basically performed over about 300 years, and, for dynamic ocean cases, over about 30,000 years with periodically synchronous coupling.

3. Results

©2019. Japan Geoscience Union. All Right Reserved.

By specifying absorb coefficients larger than that in INTH07, features of climate regime diagram are significantly changed. In dynamic ocean experiments, partially ice-covered states are obtained over 1040 ≦ S ≦ 1055 W/m^2, where S is the solar constant. The solar constant at which partially ice-covered states are obtained becomes about 300 W/m^2 smaller and the range of solar constant becomes much narrower. We also confirm the appearance of runaway greenhouse state for S > 1070 W/m^2. The latitudinal extent where large ice-cap instability occurs is wider. Although it is not easy to obtain partially ice-covered state whose ice-line is lower than 40 degrees latitude, we can discover stable partially ice-covered state with about 30 degrees ice-line when initial state and variation of solar constant are carefully chosen. Because this behavior indicates two branches for the partially ice-covered state, similar to that in R15, and we will carefully investigate the existence of solutions with low ice-line latitude. In slab ocean experiments, there are no partially ice-covered states. Therefore, we consider partially ice-covered states in dynamic ocean experiments are maintained by oceanic heat transport. Note that the setting here produces the large variation of temperature with solar constant, as calculations in R15, and the parameter range over which partially ice-covered states are obtained is potentially very narrow. It is possible that the resolution and formulation of models strongly affect the results. To evaluate the probabilities, it is necessary to conduct further experiments using slightly different parameters.

It is believed that Mars underwent drastic climate change, changing its environment from warm and wet to cold and dry. This gives rise to the idea that Mars may have hosted life in the past, and indeed, may do so even today. Atmospheric and water evolution is thus an important key to understanding the history of Martian habitability. Mars must somehow have lost most of its atmosphere and water. The evolution of the Mars environment is thought to have proceeded by some combination of atmospheric escape to space and surface-subsurface adsorption. Especially, a lack of global magnetic field on Mars must have a significant impact to the atmospheric escape. The upper atmosphere is the primary reservoir for atmospheric escape. Owing to the technical difficulties associated with observations, datasets of the upper atmosphere are limited. However, the last decade has seen a renewed interest in the upper atmosphere, thanks to the aggressive explorations by the Mars Reconnaissance Orbiter (MRO), Mars Express(MEX), and Mars Volatile Evolution (MAVEN) missions. Recent studies have highlighted various interesting facts related to the efficient of material/water transport from the lower to upper atmospheric reservoir which have an impact on the atmospheric escape or evolution.

High-altitude (above 60 km) H2O was first identified by SPICAM occultations [Maltagliati et al., 2011, 2013] in the southern summer, which happens to be a dusty season at a solar longitude of 240 degree or later. Chaffin et al. [2017] demonstrated that the high-altitude H2O can considerably increase H escape on the weekly timescale, which can potentially explain the observations. Purpose of this study is to clarify the mechanism for upward transport of H2O into the upper atmosphere and formation of the detached layer of H2O and aerosols, by using multi-spacecraft dataset in order to cover whole altitude range from lower to upper atmosphere.

Here we report the detection of an extensive layer of warm air at altitudes 70-100 km on the night side that we interpreted as the result of combinations of aerosol heating, thermal tides, and/or global circulation. Such a strong warm layer for which the current models have no explanation can maintain temperature to evaporate water ice adsorbed on the aerosols and can form the detached layer of water vapor. We also measured the mesospheric distribution sub-micron aerosols is abundant than our expectation at altitudes 70-100 km. Such a detached layer of aerosol can potentially explain the warm layer, and this implies the importance of aerosols for key processes in the Martian water cycle and climate as a whole. The remarkable heating at altitudes 70-80 km was also confirmed by our dedicated ground-based observations during global dust storm 2018. The new pathway of water loss proposed by this implies much higher loss to space, in addition to the diffuse-limited escape of H2.

[M-IS21] Gas hydrate in environmental-resource sciences

convener:Hitoshi Tomaru(Department of Earth Sciences, Chiba University), Akihiro Hachikubo(Kitami Institute of Technology), Atsushi Tani(Graduate School of Human Development and Environment, Kobe University), Shusaku Goto(Institute for Geo-Resources and Environment National Institute of Advanced Industrial Science and Technology), Chairperson:Naoto Ishida, 戸丸 仁

An increasing number of researches focusing on natural gas hydrates has recently been conducted from the environmental, material, and resource scientific viewpoints. This session aims to share and discuss the latest research results associated with natural/experimental gas hydrates to understand and examine the nature and potential of gas hydrates in the past-present-future of the Earth and the development/application for our life. Because the researches on gas hydrates are interdisciplinary, broad topics from field and experimental researches, modeling, etc. will be presented in this session.

Discussion

Equilibrium pressure of clathrate hydrates encaged $^{13}CH_4$

*Yuki Kikuchi[1], Akihiro Hachikubo[1], Takahiro Ozeki[1], Satoshi Takeya[2]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Methane molecule is composed of carbon and hydrogen, and three kinds of isotopologues, $^{12}CH_4$ (98.9%), $^{13}CH_4$ (1.1%), and CH_3D (0.013%) exist in nature. We often measure stable carbon isotope ($^{13}C/^{12}C$) of methane to understand its gas origin. Since their weight of isotopologues differ with each other, physicochemical properties of them are also different. Pure methane hydrate must be "mixed-gas hydrate" of their isotopologues. Ozeki *et al.* (2018) measured an equilibrium pressure of CH_3D hydrate, but that of $^{13}CH_4$ has not been studied yet. Fractionation of hydrogen isotope of methane during the formation of methane hydrate has been reported by Hachikubo *et al.* (2007) that δ D of hydrate-bound methane becomes several ‰smaller than that of residual methane. This result suggests that the equilibrium pressure of CH_3D hydrate is larger than that of CH_4 hydrate, and Ozeki *et al.* (2018) demonstrated the difference between these equilibrium pressures. Since Hachikubo *et al.* (2007) showed no isotopic fractionation in methane $\delta^{13}C$, the equilibrium pressures of $^{12}CH_4$ and $^{13}CH_4$ hydrates are thought to be almost the same. In this study, we measured the equilibrium pressures of $^{13}CH_4$ hydrate to check the difference from that of $^{12}CH_4$ hydrate.

