*Yoshihisa Iio[1], Manten seicmic observation group, Manten seismic observation group in the Western Tottori region

1. Disater Prevention Research Institute, Kyoto University

We estimate the stress field in the Western Tottori and Western Shimane regions by precisely analyzing focal mechanisms from dense seismic observations installed in and around the seismic belt in the San-in district, Japan. In this region, we installed a Manten seismic observation network with 50 high-gain short period seismometers in 2009, and another Manten seismic observation network with 81 high-gain short period seismometers in 2015. In this study, we utilize data from these Manten seismic observation networks and nearby permanent seismic stations, and also those obtained by the group for the dense aftershock observations of the 2000 Western Tottori Prefecture earthquake. It was inferred by previous studies that the azimuths of the maximum compressional stress axis in the seismic belt are oriented in a WNW–ESE direction, while they are aligned in almost the EW direction i in the south of the seismic belt, in the inland plate along the Nankai Trough. This spatial change in the stress field in and around the seismic belt was qualitatively explained by the aseismic slip in a ductile fault zone in the lower crust beneath the seismic belt. The results obtained in this study are summarized as follows. In the region from the aftershock area of the Western Tottori prefecture earthquake to the vicinity of Sanbe-san, rotation of $\sigma 1$ direction was observed. On the south side of the region, the direction of $\sigma 1$ is N 90 ˚E to N 110 ˚E, whereas in the region it is N 100 ˚E to N 140 ˚E, which is a rotation of 20 to 30 ˚. Rotation is large on the west side of the aftershock area of the Western Tottori prefecture earthquake and in the vicinity of Sanbe-san and small between them. In the area around the Shinji Rift zone on the north side of this area, although the number of data is small, the direction of $\sigma 1$ is N 120 ˚E to N 140 ˚E, and the rotation is the largest among the entire area. In this way, in this area, the rotation of the direction of $\sigma 1$ is seen in the central part of the San-in earthquake zone, and among them, the rotation is locally large in the west side of the aftershock area of the Western Tottori prefecture earthquake and in the vicinity of Sanbe-san. In addition, $\sigma 1$ turns greatly around the Shinji Rift zone north of the seismic belt.

In the lower crust beneath the vicinity of the seismic belt, a low velocity zone of about 50 km in width is estimated at a depth of 25 km (Tsuda et al., 2017). In the upper crust, large low velocity anomalies are seen along the Shinji Rift Belt. The stress field in this area may be formed by shortening in the orthogonal direction of the Shinji groove belt in addition to the slow slip immediately beneath the seismic belt Kawanishi et al. (2009) estimated the stress field with the seismic zone as a region, but it became clear that there is an internal structure in it.

Modeling the spatiotemporal change in stress field around Hinagu fault zone through the 2016 Kumamoto earthquake sequence, in central Kyushu, Japan

*Ayaho Mitsuoka[1], Satoshi Matsumoto[2], Azusa Shito[2], Yusuke Yamashita[3], Manami Nakamoto[4], Masahiro Miyazaki[3], Shin'ichi Sakai[5], Yoshihisa Iio[3], Group for urgent joint seismic observation of the 2016 Kumamoto earthquake

Disaster Prevention Research Institute, Kyoto University, 4. Association for the Development of Earthquake Prediction, 5. Earthquake Research Institute, The University of Tokyo

For a purpose of understanding physical process of earthquake generation, knowledge of stress condition around a fault is required. We estimated stress field and discussed its spatiotemporal change around Hinagu fault zone that was the hypocentral area of the 2016 Kumamoto earthquake sequence.
The 2016 Kumamoto earthquake sequence occurred around Hinagu and Futagawa fault zones in Kumamoto prefecture, central Kyushu Island, Japan. The largest foreshock with Mj 6.5 (Mj: magnitude by Japan Metrological Agency) on April 14, 2016 was located Hinagu fault zone. The mainshock (Mj 7.3) generated slip at both Hinagu and Futagawa fault on April 16, 2016. After that, many earthquakes occurred around these faults until now.
In this study, we estimated the spatiotemporal change in the deviatoric stress field and its differential stress. For discussing the temporal change in the target region, we divided time sequence into three periods: (1) prior to the sequence (i.e. before Mj 6.5 event), (2) between the foreshock and the mainshock, and (3) after the mainshock. We compared the deviatoric stress fields with the co-seismic stress change by faulting of this sequence. From focal mechanism solutions from January 1, 1993 to December 31, 2017, we estimated the deviatoric stress field using the method by Matsumoto [2016]. We adopted fault slip models of the fore- and mainshock, which is the slip distribution projected result by Asano and Iwata [2016] on the fault geometries determined from the distribution of hypocenters. We performed a grid search procedure for the differential stress at each spatial block with horizontal size of 0.05˚in latitude and longitude, and 5 km in depth.
As a result, we captured the stress condition in the both period (1) and (3). Before the foreshock (i.e. period (1)), the differential stress around the fore- and mainshock faults is higher than the other region, its value is from several MPa to several tens of MPa. On the other hand, the differential stress in south area of Hinagu fault zone ranges from about 0.1 to 1 MPa. We found the foreshock and mainshock occurred in the state of high differential stress.
After the mainshock (i.e. period (3)), the spatial heterogeneity of the differential stress still remained. However, the differential stress at the area around the hypocenters of the fore- and mainshock is about half of that before the foreshock. At the southeast area of Hinagu fault, the differential stress is about twice of that before, so potential of occurring earthquake becomes relatively high compared with the prior state to this sequence.

Development of the Median Tectonic Line Fault zone in Mie Prefecture, Southwest Japan : A Possible Interpretation for Strain Localization and Softening

*Toru Takeshita[1], Dong Van Bui[1], Thomas Anthony Czertowicz[1], Shun Arai[2], Takafumi Yamamoto[3], Jun-ichi Ando[3], Norio Shigematsu[4], Koichiro Fujimoto[5]

We have investigated the development of the Median Tectonic Line (MTL) fault zone in the upper-plate Ryoke granitoids in Mie Prefecture, southwest Japan. In the study area, although c. 80 m thick cataclasite develops in direct proximity to the MTL, mylonitic rocks were pervasively formed before the formation of cataclasite, which can be divided into protomylonite distributed from the MTL to the point 300 m north from it and mylonite distributed from the latter point to the one at c. 800 m further north from the MTL. However, in the protomylonite zone, ultramylonite with the thickness up to c. 50 m is developed in direct proximity to the MTL, which occur as clasts in the cataclasite zone. We also have found that the protomylonite originates from tonalite, while the mylonite originates from granite. Hence, the boundary between the protomylonite and mylonite exactly coincides with the protolith boundary.

We analyze both microstructures and c-axis fabrics in recrystallized quartz grains from the protomylonite and mylonite zones along the MTL. In the protomylonite, sizes of recrystallized grains formed by subgrain rotation (SGR) recrystallization are low ranging between 7-14 microns. In particular, in the ultramylonite, the recrystallized grain sizes ranges between 4-11 microns. The quartz c-axis fabrics mostly show a Y-maximum pattern. On the other hand, the mylonite zone can be divided into two subzones in terms of quartz microstructures. In the subzone from 300 m to 490 m from the MTL, the microstructures are characterized by elongated grains (S-type) with finer recrystallized grain sizes varying between 11-20 microns formed by SGR. On the other hand, in the zone from 490 m to 800 m from the MTL, the microstructures are characterized by relatively equant grains (P-type) with coarser recrystallized grain sizes varying between 49-107 microns and lobate grain boundaries formed by grain-boundary migration (GBM) recrystallization. In both mylonite subzones, a Y-maximum quartz c-axis fabric dominates.

We further analyze microstructures of K-feldspar, and infer deformation temperatures based on the two-feldspar geothermometry after Stormer (1975) and Stormer and Whitney (1985) in the mylonite zone which originated from granite. While K-feldspar porphyroclasts are broken in the S-type mylonite subzone, they are plastically deformed to a sigma shape in the P-type mylonite subzone. Myrmekite pervasively develops at the periphery of K-feldspar porphyroclasts from the entire mylonite zone. Using the chemical compositions of K-feldspar and plagioclase in myrmekite, we infer the deformation temperatures in the mylonite zone. At the northernmost P-type mylonite subzone, the deformation temperatures are calculated at 500 ˚C, which decrease to 400 ˚C at the boundary between the P- and S-type mylonite subzones, and further decrease in the S-type mylonite zone, ranging between 350-400 ˚C.

Plastic deformation is dominant in the granite than in the tonalite at higher temperatures than 500 ˚C, leading to the formation of mylonite in the former area alone, perhaps because granite including abundant K-feldspar is rheologically weaker than tonalite. Subsequently, with decreasing temperature,

©2019. Japan Geoscience Union. All Right Reserved.

plastic deformation becomes localized in the southern part of the mylonite zone. At 400 ˚C, only the S-type mylonite subzone continues to deform, and the protomylonite starts to deform at higher stresses than in the S-type mylonite subzone. With further decreasing temperatures, the plastic deformation of S-type mylonite subzone is abandoned at 350 ˚C, and the further plastic deformation only occurs in the ultramylonite at 300-350 ˚C, leading to the formation of very fine-recrystallized quartz grains and type-I crossed girdle quartz c-axis fabric with R-maxima, which is further followed by cataclasis. We currently do not have a good idea on why the zone of plastic deformation suddenly jumps from the southernmost S-type mylonite subzone, which is 300 m apart from the MTL, to the protomylonite zone in direct proximity to the present MTL, forming ultramylonite. However, since a type-I crossed girdle quartz c-axis fabric with R-maxima is developed in the ultramylonite, it can be inferred that water weakening of quartz either by decreasing the strength of slip systems or facilitating dynamic recrystallization occurs in the protomylonite zone, which could have been caused by infiltration of water along newly formed fractures.

[S-CG61] Dynamics in mobile belts

convener:Yukitoshi Fukahata(Disaster Prevention Research Institute, Kyoto University), Toru Takeshita(Department of Natural History Sciences, Graduate School of Science, Hokkaido University), Hikaru Iwamori(Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology), Chairperson:Tomomi Okada, Ryosuke Ando(Graduate School of Science, University of Tokyo)

The dynamic behaviours of mobile belts are expressed across a wide range of time scales, from the seismic and volcanic events that impact society during our lifetimes, to orogeny and the formation of large-scale fault systems which can take place over millions of years. Deformation occurs on length scales from microscopic fracture and flow to macroscopic deformation to plate-scale tectonics. To gain a physical understanding of the dynamics of mobile belts, we must determine the relationships between deformation and the driving stresses due to plate motion and other causes, which are connected through the rheological properties of the materials. To understand the full physical system, an integration of geophysics, geomorphology, and geology is necessary, as is the integration of observational, theoretical and experimental approaches. In addition, because rheological properties are greatly affected by fluids in the crust and fluid chemical reactions, petrological and geochemical approaches are also important. After the 2011 great Tohoku-oki earthquake, large-scale changes in seismic activity and regional scale crustal deformation were observed, making present-day Japan a unique natural laboratory for the study of the dynamics of mobile belts. This session welcomes presentations from different disciplines, such as seismology, geodesy, tectonic geomorphology, structural geology, petrology, and hydrology, as well as interdisciplinary studies, that relate to the dynamic behaviours of mobile belts.

Occurrence of any conspicuous ramp on the low angle basal detachment causes hindrance on the overall wedge progression and behaves as an asperity by localizing stress in the inter-seismic gaps. The mid-crustal ramp on the Main Himalayan Thrust (MHT) results in strain partitioning by focusing seismicity, including 2015 magnitude 7.8 Gorkha earthquake in the central Nepal Himalaya. However, the ramp structure is laterally discontinuous; even absent in some parts of the Himalaya (e.g. western Bhutan). Interestingly, it has been widely shown that the geometry of the basal detachment (in terms of presence or absence or geographic location of the ramp) provides first order control on the along strike variations in the structure, topography, low-temperature thermochronological ages, precipitation, exhumation and erosion patterns. Motivated by the absence of any mechanical explanation for these peculiar observations, we compare physical and numerical experiments with the geology of the frontal eastern Himalaya to show how the mechanically weak coal bearing Gondwana horizon controls the position of the basal detachment in space and time. Our modelling results confirm that the initial spatial distribution of the Gondwana horizon strongly influences the position of the mid-crustal ramp at different geographic location which resulted in segmented MHT structure (Fig. 1). The numerical modelling largely validates the physical experiments and explains the rock uplift and river incision pattern recorded in the Nepal Himalaya.

Control of fault weakening on the structural styles of underthrusting-dominated non-cohesive tectonic wedges

*Arthur Bauville[1], Mikito Furuichi[1]

1. Department of Mathematical Science and Advanced Techology, JAMSTEC

Underthrusting is a typical process at compressive margins responsible for nappe stacking and sediment subduction. Despite being essential for orogenesis, and the subduction cycle, the mechanics of underthrusting is still incompletely understood. The critical taper theory predicts that underthrusting occurs only in the limit where $\mu_b'=\mu'$, with μ' and μ_b' the inner and basal effective coefficient of friction, respectively. Paradoxically, in nature, underthrusting is associated with weak faults. For instance, at erosive subduction margins, sediments are dragged in subduction, while normal faulting in the middle prism suggests the plate boundary is weak. Wang et al., (2010) have proposed that dynamic fault strength variations during the earthquake cycle can reconcile these observations. In their model, underthrusting occurs during earthquakes when the fault is strong and normal faulting occurs in the prism during the interseismic period when the fault is weak. However, recent evidence (Gao and Wang, 2016) suggests that plate boundaries are relatively weak also during earthquakes.
In this contribution, we investigate the control of permanent fault weakening on the dynamics of a strong-based ($\mu_b'=\mu'$,) non-cohesive tectonic wedge. We control the wedge material strength by a spatially constant fluid overpressure factor (λ^*, and fault strength by a strain weakening factor (χ). We investigated the problem in two steps. First, we used the critical taper theory to determine a mechanical mode diagram that predicts structural styles. This diagram is deduced from the function $\Delta\alpha(\beta,\chi,\lambda^*)$ which is the difference in taper angle at a given β, between the compressively critical taper of a strong-based wedge and the extensionally critical taper of a weak-based wedge ($\mu_b'=(1-\chi)\mu'$). Then, we performed numerical simulations of accretionary wedge formation to establish the characteristics of these structural styles regarding wedge and fault geometry. We determined there is a continuum of structural styles with three end-members occurring at the theoretically determined mechanical mode transitions.

Style 1 is characterized by thin tectonic slices and little to no underthrusting.
Style 2 is characterized by thick slices and nappe stacking.
Style 3 is characterized by the complete underthrusting of the incoming sediments.

The model gives a mechanical explanation that reconciles underthrusting with weak faults. In agreement with observations, the model predicts the occurrence of style 2 in strong-based sandbox experiment. Finally, we argue that style 3 is triggered by any mechanism, such as material weakening, erosion or sedimentation, that limits the surface angle such that the incoming material is always significantly under-critical.

The *M* 7.8 Kaikoura earthquake occurred in the northern South Island on 3 Nov., 2016, involving the rupture of > 20 faults. To understand the complexity of the Kaikoura earthquake, details of fault geometry, seismic velocity distribution and stress field are necessary. We have undertaken seismic tomography and stress tensor inversion using focal mechanisms along the c. 200 km length of the rupture zone.

Data from both 51 temporary stations and 22 GEONET stations were collected from March 2011 to December 2017. Hypocenter locations and the three-dimensional velocity structure were determined using the method of Zhang and Thurber (2003 and 2006).

The hypocenter of the Kaikoura earthquake and aftershocks near the Kekerengu fault locate along lineaments where seismic velocity changes horizontally.

In the uppermost crust, lower velocities occur beneath the Emu Plain and Cape Campbell. Higher velocities occur in and around Kaikoura.
In the middle to lower crust, high Vp/Vs occurs not only in and around the hypocenter but also along the northern part of the rupture zone.
In the lowermost crustal or uppermost mantle, high Vp occurs east of the Kekerengu fault and south of the Hope fault and beneath the Canterbury plains faults. This high Vp likely corresponds to the Pacific plate.

These complexities in the seismic velocity structure may relate to the multi-rupture character of the Kaikoura earthquake. In particular, spatial correlations between rupture areas and high Vp/Vs suggests the involvement of overpressured fluid in the nucleation and propagation of rupture segments, which is also supported by the reactivation of unfavourably oriented strike-slip ruptures, many lying at c.70˚ to regional sigma-one stress trajectories.

Dynamic Rupture Simulation Reproduces Spontaneous Multifault Rupture and Arrest During the 2016 Mw 7.9 Kaikoura Earthquake

*Ryosuke Ando[1], Yoshihiro Kaneko[2]

1. Graduate School of Science, University of Tokyo, 2. GNS science

The 2016 Kaikoura (New Zealand) earthquake is characterized as one of the most complex multifault rupture events ever observed. We perform dynamic rupture simulations to evaluate to what extent relatively simple forward models accounting for realistic fault geometry can explain the characteristics of coseismic observations. Without fine parameter tuning, our model reproduces many observed features including the multifault rupture, overall slip distribution and direction, and the locations of the maximum slip and rupture arrest. In particular, our model shows spontaneous arrest of dynamic rupture at the both ends of the ruptured fault system due to smaller prestress levels expected from a regional tectonic stress field. Both the simulated and the observationally inferred source time functions show similar double peaks with a larger second peak. The results illuminate the importance of the 3-D fault geometry in understanding the dynamics of complex multifault rupture.

Ductile deformation explains the physics of friction and genesis of earthquakes

*James Daniel Paul Moore[1], Stefan Nielsen[2], Lars N Hansen[3]

1. Earth Observatory of Singapore, 2. University of Durham, 3. University of Oxford

Seismic hazard presents a significant global threat to both life and property, with increased urbanisation in the twenty-first century only intensifying the risk as populations concentrate near fault lines. It is therefore imperative to develop a clear understanding of the physical origins of earthquakes, with their associated hazards, and use that knowledge to work towards building more resilient societies. To this end, we show that ductile deformation on contact regions within fault zones explains the physics of fault friction, and the genesis of earthquakes. We find the empirical framework of rate-and-state friction may be derived from grain-scale creep processes, and that earthquakes are the macroscopic manifestation of ductile deformation at microscopic contacting regions. The governing equations are well behaved at low slip rates, the seismogenic layer emerges as a consequence of the pressure-temperature dependence of ductile creep processes, and we offer an explanation for the temporal distribution of earthquake clustering.

The physical origins of the laws of friction that govern the genesis of earthquakes have long been the subject of discussion and debate. Here we demonstrate that the empirical framework of rate-and-state friction is a natural consequence of grain-scale processes, and that fault slip is the macroscopic manifestation of creep on contact asperities, modulated by grain-size processes, at the microscopic scale.We find that common rate-and-state parameters derived from laboratory data and geodetic observations are entirely commensurate with known flow laws: diffusion creep, dislocation-accommodated grain-boundary sliding, and dislocation creep. Additionally, we find that the temperature, grain size, and stress dependence of these flow laws naturally give rise to the full spectrum of fault behaviour from stable creep, through slow slip and tremor, to bilateral ruptures. In particular a seismogenic layer emerges spontaneously from the interplay of these creep mechanisms, for which the stability is primarily determined by the grain-size dependence of the active flow law. Our framework unifies the work of friction experiments for localised deformation and flow laws governing distributed deformation, whilst simultaneously addressing a number of shortcomings of the Dieterich-Ruina form of rate-and-state friction, such as the non-physical divergence as the sliding velocity tends to zero. We present very close equivalence between rate-and-state friction and established flow laws, and provide an explanation for the emergence of the seismogenic layer.

The seismic moment, stress drop, and strain energy release for the rupture of asperities

*Mitsuhiro Matsu'ura[1]

1. Institute of Statistical Mathematics

Seismic moment and stress drop are known as the most fundamental physical quantities characterizing seismic events. The seismic moment of an event is clearly defined as the product of its rupture area (S), average fault slip (D), and the rigidity of the surrounding elastic medium (Aki, 1966; Kostrov, 1974), but the stress drop is not (Madariaga, 1979), which depends on adopted source models. In the simplest case of a circular crack model with uniform stress drop, the stress drop is proportional to D and the inverse of the square root of S, and so independent of seismic moment (e.g., Kanamori & Anderson, 1975). However, with the simplest model, Nadeau & Johnson (1998) found a clear dependence of average stress drop on seismic moment from a detailed analysis of repeating earthquakes along the Parkfield segment of SAF. This empirical scaling relationship for average stress drop is contrary to what is commonly assumed in seismology: that is the stress drop is independent of earthquake size.

Since then, many seismologists (e.g., Sammis & Rice, 2001; Anooshehpoor & Brune, 2001; Beeler, Lockner & Hickman, 2001; Johnson & Nadeau, 2002) tried to explain the observed size-dependence of stress drop by theoretically considering the loading and rupture processes of asperities, but didn't succeed. The size-dependence of stress drop seems to result from an inappropriate assumption for background slip rates [1]. Aside from that, in these theoretical studies, the asperity is modeled as a completely locked small patch surrounded by freely creeping zones. In such modeling, steady tectonic loading causes stress singularity just inside the locked patch and broad slip-deficit distribution on the surrounding freely creeping zones. The rupture of the asperity suddenly releases the concentrated stress at the small locked patch and causes fault slip so as to cancel the slip deficit distributed on the surrounding zones without stress drop. Even in such a case, we can clearly define the seismic moment by multiplying the integral of coseismic slip over the whole fault plane by the rigidity of the surrounding medium. In contrast, the definition of average stress drop is multiple (Noda, Lapusta & Kanamori, 2013), which suggests that the static stress drop on fault may not be the fundamental physical quantity.

Recently, on the basis of theoretical consideration to the equation of motion in continuum mechanics, we derived a fundamental equation that the volume integral of static stress changes caused by a seismic event over the whole elastic region is mathematically equivalent to its moment tensor [2]. Applying the fundamental equation to the energetics of shear faulting, we can obtain a quantitative relationship between the work done for shear faulting and the change in elastic strain energy in the surrounding region. This means that we should use the volume integral of static stress changes or the total strain energy change as the fundamental physical quantity characterizing seismic events.

[B-BG01] Elemental cycling in terrestrial and coastal ecosystems- Carbon and Nitrogen perspectives

convener:Punyasloke Bhadury(Indian Institute of Science Education and Research Kolkata)

Biogeochemical cycling of carbon and nitrogen hold the key to cropping cycle, monsoonal patterns and climate globally. Biological communities that make up the biosphere are essential for cycling of carbon and nitrogen and their functions are regulated by numerous factors including redox conditions, trace metal availability, and energy sources. At the same time temporal and spatial variability of biological communities such as those observed in microbes strongly affect the rate of carbon and nitrogen cycling in various environments including land and marine systems. In this session, submissions are welcomed from scientists including early career scientists working on various aspects of carbon and nitrogen cycling across terrestrial, coastal and oceanic environments. Submissions are also encouraged addressing challenges related to estimation of carbon and nitrogen budgets representing local, regional and global scales.

Forest-CEW: A Forest Ecosystems Model for Carbon-Energy-Water Processes.

*Zhenghong Tan[1]

1. Hainan University China

Forest ecosystem models (FEM) are essential tools for studying the forest carbon budget, which is an important subject in the global climate change studies. Although using FEM has a long history and there exist many types of FEM, new models are still being developed for special uses. This presentation introduces Forest-CEW, a forest ecosystems model for carbon-energy-water processes. The model is aimed at having a structure that can be configured flexibly for different forest ecosystems, a graphic interface for inexperienced users, and a command execution mode for experts. The time scale of the model is at the hourly level. Model validation using the data from Tomakomai flux research site (asiaflux.net/index.php?page_id=113) shows that the model can well reconstruct major ecosystem variables including net ecosystem exchange, soil temperature and water content. We also compared Forest-CEW with those include in the TDE ecosystem model intercomparison (cdiac.ess-dive.lbl.gov/epubs/tdemodel/models.html) and the results show that its performance is among the best of the 13 models.

Interdependent Dynamics of LAI-ET across Roofing Landscapes: the Mongolian and Tibetan Plateaus

*Li Tian[1]

1. Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences

The Mongolian and Tibetan Plateaus have experienced higher-than-global average warming in recent decades, resulting in many significant changes in ecosystem structure and function. Among them are Leaf area index (LAI) and evapotranspiration (ET) that play a fundamental role in shaping many causes and consequences of land surface processes and climate. Here, we focused on the spatiotemporal changes of the LAI, ET and their relationships on these two roofing landscapes. Based on the MODIS products from 2000 through 2014. We found that there existed a general positive relationship between LAI and ET on the Mongolia Plateau (MP), while there was not synergy on the Tibetan Plateau (TP).

Overall, 49.38% (50.62%) of land areas on the TP experienced significant increased (decreased) in LAI, while 94.92% (5.09%) on the MP. For the ET, the increased land area was 21.70% (124.10×10^3 km^2) on the TP and 88.01% (341.60×10^3 km^2) on the MP. More importantly, the relationships varied substantially across the space and over time, with mismatches found in some parts of the landscapes. Substantial additional efforts with observational and/or experimental investigations are need to explore the relationships, including the influences of vegetation characteristics and disturbances.

Keywords: ET, LAI, Eurasian continent, alpine, land surface process

Atmospheric pollution has a significant impact on human health, climate change, agriculture, and ecosystem. Air quality and the climate change is the top most concern of the World Health Organization (WHO, 2019). Bangladesh is a rapidly developing country with kinds of environmental problems. It became the top most country in the world for the human deaths due to environmental pollution, which was accounted about 27% of the total death (Lancet, 207). Only air pollution caused two thirds of these deaths (Lancet, 2017). Dhaka along with Narayanganj and Gazipur are the top ranking cities in the World for the air pollution (WHO, 2014). Volatile organic compounds (VOCs) and poly aromatic hydrocarbons (PAHs) are the major organic pollutants in the atmosphere. Until now there is no information of VOCs and PAHs regarding their occurrences, sources, seasonal variation and health impact in Bangladesh. In this study we have collected particulate matters samples on quartz filters with a low volume sampler at two big cities in Bangladesh (Capital Dhaka and North West City Rajshahi) from January 2015 to February 2019. Individual organic compounds were extracted with acetone and n-hexane from the particulate matter loaded filters. The chemical analysis was done with Gas Chromatography (GC)-Mass spectrometry (MS). The analyzed organic compounds were naphthalene, anthracene, diazinon, deltramethrin, pyrabenxoime, pyrazosulfuran, prophenophos butachlor, propiconazole, cymoxanil, cypermethrin, lamda cyhalothrin, dimethoate, chloropyriphos, carbofuran, metalaxyl, pentane, hexane, propene, isobutene, 1,3-butadiene, dichloroflouromethane, ethanol, benzene, toluene, ethylbenzene, xylene, styrene, 1,2,3trimethylbenzene, isoprene, cyclopentane, and cyclohexane. Positive matrix factorization (PMF) and air mass trajectory analysis were done for source characterization. Health risk assessment and life time cancer risk (LCR)

were determined with US EPA based model. The elevated concentrations of the determined compounds at both Dhaka and Rajshahi were observed; Dhaka values were slightly higher than Rajshahi. The concentrations of determined compounds were higher during the winter months basically December to February and lower during the monsoon period in the month of July. PMF model revealed that the sources of organic compounds in Bangladesh were diesel exhaust, coal and biomass burning, industry and gasoline exhaust. Ethyl benzene, dichlorouflouromethane, 1,2,3-trimethylbenzene have the potential carcinogenic impact.

Diversity and activity of diazotrophs in the coastal waters of Southeastern Arabian Sea (SEAS)

*JABIR THAJUDEEN[1], Mohamed Hatha Abdullah

1. Cochin University of Science and Technology India

In marine environments availability of nitrogen (N2) limits the primary productivity. Nitrogen fixing bacteria (diazotrophs) could convert atmospheric nitrogen to ammonium thereby providing significant input of new nitrogen into the ocean. The knowledge about their diversity, distribution and physiological activity are limited in tropical coastal marine environments. In this study, we determined diversity of nitrogen fixing bacteria and the nitrogen fixation rate through *nifH* based clone library analysis and 15N2 bubble method respectively. We encountered *Trichodesmium*bloom and diatom diazotrophic associations along the coastal environments of SEAS. Nitrogen fixation rate in the coastal waters were varied from 0.15 to 1.02 nmolN/L/h. *Trichodesmium*bloom in the Arabian Sea during pre-monsoon season showed higher nitrogen fixation rate of 3.6 nmolN/L/h. Clone library analysis revealed that 19 Operational Taxonomic Units (OTUs) of nitrogen fixing bacteria were observed from the coastal waters SEAS. The OTUs were related to 7 OTUs of cyanobacteria and 12 OTUs of heterotrophic diazotrophs. Major cyanobacterial OTUs are closely similar to *Trichodesmium*sp., *Richelia*sp., *Synechocystis*sp.. Major heterotrophic diazotrophs belonged to alpha-, beta-, gamma-, epislon-, proteobacteria and firmicutes. Gamma proteobacterial clones were dominating among heterotrophic diazotrophs in the coastal water column of south eastern Arabian Sea. Nitrogen fixation rate in the water column were significantly correlated with dissolved Fe (R^2= 0.66, p= 0.05) and phosphorous (R^2= 0.49, p= 0.05), which revealed these are the major factors controlling nitrogen fixation process in the coastal environments of SEAS.

Bloom of *Palmerina hardmaniana*, a marine centric planktonic diatom in a coastal mangrove ecosystem- implication for coastal carbon cycling

*Punyasloke Bhadury[1]

1. Centre for Climate and Environmental Studies and Department of Biological Sciences, Indian Institute of Science Education and Research Kolkata

Large celled diatoms play an important role in export of carbon in coastal ecosystems. In the Sundarbans mangrove ecosystem located on the delta of Ganga-Brahmaputra-Meghna riverine systems and facing the coastal Bay of Bengal, a bloom of *Palmerina hardmaniana* (Greville) Hasle was tracked in 2015. The bloom of this centric diatom species was tracked from April- July, 2015 in Sundarbans Biological Observatory Time Series (SBOTS) site of Sundarbans. During pre-bloom (April) dissolved oxygen (DO) concentration was 6.82 mg/L while during bloom (May-June) DO concentration decreased to 3.83 mg/L. This also coincided with Chlorophyll-a concentration which ranged from 0.22-6.28 mg/L during the study period, with highest concentration of 6.28 mg/L in bloom period and overwhelmingly dominated by cells belonging to *Palmerina hardmaniana* (40.8 X 10^4 cells/L). In total 72 phytoplankton species were observed from April-July, 2015 in SBOTS site. The frustules of *Palmerina hardmaniana* ranged from 291-358 μm in length and from 195 to 260 μm in width. Based on *rbc*L phylogeny of RuBISCO, the dominance of *P. hardmaniana* was also confirmed. Increased air and surface water temperatures in SBOTS site showed significant correlation with observed cell abundance of *P. hardmaniana* with the onset of bloom. This is the first report of *P. hardmaniana* bloom in the coastal Sundarbans mangrove ecosystem. Therefore, understanding the physiological success of this centric diatom species in relation to dynamic environmental conditions has consequences for tracking export of carbon by centric diatoms in coastal water and resulting implications for coastal carbon cycling.

Dynamics of Carbon and Nitrogen influx in large river system: Isotopic study from river Ganga, India

*Anurag Kumar[1], Prasanta Sanyal[1,2], Punyasloke Bhadury[3,2]

1. Department of Earth Sciences, Indian Institute of Science Education and Research Kolkata, Mohanpur 741246, India, 2. Centre for Climate and Environmental studies, Indian Institute of Science Education and Research Kolkata, Mohanpur 741246, India, 3. Department of Biological Sciences, Indian Institute of Science Education and Research Kolkata, Mohanpur 741246, India

Freshwater flux transport large amount of carbon (dissolved and particulate, organic and inorganic) and nitrogen (Dissolved) from continent into the ocean, contributing significantly to the global carbon and nitrogen cycle. The present sources and sinks of naturally as well as anthropogenically produced C and N compounds in the global carbon and nitrogen cycle remains enigmatic. Among the carbon sources in the river ecosystem, the dissolved inorganic carbon (DIC) constitute major component of carbon influx from land to ocean. These fluxes are significantly influenced by the terrestrial and estuary processes. The isotopic composition of DIC can be used to understand the sources and cycling of carbon in rivers and estuaries. In this study, $d^{13}C$ of DIC in river water of Ganga has been used to understand the dissolved inorganic carbon sources into the river. The river Ganga (2500 km) is the largest river of the Indian subcontinent which originates from the Gangotri glacier and drains into Bay of Bengal through its vast delta in the Sunderban. The $d^{13}C_{DIC}$ of river water were measured from source (Gomukh) to sink (Bay of Bengal) of the river Ganga for pre and post-monsoon period. The seasonal variation in the $d^{13}C_{DIC}$ shows enriched isotopic values in pre-monsoon compared to post-monsoon samples, indicating increased biological activities in the riverine system during pre-monsoon. A varied enrichment factor in the $d^{13}C_{DIC}$ values were observed for upper, middle and lower stretch of the river Ganga which might be indicating different sources contributing water in different stretch of the river Ganga. The $d^{18}O$ value of river water, ground water and rain water were used to delineate the different sources of water into the river Ganga. The water budget of the river Ganga shows high glacier melt in the upper stretch, high ground water influx in middle stretch and high rain water input in lower stretch of the river Ganga.

On similar note, the dissolved form of nitrogen in river water (NO_3^-) also significantly impacts the riverine as well as costal ecosystem. The increased influx of nitrate changes the competition between species causing disruption in the biological diversity. The lower stretch of the river Ganga receives maximum rain water input; therefore the region becomes prone to pollutant as result of surface runoff from the catchment areas. The isotopic composition of dissolved nitrate in water can be used to delineate the sources of NO_3^- into the riverine system. The $d^{15}N$ and $d^{18}O$ of the dissolved nitrate in river water from the lower stretch (Kolkata) of the river Ganga indicates the input of anthropogenic activities (pollutant) to river water. The data indicates manure from septic pipe lines as major source of dissolved nitrate present in the river Ganga.

The $d^{13}C_{DIC}$ of river water were measured from source (Gomukh) to sink (Bay of Bengal) of the river Ganga for pre and post-monsoon period. The seasonal variation in the $d^{13}C_{DIC}$ shows enriched isotopic values in pre-monsoon compared to post-monsoon samples, indicating increased biological activities in the riverine system during pre-monsoon. A varied enrichment factor in the $d^{13}C_{DIC}$ values were observed for upper, middle and lower stretch of the river Ganga which might be indicating different sources contributing water in different stretch of the river Ganga. The $d^{18}O$ value of river water, ground water and rain water were used to delineate the different sources of water into the river Ganga. The water budget of the river Ganga shows high glacier melt in the upper stretch, high ground water influx in middle stretch and high rain water input in lower stretch of the river Ganga.

On similar note, the dissolved form of nitrogen in river water (NO_3^-) also significantly impacts the riverine as well as costal ecosystem. The increased influx of nitrate changes the competition between species causing disruption in the biological diversity. The lower stretch of the river Ganga receives maximum rain water input; therefore the region becomes prone to pollutant as result of surface runoff from the catchment areas. The isotopic composition of dissolved nitrate in water can be used to delineate the sources of NO_3^- into the riverine system. The $d^{15}N$ and $d^{18}O$ of the dissolved nitrate in river water from the lower stretch (Kolkata) of the river Ganga indicates the input of anthropogenic activities (pollutant) to river water. The data indicates manure from septic pipe lines as major source of dissolved nitrate present in the river Ganga.

[B-BG01] Elemental cycling in terrestrial and coastal ecosystems- Carbon and Nitrogen perspectives

convener:Punyasloke Bhadury(Indian Institute of Science Education and Research Kolkata), Chairperson:Punyasloke Bhadury(Indian Institute of Science Education and Research Kolkata)

Biogeochemical cycling of carbon and nitrogen hold the key to cropping cycle, monsoonal patterns and climate globally. Biological communities that make up the biosphere are essential for cycling of carbon and nitrogen and their functions are regulated by numerous factors including redox conditions, trace metal availability, and energy sources. At the same time temporal and spatial variability of biological communities such as those observed in microbes strongly affect the rate of carbon and nitrogen cycling in various environments including land and marine systems. In this session, submissions are welcomed from scientists including early career scientists working on various aspects of carbon and nitrogen cycling across terrestrial, coastal and oceanic environments. Submissions are also encouraged addressing challenges related to estimation of carbon and nitrogen budgets representing local, regional and global scales.

Modelling nitrogen and carbon cycles in Hooghly estuary along with adjacent mangrove ecosystem

*Santanu Ray[1]

1. Systems ecology and ecological modelling laboratory, Dept. of Zoology, Visva-Bharati University, Santiniketan 731235, India

Hooghly estuary of India is very rich in natural resources and receives large amountof nutrients through litterfall from adjacent mangrove forest. Nitrogen and carbon as important nutrients occur in various forms and plays a crucial role in the regulation of productivity in this estuarine system. Modelling of nitrogen and carbon dynamics from mangrove litterfall and particularly the release of dissolved inorganic nitrogen and carbon in this estuarine system is important because of their roles in augmenting growth of phytoplankton and other higher plants and all other biological components of grazing food chain. Considering the importance of nitrogen and cabron, two dynamic models both with seven compartmentsare proposed. In these models, nitrogen and carbon of the mangrove litterfall are considered as source and its conversion into different organic and inorganic forms are considered as state variables. Some physical and chemical factors and also rate parameters such as nitrogen fraction of litter biomass, litter biomass, redox potential, soil temperature, conversion rates of nitrogen of one form to another form, phytoplankton uptake rate of dissolved inorganic nitrogen and carbon, dissolved oxygen, water temperature and water pH are considered as graph-time functions in this model. These data are collected over two years from field works and experiments. Other rate parameters are calibrated following standard procedure. Sensitivity analysis is performed before calibration. Model simulation results are properly validated with observed data. Sensitivity analysis reveals that the leaching rate of soil organic nitrogen to total organic nitrogen of water and loss rate of soil organic nitrogen as humic acid and fulvic acids are very sensitive parameters in this system. Redox potential plays an important role in the conversion of soil total nitrogen to soil inorganic nitrogen whereas soil temperature is considered to be key factor regulating the microbial activity for the conversion of soil organic nitrogen to soil inorganic nitrogen. Similarly inwater, total organic nitrogen of water including dissolved organic nitrogen and particulate organic nitrogen is dependent on soil organic nitrogen. The dissolved organic nitrogen, particulate organic nitrogen and soil inorganic nitrogen ultimately get converted into dissolved inorganic nitrogen and accumulated in water which is taken by phytoplankton and microflora as minerals.For carbon cycle model results show seasonal variations of litterfall and which is the main source of SOC pool and ultimately transportedto the estuary. Other than litterfall, the death of organisms in soil and water enriches the SOC and POC respectively. pH of water is governing factor and depending on this factor, DIC is converted to DCO_2 and DBC, which are taken up by phytoplankton during photosynthesis. Mineralization rate of SOC to SIC and uptake rate of DCO_2 and DBC are the sensitive parameters.

^{17}O-rich nitrate as a tracer for constraining nitrogen transformations in coastal sediments

*Chawalit Charoenpong[1,2], Scott D Wankel[2], Carolyn Buchwald[3,2], Wiebke Ziebis[4]

1. Chulalongkorn University, 2. Woods Hole Oceanographic Institution, 3. Dalhousie University, 4. University of Southern California

Coastal sediments are often replete in organic matter and exhibit sharp gradient in redox conditions. In addition, the oxic-anoxic interfaces are often around a few centimeters if not less below the sediment surface. This make this environment poised to harbor both oxidative and reductive nitrogen transformations. As such, the use of a single or a couple of isotope-labeling tracers to determine the rates of these many processes might suffer from the systems being underconstrained. In this work, we demonstrate how naturally-occurring, ^{17}O-rich nitrate can aid in the studying these complex systems through the ability to follow the transformations of added nitrate (NO_3^-) into other different pools of N-species and closely investigate the triple isotopic compositions (δ^{15}N, δ^{18}O, and Δ^{17}O). While we followed five different pools of N-species namely NO_3^-, NO_2^-, N_2O, NH_4^+, and total reduced N (NH_4^+ plus DON), we chose to focus this work on the intermediate nitrite, NO_2^-. For all intact flow-through core incubations done on the sediments collected from Sylt Island, Germany, sediments acted as sources for NO_2^- in all experimental manipulations including sediment type, dissolved oxygen level, and NO_3^- loading. Unlike in the environments that are solely driven by reductive processes where the changes in δ^{15}N and δ^{18}O are coupled, the co-occurrence of both oxic and anoxic in the sediments such as ones from this study cause the δ^{15}N and δ^{18}O to decouple primarily because O is often subject to more processes than N. By using three isotope systems along with the change in concentrations, we demonstrate how we can use a natural abundance appraoch and rely on a series of mathematical equations to solve for different N transformation rates.

Exploring changes in bacterioplankton community structure in response to tannic acid, a major component of litterfall, in a mangrove ecosystem: a laboratory mesocosm approach

*Anwesha Ghosh[1]

1. Integrative Tax Microb Ecol Res Group, Dept. of Biol Sci, IISERK

Litterfall constitutes a major source of allochthonous matter for bacterioplankton communities in estuarine mangroves. Tannic acid, an abundant component of mangrove litterfall, leaches out and contributes substantially to DOC and DOM pools of the adjacent estuaries. About 50% of mangrove litterfall maybe degraded and channelized into the marine microbial loop. Estuarine conditions of Sundarbans, world’ s largest contiguous mangrove, was mimicked in a laboratory mescocosm set-up using barrels to understand the influence of tannic acid on bacterioplankton communities. Estuarine water from a station, Stn3 of Sundarbans Biological Observatory Time Series (SBOTS) was enriched with tannic acid and the change in functional bacterioplankton community structure was analysed on the start (Day 0), intermediate (Day 7) and end (Day 15) of the experiment. Bacterioplankton community structure was elucidated by sequencing the V3-V4 region of 16S rRNA on an Illumina MiSeq platform. Concentration of tannic acid, gallic acid, trace elements, dissolved nutrients such as nitrate and *ortho* -phosphate along with hydrological parameters were determined on a daily basis. Degradation of tannic acid was tracked by decrease in concentration of tannic acid and generation of gallic acid, one of the final products of tannic acid degradation. Tannic acid was shown to significantly affect the concentration of dissolved nitrate and trace elements in the barrels. Proteobacteria was found to be the most dominant bacterial phylum in Control and tannic acid enriched barrels (Barrel 1 and 2) on Day 0. With the progression of experiment, the abundance of Proteobacteria decreased significantly in the Control barrel indicating the dependence of this phylum on steady flux of nutrients. The abundance of Proteobacteria in the tannic acid enriched barrels remained high indicating that members of Proteobacteria may be capable of using tannic acid as a source of carbon and nitrogen. Tannic acid appeared to inhibit other bacterioplankton phyla including Actinobacteria, Acidobacteria and Verrucomicrobia that existed in large abundance in the Control barrel on Day 15 but were absent in the tannic acid enriched barrels. At class level, Bacteroides was found to be present in highest abundance in the tannic acid enriched barrels. Bacteroides are capable of breaking down tannic acid using tannase as an enzyme. This experiment indicated that bacterioplankton communities of Sundarbans could harbour genes necessary for breakdown of complex components of litterfall and recycle them into the marine microbial loop. Breakdown of tannic acid could influence the marine nitrogen and carbon cycling by releasing DON and DOC respectively into the adjacent estuaries. An understanding of the breakdown of tannic acid and other components of mangrove litterfall and its influence on the resident biological communities of estuarine mangroves could be essential for our understanding of functioning of coastal ecosystems.

Diel variations of dissolved inorganic carbon in the Pearl River plume and the northern South China Sea shelf upwelling during summer

*Wei-Jen Huang[1], Kai-Jung Kao[1], Yu-Shih Lin[1], James T. Liu[1], Chen-Tung Arthur Chen[1]

1. National Sun Yat-sen University

Strong river-to-sea mixing, stratification, and coastal eutrophication are usually observed on a plume dominated-continental shelf, but the effects of diel variations and upwelling on the carbonate system are still unclear on the northern South China Sea continental shelf. The Pearl River plume and upwelling at the northern South China Sea were surveyed at the near-field (1 day), the mid-field (6 days), and the far-field sites (1day) along the plume trajectory. We sampled total alkalinity (TA) and dissolved inorganic carbon (DIC) and calculated buffer capacity at the near-surface and near-bottom waters. We also estimated primary productivity (PP, based on $d^{13}C$) at the near-field site and calculated net community productivity (NCP) in the mid-field site after removing the mixing effect. At this plume-upwelling hybrid system, lower salinity, TA, and DIC value and higher buffer capacity and NCP were observed in the near-surface water than the values in the near-bottom water. A good correlation between the common logarithm of light intensity and PP was observed; suggesting that the diel variation of PP was dominated by day-night light cycle. Moreover, the changes of net biological uptake (36% to 76%) were higher than the changes of salinities (3% to 8%) during the subsurface upwelling (from development, maxima, and decline stages at the middle-field site). We suggest that respiration-associated biological activities in addition to PP and physical mixing dominated the near-surface water during subsurface upwelling. Finally, at this coupled plume and upwelling system, the diel variation of carbonate system can be dominated by PP induced by periodic sunlight cycle and further affected by respiration strengthened by intensive upwelling.

Spatial and vertical variations of carbon and nitrogen isotopes of larch forest and NDVI in Eastern Siberia

*Aleksandr Nogovitcyn[1], Atsuko Sugimoto[2], Ruslan Shakhmatov[1], Tomoki Morozumi[1], Shunsuke Tei[2], Yumiko Miyamoto[2], Trofim Maximov[3,4]

1. Graduate School of Environmental Science, Hokkaido University, Sapporo, Hokkaido, Japan, 2. Arctic Research Center, Hokkaido University, Sapporo, Hokkaido, Japan, 3. Institute for Biological Problems of Cryolithozone, Siberian Blanch of Russian Academy of Sciences, Yakutsk, Yakutia, Russia, 4. International Center for Biogeoscience Educational and Scientific Trainings (BEST), North-Eastern Federal University, Yakutsk, Yakutia, Russia

Under a global climate change, taiga forest ecosystem is expected to change. Tree ring data obtained at northeast Siberian Taiga indicated tree growth decrease during warm climate (Tei et al., 2014), consequently primary production may decrease in the future. As tools for monitoring ecosystem changes, stable isotope of carbon $\delta^{13}C$ and nitrogen $\delta^{15}N$ are widely applied in ecological research. The $\delta^{13}C$ is a common proxy for water use efficiency in plants, and the $\delta^{15}N$ is for nitrogen availability that is important because boreal forest on permafrost is usually poor in the nitrogen (Popova et al., 2013).

Observations were conducted at Spasskaya Pad forest station (62˚25’ N, 129˚62’ E) near Yakutsk, Russia. The forest is usually dry, but after the extreme wet event in 2007, wet sites were distributed in the forest. Transect (60m x 510m) with 30m x 30m plots, in total 33, was set including dry sites and wet sites, to obtain needle samples from 104 trees at the height of 5-6 m were obtained in order to investigate spatial variations in $\delta^{13}C$, $\delta^{15}N$, and N contents. These spatial variations were compared with satellite-derived Normalized difference vegetation index (NDVI) using Landsat images with the resolution of 30 m. Lower NDVI and lower foliar N content were observed at wet sites than those at dry sites. A high $\delta^{13}C$ and high $\delta^{15}N$ were also observed at a wet site. After extreme wet event happened, ecosystem (and N availability) changes and NDVI also changes. We also obtained the needles from two trees at different heights in a jungle gym to investigate the vertical variations in $\delta^{13}C$ and $\delta^{15}N$. There were large differences in $\delta^{13}C$, $\delta^{15}N$ and N contents vertically.