Methane hydrate samples were synthesized in small pressure cells (volume: 5 mL). Fine ice powder (1g) was put in a pressure cell, and introduced $^{13}CH_4$ (purity: 99.5%, Taiyo-Nissan). Clathrate hydrate was formed by melting the ice powder at the temperature of 273.2K under high pressure of methane. We also prepared normal methane (purity: 99.99% for methane, but 98.9% for $^{12}CH_4$, Takachiho Chemical Industry Co. Ltd.) hydrate as a reference, using the same preparation method. These pressure cells were placed in a temperature-controlled liquid bath, and measured their equilibrium pressures from 269.5K to 277.9K.

The difference in equilibrium pressure between $^{13}CH_4$ and normal methane (mainly $^{12}CH_4$) hydrates was smaller than the measurement error. This results agree with the previous report by Hachikubo *et al.* (2007).

Hydrogen isotopic fractionation of ethane encaged in different crystallographic structure

*Jumpei Matsuda[1], Akihiro Hachikubo[1], Satoshi Takeya[2]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Methane and ethane mixed-gas hydrate forms the cubic structure II in appropriate gas composition. Hachikubo *et al.* (2009) measured isotopic compositions of Lake Baikal gas hydrates and showed that δD of hydrate-bound ethane in the structure II is smaller than that in the structure I. These results might be explained by the difference in hydrogen isotope fractionation between formation processes of the structure I and II. In the last JpGU meeting we reported that the isotopic difference between gas and hydrate phases increased to 9-12‰ in the case of the structure II, whereas the difference was 1-2‰ in the case of the structure I. However, the effect of methane on the isotopic fractionation of ethane is unknown. In this study, we choose argon instead of methane and synthesize argon and ethane mixed-gas hydrates to check the isotopic difference in ethane between gas and hydrate phases.

0.7 g of fine ice powder was introduced in a pressure cell (volume: 30 mL). Argon and ethane mixed-gas were introduced in the cell and gas hydrate sample formed at 274.2 K. Before the retrieval of gas hydrate sample, residual gas was sampled, and then gas hydrate was cooled at the temperature of liquid nitrogen and retrieved the hydrate-bound gas. We controlled the ethane composition of initial gas from 3% to 25%. We measured compositions of argon and ethane by a gas chromatograph, and hydrogen isotopic composition (δD) of ethane by a CF-IRMS. Crystallographic structure of gas hydrate was determined using a Raman spectrometer, because the Raman spectra (around 1000 cm^{-1}) of C-C stretching mode of ethane in hydrate phase provide information of the crystallographic structure.

Because ethane was concentrated into hydrate phase rather than argon, ethane compositions of hydrate-bound gas distributed from 30% to 71%. In the case of low concentration of ethane, crystallographic structure II forms due to the effect of argon (the structure II former). δD of hydrate-bound ethane was about 4-7‰ smaller than that of residual ethane in the case of structure II, where ethane composition was 30-36% in the hydrate phase. On the other hand, in the case of high concentration of ethane (around 70% in the hydrate phase) δD of hydrate-bound ethane was around 2‰ larger than that of residual ethane. In the transition zone between the structures I and II the isotopic difference between hydrate and residual gas phases seemed to be an intermediate value (1-4‰). From these results we can conclude that light ethane (C_2H_6) prefers to be encaged into the structure II clathrate hydrate, compared to heavy ethane (C_2H_5D).

Trend of effect of temperature on C–H symmetric stretching vibrational frequencies of hydrocarbon molecules in 12, 14 and 16-hedra cages of gas hydrates

*Go Fuseya[1], Satoshi Takeya[2], Akihiro Hachikubo[1]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Clathrate hydrates are crystalline inclusion compounds that consist of guest molecules of suitable sizes and shapes trapped in well-defined cages formed by water molecules. Clathrate hydrates with natural gases as guest molecules are commonly known as gas hydrates. Gas hydrates with enclathrated hydrocarbon gases that exist in sea or lake bottom sediments and permafrost layers have attracted considerable interest as a potential source of unconventional natural gas.

There are three common crystallographic structures of hydrates, structure I (sI), structure II (sII), and structure H (sH). The unit cell of sI hydrates are composed of two pentagonal dodecahedral (5^{12}) and six tetrakaidecahedral ($5^{12}6^2$) water cages. The unit cell of sII hydrates are composed of sixteen 512 cages and eight hexakaidecahedral ($5^{12}6^4$) water cages. Small guest molecules such as methane (CH_4) or ethane (C_2H_6) form sI hydrates and larger molecules such as propane (C_3H_8) form sII hydrates.

In this study, we observed the variations of Raman shifts of C–H symmetric stretching vibrations of various hydrocarbons encaged in $5^{12,}$ $5^{12}6^2$ and $5^{12}6^4$ cages of sI and sII hydrates. By changing temperature, we investigated variations of Raman shifts of C–H symmetric stretching vibrations of guest hydrocarbons. It was revealed that the vibrations of guest hydrocarbons in smaller sI 51262 cages were greater than those in bigger sII 51264 cages. These results are inconsistent with our prediction in earlier study (Fuseya et al. 2018), that is, the volume of host water cages increases, and the variations of the Raman shifts of C–H symmetric stretching vibrations of guest hydrocarbon molecules in host water cages due to change temperature increase. Taking into account the facts obtained in this study and in our earlier study, we conclude that the temperature change of Raman shifts of C–H symmetric stretching vibrations is affected by geometric asymmetry of host water cages.

The study on relations of the methane plume and atmospheric methane concentration

*Chiharu Aoyama[1]

1. Tokyo University of Marine Science and Technology

PurposeWhen methane seeps out to the sea from the seabed, the following need to be observed and confirmed if the water concentration remains the same. High methane concentration in the atmosphere directly above the seeping point and separation of methane hydrate into gas and water. Then, by confirming the impact on the environment, we propose a survey method for environmental impact assessment of surface methane hydrate.**Method**The experimental site of this research was Umitaka Spur in offshore Niigata prefecture where a large amount of surface methane hydrate plumes is confirmed and investigated on the DAIIICHI KAIYOMARU(KAIYO Engineering). The experimental period was two days, August 6 and August 7.Atmospheric methane concentration was measured during this experiment using LI-7700 (LI-COR) which introduced Flux measurement to measure ppm of specific substances present in the atmosphere. Methane concentration was measured by LI-7700 which was attached to the upper bridge so it will not be affected by the exhaust of the ship. We measure the concentration of methane in the atmosphere from departure to arrival and graphed the data every hour.Using a quantitative echo sounder, we also explored if methane plumes exist underwater the atmospheric methane concentration becomes higher.**Summary** Methane concentration in the atmosphere of the sea, the area near directly above, in the sea area where the methane seeps from the seabed to the sea tends to rise. **Proposal for environmental impact assessment** When extracting surface methane hydrate and at experimental stages at sea, it is effective to monitor methane concentration on the sea, not in the seawater to detect sudden seepage of methane into seawater as soon as possible. Even if methane hydrate leaks into the sea, there is no change in sodium concentration, so we do not have be concerned about the influence on the environment.

Sampling of Methane Bubble Plumes and Solid Gas Hydrate on the Cascadia Margin, Pacific Northwest

*John E Lupton[1], Tamara Baumberger[1], Robert W. Embley[1], Susan G. Merle[1], Camilla Wilkinson[1], Conrad Young[2]

1. NOAA Pacific Marine Environmental Laboratory, Newport, Oregon, USA, 2. Young Engineering, Ramona, CA. USA

The Cascadia Margin along California, Oregon, and Washington is host to hundreds of offshore methane seeps that produce bubble streams that ascend through the water column. In addition to the bubble streams, seismic reflection studies have detected the presence of extensive methane hydrate deposits beneath the seafloor. There are also a few sites along the Cascadia Margin where hydrate deposits are exposed and visible on the seafloor. During an expedition in 2016, our group used an ROV to collect uncontaminated samples of the bubble stream gas at several Cascadia Margin sites using special gas-tight bottles. Although we have successfully obtained samples of the bubble streams, the question remains as to whether the bubble streams are produced by the dissociation of hydrate, or instead represent free gas ascending through the sediment. We have developed a new sampler in which small samples of hydrate can be hermetically sealed into a small gas-tight volume in-situ while incorporating only a small amount of ambient seawater. The hydrate is then allowed to dissociate in the sample volume without exposure to air or other contaminates. During a return expedition to the Cascadia margin in June 2018 we successfully sampled solid methane hydrate at two sites using this new sampler and also collected additional samples of the free gas bubble streams. The paper will compare the results from these hydrate collections with the composition of the free gas.

[M-IS21] Gas hydrate in environmental-resource sciences

convener:Hitoshi Tomaru(Department of Earth Sciences, Chiba University), Akihiro Hachikubo(Kitami Institute of Technology), Atsushi Tani(Graduate School of Human Development and Environment, Kobe University), Shusaku Goto(Institute for Geo-Resources and Environment National Institute of Advanced Industrial Science and Technology), Chairperson:八久保 晶弘(北見工業大学), 戸丸 仁

An increasing number of researches focusing on natural gas hydrates has recently been conducted from the environmental, material, and resource scientific viewpoints. This session aims to share and discuss the latest research results associated with natural/experimental gas hydrates to understand and examine the nature and potential of gas hydrates in the past-present-future of the Earth and the development/application for our life. Because the researches on gas hydrates are interdisciplinary, broad topics from field and experimental researches, modeling, etc. will be presented in this session.