High heat with slow cooling of rift margin in the South China Sea, IODP Exp.368

*Arito Sakaguchi[1,2], Nobuaki Osono[1], Keita Nakano[1]

1. Yamaguchi Univ., 2. JAMSTEC

The cooling rate of the crust may depend on thermal setting including heat source, heat transportation system and thermal properties. The heat flow of the ocean plate decreases with reversed root of the plate age, and this implies that the plate tectonics is thermo dynamic system. Thermal analysis can be applied to more complex tectonic region such as marginal sea and continental divisions.

The IODP Exp. 368 has carried out at the Paleogene South China Sea, and the sediment must record thermal history of the formation of rift margin. The site U1501 is located at the most landward outer margin high of the continent-ocean transition of the rift zone. It is expected that the sediment records thermal history of initial stage of rifting. During the cruise, early Oligocene to late Eocene sediment was cored to 697 m, and high geothermal gradient of 81.4˚C/km was obtained using in-situ temperature measurement (Jian et al., 2018). The terrigenous sediment of this core includes many vitrinite fragment, and its reflectance is sensitive geo-thermometer for sediment.

The result of vitrinite reflectance from 0.21 to 0.34 % are obtained from 340 to 510 mbsf. The estimated maximum paleo-temperature is from approximately 27 to 70˚C, and obtained paleo-geothermal gradient is >250˚C/km. This is higher than present measurement value, and quite higher than world average value of the crust. In case of hot basement covers with thin sediment, apparent geo-thermal gradient gets higher, and thickening history of sediment can be measured from the deposition rate of 11mm/Ky in average (Jian et al., 2018). To satisfy the obtained vitrinite reflectance profile, this site must cool by 2.8% in million years. This cooling rate is much slower than general rate of reversed root of the plate age. This might be due to heat being transferred for a long time or being warmed by the cover sediment layer.

Manganese is the third most abundant metallic element, after iron and titanium, in the Earth’ s crust, and ferromanganese minerals are sensitive to changes in redox condition. Assessing the formation and preservation of ferromanganese minerals is important for understanding the global marine cycles of manganese and numerous associated trace elements. The most extensive manganese mineral deposits occur on abyssal plains, including those below open-ocean gyres. However, the extent of ferromanganese minerals buried in subseafloor sediments remains unclear. During the Integrated Ocean Drilling Program (IODP) Expedition 329, we drilled the entire sedimentary sequence at 6 sites in the ultra-oligotrophic region of the South Pacific Gyre (SPG), where dissolved O_2 and aerobic microbial communities are present from the seafloor to the sediment-basement interface [1]. By using high-resolution imaging techniques, we found abundant (10^8-10^9 particles cm^{-3}) micrometer-scale ferromanganese mineral particles (Mn-microparticles) in the oxic pelagic clays of the South Pacific Gyre [2]. Furthermore, we established microparticle separation technique by the combined use of density concentration and flowcytometer/particles sorting techniques. Major and trace element compositional analyses revealed that iron and manganese were the major components of Mn-microparticles, while they also contained rare-earth elements. From the number of Mn-microparticles per unit volume of sediment and the global distribution of oxic pelagic clays, we estimated the number of Mn-microparticles to be 1.5-8.8 $\times 10^{28}$ particles, which accounted for 1.28-7.62 Tt of manganese. This estimate is at least 2 orders of magnitude larger than the manganese budget for manganese nodules and manganese crusts on the seafloor. Along with the examination of manganese input, formation, and preservation, this study provides new insights into the global budget of metallic elements in the abundant Mn-microparticles present in deep subseafloor environments.

Regional stratigraphic framework, Gas Hydrate occurrence and distribution of National Gas Hydrate Program Expedition 02 (NGHP-02) Area-B, offshore eastern India

*KanHsi Hsiung[1], Saneatsu Saito[1], Toshiya Kanamatsu[1], Yoshinori Sanada[1], Yasuhiro Yamada[1], KYAW MOE[1], Yohei Hamada[1], Yasuyuki Nakamura[1], HungYu Wu[1]

1. Japan Agency for Marine-Earth Science and Technology

Gas hydrates, one of the important resources for the future energy, are abundant in nature existing in a wide variety of forms in land and marine environments. Krishna-Godavari Basin was formed along the rifted eastern continental margin of India in the Late Jurassic to Early Cretaceous, receiving amount sediments with numerous tilted fault blocks and growth faults. The offshore Krishna–Godavari Basin is considered a potential gas hydrate province as well as the presence of bottom-simulating-reflectors. The Indian National Gas Hydrate Program Expedition 02 (NGHP-02) was designed to study the occurrence of gas hydrate along the margin. Area-B of NGHP-02 contains important world-class gas hydrate accumulations and represent ideal sites for the consideration of future gas hydrate production testing. The primary goal was to explore for highly saturated gas hydrate occurrences and distribution in seismic reflectors that would become targets for future production tests.

Twelve holes were logged and measured with logging-while-drilling (LWD) and five holes were cored in Area-B of NGHP-02. This study summarized the log- and litho-units in Area-B and establish the Integrated-Units A, B and C based on the data from twelve LWD and five coring sites in Area-B. Most of the downhole log and core inferred gas hydrate occurrences are in the Late Miocene Integrated-Unit B with several sets of reservoir sections exhibiting favorable conditions for hosting gas hydrate. Based on the core-log-seismic integration, the LWD and coring results in Area-B helped to understand the geological significance of sequence stratigraphy in Krishna-Godavari Basin and identified the occurrence of gas hydrate. The thickness variations associated with the Reflectors R1 and R2 are possibly associated with the development anticlinal structure and are likely related to syn-sedimentary growth of the folding structures. Major gas hydrate zones exist in and around the Reflectors R1 and R2 near the BSR depth, and mostly have coincident with the fractures and mass-transport deposits. The Hydrate-bearing intervals can be identified by resistivity and sonic velocity logs and classified into pore-filling type, fracture-filling type, and a mixture of pore- and fracture-filling types based on borehole image characteristics. In addition, the spatial distribution of gas hydrate in the Reflectors R1 and R2 reservoirs is highly influenced by the anticlinal structure.

Fluid flow and diagenetic process in frontal thrust zone off Cape Muroto in the Nankai Trough

*Akira Ijiri[1], Shigeyuki Wakaki[1], Yoshiro Nishio[2], Yohei Hamada[1], Tsuyoshi Ishikawa[1], Fumio Inagaki[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Kochi University

During the International Ocean Discovery Program (IODP) Expedition 370 “Temperature Limit of the Deep Biosphere off Muroto” (T-Limit) in 2016, the drilling was conducted at the protothrust zone in the Nankai Trough off Cape Muroto by using the D/V *Chikyu*, which penetrated the plate boundary fault (dé collement) between 758.2 and 796.4 meters below seafloor (mbsf) and recovered the accretionary deposits down to the basement. Expedition 370 aimed to explore the limits of subseafloor life and the biosphere where temperature exceeds the known temperature maximum of microbial life (~120ºC) at the sediment/basement interface at ~1.2 km below seafloor. Within the protothrust zone, it is thought that deep sourced water and energy, which are necessary for maintaining microbial activities, are supplied by fluid flow through faults. In order to clarify the origin and migration paths of the fluid, we analyzed the stable hydrogen and oxygen isotopic composition of water (δD and δ^{18}O), the isotopic compositions of $^{87}Sr/^{86}Sr$ and $^{7}Li/^{6}Li$ ratios of the porewaters, and compared those isotopic compositions to the chemical compositions of porewater analyzed on-board. The previous study of the in-situ strength of sediments using drilling parameters shows that there are mechanically strong (potential impermeable layers) and weak (potential fluid pathway) zones at 602–648 mbsf and 800–1050 mbsf, respectively. The especially weak zone is observed between 836 and 870 mbsf. The concentration of chloride ion (Cl^-) suddenly decreases from 530 mM at ~600 mbsf to 480 mM at ~660 mbsf, below which it slightly decreases with depth and shows the minimum value of 450 mM at around ~950 mbsf. The concentration again increases from ~460 mM at ~1000 mbsf to ~550 mM, which is similar to the seawater value, at 1126 mbsf (just above the basement rock). The decrease of Cl^-concentration suggests that the dilution of the original porewater by the addition of fresh water. The depth profiles of δD and δ^{18}O show the trends corresponding to that of Cl^-. The δD value scatters in the range from −12 to −8‰ between 600 and 940 mbsf, and shows the minimum value of −12‰ around ~940 mbsf, below which it increases to −4‰ at 1126 mbsf. The δ^{18}O value increases from −4‰ at ~600 mbsf to −1.5‰ at ~800 mbsf with depth. Then the value increases to −0.6‰ at ~960 mbsf. Below the depth, it decreases to −1.2‰ at 1126 mbsf. The decrease of δD and increase of δ^{18}O accompanied with the depletion of Cl^-between ~600 and ~1000 mbsf suggest the addition of freshwater derived from in-situ clay mineral dehydration and the lateral fluid flow. The sharp decrease of the Cl^-concentration between ~600 and ~650 mbsf suggests that the sediments at this interval is a boundary of low permeability, corresponding to the mechanically strong zone estimated by the drilling parameters. Around décollement (758.2–796.4 mbsf), no remarkable changes were observed in chemical compositions in porewater. Instead, the vicinity of ~900 to ~1000 mbsf, where the lowest Cl^-concentration was observed, is probably associated with the main fluid pathway at present. On the other hand, the depth profiles of the isotopic compositions of Sr and Li as well as their concentrations were not corresponding to that of the Cl^-concentration. The maximum concentrations of Sr and Li, ~620 μM and ~790 μM, respectively, were observed at ~1080 mbsf, together with the high $^{87}Sr/^{86}Sr$ and the lowest $^{7}Li/^{6}Li$ ratio. The high concentration of Li and low δ^{7}Li around ~1080 mbsf indicate that the fluid was experienced by relatively high temperature conditions; i.e., presumably the deep sourced fluid. The discrepancy between the depth profile of $Cl^-$and those of Li and Sr suggests that there is (or was) another fluid pathway at the vicinity around ~1080 mbsf.

Recent progress and perspective on paleomagnetism by means of deep-sea drilling

*Toshitsugu Yamazaki[1], Yuhji Yamamoto[2], Toshiya Kanamatsu[3], Yuho Kumagai[4], Norihiro Nakamura[4]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Center for Advanced Marine Core Research, Kochi University, 3. Japan Agency for Marine-Earth Science and Technology, 4. Tohoku University

We review recent progress of paleomagnetism using deep-sea drilling cores since the beginning of IODP in 2003, in particular for estimations of paleomagnetic-field intensity (paleointensity) from sediments, and discuss problems to be resolved and perspectives.

For the establishment of the high-resolution relative paleointensity stack for the last 1.5 m.y., sediment cores of Exp. 303/306 from the North Atlantic were utilized. While only few records were available before about 3 m.y. previously, some Eocene to Miocene relative paleointensity records were obtained from the cores in the east equatorial Pacific taken during Exp. 320/321. Applicability of relative paleointensity to inter-core correlations and age estimations has extended to older ages accordingly. On the other hand, contamination of sediment lithological variations induced by paleoclimate changes, in particular fluctuations of the proportion of biogenic and terrigenous magnetites, to paleointensity estimations has become widely recognized. It is urgently necessary to resolve this problem and recover reliable long-term paleointensity records for tackling fundamental issues in geomagnetism such as possible dependence of field intensity to the length of polarity intervals and a possible relation between Earth’s orbital parameters and the geomagnetic field. Better understanding of the role of biogenic magnetite in remanent magnetization acquisition processes is important to solve the contamination problem. Information on the variations of time-averaged field in 10^5 to 10^6 year time-scales is also important for geomagnetism. Departure from the geocentric axial dipole (GAD) field of these time-scales may reflect boundary conditions of the geodynamo at the core-mantle boundary. The departure from GAD emerges as inclination anomalies in sediment cores. IODP cores may be useful for such studies although little studied before.

Acquisition of long deep-sea sediment cores is still required for obtaining continuous paleomagnetic records of Miocene and older ages, and IODP will continue to be the only means for this. Paleointensity estimations from sediments of older ages are hindered by dissolution of magnetite by reductive diagenesis; as sediments are buried deeper, reductive diagenesis becomes more serious. Successful expeditions resulted from the strategic selections of drilling sites; for example, the sediments of target ages are not covered with thick younger sediments (Exp. 320/321), and sediments in relatively oxic environments exist even buried under thick sediments (drift sediments of Exp. 363). Recently, the importance of silicate-hosted magnetic minerals as a carrier of remanent magnetization of sediments becomes recognized; they could escape from dissolution even in anoxic conditions. We need to revisit anoxic sediment cores to investigate the possibility for recovering paleomagnetic records from such sediments. Previously paleomagnetists just discarded them without detailed studies.

Patterns in natural fractures during transitions between stress regimes

*Nikita Dubinya[1]

1. The Schmidt Institute of Physics of the Earth of the Russian Academy of Sciences

The study is aimed at analysis of transitions between different stress regimes –Normal Fault, Strike-Slip and Reverse Fault following Anderson’s classification –in terms of natural shear fractures corresponding to each regime. The study is mostly focused on spatial orientations of shear fractures emerging at each stress regime.

It is clear that not all natural fractures existing in a rock mass have the same response to changes in surrounding stresses. Some fractures are considered to be critically stressed in the given stress state which means that a small increase in differential stress (difference between maximum and minimum principal stresses) leads to fracture growth. The fracture is considered as critically stressed if shear stress acting on its plane exceeds normal stress multiplied by internal fraction coefficient of the medium. Normal and shear stresses are calculated from principal stresses’ values and fracture spatial orientation with regard to stress tensor principal axes. That means that for any given stress tensor one is capable of obtaining all the possible spatial orientations of critically stressed fractures.

In the current paper this problem is solved for different stress states for obtaining the typical patterns of fractures’ spatial orientations when stresses are varied considerably enough to change the stress regime. Figure 1 represents a transition between Normal Fault and Strike-Slip regimes: a series of contours on Wolff nets serve as borderlines for poles to critically stressed fractures’ planes. Each color represents its own triad of principal stresses (tables provide necessary match between color and stresses’ values); maximum horizontal stress σ_H is assumed to act in North-South direction. Minimum horizontal stress σ_h and vertical stress σ_V are fixed at the values of 10 and 50 MPa respectively, while transition is caused by increase in σ_H magnitude from 10 to 160 MPa. During the first stage of transition (fig. 1(A), σ_H is between 10 and 30 MPa) poles to fractures tend to gather in Eastern and Western parts of the stereonet. On the second stage (fig. 1(B), σ_H is between 40 and 90 MPa) fractures’ orientation remains stable with slight increase observed in east-northeast, west-northwest, west-southwest, and east-southeast directions. This tendency continues at final stage of transition (fig. 1(C), σ_H is between 100 and 120 MPa) where four main areas typical for Strike-Slip fracture orientation emerge. The same analysis may be completed for other analogous transitions with two fixed principal stresses and one being varied.

Transition between stress regimes may also be observed if principal axes of stress tensor rotate with principal stresses’ magnitudes remaining constant. This scenario may take place near Earth's surface or near large faults due to changes in principal stresses' trajectories. Figure 2 represents transition from Normal Fault to Strike-Slip with principal stresses being fixed at 50, 20, and 10 MPa, while angle ϕ –angle between maximum principal stress direction and vertical –is varied between 0 and 90 degrees. Blue lines still serve as borderlines for the orientations of critically stressed fractures in each case; circles represent the directions of principal stresses (red for maximum, yellow for intermediate, and green for minimum principal stress). It should be noted that lower hemisphere Lambert equal area stereonet is used in this case.

Analogous constructions may be completed for any given stress tensor broadening the understanding of natural fractures’ patterns and their relation to stress geomechanics providing a possibility to solve the

inverse problem of in-situ stresses estimation and their changes near geological structures utilizing the previously developed methods. As a result, some problems of drilling in vicinity of faults - one of primary objects for scientific drilling - may be solved, reducing the drilling risks and costs.

ICDP DSeis 1: Introduction into JpGU 2019 papers on Drilling into Seismogenic zones of M2.0-5.5 earthquakes in South African gold mines

*Hiroshi Ogasawara[1], Bennie Liebenberg[2], Martin Ziegler[3], Yasuo Yabe[4], Ray Durrheim[5], Musa Manzi[5], Tullis C Onstott[6], Thomas Weirsberg[7]

1. Faculty of Science and Engineering, Ritsumeikan University, 2. Moab Khotsong mine, South Africa, 3. ETH, Zurich Dep. Earth Sciences, 4. Graduate School of Science, Tohoku Univ., 5. Univ. Witwatersrand, School of Geoscience, South Africa, 6. Princeton Univ., Dept. Geoscience, USA, 7. GFZ, Potzdam, Germany

The 2014-2019 ICDP Science plan states: “reaching the depths of the seismogenic zone where earthquakes nucleate has always been a challenge for fault-zone drilling projects” (Mori and Ellsworth, 2013). However, during 2016-2018, we could recover cores with a total length of about 1.6 km from seismogenic zones ahead of mining faces, M3.5 and M5.5 earthquakes by drilling collared from depths of 1.0 to 3.3 km below surface in deep South African gold mines. The drilling targets had been already elucidated by tens of near-field seismic sensors. Talc, biotite, and amorphous were found at the M5.5 fault intersection (Kaneki et al. SSJ 2018).

The reliable measurement of the magnitude and orientation of stress at depth is a significant challenge (Brodsky et al., 2009). However, we overcame the difficulty. We intersected hypersaline water where geomicrobiologists started water and gas monitoring.

This paper reviews the scientific drilling and associated activities and briefly introduces the other reports (ICDP DSeis 2-10) presented in JpGU 2019 as shown below:

Drilling into seismogenic zones of M2.0-M5.5 earthquakes in deep South Africa gold mines (DSeis Project) was undertaken in 2017–2018 near Orkney, South Africa, to understand principal mechanism of earthquakes nucleate and propagate. Drilling at two main holes, Hole A (817 m) and Hole B (700 m), was completed at the Moab Khotsong mine, and the latter hole penetrated the fault zone that slipped at the 2014 M5.5 earthquake. Fault-related material and its surrounding host rocks were successfully recovered from the hole, and the samples were analyzed in the Center for Advanced Marine Core Research, Kochi University, Japan. The main damaged zone is characterized by highly fragmented fault breccia with high amount of talc and amorphous material, which is likely to related to recent earthquake event. Nondestructive continuous measurements of physical properties (X-ray CT image, density, magnetic susceptibility, and natural gamma ray) are in progress. We will show the preliminary results about the characteristics of the M5.5 fault zone and its implication for generation of the M5.5 earthquake.

School of Mining Engeneering, University of the Witwatersrand, 7. Moab Khotsong mine

The Orkney earthquake (M5.5), South Africa, occurred on 5 August 2014 beneath a deep gold mine, of which the deepest mining horizon is ~3 km depth from ground surface. Hypocenter of the Orkney earthquake and the shallowest aftershocks were located at ~5 km and ~3.5 km depths from ground surface. Therefore, the ICDP-DSeis project was devised to investigate the geological, geomechanical and geochemical environments in and around the source region of the Orkney earthquake. Two 800 m-long boreholes (Holes A and B) were drilled from a drilling site established on a tunnel at a depth of 2.8 km in the mine. While Hole A reached the seismogenic depth, it did not intersect the aftershock cluster. Hole B success fully penetrated to the aftershock cluster. Borehole cores were almost fully recovered from these holes, though they were not oriented during drilling. Therefore, the core orientation was determined by comparing in-hole optical images and unrolled core images in this study. Then, Diametrical Core Deformation Analysis (DCDA, Funato and Ito, 2017) and Deformation Rate Analysis (DRA, Yamamoto et al., 1990) were applied to borehole cores to evaluate a spatial variation in stress state in and around the aftershock cluster. Finally, a numerical elastic model in which the depth variations along Hole A and B were reproduced was developed to understand a spatial distribution of stress state in and around the aftershock cluster that extended along upper extension of the source fault of the Orkney earthquake.

Acknowledgement. This study was supported by ICDP, JSPS-NRF bilateral research project, JSPS Core-to-Core program, Ritsumeikan University and the Ministry of Education, Culture, Sports, Science and Technology (MEXT) of Japan, under its Earthquake and Volcano Hazards Observation and Research Program. The authors thank Harmony Gold Ltd. for kindly providing an opportunity of drilling from Moab Khotsong mine.

Applications of DCDA method for in-situ crustal stress measurement - Rock core samples from NIED seismic observation wells -

*Kentaro Omura[1], Weiren Lin[2], Takatoshi Ito[3], Akio Funato[4]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Graduate School of Engineering, Kyoto University, 3. Institute of Fluid Science, Tohoku University, 4. Fukada Geological Institute

In-situ crustal stress is an important factor to understand earthquake mechanism and tectonic activities. However, the reliable in-situ stress data seems to be poor related with seismic or strain observation data. We tried to apply the DCDA (Diametrical Core Deformation Analysis) method for in-situ crustal stress measurement using boring rock core samples. DCDA method measures the circumferential diameter variation and elastic constants of core sample without complicate procedures in the borehole. We expect the method can be applied to old-time boring rock cores from seismic observation wells, and we may collect global in-situ crustal stress data in Japan island.
We used recovered hard rock cores from 7 Hi-net obsevation wells of NIED (more than 10 years ago) from the depth about 100m - 200m (one is from the depth of 2000m). The circumferential core diameter variation was measured by an especially designed apparatus that consists of an optical micrometer, a pair of motor-driven rollers and a data processing system (Funato and Ito, 2017, IJRMMS). We got the sine curves of circumferential diameter variation associated with stress relief. However, in some cases, we got the sine curve of circumferential diameter variation obviously related petrogical suructure of sedimetary rocks.The data suggest that the DCDA method is applicable to boring cores from shallow seismic obsevation wells, except for sedimetary rock cores.

Temperature profile measurements in scientific-drilling boreholes and determination of heat flow from the measured temperature profiles are important approaches to understand the temperature distribution and thermal structure around volcanic regions and seismogenic fault zones. A scientific-drilling borehole down to ~700 m deep was penetrated through the Futagawa Fault ruptured during the 2016 Mw 7.1 Kumamoto, Japan earthquake in Aso volcanic region. To obtain the fundamental features of the temperature profile in the borehole, we repeated measurements of temperature depth profile totally four times, i.e., once per two –three months from the borehole penetration was completed in March 2018. As a preliminary result, the temperature depth profile showed a popular trend between depth ranges of 200 –310 m and 430 –650 m where the formation temperature may not be influenced by weather and seasonal temperature change on surface. The temperature in the two depth ranges linearly increased with depth increasing, and showed a geothermal gradient of ~55 ˚C/km. This geothermal gradient is much higher than the global average geothermal gradient 20 –30 ˚C/km, being considered reasonable in a volcanic region. However, a very unexpected temperature distribution feature was observed in the depth range of 310 –430 m. The temperature was almost the same in the ~120 m depth interval; and the geothermal gradient was only ~1 ˚C/km. To make sure if this special temperature distribution is a natural phenomenon, we will continuous our temperature measurements and monitoring in the borehole.

Discussion

Estimation of Shear Stress and Lithology Prediction Using Machine Learning and Surface Drilling Data

Tomoya Inoue[1], *Ryuta Tanaka[1], Junya Ishiwata[1]

1. Japan Agency for Marine-Earth Science and Technology

Introduction

JAMSTEC operates the scientific deep-sea drilling vessel Chikyu. Chikyu conducted the Japan Trench Fast Drilling Program (JFAST) for study on the Tohoku earthquake. Chikyu has also started to conduct the Nankai Trough Seismogenic Zone Experiment (NanTroSEIZE).
The main purpose of the scientific drillings is to obtain core samples from sediment layers under the seabed. However, we are facing the situation that we cannot have enough core samples because the operation philosophy defines that core samples are generally assigned for a lot of separate examinations including geological, chemical, and biological examinations. It is also the reason that the coring operations are conducted at spots. This means that analyzed data, for example the shear stress, can be obtained just at spot(s).
As one of the primary goals of scientific drilling is to evaluate sediment properties, it is highly beneficial to obtain the properties of drilling layers and to characterize the lithology over the full drilling depth during drilling operations. Even an approximation of these properties could potentially provide valuable information for conducting coring operations.

Methods/Procedure

A previous study attempted to discuss the properties of sediment layers using surface drilling data, and estimated the shear stress of the sediment. In this study, we first summarize the method applied in the previous paper for estimating the torque at the drill bit, which leads to estimation of shear stress of sediment layer from the surface measured drilling data for NanTroSEIZE deep riser drilling operation.
The surface drilling data was obtatined using the surface drilling data acquisition system that we developed. The surface drilling data includes the torque of the power swivel (HPS torque) that is equipmenti to provide a torque and rotation to the drillstring. This HPS torque includes not only the drilling torque but also other torques such as friction toque between riser and drill pipe, and mechanical torque inside HPS. This paper proposes to estimate the drilling torque at the drill bit from the surface drilling data by removing other torques based the torque during a “bottom’s” up operations.
We also used machine-learning approaches to predict the lithology, where learning data was created from surface drilling data and lithology information from core samples obtained during past scientific drilling operations. Machine learning was then applied using neural network algorithms by tuning L1 regularization coefficient and the number of layers to create a predictive model. This paper discusses the preliminary attempt to predict the lithology using machine-learning approaches for NanTroSEIZE and JFAST data.

Result/Conclusions

We presented a method for estimating the drilling torque, which was compared to downhole-measured data with logging while drilling (LWD). The result of the calculation shows that the drilling torque at the bit differed from the surface measured torque, where this difference increased with increasing drilling depth. In addition, the estimated drilling torque was validated using downhole-measured torque data obtained from LWD operations. Although the deviation of the mean values between the drilling torque and the downhole measured torque was large, our method is considered valid from the viewpoint of correcting

©2019. Japan Geoscience Union. All Right Reserved.

the characteristics of the depth for the surface measured torque.
This study also presented the lithilogy predicution from machine learning approaches. Preliminary results were presented using NanTroSEIZE and JFAST data including surface drilling data and core sample data. The prediction performance obtained from the generated neural networks indicated that the lithology properties could be predicted by machine learning approaches as an interpolation problem; however, the prediction is sensitive to the structure and parameters of the neural network, along with the selection of training data due to the small learning dataset. In addition, it can be difficult to clearly classify the lithology from core samples as the core sometimes contains several rock types, leading to uncertain classification. We will continue to study lithology prediction using machine-learning methods in future studies.

Overview of drilling of crust-mantle boundary of Oman ophiolite: the ICDP Oman Drilling Project

*Eiichi TAKAZAWA[1,4], Damon A H Teagle[2], Katsuyoshi Michibayashi[3], Yoshihiko Tamura[4], Jude Ann Coggon[2], Juerg Matter[2], Peter B Kelemen[5], Oman Drilling Project Phase 2 Science Party

From the winter of 2017 to 2018 the drilling of crust-mantle transition zone (MTZ) was conducted at Wadi Zeeb (CM1&2 sites) in Wadi Tayin massif by the International Continental Scientific Drilling ProgramOman Drilling Project [6]. The MTZ of Oman ophiolite has been characterized by thick dunites accompanied by thin veins or clots of plagioclase and clinopyroxene and several centimeters to meters thick gabbro sills and wehrlite intrusions. The origin of MTZ is still under debate [2-5]. To clarify this origin, more detailed research by continuous core through MTZ is necessary.

Geological mapping on ground associated with information from the recovered cores in CM1&2 sites the thickness of the MTZ is estimated as about 150 m. The upper and lower boundaries of the MTZ has a strike in the east-west direction, and it is inclined about 30 degrees south. In the summer of 2018, the drilled cores were carefully described by scientists on the deep-sea drilling vessel "CHIKYU". The stratigraphy has been divided into four igneous sequences based on the abundance of different lithologies: Layered Gabbro Sequence, Dunite Sequence, Dunite with Gabbro Sequence, and Mantle Sequence. Dunite Sequence and Dunite with Gabbro Sequence are summarized as Crust - Mantle Transition.

Hole CM1A is inclined 60˚ northward. The upper 160 m of the core is the Layered Gabbro Sequence, mostly composed of olivine gabbro, interlayered with gabbro and a small amount of wehrlite, dunite, anorthosite and troctolite. From 160 to 310 m the Crust-Mantle Transition is divided into an upper 90 m Dunite Sequence and a lower 60 m Dunite with Gabbro Sequence containing small lenses of gabbro, troctolite and wehrlite. The dunites are highly serpentinized, and rodingite and diopsidite commonly replace minor gabbroic rocks in these sequences. The lower 80 m of the hole is the Mantle Sequence, with alternating layers of dunite and increasingly abundant, residual mantle harzburgite.

Hole CM2B is a vertical hole located 400 m north of CM1A, and samples the Crust-Mantle Transition and the Mantle Sequence. As in CM1A, the transition is divided into an upper Dunite Sequence and a lower Dunite with Gabbro Sequence. In contrast to Hole CM1A, a small amount of olivine has escaped complete serpentinization in the lower portions of the CM2B transition zone. In the Mantle Sequence, harzburgite is dominant. Dunite accounts for about 25% of this Sequence, less than in CM1A. The lowermost peridoties in Hole CM2B are strongly altered to talc+carbonate.

Geophysical Logging of Crust-Mantle boundary at Oman Ophiolite

*Yasuhiro Yamada[1], Kyaw Moe[1], Philippe Pezard[2], Juerg Matter[3], OmanDP Science Party

1. Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 2. Géosciences Montpellier, Université de Montpellier, 3. Southampton University

The boundary between the crust and mantle is a horizon that human being can reach in the Earth interior. The nature of this surface has been proposed from viewpoints of petrology, geochemistry and geophysics, and the answer needs to wait until future scientific drilling.

The Samail ophiolite exposed in Oman is one of most well-known surface exposures of the exhumed lowest part of the oceanic crust and upper part of mantle.

The Oman Drilling Project (OmanDP) drilled 12 holes at 7 sites in this ophiolite from 2016 to 2018, and has conducted a comprehensive borehole geophysical survey as logging operation in most of these holes in 2017 and 2018. The data acquired include: electrical resistivity, spectral gamma ray, magnetic susceptibility, full waveform sonic, optical / acoustic / resistivity borehole wall imaging. The extensive logging operation also includes high-definition spectroscopy measurements that contribute to further geochemical investigations. The outline of these datasets and our preliminary analysis will be presented.

Nagoya University, 8. Niigata University, 9. Columbia University, 10. University of Southampton, 11. Kanazawa University, 12. Polymouth University

We report physical property measurements of core samples from the Samail ophiolite in Oman, drilled by the ICDP Oman Drilling Project. Onboard core logging was conducted on D/V Chikyu for 4 months in total in the summers of 2017 and 2018. We analyzed 4 holes (GT1A, GT2A, GT3A and BT1B) in 2017, and 5 holes (CM1A, CM2B, BA1B, BA3A and BA4A) in 2018. The total core length of those 9 holes is about 3200 m. Cores from Holes GT1A and GT2A in the lower crust section of the ophiolite are mainly composed of gabbros (gabbro and olivine gabbro), with small amounts of ultramafic rocks (wehrlite and dunite), whereas those from Hole GT3A at the boundary between the sheeted dikes and gabbro are mainly composed of basalt and diabase, followed by gabbros (gabbro, olivine gabbro and oxide gabbro). Minor felsic trondhjemite and tonalite dikes intrude the mafic rocks. In contrast, Hole BT1B penetrated from mantle section through the basal thrust and into the metamorphic sole. The CM holes were drilled through the crust-mantle transition, from gabbroic lower crust, through dunite with minor gabbros, and in to residual mantle harzburgite. BA holes were taken from the mantle section and are composed of dunite and harzburgite intruded by minor gabbroic and pyroxenite dikes. Ultramafic rocks at both sites were extensively serpentinized, but the names of igneous protoliths are used here.

Whole-round data, including X-ray CT images, natural gamma radiation (NGR), gamma ray attenuation (GRA) density, magnetic susceptibility (MS), P-wave velocity (Vp) and noncontact electrical resistivity were obtained. Split core color spectroscopy data were also collected. Magnetic susceptibility, electrical resistivity under both nominally dry and brine-saturated conditions, P-wave velocity, bulk/grain density, porosity and thermal conductivity were measured in discrete samples. Nearly 100% core recovery allowed us to take a large data set of petrophysical data on the cores from Oman ophiolite including fault zones and highly altered intervals.
Generally, gabbroic rock types have higher density, P-wave velocity, and electrical resistivity, and lower porosity than ultramafic lithologies. Serpentinized dunite have lower density, P-wave velocity and electrical resistivity, and higher porosity than serpentinized harzburgite, and these physical properties are correlated with magnetic susceptibility, probably due to crystallization of magnetite during alteration. Average X-ray CT values are also correlated with many other physical properties in most lithologies.

Exploring the deep subseafloor biosphere and biogeochemical carbon cycling beneath the Arctic ocean

*Fumio Inagaki[1], Steffen Leth Jørgensen[2], Rolf Birger Pedersen[2]

1. Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 2. Department of Earth Science, University of Bergen, Norway

Despite the Arctic cryosphere is the most sensitive and vulnerable to the global environmental change, the nature of deep subseafloor arctic environments remains largely unknown. Active processes on the drastic climate change, including the anthropogenic global warming and subsequent ice melt, are presumably similar to those mechanisms that formed some of the major hydrocarbon resources we presently use, deeply buried in the subseafloor sediment over millions of years at high atmospheric CO_2 and global warm conditions. Continuing to advance understanding of the natural analogues beneath the Arctic ocean through scientific drilling is a powerful approach for the discoveries and understanding of life and Earth co-operating systems, and consequently will illuminate the possible resilience and sustainable strategies adopted by human society towards the future. Here, we are keenly interested in the Arctic deep biosphere and biogeochemical carbon cycling, which presumably be tightly associated with tectonics and biotic/abiotic processes through paleoceanographic events of seawater stagnations, perturbations and fertilizations in the Paleogene to Cretaceous period, and perhaps still continuing in situ over geologic time. How is diagenetic activity and microbial diversity linked to variability in Cenozoic climate and environmental changes? To what degree is carbon diagenesis linked to biotic/abiotic and tectonic processes? What fluid flow and energy transformation processes support microbial activity in situ and govern carbon sink in the Arctic sedimentary basin? How does alternation of deep oceanic crust contribute to microbial life and biogeochemical carbon cycling in the shallower habitat? In addition, what is the nature of the Arctic basement? These important scientific issues on the most climate-sensitive place on Earth remain to be explored, but using the *Chikyu*' s riser-drilling and onboard facilities, it can be addressed by the state-of-the-art interdisciplinary analyses of core samples and the long-term borehole observatory.

Utilization and curation of frozen core samples in IODP and implementation of the Nagoya Protocol in ocean drilling science

*Nan XIAO[1]

1. Japan Agency for Marine Earthe Science and Technology

Deep biosphere research has become one of the major scientific focuses in ocean drilling science. How to access to core samples with sufficient quality has been a changes for scientists. Currently there are two methods of accessing to deep biosphere samples which are participating in drilling expeditions and requesting samples from core repositories. The Kochi Core Center has curated deep biosphere samples that were processed aseptically and stored at deep frozen (-80 degree C) condition from more than 10 drilling expeditions. Increased scientific attention to microbiological research of the subseafloor envrionment raises the complications and concerns related to adherence to the Nagoya Protocol of the Convention on Biological Diversity (CBD). The Nagoya Protocol is an international agreement that aims to guide countries in developing standart protocols and protections for accessing biological materials, and sharing benefits derived from their utilization. Since its commencement, the Nagoya Protocol has placed international biological research, especially fieldwork, under greater political scrutiny and increased its complexity due to the variation in implementation between nations. We present the central points of the Nagoya Protocol on access and benefit-sharing (ABS) and discuss their relationship to ocean drilling research. In addition, we address the challenges faced by ocean drilling in complying with this internation convention.

In-situ rock strength calculated from drilling parameters. Comparison of results from various sites.

*Adam Wspanialy[1], Yasuhiro Yamada[1], Saneatsu Saito[1], KYAW MOE[1]

1. Japan Agency for Marine-Earth Science and Technology

Drilling parameters are excellent datasets to understand in-situ physical properties of the rock. Continuous core samples along with parameters such as Torque, RPM, WOB and ROP have been collected during drilling operations. The borehole data acquisition was complemented with full LWD/MWD and wireline logging. After core delivery to surface core scratch tests have been carried out to measure Unconfined Compressive Strength (UCS). Our comprehensive approach enabled us to integrate all data and conduct detailed analysis of the in-situ subsurface physical and mechanical properties of a rock cut by a drill bit.

Here we present some results from offshore and onshore drilling experiments carried out in Japan, Oman and Australia. Methods such as Specific Energy (SE) and Equivalent Strength (EST) have been used to estimate in-situ rock properties, namely UCS and analyse drilling process.

Our results demonstrate that the calculated in-situ rock strength based on SE/EST methods correlates well with sonic derived UCS and core scratch derived UCS. Utilised methods also successfully detect fractures in the formation, show developing drilling dysfunctions such as vibration, and bit balling.

Interaction between submarine landslides and subseafloor sedimentary microbiome: Chikyu SCORE Expedition 910 off Cape Erimo

*Tatsuhiko Hoshino[1], Go-Ichiro Uramoto[2], Satoshi Tonai[2], Yuki Morono[1], Akira Ijiri[1], Shino Suzuki[1], Yusuke Kubo[1], Fumio Inagaki[1], Chikyu SCORE Exp. 910 Scientists .

During the past decades, scientific ocean drilling has explored the subseafloor sedimentary biosphere down to over 2 kilometers below seafloor (Inagaki et al., 2015). The total biomass and diversity of microbial community in the subseafloor biosphere are comparable to those in the hydrosphere (Kallmeyer et al., 2012). Taxonomic composition of subseafloor microbial communities are distinct from those of other habitats on Earth’ s surface, such as ocean and soil, inferring that adaptive evolution of microbial community to the energy-limited deep sedimentary habitats have occurred. In a previous study of bioturbated layers in surface marine sediments, it has been reported that seawater-migration by macrofauna activity during the initial depositional stage notably affected microbial community structures (Chen et al. 2017). Similarly, it can be hypothesized that submarine landslides have introduced easily degradable fresh organic matter and dissolved electron acceptors (e.g., oxygen, sulfate) to the sedimentary habitats, and consequently caused a shift of microbial communities and its function.

In 2017, we conducted the Chikyu’ s first SCORE Expedition 910 at the Hidaka Trough off Cap Erimo and obtained sediment cores down to 100 meters below the seafloor. In the core column, four intervals of deformed sediments were identified, indicating the occurrences of multiple submarine landslides in this area. In those deformed sediment intervals, we observed no clear anomaly in the profile of cell abundance, which decrease with sediment depth as generally seen in the other subserfloor sediments. In addition, pore water chemistry data do not show clear anomaly either, indicating recovery of sediment geochemistry from the turbation caused by landslides. While both profiles of microbial cell abundance and pore water geochemistry did not show anomaly in the deformed sediment intervals, the DNA-based analyses, showed some unusual appearances of microbial taxa relative to the depth, suggesting the potential migration of microbes from the upper horizons by submarine landslides.

About 100 m sediment cores were taken from off Cape Erimo, Hokkaido, Japan on the Shallow Core Program (SCORE) by D/V Chikyu in 2017. The sedimentary sequence is intercalated with mass transport deposits caused by earthquake-triggered submarine landslides and/or climate changes. Here we report a result of high-resolution continuous geochemical composition of these cores using XRF core scanning technique.

Thermal property measurements of core samples retrieved from Futagawa fault drilling

*Terasu Sano[1], Weiren Lin[1], Susumu Shibutani[1,2], Nana Kamiya[1], Tatsuhiro Sugimoto[1], Kazuya Ishitsuka[1], Aiming Lin[3]

1. Graduate School of Engineering, Kyoto University, 2. Chi-ken Sogo Consultants Co., Ltd.,, 3. Graduate School of Science, Kyoto University

In 2017~2018, to retrieve rock samples from the Futagawa fault ruptured during the 2016 Kumamoto earthquake in Japan, a borehole was drilled down to 700 m depth through the fault in Mashikimachi, Kumamoto prefecture located in the southwest of the Aso volcano. In this borehole, temperature depth profile was measured from ~50 m to ~650 m below the surface (Lin et al., 2019 JpGU). As a preliminary result, an anomaly of temperature, about 1 ℃/km geothermal gradient, was found in the depth range of 310 - 430 m (Lin et al., 2019 JpGU). To examine if this this temperature anomaly comes from thermal conductivity change of the ricks, we collected rock core samples from the borehole and measured their thermal properties.

We measured density, porosity and three thermal transport properties (thermal conductivities, thermal diffusivities, specific heat capacities) of 20 cores drilled from the borehole in the depth range from 300 m to 700 m. I selected typical rock cores to cover not only the depth intervals and also all the main rock types. The rock types of cores are basal sedimentary rocks in 300 m - 353 m , andesite in 353 m - 514 m, sandstone and/or conglomerate in 514 m - 562 m, and tuff in 562 m - 700 m. Measured wet densities and porosities are 1.57 g/cm^3 - 2.02 g/cm^3, 40.0% - 47.8% for basal sedimentary rocks, 2.31 g/cm^3 - 2.95 g/cm^3, 3.1% - 25.5% for andesite, 2.29 g/cm^3 - 2.41 g/cm^3, 21.6% - 29.4% for sandstone and/or conglomerate, 1.99 g/cm^3 - 2.29 g/cm^3, 9.4 % - 35.8% for tuff. Measured thermal conductivities are 0.88 W/(mK) - 1.10 W/(mK) for basal sedimentary rocks, 1.00 W/(mK) - 1.81 W/(mK) for andesite, 1.26 W/(mK) - 1.31 W/(mK) for sandstone and/or conglomerate, 0.96 W/(mK) - 1.27 W/(mK) for tuff. And measured thermal diffusivities and specific heat capacities are 0.85 J/(g･K) - 3.46 J/(g･K) for alluvium, 0.48 m^2/s - 0.91 m^2/s, 1.36 J/(g･K) - 2.60 J/(g･K) for andesite, 0.49 m^2/s - 0.66 m^2/s, 1.95 J/(g･K) - 2.70 J/(g･K) for sandstone and/or conglomerate, 0.40 m^2/s - 0.99 m^2/s, 1.40 J/(g･K) - 2.93 J/(g･K) for tuff. From data of measured temperature of borehole and thermal conductivities of the cores, we calculated heat flow of in the borehole. Using this heat flow and thermal conductivities, we reconstructed the temperature profile in the borehole.

In this estimation, we couldn't reproduce the anomaly of measured temperature. So we conclude that the anomaly of measured temperature is not caused by the significant change of the thermal conductivity in 310 m - 430 m depth.

Results of geotechnical tests on shallow sediment cores recovered from Lord Howe Rise, off eastern Australia: Implications for future Lord Howe Rise riser drilling

*Takamitsu Sugihara[1], Kan Aoike[1], Saneatsu Saito[2], Tatsuya Murayama[1], Kentaro Takeda[1], Takuya Onodera[3], Ayumi Sumikawa[3], Yukari Kido[1], Yoshinori Sanada[1]

1. Center for deep earth exploration, Japan Agency for Marine-Science and Technology, 2. Research and development center for ocean drilling science, Japan Agency for Marine-Science and Technology, 3. Nippon Marine Enterprises, Ltd.

Lord Howe Rise (LHR) Drilling Project (871-CPP2) is an accepted IODP drilling proposal to reconstruct Cretaceous tectonic history of northern Zealandia, designated as a Chikyu riser drilling project. In order to plan a riser drilling operation, it is important to evaluate mechanical strength and physical properties of shallow sediment (0 to 100 or 200 meters below sea floor, mbsf) for setting Blow-out Prevention (BOP) system and riser with heavy weight on the seafloor. Geotechnical core test (e.g., triaxial compressive test and consolidation test) is an essential work to directly measure rock strength and physical properties of geological materials. Therefore, the geotechnical core tests are usually conducted for the surface sediment to evaluate their mechanical and physical properties. In the LHR region, calcareous sediment is broadly and predominantly distributed, and clayey sediment is not observed in shallow sediments. In general, deep seafloor is composed of clayey sediment, and their mechanical and physical properties are well understood. However, mechanical and physical properties of calcareous sediment in both ambient and confined pressure conditions are not well known.

In this study, results of geotechnical test for shallow cores taken in the LHR region are presented, and characteristics of mechanical and physical properties (especially shear strength and permeability) are discussed.

Shallow cores for geotechnical test were taken by R/V Kairei with a gravity piston corer in KR17-15C and by D/V JOIDES Resolution with a rotary core barrel (RCB) in Expedition 371. The gravity piston coring by R/V Kairei was conducted at the proposed riser drilling sites DLHR-5A and -3A, and two cores with approximately 7 m length were taken at each site. The RCB coring by D/V JOIDES Resolution was conducted at Site U1506 in Expedition 371. A whole-round sample with 40 cm length was taken from U1506A-13R for our investigation, and depth of the whole-round sample is 116.5 mbsf. In order to measure physical and mechanical properties for the core samples, geotechnical tests of Penetrometer test, Bulk density, Grain density, Liquid limit, Plastic limit, Grain size distribution, Constant rate of strain consolidation test (CRSC test), and Triaxial compressive strength test with pore pressure measurement (Consolidated-Undrained conditions) were carried out.

Most of the tests except penetrometer test were carried out by OYO Co. Procedures of those measurements and tests were based on the regulations established by Japanese Geotechnical Society (JGS) and Japanese Industrial Standards (JIS). Those are almost the same as their regulations in the ASTM.

All of core samples are composed of calcareous ooze, and grain size distribution of the core samples shows clay size fraction (less than 5 micro meters) is dominant (more than 80 %).

©2019. Japan Geoscience Union. All Right Reserved.

Based on the bulk density data, overburden stresses were calculated and consolidation pressures corresponding to depth of 10 to 240 mbsf for the triaxial test were estimated assuming k0 compaction (k0 factor = 0.5). The result of the triaxial test show shear strength profile gradually increases with depth and is almost identical to those of clayey sediment from Kumano Basin and Nankai Trough. However, the result of the penetrometer test indicates that shear strength of calcareous ooze under ambient condition is quite lower than those of clayey sediment. This observation suggests mechanical strength of calcareous ooze is easily released with depressurizing of sediment.

Based on the result of the CRSC test, it is indicated that calcareous ooze shows no obvious preconsolidation stress, and this result is in good agreement with the result of the triaxial test mentioned above. Permeability of calcareous ooze calculated from the CRSC test results is similar to sandy sediment and the results indicate calcareous ooze is more permeable as compared with clayey sediment.

Those results will be dedicated to analysis for the riser operation in the LHR area.

Mandela Mining Precinct, CSIR, 11. Council for Geoscience

ICDP drilling into the aftershock zone of the 2014 M5.5 earthquake near Orkney, South Africa commenced on 2017 and was completed in 2018. This M5.5 earthquake started from a depth about 5 km and ruptured West Rand Group below mining horizon on unknown geological structure in a deep gold mine. The mechanism of left-lateral slip of this M5.5 earthquake contradicted normal-faulting mechanisms of typical mining-induced earthquakes on mining horizons. The upper fringe of the aftershock zone was several hundreds of meters from the deepest level of the mine. Two NQ holes were collared at a depth of 2.9 km (95 level) below surface at a deep gold mine. Hole A (817m) deviated too much to intersect the M5.5 fault but Hole B (700m) intersected the M5.5 fault. A 3-m double-tube couldn't recover the fault material much, while a 1.5m triple-tube could recover the fault material more in Hole C branched from 544 m in Hole B. Geophysical logging, core logging, and water/gas monitoring followed drilling. All the core was transported to Mandela Mining Precinct, CSIR, Johannesburg and systematically described and scanned by the ICDP DMT scanner. Some of the core were selected for core stress measurements.