In previous studies, methane emissions from the seabed have been reported worldwide. The reports that methane reached the atmosphere are limited to some sea areas with shallow water depths in the Arctic Ocean. Most of the researches reported that methane does not reach the atmosphere in many other sea areas and is decomposed in the water column. However, a methane hydrate shell is formed on the surface of methane bubbles released from the seabed in the gas hydrate stability zone. The methane hydrate shell delays the dissolution of methane in the water column. Therefore, a system efficiently transports methane to a shallow location in the ocean. It is difficult to clarify the amount of methane carried by this transport system and it is pointed out that some methane may release into the atmosphere. As methane is one of the greenhouse gases like carbon dioxide, release to the atmosphere leads to an increase in atmospheric concentrations and can be a cause of climate change. On the other hand, if an increase in atmospheric concentration occurs, there is a possibility that it can help in searching the methane hydrate-bearing area from the observation with the artificial satellite. Our objectives were to investigate the influence of gas seep from the sea floor on atmospheric methane concentration. In this study, we performed continuous measurement of atmospheric methane concentration, observed gas plume and measured water temperature profile by CTD. The survey area is the Japan Sea (7 K 14 and 7 K 15 cruises) where the gas plumes were reported and the Pacific Ocean (MR 15 - 3, KH 16 - 3, KH 17 - 3 cruise) as the control area. The upper limit of the stable region of methane hydrate was estimated from the water temperature profile by CTD and the phase equilibrium curve of methane hydrate in seawater for each sea area. Atmospheric methane concentration observed in the Pacific Ocean at 1.9 ppm slightly higher than the average concentration of the whole earth. Atmospheric methane concentration observed around the Japanese islands was also the mode of 1.9 ppm, which was the highest in methane concentration (> 2.1 ppm) compared with other sea areas only in the Mogami trough and off Abashiri. As gas plume was observed in these two regions, it seems that capture the influence of the gas plume on the atmosphere. However, since the methane concentration observed in other gas plume sites (off Tokachi and off Hidaka) was almost unchanged from those in which no gas plume was observed, all gas plumes did not always influence atmospheric concentrations. A high methane concentration was observed only the surrounding of the gas plume at Mogami trough and off Abashiri. However, high concentrations are not always observed when passing through the same gas plume point, but different concentrations are observed depending on time. This is considered to be caused by the methane discharged from the sea floor is flowed by ocean currents and offshore winds, and the amount of methane discharged has changed. The upper limit of the gas hydrate stability estimated from the water temperature profile was slightly shallow in off Abashiri and Mogami trough. Heeschen et al. (2003) reported that the height of the gas plume coincided with the water depth at the upper limit of the gas hydrate stability, but the gas plume observed shallower than a depth of the upper limit off Abashiri. This results suggested that methane emitted from the seafloor reaches the atmosphere at not only the gas plume with shallow water depth but the gas plume with a shallow upper limit of the gas hydrate stability. This study was conducted under the commission from AIST as a part of the methane hydrate research project funded by METI (the Ministry of Economy, Trade, and Industry, Japan). Reaction/fixation/migration of methane within the gas chimney on the Umitaka Spur, eastern margin of the Japan Sea

*Hitoshi Tomaru[1], Ryo Matsumoto[2]

1. Department of Earth Sciences, Chiba University, 2. Gas Hydrate Research Laboratory, Meiji University

Pore water geochemistry has reported that methane is oxidized anaerobically by sulfate (anaerobic oxidation of methane: AOM) at the sulfate-methane interface (SMI), and the methane flux has been estimated using the sulfate gradient or SMI depth. The methane flux is therefore an essential factor for assessing the near-seafloor environment of high methane potential area. Gas chimney, characterized by active methane migration, often associates with methane hydrate accumulation just below the seafloor and methane plume in the overlying water column on the Umitaka Spur, eastern margin of the Japan Sea. However, the behavior of these methane cannot be examined by the change of sulfate concentration, direct measurements of the amount of methane in hydrate phase and methane seepage are required. In this research, we estimated the amount of methane that is 1) oxidized at SMI via AOM, 2) fixed in gas hydrate deposit, and 3) released into water column, using independent data sets recently obtained on the Umitaka Spur, respectively, in order to understand more practically the behavior of methane within the gas chimney.
The methane flux oxidized at the SMI was calculated to be >600 mmol/m^2/yr using the SMI depth of <1 mbsf within the gas chimney. Assuming that the methane flux has been constant and all the methane has formed hydrates of 6×10^8 m^3 within 200×250 m gas chimney in <363 ka (data from METI coring), the methane flux directly associated with hydrate was estimated to be >1500 mmol/m^2/yr. The methane flux released into the water column was calculated to be <5 mmol/m^2/yr using the methane concentration in bottom water of <1500 nM and bottom water current of <10 cm/s. These numbers are still tentative because sedimentation rate within gas chimney is rather variable among sites, gaseous methane in sediment must be accounted, a part of methane hydrate has dissolved during massive accumulation of hydrate body, etc. However, recent intensive researches on the shallow gas hydrate system have provided the better understanding of total methane behavior within the gas chimney.
This study was conducted partially under the commission from AIST as a part of the methane hydrate research project funded by METI (the Ministry of Economy, Trade and Industry, Japan).

Slope failures induced by methane hydrate dissociation: a case of submarine slide in the southwestern Oki Trough, Japan Sea

*Naoto Ishida[1], Shota Morihita[2], Takao Ebinuma[1], Hitoshi Tomaru[3], Ryo Matsumoto[4]

1. Social Systems and Civil Engineering, Graduate School of Engineering, Tottori University, 2. Department of Social Systems and Civil Engineering, Faculty of Engineering, Tottori University, 3. Department of Earth Sciences, Faculty of Science, Chiba University, 4. Gas Hydrate Research Laboratory, Organization for the Strategic Coordination of Research and Intellectual Properties, Meiji University

A huge submarine slide in the Oki Trough, Japan Sea, was examined from the viewpoint of methane hydrate dissociation due to BGHS (Base of Gas Hydrate Stability) fluctuation. The submarine slide, which occurred 34 ka, is located in the southwestern slope of the Oki Trough having a 1.6 degrees slant. Geothermal gradients were measured at the 700 m and 1000 m water depths by the side of the slide as 83.13 mK/m and 99.42 mK/m, respectively. Based on our simulation, the BGHS was situated just below the landslide masses at the time of the slope failure. The response of BGHS to the external factors, e.g. sea-level change, sedimentation, etc., is prominently involved in methane hydrate disassociation, which makes the submarine ground unstable. Relation between the slope failure and the methane hydrate disassociation is strongly suggested in the study case.

Unpublished data by surveys conducted under the commission from AIST as a part of the methane hydrate research project funded by the Ministry of Economy, Trade and Industry, Japan was used in this study.