In JpGU 2019 meeting, nine papers (ICDP DSeis 1-9) report on the outcomes. This poster (ICDP DSeis 4) compiles drilling, core logging, and in-hole geophysical logging of ICDP DSeis drilling into the M5.5 aftershock zones in a South African gold mines. A core orientation tool was used during drilling but not 100% reliable because there was a case that a bottom line in a core run was different by more than 90 degrees from the bottom line in the next core run. We elaborated to compare OTV image with core to carefully check the core orientation. The modified core orientation allowed us to modify the maximum stress direction that Ishida et al. (2018) measured. We could confirm good consistency with borehole breakout analysis (Richenbacher 2018; ETH master thesis). We will report on other associated outcomes. Refer other papers (ICDP DSeis 1-3, 5-9) for other related outcomes.

ICDP drilling into the aftershock zone of the 2014 M5.5 earthquake near Orkney, South Africa commenced on 2017 and was completed in 2018. Drilling was designed to minimize damage on core and borehole, being able to maximize core recovery. Hole A (817m) was drilled in 2017. It unfortunately didn't intersect the M5.5 fault, running eventually sub-parallel and roughly 100m from the aftershock zone. As the hole was stable we could recover almost 100% of core from the area traversing the periphery of the M5.5 aftershock zone for a distance of several hundreds of meters. Ishida et al. (2018) carried out Diametrical Core Diameter Analysis (Ito and Funato, 2017). This analysis measures the change in core diameter with roll angle around the core axis, which was caused by a relief of anisotropic stress during drilling. We used this analysis because (1) the expected stress was too high for hydrofracturing method, (2) uncertainty in stress magnitude is unavoidable in damage interpretations, (3) DSeis hole were too long for overcoring technique, and (4) DCDA is non-destructive and very easy to make if core is recovered. Ishida et al. (2018) measured 186 pieces of core from Hole A (817m collared at 2.9km depth) that were recovered near the M5.5 aftershock zone. They successfully illustrated spatial variation in differential stress in a plane perpendicular to Hole A axis. They found stress concentration at intrusives with one located at the depth of the upper fringe of the M5.5 aftershock zone. We carried out additional measurement for the remaining part of Hole A and Hole B. With additional data measured at adjacent locations, we could confirm that the stress concentration Ishida et al (2018) found at intrusives was not an outlier. We will report how Hole B that intersected the M5.5 fault differ from Hole A stress.

This is one of nine ICDP DSeis papers (ICDP DSeis 1-9) presented in JpGU 2019. Refer other papers for other topic on drilling, logging, other stress measurement, fault materials, comparison with calculated stress, legacy 3D seismic reflection data, and relocated aftershocks.

ICDP DSeis 6: Deformation Rate Analysis of the M5.5 aftershock zone core - stress concentration at reflective intrusives

*Kanematsu Makoto[1], Mitsuya Higashi[1], Yasuo Yabe[2], Shuhei Abe[2], Bryan Watson[3], Ray Durrheim[3], Hiroshi Ogasawara[1]

1. Ritsumeikan Univ., 2. Tohoku Univ., 3. Univ. Witwatersrand

ICDP drilling into the aftershock zone of the 2014 M5.5 earthquake near Orkney, South Africa commenced on 2017 and was completed in 2018. Ishida et al. (2018) and Sugimura et al. (2019; ICDP DSeis 5) report on spatial variation of differential stress in a plane perpendicular to the borehole axis. It is ideal to have different stress component especially at critical location where significant characteristics were found. Deformation Rate Analysis (Yamamoto, 2009) can measure stress in any direction although the method takes time and the specimen are not reusable for other test. So, we planned to selected samples where characteristic spatial variation was found by DCDA method (Ishida et al. 2018 and Sugimura et al. 2019). It was confirmed also in normal stress component along the borehole axis that stress was concentrated at the intrusive at about 400m.

This is one of nine ICDP DSeis papers (ICDP DSeis 1-9) presented in JpGU 2019. Refer other papers for other topics on drilling, logging, other stress measurement, fault materials, comparison with calculated stress, legacy 3D seismic reflection data, and relocated aftershocks.

College of Science and Engineering, Ritsumeikan Univ., 4. Inst. Fluid Science, Tohoku Univ., 5. Fukada Geological Institute

ICDP drilling into the aftershock zone of the 2014 M5.5 earthquake near Orkney, South Africa commenced on 2017 and was completed in 2018. Spatial variation in stress was measured by Ishida et al. (2018) and Sugimura et al. (2019; ICDP DSeis 5) by DCDA method (Funato and Ito, 2017) and Kanematsu et al. (2019; ICDP DSeis 6). This poster reports on compilation of stress information including the other information sources and compares with calculated stress.

We first compared with a 3D stress state that Ogasawara et al. (2012) measured in 2011 at 98L (3.0 km depth from surface). We assume zero stress on surface, the measured 3D stress (normal faulting stress regime) at 3.0 km, and stress linearly increasing with depth. The calculated stress was consistent with DCDA results measured in the initial 100m section in Hole A, while inconsistent in deeper section. The calculated direction of maximum stress in a plane perpendicular to the borehole axis was also inconsistent with the measured stress information (Yoshida et al. 2019 JpGU; ICDP DSeis 5). Except for the stress concentration measured at intrusives, the measured DCDA results were systematically lower than the calculated stress. In a stress regime that caused the left-lateral horizontal slip on the M5.5 fault, horizontal stress should be larger, which will increase horizontal stress component in a plane perpendicular to the Hole A axis. This increase should decrease difference in stress in the plane perpendicular to the Hole A axis. By JpGU 2019, we will make additional effort to interpret more from the comparison between the measured and calculated stress.

This is one of nine papers (ICDP DSeis 1-9). Refer other papers for other topic on drilling, logging, other stress measurement, fault materials, legacy 3D seismic reflection data, and relocated aftershocks.

ICDP DSeis 8: the M5.5 fault structure and reflective intrusives in legacy 3D seismic reflection data

*Noda Taku[1], Musa Manzi[2], Hiroyuki Ogasawara[1], Lindsay Linzer[2], Stephanie Enslin[2], Ray Durrheim[2], Hiroshi Ogasawara[1]

1. Ritsumeikan Univ., 2. Univ. Witwatersrand

ICDP drilling into the aftershock zone of the 2014 M5.5 earthquake near Orkney, South Africa commenced on 2017 and was completed in 2018. Hiroyuki et al. (2017 AGU) reported on legacy seismic reflection to analyze geological structures in the southern most area of the M5.5 aftershock zones. They found vertical structures in four 2-D lines that were potentially responsible for the M5.5 earthquake and illustrated cross-cutting relations of the M5.5 structure and other known faults that dislocated gold reefs more than several hundreds of meters both horizontally and vertically. Another legacy seismic reflection data which was recorded in 1996 and covered much wider area of the M5.5 aftershock zone was found. We calibrated velocity structure by tying with borehole data including DSeis Holes A and B, we found some of intrusives (sills) that Hole A and B were strong reflectors in the legacy 3D seismic reflection data.

Aftershocks located by in-mine 46 geophones are dense at the southern upper fringe, with a sharp cut-off dipping about 20 degrees to the south; some clear stripes of aftershocks are also seen, in parallel to the upper fringe (Tadokoro et al., JpGU2019, ICDP DSeis 9). It is interesting to note that the reflector (sills) are also in parallel to the upper fringe of the aftershock zone and the aftershock stripes. It is also notable that stress concentration is reported at the intrusives by Sugimura et al. (JpGU2019; ICDP DSeis 5) and Kanematsu et al. (JpGU2019; ICDP DSeis 6). Some mechanism that controls the extent of the aftershocks should exist.

This paper is one of nine papers (ICDP DSeis 1-9). Refer other papers for other topics, e.g. on drilling, logging, stress measurements and evaluation, fault materials, and relocated aftershocks.

ICDP drilling into the aftershock zone of the 2014 M5.5 earthquake near Orkney, South Africa commenced on 2017 and was completed in 2018. Aftershocks located by in-mine 46 geophones are dense at the southern upper fringe, with a sharp cut-off dipping about 20 degrees to the south. Some clear stripes of aftershocks are also seen, in parallel to the upper fringe. It is interesting to note that the reflector (sills) are also in parallel to the upper fringe of the aftershock zone and the aftershock stripes. It is also notable that stress concentration is reported at the intrusives by Sugimura et al. (JpGU2019; ICDP DSeis 5) and Kanematsu et al. (JpGU2019; ICDP DSeis 6). Some mechanism that controls the extent of the aftershocks should exist.

In order to discuss further, we relocated aftershocks with the Double-Difference method (Waldhouser and Ellsworth, 2004). At the moment, we could relocate only 60 events at the upper fringe of the aftershocks. We used in-mine seismic network data of Anglogold Ashanti. P- and S- arrival times that the algorithm of Horiuchi et al. (2011) was used. A sharper alignment of aftershocks is successfully illustrated. By JpGU 2019, we will make additional efforts to extend the area of relocation to discuss more.

[M-IS02] Drilling Earth Science

convener:Yasuhiro Yamada(Japan Agency for Marine-Earth Science and Technology (JAMSTEC), R&D Center for Ocean Drilling Science (ODS)), Yumiko Harigane(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST)), Azumi Kuroyanagi(Tohoku University Museum, The Center for Academic Resources and Archives, Tohoku University), Kosei E. Yamaguchi(Toho University and NASA Astrobiology Institute)

"Earth Drilling Science" session aims to exchange the latest information and scientific achievements in Ocean/Continental drilling projects and to promote the interdisciplinary science. The session covers a wide range of drilling sciences, earth dynamics, environments, and the drilling-related technologies. The overview of the recent IODP cruises as well as future projects of any types of scientific drilling will be reported.

Utilization and curation of frozen core samples in IODP and implementation of the Nagoya Protocol in ocean drilling science

*Nan XIAO[1]

1. Japan Agency for Marine Earthe Science and Technology

Deep biosphere research has become one of the major scientific focuses in ocean drilling science. How to access to core samples with sufficient quality has been a changes for scientists. Currently there are two methods of accessing to deep biosphere samples which are participating in drilling expeditions and requesting samples from core repositories. The Kochi Core Center has curated deep biosphere samples that were processed aseptically and stored at deep frozen (-80 degree C) condition from more than 10 drilling expeditions. Increased scientific attention to microbiological research of the subseafloor envrionment raises the complications and concerns related to adherence to the Nagoya Protocol of the Convention on Biological Diversity (CBD). The Nagoya Protocol is an international agreement that aims to guide countries in developing standart protocols and protections for accessing biological materials, and sharing benefits derived from their utilization. Since its commencement, the Nagoya Protocol has placed international biological research, especially fieldwork, under greater political scrutiny and increased its complexity due to the variation in implementation between nations. We present the central points of the Nagoya Protocol on access and benefit-sharing (ABS) and discuss their relationship to ocean drilling research. In addition, we address the challenges faced by ocean drilling in complying with this internation convention.

In-situ rock strength calculated from drilling parameters. Comparison of results from various sites.

*Adam Wspanialy[1], Yasuhiro Yamada[1], Saneatsu Saito[1], KYAW MOE[1]

1. Japan Agency for Marine-Earth Science and Technology

Drilling parameters are excellent datasets to understand in-situ physical properties of the rock. Continuous core samples along with parameters such as Torque, RPM, WOB and ROP have been collected during drilling operations. The borehole data acquisition was complemented with full LWD/MWD and wireline logging. After core delivery to surface core scratch tests have been carried out to measure Unconfined Compressive Strength (UCS). Our comprehensive approach enabled us to integrate all data and conduct detailed analysis of the in-situ subsurface physical and mechanical properties of a rock cut by a drill bit.

Here we present some results from offshore and onshore drilling experiments carried out in Japan, Oman and Australia. Methods such as Specific Energy (SE) and Equivalent Strength (EST) have been used to estimate in-situ rock properties, namely UCS and analyse drilling process.

Our results demonstrate that the calculated in-situ rock strength based on SE/EST methods correlates well with sonic derived UCS and core scratch derived UCS. Utilised methods also successfully detect fractures in the formation, show developing drilling dysfunctions such as vibration, and bit balling.

Interaction between submarine landslides and subseafloor sedimentary microbiome: Chikyu SCORE Expedition 910 off Cape Erimo

*Tatsuhiko Hoshino[1], Go-Ichiro Uramoto[2], Satoshi Tonai[2], Yuki Morono[1], Akira Ijiri[1], Shino Suzuki[1], Yusuke Kubo[1], Fumio Inagaki[1], Chikyu SCORE Exp. 910 Scientists .

During the past decades, scientific ocean drilling has explored the subseafloor sedimentary biosphere down to over 2 kilometers below seafloor (Inagaki et al., 2015). The total biomass and diversity of microbial community in the subseafloor biosphere are comparable to those in the hydrosphere (Kallmeyer et al., 2012). Taxonomic composition of subseafloor microbial communities are distinct from those of other habitats on Earth’ s surface, such as ocean and soil, inferring that adaptive evolution of microbial community to the energy-limited deep sedimentary habitats have occurred. In a previous study of bioturbated layers in surface marine sediments, it has been reported that seawater-migration by macrofauna activity during the initial depositional stage notably affected microbial community structures (Chen et al. 2017). Similarly, it can be hypothesized that submarine landslides have introduced easily degradable fresh organic matter and dissolved electron acceptors (e.g., oxygen, sulfate) to the sedimentary habitats, and consequently caused a shift of microbial communities and its function.

In 2017, we conducted the Chikyu’ s first SCORE Expedition 910 at the Hidaka Trough off Cap Erimo and obtained sediment cores down to 100 meters below the seafloor. In the core column, four intervals of deformed sediments were identified, indicating the occurrences of multiple submarine landslides in this area. In those deformed sediment intervals, we observed no clear anomaly in the profile of cell abundance, which decrease with sediment depth as generally seen in the other subserfloor sediments. In addition, pore water chemistry data do not show clear anomaly either, indicating recovery of sediment geochemistry from the turbation caused by landslides. While both profiles of microbial cell abundance and pore water geochemistry did not show anomaly in the deformed sediment intervals, the DNA-based analyses, showed some unusual appearances of microbial taxa relative to the depth, suggesting the potential migration of microbes from the upper horizons by submarine landslides.

About 100 m sediment cores were taken from off Cape Erimo, Hokkaido, Japan on the Shallow Core Program (SCORE) by D/V Chikyu in 2017. The sedimentary sequence is intercalated with mass transport deposits caused by earthquake-triggered submarine landslides and/or climate changes. Here we report a result of high-resolution continuous geochemical composition of these cores using XRF core scanning technique.

Thermal property measurements of core samples retrieved from Futagawa fault drilling

*Terasu Sano[1], Weiren Lin[1], Susumu Shibutani[1,2], Nana Kamiya[1], Tatsuhiro Sugimoto[1], Kazuya Ishitsuka[1], Aiming Lin[3]

1. Graduate School of Engineering, Kyoto University, 2. Chi-ken Sogo Consultants Co., Ltd.,, 3. Graduate School of Science, Kyoto University

In 2017~2018, to retrieve rock samples from the Futagawa fault ruptured during the 2016 Kumamoto earthquake in Japan, a borehole was drilled down to 700 m depth through the fault in Mashikimachi, Kumamoto prefecture located in the southwest of the Aso volcano. In this borehole, temperature depth profile was measured from ~50 m to ~650 m below the surface (Lin et al., 2019 JpGU). As a preliminary result, an anomaly of temperature, about 1 ℃/km geothermal gradient, was found in the depth range of 310 - 430 m (Lin et al., 2019 JpGU). To examine if this this temperature anomaly comes from thermal conductivity change of the ricks, we collected rock core samples from the borehole and measured their thermal properties.

We measured density, porosity and three thermal transport properties (thermal conductivities, thermal diffusivities, specific heat capacities) of 20 cores drilled from the borehole in the depth range from 300 m to 700 m. I selected typical rock cores to cover not only the depth intervals and also all the main rock types. The rock types of cores are basal sedimentary rocks in 300 m - 353 m , andesite in 353 m - 514 m, sandstone and/or conglomerate in 514 m - 562 m, and tuff in 562 m - 700 m. Measured wet densities and porosities are 1.57 g/cm^3 - 2.02 g/cm^3, 40.0% - 47.8% for basal sedimentary rocks, 2.31 g/cm^3 - 2.95 g/cm^3, 3.1% - 25.5% for andesite, 2.29 g/cm^3 - 2.41 g/cm^3, 21.6% - 29.4% for sandstone and/or conglomerate, 1.99 g/cm^3 - 2.29 g/cm^3, 9.4 % - 35.8% for tuff. Measured thermal conductivities are 0.88 W/(mK) - 1.10 W/(mK) for basal sedimentary rocks, 1.00 W/(mK) - 1.81 W/(mK) for andesite, 1.26 W/(mK) - 1.31 W/(mK) for sandstone and/or conglomerate, 0.96 W/(mK) - 1.27 W/(mK) for tuff. And measured thermal diffusivities and specific heat capacities are 0.85 J/(g･K) - 3.46 J/(g･K) for alluvium, 0.48 m^2/s - 0.91 m^2/s, 1.36 J/(g･K) - 2.60 J/(g･K) for andesite, 0.49 m^2/s - 0.66 m^2/s, 1.95 J/(g･K) - 2.70 J/(g･K) for sandstone and/or conglomerate, 0.40 m^2/s - 0.99 m^2/s, 1.40 J/(g･K) - 2.93 J/(g･K) for tuff. From data of measured temperature of borehole and thermal conductivities of the cores, we calculated heat flow of in the borehole. Using this heat flow and thermal conductivities, we reconstructed the temperature profile in the borehole.

In this estimation, we couldn't reproduce the anomaly of measured temperature. So we conclude that the anomaly of measured temperature is not caused by the significant change of the thermal conductivity in 310 m - 430 m depth.

Results of geotechnical tests on shallow sediment cores recovered from Lord Howe Rise, off eastern Australia: Implications for future Lord Howe Rise riser drilling

*Takamitsu Sugihara[1], Kan Aoike[1], Saneatsu Saito[2], Tatsuya Murayama[1], Kentaro Takeda[1], Takuya Onodera[3], Ayumi Sumikawa[3], Yukari Kido[1], Yoshinori Sanada[1]

1. Center for deep earth exploration, Japan Agency for Marine-Science and Technology, 2. Research and development center for ocean drilling science, Japan Agency for Marine-Science and Technology, 3. Nippon Marine Enterprises, Ltd.

Lord Howe Rise (LHR) Drilling Project (871-CPP2) is an accepted IODP drilling proposal to reconstruct Cretaceous tectonic history of northern Zealandia, designated as a Chikyu riser drilling project. In order to plan a riser drilling operation, it is important to evaluate mechanical strength and physical properties of shallow sediment (0 to 100 or 200 meters below sea floor, mbsf) for setting Blow-out Prevention (BOP) system and riser with heavy weight on the seafloor. Geotechnical core test (e.g., triaxial compressive test and consolidation test) is an essential work to directly measure rock strength and physical properties of geological materials. Therefore, the geotechnical core tests are usually conducted for the surface sediment to evaluate their mechanical and physical properties. In the LHR region, calcareous sediment is broadly and predominantly distributed, and clayey sediment is not observed in shallow sediments. In general, deep seafloor is composed of clayey sediment, and their mechanical and physical properties are well understood. However, mechanical and physical properties of calcareous sediment in both ambient and confined pressure conditions are not well known.

In this study, results of geotechnical test for shallow cores taken in the LHR region are presented, and characteristics of mechanical and physical properties (especially shear strength and permeability) are discussed.

Shallow cores for geotechnical test were taken by R/V Kairei with a gravity piston corer in KR17-15C and by D/V JOIDES Resolution with a rotary core barrel (RCB) in Expedition 371. The gravity piston coring by R/V Kairei was conducted at the proposed riser drilling sites DLHR-5A and -3A, and two cores with approximately 7 m length were taken at each site. The RCB coring by D/V JOIDES Resolution was conducted at Site U1506 in Expedition 371. A whole-round sample with 40 cm length was taken from U1506A-13R for our investigation, and depth of the whole-round sample is 116.5 mbsf. In order to measure physical and mechanical properties for the core samples, geotechnical tests of Penetrometer test, Bulk density, Grain density, Liquid limit, Plastic limit, Grain size distribution, Constant rate of strain consolidation test (CRSC test), and Triaxial compressive strength test with pore pressure measurement (Consolidated-Undrained conditions) were carried out.

Most of the tests except penetrometer test were carried out by OYO Co. Procedures of those measurements and tests were based on the regulations established by Japanese Geotechnical Society (JGS) and Japanese Industrial Standards (JIS). Those are almost the same as their regulations in the ASTM.

All of core samples are composed of calcareous ooze, and grain size distribution of the core samples shows clay size fraction (less than 5 micro meters) is dominant (more than 80 %).

©2019. Japan Geoscience Union. All Right Reserved.

Based on the bulk density data, overburden stresses were calculated and consolidation pressures corresponding to depth of 10 to 240 mbsf for the triaxial test were estimated assuming k0 compaction (k0 factor = 0.5). The result of the triaxial test show shear strength profile gradually increases with depth and is almost identical to those of clayey sediment from Kumano Basin and Nankai Trough. However, the result of the penetrometer test indicates that shear strength of calcareous ooze under ambient condition is quite lower than those of clayey sediment. This observation suggests mechanical strength of calcareous ooze is easily released with depressurizing of sediment.

Based on the result of the CRSC test, it is indicated that calcareous ooze shows no obvious preconsolidation stress, and this result is in good agreement with the result of the triaxial test mentioned above. Permeability of calcareous ooze calculated from the CRSC test results is similar to sandy sediment and the results indicate calcareous ooze is more permeable as compared with clayey sediment.

Those results will be dedicated to analysis for the riser operation in the LHR area.

Mandela Mining Precinct, CSIR, 11. Council for Geoscience

ICDP drilling into the aftershock zone of the 2014 M5.5 earthquake near Orkney, South Africa commenced on 2017 and was completed in 2018. This M5.5 earthquake started from a depth about 5 km and ruptured West Rand Group below mining horizon on unknown geological structure in a deep gold mine. The mechanism of left-lateral slip of this M5.5 earthquake contradicted normal-faulting mechanisms of typical mining-induced earthquakes on mining horizons. The upper fringe of the aftershock zone was several hundreds of meters from the deepest level of the mine. Two NQ holes were collared at a depth of 2.9 km (95 level) below surface at a deep gold mine. Hole A (817m) deviated too much to intersect the M5.5 fault but Hole B (700m) intersected the M5.5 fault. A 3-m double-tube couldn't recover the fault material much, while a 1.5m triple-tube could recover the fault material more in Hole C branched from 544 m in Hole B. Geophysical logging, core logging, and water/gas monitoring followed drilling. All the core was transported to Mandela Mining Precinct, CSIR, Johannesburg and systematically described and scanned by the ICDP DMT scanner. Some of the core were selected for core stress measurements.

In JpGU 2019 meeting, nine papers (ICDP DSeis 1-9) report on the outcomes. This poster (ICDP DSeis 4) compiles drilling, core logging, and in-hole geophysical logging of ICDP DSeis drilling into the M5.5 aftershock zones in a South African gold mines. A core orientation tool was used during drilling but not 100% reliable because there was a case that a bottom line in a core run was different by more than 90 degrees from the bottom line in the next core run. We elaborated to compare OTV image with core to carefully check the core orientation. The modified core orientation allowed us to modify the maximum stress direction that Ishida et al. (2018) measured. We could confirm good consistency with borehole breakout analysis (Richenbacher 2018; ETH master thesis). We will report on other associated outcomes. Refer other papers (ICDP DSeis 1-3, 5-9) for other related outcomes.

ICDP DSeis 5: Diametrical Core Deformation Analysis of the M5.5 aftershock zone core - stress concentration at reflective intrusives and transition in stress regimes.

*Kosuke Sugimura[1], Shunsuke YOSHIDA[1], Ryogo Tadokoro[1], Hiroshi Ogasawara[2], Akimasa Ishida, Yasuo Yabe[3], Takatoshi Ito[4], Akio Funato[5], Siyanda Mngadi[6], Ray Durrheim[6]

1. Graduate school of science and engineering, Ritsumeikan, 2. College of Science and Engineering, Ritsumeikan Univ., 3. Graduate School of Science, Tohoku Univ., 4. Inst. Fluid Science, Tohoku Univ., 5. Fukada Geological Institute, 6. Univ. Witwatersrand, School of Geoscience

ICDP drilling into the aftershock zone of the 2014 M5.5 earthquake near Orkney, South Africa commenced on 2017 and was completed in 2018. Drilling was designed to minimize damage on core and borehole, being able to maximize core recovery. Hole A (817m) was drilled in 2017. It unfortunately didn't intersect the M5.5 fault, running eventually sub-parallel and roughly 100m from the aftershock zone. As the hole was stable we could recover almost 100% of core from the area traversing the periphery of the M5.5 aftershock zone for a distance of several hundreds of meters. Ishida et al. (2018) carried out Diametrical Core Diameter Analysis (Ito and Funato, 2017). This analysis measures the change in core diameter with roll angle around the core axis, which was caused by a relief of anisotropic stress during drilling. We used this analysis because (1) the expected stress was too high for hydrofracturing method, (2) uncertainty in stress magnitude is unavoidable in damage interpretations, (3) DSeis hole were too long for overcoring technique, and (4) DCDA is non-destructive and very easy to make if core is recovered. Ishida et al. (2018) measured 186 pieces of core from Hole A (817m collared at 2.9km depth) that were recovered near the M5.5 aftershock zone. They successfully illustrated spatial variation in differential stress in a plane perpendicular to Hole A axis. They found stress concentration at intrusives with one located at the depth of the upper fringe of the M5.5 aftershock zone. We carried out additional measurement for the remaining part of Hole A and Hole B. With additional data measured at adjacent locations, we could confirm that the stress concentration Ishida et al (2018) found at intrusives was not an outlier. We will report how Hole B that intersected the M5.5 fault differ from Hole A stress.

This is one of nine ICDP DSeis papers (ICDP DSeis 1-9) presented in JpGU 2019. Refer other papers for other topic on drilling, logging, other stress measurement, fault materials, comparison with calculated stress, legacy 3D seismic reflection data, and relocated aftershocks.

ICDP DSeis 6: Deformation Rate Analysis of the M5.5 aftershock zone core - stress concentration at reflective intrusives

*Kanematsu Makoto[1], Mitsuya Higashi[1], Yasuo Yabe[2], Shuhei Abe[2], Bryan Watson[3], Ray Durrheim[3], Hiroshi Ogasawara[1]

1. Ritsumeikan Univ., 2. Tohoku Univ., 3. Univ. Witwatersrand

ICDP drilling into the aftershock zone of the 2014 M5.5 earthquake near Orkney, South Africa commenced on 2017 and was completed in 2018. Ishida et al. (2018) and Sugimura et al. (2019; ICDP DSeis 5) report on spatial variation of differential stress in a plane perpendicular to the borehole axis. It is ideal to have different stress component especially at critical location where significant characteristics were found. Deformation Rate Analysis (Yamamoto, 2009) can measure stress in any direction although the method takes time and the specimen are not reusable for other test. So, we planned to selected samples where characteristic spatial variation was found by DCDA method (Ishida et al. 2018 and Sugimura et al. 2019). It was confirmed also in normal stress component along the borehole axis that stress was concentrated at the intrusive at about 400m.

This is one of nine ICDP DSeis papers (ICDP DSeis 1-9) presented in JpGU 2019. Refer other papers for other topics on drilling, logging, other stress measurement, fault materials, comparison with calculated stress, legacy 3D seismic reflection data, and relocated aftershocks.

College of Science and Engineering, Ritsumeikan Univ., 4. Inst. Fluid Science, Tohoku Univ., 5. Fukada Geological Institute

ICDP drilling into the aftershock zone of the 2014 M5.5 earthquake near Orkney, South Africa commenced on 2017 and was completed in 2018. Spatial variation in stress was measured by Ishida et al. (2018) and Sugimura et al. (2019; ICDP DSeis 5) by DCDA method (Funato and Ito, 2017) and Kanematsu et al. (2019; ICDP DSeis 6). This poster reports on compilation of stress information including the other information sources and compares with calculated stress.

We first compared with a 3D stress state that Ogasawara et al. (2012) measured in 2011 at 98L (3.0 km depth from surface). We assume zero stress on surface, the measured 3D stress (normal faulting stress regime) at 3.0 km, and stress linearly increasing with depth. The calculated stress was consistent with DCDA results measured in the initial 100m section in Hole A, while inconsistent in deeper section. The calculated direction of maximum stress in a plane perpendicular to the borehole axis was also inconsistent with the measured stress information (Yoshida et al. 2019 JpGU; ICDP DSeis 5). Except for the stress concentration measured at intrusives, the measured DCDA results were systematically lower than the calculated stress. In a stress regime that caused the left-lateral horizontal slip on the M5.5 fault, horizontal stress should be larger, which will increase horizontal stress component in a plane perpendicular to the Hole A axis. This increase should decrease difference in stress in the plane perpendicular to the Hole A axis. By JpGU 2019, we will make additional effort to interpret more from the comparison between the measured and calculated stress.

This is one of nine papers (ICDP DSeis 1-9). Refer other papers for other topic on drilling, logging, other stress measurement, fault materials, legacy 3D seismic reflection data, and relocated aftershocks.

ICDP DSeis 8: the M5.5 fault structure and reflective intrusives in legacy 3D seismic reflection data

*Noda Taku[1], Musa Manzi[2], Hiroyuki Ogasawara[1], Lindsay Linzer[2], Stephanie Enslin[2], Ray Durrheim[2], Hiroshi Ogasawara[1]

1. Ritsumeikan Univ., 2. Univ. Witwatersrand

ICDP drilling into the aftershock zone of the 2014 M5.5 earthquake near Orkney, South Africa commenced on 2017 and was completed in 2018. Hiroyuki et al. (2017 AGU) reported on legacy seismic reflection to analyze geological structures in the southern most area of the M5.5 aftershock zones. They found vertical structures in four 2-D lines that were potentially responsible for the M5.5 earthquake and illustrated cross-cutting relations of the M5.5 structure and other known faults that dislocated gold reefs more than several hundreds of meters both horizontally and vertically. Another legacy seismic reflection data which was recorded in 1996 and covered much wider area of the M5.5 aftershock zone was found. We calibrated velocity structure by tying with borehole data including DSeis Holes A and B, we found some of intrusives (sills) that Hole A and B were strong reflectors in the legacy 3D seismic reflection data.

Aftershocks located by in-mine 46 geophones are dense at the southern upper fringe, with a sharp cut-off dipping about 20 degrees to the south; some clear stripes of aftershocks are also seen, in parallel to the upper fringe (Tadokoro et al., JpGU2019, ICDP DSeis 9). It is interesting to note that the reflector (sills) are also in parallel to the upper fringe of the aftershock zone and the aftershock stripes. It is also notable that stress concentration is reported at the intrusives by Sugimura et al. (JpGU2019; ICDP DSeis 5) and Kanematsu et al. (JpGU2019; ICDP DSeis 6). Some mechanism that controls the extent of the aftershocks should exist.

This paper is one of nine papers (ICDP DSeis 1-9). Refer other papers for other topics, e.g. on drilling, logging, stress measurements and evaluation, fault materials, and relocated aftershocks.

ICDP DSeis 9: are streaks in the M5.5 aftershocks potentially located on highly stressed intrusive?

*Ryogo Tadokoro[1], Katsuya Ishibashi[2], Horiuchi Shigeki[3], Hiroshi Ogasawara[4]

1. Graduate School of Science and Engineering, Ritsumeikan Univ., 2. School of Science and Engineering, Ritsumeikan Univ., 3. Homeseismo ltd., 4. College of Science and Engineering, Ritsumeikan Univ.

ICDP drilling into the aftershock zone of the 2014 M5.5 earthquake near Orkney, South Africa commenced on 2017 and was completed in 2018. Aftershocks located by in-mine 46 geophones are dense at the southern upper fringe, with a sharp cut-off dipping about 20 degrees to the south. Some clear stripes of aftershocks are also seen, in parallel to the upper fringe. It is interesting to note that the reflector (sills) are also in parallel to the upper fringe of the aftershock zone and the aftershock stripes. It is also notable that stress concentration is reported at the intrusives by Sugimura et al. (JpGU2019; ICDP DSeis 5) and Kanematsu et al. (JpGU2019; ICDP DSeis 6). Some mechanism that controls the extent of the aftershocks should exist.

In order to discuss further, we relocated aftershocks with the Double-Difference method (Waldhouser and Ellsworth, 2004). At the moment, we could relocate only 60 events at the upper fringe of the aftershocks. We used in-mine seismic network data of Anglogold Ashanti. P- and S- arrival times that the algorithm of Horiuchi et al. (2011) was used. A sharper alignment of aftershocks is successfully illustrated. By JpGU 2019, we will make additional efforts to extend the area of relocation to discuss more.

The efforts of Mt.Daisetsu-Kamuymintar Geopark Project

*hideyuki kawabe[1]

1. -

In this area, we are promoting the "Mt.Daisetsu-Kamuymintar Geopark Project" ranging from Asahikawa City, Takasu Town, Higashikagura Town, Pippu Town, Tohma Town, Aibetsu Town, Kamikawa Town and Higashikawa Town.
We set up a preparatory organization by authorized municipalities and civil society in 2017, As an aiming area we joined the Japan Geopark Network as an associate member, in the background of resident activities such as "Kamuy's Earth" Geo-Tour and Geo-Forum etc. that "Association of Asahikawa Geoparks" has been doing since 2012.
We have been shifted promotion system to a council added by business organizations and others in August 2018.
In this presentation, we introduce Mt.Daisetsu-Kamuymintar Geopark Project and its efforts.

Re-examination of meaning indicated by "Nigori-Sumi (Muddy and clear) Bridge" ~Turbidity Characteristic of Meeting Point of the Ushikubi River and the Ozo River, in Hakusan Tedorigawa Geopark ~

*Tatsuto Aoki[1]

1. School of Regional Development Studies, Kanazawa University

Two main flow paths consisting the Tedori river water system that flows through the Hakusan Tedorigawa Geopark, the Ushikubi River, the main stream path, originating from the west side of Mt. Hakusan, and the Ozo River, tributary originating from the former the north of Mt. Hakusan. These two flow paths join in the vicinity of the "Nigori-Sumi Bridge" in the Seto area, then turn northward as the Tedori River. The word of "Nigori-Sumi" means "Muddiness and clearness" and this shows the difference in the turbidity between the two flow paths. On the webpage of Hakusan Tedorigawa Geopark, it is written as follows and is accompanied by photographs showing the state that high turbidity water and low water are joining.

“There is a point that the Ozo River meets the Tedori River, and only the Ozo River didn’ t settle down for a while during rugged weather, so it is sometimes possible to see a two-colored flow, muddy and clear water, at the meeting point. Thus this bridge was named Nigorisumi Bridge (nigori means muddy and sumi means clear).”

In this report, the author measured the turbidity of these two flow paths, organized the relationship with artificial river management, and re-examined the meaning of today's word of "Nigori-Sumi".

The Ushikubi River originated form Hakusan Gozengamine (2702 m), and Ozo River originated from Hakusan Onanjimine (2684 m), and joins at an altitude of 240 m near the Nigori-Sumi Bridge. The length of the flow path to the confluence point is 34.3 km for the Ushikubi River (average bed slope 71.8 ‰), and 24.5 km for the Ozo River (107.9 ‰). The Ozo River is steeper than the

Ushikubi River. Many of landslides are distributed in the both basin. However, it is believed that there was a crater of Paleo-Hakusan volcano in the Jigokudani of the Ozo River basin (Nagaoka, 1972), and severe degeneration is recognized. The Tedori dam is built in the Ushikubi River, and its flow is controlled by that dam. On the other hand, there is no artificial dam and the flow is not controlled in the Ozo River.

Five sites for water sampling are set in the basin, and sampled water immediately after the large-scale flood caused by the typhoon. As a result, immediately after large-scale flooding, the flow rate and turbidity are high in the Ozo River where the flow rate is not controlled and the geology of the catchment area is brittle. On the other hand, On the Ushikubi River controlled by a dam, water and suspended sediment are stored in the dam, so the increase in flow rate and turbidity is suppressed. As a result, in the vicinity of Nigori-Sumi bashi Bridge, the Ozo River becomes "muddy" and the Ushikubi River becomes "clear". When

©2019. Japan Geoscience Union. All Right Reserved.

time passes after flooding, the flow rate rapidly approaches the base flow rate in the Ozo River, and the contents of suspended sediment also decreases. On the contrary, in the Ushikubi River where discharge from the dam continues, the flow rate and turbidity is kept high because of the spouting water from the dam. As a result, the situation occurred where the Ushikubi River was "muddy" and the Ozo River was "clear".

Efforts of ‘Grant-in-aid for Science Research in San’ in Kaigan UGGp’

*Suzuka Koriyama[1]

1. Sanin Kaigan Geopark Promotion Council

The San’ in Kaigan UNESCO Global Geopark is a bounded area comprising the entire municipalities of Kyotango City in Kyoto Prefecture; Toyooka City, Kami Town, and Shin’ onsen Town in Hyogo Prefecture; and Iwami Town in Tottori Prefecture; and the northern part of the municipality of Tottori City in Tottori Prefecture.
The San’ in Kaigan UGGp provides territorial cohesion as an area featuring natural scenery with a wide variety of rocks, strata, coastal landforms, and inland waterfalls and gorges, which show the span of history from the times when the Japanese Archipelago was not yet separated from the Asian Continent, through the formation of the Japan Sea, to the present. The Geopark area has also been home to unique human lifestyles based on such natural features.

In 2007, San’ in Kaigan Geopark Promotion Council was established. San’ in Kaigan Geopark was certified as a member of Japanese Geoparks Network (JGN) in 2008 and Global Geoparks Network (GGN) in 2010.

Since the foundation, grant-in-aid program for science research has been conducted. For the revalidation of GGN every four years, this research program plays the important role. This program called ‘Grant-in-aid for Science Research in San’ in Kaigan UGGp’ has been continued since 2009. Through this program, we have awarded 77 researches the grants.
On the other hand, current conditions and challenges are that the latest researches reported every year are not used enough to activate Geopark.

In this presentation, we discuss how this 10-year program had effected on San’ in Kaigan UGGp and researchers who awarded the grant.

Practical applications in the Tosashimizu Geopark Plan of site monitoring by local residents: Landform change of Sakurahama Beach

*Satoru Imai[1], Hisaaki Sato[1], Yorihisa Hirano

1. Tosashimizu Geopark Promotion Council

In order to properly manage sites in the geopark, utilizing site monitoring surveys to understand site change over time is important. The Tosashimizu Geopark Plan Committee is at the center of all monitoring surveys in Tosashimizu and the fact that it allows for many different people to easily get involved and cooperate is an advantage. However, it can be said that the term and frequency of monitoring surveys has been inadequate. As a result, the scientific value of the geosites has become beset by problems. Therefore, the Tosashimizu Geopark Plan Committee has begun to supplement its informational database with pictures and research gathered by local residents of the respective geosites. In addition, local residents have been accumulating such data before becoming involved with geopark activities. It is an important role of the Tosashimizu Geopark Plan Committee specialists to teach local residents about the scientific value of their research.
The focus of this presentation, Sakurahama beach, is a pocket beach located in central Tosashimizu. It has been renowned as a place of scenic beauty since the Edo period. It is known that flat coasts such as Sakurahama beach are easily affected by human influence and environmental changes and local residents have been aware of the reduction of the beach area over time. Also, Sakurahama beach is a spawning ground that many living organisms temporarily inhabit. Consequently, detailed monitoring studies are highly significant. One local resident, Hirano Yorihisa, takes photographs of the same area of Sakurahama beach almost every day. In those pictures, the changes in landform before and after typhoons, the change in granularity of beach sand over time, and loggerhead sea turtle hatchlings can be evidenced. This presentation will analyze the photographic records of Hirano Yorihisa and discuss the future prospects for such research.

Geological and geomorphological environment of the Jikumaru terraced paddy field (one of the Top 100 Terraced Paddy Fields in Japan) in the Oita Bungoono Geopark

*Toshikazu Yoshioka[1]

1. Oita Bungoono Geopark Promotion Council

The Jikumaru terraced paddy field in the Oita Bungoono Geopark is selected as one of the Top 100 Terraced Paddy Fields in Japan. This area is placed between the Ono and Ogata Rivers and the terraced paddy fields are developed in the small and shallow valleys. The bedrock of this area consists of the sandstone and conglomerate of the Late Cretaceous Onogawa Group Ryozen Formation. The non- to weakly welded Aso-3 and Aso-4 pyroclastic flow deposits covered over the Onogawa Group. The Aso-4 pyroclastic flow deposit along the Ono and Ogata Rivers is densely welded. It indicates the sedimentary rocks of the Onogawa Group formed small hills before the Aso-3 and Aso-4 pyroclastic flows. The pyroclastic flow deposits are thin and easy to erode. Accordingly, the small and shallow valleys where terraced paddy fields are developed are formed in this area. The formation of the Jikumaru terraced paddy field is related to the geology and geomorphology of this area and it may be one of the important elements of the Oita Bungoono Geopark.

Keywords: Jikumaru terraced paddy field, Top 100 Terraced Paddy Fields in Japan, Onogawa Group, Aso pyroclastic flow, Oita Bungoono Geopark

The relationship of land utilization and vegetation at the Jikumaru terraced paddy field in the Oita Bungoono Geopark

*Miki Iwasato[1], Toshikazu Yoshioka[2]

1. Bungoono City, Trade, Industry and Tourism Division, 2. Oita Bungoono Geopark Promotion Council

The Jikumaru terraced paddy field in the Oita Bungoono Geopark is located between Ono River and Ogata River and selected as one of the Top 100 Terraced Paddy Fields in Japan. It is suggested that there are a lot of plants for various geography in the Jikumaru terraced paddy field, so we surveyed vegetation in this area.
Result of survey, in the Jikumaru terraced paddy field, we identified 281 plants species. There were 106 plants for example *Ottelia alismoides* (L.) Pers., *Eclipta thermalis* Bunge and *Schoenoplectus hotarui* (Ohwi) Holub, at the paddy field and its ridge. Under the artificial forests of Japanese cedar trees and oak forests, various plants had grown for example *Quercus serrata* Murray subsp. var. *serrata*, *Rubus buergeri* Miq. and *Ardisia japonica* (Thunb.) Blume var. *japonica*. Planting species as *Lycoris radiata* (L'Hér.) Herb. var. *radiata* and *Hydrangeaceae*, were checked in this area.
In the Jikumaru terraced paddy field, it was found that vegetation of characterized terraced paddy field for we checked both of mountain and paddy field plants in various geography. This is shown that the Jikumaru terraced paddy field may be one of the elements on the Oita Bungoono Geopark.

Outreach activities of Aso UNESCO Global Geopark

*Tsuneomi Kagiyama[1], Kazunori Watanabe[1], Shinichiro Ikebe[1], Akinobu Ishimatsu[1], Katsunori Toyomura[2], Natsuko Kodama[1], Shuhei Takamori[1], Shino Miyakita[1]

1. Aso Geopark Promotion Council, 2. Aso Volcano Museum

Aso UNESCO Global Geopark made an action plan to clear a revalidation process by UNESCO. One of the plans was to reinforce sending an information on ourselves. Just after the 2016 Kumamoto Earthquake, we have collected records on hazards of this earthquake and eruptions in Aso Volcano, and have shown the recovering process from these hazards. In 2018, we have made some new Geo-tours reflecting these results. We also have collected more information about the earth activities causing hazards, and have made some educational programs and some SNS output. We will report some of these activities as follows.

Geo-tour:

In Tateno Gorge Geosite, we added to explain a close relation between a view of this site and Futagawa Active Fault, a part of Oita-Kumamoto Tectonic Line. In Uchinomaki Geosite, many hot springs did not work just after the Kumamoto Earthquake. We examined the reason, and could recover the hot springs. We introduced this recovering process in our tour. In Nakadake Geosite, we added to explain about phreatomagmatic explosion in October, 2016. And also we cooperated with the Ministry of the Environment to renew the explanations of the sign installed in National Park.

Educational Program:

We opened educational program on "Aso Geopark" in Aso-Chuo-High School; volcanic activity in Aso, recovering activities from Kumamoto Earthquake disaster, sightseeing in Aso and maintenance in grassland. Exhibition of Aso Volcano Museums was revised based on a recent research result. Visitors can see the crater and the observational data which indicates a volcanic activity in real time.

Activity by SNS:

We effectively use Facebook, Blog, Instagram. We introduced beautiful pictures, information performed within Aso and information on disaster mitigation, etc. We also opened the SNS pages which explain documents published by the Meteorological Agency on volcanic activity of Aso.

Geoscientific Setting and Educational Significances of Yonaguni Island in the Ryukyu Arc, Eastern Asia

*Takayuki Ogata[1], Masakazu Nara[2], Makoto Otsubo[3], Tadahiro Shibata[4]

1. Disaster Prevention Research Center for Island Regions, University of the Ryukyus, 2. Sciences Unit, Natural Sciences Cluster, Research and Education Faculty, Kochi University, 3. Geological Survey of Japan, Research Institute of Earthquake and Volcano Geology, 4. The Unit of Natural Monuments, Monuments and Sites Division, Cultural Properties Department, Agency for Cultural Affaire

The Ryukyu Arc lies along the subduction zone between Eurasia and Philippine Sea Plates. Yonaguni Island is located in southwestern most of the Ryukyu Arc, where geological setting connects the Taiwan central range and the Luzon volcanic arc. Miocene sandstone (Yaeyama group) is broadly exposed on island surface which forms low altitude mountains and hills (maximum elevation is 231 m). The Yaeyama Group, of which sandstones show some distinct physical sedimentary structures, such as hummocky or ripple cross-stratification, suggesting deposition in shallow-marine to marginal-marine settings, is characterized by pervasive occurrences of well-preserved trace fossils. Sandstone surfaces in wave-splash zone often show a honeycomb structure (tafoni) indicating physical disintegration by salt weathering under present coastal environments with strong wind. This honeycomb geometry seems to be controlled by the horizontal and vertical distances from coast line and sea level. Pleistocene limestone (Ryukyu group) partly covers the Yaeyama group and forms uplifted marine terraces made mainly from coral reef sediments. As the permeable limestones of Ryukyu Group broadly covers the less permeable Yaeyama Group, a number of natural springs rise at the bottom of the precipitous limestone cliffs, and provide water resources and scenic landscapes. Such stratigraphical, paleontological, geomorphological and hydrological features present significant sites to study seamless geoscience. Geoscientist should discuss scientific significances for conservation of several geosites in Yonaguni Island.

Re-examination of meaning indicated by "Nigori-Sumi (Muddy and clear) Bridge" ~Turbidity Characteristic of Meeting Point of the Ushikubi River and the Ozo River, in Hakusan Tedorigawa Geopark ~

*Tatsuto Aoki[1]

1. School of Regional Development Studies, Kanazawa University

Two main flow paths consisting the Tedori river water system that flows through the Hakusan Tedorigawa Geopark, the Ushikubi River, the main stream path, originating from the west side of Mt. Hakusan, and the Ozo River, tributary originating from the former the north of Mt. Hakusan. These two flow paths join in the vicinity of the "Nigori-Sumi Bridge" in the Seto area, then turn northward as the Tedori River. The word of "Nigori-Sumi" means "Muddiness and clearness" and this shows the difference in the turbidity between the two flow paths. On the webpage of Hakusan Tedorigawa Geopark, it is written as follows and is accompanied by photographs showing the state that high turbidity water and low water are joining.

“There is a point that the Ozo River meets the Tedori River, and only the Ozo River didn’ t settle down for a while during rugged weather, so it is sometimes possible to see a two-colored flow, muddy and clear water, at the meeting point. Thus this bridge was named Nigorisumi Bridge (nigori means muddy and sumi means clear).”

In this report, the author measured the turbidity of these two flow paths, organized the relationship with artificial river management, and re-examined the meaning of today's word of "Nigori-Sumi".

The Ushikubi River originated form Hakusan Gozengamine (2702 m), and Ozo River originated from Hakusan Onanjimine (2684 m), and joins at an altitude of 240 m near the Nigori-Sumi Bridge. The length of the flow path to the confluence point is 34.3 km for the Ushikubi River (average bed slope 71.8 ‰), and 24.5 km for the Ozo River (107.9 ‰). The Ozo River is steeper than the

Ushikubi River. Many of landslides are distributed in the both basin. However, it is believed that there was a crater of Paleo-Hakusan volcano in the Jigokudani of the Ozo River basin (Nagaoka, 1972), and severe degeneration is recognized. The Tedori dam is built in the Ushikubi River, and its flow is controlled by that dam. On the other hand, there is no artificial dam and the flow is not controlled in the Ozo River.

Five sites for water sampling are set in the basin, and sampled water immediately after the large-scale flood caused by the typhoon. As a result, immediately after large-scale flooding, the flow rate and turbidity are high in the Ozo River where the flow rate is not controlled and the geology of the catchment area is brittle. On the other hand, On the Ushikubi River controlled by a dam, water and suspended sediment are stored in the dam, so the increase in flow rate and turbidity is suppressed. As a result, in the vicinity of Nigori-Sumi bashi Bridge, the Ozo River becomes "muddy" and the Ushikubi River becomes "clear". When

©2019. Japan Geoscience Union. All Right Reserved.

time passes after flooding, the flow rate rapidly approaches the base flow rate in the Ozo River, and the contents of suspended sediment also decreases. On the contrary, in the Ushikubi River where discharge from the dam continues, the flow rate and turbidity is kept high because of the spouting water from the dam. As a result, the situation occurred where the Ushikubi River was "muddy" and the Ozo River was "clear".

Efforts of ‘Grant-in-aid for Science Research in San’ in Kaigan UGGp’

*Suzuka Koriyama[1]

1. Sanin Kaigan Geopark Promotion Council

The San’ in Kaigan UNESCO Global Geopark is a bounded area comprising the entire municipalities of Kyotango City in Kyoto Prefecture; Toyooka City, Kami Town, and Shin’ onsen Town in Hyogo Prefecture; and Iwami Town in Tottori Prefecture; and the northern part of the municipality of Tottori City in Tottori Prefecture.
The San’ in Kaigan UGGp provides territorial cohesion as an area featuring natural scenery with a wide variety of rocks, strata, coastal landforms, and inland waterfalls and gorges, which show the span of history from the times when the Japanese Archipelago was not yet separated from the Asian Continent, through the formation of the Japan Sea, to the present. The Geopark area has also been home to unique human lifestyles based on such natural features.

In 2007, San’ in Kaigan Geopark Promotion Council was established. San’ in Kaigan Geopark was certified as a member of Japanese Geoparks Network (JGN) in 2008 and Global Geoparks Network (GGN) in 2010.

Since the foundation, grant-in-aid program for science research has been conducted. For the revalidation of GGN every four years, this research program plays the important role. This program called ‘Grant-in-aid for Science Research in San’ in Kaigan UGGp’ has been continued since 2009. Through this program, we have awarded 77 researches the grants.
On the other hand, current conditions and challenges are that the latest researches reported every year are not used enough to activate Geopark.

In this presentation, we discuss how this 10-year program had effected on San’ in Kaigan UGGp and researchers who awarded the grant.

Practical applications in the Tosashimizu Geopark Plan of site monitoring by local residents: Landform change of Sakurahama Beach

*Satoru Imai[1], Hisaaki Sato[1], Yorihisa Hirano

1. Tosashimizu Geopark Promotion Council

In order to properly manage sites in the geopark, utilizing site monitoring surveys to understand site change over time is important. The Tosashimizu Geopark Plan Committee is at the center of all monitoring surveys in Tosashimizu and the fact that it allows for many different people to easily get involved and cooperate is an advantage. However, it can be said that the term and frequency of monitoring surveys has been inadequate. As a result, the scientific value of the geosites has become beset by problems. Therefore, the Tosashimizu Geopark Plan Committee has begun to supplement its informational database with pictures and research gathered by local residents of the respective geosites. In addition, local residents have been accumulating such data before becoming involved with geopark activities. It is an important role of the Tosashimizu Geopark Plan Committee specialists to teach local residents about the scientific value of their research.
The focus of this presentation, Sakurahama beach, is a pocket beach located in central Tosashimizu. It has been renowned as a place of scenic beauty since the Edo period. It is known that flat coasts such as Sakurahama beach are easily affected by human influence and environmental changes and local residents have been aware of the reduction of the beach area over time. Also, Sakurahama beach is a spawning ground that many living organisms temporarily inhabit. Consequently, detailed monitoring studies are highly significant. One local resident, Hirano Yorihisa, takes photographs of the same area of Sakurahama beach almost every day. In those pictures, the changes in landform before and after typhoons, the change in granularity of beach sand over time, and loggerhead sea turtle hatchlings can be evidenced. This presentation will analyze the photographic records of Hirano Yorihisa and discuss the future prospects for such research.

Geological and geomorphological environment of the Jikumaru terraced paddy field (one of the Top 100 Terraced Paddy Fields in Japan) in the Oita Bungoono Geopark

*Toshikazu Yoshioka[1]

1. Oita Bungoono Geopark Promotion Council

The Jikumaru terraced paddy field in the Oita Bungoono Geopark is selected as one of the Top 100 Terraced Paddy Fields in Japan. This area is placed between the Ono and Ogata Rivers and the terraced paddy fields are developed in the small and shallow valleys. The bedrock of this area consists of the sandstone and conglomerate of the Late Cretaceous Onogawa Group Ryozen Formation. The non- to weakly welded Aso-3 and Aso-4 pyroclastic flow deposits covered over the Onogawa Group. The Aso-4 pyroclastic flow deposit along the Ono and Ogata Rivers is densely welded. It indicates the sedimentary rocks of the Onogawa Group formed small hills before the Aso-3 and Aso-4 pyroclastic flows. The pyroclastic flow deposits are thin and easy to erode. Accordingly, the small and shallow valleys where terraced paddy fields are developed are formed in this area. The formation of the Jikumaru terraced paddy field is related to the geology and geomorphology of this area and it may be one of the important elements of the Oita Bungoono Geopark.

The relationship of land utilization and vegetation at the Jikumaru terraced paddy field in the Oita Bungoono Geopark

*Miki Iwasato[1], Toshikazu Yoshioka[2]

1. Bungoono City, Trade, Industry and Tourism Division, 2. Oita Bungoono Geopark Promotion Council

The Jikumaru terraced paddy field in the Oita Bungoono Geopark is located between Ono River and Ogata River and selected as one of the Top 100 Terraced Paddy Fields in Japan. It is suggested that there are a lot of plants for various geography in the Jikumaru terraced paddy field, so we surveyed vegetation in this area.
Result of survey, in the Jikumaru terraced paddy field, we identified 281 plants species. There were 106 plants for example *Ottelia alismoides* (L.) Pers., *Eclipta thermalis* Bunge and *Schoenoplectus hotarui* (Ohwi) Holub, at the paddy field and its ridge. Under the artificial forests of Japanese cedar trees and oak forests, various plants had grown for example *Quercus serrata* Murray subsp. var. *serrata*, *Rubus buergeri* Miq. and *Ardisia japonica* (Thunb.) Blume var. *japonica*. Planting species as *Lycoris radiata* (L'Hér.) Herb. var. *radiata* and *Hydrangeaceae*, were checked in this area.
In the Jikumaru terraced paddy field, it was found that vegetation of characterized terraced paddy field for we checked both of mountain and paddy field plants in various geography. This is shown that the Jikumaru terraced paddy field may be one of the elements on the Oita Bungoono Geopark.

Outreach activities of Aso UNESCO Global Geopark

*Tsuneomi Kagiyama[1], Kazunori Watanabe[1], Shinichiro Ikebe[1], Akinobu Ishimatsu[1], Katsunori Toyomura[2], Natsuko Kodama[1], Shuhei Takamori[1], Shino Miyakita[1]

1. Aso Geopark Promotion Council, 2. Aso Volcano Museum

Aso UNESCO Global Geopark made an action plan to clear a revalidation process by UNESCO. One of the plans was to reinforce sending an information on ourselves. Just after the 2016 Kumamoto Earthquake, we have collected records on hazards of this earthquake and eruptions in Aso Volcano, and have shown the recovering process from these hazards. In 2018, we have made some new Geo-tours reflecting these results. We also have collected more information about the earth activities causing hazards, and have made some educational programs and some SNS output. We will report some of these activities as follows.

Geo-tour:

In Tateno Gorge Geosite, we added to explain a close relation between a view of this site and Futagawa Active Fault, a part of Oita-Kumamoto Tectonic Line. In Uchinomaki Geosite, many hot springs did not work just after the Kumamoto Earthquake. We examined the reason, and could recover the hot springs. We introduced this recovering process in our tour. In Nakadake Geosite, we added to explain about phreatomagmatic explosion in October, 2016. And also we cooperated with the Ministry of the Environment to renew the explanations of the sign installed in National Park.

Educational Program:

We opened educational program on "Aso Geopark" in Aso-Chuo-High School; volcanic activity in Aso, recovering activities from Kumamoto Earthquake disaster, sightseeing in Aso and maintenance in grassland. Exhibition of Aso Volcano Museums was revised based on a recent research result. Visitors can see the crater and the observational data which indicates a volcanic activity in real time.

Activity by SNS:

We effectively use Facebook, Blog, Instagram. We introduced beautiful pictures, information performed within Aso and information on disaster mitigation, etc. We also opened the SNS pages which explain documents published by the Meteorological Agency on volcanic activity of Aso.

Geoscientific Setting and Educational Significances of Yonaguni Island in the Ryukyu Arc, Eastern Asia

*Takayuki Ogata[1], Masakazu Nara[2], Makoto Otsubo[3], Tadahiro Shibata[4]

1. Disaster Prevention Research Center for Island Regions, University of the Ryukyus, 2. Sciences Unit, Natural Sciences Cluster, Research and Education Faculty, Kochi University, 3. Geological Survey of Japan, Research Institute of Earthquake and Volcano Geology, 4. The Unit of Natural Monuments, Monuments and Sites Division, Cultural Properties Department, Agency for Cultural Affaire

The Ryukyu Arc lies along the subduction zone between Eurasia and Philippine Sea Plates. Yonaguni Island is located in southwestern most of the Ryukyu Arc, where geological setting connects the Taiwan central range and the Luzon volcanic arc. Miocene sandstone (Yaeyama group) is broadly exposed on island surface which forms low altitude mountains and hills (maximum elevation is 231 m). The Yaeyama Group, of which sandstones show some distinct physical sedimentary structures, such as hummocky or ripple cross-stratification, suggesting deposition in shallow-marine to marginal-marine settings, is characterized by pervasive occurrences of well-preserved trace fossils. Sandstone surfaces in wave-splash zone often show a honeycomb structure (tafoni) indicating physical disintegration by salt weathering under present coastal environments with strong wind. This honeycomb geometry seems to be controlled by the horizontal and vertical distances from coast line and sea level. Pleistocene limestone (Ryukyu group) partly covers the Yaeyama group and forms uplifted marine terraces made mainly from coral reef sediments. As the permeable limestones of Ryukyu Group broadly covers the less permeable Yaeyama Group, a number of natural springs rise at the bottom of the precipitous limestone cliffs, and provide water resources and scenic landscapes. Such stratigraphical, paleontological, geomorphological and hydrological features present significant sites to study seamless geoscience. Geoscientist should discuss scientific significances for conservation of several geosites in Yonaguni Island.

Keywords: Ryukyu Arc, Eurasia Plate, Philippine Sea Plate, sandstone, weathering, Yaeyama group

Normal faults observed in the Yonaguni-jima Island, Okinawa Prefecture, southwestern Japan

*Makoto Otsubo[1], Kiyokazu Oohashi[2], Takayuki Ogata[3], Tadahiro Shibata[4]

1. Geological Survey of Japan, 2. Yamaguchi University, 3. University of the Ryukyus, 4. Agency for Cultural Affairs

Yonaguni-jima Island, Okinawa prefecture is an island located at the westernmost tip of Japan and belongs to the Southern part of the Ryukyu arc. In Yonaguni-jima Island, many normal faults cut the Miocene Yaeyama Group and the Quaternary Ryukyu Group to make the diamond island shape. The fault found at the Sanninudai located in the southeastern part of the Yonaguni-jima Island has all parts of the fault zone; fault gouge part, fault damage zone, wall rock zone. The fault found at the Sanninudai can be activated by the stress field similar to the one in the Okinawa Trough (active back arc basin). Our results indicate that the stress field in the Yonaguni-jima Island may be different from the one in island part of the South Ryukyu arc (e.g., Miyako-jima Island and Ishigaki-jima Island). The relationship between the width of the fault zone and the length of the fault and the relationship between the total displacement and the width of the fault core are similar to them of the typical characteristics of faults. Based on our results, we discuss the possibility that the fault found at the Sanninudai is a suitable site to understand the crustal dynamics (back arc opening) of subdaction zone.

Keywords: Backarc basin, Normal fault, Okinawa Trough, Quaternary, Ryukyu Arc

Example of Study of the Itoigawa-Shizuoka Tectonic Line using “NIED Quake map!”

*Ko Takenouchi[1], Yousuke Ibaraki[1], Takahiko Ogawara[1], Hiroshi Miyajima[1], Makoto Matsubara[2], Azusa Nishizawa[2], Shin Aoi[2], Yoshihiro Hiramatsu[3], Kazuyuki Nakagawa[4]

1. Fossa Magna Museum, 2. National Research Institute for earth Science and Disaster Resilience, 3. Kanazawa University, 4. Jiji Press

1. Background
The Itoigawa Geopark in Niigata Prefecture features an educational park centered on a fault exposure of the Itoigawa-Shizuoka Tectonic Line (ISTL) called the Fossa Magna Park which was first opened in 1990. It is a roughly 10 minute walk from the main parking lots along National Route 148 to the fault exposure. One of the interpretive panels near the exposure features a QR code inviting visitors to examine the 'NIED Quake map!', a page which records seismic activity managed by the National Research Institute for Earth Science and Disaster Resilience (NIED). This report presents one example of academic study using the 'NIED Quake map' with high school students.

2. Earthquake and Fault Study Example (Private High School in Kanagawa Prefecture)
(1) Explanation of the Fossa Magna and Earthquakes (Via Outdoor Interpretive Panels)
The students learn that the ISTL forms the western fault boundary of the Fossa Magna, that has a very close connection to the formation of the Japanese Archipelago, and that the movement of faults causes earthquakes and particularly large fault movements cause the faults to reach the surface where they are called active faults, and that these movements over time form and shape the land around us.
(2) Information from 'Quake map!'
The students use their own smartphones to access the 'NIED Quake map!' site where they can observe the earthquake activity for past ten years in the Itoigawa Area. Through this the students understand the following:
There are many earthquakes occurring around us, even if we don't feel them.
There are distinct areas where earthquakes do and don't occur.
There are earthquakes which concentrate in a line or elliptical shape.
Inland earthquakes occur at depths shallower than 10 km.
There are earthquakes which occur both along and away from active faults.
Along the same active fault, there are areas that do and do not have earthquakes.
Itoigawa experiences no historically large earthquakes, so there is no active fault.
Areas which experienced historic earthquakes have a greater concentration of earthquakes.
Afterwards, the students look at the 5 year, 1 year, 30 day, weekly and 24 hour maps. On the 24 hour map they can see recent earthquakes, where many students are surprised by how many earthquakes occur without being felt.
(3) Fault Exposure
The students see that the fault exposure is crumbling and the rocks have been broken. The gaps among the fault breccia are filled with even more broken fine material (fault gouge) which can be easily depressed with a finger. In fault gouge, striations which show the direction of fault movement can be observed, so the students can understand how fault gouge was formed by the crushing of rock by fault movement. An earthquake of magnitude 7 causes a change in elevation of about 1.5 to 2 m, so the gap seen along the ISTL (over 6,000 m) can be understood to have formed over 3000-4000 fault movements. Through this the students can imagine how deep the Fossa Magna is. They can also understand how faults

©2019. Japan Geoscience Union. All Right Reserved.

expand.

3. Conclusion
The earthquake distribution map of 'NIED Quake map!' allows for visual understanding of Japan's most tectonically active places and is a valuable tool for understanding the connection between earthquakes and faults. Studying the fault exposure allows seeing only the result of geological processes, but using 'Quake map', the students get a better image of these processes and how they are continuing beneath us. Hopefully further experience in using 'Quake map' for high school students can be used to improve its use in earthquake risk reduction education.

The Opening of ‘NIED Quake map!’ and result of questionnaire survey about interest of local seismicity

*Makoto MATSUBARA[1], Azusa Nishizawa[1], Shin Aoi[1], Ko Takenouchi[2], Yoshihiro Hiramatsu[3], Kazuyuki Nakagawa[4]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Fossa Magna Museum, Itoigawa City, 3. School of Geosciences and Civil Engineering, College of Science and Engineering, Kanazawa University, 4. Jiji Press

1. Introduction
The Seismological Society of Japan (SSJ) established the committee to support the activity of Geopark in order to notify people of the current condition of seismology with the same perspective of people. Geoparks are single, unified geographical areas where sites and landscapes of international geological significance are managed with a holistic concept of protection, education and sustainable development. There are many both natural and cultural heritages of earthquakes in Geoparks. However, there is also a lack of introduction to recognize the local seismicity.
National Research Institute for Earth Science and Disaster Resilience (NIED) opened the web site named as 'NIED Quake map!' to visualize the local seismicity at a geosite in July 2018. It is easy to observe current seismicity detected by Monitoring of Waves in Land and Seafloor (MOWLAS) and historical earthquakes. This shows the seismicity in central Japan around the Itoigawa Global UNESCO Geopark through the QR code on the guide plate at the Fossa Magna Park.

2. 'NIED Quake map!'
This page first shows the local seismicity in one year. The color and size show the depth and magnitude of the earthquake, respectively. The latest earthquake is shown with the star. There are volcanoes, active faults, and rivers to grasp the place. People can recognize the seismicity within the ground with seeing both the memorized large earthquakes and no feeling microearthquakes.

3. Results of views
We confirm about 20-30 accesses from the outside. In the case of the field trip by the group at Fossa Magna Park, there were 50-60 accesses.

4. Cooperation with geopark
NIED concluded the Comprehensive Partnership Agreement with Japan Geopark Network (JGN) on the use of the data and research results at the Geoparks on October 13, 2018. NIED also concluded the memorandum regarding the use of the 'NIED Quale map!' NIED plan to open web sites according to request from the Geoparks through JGN.

5. Questionnaire survey about interest of local seismicity and expansion of 'NIED Quake map!'
The committee of the SSJ gave seminars of seismology for Geoparks. We explained the use of the historical earthquakes in 2018 and conducted the questionnaire survey for regions composing the Japan Geopark Network, which consists of the UNESCO Geoparks, the Japan Geoparks, and associate members for proceeding to be Japan Geoparks. We obtained the answer from 26 Geoparks and seven associate members. We note as Geopark both Geopark and the associate members.
There are geosites of historical earthquake in 46 % of Geoparks. About 91 % of Geopark have interest in the local seismicity, however, there are some display of local seismicity in only 27 Geoparks. About 82 % Geoparks have an interest to introduction of local seismicity, however, it depends on the cost. Geoparks

©2019. Japan Geoscience Union. All Right Reserved.

only share the cost for display of local seismicity since NIED construct and manage the web site of the 'NIED Quake map!' NIED plans to construct and supply the web sites in accordance with the request from the Geoparks

Keywords: NIED Quake map!, display of local seismicity

Bandaisan Geopark's traveling exhibitions and lectures on "Debris avalanche in the world"

*Hiroshi Sato[1], Tadahide UI[2]

1. Mt.Bandai Museum, 2. CeMI

Bandaisan Geopark was built with the aim of showing visitors how the landform and people's lives were affected by the mountain collapse which occurred 2 times in 50,000 years ago and 1888. Mt. Bandai Museum is the core exhibition facility.
The year 2018 marked a turning point, 130 years after the collapse, and 30 years after the museum opened.
Since rock avalanches (debris avalanche) occur only about once in 100 years in Japanese Island, a special exhibition was held at the Museum to highlight the avalanche, which is not well known to the public. In addition, the traveling exhibition was also carried out in the volcanic museum in the whole country.
Believing that this traveling exhibition would promote cooperation and mutual understanding among the geoparks that participated in the event, we also held symposiums for public and lectures for school children.
In this presentation, the outline of planned exhibition, symposium and lectures are introduced, and the difference of understanding of volcano by region is introduced from the participant’ s questionnaire carried out in delivery lectures.

PLANETARY SCIENCE Education in Geoparks-Science Festival for Youth Formation experiment of Izumo Plain in Shimane convention

*Kunihiro Abe[1]

1. Shimane Penunsula Shinjiko Narumi, Kuibiki Geopark Promotion Committee

The Shinji Lake Nakaumi Geopark, Shimane Peninsula, has been certified as a Japan Geopark for the third year. The Geopark certification in Shimane Prefecture will be second after the Oki Global Geopark. Although the popularity of the Oki Geopark has been recognized by the prefectural residents, the Shinji Lake Nakaumi is still strong in the Shimane Peninsula. In conjunction with cognitive activities, the Promotion Council is strongly required to utilize geoparks and to promote educational activities. The 18th Annual Science Festival for Youth at the Shimane Convention, the booth of the Shimane Peninsula and the Shinji Lake Nakaumi Geopark exhibited in Shimane Prefecture, the booth of the "Shinji Lake, the birth of the Izumo plain" and it is compatible to, 360 ×270 ×By making the basin topography of the Hiikawa and Shinmon River with the sand in the mold of 120cm, fixing the watering hose to the headwaters of the two rivers, and continuing watering, the sediment is gradually deposited in the waters sandwiched between the Chinese mountains and the Shimane Peninsula, according to the sedimentary experiment by running water. It is the one to understand the state that the Shinji Lake is formed with the passage of time while observing the process that the Izumo plain is done. The west side of Izumo Taisha is a plain and it is not a sea area. The effects of the eruption of Mijar volcano, located in the Kamimon Basin, cannot be ignored. Photos and materials of the Shinji Lake Nakaumi of the geopark that the Izumo plain was formed between the Shimane Peninsula and the Chugoku Mountains located in the north by the volcanic activity of Mt. Hiikawa, the Kamikadawa River, the granite of the Chugoku Mountains, and the Sanjar Mountain which formed the Izumo plain known for Tsukiji Matsu The experiment was performed while contrasting it with the rock sample.

Investigating the mechanism maintaining a subsurface ocean is necessary to understand the condition under which aqua planets can form. Recent planetary exploration missions suggest the presence of subsurface oceans in several outer Solar System bodies. Most of them are icy satellites of giant planets, and tidal heating is considered to play a major role in maintaining their subsurface oceans. The presence of a subsurface ocean is also suggested for Pluto, though tidal heating is negligible. In order for heat-depleted Pluto to possess a subsurface ocean, thermal convection should not occur in the ice shell above the ocean, suggesting its high viscosity. This suggestion is consistent with studies of viscous relaxation of the ice shell. This may be due to a high concentration of contaminants, such as ammonia, in the ocean, resulting in an extremely low temperature ocean; however, ammonia is not observed on Pluto’ s surface, and comets, whose bulk chemistry should be similar to that of Pluto, contains ammonia only little. Thus, the reason why Pluto possesses a subsurface ocean is a mystery.

Here we propose a thin gas hydrate layer exists between the ice shell and a subsurface ocean, and it prevents freezing of a subsurface ocean. Gas hydrates act as a thermal insulator because of its low thermal conductivity. We perform numerical calculations of long-term thermal evolution and show that a warm ocean and a cold ice shell can be maintained for a long time and that the freezing of the ocean is ineffective. We also perform numerical calculations of long-term viscoelastic deformation and show that the significant viscous relaxation requires billions of years. Our proposal does not require large amounts of contaminants. Comets contain a few % of methane with respect to water, for example, and this concentration is sufficient for creating a thin gas hydrate layer prohibiting the ocean freezing. Some gas species are easily trapped in gas hydrates while others are not, and this selective trapping may explain a large difference in volatile compositions of comets and Pluto’ s surface. The subsurface ocean maintenance mechanism we propose here would also be applicable to larger icy bodies other than Pluto. In addition, our proposal may explain the diversity of surface chemistry of Kuiper Belt Objects.

Isotopic measurement of gas hydrate sample simulating environment of icy satellite and icy planet: Equipment development and consideration for observation method

*Kushi Kudo[1], Atsushi Tani[1], Naohiro Yoshida[2,3]

1. Graduate School of Human Development and Environment, Kobe University, 2. Department of Chemical Science and Engineering, School of Materials and Chemical Technology, Tokyo Institute of Technology, 3. Earth–Life Science Institute

According to recently observation using Cassini, icy satellites and icy planets are known for having plume including the organic matter, liquid internal ocean and rocky crust (e.g. Porco et al. 2006; Waite et al. 2006, 2009, 2017). From this fact, extraterrestrial life is regarded as being likely to exist in icy satellites and icy planets. Especially in plume gas species, methane (CH_4) is regarded as one of the candidate of signature of biological activity due to CH_4 formation reaction by methanogen. However CH_4 gas in plume is consisted of not only microbial origin but also primitive CH_4 and hydrothermal formation and this fact does not let CH_4 detection is sufficient for conclusion for existence of biological activity by microbe. Therefore, we consider evaluation of the elementary process of CH_4 isotopic fractionation ($\delta^{13}C$, δD of CH_4) via room experiment important for isotopic observation of icy satellite and icy planet in nearly future.

In this study, we focus on CH_4 hydrate which is reservoir to produce the plume (Kieffer et al. 2006) and want to evaluate isotopic fractionation with its formation. Isotopic fractionation with hydrate formation has been found at only δD of CH_4 (~10‰) at the Earth condition (P: ~10 MPa) (e.g. Hachikubo et al. 2007, 2015; Lapham et al. 2012). In the case of condition of icy satellite and icy planet, pressure range of icy satellite and icy planet is wider than of the Earth, and therefore we need to estimate isotopic fractionation at 10–100 MPa scale. Thus we started design for cell for hydrate formation experiment at ice crust condition (P: ~150 MPa). In presentation, we will mainly introduce progress of the equipment development and observation method.

As next stage, we are also planning analyze isotopic fractionation of surface rocky core, and CH_4 translation process using 3-D flow simulation for evaluate CH_4 isotope changing in icy satellite and icy planet. We will subject to Enceladus, Europe and Triton as target.

Dynamics of icy crust of the Enceladus with tidal heating and asymmetric distribution of heat generation in the rocky core

*Kaho Harada[1,2], Takashi Nakagawa[3], Manabu Morishige[2], Shigenobu Hirose[2]

We investigate the dynamics of icy crust of the Enceladus, that is the sixth-largest moon of the Saturn, for understanding the diversity of the surface geology found from the planetary explorations. Especially, we have an interest in the ‘Tiger Stripes’ found around the south pole with heat release of 15.8 GW. The mechanism of formation of the Tiger Stripes is recognized as active terrains caused by thermal convection of icy crust driven by tidal heating. However, such active terrains caused by the tidal heating could not be explained by the tidal heating solely because they are only found around the south pole. Several researches concerning the convective dynamics of icy crust on the Enceladus have suggested some north-south asymmetries, for example in the thickness of icy crust or viscosity, but they have not been well-understood for the origin.

Here, to resolve the formation mechanism of Tiger Stripes, we propose the hypothesis on the north-south asymmetric distribution of heat producing elements in Enceladus’ s rocky core. We assume that the more heat producing elements can be concentrated into the southern hemisphere. Since, regarding the formation mechanism of the Enceladus, the rocky core would not be likely to experience the large-scale melting events such as the magma ocean, the Enceladus still tends to maintain the chemical structure of the early distribution. Hence, the current chemical structure of rocky core may be heterogeneous, which can lead to north-south asymmetric distribution of heat generation. We test the hypothesis for using a numerical model of icy crust dynamics including tidal heating and north-south asymmetric distribution of heat generation in the rocky core. For tidal heating of the icy crust, we impose an analytical solution of tidal deformation considering viscoelasticity in a thin shell on the surface (e.g., Ojakangas and Stevenson, 1989). For north-south asymmetric distribution in heat generation in the rocky core, we set the temperature of the bottom of the icy crust as 273 K in the northern hemisphere, 283 K in the southern hemisphere.

Our results indicate that heat upwelling around the south pole and heat downwelling around the north pole when we assume tidal heating and north-south asymmetric distribution of heat generation. Rather, the asymmetric distribution of heat generation is more important for finding the more active dynamics around the south pole. A quantitative test indicates that the plume heat flow coming from the south pole region is about 300 GW, which is about 20 times as large as the observational constraints (15.8 GW). This suggests that the amplitude of heterogeneous heat generation is too large. Again, although the amplitude of heat transfer of plume in southern hemisphere is too large, the geographical distribution of plumes can form the north-south asymmetric distribution of heat generation. Therefore, this hypothesis provided here would be promising to reveal the origin of the hydrogen plumes on the Enceladus found by the Cassini mission.

Chlorine-bearing aqueous fluid at crust/mantle boundary in mid-ocean ridge hydrothermal system: a case study of crustal diopsidite from Oman ophiolite

*Norikatsu Akizawa[1], Akira Miyake[2], Akira Tsuchiyama[2]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Graduate School of Science, Kyoto University

Hydrothermal circulation in the mid-ocean ridge system is responsible for elemental enrichment, and modification of original chemical composition of the oceanic crust. In recent times, deep-rooted hydrothermal circulation down to crust/mantle boundary has been introduced regarding geological investigations and numerical models. The deep-rooted hydrothermal circulation in the mid-ocean ridge system can be one of the necessary mechanisms generating plate tectonics due to mantle hydration lowering mantle viscosity. In order to assess the mechanism of the mantle hydration in the mid-ocean ridge system, chemical composition of mantle-buffered hydrothermal fluids must be characterized. Here, we present a series of intense investigations for aqueous fluid inclusions in crustal diopsidites from Oman ophiolite. The crustal diopsidite is considered as a reaction product between gabbro (lowermost crustal material) and seawater-derived hydrothermal fluids en route from the mantle to the crust. Considering that Cr-rich minerals such as chromian spinel (Cr-spinel) and chromian garnet (uvarovites) are contained in the crustal diopsidites, the hydrothermal fluids involved were enriched in Cr. A few micrometer-sized inclusion of aqueous fluid with chromian spinel grains was frozen with a nitrogen gas-cooled cold stage, and investigated with a focused ion beam equipped with a scanning electron microscope and an energy dispersive X-ray spectrometer (cryo-FIB-SEM-EDS system). The results showed that the Cr-spinel-bearing aqueous fluid inclusion contains Cl. Regarding the mass and chemical composition of the Cr-spinels in the aqueous fluid inclusion, Cr content in the aqueous fluid was estimated at ~71400 ppm. Although Cr is considered relatively insoluble in aqueous fluids, solubility of Cr depends strongly on the activity of Cl due to complexation reactions with Cl. We propose a possibility that seawater-derived hydrothermal fluids penetrated throughout the crustal section reacted with Cl-bearing magma portion. Flow direction of the hydrothermal fluids probably changed from downward to upward in response to the heat release of the magma to the hydrothermal fluid.

Phase relation of the $MgSO_4$-H_2O system under high pressure

*Tadashi Kondo[1], Keita Harada[1], Miki Sirata[1], Takumi Kikegawa[2]

1. Department of Earth and Space Science, Graduate School of Science Osaka University, 2. Institute for Material Structure Science, KEK

Resent planetary exploration projects suggest existence of internal ocean in the several icy satellites. Spectral analysis of surface material of such satellite indicate sulfate materials as solute in the water ocean. Salts change generally the phase relation such as melting temperature and generation of a kind of hydrate, and affects the internal structure of the satellite. For the $MgSO_4$-H_2O system, which was considered as a possible major component in internal ocean, Nakamura and Ohtani (2011) has proposed the phase relation under pressure condition up to 4.5 GPa with existence of epsomite($MgSO_4 \cdot {}_7H_2O$), and discussed a deep internal ocean in the Ganymede. However, the X-ray diffraction pattern they reported as epsomite includes many unidentified diffraction peaks. In this study, we re-examined the phase relation in the system $MgSO_4$-H_2O under pressure by optical observation, micro-Raman, X-ray diffraction at synchrotron facility. High pressure experiments was performed using diamond anvil cell(DAC) up to about 5GPa at room temperature for 5 to 25wt% $MgSO_4$ solution. The results show a quite different phase relation from Nakamura and Ohtani(2011) in $MgSO_4$-rich side and solidified phases. The eutectic composition is almost same as previous report, but pentahydrate($MgSO_4 \cdot 5H_2O$) is newly observed as coexisting phase with Ice VI-VII in solid, and also liquidus phase in $MgSO_4$-rich solution. We observed direct conversion from low-pressure pentahydrate to high-pressure pentahydrate which reported by Wang et al.(2018). We also evaluate the relative density difference between liquid and solid for all composition by gravitational method in DAC. Ice VI is always denser than liquid while hydrate is always less denser than liquid. We will discuss internal structure and evolution of icy satellite based on this new results.

The Origin of Earth's Volatile Composition: Effects of Impact-induced Atmospheric Erosion and Core Formation

*Sakuraba Haruka[1], Hiroyuki Kurokawa[2], Hidenori Genda[2], Kenji Ohta[1]

1. Tokyo Institute of Technology, 2. Earth-Life Science Institute

Unveiling the origin of Earth's volatile composition is crucial for understanding how Earth developed its habitable environment. Carbon (C), nitrogen (N), and hydrogen (H) are the backbone for the chemistry of life and main components of the atmosphere and oceans (e.g., Katling & Casting, 2017). The volatiles in rocky planets are thought to have been delivered by chondritic materials. However, the elemental composition of the bulk silicate Earth (BSE) shows the depletion of C and N relative to H, a high C/N ratio, and a low C/H ratio compared to chondrites (e.g., Hirschmann, 2016; Bergin et al., 2015).

The volatiles delivered to the accreting planet were potentially lost to space by impacts or sequestered in the core. In order to understand how these processes affect the Earth's volatile composition, we modeled both the main accretion stage and the late accretion stage. The former considered the elemental partitioning between the atmosphere, MO, and metal which segregates into the core (e.g., Hirschmann, 2016; Bergin et al., 2015). The latter considered the partitioning between the atmosphere, oceans, and carbonate (the crust) (e.g., Sakuraba et al., 2019). By calculating the evolution for the range of partitioning coefficient, solubilities, and impactor properties, we evaluated how the resulting volatile composition of BSE depends on these input parameters.

As a result, we succeeded to reproduce the elemental composition of major volatile elements in current BSE from a chondritic source when we chose the appropriate parameter values. While the elemental fractionation during the main accretion ended up with the excess of N/C, the preferential loss of N from the atmosphere during the late accretion reproduced BSE's volatile pattern. During the main accretion, C was most affected by the core segregation because C is the most siderophile among the volatile elements. During the late accretion, N was most affected by the atmospheric erosion because C and H were trapped in the surface reservoirs. The different BSE's composition patterns were obtained depending on parameters such as impactor's composition, impactor's size-distribution, and element partitioning properties. Our results suggest that the current Earth's composition can be obtained by the homogeneous accretion of chondritic planetesimals.

Finding of oxidized sulfur species in carbonates from a Martian meteorite Allan Hills 84001 using μ-XANES

*Kajitani Iori[1], Gaku Tanabe[1], Ryoichi Nakada[2], Tomohiro Usui[3], Mizuho Koike[3], Fumihiro Matsuura[4], Tetsuya Yokoyama[1]

1. Tokyo Institute of Technology, 2. Japan Agency for Marine-Earth Science and Technology, 3. Institute of Space and Astronautical Science, 4. Earth-Life Science Institute

The widespread evidence of liquid water on Mars has led to detailed studies of Martian habitable surface environments [1]. Among them is the geochemical study of carbonate in the 4-billion-year old meteorite Allan Hills (ALH) 84001 because the carbonate is interpreted to have formed from fluids in the early stage of Mars history (~4 Ga) [2]. This study examined speciation of sulfur in carbonates of ALH 84001 as a proxy to trace the chemical evolution of fluids that formed the ALH 84001 carbonates.

We conducted sulfur K-edge (2472 eV) micro X-ray absorption near edge structure (μ-XANES) analysis at BL27SU at SPring-8. X-ray beam was focused using a K-B mirror to a final spot size of 15 (H) ×15 (V) μm^2. Prior to the μ-XANES analysis, X-ray fluorescence mapping which was scanned in 20 μm step was obtained to determine the analytical spot with referring to the petrological observation and backscattered electron images using electron prove micro analyzer (EPMA).

A diagnostic signature of oxidized sulfur [S(VI)] was observed in all the analytical points, whereas X-ray absorption peaks corresponding to S(-II) and an organic sulfur (Di-n-octadecyl disulfide) were observed in some analytical spots. We propose two possible processes for the incorporation of S(VI) species in the carbonate grains of ALH 84001 on the Martian surface: (co-)precipitation of sulfate minerals with the carbonate or substitution of sulfate ion for carbonate ion (carbonate associated sulfate: CAS). The incorporation of trace amount of sulfate minerals is consistent with the widespread distribution of sulfate-bearing deposits in Noachian terranes [3]. However, any type of sulfate minerals has not been observed in the carbonate grains of ALH 84001 even using the transmission electron microscope observations [4]. On the other hand, the CAS-bearing carbonates are common on Earth, though the concentration of CAS in carbonate is typically low (~100s-1,000s ppm) [5]. We conducted thermodynamic calculations under conditions proposed to explain the ALH 84001 carbonates [6, 7]. The thermodynamic calculations indicated that sulfur mainly occurred as sulfate ion in water at Eh-pH conditions where the ALH 84001 carbonate precipitated. This result suggests a possibility that the observed S(VI) species could have occurred as CAS in the ALH 84001 carbonates under the fluid conditions ranging from 6 to 9 for pH and -0.25 to 0 for Eh (V).

A study on Martian water environment based on the μ-XRF-XANES analysis for the secondary minerals formed in a nakhlite meteorite (Y 000593) vein

*Keika Suzuki[1], Hiroki Suga[1], Akira Yamaguchi[2], Tomohiro Usui[3], Oki Sekizawa[4], Kiyofumi Nitta[4], Yoshio Takahashi[1]

1. University of Tokyo, 2. National Institute of Polar Research, 3. JAXA, ISAS, 4. JASRI/SPring-8

Martian meteorite nakhlite has attracted attention because it has various secondary mineral assemblages (such as iddingsite) formed by water-rock reaction on the Mars. The iddingsite holds physicochemical information of water when it formed on Mars. However, the formation processes of the minerals are not clear because both carbonates (precipitate under reductive alkaline conditions) and sulfates (precipitate under oxidative acidic conditions) that cannot coexist under an equilibrium condition were found. Among these minerals, sulfate minerals are considered as a terrestrial contamination in several researches in contrast to carbonate minerals accompanied with various secondary minerals such as saponite and serpentine. Here, we examined trace element distribution within the carbonate phases in Y 000593 by FE-SEM-EDS/FE-EPMA and synchrotron-based μ-XRF-XANES in order to determine the transition history of the Eh-pH conditions during the carbonate formation, which reconcile the coexistence of carbonate and sulfate phases in the iddingsite. The detailed understanding of environment (*e.g.,* fluid chemistry) allows us to give a new constraint on the physicochemical evolution of the water that altered the nakhlite body during the last ~6.5 million years.

The polished thin section (PTS: #58-1 in NIPR) of Y 000593 was used for this study. First, the identification of secondary mineral phases in the iddingsite were conducted by FE-SEM-EDS and FE-EPMA at the University of Tokyo. After that, we investigated distribution of trace elements by μ-XRF-XANES at BL37XU of SPring-8, and BL-4A/15A of KEK-PF. Subsequently, we tried to constrain the iddingsite formation environment (such as Eh-pH conditions) from the proportion of secondary minerals.

Carbonates ($FeCO_3$, $MnCO_3$, $CaCO_3$), iron oxides (FeOOH), clay minerals (Fe-rich saponite), and Si-rich vein were identified in the iddingsite from the outside to the center of vein by FE-SEM-EDS and FE-EPMA analysis. In particular, carbonate aggregates were mainly composed of $(Mn,Fe)CO_3$ and $(Ca,Fe)CO_3$. This result suggested that the iddingsite was altered by CO_2-rich reductive alkaline fluid (Eh≦0.2: pH=9.0~11) [Brookins, 1998]. The difference between distributions of Mn and Ca suggests that fluid with different Eh-pH conditions flowed several times or water condition was changed during carbonate formation because $(Mn,Fe)CO_3$ and $(Ca,Fe)CO_3$ cannot overlap in the Eh-pH diagrams ($(Mn,Fe)CO_3$ precipitate at Eh=-0.4~-0.0: pH=9.0~9.5; $(Ca,Fe)CO_3$ precipitate at Eh=-0.3~-0.1: pH=6.5~9.0). The μ-XANES analysis revealed that Cr(III) coexisted in $(Mn,Fe)CO_3$, since Cr cannot be enriched in MnO_2 in general. It is presumed that Mn precipitated originally as MnOOH, which was transformed into $MnCO_3$ in the presence of alkaline fluid. In $(Ca,Fe)CO_3$, 20% of Fe was present as FeOOH. It was implied that FeOOH is precursor of the $FeCO_3$. In addition, we detected S(VI) in the iddingsite, of which chemical species are the clay mineral adsorbent (Fe-rich saponite), $Mn^{2+}(Mn^{3+})O_4$, and $MnCO_3$ by XANES fitting. This results suggested that sulfate-bearing alkaline fluid flowed in the final stage of the iddingsite formation. Besides, its concentration decrease from the mesostasis phase. Therefore, S(VI) in the clay minerals portion related to the FeS in the mesostasis, and apart of FeS might flowed out as alkaline fluid.

©2019. Japan Geoscience Union. All Right Reserved.

From this study, we conclude that the carbonates in iddingsite formed by reductive alkaline fluid (Eh≦0.2: pH=9.0-11), opposite to sulfate formation. However, it is still not clear whether these carbonate minerals were locally formed or widespread in the nakhlite from the spatial distribution point of view. Therefore, we are trying to observe the 3D structure/elemental distribution of the iddingsite by XAFS-CT method in order to clarify the fluid path related to the formation process of the carbonate minerals.

Influence of water and clay minerals for slope angles on Mars

*Yuhki Matsuoka[1], Ikuo Katayama[1], Rina Noguchi[2], Tomohiro Usui[2]

1. Department of Earth and Planetary Systems Science, Hiroshima University, 2. Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency

An internal frictional angle is determined from a frictional coefficient, which is largely influenced by water and clay minerals. Pore water reduces effective stress, then slope angles becomes smaller. Therefore, slope angles are approximately 25 under hydrostatic condition in contrast with ~35 under dry condition. Most mineral exhibit a constant frictional coefficient μ=0.6-0.85, whereas clay minerals are characterized by a markedly lower frictional coefficient ~0.1 at presence of water (e.g. Behnsen and Faulkner, 2012; Moore and Lockner, 2004). Since a slope angle is roughly equivalent to an internal frictional angle, it is considered that slope angles are affected to become smaller by presence of water and clay minerals including water.
Clay minerals are widely recognized on Mars (Ehlmann and Edwards, 2014) by infrared spectroscopic tools. We focus on a slope angle of Martian topography and research the areas where water might exist.

We focus on Recurring Slope Lineae (RSL) which might suggest the existence of flowing water on Mars (e.g. McEwen et al., 2011; Stillman et al., 2017). Some RSL are found in Coprates Chasma, eastern part of Valles Marineris. We compared slope angles of RSL confirmed points with not confirmed points.
We measured slope angles about 10 points in Coprates Chasma. Slope angles are 31-37 in almost all points and there is no tendency by the presence of RSL and hydroxylated silicates. Therefore, we considered that the contributions of water and clay minerals for slope angles are not prominent in Coprates Chasma.
Furthermore, we verified whether there is contribution of water for slope angles on other areas where water might exist in the same way.

Dark Streak Features in Mongolia: Implications for Formation Mechanisms of Recurring Slope Lineae on Mars

*Maya Nakamura[1,2], Yasuhito Sekine[1], Keisuke Fukushi[3], Noriko Hasebe[3], Davaadorj Davaasuren[4], Yoshio Takahashi[2], Hitoshi Hasegawa[5], Takuro Ogura[6], Koki Morida[3], Tuvshin Gerelmaa[4]

Institute of Nature & Environmental Technology, Kanazawa University, 4. Department of Geography, National University of Mongolia, 5. Department of Global Environment and Disaster Prevention, Kochi University, 6. Department of Socio-Cultural Environmental Science, The University of Tokyo

Recurring Slope Lineae (RSL) are dark, narrow features that appear and lengthen on steep (~30°) slopes in warm seasons and fade in cold seasons of Mars (e.g., McEwen et al., 2011). Although the formation mechanism of RSL is still in debate, several processes have been proposed, including liquid brine flows triggered by melting of subsurface ice (a wet process) (e.g., Stillman et al., 2016), and granular flows on slopes (a dry process) (e.g., Schmidt et al., 2017). However, neither wet nor dry processes can explain all of the observables of RSL. In especially, the wet process seems to be inconsistent with the absence of absorptions due to liquid water on RSL and the fact that RSL appear only on steep slopes (McEwen et al., 2014).

Here, we report RSL-like dark streak features in cold, arid areas of Khangai Mountains, Mongolia, on Earth. In this area, discontinuous permafrost and underground ice melt seasonally (Szuminska, 2016). We find that dark streak features in this area show seasonal variation similar to RSL on Mars. Although the slope angles of the terrestrial analogues (~10°) are shallow, the observed similarities in morphology and seasonal activity suggest that the streak features in Mongolia can be promising terrestrial analogues of RSL on Mars.

We also conducted geological survey for the terrestrial RSL analogues found in Mongolia in August 2018. By analyzing the visual images taken by a unmanned aerial vehicle, a three-dimensional topographic structure was constructed. In the geological survey, we measured water contents of soils on site on and outside the dark streak features. The mineralogical compositions and grain size distributions were measured for the collected soil samples.

Although no water flowed during the survey, dark streak features appeared in the terrestrial RSL analog sites in Mongolia. The upstream of the dark streaks are dented in a few centimeters, which becomes shallower toward the downstream. These observations suggest that erosion of surface soils occurred along with the dark streak features in the past. This view is supported by our results of the flow accumulation analysis. Although the formation of the dark streaks relate with water flow, darkening itself is not caused by the presence of liquid water. Water contents in surface soils on the dark streaks show no significant difference from those outside the streaks within errors. The surface of the dark streaks contains less bright sands and more dark silts than the surfaces outside the dark streaks. These results suggest that selective traction of the bright sand-sized grains by surface runoff results in remnant of the dark silt-sized grains on the slopes, which darkens the streak features after dryness. The required friction velocity for the traction is estimated to be ~20 mm/sec, consistent with flow rate due to melting of ground ice in the research area.