Origin and evolution of H_2S-bearing methane hydrate in the Sea of Japan

*Ryo Matsumoto[1], Tomoko Fukazawa[2], Akihiro Hiruta[1], Glen Snyder[1]

1. Organization for the Strategic Laboratory of Research and Intellectual Properties, Meiji University, 2. Department of Applied Chemistry, School of Science and Technoloty, Meiji University

Thick massive deposits of hydrates of the Sea of Japan have accumulate in gas chimneys in two steps. The first step is related to a 25 million years' rifting of the Sea of Japan, characterized by a high heat flows, high TOC sediments and a tectonic inversion at a few million years ago. Tectonic inversion has developed deep reverse faults and tight folds with open fracture systems, which facilitated the development of gas chimney structures. Second one is a glacial-interglacial cycles for a few 100 ka. Eustatic sea level fall resulted in a shoal up the base of gas hydrate stability (BGGS), dissociation of deep-seated hydrates, and enhanced methane-flux and massive accumulation of hydrates. Shallow hydrates are characterized by high H2S contents up to a few %v/v, reflecting AOM in shallow subsurface. Shallow H2S-bearing hydrates have repeatedly and intermittently accumulated on the top of gas chimneys at glacial period, while the H2S contents rapidly decreased with depth due to recrystallization perhaps through molecular diffusion during burial diagenesis. Key conditions to develop massive deposits of shallow hydrates are strong flux of mixed-microbial and thermogenic gases and a recycling of deep-seated hydrates during the glacial-interglacial.

Discovery of gas hydrate at the new point off Abashiri, the Sea of Okhotsk

*Akihiro Hachikubo[1], Jumpei Matsuda[1], Satoshi Yamashita[1], Hirotoshi Sakagami[1], Masaaki Konishi[1], Hirotsugu Minami[1], Kenji Nishina[2], Kenji Sakaguchi[3]

1. Kitami Institute of Technology, 2. Geological Survey of Hokkaido, Hokkaido Research Organization, 3. Kushiro Fisheries Research Institute, Hokkaido Research Organization

To understand environment of near-surface gas hydrates at the sea floor, HKS16, HKS17, and HKS18 cruses were conducted using RV Hokushin-Maru (255t) of the Kushiro Fisheries Research Institute off Abashiri, the Sea of Okhotsk, in a framework of joint research between Kitami Institute of Technology and Hokkaido Research Organization. We report success in retrieval of hydrate-bound sediment cores using a research vessel belonging to Hokkaido Prefecture. In this area, natural gas hydrates have been recovered in the NT13-20 and C020 cruises using RV Natsushima and TS Oshoro-maru, respectively. We also observed gas hydrate crystals with many crabs at the seepage sites using a remotely operated vehicle (ROV, KAIYO3000) in the 1KY17 cruise. In the cruise of HKS18, we got gas hydrate samples from a gas seepage site, located 2 km south from the 1KY17 site.

In the HKS18 cruise, we used a hydrostatic corer optimally tuned for a small vessel and a transponder to know exact position of the corer. We obtained nine sediment cores, including two hydrate-bound cores. Gas hydrate crystals were preserved in liquid nitrogen, and sediment gases were obtained by a headspace gas method. Raman spectroscopic analysis was conducted to know crystallographic structure, hydration number and cage occupancies. Molecular and isotopic compositions of gas samples were measured using a gas chromatograph and an isotope ratio mass spectrometer, respectively.

Crystallographic structure of gas hydrate samples belonged to the structure I, and hydration number was estimated as 6.00±0.02. Hydrate-bound H_2S molecules were also detected in the Raman spectra. Hydrate-bound gas was mainly methane, and C_1 / (C_2 + C_3) distributed between 30,000 and 60,000. C_1 $\delta^{13}C$ and δD were -66‰ and -197‰. These molecular and isotopic compositions of hydrate-bound hydrocarbons suggested microbial origin. The depths of sulfate-methane interface (SMI) in HC1807, HC1808, and HC1810 cores were less than 30 cm, indicating high gas flux. Concentrations of H_2S in the headspace gas samples were in the same order (around 1 mM), therefore process of anaerobic oxidation of methane was active. C_1 / (C_2 + C_3) of headspace gases in the hydrate-bound cores (HC1807 and HC1808) distributed between 4,000 and 9,000, and those of other sediment cores were relatively small, indicating that they are in the oxidation layer above the SMI depth. Headspace gas in the HC1808 core contained a lot of isobutane. It is possible that thermogenic gas supplied from deeper sediment layer partly mixes with microbial gas.

All about gas hydrates and heat flow offshore Chile

*LUCIA ALEJANDRA VILLAR MUNOZ[1], IVAN VARGAS-CORDERO[2], JOAQUIM P. BENTO[3], JAN BEHRMANN[1], UMBERTA TINIVELLA[4], MICHELA GIUSTINIANI[4]