Based on the formation mechanism of the terrestrial RSL analogues, we can address the two issues in the

©2019. Japan Geoscience Union. All Right Reserved.

wet process for RSL formation on Mars; 1) no remote-sensing detection of liquid water, and 2) the fact that RSL appear only on steep slopes. At RSL sites on Mars, a thin layer of fine soils is considered to cover basaltic bedrocks on the slopes (Ruff and Christensen, 2002). If liquid brine flows due to melting of underground ice, this can remove fine sands on the slopes. Consequently, dark streak features appear on the slopes due to exposure of underlying basaltic bedrocks after dryness of brine. Given the difference in gravity between Earth and Mars, we suggest that a friction velocity of surface runoff similar to the terrestrial RSL analogs can be achieved when a slope with angle > ~25–30° on Mars, if the depth and width of water flow are same. Our results suggest that RSL on Mars would appear only on steep slopes due to its low gravity.

The occurrence of perchlorate salt in and around the Taklimakan Desert, China

*Haibo Qin[1,2], Shitong Yang[1], Qing Chang[3], Chihiro Miyamoto[1], Yoshio Takahashi[1]

1. Department of Earth and Planetary Science, Graduate School of Science, 2. State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, 3. Japan Agency for Marine-Earth Science and Technology

The formation and preservation of perchlorate (ClO_4^-) in arid and semi-arid deserts on Earth is of growing concern, because the desert could serve as a viable analog for Martian landscape where high perchlorate has been recently discovered. In this study, perchlorate in samples collected from the Taklimakan Desert, Xinjiang, NW China was extracted by water and then measured by IC-MS/MS. The Cl speciation was determined by Cl K-edge XANES analysis to provide direct spectroscopic evidences for the presence of perchlorate. Results showed that the moraine sample contains a higher perchlorate concentration and the ClO_4^-/Cl^- ratio in comparison with sand, river sediment and loess samples. Furthermore, $KClO_4$ was identified as the dominant perchlorate species in the hotspot of moraine sample by μ-XANES analysis, which is significantly different from the dominant presence of $Ca(ClO_4)_2$ and $Mg(ClO_4)_2$ species on Martial soil. This result could be explained by the lowest solubility for $KClO_4$, while other perchlorate salts would be easily leached and mobile on Earth in contrast to Mars where much lesser liquid water is present in the history and present-day. Thus, the finding in this study would provide important insights into the prevalence of perchlorate on Mars.

Measurement technique to quantify OH radicals photochemically generated on the ice surface

*Akihiro Yabushita[1], Hiroaki Nishimoto[1], Akira Harata[1]

1. Interdisciplinary Graduate School of Engineering Sciences, Kyushu University

Reaction processes of many molecules are presumably involved in oxidative atoms/molecules generated by photodecomposition of molecules adsorbed on cold dust grains. Hydroxyl (OH) radicals are considered as one of them. The chemistry of OH radicals plays a key role in the radiolysis and photolysis of water-rich ices of astrochemical origin. Measurements of OH radical in water-ice in the laboratory have been done by UV, EPR, X-ray absorption, and infrared absorption measurements. However, quantification of OH radicals on the ice surface has not yet been made. In the present work, we have tried to develop the measurement technique to quantify OH radicals photochemically generated on the surface of ice film. In this technique, OH are converted to the different molecule by utilizing the chemical reaction, and monitored through reflection absorption infrared spectroscopy. We have investigated the effect of ice temperature on abundance of OH radicals on the ice surface at 8-70 K. In addition, the effect of ice surface morphology on abundance of OH radicals has been studied by preparing the amorphous solid water and polycrystalline ice. The present study experimentally shows both the temperature and surface morphology plays an important role in abundance of OH radicals on the ice surface.

Root functional traits could vary among plant species. Root traits are known to respond to a decrease in nutrient availability along with soil aging and plant succession, while root plasticity of single tree species to soil aging is still unclear on a soil profile scale. We investigated whether trees develop finer root architecture along with soil aging in coniferous forest dominated by single species (*Pinus sylvestris*) in Estonia. We measured depth distribution of root biomass and traits (specific root length and tissue density). We compared ca. 100, 300, and 500 years old soils (podzols) on two coastal dune chrnosequence that differ in abundance of soil clay or Al and Fe oxides; Hiiumaa island (facing Balt Sea) and Juminda (facing Finland Gulf), where ridge-swale topography has been developed by isostacy. On Juminda chronosequence where oxalate-extractable P (oxide-bonded) is accumulated in the shallow subsoil, fine roots are concentrated in oxide-rich soil horizons. On oxide-poor Hiiumaa chronosequence where P is translocated in the deeper soil, fine roots are concentrated in organic horizon. Tree roots could change root distribution and surface area depending on extent of P occlusion in clays or leaching in soil aging. Tree community shift toward finer root architecture along with migration of Al and Fe oxides or selection of individuals with finer root structure could occur.

Dissimilatory nitrate reduction to ammonium (DNRA) is one of the most important processes of nitrate removal in an anaerobic condition. The 2011 Great East Japan Earthquake and subsequent tsunami attack widely created the intertidal salt marsh along the coast due to sea water intrusion and large ground subsidence. It is necessary to elucidate the ecosystem functions of the newly created salt march. Salt marsh is located in the conjunction point of river and sea, therefore the conversion of dissolved inorganic nitrogen concentrations and forms in the salt marsh may directly impact the productivity and biodiversity of marine ecosystems. However it is still unknown that the role of this specific salt marsh in nutrient dynamics. In September 2017, the surface sediments were collected at the intertidal and subtidal points of the salt marsh, and their potential rates of denitrification, DNRA, and anaerobic ammonium oxidation (Anammox) were estimated by using a 15N tracer technique. As for the nitrate-nitrogen removal in the sediments, the rate of DNRA was ranged from 24.8 to 177 nmol g-1 h-1, while the denitrification rate was ranged from 2.9 to 32.8 nmol g-1 h-1. Our results demonstrate that the DNRA would be significantly important in nitrate removal, and it also suggests that the conversion of inorganic nitrogen form nitrate to ammonium in the salt marsh might affect the species composition of phytoplankton and the primary production in the marsh and the coastal area connected with the marsh.

Succession of soil nitrification potential at a glacier foreland in Svalbard

*Kentaro Hayashi[1], Yukiko Tanabe[2,3], Keisuke Ono[1], Maki Asano[4], Shohei Hattori[5], Masaki Uchida[2,3], Masahito Hayatsu[1]

1. Institute for Agro-Environmental Sciences, NARO, 2. National Institute of Polar Research, 3. SOKENDAI, 4. University of Tsukuba, 5. Tokyo Institute of Technology

Glaciers in Svalbard particularly in the western part of the archipelago has experienced retreating since 20th century. It is concerned that the retreat has been accelerated recently. Glacier retreat on the land uncovers the ground surface under ice. This is a restart of soil genesis as the past soil was lost due to ice erosion. What does happen in nitrogen cycle of the redeveloping soil, and how does ongoing climate warming affect the redeveloping soil nitrogen cycle? In the present study, we focus on nitrification as a source of nitrate. Nitrification is a two-step microbial process consisting of ammonia oxidation to nitrite and nitrite oxidation to nitrate, in which ammonia oxidation is the rate limiting step. Nitrifiers are basically autotrophic and therefore contribute to soil nitrogen cycle from the early stage of soil genesis. It is also interesting that nitrifiers exist across the two domains, bacteria and archaea. The purposes of the present study are to investigate nitrification properties (ammonia oxidation potential [AOP] and flora of nitrifiers) and their time-series changes in the surface soil in the foreland of East Brøgger Glacier near Ny-Ålesund, Svalbard and to elucidate responses of the nitrification properties to environmental manipulations (passive warming and accompanied changes in soil moisture) using open top chambers (OTC). We have been conducting a field experiment at two permanent exclosures established by NIPR in the foreland, i.e., Site 1 (N78˚54'46", E11˚50'18") and Site 2 (N78˚54'54", E11˚49'38"). It is inferred from aerial photos that Site 1 lost its ice coverage between 1969 and 1977, and Site 2 in 1950s or 1960s. Although the foreland was abundant with rocks and stones, the surface was partly covered with mineral soil consisting of fine sand and silt. The field experiment started in July 2015. A passive warming plot and a control plot were set at each site. Twenty polyvinylchloride cores filled with 4-mm sieved and well mixed surface soil collected at each site were set at each of the warming and control plots, of which 5 cores were used to measure soil temperature and volumetric water content and the rest 15 cores were for determining nitrification properties of topsoil (0-2 cm) and subsoil (2-4 cm) collecting 3 cores every July. The field experiment will be end in the summer of 2020. AOP was determined as the nitrite production rate of soil by aerobic shaking incubation with substrate (ammonium sulfate) at 10 and 20 ˚C. Nitrifiers' flora, i.e., gene abundance and species composition of ammonia oxidizing bacteria and archaea will be identified after the completion of field experiment. Annual mean warming effects of the OTC were 0.4–0.5 ˚C at Site 1 and 0.5–0.7 ˚C at Site 2; however, stronger warming effect appeared in the snow season. OTC effects to soil moisture were moistening at the warming plots for the first year, but it turned into drying after that. The determined AOPs at Site 2 were roughly double of those at Site 1. Differences in AOP between the warming and control plots and between the topsoil and subsoil were not significant. The time-series changes in AOP were not monotonous. Meanwhile, AOPs at 20 ˚C were significantly larger than those at 10 ˚C for sites, topsoil and subsoil, and time-series changes. Annual mean soil temperatures at the two sites were from −1.5 to 0.3 ˚C, from 5 to 6 ˚C in the snowless season, and 14 ˚C as the maximum daily mean. The positive response of AOP to a high temperature of 20 ˚C implies that future climate warming accelerates soil nitrification in the foreland. Although it is early to conclude, the succession of AOP at 10 ˚C was unclear and that at 20 ˚C showed an increasing trend. This study was supported by Grants-in-Aid for Scientific Research (No. 26304018) provided by the Japan Society for the Promotion of Science. This study was also partly supported by the National Institute of Polar Research, Japan, through Project

Soil organic carbon (SOC) is generated from organic components by receiving biological and chemical transformations in soils. In volcanic ash soils, mean resident time of SOC is generally long, so the mechanisms of the long lives are of interest for the development of techniques for carbon sequestration in soils. In the present study, we aim to elucidate the transformation process of SOC by fractionating SOC representing the transition stage of the original organic components and characterized the SOC fractions by isotopic and nuclear magnetic resonance spectroscopic analyses.

In this study, we analyzed SOC from a buried soil layer formed between 6,200 and 9,400 cal yBP, because the SOC can be well conserved without the influence of serious human activity. In addition, the age of those buried SOC can be determined by ^{14}C analysis with high accuracy. The soil samples were collected from a buried soil horizon (six samples collected from the depth between 152 and 182 cm at 5 cm intervals) close to Towada volcano, Japan. From each of the soil sample, SOC were extracted and fractionated by precipitation with controlling pH of the extracted solution (Hiradate *et al.*, 2007), resulting in humin, humic acid, and four fulvic acid fractions (two hydrophilic fulvic acid fractions: FA_1 and FA_2, and two hydrophobic fulvic acid fractions: FA_3, and FA_{IHSS}). The SOC fractions were freeze-dried and analyzed for determining $\delta^{13}C$ and $\delta^{15}N$ values by using isotope ratio mass spectrometer and for ^{14}C dating by using accelerator mass spectrometer. Solid-state ^{13}C CPMAS NMR analysis was also conducted to investigate the structural characteristics and quantify the carbon species of the SOC fractions.

The $\delta^{13}C$ values of humic acid, FA_1, FA_2, FA_3, and FA_{IHSS} fractions were -23.85±0.36, -20.75±0.32, -21.10 ±0.38, -22.81±0.41, and -23.22 ±0.33‰, respectively, while $\delta^{15}N$ values were 3.00±0.37, 8.16±1.73, 9.66±0.54 , 4.73±0.83, and 5.20±0.54‰, respectively. The ^{14}C age of humic acid, FA_1, FA_2, FA_3, and FA_{IHSS} fractions was 6130±300, 5630±240, 5400±200, 5410±230, and 5680±260 cal yBP, respectively. Decomposition and recycling of plant residues during the transformation of SOC result in enrichment of heavier carbon and nitrogen isotopes due to preferential stabilization (Wada *et al.*, 2013). Therefore, the increase of $\delta^{13}C$ and $\delta^{15}N$ values in SOC fractions corresponds to successive transformation of SOC. The slope of the relationship between $\delta^{13}C$ and $\delta^{15}N$ values was 1.69, and the results were similar to the result of Wada *et al.* (2013), indicating successive transformation of SOC from plant organic matter to hydrophilic fulvic acid fraction. The hydrophilic fulvic acid fraction would be more microbially processed than hydrophobic fulvic acid and humic acid fractions. Because the humic acid fractions were rich in aromatic structure, they would be formed in the early stage of the formation right after C fixation by plants and chemically stabilized in the soil horizon by fire event etc. The hydrophobic fulvic acid horizons, which are less rich in aromatic C but relatively rich in aliphatic C, would be formed by microbial transformation

©2019. Japan Geoscience Union. All Right Reserved.

and stabilized by chemical and physical factor. The hydrophilic fulvic acid fractions, which are rich in *O* -alkyl C, would be microbially metabolized many times and stabilized physically in the soil horizons.

The validity of the chemical fractionation of SOC on the soil dynamics study has been discussed and sometimes regarded as questionable, but at least in our study on a buried volcanic ash soil, the chemical fractionation procedure successfully separated SOC receiving different metabolisms and having different genesis and chemical structural features.

1. NARO, Institute for Agro-Environmental Sciences, 2. Nagasaki Institute of Applied Science, 3. University of Tsukuba, 4. University of Tokyo

Organic matter (OM) in soil represents the largest carbon pool on land. The production of CO2 via microbial degradation of soil OM therefore has a strong impact on global C cycle and anticipated global warming. Previous studies have shown that any soil holds multiple OM pools of varying stability against microbial attack. Growing number of studies suggests protective effect of specific mineral phases and mineral matrix. OM, however, interacts with soil minerals in highly complex ways including co-precipitation of organic ligands with multivalent metals at molecular scale and physical aggregation of OM with mineral particles at micron and larger scales.

Here we examined the relationship between the isotopic compositions (C-13, C-14, and N-15) and mineralogical characteristics (surface area and elemental composition, pedogenic metal oxides) among density fractions using a range of surface soils of contrasting mineralogy including volcanic soils rich in short-range-order minerals and much more weathered soils from both agricultural and natural systems. Each soil was separated into 4-7 density fractions after mechanical shaking with sodium polytungstate. From LF to higher-density fractions, We assessed how C aging is related to C13 and N15 enrichment and to what extent these isotopic variations among the fractions were controlled by the mineralogical characteristics.

Nutrient sources in some Japanese forest ecosystems: the contribution of precipitation, weathering and litter fall

*Yoshiyuki Inagaki[1], Kazumichi Fujii[1]

1. Forestry and Forest Products Research Institute

Base cation such as calcium and potassium is important nutrient for tree growth in forest ecosystems. Major sources of base cation to forest soil are precipitation, weathering of parent material and litter fall. Weathering rate of base cation is estimated from the input from precipitation, runoff from stream and uptake by vegetation. For plant uptake two different properties, i.e., long-term accumulation in plant biomass and annual uptake should be quantified. Nutrient cycling of many Japanese forest ecosystems has been studied but information about the contribution of these sources is limited. This study compared three nutrient sources in four forest ecosystems in Japan. These forests are Oyasan (Gunma Pref.), Kamikamo (Kyoto Pref.), Kiryu (Shiga pref.) and Takatori (Kochi Pref.). We calculated nutrient budget of potassium, calcium and magnesium. The rate of rock weathering of base cation ranged from 0.22 to 4.37 kmolc ha^{-1} yr^{-1} and increased in the order of Kamigamo < Kiryu <Oyasan < Takatori. In potassium cycling, the contribution of litter fall was greater than that of weathering or precipitation. The runoff of calcium and magnesium from soil was greater in Takatori, where the rate of weathering was high. Although the rate of weathering varied substantially among forest ecosystems, the annual flux of litter fall was relatively constant. Similar calculation was applied for nitrogen cycling and the source from soil was treated as that from nitrogen accumulated during the past pedogenesis. Nitrogen input from the accumulated soil source was 36 % in Oyasan whereas that in other three forestswas 0%. Oyasan was considered as a nitrogen-saturated forest and the result of the study suggest the ecosystem relies on different nitrogen source.

This study aimed to clarify alternations of the quality of dissolved organic matter (DOM) in rainwater moving through temperate forests. For this, we compared the molecular composition of dissolved organic matter (DOM) between bulk deposition (rainfall), throughfall and soil water in Japanese cypress (*Cryptomeria japonica*) and Japanese stone oak (*Lithocarpus edulis*) stands, which were regarded as coniferous and broad-leaved stands, respectively, during a rain event. Analyses of ultrahigh-resolution Fourier transform ion cyclotron resonance mass spectrometry revealed that the number of DOM molecular species detected was significantly greater in throughfall and soil water than in rainfall ($p < 0.05$). In contrast, the number of molecular species did not significantly differ between throughfall and soil water ($p > 0.05$). There were no significant differences in the number of molecular species in both throughfall and soil water between coniferous and broad-leaved stands ($p > 0.05$). These results suggest that a diverse array of DOM molecules are provided from the tree canopies and soils to the rainwater in both stands. Approximately 52%–59% of the total molecular species in throughfall samples ($n = 6$) were unique to throughfall. Additionally, approximately a half of the total molecular species in soil water samples ($n = 5$) were unique to soil water. The classification of molecular species into seven biomolecular classes using a van Krevelen diagram revealed that throughfall samples contained many of lipid and protein molecules compared to rainfall and soil water samples, whereas approximately 70% of the total molecular species in soil water were lignin-like molecules. The analysis of multidimensional scaling revealed that molecular species were significantly differentiated between rainfall, throughfall and soil water ($p < 0.05$). These results indicate that there are diverse molecules unique to throughfall and soil water and that the quality of DOM drastically changes in rainwater as it moves through temperate forests.

Basin-scale transport of allochthonous humic-like fluorescent dissolved organic matter by the North Pacific Intermediate water

*Youhei Yamashita[1], Jun Nishioka[2], Hajime Obata[3], Hiroshi Ogawa[3]

1. Faculty of Environmental and Earth Science, 2. Institute of Low Temperature Science, Hokkaido University, 3. Atmosphere and Ocean Research Institute, The University of Tokyo

The levels of humic-like fluorescent dissolved organic matter (FDOM) in the open ocean generally showed nutrient-type vertical profile. In the surface water, low levels of humic-like FDOM is due to degradation by sunlight. In the dark ocean, linear relationships between levels of humic-like FDOM and apparent oxygen utilization (AOU) have been observed throughout the global ocean, indicating that humic-like FDOM is produced in situ in the ocean interior as organic matter is oxidized by microbes and is resistant to microbial degradation with time scales of thermohaline circulation.

While, it has also been observed that some plots of humic-like FDOM vs AOU in the specific water masses, namely, the North Pacific Intermediate Water (NPIW) and the North Atlantic Deep Water (NADW), seemed to deviate from the general relationship between humic-like FDOM and AOU. The previous studies showed that concentrations of lignin phenols, a unique biomarker of vascular plants, were found to be higher in the NPIW and the NADW compared with other water masses. Thus, the deviations of plots between humic-like FDOM and AOU in the NPIW and the NADW can be considered to be derived from terrestrial (allochthonous) humic-like FDOM.

In this study, we determined a basin-scale distribution of humic-like FDOM from the Sea of Okhotsk to the western subtropical North Pacific. We found the linear relationship between levels of humic-like FDOM and AOU in the deep layer (>1000 m) of the western North Pacific. While, we also found plots in the mesopelagic layer, corresponding to the NPIW, were significantly deviated from the relationship observed in the deep layer. Such distributional pattern implies that allochthonous humic-like FDOM derived from the Sea of Okhotsk is transported widely to the intermediate layer of the North Pacific by the NPIW.

Bacterial contribution to dissolved organic matter in a large monomictic lake (Lake Biwa) indicated by amino acids enantiomers

*Yasuhiko T. Yamaguchi[1], Chikage Yoshimizu[2], Ichiro Tayasu[2], Keisuke Koba[3], Kazuhide Hayakawa[1]

Dissolved organic matter (DOM) plays crucial roles in the biogeochemical cycles in aquatic environments. A number of past studies have strongly indicated that heterotrophic bacteria represent a major source to the ocean DOM pool, suggesting that microbial processes may underlie the mechanisms for DOM preservation ("microbial carbon pump"). In particular, enantiomeric (D/L) analysis of amino acids (AA) in DOM has been used to characterize sources of DOM, and high abundance of specific D-AA bacterial biomarkers have suggested that bacterially-sourced organic matter may be a key in formation of the ocean's recalcitrant DOM pool (e.g., McCarthy et al., 1998; Kaiser & Benner, 2008; Yamaguchi & McCarthy, 2018). In contrast to the marine environments, the distribution of D-AA bacterial biomarkers in DOM has been severely understudied in lacustrine environments. To our knowledge, there has been just one report of D-AA concentration in DOM for a freshwater lake water column (Kawasaki et al., 2013: in eutrophic Lake Kasumigaura, Japan).

Our study explores the use of D-AA bacterial biomarkers as an effective approach to estimate bacterial contribution to the DOM pools in lacustrine environments. First, we have developed a new analytical approach using GC-MS for D-AA concentration in the total DOM pool of lake water. This method can detect unusual D-AA molecules (e.g., D-Val, D-Phe, D-Tyr) together with the major four bacterial biomarkers (D-Ala, D-Glu, D-Asp, and D-Ser) which have been analyzed by the conventional HPLC method. Second, we determined vertical and seasonal variations in the D-AA concentrations of DOM in a large monomictic lake (Lake Biwa, Japan). To our knowledge, this study is the first report of D-AA concentrations of DOM in a meso/oligotrophic lake. Finally, we conducted an incubation experiment using natural microbial community in Lake Biwa to estimate the D-AA yields in freshly-produced bacterial DOM in the lake environment, which are essential for the calculation of bacterial contribution to the natural DOM pools.

From the vertical distribution of D-AA concentration during the stratified period (summer and fall), we estimated that a substantial fraction (30-40%) of the recalcitrant pool of dissolved organic carbon (DOC) is bacterial origin. In contrast, the bacterial contribution was less than 20% to the semi-labile DOC pool which accumulates in the lake epilimnion during summer. These results suggest that the "microbial carbon pump" (production of recalcitrant DOM by heterotrophic bacteria) is an important process in the biogeochemical cycles of lakes.

Ecology of bacterioplankton inhabiting oxygenated hypolimnia of deep freshwater lakes

*Yusuke Okazaki[1]

1. National Institute of Advanced Industrial Science and Technology

In marine and freshwater systems, there are 10^4–10^7 cells mL^{-1} of bacterioplankton in the water column, playing central roles in the microbial food web and biogeochemical cycling. In oligo-mesotrophic deep freshwater lakes, such as Lake Biwa, Baikal and The Laurentian Great Lakes, the hypolimnion is a dark, cold, aerobic water layer below the thermocline that accounts for a majority of the lake volume. Analogous to the deep ocean, the oxygenated hypolimnion is a realm for important biogeochemical processes, such as accumulation and decomposition of semilabile organic matter, nitrification, and methane oxidation. However, our knowledge for the diversity and ecology of the bacterioplankton in the oxygenated hypolimnion is still limited and even poorer than that in the deep ocean. To fill this gap, the present study comprehensively investigated the bacterioplankton community composition in the oxygenated hypolimnia of deep freshwater lakes.

To obtain data from lakes with varying depth, surface area, water temperature, trophic state, pH, lake origin and water retention time, 13 Japanese lakes and 7 European perialpine lakes have been sampled so far. The waters were collected vertically at the deepest point in each lake and the bacterial community composition was determined by 16S rRNA gene amplicon sequencing and catalyzed reporter deposition-fluorescence *in situ* hybridization (CARD-FISH). The result revealed that the oxygenated hypolimnion is inhabited by hypolimnion-specific bacterioplankton lineages that were phylogenetically different by phylum-level from commonly-known freshwater bacterioplankton lineages dominating in epilimnia. While most of the hypolimnion-specific lineages were uncultured and thus their eco-physiology was not well understood, the fact that they commonly predominate in global lakes suggests their importance in the microbial food web and biogeochemical cycling in deep freshwater lakes.

Among the hypolimnion-specific lineages, the CL500-11 lineage (phylum Chloroflexi) is particularly abundant, accounting for more than 10% of bacterioplankton cells in the hypolimnion in many lakes. CARD-FISH analysis revealed their relatively large cell size (1–2 μm), suggesting their contribution in biovolume is even greater. Together with the information collected from literatures and sequence databases, the results demonstrated that CL500-11 inhabit most freshwater lakes with the oxygenated hypolimnion, although their low abundances were observed in lakes with low pH, shallow depth, or short water retention time (<1 year). The results as well as metagenomic and geochemical insights from published studies allowed to hypothesize possible characteristics of substrates supporting CL500-11 growth, most likely nitrogen-rich autochthonous dissolved organic matter (DOM) ubiquitously available in the hypolimnion that may turnover within an annual timescale; for instance, DOM derived from the epilimnion transferred by winter vertical mixing, or DOM secondary produced in the hypolimnion, such as cellular debris from other microbes.

In conclusion, this study revealed that the microbial food web and biogeochemical processes in the oxygenated hypolimnia of deep freshwater lakes are driven by a specific bacterioplankton communities that have eluded previous studies only focusing on the surface waters. Future works should further investigate the ecophysiology of the individual lineages by a metagenomic-based approach or by establishment of their isolated cultures.

Nitrous oxide emission from the drainage and the production processes in oil palm plantation on peatland

*Kazuya Nishina[1], Lulie Melling[2], Ryuichi Hirata[1], Yoshiyuki Takahashi[1], Sakae Toyoda[3], Kotaro Terajima[3], Masayuki Itoh[4]

1. NIES National Institute of Environmental Studies, 2. SARAWAK Tropical Peat Research Institute, 3. Tokyo Institute of Technology, 4. University of Hyogo

In South-East Asia, oil palm plantation has rapidly expanded in the past few decades even in peatland areas. In the light of nitrogen cycling, this land-use change would result in enrichment on the ecosystem N cycling due to the N fertilization for the maintaining oil palm growth and the wastewater emission from the palm mills in the plantation. Oil palm plantations converted from peat swamp forests require the drainage to keep cultivation and thus has unique hydrological characteristics. In such plantation, drainage water surface dominates up to 5% of plantation area and therefore it is important to evaluate the gas exchange between the drainage water and atmosphere.

In this study, we have conducted spatial sampling for dissolved N_2O concentration (dN_2O) in the oil palm plantation on drained peat soil in July 2018, in Sarawak, Malaysia in order to evaluate the indirect N_2O emission from palm oil plantation. We have intensively sampled the water samples from the drainage in the plantation (ca. 120 km^2) and the water samples from Raja river, which is adjacent to the plantation. 90% of samples (N = 84) in the drainage water showed over-saturation in dissolved N_2O concentration (up to 570%), suggesting that the drainage water in the oil palm plantation acts the source of N_2O to the atmosphere. The emission factor for indirect emission (EFr: i.e., dN_2O/nitrate concentration) showed relatively higher than the default EFr in IPCC. However, there were no clear linear relationships between the water qualities (including nitrate) and dN_2O. We have also analyzed the isotopic composition of dN_2O in both drainage and river samples. This analysis suggested the denitrification contributed dN_2O in the drainage water.

Biomolecular composition changes and biochemical processes associated with indicators of organic matter degradation

*Satoru Hobara[1], Hiroshi Ogawa[2]

1. Rakuno Gakuen University, 2. The University of Tokyo

Degrading organic matter is the dominant carbon form in the Earth’ s surface, and an essential source of energy and nutrients for organisms. The availability of degrading organic matter is strongly constrained by its chemical composition. Many studies conducted for terrestrial and marine environment have found that degradation process usually lead to changes in these biomolecular compositions of organic matter. However, little is understood on its factors controlling the changes. In addition, few reports are available on the difference in features of useful indicators representing the decomposition stage. In this study, we review and compare the known degradation indicators based on biomolecules of decomposed organic matter and also develop more simple and useful indicators. We observed unidirectional increase/decrease in some of the well-analyzed amino acids in organic matter through decomposition, suggesting that it occurred regardless of short-term or long-term, and land or ocean, spatio-temporally. By investigating the amino acids increased or decreased during degradation, various biochemical processes occurring in the background of decomposition which has not been discussed were newly suggested.

Community and metabolic responses of marine bacteria to the dissolved organic matter derived from phytoplankton

*Yuya Tada[1], Koji Suzuki[2], Youhei Yamashita[2]

1. National Institute For Minamata Disease, 2. Hokkaido University

Dissolved organic matter (DOM) representing one of the largest reduced carbon pools in the ocean, are strongly involved in the global biogeochemical processes. It is considered that a large part of labile DOM in the marine environments is derived from the photosynthesis and cell lysis of phytoplankton. Dissolved organic matter derived from phytoplankton (DOMP) can affect the bacterial community composition and metabolisms. However, little is known about the characteristics of DOMP, and the community and metabolic response of marine bacteria to the addition of DOMP. In this study, we analyzed amino acid composition in the DOMP-lysates from two different phytoplankton cultures, the diatom *Thalassiosira oceanica* (CCMP1005) and the haptophyte *Emiliania huxleyi* (CCMP374), and examined the community and metabolism of marine bacteria in response to these DOMP-lysates using metagenomic approaches. Amino acid analyses for the DOMP-lysates from two strains showed distinctive free amino acid (FAA) compositions, but little changes in their hydrolytic amino acid (HAA) fractions. The proportions of arginine, gamma-aminobutyric acid (GABA) and serine to the total FAAs in *E. huxleyi* were relatively higher than those in *T. oceanica*. However, glutamate and ornithine were the dominant FAAs in the DOMP-lysates from *T. oceanica*. As for the HAA, glutamate and alanine were dominant HAAs in both phytoplankton cultures. In addition, we conducted incubation experiments using natural seawater amended with the lysates from both diatom and haptophyte. Analysis of 16S rRNA genes in the metagenomic sequences revealed that community shifts of marine bacteria in response to DOMP-lysate additions. Relative abundance of *Firmicutes* increased in both DOMP treatments. *Bacteroidetes* increased in response to the addition of DOMP derived from the diatom. Metagenomics analysis of functional genes showed that the genes involved in histidine-, sulfur-, lipopolysaccharide-metabolisms, and polyamine biosynthesis increased in both DOMP treatments. In contrast, the relative abundance of genes associated with glycosaminoglycan metabolism and phosphotransferase system decreased. Fluorescent DOM analysis for initial and amended seawater showed that the fluorescence intensity of a protein-like matter from *E. huxleyi* decreased during incubation. These data suggest that the DOMP-lysates derived from phytoplankton can be a primary factor to change the community composition and metabolisms of marine bacteria, and may change the DOM characteristics in the marine environments.

High production of benthic algae promoted by increased available phosphate in the Obitsu River tidal flat

*Yuzuki Takagai[1], Muneoki Yoh[1]

1. Tokyo University of Agriculture and Technology

Tidal flats are an environment of high biological productivity, with many benthic organisms such as crabs and bivalves. Major primary producers in tidal ecosystems are regarded as benthic algae inhabiting on the sediment surface. So far, such a eutrophic property has been attributed to organic matter and nutrients derived from the upper stream. Here, we raise a hypothesis that photosynthesis of benthic algae is promoted by available phosphate (PO_4^{3-}) that is increased abiotically in tidal flats, which can support higher trophic level organisms. Phosphate bound to iron oxides is expected to be released accompanied with iron reduction under reductive environment, which is easily formed in sediments of tidal flats. In this study, we aimed to quantitatively show the production of benthic algae promoted by the available phosphate.

A monthly survey was conducted from June to December 2018 (except August) in a small creek beside the Obitsu River estuary in Kisarazu City, Chiba Prefecture. At two station of a downstream site (St.1) and an upper stream site (St.2) of the blind tubular creek, photosynthesis was measured by in situ light and dark chambers, and water analysis of pore water and properties of surface sediments were also determined. Phosphate concentration was measured by the molybdenum blue method, and the ammonium concentration by the indophenol blue method. The flux of phosphate and ammonium from sediments was measured from the concentration change in the chamber with time. Chl a, particle size composition and organic matter contents were measured for surface sediments.

Positive phosphate flux from the sediment surface was detected. At an upper stream site of a small creek, the dissolved oxygen flux was positive in the light condition and negative in the dark condition, showing the photosynthesis of benthic algae. The maximum photosynthesis rate (185 mg $O_2 m^{-2} h^{-1}$) was higher than previous reports. On the other hand, at a lower stream site, the dissolved oxygen flux was often negative not only under dark condition but under light condition. This fact implies that, despite high Chl a concentration and sufficient light onto the sediment surface, oxygen consumption due to organic decomposition surpassed photosynthesis. Organic contents were St.1>St.2. The particle size was smaller at St.1. The average N/P ratio of the pore water was 14 in St.2, whereas 4.8 at St.1, being much lower than the Redfield ratio. This remarkable low N/P ratio suggests the occurrence of abiotic phosphate production within the sediment at this site.

Results show that available phosphate is produced to promote the active primary production of benthic algae in this tidal creek. On the other hand, this creek showed a remarkable spatial difference in organic matter contents and N/P ratio.

High Concentration of Phosphate and its Mechanism in "Gomi-kui" and "Gata-do"

*KOWATA Satoshi[1], Muneoki Yoh[1]

1. Tokyo University of Agriculture and Technology

[Introduction]
River and creeks (waterways) network is developed in Saga plain, which has water and water storage functions. Silt from the upper stream and suspension clay carried by tidal effect are accumulated in creeks and rivers. Mud sediment in creeks has been used as a fertilizer until the spread of chemical fertilizer (Kato 1997). This work is called "Gomi-kui". On the other hand, the mud sediment deposited in the flow passage of the river tidal area such as the Rokkaku River is called "Gata-do". This has been considered to be a nutrient supply source to the Ariake Sea by solutes of nutrient (Mishima 2017). The present study hypothesized "Gomi-kui" and "Gata-do" is abundant in nutrients through a phosphate release by reduction of iron oxide in reductive sediments. We investigated to clarify this hypothesis.
[Results and Discussion]
Concentration of PO_4^{3-} in pore water of “Gata-do” increased along the flowing-down the river. The highest concentration of 73.5 μmol L^{-1} was observed at the point of 5.5 km from the river mouth (Fig. 1). This increase in PO_4^{3-} concentration was associated with the increase in clay content and the decrease in DO (Fig. 2). That is, the development of reductional environment apparently influenced the increase of PO_4^{3-} concentration. From the upstream to the 19.6 km point, the concentration of Fe^{2+} and S^{2-} in the pore water also increased. From the downstream side of 19.6 km point, however, Fe^{2+} and S^{2-} concentration decreased, while the PO_4^{3-} concentration continued to increase. A positive correlation was found between the increase in EC and the increase in PO_4^{3-} concentration ($p < 0.05$). It is likely from this result that the formation of iron sulfide (FeS) is involved in increasing the concentration of PO_4^{3-}. In the reductive sediment, PO_4^{3-} would be released in association with Fe reduction. In addition, as an effect of seawater intrusion, the reduction of SO_4^{2-} would produce abundant S^{2-} to remove Fe^{2+} as FeS. PO_4^{3-} would remain in dissolved state without being affected by Fe^{2+} (Hartzell and Jordan 2012). This mechanism is expected to contribute to high PO_4^{3-} concentration.
Similar results were observed for “Gomi-kui” mud: high PO_4^{3-} concentration, tendency of increase and decrease in Fe^{2+} and S^{2-} concentration, decrease in DO, and increase in clay content. Results suggest that phosphate concentration is remarkably incresed due to the mechanism associated with Fe reduction in “Gomi-kui” and “Gata-do”. Phosphate released from lowlying areas could be a source to coastal areas.

Estimation of the formation and reduction of organic mud in tidal river using sulfate ionic flux and principal component analysis

Hiroki Itamura[1], *Yoriko Yokoo[1]

1. Faculty of Science and Engineering, Doshisha University

We determined the elemental compositions of river water and pore water in order to estimate the sites where the formation and reduction of organic mud occur in delta rivers using the principal component analysis. We collected river water and bed sediment samples at river mouth with tidal intrusion in Ota River, Hiroshima prefecture, and analyze the elemental concentrations using IC and ICP-MS.
We calculated major cations and SO_4^{2-} flux (J_{SO4}). There was positive correlation between J_{Ca} and J_{SO4}. At the sites where their J_{SO4} showed negative values, J_{SO4} had strongly positive correlation to J_{Ca}. These results demonstrate that SO_4^{2-} concentrations in pore water decreased and J_{SO4} showed negative values due to the reduction of SO_4^{2-}, therefore, the formation and reduction of organic mud could occur at those sites and SO_4^{2-} has same behavior to Ca^{2+}. We conducted the principal component analysis using eight factors such as J_{Ca}, J_{SO4}, water content, porosity, salinity, pH of pore water and concentration of Mn and Fe in pore water for the sites where their J_{SO4} showed negative values. The first principal component loadings of Fe and Mn concentrations, J_{Ca}, J_{SO4} and porosity were positive and the second principal component loadings of water content, pH, J_{SO4}, and J_{Ca} were negative, indicating that the first and second principal component are the index of redox and the formation of organic mud, respectively. The reduction of organic mud could occur at sites plotted in the range of the negative first principal component loadings and the positive second principal component loadings.

Evaluating the relationship among energy, water and carbon in soil by using multi-layered land surface model, BEAMS

*Keisuke Komiyama[1], Takahiro Sasai[1]

1. Tohoku University Graduate School of Science

The amount of carbon released from the soil to the atmosphere is recently increasing along with climate change. One of the most focusing point is a response of soil carbon dynamics on global warming. However, since the complexity of the relationship among soil energy, water and carbon processes, we have not still understood the scientific understanding relevant to soil carbon dynamics, leading a need to more accurately develop the land surface model. Particularly, the quantitative understanding of the role of soil carbon in the subsurface layer is lacking because the importance of the surface processes has only been recognized recently. The existing models cannot sufficiently reproduce the soil carbon processes in the subsurface layer. Only few studies have focused on the response of the subsurface soil carbon to the changes in soil temperature, soil water content and freezing rate that are the key elements of soil heat and water environment. In this study, we aim to estimate the response of the soil carbon decomposition rate to the changes in soil heat and water environment of the vertically multilayered soil. By integrating an elaborate hydrological model into the existing Biosphere model integrating Eco-physiological And Mechanistic approaches using Satellite data (BEAMS) (Sasai et al., 2016), we developed a new land surface model, and estimated the 1° grid terrestrial carbon fluxes from 1982 to 2011.

As a result, the global average soil carbon decomposition rate increased throughout the model experiment period. The sensitivity experiments showed that 16% of the increasing trend resulted from the changes of the soil heat and water environment. The soil heat and water environment in the top layer (0.00m ~ 0.05m) explained 8.1%, in the middle layer (0.05m ~ 0.30m) explained 5.7%, and in the bottom layer (0.30m ~ 1.00m) explained 2.2% of the increasing trend. These results suggest that the response of the soil decomposition rate on the changes of soil heat and water environment decreases with the soil depth, so that the soil carbon below the surface layer is less affected by the changes in the soil heat and water environment than the soil carbon in the surface layer.

However, this pattern is not universal. In several regions, such as cold regions in the northern hemisphere and grassland in the southern part of Africa, the response of the bottom layer is large. We emphasize that in these regions, the role of the subsurface soil carbon is particularly important.

[M-IS13] Biogeochemistry

convener:Keisuke Koba(Center for Ecological Research, Kyoto University), Hideaki Shibata(Field Science Center fot Northern Biosphere, Hokkaido University), Naohiko Ohkouchi(Japan Agency for Marine-Earth Science and Technology), Youhei Yamashita(Faculty of Environmental Earth Science, Hokkaido University)

Biogeochemistry is an interdisciplinary study field including ecology, geochemistry, oceanography, limnology, hydrology, soil science and environmental sciences. Respective researches have tended to be conducted separately so far. This session aims to provide a common platform for biogeochemists of different disciplines, which facilitates the interactive discussion and information exchanges for further development of biogeochemical studies.

Biomolecular composition changes and biochemical processes associated with indicators of organic matter degradation

*Satoru Hobara[1], Hiroshi Ogawa[2]

1. Rakuno Gakuen University, 2. The University of Tokyo

Degrading organic matter is the dominant carbon form in the Earth’ s surface, and an essential source of energy and nutrients for organisms. The availability of degrading organic matter is strongly constrained by its chemical composition. Many studies conducted for terrestrial and marine environment have found that degradation process usually lead to changes in these biomolecular compositions of organic matter. However, little is understood on its factors controlling the changes. In addition, few reports are available on the difference in features of useful indicators representing the decomposition stage. In this study, we review and compare the known degradation indicators based on biomolecules of decomposed organic matter and also develop more simple and useful indicators. We observed unidirectional increase/decrease in some of the well-analyzed amino acids in organic matter through decomposition, suggesting that it occurred regardless of short-term or long-term, and land or ocean, spatio-temporally. By investigating the amino acids increased or decreased during degradation, various biochemical processes occurring in the background of decomposition which has not been discussed were newly suggested.

Community and metabolic responses of marine bacteria to the dissolved organic matter derived from phytoplankton

*Yuya Tada[1], Koji Suzuki[2], Youhei Yamashita[2]

1. National Institute For Minamata Disease, 2. Hokkaido University

Dissolved organic matter (DOM) representing one of the largest reduced carbon pools in the ocean, are strongly involved in the global biogeochemical processes. It is considered that a large part of labile DOM in the marine environments is derived from the photosynthesis and cell lysis of phytoplankton. Dissolved organic matter derived from phytoplankton (DOMP) can affect the bacterial community composition and metabolisms. However, little is known about the characteristics of DOMP, and the community and metabolic response of marine bacteria to the addition of DOMP. In this study, we analyzed amino acid composition in the DOMP-lysates from two different phytoplankton cultures, the diatom *Thalassiosira oceanica* (CCMP1005) and the haptophyte *Emiliania huxleyi* (CCMP374), and examined the community and metabolism of marine bacteria in response to these DOMP-lysates using metagenomic approaches. Amino acid analyses for the DOMP-lysates from two strains showed distinctive free amino acid (FAA) compositions, but little changes in their hydrolytic amino acid (HAA) fractions. The proportions of arginine, gamma-aminobutyric acid (GABA) and serine to the total FAAs in *E. huxleyi* were relatively higher than those in *T. oceanica*. However, glutamate and ornithine were the dominant FAAs in the DOMP-lysates from *T. oceanica*. As for the HAA, glutamate and alanine were dominant HAAs in both phytoplankton cultures. In addition, we conducted incubation experiments using natural seawater amended with the lysates from both diatom and haptophyte. Analysis of 16S rRNA genes in the metagenomic sequences revealed that community shifts of marine bacteria in response to DOMP-lysate additions. Relative abundance of *Firmicutes* increased in both DOMP treatments. *Bacteroidetes* increased in response to the addition of DOMP derived from the diatom. Metagenomics analysis of functional genes showed that the genes involved in histidine-, sulfur-, lipopolysaccharide-metabolisms, and polyamine biosynthesis increased in both DOMP treatments. In contrast, the relative abundance of genes associated with glycosaminoglycan metabolism and phosphotransferase system decreased. Fluorescent DOM analysis for initial and amended seawater showed that the fluorescence intensity of a protein-like matter from *E. huxleyi* decreased during incubation. These data suggest that the DOMP-lysates derived from phytoplankton can be a primary factor to change the community composition and metabolisms of marine bacteria, and may change the DOM characteristics in the marine environments.

High production of benthic algae promoted by increased available phosphate in the Obitsu River tidal flat

*Yuzuki Takagai[1], Muneoki Yoh[1]

1. Tokyo University of Agriculture and Technology

Tidal flats are an environment of high biological productivity, with many benthic organisms such as crabs and bivalves. Major primary producers in tidal ecosystems are regarded as benthic algae inhabiting on the sediment surface. So far, such a eutrophic property has been attributed to organic matter and nutrients derived from the upper stream. Here, we raise a hypothesis that photosynthesis of benthic algae is promoted by available phosphate (PO_4^{3-}) that is increased abiotically in tidal flats, which can support higher trophic level organisms. Phosphate bound to iron oxides is expected to be released accompanied with iron reduction under reductive environment, which is easily formed in sediments of tidal flats. In this study, we aimed to quantitatively show the production of benthic algae promoted by the available phosphate.

A monthly survey was conducted from June to December 2018 (except August) in a small creek beside the Obitsu River estuary in Kisarazu City, Chiba Prefecture. At two station of a downstream site (St.1) and an upper stream site (St.2) of the blind tubular creek, photosynthesis was measured by in situ light and dark chambers, and water analysis of pore water and properties of surface sediments were also determined. Phosphate concentration was measured by the molybdenum blue method, and the ammonium concentration by the indophenol blue method. The flux of phosphate and ammonium from sediments was measured from the concentration change in the chamber with time. Chl a, particle size composition and organic matter contents were measured for surface sediments.

Positive phosphate flux from the sediment surface was detected. At an upper stream site of a small creek, the dissolved oxygen flux was positive in the light condition and negative in the dark condition, showing the photosynthesis of benthic algae. The maximum photosynthesis rate (185 mg $O_2 m^{-2} h^{-1}$) was higher than previous reports. On the other hand, at a lower stream site, the dissolved oxygen flux was often negative not only under dark condition but under light condition. This fact implies that, despite high Chl a concentration and sufficient light onto the sediment surface, oxygen consumption due to organic decomposition surpassed photosynthesis. Organic contents were St.1>St.2. The particle size was smaller at St.1. The average N/P ratio of the pore water was 14 in St.2, whereas 4.8 at St.1, being much lower than the Redfield ratio. This remarkable low N/P ratio suggests the occurrence of abiotic phosphate production within the sediment at this site.

Results show that available phosphate is produced to promote the active primary production of benthic algae in this tidal creek. On the other hand, this creek showed a remarkable spatial difference in organic matter contents and N/P ratio.

High Concentration of Phosphate and its Mechanism in "Gomi-kui" and "Gata-do"

*KOWATA Satoshi[1], Muneoki Yoh[1]

1. Tokyo University of Agriculture and Technology

[Introduction]
River and creeks (waterways) network is developed in Saga plain, which has water and water storage functions. Silt from the upper stream and suspension clay carried by tidal effect are accumulated in creeks and rivers. Mud sediment in creeks has been used as a fertilizer until the spread of chemical fertilizer (Kato 1997). This work is called "Gomi-kui". On the other hand, the mud sediment deposited in the flow passage of the river tidal area such as the Rokkaku River is called "Gata-do". This has been considered to be a nutrient supply source to the Ariake Sea by solutes of nutrient (Mishima 2017). The present study hypothesized "Gomi-kui" and "Gata-do" is abundant in nutrients through a phosphate release by reduction of iron oxide in reductive sediments. We investigated to clarify this hypothesis.
[Results and Discussion]
Concentration of PO_4^{3-} in pore water of “Gata-do” increased along the flowing-down the river. The highest concentration of 73.5 μmol L^{-1} was observed at the point of 5.5 km from the river mouth (Fig. 1). This increase in PO_4^{3-} concentration was associated with the increase in clay content and the decrease in DO (Fig. 2). That is, the development of reductional environment apparently influenced the increase of PO_4^{3-} concentration. From the upstream to the 19.6 km point, the concentration of Fe^{2+} and S^{2-} in the pore water also increased. From the downstream side of 19.6 km point, however, Fe^{2+} and S^{2-} concentration decreased, while the PO_4^{3-} concentration continued to increase. A positive correlation was found between the increase in EC and the increase in PO_4^{3-} concentration ($p < 0.05$). It is likely from this result that the formation of iron sulfide (FeS) is involved in increasing the concentration of PO_4^{3-}. In the reductive sediment, PO_4^{3-} would be released in association with Fe reduction. In addition, as an effect of seawater intrusion, the reduction of SO_4^{2-} would produce abundant S^{2-} to remove Fe^{2+} as FeS. PO_4^{3-} would remain in dissolved state without being affected by Fe^{2+} (Hartzell and Jordan 2012). This mechanism is expected to contribute to high PO_4^{3-} concentration.
Similar results were observed for “Gomi-kui” mud: high PO_4^{3-} concentration, tendency of increase and decrease in Fe^{2+} and S^{2-} concentration, decrease in DO, and increase in clay content. Results suggest that phosphate concentration is remarkably incresed due to the mechanism associated with Fe reduction in “Gomi-kui” and “Gata-do”. Phosphate released from lowlying areas could be a source to coastal areas.

Estimation of the formation and reduction of organic mud in tidal river using sulfate ionic flux and principal component analysis

Hiroki Itamura[1], *Yoriko Yokoo[1]

1. Faculty of Science and Engineering, Doshisha University

We determined the elemental compositions of river water and pore water in order to estimate the sites where the formation and reduction of organic mud occur in delta rivers using the principal component analysis. We collected river water and bed sediment samples at river mouth with tidal intrusion in Ota River, Hiroshima prefecture, and analyze the elemental concentrations using IC and ICP-MS.
We calculated major cations and SO_4^{2-} flux (J_{SO4}). There was positive correlation between J_{Ca} and J_{SO4}. At the sites where their J_{SO4} showed negative values, J_{SO4} had strongly positive correlation to J_{Ca}. These results demonstrate that SO_4^{2-} concentrations in pore water decreased and J_{SO4} showed negative values due to the reduction of SO_4^{2-}, therefore, the formation and reduction of organic mud could occur at those sites and SO_4^{2-} has same behavior to Ca^{2+}. We conducted the principal component analysis using eight factors such as J_{Ca}, J_{SO4}, water content, porosity, salinity, pH of pore water and concentration of Mn and Fe in pore water for the sites where their J_{SO4} showed negative values. The first principal component loadings of Fe and Mn concentrations, J_{Ca}, J_{SO4} and porosity were positive and the second principal component loadings of water content, pH, J_{SO4}, and J_{Ca} were negative, indicating that the first and second principal component are the index of redox and the formation of organic mud, respectively. The reduction of organic mud could occur at sites plotted in the range of the negative first principal component loadings and the positive second principal component loadings.

Evaluating the relationship among energy, water and carbon in soil by using multi-layered land surface model, BEAMS

*Keisuke Komiyama[1], Takahiro Sasai[1]

1. Tohoku University Graduate School of Science

The amount of carbon released from the soil to the atmosphere is recently increasing along with climate change. One of the most focusing point is a response of soil carbon dynamics on global warming. However, since the complexity of the relationship among soil energy, water and carbon processes, we have not still understood the scientific understanding relevant to soil carbon dynamics, leading a need to more accurately develop the land surface model. Particularly, the quantitative understanding of the role of soil carbon in the subsurface layer is lacking because the importance of the surface processes has only been recognized recently. The existing models cannot sufficiently reproduce the soil carbon processes in the subsurface layer. Only few studies have focused on the response of the subsurface soil carbon to the changes in soil temperature, soil water content and freezing rate that are the key elements of soil heat and water environment. In this study, we aim to estimate the response of the soil carbon decomposition rate to the changes in soil heat and water environment of the vertically multilayered soil. By integrating an elaborate hydrological model into the existing Biosphere model integrating Eco-physiological And Mechanistic approaches using Satellite data (BEAMS) (Sasai et al., 2016), we developed a new land surface model, and estimated the 1° grid terrestrial carbon fluxes from 1982 to 2011.

As a result, the global average soil carbon decomposition rate increased throughout the model experiment period. The sensitivity experiments showed that 16% of the increasing trend resulted from the changes of the soil heat and water environment. The soil heat and water environment in the top layer (0.00m ~ 0.05m) explained 8.1%, in the middle layer (0.05m ~ 0.30m) explained 5.7%, and in the bottom layer (0.30m ~ 1.00m) explained 2.2% of the increasing trend. These results suggest that the response of the soil decomposition rate on the changes of soil heat and water environment decreases with the soil depth, so that the soil carbon below the surface layer is less affected by the changes in the soil heat and water environment than the soil carbon in the surface layer.

However, this pattern is not universal. In several regions, such as cold regions in the northern hemisphere and grassland in the southern part of Africa, the response of the bottom layer is large. We emphasize that in these regions, the role of the subsurface soil carbon is particularly important.

[M-IS14] Global climate change driven by the Southern Ocean and the Antarctic Ice Sheet

convener:Osamu Seki(Institute of Low Temperature Science, Hokkaido University), Akira Oka(Atmosphere and Ocean Research Institute, The University of Tokyo), Ryu Uemura(University of the Ryukyus), Ryosuke Makabe(National Institute of Polar Research), Chairperson:Yuji Kato(Kochi University)

The Southern Ocean and Antarctic ice sheet, which are the giant reservoirs of heat, water, and materials, have a potential to play central roles in long-term global climate change. This system is composed of the following sub-systems; ice shelf which is a place of the interaction of ice sheet and ocean, flowing iceberg, seasonal sea ice zone, Antarctic bottom water which drives the thermohaline circulation, active biological production and Antarctic Circumpolar Current. These sub-systems are interacted with each other and have significant impact on changes in the global environmental system. This session aim to summarize recent observational and simulation studies from various fields relating to the past and present changes in the Antarctic Ice sheet and Southern Ocean, which are essential elements for unraveling the changes in the global climate system. Further, future science plans for understanding of the environmental changes of the Antarctic Cryosphere is also discussed.

Mass loss of the Antarctic ice sheet under the influence of ice-ocean interaction

*Shin Sugiyama[1]

1. Institute of Low Temperature Science, Hokkaido University

The Antarctic ice sheet covers 8.3% of the global land surface with a mean ice thickness of 1937 m. The mass of the ice accounts for ~90% of freshwater on the earth and has a potential of 58.3 m sea level rise. Mass change of the ice sheet has a large impact on the Antarctic and global environment since meltwater discharge affects not only sea level, but also ocean circulation and marine ecosystems. Therefore, quantification of ice sheet mass balance and understanding the driving mechanisms are crucially important.

Our understanding of the Antarctic ice sheet mass balance has been greatly improved over the last two decades. Novel satellite measurement techniques enabled us to quantify year to year variations in the mass balance, as well as to investigate key processes such as ice speed, calving and ice shelf basal melting. These new observations have shown a trend of ice sheet mass loss since 1990s. The most significant changes are observed at fast flowing glaciers and ice shelves along the coast in West Antarctica. More detailed studies strongly suggest that the mass loss is due to increasing ice shelf basal melting and ice flow acceleration. To clarify the mechanism of the observed changes, further investigations are in progress on the ice sheet and in the ocean. Study results indicate that the ice sheet is losing mass under the influence of changing ocean, and meltwater discharge is affecting the ocean environment in turn.

In this presentation, we review progress in understanding of the Antarctic ice sheet mass balance and mechanisms driving the recent mass trends. Based on the existing knowledge, we discuss future research directions required for satellite and in-situ measurements as well as numerical investigations.

Accurate chronology and climatic reconstruction around MIS 11 (interglacial period ~400,000 years ago) from Dome Fuji ice core, Antarctica

*Kenji Kawamura[1,2,3], Ikumi Oyabu[1], Shuji Aoki[4], Takakiyo Nakazawa[4], Ayako Abe-Ouchi[5,3], Fuyuki SAITO[3]

1. National Institute of Polar Research, Research Organization of Information and Systems, 2. SOKENDAI (The Graduate University of Advanced Studies), 3. JAMSTEC, 4. Tohoku University, 5. University of Tokyo

Marine Isotope Stage (MIS) 11 is characterized by long duration of glacial termination and interglacial, with higher sea level than today, despite moderate atmospheric CO_2 concentration and small variations in northern summer insolation (due to small orbital eccentricity). To investigate the roles of different forcings (e.g. orbital variations and greenhouse gases) on climate and ice sheets (sea level), paleoclimatic proxy records need to be accurately dated and precisely synchronized with each other. An accurate chronology for the past 360 ky was constructed through orbital tuning of O_2/N_2 ratio of trapped air in the Dome Fuji and Vostok ice cores with local summer insolation (Kawamura et al., 2007), and its improvement has been underway (Oyabu et al., this session). We have also been extending the O_2/N_2 chronology to older periods by analyzing the second Dome Fuji ice core, and constrain the timing and duration of the past interglacial periods.

Marine sediment cores from northern North Atlantic region exhibit millennial-scale variations, including abrupt climatic shifts and bipolar seesaw, during glacial periods and terminations in various proxy records (e.g. sea surface temperature and ice-rafted debris). By correlating the millennial-scale changes recorded in the marine sediment cores with those in the Dome Fuji ice core (CH_4 concentration and d18O of ice), it may be possible to transfer the Dome Fuji chronology to the marine cores from the North Atlantic. We first attempted to correlate planktonic $\delta^{18}O$ and IRD records from the marine core ODP 980 with the Dome Fuji CH_4 around MIS 11 and constrain the durations of interglacial periods recorded in the marine core, with some success. However, the current resolution of the Dome Fuji gas records (~2000 years on average) is not sufficient to undoubtedly identify all millennial-scale events, thus we will start new measurements to improve the resolution. In the presentation, we will show the results of the new measurements and synchronization, and discuss the timing, duration and mechanism of climatic changes over Termination V and MIS 11.

Study on physics and layers of ice cores containing information of climate change over the past 720 k-years, and study on the "oldest ice"

*Shuji Fujita[1,2], Motohiro Hirabayashi[1], Iizuka Yoshinori[3], Hiroshi Ohno[4]

1. National Institute of Polar Research, Research Organization of Information and Systems(ROIS), 2. Department of Polar Science, The Graduate University for Advanced Studies (SOKENDAI), Japan, 3. Institute of Low Temperature Science, Hokkaido University, Japan, 4. Kitami Institute of Technology, Japan

Purpose and Background of the Research

Ice cores collected in inland of Antarctica is one of important information sources for histories of climatic changes that occurred over 1.5 M years. At ice core drilling sites, ice is older in deeper layers; such deep layers are subject to vertical compressions by ice flow. In addition, various time-dependent metamorphic processes undergoes by influences of the geothermal heat flux. If such very deep signals are once resolved with high time resolutions, we can uncover the history of rapid climate changes. Such ice-core-based knowledge will be crucial for building strategies to make sustainable society under global warming. However, current state of our knowledge is based on limited and discrete sampling from ice cores. High resolution continuous methods for analysis has just begun in recent years. In this study, we will use cutting-edge methods for high-resolution and continuous measurements for ice cores, based on crystal physics and continuous flow analysis (CFA); we will analyze layers of ice cores spanning ca. 200,000 years and ca. 720,000 years. Based on it, we will (i) produce valuable information of the climate in the past, (ii) clarify nature of the time-dependent metamorphic processes, (iii) synchronize multiple very deep ice cores, and (iv) predict quality of information from ice cores that cover 1.5 M years.

Research Methods

At an inland site called Dome Fuji in East Antarctica, ice core researchers organized by the National Institute of Polar Research, Japan, collected ice cores covering 720,000 years. We will analyze portions of the ice cores spanning ca. 200,000 years and ca. 720,000 years. Such very old portion constitute deepest ~1000 m span within the ~3000 m-thick ice sheet. Such layers are subject to vertical compressions. In this study, key questions are as follows:
(i) Can we synchronize these very old portions of ice between to major ice cores drilled at Dome Fuji and Dome C?
(ii) How old age of ice back in time, can we clarify detailed histories of rapid changes of climate?
As actions tackling the questions, we will use two major methods to read the layered strata. One of them is to read layers of crystal textures using a method to measure dielectric permittivity tensor with the millimeter wave resonators. Spatial resolutions of this method is ~20mm. Another method is "Continuous Flow Analysis" (CFA) method to read layers of Si, Na and Ca, with a resolutions of ~10 mm.

Expected Research Achievements and Scientific Significance

First, we will produce invaluable ice core data. The data will be used to tackle the key questions. Based on the data, we will synchronize two very old ice cores at Dome Fuji and Dome C, based on collaborations of the European deep ice study community. In addition, we will examine timing difference between the climatic change records between the two ice cores. We aim to accomplish the first reliable and detailed synchronization between very old ice cores up to 720,000 years back in time. we will study change of the climatic mode over the 720,000 years. Furthermore, we will study how very old ice older than 1 M years, can be preserved near the base of the ice sheet.

Reconstructions of the Antarctic Polar Front through the glacial/interglacials

*Hiroki Matsui[1], Yuji Kato[1,2], Itsuki Suto[3], Minoru Ikehara[1]

1. Center for Advanced Marine Core Research, Kochi University, 2. JSPS PD, 3. Graduate School of Environmental Studies, Nagoya University

Understanding the Antarctic Circumpolar Current (i.e., Antarctic Polar Front and Subantarctic front), which connects major three Oceans and major components of the Southern Ocean and Antarctic ice sheets system, is important (from past to present). Modern polar front ranges from 44˚S to 64˚S and is defined by the southern bound of strong SST gradient (>1.5˚ over 100 km) (Freeman et al., 2016). The observed PF position from 2002 to 2014 does not show discernable trend (either northward or southward) in response to the global warming. For the Last Glacial Maximum (LGM), the PF moved northward by 5 degrees (e.g., Gersonde et al., 2005). However, there is difficulty to reconstruct paleo SST gradient because of paucity of surface sediments, and the alternative definition of the PF (e.g., 4 degrees C surface isotherm) was applied (Kohfeld et al., 2013). In this presentation, we summarize current state of knowledge and obstacles of reconstruction of the PF through the glacial/interglacials. We also discuss appropriate methods to certainly track the past PF position.

Integrated observations for marin earth science have been done in the Indian sector of the Southern Ocean during the KH-19-1 cruise by R/V Hakuho-maru in early 2019. Multichannel seismic (MCS) reflection and bathymetric survey were conducted at three sites on the Del Cano Rise and the Conrad Rise, and these site survey for IODP proposal 918 was successfully completed. We also obtained sediment cores from the proposed sites DCR-03A and DCR-02A, and sedimentary archives of a piston core DCR-2PC (at DCR-02A) show obviously glacial-interglacial cycles based on magnetic susceptibility and color reflectance. Various rock samples were collected by dredge observation at the Conrad Rise and the obtained materials to be used for understanding of origin of rise and tectonics in the southwest Indian Ocean. Sediment trap samples were also recovered from a site ECR-1, where is located under the biogenic silica belt south of polar front. Flux of settling particles was increased in summer, suggesting that typical seasonal change was occurred in the Southern Ocean. In addition, multichannel seismic (MCS) reflection and bathymetric survey were also done on the across transect of the deep-sea valleys off Cape Darnley, East Antarctica. By analyzing these materials and data, it is expected to advance the research leading to changes in the sedimentation process accompanying expansion and retreat of the Antarctic ice sheets and elucidation of the history of the Cape Darnley bottom water.

[M-IS14] Global climate change driven by the Southern Ocean and the Antarctic Ice Sheet

convener:Osamu Seki(Institute of Low Temperature Science, Hokkaido University), Akira Oka(Atmosphere and Ocean Research Institute, The University of Tokyo), Ryu Uemura(University of the Ryukyus), Ryosuke Makabe(National Institute of Polar Research), Chairperson:Sam Sherriff-Tadano(University of Tokyo)

The Southern Ocean and Antarctic ice sheet, which are the giant reservoirs of heat, water, and materials, have a potential to play central roles in long-term global climate change. This system is composed of the following sub-systems; ice shelf which is a place of the interaction of ice sheet and ocean, flowing iceberg, seasonal sea ice zone, Antarctic bottom water which drives the thermohaline circulation, active biological production and Antarctic Circumpolar Current. These sub-systems are interacted with each other and have significant impact on changes in the global environmental system. This session aim to summarize recent observational and simulation studies from various fields relating to the past and present changes in the Antarctic Ice sheet and Southern Ocean, which are essential elements for unraveling the changes in the global climate system. Further, future science plans for understanding of the environmental changes of the Antarctic Cryosphere is also discussed.

The Southern Ocean (SO) is a place of primordial importance to the understanding of global ocean circulation as it connects the Atlantic, the Pacific and the Indian oceans and thus actively participates in global climate changes. Climate processes and variations in the Indian sector of the SO are not as well understood as processes in the Atlantic sector. This why this project documents climate variations and migrations of the Antarctic Circumpolar Current (ACC) hydrological fronts in the Kerguelen area over the last glacial-interglacial cycle. In this study sea surface temperatures (SST) are reconstructed in two sediment cores, the MD11-3353 (PFZ) and MD12-3396CQ (SAZ), with radiolarian and diatoms microfossil assemblages. By comparing the results given by these two proxies different signals were identified for surface and subsurface waters suggesting a decoupling of these two water masses in the SAZ East of the Kerguelen Plateau. But in the PFZ, both proxies showed similar results. The comparison between these results leads us to think of an influence of lower latitudes warm water in the SAZ whereas this influence is absent in the PFZ in this region.

Present-day crustal motion and gravity change in East Antarctica: implications for the mantle viscosity and Holocene Antarctic Ice Sheet change inferred from GIA modeling

*Jun'ichi Okuno[1,2], Koichiro Doi[1,2], Yuichi Aoyama[1,2], Takeshige Ishiwa[1], Akihisa Hattori[2], Yoichi Fukuda[3]

Geodetic and geomorphological observations in the coastal part of Antarctica indicate the uplift trend associated with the removal mass of the Antarctic Ice Sheet (AIS) in the last deglaciation. The numerical calculations of crustal motion derived from the glacial isostatic adjustment (GIA) modeling have played the role of inferring the ice mass change of AIS from observations related to solid Earth deformation. The deglaciation histories of the AIS inferred from the comparisons between the geomorphological sea-level records, and GIA modeling shows the monotonic Holocene retreat for the AIS (e.g., Whitehouse et al., 2012). However, GNSS observations in some regions in the coastal part of Antarctica cannot be explained the amplitudes of the uplift by only glacial rebound due to the last deglaciation of the AIS. Also, recent studies (e.g., Kingslake et al., 2018) concerning bedrock topography in the margin of AIS inferred that some portions of the ice sheet might have re-advanced after retreating behind the present-day margin in mid-to-late Holocene. Therefore, this re-advance of AIS in Holocene may be caused to arise the mismatch between GNSS observations and numerical predictions. On the other hand, GNSS observations include not only the components of the GIA due to the last deglaciation and also elastic deformation due to present-day surface mass balance (e.g., Hattori et al., 2018). Similarly, this effect could cause a difference between the GNSS observations and the GIA calculations. In this presentation, we will show the crustal deformation rates and gravity changes calculated by the GIA modeling using the previously published deglaciation histories and the comparisons with these observations obtained from East Antarctica. We intend to discuss the influences of AIS mass changes and choice of mantle viscosity profile on the geodetic measurements in East Antarctica.

Reconstructing past variability of the Antarctic ice sheets is essential to understand their stability and to anticipate their contribution to future sea level rise. However, magnitude and timing of ice sheet changes during the last several million years have not been well constrained, especially in central & eastern Droning Maud Land, East Antarctica. Recently, we have carried out several field campaigns in this area to reconstruct changes in thickness, geographical extent, and timing of retreat of the East Antarctic Ice Sheet based on the detailed geomorphological survey, cosmogenic exposure dating, and lake/shallow marine sediment records coupled with glacial isostatic adjustment modeling (GIA). In this presentation, we will introduce these recent achievements from the field campaigns and discuss scientific plans for the next few seasons.

Vertical ice flow motions obtained from year-round GNSS observations on Shirase Glacier, Antarctica

*Yuichi Aoyama[1,2], Koichiro Doi[1,2], Daisuke Hirano[3], Takeshi Tamura[1,2], Shigeru Aoki[3], Kazuo Shibuya[1]

The Antarctic ice sheet is a huge heat sink acting as a feedback controller for adjusting global warming, so a loss of its mass would cause a great impact on the global climate change. It is valuable to evaluate an Antarctic ice mass balance, which is a consequence of competition between an ice discharge and a snow accumulation. With an objective of estimating the ice discharge around Lützow-Holmbukta, East Antarctica, we have measured three-dimensional (3D) ice flow motions around a grounding line of Shirase Glacier, which is fastest and largest ice stream in Lützow-Holmbukta.

We first performed one-month GPS measurement near the calving front of Shirase Glacier in 2011/2012 austral summer. The three-dimensional position of this site was determined by the kinematic precise point positioning (kPPP) method at every 30 seconds with a 4-5-cm precision for 25 days. From the 30-s interval position, we estimated the ice flow velocity vector, the basal melting rate of the iceberg, and ocean tidal variations (Aoyama et al. 2016). Subsequently, a year-round GNSS measurement system was installed six kilometers downstream from the grounding line of Shirase Glacier at the end of Jan. 2015. By maintaining this year-round system (changing SD card and battery) every austral summer season, we have already obtained a three-years continuous data from Jan. 30, 2015 to Dec. 30, 2017.
We analyzed the time series of the three-dimensional position of this system with kPPP method. The time series revealed the ice flow motion downstream from the grounding line of Shirase Glacier during 2015-2017. Focusing on the vertical motion, there is no remarkable ocean tidal variation. And the obtained vertical flow motion shows gradually descent, then rise, again descent slope. In order to clarify whether such vertical change is local or wide area, we compared with a TanDEM-X 90m DEM (Rizzoli et al., 2017). In the presentation, we will show properties of the ice flow motion downstream the grounding line of Shirase Glacier.

Operation plan and design of the Antarctic exploration AUV "MONACA"

*Hirokazu Yamagata[1], Toshihiro Maki[1], Hiroshi Yoshida[2], Yoshifumi Nogi[3]

1. Institute of Industrial Science, The University of Tokyo, 2. Japan Marine Science and Technology Center, 3. National Institute of Polar Research

Autonomous Underwater Vehicles (AUVs) have been used for under-ice explorations of the Antarctic Ocean. Most of the current under ice AUVs are large and are used for the long-distance survey. Survey results of these AUVs are extremely precise, but there is a trade-off between precision and running cost and/or risk of losing AUVs.

In this presentation, the authors propose a variable and compact AUV MONACA (Mobility Oriented Nadir AntarctiC Adventurer) which can offer the necessary and sufficient compositions for various survey needs by the modular design. Development of MONACA is supported by JSPS Grant-in-Aid for Scientific Research on Innovative Areas No.4902, to measure the sea ice/shelf ice and ocean floor for research of ice sheet-ocean interaction.

MONACA is 2 m long, 230 kg weight, and it can cruise for about 8 hours. Depth rating is 1500m. The vehicle is designed to go into ice-covered oceans as far as 10 km. The flat body is filled with buoyancy materials at the top so that the battery units and main unit can be accessed from the side. The vehicle has five degrees of freedom (surge, heave, roll, pitch, and yaw) by 4 vertical thrusters and 2 horizontal thrusters. Although the survey range is limited compared with large AUVs, it can conduct a highly precise survey with lower costs.

The three missions are considered as shown in the figure. (A: Seafloor tracking, B: Ice tracking, C: Water survey in constant depth). In the missions A and B, the shape of the seafloor or the ice is mapped by a multi-beam sonar while tracking it by a probabilistic approach using a scanning sonar. The multi-beam sonar measures 480 points in the swath width of 120˚. The vehicle has two set of releasable ballasts for diving and surfacing. The vehicle is designed to follow the seafloor or ice at the reference altitude of 50 m. In the mission C, the vehicle navigates at a constant depth, measuring water quality by a CTD sensor. Resolution of the CTD sensor is Temperature = +/- 0.0001 ˚C, Conductivity = +/- 0.0001 mS / cm, Depth = 0.03 m.

In order to realize these three missions under the size limitation, MONACA has the sensor unit that can be flipped upside down. The sensor unit includes the multi-beam sonar, an INS, and a DVL. Therefore, MONACA can navigate only by the sensor unit in case there are no obstacles in the seafloor.
MONACA is currently under construction, to be launched in 2019.

Geophysical insights into tectonic, volcanic, sedimentation, and glacial processes in Indian and Southern Oceans: Preliminary geophysical results of R/V *Hakuho-maru* KH-19-1 cruise

*Masakazu Fujii[1], Hiroshi Sato[2], Minoru Ikehara[3], Yoshifumi Nogi[1], Taichi Sato[4], Yasuyuki Nakamura[5], Eri Helen Amsler[6], Sam Sherriff-Tadano[7]

1. National Institute of Polar Research and SOKENDAI, 2. Senshu University, 3. Kochi University, 4. AIST, 5. JAMSTEC, 6. University of Bern, 7. AORI, UTokyo

The seafloor covers more than 70 percent of the solid-earth surface and has been progressively investigated since the 20th century, however most parts have not been explored because of observation difficulties in the ocean. Particularly, the seafloor of the Indian and Southern Oceans are expected to preserve significant records of paleo glacial processes and submarine volcanism as well as continental breakup and seafloor spreading. Here, we show new geophysical dataset just obtained during the R/V *Hakuho-maru*KH-19-1 cruise in early 2019. Underway geophysical mapping as well as multichannel reflection surveys and dredge rock samplings were conducted in this cruse. Specific scientific target area were set to 1) the Southwest Indian Ridge to reveal the seafloor spreading process in the Cenozoic era; 2) Conrad Rise to understand its origin and surrounding magmatism; 3) Del Cano Rise to reveal how it has been formed; 4) off Cape Darnley to reveal relationship between solid-earth processes and presently formed Antarctic bottom water; and 5) Southeast Indian Ridge to reveal the mid-ocean ridge oscillation. Multibeam bathymetry, total and vector magnetic fields, gravity, and sub-bottom profiler data were successfully acquired along the ship tracks which covers Fremantle to Mauritius in leg-1 (2 Jan to 11 Jan 2019) and Mauritius to Fremantle via mentioned target area in leg-2 (16 Jan to 12 Feb 2019). We overview preliminary geophysical results which were combined with previous *Hakuho-maru*cruises of KH-07-04, KH-09-05, KH-10-07, and KH-16-01 and data acquired during Japanese Antarctic Research Expedition by using Japanese icebreaker *Shirase*. Finally, we discuss geophysical insights into tectonic, volcanic, sedimentation, and glacial processes in Indian and Southern Oceans.

Simulations of glacial ocean carbon cycle with a parameterization of stratification dependence of vertical diffusivity

*Hidetaka Kobayashi[1], Akira Oka[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

Paleo-ocean reconstructions supporting the Southern Ocean hypothesis, in which carbon storage in the deep Southern Ocean increases during the glacial ages, has not been sufficiently reproduced by previous paleoclimate modeling studies. In this study, we apply salinity restoring in the Southern Ocean and a parameterization of stratification dependence of vertical diffusivity to an ocean general circulation model and attempt to reproduce oceanic properties reconstructed from paleo-ocean proxy data at the Last Glacial Maximum (LGM). An LGM simulation including the salinity restoring expresses high bottom-water salinity associated with larger sea ice production at the LGM, and reproduces the reconstructed salinity distribution. Moreover, by considering the stratification dependence of vertical diffusivity in the global ocean, the reduced vertical mixing due to enhanced salinity stratification increases ventilation ages in the intermediate to the deep ocean. As a result, more carbon is stored in the deep ocean and the vertical gradient of dissolved inorganic carbon enlarges. This redistribution of carbon reduces atmospheric carbon dioxide concentration (pCO_2). In addition, the subsequent response of carbonate compensation may amplify the glacial reduction of atmospheric pCO_2. In our presentation, we plan to report the glacial variation of atmospheric pCO_2 explained by the response of the ocean carbon cycle including carbonate compensation in numerical simulations using an ocean general circulation model.

Impacts of precession on the periodicity of climate and AMOC variabilities

*Sam Sherriff-Tadano[1]

1. Atmosphere and Ocean Research Institute, the University of Tokyo

Over the glacial period, climate varied on centennial to millennial time scale between the warm instersadial and the cold staidial. Recent ice core and modelling studies have shown that changes in CO2 and the glacial ice sheet played a critical role in controlling the periodicity of the climate variability through affecting the Atlantic Meridional Overturning Circulation (AMOC). Here, by analysing simulation data from a climate model GFDL, it is shown that changes in insolation pattern due to changes in precession also exert a substantial impact on the periodicity of the climate and AMOC variability. Model results show that a change from a Northern Hemisphere summer solstice perihelion to winter solstice perihelion causes an increase in the periodicity of the AMOC variability from decadal to millennial. Analysis reveals that an increase of sea ice over the Northern Hemisphere and a decrease in sea ice over the Southern Ocean due to insolation changes play a role in increasing the periodicity through stabilising both the vigorous AMOC and weak AMOC. These results may have some implications in interpreting the ice core data.

Warming and climate feedbacks in the southern high latitude driven by obliquity, precession-eccentricity, and atmospheric CO2

*Kanon Kino[1], Ayako Abe-Ouchi[1,2], Ryouta O'ishi[1], Fuyuki SAITO[2], Masakazu Yoshimori[1]

1. Atmosphere and Ocean Research Institute, the University of Tokyo, 2. Japan Agency for Marine-Earth Science and Technology

Polar amplification is widely known as a major characteristic of observed and simulated global warming which induced by increasing atmospheric CO2. In the southern high latitude, a study using GCM investigated climate feedback system to reproduce the warming (Lu and Cai, 2009). A latest study of the Antarctic ice core precisely analyzed phase relationship between temperature changes in the past ages and the periodic changes in the Earth’ s orbital parameters (obliquity, precession and eccentricity (Uemura et al., 2018). In this study, we use MIROC-GCM to investigate the warming in the southern high latitude due to the orbital parameter changes, and climate feedback responses. Results are compared with the doubling CO2 experiment.
We use an AGCM with slab ocean of MIROC-GCM (Hasumi and Emori, 2004) and performed experiments with (1) large obliquity, (2) large precession and the winter solstice (austral summer) at the aphelion (Maximum values in the past ages are used). A seasonal surface feedback analysis method (Lu and Cai, 2009) is also applied.
Results show that warming on the Antarctica (covered by the ice-sheet) due to the orbital parameter change is dominated by short-wave radiation which is not interrupted by cloud, in contrast that the warming due to increasing atmospheric CO2 is dominated by downward long-wave radiation. Results also show that seasonal warming and climate feedback responses on the Southern Ocean are qualitatively common in the insolation and CO2 cases, as well as warming in the Arctic Ocean; little warming in the summer with absorption of energy and large warming in the autumn and winter with releasing of the energy. The strengths of the warming are qualitatively different whether the seasonality, especially spring and early summer, of radiative forcing is favorable for sea ice melt.
We will investigate the changes of the atmospheric circulation, precipitation, and the influence of the oceanic circulation.

Keywords: GCM, Antarctica, orbital parameter, feedback

Origin of Circumpolar Deep Water intruding onto the Amundsen and Bellingshausen Sea continental shelves

*Yoshihiro Nakayama[1,2], Menemenlis Dimitris[2], Hong Zhang[2], Michael Schodlok[2], Eric Rignot[2,3]

1. Institute of Low Temperature Science, Hokkaido University, 2. NASA's Jet Propulsion Laboratory, 3. Uniersity of California, Irvine

Melting of West Antarctic ice shelves is enhanced by Circumpolar Deep Water (CDW) intruding onto the Amundsen and Bellingshausen Seas (ABS) continental shelves. Despite existing studies of cross-shelf and on-shelf CDW transports, CDW pathways onto the ABS originating from further offshore have never been investigated. Here, we investigate CDW pathways onto the ABS using a regional ocean model. Simulated CDW tracers from a zonal section across 67˚S (S04P) circulate along the Antarctic Circumpolar Current (ACC) and Ross Gyre (RG) and travel into ABS continental shelf after 3–5 years, but source locations are shifted westward by ~900 km along S04P in 2001–2006 compared to 2009–2014. We find that simulated on- and off-shelf CDW is ~0.1–0.2 ˚C warmer in the 2009–2014 case than in the 2001–2006 case together with changes in simulated ocean circulation. These differences are primarily caused by lateral, rather than surface, boundary conditions, implying that large-scale atmospheric and ocean circulations are able to control CDW pathways and thus off- and on-shelf CDW properties.

Ocean and material circulation in the southern part of the Australian Antarctic Basin in 2018/2019 summer - preliminary results from Kaiyomaru KY18-04 cruise

*Katsuro Katsumata[1], Daisuke Hirano[2], Daiki Nomura[2], Kaihe Yamazaki[2], Yoichiro Koh[2], Masaaki Kiuchi[2], Shigeru Aoki[2], Hiroto Murase[3]

1. JAMSTEC, 2. Hokkaido Univ., 3. NRI-FSF

The Australian Antarctic Basin collects dense shelf water from the Ross Sea and off Adelie Coast along the westward-flowing Antarctic Slope Current and modifies its property through mixing before initiating the bottom branch of the meridional overturning circulations in the Indian and Pacific oceans. It is necessary to monitor the current status of the near-bottom circulation in the basin in order to understand how the recently-reported volume decrease of the Antarctic Bottom Water and changes in the atmosphere-ocean and cryosphere-ocean interactions are related. It is established that the Southern Ocean, particularly at the north of the Antarctic Circumpolar Current (ACC), acts as a sink of anthropogenic carbon through its low surface pCO2 and mode and intermediate watermass production. Then, is the south of the ACC source or sink of anthropogenic carbon with its dense shelf water production in the face of upwelling of carbon-rich deep water masses? How do these changes in the environment affect the biosphere and ecosystem in the Southern Ocean?
With these questions in mind, R/V Kaiyomaru, Japan Fishery Agency, conducted a research cruise in the basin, in proximity of its seasonal ice edge, from December 2018 to March 2019. This part of the basin has been observed by an Australian team in 1996. At the time of writing, more than 40 stations have been occupied for CTD and LADCP observations and bottle sampling, more than 80 XCTD probes have been deployed. Preliminary analysis shows the changes in the bottom water masses. The Figure below shows the CTD/LADCP/sampling stations (black dots) and XCTD deployments (crosses) for Leg1 (5 Dec 2018 to 16 Jan 2019) with AMSR2 derived ice concentration, which is a combination of west of 90E (observed on 17 Dec 2018), between 90E and 107E (24 Dec 2018) and east of 107E (31 Dec 2018). In the talk, the latest results and its outlook will be discussed.

Mooring observation aiming direct current measurement and quantitative evaluation of Meridional Circulation of Southern Ocean

*Kitade Yujiro[1], Kohei Mizobata[1], Kazuho Watanabe[1], Linquiao Chen[3], Gaopin Guo[3], Shigeru Aoki[2], Shyuki Ushio[4], Keishi Shimada[1], Kay I. Ohshima[2]

1. Tokyo University of Marine Science and Technology, 2. Hokkaido University, 3. Shanghi Ocean University, 4. National Institute of Polar Research

The deep Global circulation is a large-scale thermohaline circulation over the Earth and plays an important role in maintaining a stable climate.

In recent years, as rising temperature and freshening of Antarctic bottom water is being observed in various places, in order to quantitatively understand its freshening mechanism and the flow rate and change of Southern Ocean meridional circulation, We are planning to construct a large mooring observation network.

Therefore, as the first attempt, we deployed two moorings (January 2017 - January 2018) by TR/V Umitaka-maru in order to carry out direct current measurement of Meridional circulation. At the time of deployment and recovery of mooring system, we carried out CTD observation up to the sea floor along 110 ˚E line and off Vincennes Bay. At the northern edge of the seasonal sea ice zone, station KMN (60-56 S, 110-07 E, depth of water: 4180 m), we deployed five current meters, one ADP current meter, four MicroCat-CTDs and six RBR soloTs. At KMS (63 - 32 S, 108 - 02 E, depth: 3201 m) in the vicinity of the summer divergence zone, we deployed 10 MicroCats, 3 CTs sensors, 30 soloTs. Because the top buoy of the mooring system at KMN had come up to the sea surface, the two buoys were damaged due to the overhang of the sea ice in winter, but all the sensors were successfully recovered.

Mooring revealed that a flow field suggesting the structure of circulation and periodic fluctuations due to medium-scale eddies and seasonal fluctuations. In this report, we introduce the whole of the observation, the digestive result of the moored observation. The annual averages of current velocitiy [u, v (cm / s)] obtained with 5 current meters are [2.15, -1.26] at 429 db, [1.46, - 0.88] at 859 db, 0.26, -1.26 at 1918 db, [-1.32, -0.78] at 3366 db, and [-1.65, -1.77] at 4080 db. The east-west current structure shows eastward in the upper three layers and westward in the lower two layers, indicating a reasonable zonal current velocity structure. In north - south component, it is slightly larger at the lowest layer, but in other depths it shows southward flow of about 1 cm/s. The 1 cm/s agree well with the current velocity estimated form Sverdrup transport by the wind stress field in this area.

In addition, at around 400 m depth, water masses around 2 degree considered to be the Circumpolar Deep Water were distributed, and it appeared that the temperature rose synchronously with the periodic southward current. We believe that these flow velocity structures and variations are the first approximate features of the circulation of the sea area. In addition, we investigated the fluctuation of Curl of wind stress using WindSat's wind data and found periodic period fluctuations corresponding to some of current fluctuations. In this summary, only the qualitative features which are known from the preliminary report value are described, but at the time of the presentation, other mooring data will be also added and the contents which we entered into more quantitative discussion are introduced.

[J] Poster | M (Multidisciplinary and Interdisciplinary)：M-IS Intersection

Mon. May 27, 2019 3:30 PM - 5:00 PM JST | Mon. May 27, 2019 6:30 AM - 8:00 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_21

[M-IS14] Global climate change driven by the Southern Ocean and the Antarctic Ice Sheet

convener:Osamu Seki(Institute of Low Temperature Science, Hokkaido University), Akira Oka(Atmosphere and Ocean Research Institute, The University of Tokyo), Ryu Uemura(University of the Ryukyus), Ryosuke Makabe(National Institute of Polar Research)

The Southern Ocean and Antarctic ice sheet, which are the giant reservoirs of heat, water, and materials, have a potential to play central roles in long-term global climate change. This system is composed of the following sub-systems; ice shelf which is a place of the interaction of ice sheet and ocean, flowing iceberg, seasonal sea ice zone, Antarctic bottom water which drives the thermohaline circulation, active biological production and Antarctic Circumpolar Current. These sub-systems are interacted with each other and have significant impact on changes in the global environmental system. This session aim to summarize recent observational and simulation studies from various fields relating to the past and present changes in the Antarctic Ice sheet and Southern Ocean, which are essential elements for unraveling the changes in the global climate system. Further, future science plans for understanding of the environmental changes of the Antarctic Cryosphere is also discussed.

Preliminary study on the effect of low-salinity ice melting water on biomass and composition of ice algae

*Keigo Takahashi[1], Ryosuke Makabe[2,3], Shintaro Takao[2,3], Tsuneo Odate[2,3], Masato Moteki[1,2]

1. Tokyo University of Marine Science and Technology, 2. National Institute of Polar Research, 3. The Graduate University for Advanced Studies (SOKENDAI)

Upon sea ice melting ice algae are subject to low salinity water, sometimes nearly freshwater, while sea ice produces a brine (high salinity). Certain taxa of ice algae, primarily diatom, increase in cell number after released in water column (seeding). Since lower salinity water deteriorates photosynthetic efficiency of ice algae, such a variability of salinity is likely to influence seeding of ice algae during melting season. However, it is not clear how biomass, abundance, composition and mortality of ice-algal community changes under different salinity conditions. To further understand the mechanism for seeding of ice algae, we conducted a shipboard experiment in the Indian Sector of the Southern Ocean during austral summer.

We collected pack ice and surface seawater in the ice edge (65º17.9’ S, 109º40.9’ E) on January 16th, 2019 during the 22nd Antarctic voyage by the training vessel *Umitaka-maru*. Sea ice was melted with different volume of filtered seawater (moderate salinity: 10.0 kg ice+90 L filtered sea water, FSW, low salinity: 8.6 kg ice+10 L FSW) to simulate different final salinity (moderate: 30.05, low: 18.00). We incubated the algal communities in seawater and two types of sea-ice melting water (moderate and low salinity conditions) under a natural light condition for 24 hours, with temperature maintained by a circulating surface seawater. Before and after the incubation, we obtained chlorophyll *a* concentration (bulk and size-fraction), Lugol-fixed samples for microscopic analysis and cell viability (live or dead).

After 24 hours, <10 μm size class of ice-algal communities in both moderate and low salinity conditions showed a significant difference in the ratio of chlorophyll *a* concentration (chl *a* fin. /chl *a* ini.) relative to the bulk and >10 μm size class (Tukey-Kramer test, Fig.). The ratio of chl *a* (mean±SD, *n*=3) in this size class was highest (moderate: 2.1±0.1, low: 1.8±0.2) among the samples. This suggests that algal community of <10 μm have an ability to acclimate to low salinity water. This study discussed the changes in species composition and abundance of the algal communities as well.

Effects of lugol’s fixtation on preservation of samples for carbon and nitrogen stable isotope and molecular analyses

*Masayoshi Sano[1], Ryosuke Makabe[1,2], Ayu Yamamoto[3], Norio Kurosawa[4], Masato Moteki[2,3], Tsuneo Odate[1,2]

1. National Institute of Polar Research, 2. The Graduate University for Advanced Studies, 3. Tokyo University of Marine Science and Technology, 4. Soka University

Recently, carbon and nitrogen stable isotope analysis and molecular analysis are commonly used as powerful tools in marine ecological studies including sediment trap experiments. In the southern ocean ecosystem studies, moored sediment trap samples are important to obtain information all-year around including winter season when we cannot observe directly by research vessels. Usually, collecting cups of sediment traps were filled with formalin for preventing degradation of samples during deployment periods, but formalin fixtation is not suitable for those analyses because of crosslinking and fragmantation of DNA and alteration of carbon stable isotope. On the other hand, lugol’s iodine solution is commonly used as fixatives of microzooplankton and phytoplankton samples, but its usefulness as a long term preservative of samples for stable isotope analysis and molecular analysis is still not examined. In this study, we compared carbon and nitrogen stable isotope ratios of zooplankton samples fixed by lugol’s iodine solution and other methods over 6 months and extract DNA from lugol fixed samples after 16 months preservation for examining the usefulness of lugol’s iodine solution. Samples were collected by ORI net during a cruise of training vessel *Umitaka-maru* in 2017. Collected samples were fixed by 5%, 10% lugol’s iodine seawater solution or 5% buffered formalin seawater or frozen at -80˚C on board. Samples were sorted after 1 week, 1 month, 3 months and 6 months preservation and used for stable isotope analysis. DNA was extracted from samples after 16 months preservation and amplified by PCR. In most cases, carbon stable isotope ratios were significantly different between formalin fixed samples and other samples after 1 week preservation. Nitrogen stable isotope ratios were also significantly different between formalin fixed samples and other samples after 1 month preservation. There are no significant differences in carbon and nitrogen stable isotope ratios between samples fixed by 10% lugol solution and frozen samples in all the periods. Amplification of DNA extracted from lugol fixed samples was detected by a gel electrophoresis. Thus, lugol’s fixtation is considered to be suitable for long term preservation of samples for both stable isotope analysis and molecular analysis.

The application of environmental DNA for the monitoring of Antarctic marine ecosystem

*Aiko Tachibana[1], Ryosuke Makabe[2], Masato Moteki[1]

1. Tokyo University of Marine Science and Technology, 2. National Institute of Polar Research

A monitoring of biological community structure and diversity is essential to understand the global climate impact on the Antarctic marine ecosystem. Traditional biomonitoring methods typically rely on sampling methods, combined with morphology-based identification, which is time-consuming and requires sophisticated expertise. To elucidate the full impact of rapidly shifting climate on the Antarctic ecosystem, efficient and effective tools are required to understand spatial and temporal variations in biological communities. Environmental DNA (eDNA) –genomic material extracted from cells and tissue shed by organisms into environmental samples, such as soil, sediments and water –is a possible tool for rapid assessing marine biodiversity and community composition. We conducted an eDNA observation in January 2019 along the 110˚E transect off Wilkes Land, East Antarctica, by the training vessel *Umitaka-maru*, Tokyo University of Marine Science and Technology. In total, 189 samples were collected from surface to deep layers covering various water mass which was located from 40˚S to 65˚S along the 110˚E transect. We will generate DNA-based biodiversity data from these samples to produce the first comprehensive analysis of metazoan genetic diversity in the Southern Ocean. The eDNA observation and preliminary experiments are outlined here, and a future plan of analyses are discussed.

Coincidental occurrence process of frazil ice and high biomass off Amery Ice Shelf

*Yoshihiko Machimura[1], Kay I. Ohshima[2], Kazuki Nakata[3], Masato Ito[2], Yasushi Fukamachi[2,4], Ryosuke Makabe[5], Shintaro Takao[5], Sohey Nihashi[6]

1. Graduate School of Environmental Sciences, Hokkaido University, 2. Institute of Low Temperature Science, Hokkaido University, 3. Remote Sensing Technology Center of Japan, 4. Arctic Research Center, Hokkaido University, 5. National Institute of Polar Research, 6. National Institute of Technology, Tomakomai College

Antarctic coastal regions are the most productive regions in the Southern Ocean and could dramatically influence global carbon cycle and ecosystems. During the austral spring, large phytoplankton blooms develop in polynyas with peak productivity occurring from December to January. According to the chlorophyll estimation from satellite, net primary production (NPP) in the Antarctic coastal polynyas rapidly declines from February to March (Arrigo et al., 2015).
Recent studies have found the regions with high biomass in Antarctic coastal regions during February-March (Lieser et al., 2015; DeJong et al., 2018). This high biomass is collaterally observed with frazil ice. Chlorophyll estimation algorithms using Moderate Resolution Imaging Spectroradiometer (MODIS) data mask pixels with high sea ice coverage to prevent the contamination by excess reflection of visible light. Therefore, the regions with high biomass collaterally observed with frazil ice have not been counted in NPP estimation in Antarctic coastal regions. These high biomass regions potentially have a large impact for global carbon cycle as the CO_2 sink. However, incidence processes and causes of frazil ice with high biomass have not been investigated in details. In this study, we focus on the regions of the Cape Darnley polynya and offshore of the Amery Ice Shelf in February and March during 2003-2011 to understand the processes and causes of high biomass collaterally observed with frazil ice.
First, we calculated Green Index from MODIS surface reflectance data obtained from the study area to identify green colored regions implicate high biomass. Second, we identified the region of frazil ice, using the algorithm that discriminates ice type between frazil ice and thin solid ice from AMSR-E passive microwave data (Nakata et al., 2019). These two analyses clearly show that the high biomass and frazil ice coincidentally occur both temporally and spatially in late summer. In particular, both of high biomass and frazil ice have a peak in their distributions at the same location about 50 km offshore of the Amery Ice Shelf in March. This is also suggesting an unknown frazil ice formation process distinctly different from a coastal polynya process.
We consider Ice Shelf Water (ISW) as a trigger of coincidental occurrence of frazil ice and high biomass. According to the CTD-tag data obtained from seals in the region off Amery Ice Shelf in late summer, ISW that is partly supercooled exists at depths of 250-400 m and the surface water is heated by solar radiation in the region from the ice shelf front to 68.3 deg. S. While in the region north of 68.2 deg. S, the surface water has reached the freezing point. Previous studies reported that ISW flows out to 50-100 km offshore from the ice shelf front and generates frazil ice at depths of 250-300 m (Dieckmann et al., 1986; Hughes et al., 2013).
To summarize the above analyses, coincidental occurence of frazil ice and high biomass is assumed to be caused by the following processes.
1. ISW is formed and flows out to the outside of Amery Ice Shelf cold cavity.
2. ISW becomes supercooled during the outflow, and frazil ice is generated.
3. Generated frazil ice gradually rises toward the surface. In the region south of 68.3deg. S, frazil ice is melted because of heated surface water. Frazil ice can appear at the surface in the region north of 68.2 deg. S, where the surface water reaches the freezing point.