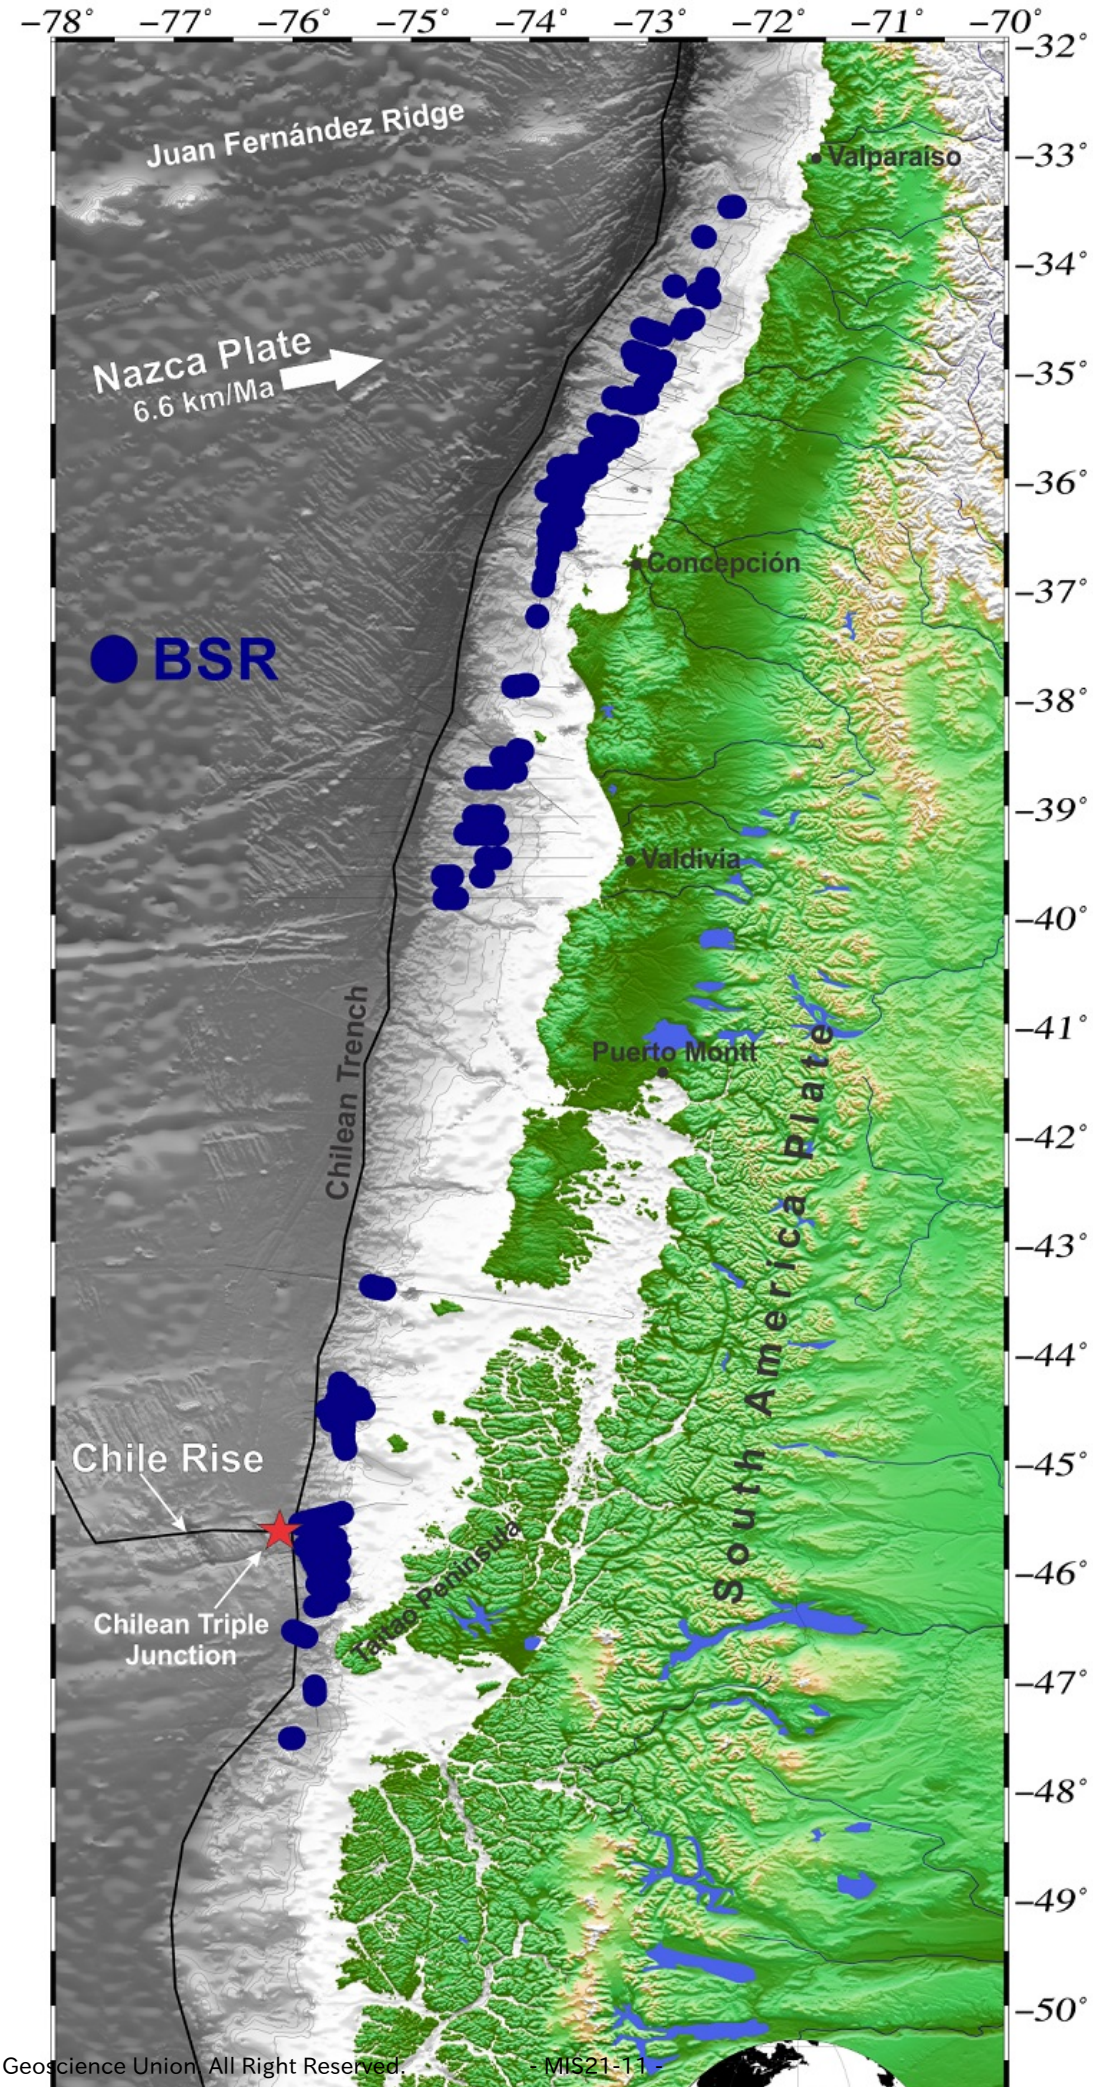
1. Helmholtz Centre for Ocean Research, 2. Universidad Andres Bello , 3. Pontificia Universidad Catolica de Valparaiso, 4. Istituto Nazionale di Oceanografia e di Geofisica Sperimentale

From a geological point of view, Chile lies in an incomparable area of the globe, which include four tectonic plates moving against (Nazca, Antarctic, South American and Scotia plates), two triple junctions (Chile and Fuegian triple junctions), numerous mega-earthquakes and tsunami-related, more than 500 active volcanoes, the Andes, and several mineral resources. One of the last natural resources where the Chilean government and institutions have focused on is in gas hydrate, which is a solid ice-like form of water that contains gas molecules highly-concentrated in methane. Since Chile import most of its gas budget, hence the discovery of this new resource open a new window for the national economy, but also for geosciences, due to methane that escapes from sediments and enter to the ocean or even reach the atmosphere could pose a great environmental threat. To identify the presence of hydrates, in this thesis it was used the bottom-simulating reflector BSR, which has the half amplitude and opposite polarity relative to the seafloor.

Moreover, fluids play a key role in the nucleation and rupture propagation of earthquakes in convergent margins, since are a major agent of advective heat transfer from depth to the Earth’ s surface. If provide enough information for the regional heat flow we will improve our knowledge of these violent shakes of plate motion. For this purpose, it is crucial to know the BSR-depth, which serves to calculate the steady-state heat flow q (mW m^{-2}), and therefore, the heat flow can be envisaged in a regional overview.

This work aims to investigate the tectonic processes of the Chilean forearc through the calculation of the regional BSR-derived heat flow, identification of fluid escape sites, description of the distribution of gas hydrates and estimation of the gas hydrate and free gas reservoirs .

One of the major results is the regional overview of the thermal regime and BSR-based gas hydrate distribution along the Chilean forearc. Here, the BSR was identified into the marine sediments mainly along the accretionary prism between 33˚-57˚S, around 2000 m water depth, and between 90-600 m below seafloor. The heat flow estimated through the forearc on the upper and middle continental slope, from Valparaiso to Chiloe (33˚-43˚S), shows common values of heat flow for the continental basement and overlying slope sediments. However, on the lower slope of the actively deforming accretionary wedge, some places show unexpected values, which indicates that advecting pore fluids from deeper may transport a considerable part of the heat there.



Southern, a second approach was made over a large area of extremely anomalous heat flow that is associated with a major tectonic feature: the Chile Triple Junction. In this unusual place, the Nazca, Antarctic and South American plate converge in a common point; while an active spreading centre (the Chile Rise) is subducting beneath the continental plate. Here, gas hydrates are located in very shallow sediments and the extreme values of heat flow estimated (<280 mW m^{-2}) indicate that the overriding South American Plate is effectively heated by subjacent zero-age oceanic plate material. In order to improve the understanding of the geological risk, in case the methane is released to the ocean/atmosphere system, it was estimated the concentration of gas hydrate in this particular region.

Finally, in the southernmost tip of the continent (offshore Patagonia), the heat flow estimated once again shows a range of values typical for subduction zones of oceanic crust older than 10 Ma. Here, a high concentration of methane hydrate is present beneath the active margin. The average thickness of the gas hydrate layer modelled is almost 300 m and the volume of methane estimated is more than $3x10^{13}$ m^3 at standard pressure-temperature conditions, concluding that the active forearc of the Chilean Patagonia is an important reservoir of methane hydrates.

[M-IS27] Atmospheric electricity: Applications toward natural disaster mitigation

convener:Yasuhide Hobara(Graduate School of Information and Engineering Department of Communication Engineering and Informatics, The University of Electro-Communications), Masashi Kamogawa(Department of Physics, Tokyo Gakugei University), Chairperson:Takeshi Morimoto

In recent years, various types of natural disasters caused by climate change, earthquake, etc. occur frequently in the world. In 2018 heavy precipitation in various regions of Japan and the earthquakes in Hokkaido and Indonesiaproduced/greater human and economic/damage.

In 2019JpGU Atmospheric Electricity (AE) session, invited experts are going to introduce their scientific challenges in order to monitor, predict and mitigate natural disasters by using knowledge of the atmospheric electricity. For example, monitoring and prediction of extreme weather by the latest weather radar system and lightning observations, electromagnetic phenomena prior to earthquakes, etc. will be included. We certainly welcome contributed papers regarding all topics on atmospheric electricityincluding global circuit, ion and fair weather electricity, thunderstorm electrification, lightning physics, lightning and meteorology, electrical effects of thunderstorms on the middle and upper atmosphere such as transient luminous events and high energy phenomena, lightning protection, terrestrial electromagnetic environment and so on.

Recent progress of information and communication technologies has been enabling us to realize a rapid scanning radar system. In 2012, Toshiba Corporation and Osaka University succeeded in developing a new type of Phased Array Radar (PAR) system (Yoshikawa et al. 2013, Ushio et al. 2015, Mizutani et al. 2018) under a grant of National Institute of Communication and Information Technology (NICT), and installed in Suita Campus, Osaka University. This PAR system can scan the whole sky within 30 seconds up to 60 km in radius over 100 elevation angles with digital beam forming technique, and the initial observation results demonstrate the unique capability of the new PAR system. However, the observation is sometimes seriously contaminated by strong ground clutter through relatively high sidelobes at transmitting stage. In this study, a new clutter mitigation algorithm from adaptive beam forming technique on Minimum Mean Square Error (MMSE) formulation was investigated, and succeeded in suppressing not only the ground clutter but also ghost echo from strong precipitation echo nearby more than 20dB. And also the adaptive algorithm was applied to supress the range sidelobe and showed the sidelobe level of -60dB. In this presentation, the advantages and disadvantages of the PAR will be discussed based on the observation results.