©2019. Japan Geoscience Union. All Right Reserved.

4. Frazil ice scavenges phytoplankton existing in water column and carries it to the surface. Simultaneously, iron contained in ISW enhances the biological production and increases biomass. The process proposed in this study may also occur in regions just off other ice shelves. In the future, we should clarify the details of the process off Amery Ice Shelf with in-situ observation and explore the possibility of occurrence in regions off the other ice shelves.

Feeding habit of the Antarctic amphipod *Themisto gaudichaudii*of Vincennes Bay (East Antarctica) during austral summer

*Junji Matsushita[1], Ryosuke Makabe[2], Masato Moteki[1]

1. Tokyo University of Marine Science and Technology, 2. National Institute of Polar Research

Amphipods are key components of macrozooplankton to link lower trophic levels to higher predators in the krill-independent food web in the Southern Ocean (SO). The carnivorous amphipod *Themisto gaudichaudii*, widely distributed in SO, is an opportunistic predator. They are known to feed on copepods, euphausiids, salps and various zooplankton in the Atlantic Ocean sector, while their food habits are poorly known in the Indian Ocean sector. This study analyzed gut contents of *T. gaudichaudii* collected along the 110˚E transect in SO in January 2019 to clarify food habit of *T. gaudichaudii*. Fecal pellet obtained from onboard experiment were supplementary used to verify the estimated food habit. We’ll preliminary demonstrate here the food web related to *T. gaudichaudii* in the Indian Ocean sector during austral summer.

Time-series observation of subsurface chlorophyll *a* maximum in the seasonal ice zone of the Southern Ocean

*Ayuko Kagesawa[1], Masayoshi Sano[2], Shintaro Takao[1,2], Ryosuke Makabe[1,2], Kohei Mizobata[3], Norio Kurosawa[4], Masato Moteki[2,3], tuneo Odate[2]

1. The Graduate University for Advanced Studies, 2. National Institute of Polar Research, 3. Tokyo University of Marine Science and Technology, 4. Soka University

A persistent subsurface chlorophyll *a* maximum (SCM) is often found during the summer-fall season after the ice-edge bloom in the seasonal ice zone of the Southern Ocean, so that SCM would be considered important for biogeochemical cycling through the lower trophic levels. The relevant studies, however, have been qualitative in nature. This study aimed to reveal the dynamics and ecological role of the SCM in the seasonal ice zone.
We carried out Lagrangian observations using a drifter with two time-series sediment traps, an Acoustic Doppler Current Profiler (ADCP) and four sensor flames (Fig. 1). The drifter was deployed at 63.5˚S, 110.0˚E in January 14th 2019, and 5-day continuous observation was performed. In the vicinity of the drifter, 4 ship-based observations including net sampling and CTD casts were made until the drifter was recovered. Physical environments were measured by CTD, and sea water samples were collected for measurements of chlorophyll *a* (chl. *a*) concentration, nutrients, particle organic carbon, dissolved organic carbon, abundance of phytoplankton, micro-zooplankton, bacteria and nano-/pico-phytoplankton. We also conducted an incubation experiment for determining net primary production.
The temperature minimum layer, found between 37 and 52 m depth, decreased from -0.82 ºC to -1.28 ºC during the study period. The maximum chl. *a* concentration (1.0-2.0 μg/l), comparable to that in typical ice edge blooms, was observed at 40 m depth (Fig. 2). Such a high chl. *a* concentration might have important roles for food web and for material cycling. We will discuss especially on phytoplankton dynamics showing results of microscopic and chemical analyses.

Seasonality in sulfur isotopic compositions of atmospheric sulfate and its implications for atmospheric sulfur cycles in East Antarctica

*Sakiko Ishino[1], Shohei Hattori[1], Joel Savarino[2], Michel Legrand[2], Susanne Preunkert[2], Bruno Jourdain[2], Francis Albarede[3], Emmanuelle Albalat[3], Naohiro Yoshida[1,4]

1. Department of Chemical Science and Engineering, School of Materials and Chemical Technology, Tokyo Institute of Technology, 2. Institut des Geoscience de l' Environnement, Université Grenoble Alpes/CNRS, 3. Ecole Normale Supérieure (LGL-TPE), 4. Earth-Life Science Institute, Tokyo Institute of Technology

Atmospheric sulfate in Antarctica is produced mainly from a marine biogenic sulfur compound, dimethyl sulfide. They are therefore a subject of study related to the linkage between marine biogenic activity and climate. We investigate year-round observations of sulfur isotopic compositions of atmospheric sulfate (SO_4^{2-}) at inland (Dome C) and coastal (Dumont d' Urville) sites in East Antarctica to quantify the relative importance of marine biogenic (mb) and non-marine biogenic (nmb) SO_4^{2-} for the Antarctic atmospheric sulfur cycle. The $\delta^{34}S$ values of non-sea salt sulfate showed clear seasonal variations with summer maxima and winter minima, and showed homogeneity between inland and coastal sites throughout the year. This result suggests that the isotopic fractionation through chemical reactions during transportation from coastal to inland areas insignificantly affects the observed $\delta^{34}S_{nss}$ values. The observed $\delta^{34}S_{nss}$ values are controlled mainly by the relative importance of mb-SO_4^{2-} and nmb-SO_4^{2-}. This finding, in conjunction with the SO_4^{2-} records in Antarctic ice cores, will open a perspective implying the increased relative importance of nmb-SO_4^{2-} during glacial periods. We also found a significant increase in nmb-SO_4^{2-} concentrations in November, especially for the inland site. This nmb-SO_4^{2-} increase is correlated with the ^{210}Pb concentration, suggesting the existence of long-range transport of continental nmb-SO_4^{2-} from lower latitudes to the Antarctic inland. Identification of the sources of those nmb-SO_4^{2-} will be a key step for elucidation of the linkage between Antarctic atmosphere/climate and environmental changes at lower latitudes from the past through the future.

Penultimate glacial-interglacial transition viewed from the Dome Fuji ice core, Antarctica

*Ikumi Oyabu[1,2], Kenji Kawamura[1,3,4], Kyotaro Kitamura[1]

1. National Institute of Polar Research, Research Organization of Information and Systems, 2. Japan Society for the Promotion of Science, 3. SOKENDAI (The Graduate University of Advanced Studies), 4. Japan Agency for Marine Science and Technology (JAMSTEC)

Paleoclimatic proxies provide information about the variations of climate forcings and responses, such as atmospheric CO_2concentration, temperature and sea level, as well as their magnitudes and phase relationships. Accurate chronological constraints are particularly important for numerical simulations, both for their input and validation data, to better understand the transient behaviors of climate and ice sheets. During the last interglacial period (~130 to ~120 thousand years before present (kyr BP)), the peak global mean surface temperature was ~1 degree higher than the preindustrial period, and the global sea level was ~6 –9 m higher than today with significant contribution from the Antarctic ice sheet, whereas atmospheric CO_2levels were similar to those in the preindustrial period (Dutton et al., 2015). The last interglacial period and the preceding transition from the penultimate glacial period are important targets for the paleoclimatic research to investigate the mechanisms for warming and ice-sheet reductions. However, responses (sequences, timing or magnitude) of ice sheets, temperature or ocean circulations to climate forcing during this period are much less well understood, partly because the number of proxies and time resolution are limited, and the chronological uncertainties are relatively large. A chronology of the Dome Fuji (DF) ice core was constructed by synchronizing variations in O_2/N_2ratio of occluded air with local summer insolation (Kawamura et al., 2007), but relatively large errors were later reported around the last interglacial (Fujita et al., 2015). Here, we reanalyzed the O_2/N_2ratio of the DF core by improving the methods for sample treatment, air extraction and mass spectrometry between 57 and 165 kyr BP to revise the DF chronology. The new chronology agrees within 1.2 kyr with a radiometric (U-Th) chronology of Chinese speleothems, the whose stated error is less than 1 kyr (Cheng et al., 2009), suggesting successful improvement of our ice-core chronology. Using $\delta^{18}O$ of atmospheric O_2($\delta^{18}O_{atm}$) and CH_4records measured on the same ice samples as used for the O_2/N_2measurements, we investigate climatic variations during the penultimate glacial period and deglaciation. We found that $\delta^{18}O_{atm}$ becomes heavier while CH_4concentration increased at 138.4 kyr BP during the penultimate glacial maximum; this characteristic relationship was observed at Heinrich Event 2 (at ~24 kyr BP) during the last glacial maximum (Severinghaus et al., 2009; Rhodes et al., 2015). Other well-dated paleoclimatic records show major climatic changes around 138 kyr BP; an abrupt weakening of the Asian monsoon occurred at 138 kyr BP (Wang et al., 2008), and the onset of relative sea level rise was suggested at 139±1 kyr BP from seawater $\delta^{18}O$ of Red Sea (Grant et al., 2012) and at 137 kyr BP from U-Th dating of Tahiti fossil corals (Thomas et al., 2009). The similarity of these ages suggests that a massive iceberg discharge event occurred at ~138 kyr BP, and it marked the onset of penultimate deglaciation. Our new data may provide better chronological constraints on the climatic forcings and responses around the penultimate deglaciation and last interglacial period.

Reconstruction of Antarctic ice sheet dynamics in the Last Interglacial

*Mutsumi Iizuka[1], Osamu Seki[1], Takuya Itaki[2], Tomohisa Irino[1], Minoru Ikehara[4], Saiko Sugisaki[2], Masanobu Yamamoto[1], Keiji Horikawa[5], Yuusuke Suganuma[3]

1. Hokkaido university, 2. Geological Survey of Japan, 3. National Institute of Polar Research , 4. Center for Advanced Marine Core Research, Kochi University, 5. University of Toyama

Ongoing global warming could cause various problems in the future. One of the serious concerns is a sea level rise due to the melting of the ice sheet. Antarctic ice sheet, which hold a massive amount of fresh water was considered to be stable even if global warming progresses in the future. However, recent studies have shown that Antarctic ice sheet is more sensitive to global warming than previously thought. Therefore, it is an important to better understand extent to which Antarctic ice sheet is sensitive to global warming.

Study of past warm period proves an useful insight into the prediction of sea level rise in a future. Especially, Sea level in the last interglacial (MIS 5e), which was ~1˚C warmer than the preindustrial was estimated to be several meters higher than that of the present with the sudden and abrupt rises in sea level. This suggests significant loss of Antarctic ice sheet during MIS 5e. However, Antarctic ice sheet variability during the MIS 5e has been poorly understood. In this study, we reconstruct dynamics of Antarctic ice sheet during MIS 5e from the marine sediment core GC1407 collected from Dumont d'Urville Sea, East Antarctica (130.518˚E, 63.74˚S).

Interval of MIS 5e has been determined based on abundance of radiolaria in GC1407. Variability of iceberg discharge is reconstructed by measurement of iceberg rafted debris (IBRD) in sediments. IBRDs are found to be recognized only during MIS 5e. This suggests that the significant discharge of large icebergs possibly from Wilkes Land basin, East Antarctica happened only during warmer than present climate condition.

Pliocene CO2 concentration estimated from Southern Ocean SST

*Osamu Seki[1], Tomohiro Shimono[2]

1. Institute of Low Temperature Science, Hokkaido University, 2. Guraduate School of Environmental Science

Prediction of temperature change by the climate model depends on climate sensitivity, which is the temperature change associated with doubling of CO_2 concentration. The constraint on climate sensitivity is the key part in the IPCC and thus is critical for the future climate prediction. However, despite considerable efforts for constraint on climate sensitivity, the climate sensitivity still remains uncertainty. Furthermore, recent paleoclimate studies revealed that climate sensitivity depends on climate state. This highlights the necessity to know the climate sensitivity in the warmer than the present climate for the future prediction. The Pliocene Warm Period (3-4.5 million years ago) is often regarded as the best analogue of climate in the near future and thus is ideal to investigate climate sensitivity in the warm climate state. In this study, we reconstruct CO_2 concentration based on the new empirical approach (average SST in mid latitude of Southern Ocean) to estimate climate sensitivity in the Pliocene Warm Period.

Lithogenic fluxes across a transect in the SW Indian Ocean since the last glacial inception

*Eri Helen Amsler[1], Walter Geibert[2], Gerhard Kuhn[2], Minoru Ikehara[3], Samuel Jaccard[1]

On glacial-interglacial time scale the Southern Ocean plays a prominent role in modulating climate by storing and redistributing heat, fresh water, carbon and nutrients globally. Atmospheric CO_2 is taken up by algae and sequestered in the deep ocean through the biological carbon pump. On the other hand, CO_2 is released back to the atmosphere through upwelling and vertical mixing [1]. The relative contribution of these two mechanisms controls the efficiency through which carbon can be sequestered in the ocean interior.

The effect of iron fertilization on biological productivity has previously been documented in the Atlantic and Pacific sectors of the Southern Ocean [2, 3]. During glacial periods higher input of Fe-bearing dust increased phytoplankton growth and carbon sequestration, thus leading to the drawdown of atmospheric CO_2, accounting for about half of the glacial-interglacial CO_2 amplitude [4].

Here we present ^{230}Th-normalized lithogenic fluxes in a set of marine sediment cores spanning a meridional transect in the Indian sector of the Southern Ocean further away from the Patagonian dust plume and show that increased Fe flux impacted export production patterns, contributing to the sequestration of carbon away from the atmosphere.

Changes in composition of fossil diatoms from Ross Sea under gradual warming climate from MIS M2

*Saki Ishino[1], Itsuki Suto[2], Rob M. McKay[3], Laura De Santis[4], Denise K. Kluhanek[5], Expedition 374 Scientists

1. National Institute of Advanced Industrial Science and Technology, 2. Department of Earth and Planetary Sciences Graduate School of Environmental Studies, Nagoya University, 3. Victoria University, 4. Instituto Nazionale di Oceanografia e di Geofisica Sperimentale, 5. Texas A&M University

Understanding past polar environmental changes under warming climate process will help predicting future global warming. The paleoceanographic record near Antarctic ice-proximal area provides important insight into West Antarctica Ice Sheet (WAIS) vulnerability. Antarctic sediments contain numerous fossil diatoms, which are helpful to clarify past oceanographic conditions.

International Ocean Discovery Program (IODP) Expedition 374 drilled five sites from Ross Sea continental shelf and rise to investigate WAIS evolution under warm climates. Site U1524A (74° 13.05’ S and 173° 37.98’ W, 2394 m water depth) drilled from continental rise, which lies beneath cascading Antarctic Bottom Water current, preserves high resolution Pliocene sediments. We present preliminary results of composition changes of diatom assemblages focusing on the ages from MIS M2 to warmer climate around the interval between 3.3 and 3.0 Ma. Diatom records including abundance changes in sea-ice indicator species and *Chaetoceros*resting spores contribute to evaluate the past sea-ice coverage, primary productivity, and vertical mixing in Pliocene warm condition.

Geological insights into formation of Conrad Rise, Southern Ocean: Preliminary geological results of R/V *Hakuho-maru* KH-19-1 cruise

*Hiroshi Sato[1], Masakazu Fujii[2,3], Hiroki Matsui[4], Minoru Ikehara[4]

1. School of Business Administration, Senshu University, 2. NIPR, 3. SOKENDAI, 4. Center for Advanced Marine Core Research, Kochi University

Conrad Rise is one of plateaus situated at the Indian-sector of the Southern Ocean. Origin of the rise are considered to be a sort of the Large Igneous Provinces or hotspot. Previously Borisova et al. (1996) reported alkaline igneous rocks which have similar geochemical signature to the Kelgueren Plateau. However, detailed investigations have not been performed until our recent study. We performed geological and geophysical investigations during three R/V *Hakuho-maru* cruises, KH-10-7, KH-16-1, and KH-19-1. Particularly, we had five dredge operations during KH-10-7 and KH-19-1 cruises and obtained geological (and biological) materials that have important keys to understanding the origin and development of Conrad Rise. Geological materials collected during KH-10-7 cruise had already reported by Ishizuka et al. (2011), Sato et al. (2012), and Kobayashi et al. (2013). In this presentation, we report preliminary results of recovered geological and biological materials during KH-19-1 cruise.

Two dredge operations were performed during KH-19-1 Leg 2 (16 Jan to 12 Feb 2019). Dredge site KH-19-1D4 is situated at one of peaks of unnamed small knoll that is located north of Ob seamount. Approximately 50 kg of geological and biological materials including igneous rocks, metamorphic rocks, and deep-sea coral were recovered. Dredge site KH-19-1D5 is situated at north-south trending spur on the northern slope of Ob seamount. Approximately 50 kg of materials including igneous rocks, sedimentary rocks, metamorphic rocks, deep-sea coral, and living shell were recovered.

Fossil chrysophyte cysts as a new paleoenvironmental proxy

*Yuji Kato[1,2], Itsuki Suto[1]

1. Graduate School of Environmental Studies, Nagoya University, 2. Center for Advanced Marine Core Research, Kochi University (JSPS Research Fellowship for Young Scientists)

Most Neogene–Quaternary sediments in the Southern Ocean have high biogenic silica contents with large amounts of siliceous microfossils including chrysophyte cysts as well as diatoms. Fossil chrysophyte cysts are considered to be potentially useful paleoenvironmental indicators, however no general consensus exists about their paleoenvironmental significance. In this study, data on fossil chrysophyte cyst abundances of late Miocene to Pliocene (ca. 9–3 Ma) age are presented from two marine sediment cores, Ocean Drilling Program Site 689 and Deep Sea Drilling Project Site 513, both located in the Atlantic sector of the Southern Ocean. Changes in the chrysophyte cyst abundances are compared to those in the diatom abundances, and the potential of fossil chrysophyte cysts as paleoceanographic indicators around the Antarctica is discussed.
As a result, similarity in the fluctuation of freshwater diatom and chrysophyte cyst abundances were observed in both sites. In addition, occurrences of chrysophyte cysts similar to previously reported ones from freshwater habitats were recognized. These results suggest that the fossil chrysophyte cysts from Sites 689 and 513 were originated from terrestrial freshwater habitats. Since freshwater input into the Southern Ocean are mainly derived from Antarctic terrestrial freshwater (i.e. meltwater of glaciers or ice sheet), fossil chrysophyte cysts in the Southern Ocean sediments can be a new useful tool to reconstruct the Antarctic Ice Sheet's fluctuation history. In addition, comparison between changes in abundance of chrysophyte cysts and the δ18O stack of benthic foraminifera (Zachos et al. 2001) shows opposite trends: matching of increases of chrysophyte cysts corresponds to decreases of δ^{18}O values (i.e. decreased ice sheet volume), which also supports the possible relationship between the fluctuations of fossil chrysophyte cysts and Antarctic Ice Sheets. On the other hand, coexistence of chrysophyte cysts and sea-ice related diatoms (e.g. 4.4–3.3 Ma at Site 689) suggests that some of the chrysophyte cysts originated from sea-ice. Further taxonomic and biogeographic studies on fossil chrysophyte cysts are needed to provide a new approach for paleoenvironmental reconstruction.

Spatiotemporal variability of surface mass balance along the JARE traverse route for 1991–2019

*Shun Tsutaki[1], Hideaki Motoyama[2,3], Ayako Abe-Ouchi[1,4], Shuji Fujita[2,3], Kenji Kawamura[2,3,4]

1. The University of Tokyo, 2. National Institute of Polar Research, 3. The Graduate University for Advanced Studies, 4. Japan Agency for Marine-Earth Science and Technology

Satellite-based observations revealed the recent mass loss of the Antarctic ice sheet, and there is concern about its influence on sea level rise. Although significant mass loss has been reported in the West Antarctica, spatial and temporal variability of surface mass balance (SMB) is poorly understood in the East Antarctica where the ice volume is more than 10 times, due to complexity in snow accumulation in space and time, resulting in relatively large uncertainty to quantify ongoing and future mass loss from the Antarctic ice sheet. Therefore, it is crucial to accurately quantify SMB in East Antarctica. SMB has been measured along the traverse route between coastal area (S16) and the inland Dome Fuji region as a part of the Japanese Antarctic Research Expedition (JARE) since 1991. Net snow accumulation was measured by the stake method at approximately 500 points every 2 km. In this study, we re-evaluate spatial and temporal variability of SMB between S16 and Dome Fuji region during the period of 1991–2019. Uncertainty of the SMB measurements is discussed by the data obtained from stake farms and stake rows along the survey route. Spatiotemporal variability of SMB is discussed with surface slope of the ice sheet as well as wind speed and direction in order to evaluate the influence of surface topography and katabatic wind blowing on the ice sheet surface on snow accumulation.

The weathering of granitic rocks in the Sør-Rondane Mountains, East Antarctica

*Tatsuo Kanamaru[1], Yusuke Suganuma[2], hisashi Oiwane[3], Hideki Miura[2], Makoto Miura[4], Jun'ichi Okuno[2], Hideaki Hayakawa[5]

1. Department of Earth and Environmental Sciences, College of Humanities & Sciences, Nihon University, 2. National Institute of Polar Research, 3. Musuhi LLC, 4. Department of Earth and Planetary Sciences, Kanazawa University, 5. Institute for Cosmic Ray Research, University of Tokyo

Weathering processes in hyper-arid and hypothermal environments are key to our understanding of geomorphological processes and landscape evolution in Antarctica. Here, we explore the weathering of granitic rocks and the associated weathering products in the Sør-Rondane Mountains of East Antarctica, to obtain quantitative information regarding the physical and chemical weathering of granitic rocks in hyper-arid and hypothermal environments. Various petrological techniques, including whole-rock chemistry, loss on ignition measurement, mineral chemistry, laser-Raman microspectroscopy, in addition to color measurement and hardness test for the rock samples, were used to analyze the physical and chemical weathering of the rocks. These measurments reveal that the weathering of granitic rocks in the Sør-Rondane Mountains of East Antarctica is controlled mainly by oxidation, including iron hydroxide formation in veins formed by the thermal expansion and contraction of rock-forming minerals, frost shattering and/or salt fretting, and Fe–Ti oxide alteration in the rock interior. Importantly, these physical and chemical weathering processes are unlikely to require a liquid water supply from the environment, and the restricted supply of liquid water and salt is the most probable explanation for the extremely slow weathering rates in the Sør-Rondane Mountains.

Late Pleistocene to Holocene sea-level change in East Antarctica revealed by glacial isostatic adjustment modeling

*Takeshige Ishiwa[1], Jun'ichi Okuno[1,2], Yusuke Suganuma[1,2], Hideki Miura[1,2]

1. National Institute of Polar Research, 2. SOKENDAI

Antarctic Ice Sheet (AIS) is the most significant storage of freshwater in the Earth’ s surface and most concerned in considering future sea-level rise. Present studies attempt to assess the mass loss or gain in AIS using GNSS and satellite dataset. Moreover, past AIS variability should be considered to achieve the accurate present AIS change, since presently-observed vertical movement in Antarctica includes the effect of glacial-hydro isostasy due to past AIS variability. Glacial isostatic adjustment (GIA) modeling can provide sea-level histories in Antarctica following sea-level equation. Comparison of field-based sea-level records with predicted sea-level by GIA modeling is required to constraint past AIS histories, leading to the accurate prediction of future sea-level rise.
We document predicted sea-level change in East Antarctica by GIA modeling using several Antarctica ice-loading histories and also compare with previously reported observed sea-level records. Moreover, potential sites for future sampling to obtain observed sea-level records in East Antarctica will be presented by GIA modeling.

An modeling study of Antarctic ice sheet of the Last Glacial Maximum and the last deglaciation

*Takashi Obase[1], Ayako Abe-Ouchi[1,2], Ralf Greve[3], Fuyuki SAITO[2]

1. Atmosphere and Ocean Research Institute, the University of Tokyo, 2. Japan Agency for Marine-Earth Science and Technology, 3. Institute of Low Temperature Science, Hokkaido University

Reconstructions indicate Antarctic ice sheet extent and volume were decreased during the last deglaciation. Sea level reconstruction of the Last Interglacial (LIG), after the penultimet deglaciation, indicate the volume of Antarctic ice sheet was smaller than the present interglacial. Climate reconstructions indicate surface temperature in the Antarctic continent and sea surface temperature in the Southern Ocean during the LIG were higher than the present interglacial. A transient climate simulation of the last deglaciation using MIROC suggests that this higher surface temperature in the Antarctic region is a result of weaker AMOC during the deglaciation and bipolar warming in the Southern Hemisphere.

In the present study, we utilize a 3-dimensional Antarctic ice sheet model (SICOPOLIS) to conduct quantitive assessment of the impact on retreat of Antarctic ice sheet during deglaciations. At first, the configuration of LGM Antarctic ice sheet is prepared using reconstructed climate and sea level changes, and is compared with reconstructions to verify the initial state of deglaciation. We will present preliminary results of Antarctic ice sheet changes of the last deglaciation using climate model outputs of the last deglaciation.

Development of a coupled ice-sheet/earth rebound model for Antarctic ice-sheet simulation

*Fuyuki SAITO[1], Ayako Abe-Ouchi[2,1], Jun'ichi Okuno[3], Takashi Obase[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Atmosphere and Ocean Research Institute, University of Tokyo, 3. National Institute of Polar Research

Feedback between changes in the ice-sheet and the earth's isostatic rebound is considered to be an important process for the evolution of the past ice-sheets in glacial cycles. We have been developing a coupled ice-sheet/earth rebound model which were applied for northern hemisphere ice sheet simulation during glacial/interglacial cycles. Earth rebound model is based on a self-gravitating visco-elastic multi-layer model developed by Okuno and Nakada (2001), while the ice-sheet model is IcIES (Abe-Ouchi 2013). The results are compared with the previous IcIES results which coupled with a simple isostatic model (i.e., a local lithosphere/relaxing asthenosphere) which is controled by two parameters (the mantle density and the time scale of isostatic response), in order to discuss the effect of more realistic visco-elastic structure of the earth.

Polar amplifications in the past warm periods obtained from MIROC 4m AOGCM

*Taro Higuchi[1], Ayako Abe-Ouchi[1], Wing-Le Chan[1], Sam Sherriff-Tadano[1]

1. Atmospheric and Ocean Research Institute, the University of Tokyo

The Earth has experienced several warm periods (e.g., early Eocene and Cretaceous), which had warm climates, comparable to global warming prediction of near future due to rising CO2 concentration in the atmosphere. Paleoclimatic proxies indicate that the common characteristics of these periods are remarkable temperature amplifications in the high-latitude and polar region (Bice et al., 2003; Huber, 2008), resulting in small equator-to-polar temperature difference. However, simulations of warm periods climate using General Circulation Models tend to underestimate the polar amplifications than those suggested from geological records. The discrepancy between proxy data and climate models is one of the greatest challenges of warm climate study. Although it is important to consider the effects of the ocean circulation and vegetation feedback to reproduce the polar amplifications in the past warm periods, there were few studies using Atmosphere-Ocean coupled General Circulation Model (AOGCM). In this study, we simulate Present Day, early Eocene, and late Cretaceous climates with different CO2 levels using AOGCM MIROC 4m, additionally full-coupled with dynamic vegetation model, and get the climatology in full equilibrium with longer than 3000 years. The simulated temperatures of early Eocene and late Cretaceous experiments are compared with surface temperature reconstructions based on paleoclimatic proxies. We also investigate the difference of physical process to polar amplification between warm periods (early Eocene and late Cretaceous) and Present Day by using an energy flux analysis. Despite using the fully coupled model with paleo-configuration, the polar amplification in this study is not enough to fully reproduce proxy-indicated polar temperatures. This result implies that we need to re-verify model-performance to the polar climate in GCMs and physical feedback process to global warming due to rising greenhouse gasses in the atmosphere.

Using a coupled AOGCM to study the Antarctic climate of the mid-Pliocene warm period

*Wing-Le Chan[1], Ayako Abe-Ouchi[1,2]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. National Institute of Polar Research

The mid-Pliocene warm period, 3.3-3.0 million years ago, was a period of sustained warmth before global cooling occurred and a shift to repeated glacial cycles. It was also the most recent time in the history of Earth when atmospheric carbon dioxide levels were similar to those of present day. The study of this period is thus of much importance, given the growing concerns over future climate change associated with anthropogenic emissions of greenhouse gases. In particular, ice coverage in West Antarctica, as well as in Greenland, reduced significantly and there is evidence to suggest a retreat of ice sheet in the coastal areas and in the Wilkes Subglacial Basin of East Antarctica during that time.

In this study, we use the mid-resolution MIROC4m coupled atmosphere-ocean general circulation model and apply ice sheet configuration, land-sea mask and biome distribution from PRISM3 data sets, as set forth in the latest, second phase of the Pliocene Model Intercomparison Project. We conduct a series of experiments, including those which look into a range of atmospheric carbon dioxide levels given the spread in values suggested by various sources of proxy data. We show the degree of warming over Antarctica and how the precipitation responds to changes in the moisture transport.

CMIP5 model analysis of future changes in ocean net primary production by focusing on different response among the individual oceans and models

*Akira Oka[1], Yuki Nakamura[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

Previous modeling studies show that global primary production will decrease in the future because stratification caused by global warming reduces supply of nutrient from the deep ocean. Previous studies mainly emphasized the importance of nutrient limitation in explaining the changes in primary production; however, phytoplankton growth is actually determined by temperature limitation, light limitation and nutrient limitation. Moreover, although future changes of primary production differ depending on areas, many prior researches discuss only global mean mechanisms and it is not well understood how the mechanisms differ depending on the individual oceans. The purpose of this study is to quantitatively evaluate contribution of each limitation factor for explaining the future changes in primary production in the individual oceans by using 9 CMIP5 models. First, we calculate temperature limitation, light limitation and nutrient limitation for each model, which are not directly available from CMIP5 output data. After that, we quantitatively evaluate main drivers for changes in primary production not only for the global ocean but also for low latitudes, the North Atlantic Ocean, the North Pacific Ocean, the Arctic Ocean and the Southern Ocean, separately. By quantitative evaluation on limitation factors of primary production, we show that the future changes in primary production due to global warming is controlled by not only nutrient limitation but also warming-induced enhancement of phytoplankton growth and decreasing biomass caused by enhanced grazing. Moreover, we show that future changes in primary production and its mechanisms differ among the individual oceans.

Factor analysis of the millennial time-scale climate variability in glacial periods

*Miki Akari[1], Ayako Abe-Ouchi[2], Sam Sherriff-Tadano[2]

1. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, 2. Atmosphere and Ocean Research Institute, the University of Tokyo

It is well known that in the glacial periods, air temperature changed abruptly over the North Atlantic on millennial time-scale. It is also known that temperature changes over the Southern Ocean were opposite to the North Atlantic, called a bipolar seesaw relationship. It is suggested that changes in the strength of the Atlantic Meridional Overturning Circulation (AMOC) were closely related to such global climate changes.

In recent years, the idea that freshwater forcing causes the climate changes has been questioned. Spontaneous oscillations in AMOC can be reproduced by experiments using atmosphere-ocean coupled general circulation models (AOGCM). These studies proposed that oceanic feedbacks within the North Atlantic surface - subsurface ocean are important in inducing the spontaneous AMOC variabilities. However, the oscillation cycles shown in previous studies (Peltier and Vettoretti, 2014; Brown and Galbraith, 2016) are several hundred years, which are shorter compared to climate variabilities documented in ice core data. On the other hand, in experiments carried out with MIROC4m AOGCM under the medium glacial condition, millennial time-scale climate and AMOC variabilities are reproduced. Therefore, in this study, we analyze factors controlling the millennial time-scale climate variability obtained from MIROC4m AOGCM. Focusing on the fact that this oscillation cycle is close to the time-scale of the Southern Ocean and the bottom ocean circulation, we analyze the behavior of the Southern Ocean and the bottom ocean in detail, especially deeper than 2500 meters, in addition to oceanic feedback suggested by previous studies.

As a result, it is suggested that the density change at the bottom ocean, which is caused by changes in sea ice formation over the Southern Ocean, plays an important role in controlling the oscillation of AMOC on millennial time-scale.

First continuous profiler observation of wintertime Antarctic coastal polynya

*Shigeru Aoki[1], Kazuya Ono[1], Daisuke Hirano[1], Masato Itoh[1], Tomohide Noguchi[2], Satoshi Ozawa[2]

1. Hokkaido University, 2. Marine Works Japan

Antarctic coastal polynyas are the regions where sea ice forms vigorously, leading to supply of dense abyssal water for the global ocean. Monitoring the sea state of coastal polynyas especially in winter hence has global implications. To fully understand the development of water characteristics, capturing of the whole water column is required. However, the wintertime observations of seasonal ice zone such as polynya is not abundant so far, due to the severe and variable conditions of polar oceans.

To realize a near-realtime observation of water column in coastal polynya, we deployed a tethered profiling float over the whole winter in Cape Darnley polynya, East Antarctica (bottom depth of 230 m). The tethered float was manufactured by IHI Corporation, with a temperature and salinity sensor (SBE37 of Seabird Scientific) attached.

The float observation was successful in operation for more than eight months from Feb. 26 to Nov. 13, 2017. This float was designed to park at 150 dbar depth and to surface (upto 20 dbar when sea ice is supposed to exist) at 10-day interval. During this period, 26 profiles for the water column from 180 dbar to 20 dbar were obtained. The whole 160-dbar depth range was covered by nearly half of the 26 profiles, and the total ratio of depth coverage was 81%. Comparison with a current meter record nearby (one mile distance) revealed that the minimum depth achieved did not correlate with the current speed.

The obtained record clearly revealed a seasonal development of the whole water column. While relatively warm water initially remained in the water column, significant freshening occurred and temperature decreased to the freezing point throughout the column from March to April. Then salinity gradually increased to about 35 (150 dbar) in October, successfully covering the whole cycle of sea ice production. The layer near the parking depth (between 120 dbar and 180 dbar) was covered with much higher temporal resolution, showing variations of higher frequencies.

Although the satellite data transmission was not successful due to the battery shortage, signal transmission was successful at the preparation stage. A revision of this platform will enable the monitoring of seasonal ice zone in the polar oceans, to help filling the remaining gap of the global ocean monitoring array.

Surface topography survey for bared rock and accumulated snow in Antarctica by Unmanned Aero Vehicle

*Yuichi Aoyama[1,2,3], Akihisa Hattori[2,3], Hajime Oishi[3,4], Koichiro Doi[1,2,3], Yoshifumi Nogi[1,2]

1. National Institute of Polar Research, 2. SOKENDAI, 3. The 59th Japanese Antarctic Research Expedition, 4. NEC Networks & System Integration Corporation

In the last decade, Gravity Recovery and Climate Experiment (GRACE) mission demonstrated an increase of surface mass in the Dronning Maud Land (DML), East Antarctica. Actually, snow accumulation has increased at Syowa Station located in DML, and its effect has been detected by superconducting gravimeter and GNSS measurements. For quantifying this effect, it is necessary to measure the distribution of the snow accumulation.
The distribution of the snow accumulation can be estimated from difference in accurate digital surface models (DSM) between the bared rock and the accumulated snow. These DSMs are derived from aerial photography byunmanned aerial vehicle (UAV) with structure from motion (SfM) analysis. In the activity of the 59th Japanese Antarctic Research Expedition (JARE59) during Dec. 2017 - Dec. 2018, some aerial photography surveys were conducted with the fixed-wing small UAV, senseFly eBee plus, and with the rotary-wing drone, DJI Inspire 2 over Syowa Station. There is a report that the eBee plus, having dual-frequency GNSS receiver, enables to generate DSM precisely without ground control point (GCP). We evaluated the accuracy of such DSM by comparing with DSM computed with GCP. We also compared with the DSM computed from aerial photography by Inspire 2 which has single-frequency GNSS for evaluating the advantage of the dual-frequency GNSS tracking. The DSMs in Langhovde, Akarui Misaki, Rundvagshetta located around Lutzow-Holmbukta are also computed from aerial photography by eBee plus.

The analysis of long-term Mooring observation records in the northernmost area of seasonal sea ice zone in the Southern Ocean

*Kazuho Watanabe[1], Kohei Mizobata[1], Yujiro Kitade[1]

1. Tokyo University of Marine Science and Technology

The meridional overturning is thought to be the contributor for the stability of the climate system via latitudinal exchange of oceanic heat in the Southern Ocean. To clarify details of the meridional overturning, mooring observations using T/RV *Umitaka-maru* were conducted by physical oceanography group mainly constructed by Tokyo University of Marine science and Technology. In this study, we analyzed the one-year record of the mooring observation and CTD measurements obtained when the mooring system was deployed and recovered.

Results from current meter analysis shows the variability (from 30-day to 90-day cycle) of ocean current. Geostrophic velocity derived from sea level anomaly map distributed by AVISO/Altimetry also shows similar variability of ocean current due to eddies. Furthermore, the location of the mooring system was far from the main axis of the Antarctic Circumpolar Current (ACC). Those results suggest us that the variability of ocean current was resulted from the mesoscale eddy field.

Even though the variability of ocean current was recoded, results also indicate the meridional overturning. The progressive vector diagram based on current meter record illustrated poleward transport at about around 400db and eastward transport at about 4000db. One-year mooring observation also revealed ocean current shear structure (about 10cm/s at about 400db and 4cm/s at about 4000db) when poleward transport was continuously captured. During poleward transport with shear structure was captured, the increase in temperature over 2.1 $^{\circ}$C from October to February at about 400db was frequently observed. Based on hydrographic data, warm water captured around 400db was identified as the Circumpolar Deep Water (CDW). Cross correlation analysis revealed that warm CDW intrusion occurred about 8-day following southward current at 400db. During the season when sea ice covered the ocean, similar event also happened but temperature at about 400db increased up to around 2°C. Our results indicate that CDW’ s southward transport is changing by seasonal and the event of mesoscale eddy passage.

Preliminary observation report on chlorofluorocarbons (CFCs) and sulfur hexafluoride (SF_6) off the Cape Darnley in the summer of 2019

*Yoshihiko Ohashi[1], Michiyo Yamamoto-Kawai[1], Kenichi Sasaki[2], Sayaka Kumakawa[1], Naoyuki Tamura[1], Kay I. Ohshima[3]

1. Tokyo University of Marine Science and Technology, 2. Japan Agency for Marine-Earth Science and Technology, 3. Institute of Low Temperature Science, Hokkaido University

Antarctic Bottom Water (AABW) occupies the largest volume of water mass in the global ocean and its formation is a key process of global ocean circulation. Ohshima et al. (2013) found newly formed AABW off the Cape Darnley (Cape Darnley Bottom Water; CDBW). However, little is known about the circulation of CDBW and its time scale. To quantitatively understand the spread and circulation of CDBW, it is effective to use the chemical tracer such as chlorofluorocarbons (CFCs) and sulfur hexafluoride (SF_6). We carried out CTD observation and water sampling off the Cape Darnley in the summer of 2019. Water sampling was performed from ocean surface to the bottom at 16 Stations (along the Wild Canyon and its west). CFCs and SF_6 of the samples were measured by an analytical system developed at JAMSTEC based on Bullister and Wisegarver (2008). The concentrations of CFCs and SF_6 were significantly high near the surface (< 100 m) (CFC11 > 2.0 pmol kg^{-1}; CFC12 > 1.2 pmol kg^{-1}; SF_6 > 1.4 fmol kg^{-1}). They showed a minimum at depths of 800–1500 m and then increased to the bottom. The relatively high concentrations of CFCs and SF_6 near the bottom, together with the low temperature (< −0.4°C), reflects the spread of CDBW. At the presentation, we will discuss mean age and circulation of CDBW.

Mechanism of sea-ice production variation in Amundsen Sea Polynya

*Sohey Nihashi[1], Kouta Mine[1], Kazuki Nakata[2]

1. National Institute of Technology, Tomakomai College, 2. RESTEC

A coastal polynya is an area of high ice production and dense water formation. This dense water is a major source of the Antarctic Bottom Water. Since winter polynya is a difficult site to observe, the mechanism of polynya formation and variation had not been understood well. About ten years ago, an algorithm was developed that uses satellite passive microwave data to detect polynyas and estimates thin ice thickness on a daily timescale. The satellite data revealed the detailed distribution and variation of polynyas (e.g., Tamura et al., 2007; 2008). Use of AMSR-E/AMSR2 data with a finer spatial resolution (about 5-6 km), can reveal the more detailed spatial distribution of polynyas. For example, it was revealed that most of coastal polynyas form on the west side of landfast ice (fast ice: stationary sea ice attached to coastal features such as shoreline and grounded icebergs). This close relationship indicates a vital role of fast ice for formation and variation of coastal polynyas (Nihashi and Ohshima, 2015; Nihashi et al., 2017). The Amundsen Sea Polynya (ASP), located in West Antarctica, is the third largest ice production area and is formed on the west side of fast ice protruding into the ocean. Thwaites Glacier adjacent to the fast ice has been suggested that a rapid melting occurs in recent decades (Rignot et al., 2008; Milio et al., 2019). Grounded icebergs that act as anchor points play an essential role in the formation of fast ice protruding into the ocean. Since the sources of an iceberg are glacier and ice sheet, the rapid melting possibly affects the formation and distribution of fast ice and accordingly adjacent polynyas.

In this study, we compare the ice production in the ASP with atmospheric parameters and fast ice extent to investigate factors for causing ice production variation. Ice production estimated from heat flux calculation with daily thin ice thickness from AMSR-E/AMSR2 data (Nihashi and Ohshima, 2015; Nihashi et al., 2017) is used. For fast ice, monthly extent detected from AMSR-E/AMSR2 data is used. We also use ice production estimated using thin ice thickness by an improved algorithm in which ice types (active frazil and thin solid ice) are considered (Nakata et al., 2019). As atmospheric data, we use ERA5.

Ice production is positively correlated with wind speed regardless of daily or monthly data with the coefficient of 0.54-0.73. Here, we use a wind component with the highest correlation; components of the wind vector are projected in all directions of every 1˚ from 0˚ (northerly wind) clockwise to 360˚, and then, correlation coefficients are calculated. The wind component is oriented to the west rather than to the offshore (north) against the land. This is a direction towards the offshore against the shoreline defined by both the land and fast ice. This result supports the analysis using only AMSR-E data (Nihashi and Ohshima, 2015). If ice production in which thin ice types are considered is used, the wind component is oriented toward further west when active frazil is dominant. This direction is to the offshore against the fast ice. Further, active frazil tends to form along fast ice. On the other hand, the wind component is northward (to the offshore against land) when thin solid ice is dominant. Multiple regression analysis is performed on the ice production using air temperature, wind speed, and fast ice extent averaged over the freezing season (May-August). Ice production can be explained by these parameters with R=0.77. This indicates that ice production in the ASP before the satellite observation era can be reproduced to some extent from atmospheric data by using this regression line. The results presented in this study suggest that fast ice plays a vital role in the formation and variation of the ASP. Continuous monitoring of Antarctic coastal polynyas and fast ice from passive microwave satellite sensor is quite meaningful understanding climate change.

Estimation of thin ice thickness and discrimination of ice type from AMSR2 passive microwave data

*Kazuki Nakata[1], Tamaru Naoya[1], Sohey Nihashi[2], Kay I. Ohshima[3]

1. Remote Sensing Technology Center of Japan, 2. National Institute of Technology, Tomakomai College, 3. Institute of Low Temperature Science, Hokkaido University

Antarctic coastal polynyas (thin ice and/or low ice concentration area) are areas of high ice production due to huge heat loss to the atmosphere. Dense water formed by the high ice production is a significant source of Antarctic Bottom Water. Thin ice thickness algorithms that use satellite passive microwave data have been developed to detect coastal polynyas and estimates thin ice thickness on a daily timescale. In these algorithms, ice thickness of <20 cm is empirically estimated based on a negative correlation relationship between polarization ratio (PR) of brightness temperatures (TBs) and ice thickness (hi). However, the dispersion of the data points of PR-hi relationship was relatively large. Nakata et al. (2019) revealed that two thin ice types (active frazil and thin solid ice) cause this dispersion using AMSR-E data (2002-2011). They detected these ice types based on a PR-GR (Gradient Ratio) relationship. And thin ice thickness was estimated from PR-hi relationships for each ice type. This new thin ice algorithm can improve the accuracy of the thin-ice thickness estimation. In this study, we have examined whether this new algorithm can apply to data from AMSR2 which the successor of AMSR-E. The footprint size of AMSR2 is improved by about 85% from AMSR-E in spite of the frequency channels are the same. By adding AMSR2 data, thin-ice thickness, ice type, and ice production data set with a higher spatial resolution can be obtained from 2002 to the present.
We use TBs at 36 and 89 GHz from AMSR2 Level 1B data. The footprint sizes are 12 km ×7 km and 5 km × 3 km, respectively. Ice thickness for comparison with AMSR2 PR is derived from clear-sky thermal infrared images by MODIS with a spatial resolution of 1 km. Backscatter images acquired by C-band SAR (C-SAR) on the ESA’s Sentinel-1 satellite with a spatial resolution of 90 m are used to validate two thin ice types. We use these satellite data obtained at Ross Ice Shelf and Cape Darnley polynya areas.
AMSR2 PR-hi relationships for two ice types differs clearly as in Nakata et al. (2019). We estimate ice thickness using lines that best fit into the AMSR-E PR-hi relationships (Nakata et al., 2019) using AMSR2 data. And then, mean bias and root-mean-square error (RMSE) of the data points from the lines are calculated. The errors are slightly larger than the cases of AMSR-E data. When ice thickness is <10 cm, mean bias and RMSE for active frazil are -2.0 and 1.0 cm, respectively, while those for thin solid ice are -6.2 and 9.8 cm, respectively. For ice thickness of 10-20 cm (only for thin solid ice), the bias and RMSE are -5.9 and 9.9 cm, respectively. We also have confirmed that two ice types can be detected using AMSR2 data by a method for AMSR-E data proposed by Nakata et al. (2019). The results of this study indicate that the new thin ice algorithm for AMSR-E data can apply to the AMSR2 data.

Mon. May 27, 2019 5:15 PM - 6:30 PM JST | Mon. May 27, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_35

[M-IS14] Global climate change driven by the Southern Ocean and the Antarctic Ice Sheet

convener:Osamu Seki(Institute of Low Temperature Science, Hokkaido University), Akira Oka(Atmosphere and Ocean Research Institute, The University of Tokyo), Ryu Uemura(University of the Ryukyus), Ryosuke Makabe(National Institute of Polar Research)

The Southern Ocean and Antarctic ice sheet, which are the giant reservoirs of heat, water, and materials, have a potential to play central roles in long-term global climate change. This system is composed of the following sub-systems; ice shelf which is a place of the interaction of ice sheet and ocean, flowing iceberg, seasonal sea ice zone, Antarctic bottom water which drives the thermohaline circulation, active biological production and Antarctic Circumpolar Current. These sub-systems are interacted with each other and have significant impact on changes in the global environmental system. This session aim to summarize recent observational and simulation studies from various fields relating to the past and present changes in the Antarctic Ice sheet and Southern Ocean, which are essential elements for unraveling the changes in the global climate system. Further, future science plans for understanding of the environmental changes of the Antarctic Cryosphere is also discussed.

Preliminary study on the effect of low-salinity ice melting water on biomass and composition of ice algae

*Keigo Takahashi[1], Ryosuke Makabe[2,3], Shintaro Takao[2,3], Tsuneo Odate[2,3], Masato Moteki[1,2]

1. Tokyo University of Marine Science and Technology, 2. National Institute of Polar Research, 3. The Graduate University for Advanced Studies (SOKENDAI)

Upon sea ice melting ice algae are subject to low salinity water, sometimes nearly freshwater, while sea ice produces a brine (high salinity). Certain taxa of ice algae, primarily diatom, increase in cell number after released in water column (seeding). Since lower salinity water deteriorates photosynthetic efficiency of ice algae, such a variability of salinity is likely to influence seeding of ice algae during melting season. However, it is not clear how biomass, abundance, composition and mortality of ice-algal community changes under different salinity conditions. To further understand the mechanism for seeding of ice algae, we conducted a shipboard experiment in the Indian Sector of the Southern Ocean during austral summer.