Initial Observations with X-band Dual Polarimetric Phased Array Weather Radar in Tokyo

*Hiroshi Kikuchi[1], Taku Suezawa[2], Yasuhide Hobara[1], Tomoo Ushio[2]

1. The University of Electro-Communications, 2. Tokyo Metropolitan University

The weather radars using parabolic dish antenna generally require 5-10 minutes to mechanically rotate and to tilt upwards as they sample the atmosphere at several different elevation angles. The number of the observable elevation angles is about ten or so. The single polarization phased array weather radar (SP-PAWR), which has been developed in 2012, was designed to conduct precipitation measurement of a radar reflectivity factor, in less than 10 or 30 seconds in a range of 20 or 60 km in real-time, respectively. As a next radar development project, a dual polarimetric phased array weather radar (Multi-parameter phased array radar; MP-PAWR) is being developed. It can provide multi-parameter measurements that reveal detailed microphysics of storms in addition to accurate precipitation estimation, and can improve weather forecasts.
The first made MP-PAWR, which simultaneously transmits pulses of horizontal and vertical polarized radiation, has been developed and installed in December 2017, at Saitama University, Japan. The center of frequency is 9.4GHz (X-band). The MP-PAWR has a scanning scheme similar to the SP-PAWR, which uses the mechanical and electronic scanning in azimuth and elevation angles, respectively. The MP-PAWR provides the polarimetric precipitation measurements in three-dimensional volume scanning in less than 30 or 60 seconds in a range of 60 or 80 km in real-time, respectively.
In this presentation, we will show the initial observation results. To confirm reliability of the measurements and to evaluate the accuracy of the measurements by the MP-PAWR, the initial observation results of the MP-PAWR are compared with an optical disdrometer data.

Three-dimensional total lightning characteristics of convective cells observed by the Tokyo LMA in the summer season in Tokyo Metropolitan area

*Namiko Sakurai[1], Paul R. Krehbiel[2], William Rison[2], Ronald J. Thomas[2], Daniel Rodeheffer[2], Shingo Shimizu[1], Koyuru Iwanami[1], Takeshi Maesaka[1], Kaori Kieda[1], Yasushi Uji[1]

1. National Research Institute For Earth Science and Disaster Resilience, 2. New Mexico Tech.

The National research Institute for Earth science and Disaster resilience, Japan (NIED) has observed three-dimensional total lightning with Lightning Mapping Array in Tokyo metropolitan area (Tokyo LMA) since 2017. In this study, we report various total lightning characteristics of convective cells observed by the Tokyo LMA in the summer season. Three convective cells developed at around 14:00 JST on 30 August 2017 in Tokyo. They were located at a short distance each other, and they merged into a multi-cell thunderstorm after a while. The total lightning characteristics of the three convective cells before they merged into the multi-cell thunderstorm are as follows: in one convective cell which was located in the middle of the cells, IC lightning flashes preceded the first CG lightning for about 20 minutes. On the other hand, a CG lightning flash firstly occurred in another convective cell. In the other convective cell, IC lightning flashes predominated. These three cells and the multi-cell thunderstorm had normal tripole structures. In addition, several bolt-from-the-blue were observed in these three cells.

Estimating rainfall in heavy rain events using lightning data in Japan

*Ogawa Tetsuya[1], Yasuhide Hobara[1], Hiroyuki IWASAKI[2], Stan Heckman[3], Michael Stock[3]

1. University of Electro-Communications, 2. Gunma University, 3. EarthNetworks

In this study, we examined the relationship between total lightning (TL) and heavy rainfall in high spatio-time resolution by using 37 severe thunderstorms in Japan. TL is continuously monitored by the Japanese Total Lightning Network (JTLN) deployed by UEC and operated jointly by UEC and EarthNetworks, whilst high spatio-temporal precipitation data is obtained by eXtended Rader Information Network (XRAIN) operated by Ministry of Land, Infrastructure, Transport and Tourism in Japan. As a result, positive linear relation with rather high cross correlation (r2 ~ 0.54 between TL and Precipitation Volume (PV) [m3] has been obtained. The cross correlation between TL and PV is much higher than that for cloud-to-ground lightning (CG) and PV. Although the slope of linear relation (TL vs. PV) varies depending on heavy rain events, TL can be promising tool to estimate severe rainfall.

The Effect of Lightning Phenomena on Lightning Protection for Objects on the Ground

*Yokoyama Shigeru[1]

1. Shizuoka University

When lightning strikes the transmission line or the distribution line, high voltage is generated between the wire and the earth, discharge occurs in the insulator, and power failure occurs. A high voltage is generated when the peak value of the lightning current is large. Also, as the wave front length of the current is shorter, a higher voltage is generated. On the other hand, the lightning rod fails to catch the lightning discharge and destroys the roof and wall of the building even with the low peak value of the lightning current. Furthermore, damage caused by lightning arrester burnout is not much affected by the length of wave front length, and it is greatly influenced by the duration (charge amount) of the lightning current. Table 1 shows the relationship between the types of lightning damage and lightning parameters. Since lightning properties related to lightning damage of ground structures depend upon the object, it is important to fully understand the lightning phenomena to take countermeasures against lightning damages. Moreover, it is also necessary to clarify the seasonal and local characteristics of lightning from the viewpoint of risk management because there are lightning with significantly different properties from ordinary summer lightning such as the Japanese winter lightning. In this paper I will explain the lightning properties necessary for countermeasures against lightning damage and consider the issues of lightning observations in the future.