We collected pack ice and surface seawater in the ice edge (65º17.9’ S, 109º40.9’ E) on January 16th, 2019 during the 22nd Antarctic voyage by the training vessel *Umitaka-maru*. Sea ice was melted with different volume of filtered seawater (moderate salinity: 10.0 kg ice+90 L filtered sea water, FSW, low salinity: 8.6 kg ice+10 L FSW) to simulate different final salinity (moderate: 30.05, low: 18.00). We incubated the algal communities in seawater and two types of sea-ice melting water (moderate and low salinity conditions) under a natural light condition for 24 hours, with temperature maintained by a circulating surface seawater. Before and after the incubation, we obtained chlorophyll *a* concentration (bulk and size-fraction), Lugol-fixed samples for microscopic analysis and cell viability (live or dead).

After 24 hours, <10 μm size class of ice-algal communities in both moderate and low salinity conditions showed a significant difference in the ratio of chlorophyll *a* concentration (chl *a* fin. /chl *a* ini.) relative to the bulk and >10 μm size class (Tukey-Kramer test, Fig.). The ratio of chl *a* (mean±SD, *n*=3) in this size class was highest (moderate: 2.1±0.1, low: 1.8±0.2) among the samples. This suggests that algal community of <10 μm have an ability to acclimate to low salinity water. This study discussed the changes in species composition and abundance of the algal communities as well.

Effects of lugol’s fixtation on preservation of samples for carbon and nitrogen stable isotope and molecular analyses

*Masayoshi Sano[1], Ryosuke Makabe[1,2], Ayu Yamamoto[3], Norio Kurosawa[4], Masato Moteki[2,3], Tsuneo Odate[1,2]

1. National Institute of Polar Research, 2. The Graduate University for Advanced Studies, 3. Tokyo University of Marine Science and Technology, 4. Soka University

Recently, carbon and nitrogen stable isotope analysis and molecular analysis are commonly used as powerful tools in marine ecological studies including sediment trap experiments. In the southern ocean ecosystem studies, moored sediment trap samples are important to obtain information all-year around including winter season when we cannot observe directly by research vessels. Usually, collecting cups of sediment traps were filled with formalin for preventing degradation of samples during deployment periods, but formalin fixtation is not suitable for those analyses because of crosslinking and fragmantation of DNA and alteration of carbon stable isotope. On the other hand, lugol’s iodine solution is commonly used as fixatives of microzooplankton and phytoplankton samples, but its usefulness as a long term preservative of samples for stable isotope analysis and molecular analysis is still not examined. In this study, we compared carbon and nitrogen stable isotope ratios of zooplankton samples fixed by lugol’s iodine solution and other methods over 6 months and extract DNA from lugol fixed samples after 16 months preservation for examining the usefulness of lugol’s iodine solution. Samples were collected by ORI net during a cruise of training vessel *Umitaka-maru* in 2017. Collected samples were fixed by 5%, 10% lugol’s iodine seawater solution or 5% buffered formalin seawater or frozen at -80˚C on board. Samples were sorted after 1 week, 1 month, 3 months and 6 months preservation and used for stable isotope analysis. DNA was extracted from samples after 16 months preservation and amplified by PCR. In most cases, carbon stable isotope ratios were significantly different between formalin fixed samples and other samples after 1 week preservation. Nitrogen stable isotope ratios were also significantly different between formalin fixed samples and other samples after 1 month preservation. There are no significant differences in carbon and nitrogen stable isotope ratios between samples fixed by 10% lugol solution and frozen samples in all the periods. Amplification of DNA extracted from lugol fixed samples was detected by a gel electrophoresis. Thus, lugol’s fixtation is considered to be suitable for long term preservation of samples for both stable isotope analysis and molecular analysis.

The application of environmental DNA for the monitoring of Antarctic marine ecosystem

*Aiko Tachibana[1], Ryosuke Makabe[2], Masato Moteki[1]

1. Tokyo University of Marine Science and Technology, 2. National Institute of Polar Research

A monitoring of biological community structure and diversity is essential to understand the global climate impact on the Antarctic marine ecosystem. Traditional biomonitoring methods typically rely on sampling methods, combined with morphology-based identification, which is time-consuming and requires sophisticated expertise. To elucidate the full impact of rapidly shifting climate on the Antarctic ecosystem, efficient and effective tools are required to understand spatial and temporal variations in biological communities. Environmental DNA (eDNA) –genomic material extracted from cells and tissue shed by organisms into environmental samples, such as soil, sediments and water –is a possible tool for rapid assessing marine biodiversity and community composition. We conducted an eDNA observation in January 2019 along the 110˚E transect off Wilkes Land, East Antarctica, by the training vessel *Umitaka-maru*, Tokyo University of Marine Science and Technology. In total, 189 samples were collected from surface to deep layers covering various water mass which was located from 40˚S to 65˚S along the 110˚E transect. We will generate DNA-based biodiversity data from these samples to produce the first comprehensive analysis of metazoan genetic diversity in the Southern Ocean. The eDNA observation and preliminary experiments are outlined here, and a future plan of analyses are discussed.

Coincidental occurrence process of frazil ice and high biomass off Amery Ice Shelf

*Yoshihiko Machimura[1], Kay I. Ohshima[2], Kazuki Nakata[3], Masato Ito[2], Yasushi Fukamachi[2,4], Ryosuke Makabe[5], Shintaro Takao[5], Sohey Nihashi[6]

Arctic Research Center, Hokkaido University, 5. National Institute of Polar Research, 6. National Institute of Technology, Tomakomai College

Antarctic coastal regions are the most productive regions in the Southern Ocean and could dramatically influence global carbon cycle and ecosystems. During the austral spring, large phytoplankton blooms develop in polynyas with peak productivity occurring from December to January. According to the chlorophyll estimation from satellite, net primary production (NPP) in the Antarctic coastal polynyas rapidly declines from February to March (Arrigo et al., 2015).
Recent studies have found the regions with high biomass in Antarctic coastal regions during February-March (Lieser et al., 2015; DeJong et al., 2018). This high biomass is collaterally observed with frazil ice. Chlorophyll estimation algorithms using Moderate Resolution Imaging Spectroradiometer (MODIS) data mask pixels with high sea ice coverage to prevent the contamination by excess reflection of visible light. Therefore, the regions with high biomass collaterally observed with frazil ice have not been counted in NPP estimation in Antarctic coastal regions. These high biomass regions potentially have a large impact for global carbon cycle as the CO_2 sink. However, incidence processes and causes of frazil ice with high biomass have not been investigated in details. In this study, we focus on the regions of the Cape Darnley polynya and offshore of the Amery Ice Shelf in February and March during 2003-2011 to understand the processes and causes of high biomass collaterally observed with frazil ice.
First, we calculated Green Index from MODIS surface reflectance data obtained from the study area to identify green colored regions implicate high biomass. Second, we identified the region of frazil ice, using the algorithm that discriminates ice type between frazil ice and thin solid ice from AMSR-E passive microwave data (Nakata et al., 2019). These two analyses clearly show that the high biomass and frazil ice coincidentally occur both temporally and spatially in late summer. In particular, both of high biomass and frazil ice have a peak in their distributions at the same location about 50 km offshore of the Amery Ice Shelf in March. This is also suggesting an unknown frazil ice formation process distinctly different from a coastal polynya process.
We consider Ice Shelf Water (ISW) as a trigger of coincidental occurrence of frazil ice and high biomass. According to the CTD-tag data obtained from seals in the region off Amery Ice Shelf in late summer, ISW that is partly supercooled exists at depths of 250-400 m and the surface water is heated by solar radiation in the region from the ice shelf front to 68.3 deg. S. While in the region north of 68.2 deg. S, the surface water has reached the freezing point. Previous studies reported that ISW flows out to 50-100 km offshore from the ice shelf front and generates frazil ice at depths of 250-300 m (Dieckmann et al., 1986; Hughes et al., 2013).
To summarize the above analyses, coincidental occurence of frazil ice and high biomass is assumed to be caused by the following processes.
1. ISW is formed and flows out to the outside of Amery Ice Shelf cold cavity.
2. ISW becomes supercooled during the outflow, and frazil ice is generated.
3. Generated frazil ice gradually rises toward the surface. In the region south of 68.3deg. S, frazil ice is melted because of heated surface water. Frazil ice can appear at the surface in the region north of 68.2 deg. S, where the surface water reaches the freezing point.

©2019. Japan Geoscience Union. All Right Reserved.

4. Frazil ice scavenges phytoplankton existing in water column and carries it to the surface. Simultaneously, iron contained in ISW enhances the biological production and increases biomass. The process proposed in this study may also occur in regions just off other ice shelves. In the future, we should clarify the details of the process off Amery Ice Shelf with in-situ observation and explore the possibility of occurrence in regions off the other ice shelves.

Feeding habit of the Antarctic amphipod *Themisto gaudichaudii*of Vincennes Bay (East Antarctica) during austral summer

*Junji Matsushita[1], Ryosuke Makabe[2], Masato Moteki[1]

1. Tokyo University of Marine Science and Technology, 2. National Institute of Polar Research

Amphipods are key components of macrozooplankton to link lower trophic levels to higher predators in the krill-independent food web in the Southern Ocean (SO). The carnivorous amphipod *Themisto gaudichaudii*, widely distributed in SO, is an opportunistic predator. They are known to feed on copepods, euphausiids, salps and various zooplankton in the Atlantic Ocean sector, while their food habits are poorly known in the Indian Ocean sector. This study analyzed gut contents of *T. gaudichaudii* collected along the 110˚E transect in SO in January 2019 to clarify food habit of *T. gaudichaudii*. Fecal pellet obtained from onboard experiment were supplementary used to verify the estimated food habit. We’ll preliminary demonstrate here the food web related to *T. gaudichaudii* in the Indian Ocean sector during austral summer.

Time-series observation of subsurface chlorophyll *a* maximum in the seasonal ice zone of the Southern Ocean

*Ayuko Kagesawa[1], Masayoshi Sano[2], Shintaro Takao[1,2], Ryosuke Makabe[1,2], Kohei Mizobata[3], Norio Kurosawa[4], Masato Moteki[2,3], tuneo Odate[2]

1. The Graduate University for Advanced Studies, 2. National Institute of Polar Research, 3. Tokyo University of Marine Science and Technology, 4. Soka University

A persistent subsurface chlorophyll *a* maximum (SCM) is often found during the summer-fall season after the ice-edge bloom in the seasonal ice zone of the Southern Ocean, so that SCM would be considered important for biogeochemical cycling through the lower trophic levels. The relevant studies, however, have been qualitative in nature. This study aimed to reveal the dynamics and ecological role of the SCM in the seasonal ice zone.
We carried out Lagrangian observations using a drifter with two time-series sediment traps, an Acoustic Doppler Current Profiler (ADCP) and four sensor flames (Fig. 1). The drifter was deployed at 63.5˚S, 110.0˚E in January 14th 2019, and 5-day continuous observation was performed. In the vicinity of the drifter, 4 ship-based observations including net sampling and CTD casts were made until the drifter was recovered. Physical environments were measured by CTD, and sea water samples were collected for measurements of chlorophyll *a* (chl. *a*) concentration, nutrients, particle organic carbon, dissolved organic carbon, abundance of phytoplankton, micro-zooplankton, bacteria and nano-/pico-phytoplankton. We also conducted an incubation experiment for determining net primary production.
The temperature minimum layer, found between 37 and 52 m depth, decreased from -0.82 ºC to -1.28 ºC during the study period. The maximum chl. *a* concentration (1.0-2.0 μg/l), comparable to that in typical ice edge blooms, was observed at 40 m depth (Fig. 2). Such a high chl. *a* concentration might have important roles for food web and for material cycling. We will discuss especially on phytoplankton dynamics showing results of microscopic and chemical analyses.

Seasonality in sulfur isotopic compositions of atmospheric sulfate and its implications for atmospheric sulfur cycles in East Antarctica

*Sakiko Ishino[1], Shohei Hattori[1], Joel Savarino[2], Michel Legrand[2], Susanne Preunkert[2], Bruno Jourdain[2], Francis Albarede[3], Emmanuelle Albalat[3], Naohiro Yoshida[1,4]

1. Department of Chemical Science and Engineering, School of Materials and Chemical Technology, Tokyo Institute of Technology, 2. Institut des Geoscience de l' Environnement, Université Grenoble Alpes/CNRS, 3. Ecole Normale Supérieure (LGL-TPE), 4. Earth-Life Science Institute, Tokyo Institute of Technology

Atmospheric sulfate in Antarctica is produced mainly from a marine biogenic sulfur compound, dimethyl sulfide. They are therefore a subject of study related to the linkage between marine biogenic activity and climate. We investigate year-round observations of sulfur isotopic compositions of atmospheric sulfate (SO_4^{2-}) at inland (Dome C) and coastal (Dumont d' Urville) sites in East Antarctica to quantify the relative importance of marine biogenic (mb) and non-marine biogenic (nmb) SO_4^{2-} for the Antarctic atmospheric sulfur cycle. The $\delta^{34}S$ values of non-sea salt sulfate showed clear seasonal variations with summer maxima and winter minima, and showed homogeneity between inland and coastal sites throughout the year. This result suggests that the isotopic fractionation through chemical reactions during transportation from coastal to inland areas insignificantly affects the observed $\delta^{34}S_{nss}$ values. The observed $\delta^{34}S_{nss}$ values are controlled mainly by the relative importance of mb-SO_4^{2-} and nmb-SO_4^{2-}. This finding, in conjunction with the SO_4^{2-} records in Antarctic ice cores, will open a perspective implying the increased relative importance of nmb-SO_4^{2-} during glacial periods. We also found a significant increase in nmb-SO_4^{2-} concentrations in November, especially for the inland site. This nmb-SO_4^{2-} increase is correlated with the ^{210}Pb concentration, suggesting the existence of long-range transport of continental nmb-SO_4^{2-} from lower latitudes to the Antarctic inland. Identification of the sources of those nmb-SO_4^{2-} will be a key step for elucidation of the linkage between Antarctic atmosphere/climate and environmental changes at lower latitudes from the past through the future.

Penultimate glacial-interglacial transition viewed from the Dome Fuji ice core, Antarctica

*Ikumi Oyabu[1,2], Kenji Kawamura[1,3,4], Kyotaro Kitamura[1]

1. National Institute of Polar Research, Research Organization of Information and Systems, 2. Japan Society for the Promotion of Science, 3. SOKENDAI (The Graduate University of Advanced Studies), 4. Japan Agency for Marine Science and Technology (JAMSTEC)

Paleoclimatic proxies provide information about the variations of climate forcings and responses, such as atmospheric CO_2concentration, temperature and sea level, as well as their magnitudes and phase relationships. Accurate chronological constraints are particularly important for numerical simulations, both for their input and validation data, to better understand the transient behaviors of climate and ice sheets. During the last interglacial period (~130 to ~120 thousand years before present (kyr BP)), the peak global mean surface temperature was ~1 degree higher than the preindustrial period, and the global sea level was ~6 –9 m higher than today with significant contribution from the Antarctic ice sheet, whereas atmospheric CO_2levels were similar to those in the preindustrial period (Dutton et al., 2015). The last interglacial period and the preceding transition from the penultimate glacial period are important targets for the paleoclimatic research to investigate the mechanisms for warming and ice-sheet reductions. However, responses (sequences, timing or magnitude) of ice sheets, temperature or ocean circulations to climate forcing during this period are much less well understood, partly because the number of proxies and time resolution are limited, and the chronological uncertainties are relatively large. A chronology of the Dome Fuji (DF) ice core was constructed by synchronizing variations in O_2/N_2ratio of occluded air with local summer insolation (Kawamura et al., 2007), but relatively large errors were later reported around the last interglacial (Fujita et al., 2015). Here, we reanalyzed the O_2/N_2ratio of the DF core by improving the methods for sample treatment, air extraction and mass spectrometry between 57 and 165 kyr BP to revise the DF chronology. The new chronology agrees within 1.2 kyr with a radiometric (U-Th) chronology of Chinese speleothems, the whose stated error is less than 1 kyr (Cheng et al., 2009), suggesting successful improvement of our ice-core chronology. Using $\delta^{18}O$ of atmospheric O_2($\delta^{18}O_{atm}$) and CH_4records measured on the same ice samples as used for the O_2/N_2measurements, we investigate climatic variations during the penultimate glacial period and deglaciation. We found that $\delta^{18}O_{atm}$ becomes heavier while CH_4concentration increased at 138.4 kyr BP during the penultimate glacial maximum; this characteristic relationship was observed at Heinrich Event 2 (at ~24 kyr BP) during the last glacial maximum (Severinghaus et al., 2009; Rhodes et al., 2015). Other well-dated paleoclimatic records show major climatic changes around 138 kyr BP; an abrupt weakening of the Asian monsoon occurred at 138 kyr BP (Wang et al., 2008), and the onset of relative sea level rise was suggested at 139±1 kyr BP from seawater $\delta^{18}O$ of Red Sea (Grant et al., 2012) and at 137 kyr BP from U-Th dating of Tahiti fossil corals (Thomas et al., 2009). The similarity of these ages suggests that a massive iceberg discharge event occurred at ~138 kyr BP, and it marked the onset of penultimate deglaciation. Our new data may provide better chronological constraints on the climatic forcings and responses around the penultimate deglaciation and last interglacial period.

Reconstruction of Antarctic ice sheet dynamics in the Last Interglacial

*Mutsumi Iizuka[1], Osamu Seki[1], Takuya Itaki[2], Tomohisa Irino[1], Minoru Ikehara[4], Saiko Sugisaki[2], Masanobu Yamamoto[1], Keiji Horikawa[5], Yuusuke Suganuma[3]

1. Hokkaido university, 2. Geological Survey of Japan, 3. National Institute of Polar Research , 4. Center for Advanced Marine Core Research, Kochi University, 5. University of Toyama

Ongoing global warming could cause various problems in the future. One of the serious concerns is a sea level rise due to the melting of the ice sheet. Antarctic ice sheet, which hold a massive amount of fresh water was considered to be stable even if global warming progresses in the future. However, recent studies have shown that Antarctic ice sheet is more sensitive to global warming than previously thought. Therefore, it is an important to better understand extent to which Antarctic ice sheet is sensitive to global warming.

Study of past warm period proves an useful insight into the prediction of sea level rise in a future. Especially, Sea level in the last interglacial (MIS 5e), which was ~1˚C warmer than the preindustrial was estimated to be several meters higher than that of the present with the sudden and abrupt rises in sea level. This suggests significant loss of Antarctic ice sheet during MIS 5e. However, Antarctic ice sheet variability during the MIS 5e has been poorly understood. In this study, we reconstruct dynamics of Antarctic ice sheet during MIS 5e from the marine sediment core GC1407 collected from Dumont d'Urville Sea, East Antarctica (130.518˚E, 63.74˚S).

Interval of MIS 5e has been determined based on abundance of radiolaria in GC1407. Variability of iceberg discharge is reconstructed by measurement of iceberg rafted debris (IBRD) in sediments. IBRDs are found to be recognized only during MIS 5e. This suggests that the significant discharge of large icebergs possibly from Wilkes Land basin, East Antarctica happened only during warmer than present climate condition.

Pliocene CO2 concentration estimated from Southern Ocean SST

*Osamu Seki[1], Tomohiro Shimono[2]

1. Institute of Low Temperature Science, Hokkaido University, 2. Guraduate School of Environmental Science

Prediction of temperature change by the climate model depends on climate sensitivity, which is the temperature change associated with doubling of CO_2 concentration. The constraint on climate sensitivity is the key part in the IPCC and thus is critical for the future climate prediction. However, despite considerable efforts for constraint on climate sensitivity, the climate sensitivity still remains uncertainty. Furthermore, recent paleoclimate studies revealed that climate sensitivity depends on climate state. This highlights the necessity to know the climate sensitivity in the warmer than the present climate for the future prediction. The Pliocene Warm Period (3-4.5 million years ago) is often regarded as the best analogue of climate in the near future and thus is ideal to investigate climate sensitivity in the warm climate state. In this study, we reconstruct CO_2 concentration based on the new empirical approach (average SST in mid latitude of Southern Ocean) to estimate climate sensitivity in the Pliocene Warm Period.

Lithogenic fluxes across a transect in the SW Indian Ocean since the last glacial inception

*Eri Helen Amsler[1], Walter Geibert[2], Gerhard Kuhn[2], Minoru Ikehara[3], Samuel Jaccard[1]

1. Institute of Geological Sciences and Oeschger Centre for Climate Change Research, University of Bern, Switzerland, 2. Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Bremerhaven, Germany, 3. Center for Advanced Marine Core Research, Kochi University, Kochi, Japan

On glacial-interglacial time scale the Southern Ocean plays a prominent role in modulating climate by storing and redistributing heat, fresh water, carbon and nutrients globally. Atmospheric CO_2 is taken up by algae and sequestered in the deep ocean through the biological carbon pump. On the other hand, CO_2 is released back to the atmosphere through upwelling and vertical mixing [1]. The relative contribution of these two mechanisms controls the efficiency through which carbon can be sequestered in the ocean interior.

The effect of iron fertilization on biological productivity has previously been documented in the Atlantic and Pacific sectors of the Southern Ocean [2, 3]. During glacial periods higher input of Fe-bearing dust increased phytoplankton growth and carbon sequestration, thus leading to the drawdown of atmospheric CO_2, accounting for about half of the glacial-interglacial CO_2 amplitude [4].

Here we present ^{230}Th-normalized lithogenic fluxes in a set of marine sediment cores spanning a meridional transect in the Indian sector of the Southern Ocean further away from the Patagonian dust plume and show that increased Fe flux impacted export production patterns, contributing to the sequestration of carbon away from the atmosphere.

Changes in composition of fossil diatoms from Ross Sea under gradual warming climate from MIS M2

*Saki Ishino[1], Itsuki Suto[2], Rob M. McKay[3], Laura De Santis[4], Denise K. Kluhanek[5], Expedition 374 Scientists

1. National Institute of Advanced Industrial Science and Technology, 2. Department of Earth and Planetary Sciences Graduate School of Environmental Studies, Nagoya University, 3. Victoria University, 4. Instituto Nazionale di Oceanografia e di Geofisica Sperimentale, 5. Texas A&M University

Understanding past polar environmental changes under warming climate process will help predicting future global warming. The paleoceanographic record near Antarctic ice-proximal area provides important insight into West Antarctica Ice Sheet (WAIS) vulnerability. Antarctic sediments contain numerous fossil diatoms, which are helpful to clarify past oceanographic conditions.

International Ocean Discovery Program (IODP) Expedition 374 drilled five sites from Ross Sea continental shelf and rise to investigate WAIS evolution under warm climates. Site U1524A (74° 13.05’ S and 173° 37.98’ W, 2394 m water depth) drilled from continental rise, which lies beneath cascading Antarctic Bottom Water current, preserves high resolution Pliocene sediments. We present preliminary results of composition changes of diatom assemblages focusing on the ages from MIS M2 to warmer climate around the interval between 3.3 and 3.0 Ma. Diatom records including abundance changes in sea-ice indicator species and *Chaetoceros*resting spores contribute to evaluate the past sea-ice coverage, primary productivity, and vertical mixing in Pliocene warm condition.

Geological insights into formation of Conrad Rise, Southern Ocean: Preliminary geological results of R/V *Hakuho-maru* KH-19-1 cruise

*Hiroshi Sato[1], Masakazu Fujii[2,3], Hiroki Matsui[4], Minoru Ikehara[4]

1. School of Business Administration, Senshu University, 2. NIPR, 3. SOKENDAI, 4. Center for Advanced Marine Core Research, Kochi University

Conrad Rise is one of plateaus situated at the Indian-sector of the Southern Ocean. Origin of the rise are considered to be a sort of the Large Igneous Provinces or hotspot. Previously Borisova et al. (1996) reported alkaline igneous rocks which have similar geochemical signature to the Kelgueren Plateau. However, detailed investigations have not been performed until our recent study. We performed geological and geophysical investigations during three R/V *Hakuho-maru* cruises, KH-10-7, KH-16-1, and KH-19-1. Particularly, we had five dredge operations during KH-10-7 and KH-19-1 cruises and obtained geological (and biological) materials that have important keys to understanding the origin and development of Conrad Rise. Geological materials collected during KH-10-7 cruise had already reported by Ishizuka et al. (2011), Sato et al. (2012), and Kobayashi et al. (2013). In this presentation, we report preliminary results of recovered geological and biological materials during KH-19-1 cruise.

Two dredge operations were performed during KH-19-1 Leg 2 (16 Jan to 12 Feb 2019). Dredge site KH-19-1D4 is situated at one of peaks of unnamed small knoll that is located north of Ob seamount. Approximately 50 kg of geological and biological materials including igneous rocks, metamorphic rocks, and deep-sea coral were recovered. Dredge site KH-19-1D5 is situated at north-south trending spur on the northern slope of Ob seamount. Approximately 50 kg of materials including igneous rocks, sedimentary rocks, metamorphic rocks, deep-sea coral, and living shell were recovered.

Fossil chrysophyte cysts as a new paleoenvironmental proxy

*Yuji Kato[1,2], Itsuki Suto[1]

1. Graduate School of Environmental Studies, Nagoya University, 2. Center for Advanced Marine Core Research, Kochi University (JSPS Research Fellowship for Young Scientists)

Most Neogene–Quaternary sediments in the Southern Ocean have high biogenic silica contents with large amounts of siliceous microfossils including chrysophyte cysts as well as diatoms. Fossil chrysophyte cysts are considered to be potentially useful paleoenvironmental indicators, however no general consensus exists about their paleoenvironmental significance. In this study, data on fossil chrysophyte cyst abundances of late Miocene to Pliocene (ca. 9–3 Ma) age are presented from two marine sediment cores, Ocean Drilling Program Site 689 and Deep Sea Drilling Project Site 513, both located in the Atlantic sector of the Southern Ocean. Changes in the chrysophyte cyst abundances are compared to those in the diatom abundances, and the potential of fossil chrysophyte cysts as paleoceanographic indicators around the Antarctica is discussed.
As a result, similarity in the fluctuation of freshwater diatom and chrysophyte cyst abundances were observed in both sites. In addition, occurrences of chrysophyte cysts similar to previously reported ones from freshwater habitats were recognized. These results suggest that the fossil chrysophyte cysts from Sites 689 and 513 were originated from terrestrial freshwater habitats. Since freshwater input into the Southern Ocean are mainly derived from Antarctic terrestrial freshwater (i.e. meltwater of glaciers or ice sheet), fossil chrysophyte cysts in the Southern Ocean sediments can be a new useful tool to reconstruct the Antarctic Ice Sheet's fluctuation history. In addition, comparison between changes in abundance of chrysophyte cysts and the δ18O stack of benthic foraminifera (Zachos et al. 2001) shows opposite trends: matching of increases of chrysophyte cysts corresponds to decreases of δ^{18}O values (i.e. decreased ice sheet volume), which also supports the possible relationship between the fluctuations of fossil chrysophyte cysts and Antarctic Ice Sheets. On the other hand, coexistence of chrysophyte cysts and sea-ice related diatoms (e.g. 4.4–3.3 Ma at Site 689) suggests that some of the chrysophyte cysts originated from sea-ice. Further taxonomic and biogeographic studies on fossil chrysophyte cysts are needed to provide a new approach for paleoenvironmental reconstruction.

Spatiotemporal variability of surface mass balance along the JARE traverse route for 1991–2019

*Shun Tsutaki[1], Hideaki Motoyama[2,3], Ayako Abe-Ouchi[1,4], Shuji Fujita[2,3], Kenji Kawamura[2,3,4]

1. The University of Tokyo, 2. National Institute of Polar Research, 3. The Graduate University for Advanced Studies, 4. Japan Agency for Marine-Earth Science and Technology

Satellite-based observations revealed the recent mass loss of the Antarctic ice sheet, and there is concern about its influence on sea level rise. Although significant mass loss has been reported in the West Antarctica, spatial and temporal variability of surface mass balance (SMB) is poorly understood in the East Antarctica where the ice volume is more than 10 times, due to complexity in snow accumulation in space and time, resulting in relatively large uncertainty to quantify ongoing and future mass loss from the Antarctic ice sheet. Therefore, it is crucial to accurately quantify SMB in East Antarctica. SMB has been measured along the traverse route between coastal area (S16) and the inland Dome Fuji region as a part of the Japanese Antarctic Research Expedition (JARE) since 1991. Net snow accumulation was measured by the stake method at approximately 500 points every 2 km. In this study, we re-evaluate spatial and temporal variability of SMB between S16 and Dome Fuji region during the period of 1991–2019. Uncertainty of the SMB measurements is discussed by the data obtained from stake farms and stake rows along the survey route. Spatiotemporal variability of SMB is discussed with surface slope of the ice sheet as well as wind speed and direction in order to evaluate the influence of surface topography and katabatic wind blowing on the ice sheet surface on snow accumulation.

The weathering of granitic rocks in the Sør-Rondane Mountains, East Antarctica

*Tatsuo Kanamaru[1], Yusuke Suganuma[2], hisashi Oiwane[3], Hideki Miura[2], Makoto Miura[4], Jun'ichi Okuno[2], Hideaki Hayakawa[5]

Weathering processes in hyper-arid and hypothermal environments are key to our understanding of geomorphological processes and landscape evolution in Antarctica. Here, we explore the weathering of granitic rocks and the associated weathering products in the Sør-Rondane Mountains of East Antarctica, to obtain quantitative information regarding the physical and chemical weathering of granitic rocks in hyper-arid and hypothermal environments. Various petrological techniques, including whole-rock chemistry, loss on ignition measurement, mineral chemistry, laser-Raman microspectroscopy, in addition to color measurement and hardness test for the rock samples, were used to analyze the physical and chemical weathering of the rocks. These measurments reveal that the weathering of granitic rocks in the Sør-Rondane Mountains of East Antarctica is controlled mainly by oxidation, including iron hydroxide formation in veins formed by the thermal expansion and contraction of rock-forming minerals, frost shattering and/or salt fretting, and Fe–Ti oxide alteration in the rock interior. Importantly, these physical and chemical weathering processes are unlikely to require a liquid water supply from the environment, and the restricted supply of liquid water and salt is the most probable explanation for the extremely slow weathering rates in the Sør-Rondane Mountains.

Late Pleistocene to Holocene sea-level change in East Antarctica revealed by glacial isostatic adjustment modeling

*Takeshige Ishiwa[1], Jun'ichi Okuno[1,2], Yusuke Suganuma[1,2], Hideki Miura[1,2]

1. National Institute of Polar Research, 2. SOKENDAI

Antarctic Ice Sheet (AIS) is the most significant storage of freshwater in the Earth’ s surface and most concerned in considering future sea-level rise. Present studies attempt to assess the mass loss or gain in AIS using GNSS and satellite dataset. Moreover, past AIS variability should be considered to achieve the accurate present AIS change, since presently-observed vertical movement in Antarctica includes the effect of glacial-hydro isostasy due to past AIS variability. Glacial isostatic adjustment (GIA) modeling can provide sea-level histories in Antarctica following sea-level equation. Comparison of field-based sea-level records with predicted sea-level by GIA modeling is required to constraint past AIS histories, leading to the accurate prediction of future sea-level rise.
We document predicted sea-level change in East Antarctica by GIA modeling using several Antarctica ice-loading histories and also compare with previously reported observed sea-level records. Moreover, potential sites for future sampling to obtain observed sea-level records in East Antarctica will be presented by GIA modeling.

An modeling study of Antarctic ice sheet of the Last Glacial Maximum and the last deglaciation

*Takashi Obase[1], Ayako Abe-Ouchi[1,2], Ralf Greve[3], Fuyuki SAITO[2]

1. Atmosphere and Ocean Research Institute, the University of Tokyo, 2. Japan Agency for Marine-Earth Science and Technology, 3. Institute of Low Temperature Science, Hokkaido University

Reconstructions indicate Antarctic ice sheet extent and volume were decreased during the last deglaciation. Sea level reconstruction of the Last Interglacial (LIG), after the penultimet deglaciation, indicate the volume of Antarctic ice sheet was smaller than the present interglacial. Climate reconstructions indicate surface temperature in the Antarctic continent and sea surface temperature in the Southern Ocean during the LIG were higher than the present interglacial. A transient climate simulation of the last deglaciation using MIROC suggests that this higher surface temperature in the Antarctic region is a result of weaker AMOC during the deglaciation and bipolar warming in the Southern Hemisphere.

In the present study, we utilize a 3-dimensional Antarctic ice sheet model (SICOPOLIS) to conduct quantitive assessment of the impact on retreat of Antarctic ice sheet during deglaciations. At first, the configuration of LGM Antarctic ice sheet is prepared using reconstructed climate and sea level changes, and is compared with reconstructions to verify the initial state of deglaciation. We will present preliminary results of Antarctic ice sheet changes of the last deglaciation using climate model outputs of the last deglaciation.

Development of a coupled ice-sheet/earth rebound model for Antarctic ice-sheet simulation

*Fuyuki SAITO[1], Ayako Abe-Ouchi[2,1], Jun'ichi Okuno[3], Takashi Obase[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Atmosphere and Ocean Research Institute, University of Tokyo, 3. National Institute of Polar Research

Feedback between changes in the ice-sheet and the earth's isostatic rebound is considered to be an important process for the evolution of the past ice-sheets in glacial cycles. We have been developing a coupled ice-sheet/earth rebound model which were applied for northern hemisphere ice sheet simulation during glacial/interglacial cycles. Earth rebound model is based on a self-gravitating visco-elastic multi-layer model developed by Okuno and Nakada (2001), while the ice-sheet model is IcIES (Abe-Ouchi 2013). The results are compared with the previous IcIES results which coupled with a simple isostatic model (i.e., a local lithosphere/relaxing asthenosphere) which is controled by two parameters (the mantle density and the time scale of isostatic response), in order to discuss the effect of more realistic visco-elastic structure of the earth.

Polar amplifications in the past warm periods obtained from MIROC 4m AOGCM

*Taro Higuchi[1], Ayako Abe-Ouchi[1], Wing-Le Chan[1], Sam Sherriff-Tadano[1]

1. Atmospheric and Ocean Research Institute, the University of Tokyo

The Earth has experienced several warm periods (e.g., early Eocene and Cretaceous), which had warm climates, comparable to global warming prediction of near future due to rising CO2 concentration in the atmosphere. Paleoclimatic proxies indicate that the common characteristics of these periods are remarkable temperature amplifications in the high-latitude and polar region (Bice et al., 2003; Huber, 2008), resulting in small equator-to-polar temperature difference. However, simulations of warm periods climate using General Circulation Models tend to underestimate the polar amplifications than those suggested from geological records. The discrepancy between proxy data and climate models is one of the greatest challenges of warm climate study. Although it is important to consider the effects of the ocean circulation and vegetation feedback to reproduce the polar amplifications in the past warm periods, there were few studies using Atmosphere-Ocean coupled General Circulation Model (AOGCM). In this study, we simulate Present Day, early Eocene, and late Cretaceous climates with different CO2 levels using AOGCM MIROC 4m, additionally full-coupled with dynamic vegetation model, and get the climatology in full equilibrium with longer than 3000 years. The simulated temperatures of early Eocene and late Cretaceous experiments are compared with surface temperature reconstructions based on paleoclimatic proxies. We also investigate the difference of physical process to polar amplification between warm periods (early Eocene and late Cretaceous) and Present Day by using an energy flux analysis. Despite using the fully coupled model with paleo-configuration, the polar amplification in this study is not enough to fully reproduce proxy-indicated polar temperatures. This result implies that we need to re-verify model-performance to the polar climate in GCMs and physical feedback process to global warming due to rising greenhouse gasses in the atmosphere.

Using a coupled AOGCM to study the Antarctic climate of the mid-Pliocene warm period

*Wing-Le Chan[1], Ayako Abe-Ouchi[1,2]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. National Institute of Polar Research

The mid-Pliocene warm period, 3.3-3.0 million years ago, was a period of sustained warmth before global cooling occurred and a shift to repeated glacial cycles. It was also the most recent time in the history of Earth when atmospheric carbon dioxide levels were similar to those of present day. The study of this period is thus of much importance, given the growing concerns over future climate change associated with anthropogenic emissions of greenhouse gases. In particular, ice coverage in West Antarctica, as well as in Greenland, reduced significantly and there is evidence to suggest a retreat of ice sheet in the coastal areas and in the Wilkes Subglacial Basin of East Antarctica during that time.

In this study, we use the mid-resolution MIROC4m coupled atmosphere-ocean general circulation model and apply ice sheet configuration, land-sea mask and biome distribution from PRISM3 data sets, as set forth in the latest, second phase of the Pliocene Model Intercomparison Project. We conduct a series of experiments, including those which look into a range of atmospheric carbon dioxide levels given the spread in values suggested by various sources of proxy data. We show the degree of warming over Antarctica and how the precipitation responds to changes in the moisture transport.

Keywords: Antarctica, Pliocene, modeling

CMIP5 model analysis of future changes in ocean net primary production by focusing on different response among the individual oceans and models

*Akira Oka[1], Yuki Nakamura[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

Previous modeling studies show that global primary production will decrease in the future because stratification caused by global warming reduces supply of nutrient from the deep ocean. Previous studies mainly emphasized the importance of nutrient limitation in explaining the changes in primary production; however, phytoplankton growth is actually determined by temperature limitation, light limitation and nutrient limitation. Moreover, although future changes of primary production differ depending on areas, many prior researches discuss only global mean mechanisms and it is not well understood how the mechanisms differ depending on the individual oceans. The purpose of this study is to quantitatively evaluate contribution of each limitation factor for explaining the future changes in primary production in the individual oceans by using 9 CMIP5 models. First, we calculate temperature limitation, light limitation and nutrient limitation for each model, which are not directly available from CMIP5 output data. After that, we quantitatively evaluate main drivers for changes in primary production not only for the global ocean but also for low latitudes, the North Atlantic Ocean, the North Pacific Ocean, the Arctic Ocean and the Southern Ocean, separately. By quantitative evaluation on limitation factors of primary production, we show that the future changes in primary production due to global warming is controlled by not only nutrient limitation but also warming-induced enhancement of phytoplankton growth and decreasing biomass caused by enhanced grazing. Moreover, we show that future changes in primary production and its mechanisms differ among the individual oceans.

Factor analysis of the millennial time-scale climate variability in glacial periods

*Miki Akari[1], Ayako Abe-Ouchi[2], Sam Sherriff-Tadano[2]

1. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, 2. Atmosphere and Ocean Research Institute, the University of Tokyo

It is well known that in the glacial periods, air temperature changed abruptly over the North Atlantic on millennial time-scale. It is also known that temperature changes over the Southern Ocean were opposite to the North Atlantic, called a bipolar seesaw relationship. It is suggested that changes in the strength of the Atlantic Meridional Overturning Circulation (AMOC) were closely related to such global climate changes.

In recent years, the idea that freshwater forcing causes the climate changes has been questioned. Spontaneous oscillations in AMOC can be reproduced by experiments using atmosphere-ocean coupled general circulation models (AOGCM). These studies proposed that oceanic feedbacks within the North Atlantic surface - subsurface ocean are important in inducing the spontaneous AMOC variabilities. However, the oscillation cycles shown in previous studies (Peltier and Vettoretti, 2014; Brown and Galbraith, 2016) are several hundred years, which are shorter compared to climate variabilities documented in ice core data. On the other hand, in experiments carried out with MIROC4m AOGCM under the medium glacial condition, millennial time-scale climate and AMOC variabilities are reproduced. Therefore, in this study, we analyze factors controlling the millennial time-scale climate variability obtained from MIROC4m AOGCM. Focusing on the fact that this oscillation cycle is close to the time-scale of the Southern Ocean and the bottom ocean circulation, we analyze the behavior of the Southern Ocean and the bottom ocean in detail, especially deeper than 2500 meters, in addition to oceanic feedback suggested by previous studies.

As a result, it is suggested that the density change at the bottom ocean, which is caused by changes in sea ice formation over the Southern Ocean, plays an important role in controlling the oscillation of AMOC on millennial time-scale.

First continuous profiler observation of wintertime Antarctic coastal polynya

*Shigeru Aoki[1], Kazuya Ono[1], Daisuke Hirano[1], Masato Itoh[1], Tomohide Noguchi[2], Satoshi Ozawa[2]

1. Hokkaido University, 2. Marine Works Japan

Antarctic coastal polynyas are the regions where sea ice forms vigorously, leading to supply of dense abyssal water for the global ocean. Monitoring the sea state of coastal polynyas especially in winter hence has global implications. To fully understand the development of water characteristics, capturing of the whole water column is required. However, the wintertime observations of seasonal ice zone such as polynya is not abundant so far, due to the severe and variable conditions of polar oceans.

To realize a near-realtime observation of water column in coastal polynya, we deployed a tethered profiling float over the whole winter in Cape Darnley polynya, East Antarctica (bottom depth of 230 m). The tethered float was manufactured by IHI Corporation, with a temperature and salinity sensor (SBE37 of Seabird Scientific) attached.

The float observation was successful in operation for more than eight months from Feb. 26 to Nov. 13, 2017. This float was designed to park at 150 dbar depth and to surface (upto 20 dbar when sea ice is supposed to exist) at 10-day interval. During this period, 26 profiles for the water column from 180 dbar to 20 dbar were obtained. The whole 160-dbar depth range was covered by nearly half of the 26 profiles, and the total ratio of depth coverage was 81%. Comparison with a current meter record nearby (one mile distance) revealed that the minimum depth achieved did not correlate with the current speed.

The obtained record clearly revealed a seasonal development of the whole water column. While relatively warm water initially remained in the water column, significant freshening occurred and temperature decreased to the freezing point throughout the column from March to April. Then salinity gradually increased to about 35 (150 dbar) in October, successfully covering the whole cycle of sea ice production. The layer near the parking depth (between 120 dbar and 180 dbar) was covered with much higher temporal resolution, showing variations of higher frequencies.

Although the satellite data transmission was not successful due to the battery shortage, signal transmission was successful at the preparation stage. A revision of this platform will enable the monitoring of seasonal ice zone in the polar oceans, to help filling the remaining gap of the global ocean monitoring array.

Surface topography survey for bared rock and accumulated snow in Antarctica by Unmanned Aero Vehicle

*Yuichi Aoyama[1,2,3], Akihisa Hattori[2,3], Hajime Oishi[3,4], Koichiro Doi[1,2,3], Yoshifumi Nogi[1,2]

1. National Institute of Polar Research, 2. SOKENDAI, 3. The 59th Japanese Antarctic Research Expedition, 4. NEC Networks & System Integration Corporation

In the last decade, Gravity Recovery and Climate Experiment (GRACE) mission demonstrated an increase of surface mass in the Dronning Maud Land (DML), East Antarctica. Actually, snow accumulation has increased at Syowa Station located in DML, and its effect has been detected by superconducting gravimeter and GNSS measurements. For quantifying this effect, it is necessary to measure the distribution of the snow accumulation.
The distribution of the snow accumulation can be estimated from difference in accurate digital surface models (DSM) between the bared rock and the accumulated snow. These DSMs are derived from aerial photography byunmanned aerial vehicle (UAV) with structure from motion (SfM) analysis. In the activity of the 59th Japanese Antarctic Research Expedition (JARE59) during Dec. 2017 - Dec. 2018, some aerial photography surveys were conducted with the fixed-wing small UAV, senseFly eBee plus, and with the rotary-wing drone, DJI Inspire 2 over Syowa Station. There is a report that the eBee plus, having dual-frequency GNSS receiver, enables to generate DSM precisely without ground control point (GCP). We evaluated the accuracy of such DSM by comparing with DSM computed with GCP. We also compared with the DSM computed from aerial photography by Inspire 2 which has single-frequency GNSS for evaluating the advantage of the dual-frequency GNSS tracking. The DSMs in Langhovde, Akarui Misaki, Rundvagshetta located around Lutzow-Holmbukta are also computed from aerial photography by eBee plus.

The analysis of long-term Mooring observation records in the northernmost area of seasonal sea ice zone in the Southern Ocean

*Kazuho Watanabe[1], Kohei Mizobata[1], Yujiro Kitade[1]

1. Tokyo University of Marine Science and Technology

The meridional overturning is thought to be the contributor for the stability of the climate system via latitudinal exchange of oceanic heat in the Southern Ocean. To clarify details of the meridional overturning, mooring observations using T/RV *Umitaka-maru* were conducted by physical oceanography group mainly constructed by Tokyo University of Marine science and Technology. In this study, we analyzed the one-year record of the mooring observation and CTD measurements obtained when the mooring system was deployed and recovered.

Results from current meter analysis shows the variability (from 30-day to 90-day cycle) of ocean current. Geostrophic velocity derived from sea level anomaly map distributed by AVISO/Altimetry also shows similar variability of ocean current due to eddies. Furthermore, the location of the mooring system was far from the main axis of the Antarctic Circumpolar Current (ACC). Those results suggest us that the variability of ocean current was resulted from the mesoscale eddy field.

Even though the variability of ocean current was recoded, results also indicate the meridional overturning. The progressive vector diagram based on current meter record illustrated poleward transport at about around 400db and eastward transport at about 4000db. One-year mooring observation also revealed ocean current shear structure (about 10cm/s at about 400db and 4cm/s at about 4000db) when poleward transport was continuously captured. During poleward transport with shear structure was captured, the increase in temperature over 2.1 $^{\circ}$C from October to February at about 400db was frequently observed. Based on hydrographic data, warm water captured around 400db was identified as the Circumpolar Deep Water (CDW). Cross correlation analysis revealed that warm CDW intrusion occurred about 8-day following southward current at 400db. During the season when sea ice covered the ocean, similar event also happened but temperature at about 400db increased up to around 2°C. Our results indicate that CDW’ s southward transport is changing by seasonal and the event of mesoscale eddy passage.

Preliminary observation report on chlorofluorocarbons (CFCs) and sulfur hexafluoride (SF_6) off the Cape Darnley in the summer of 2019

*Yoshihiko Ohashi[1], Michiyo Yamamoto-Kawai[1], Kenichi Sasaki[2], Sayaka Kumakawa[1], Naoyuki Tamura[1], Kay I. Ohshima[3]

1. Tokyo University of Marine Science and Technology, 2. Japan Agency for Marine-Earth Science and Technology, 3. Institute of Low Temperature Science, Hokkaido University

Antarctic Bottom Water (AABW) occupies the largest volume of water mass in the global ocean and its formation is a key process of global ocean circulation. Ohshima et al. (2013) found newly formed AABW off the Cape Darnley (Cape Darnley Bottom Water; CDBW). However, little is known about the circulation of CDBW and its time scale. To quantitatively understand the spread and circulation of CDBW, it is effective to use the chemical tracer such as chlorofluorocarbons (CFCs) and sulfur hexafluoride (SF_6). We carried out CTD observation and water sampling off the Cape Darnley in the summer of 2019. Water sampling was performed from ocean surface to the bottom at 16 Stations (along the Wild Canyon and its west). CFCs and SF_6 of the samples were measured by an analytical system developed at JAMSTEC based on Bullister and Wisegarver (2008). The concentrations of CFCs and SF_6 were significantly high near the surface (< 100 m) (CFC11 > 2.0 pmol kg^{-1}; CFC12 > 1.2 pmol kg^{-1}; SF_6 > 1.4 fmol kg^{-1}). They showed a minimum at depths of 800–1500 m and then increased to the bottom. The relatively high concentrations of CFCs and SF_6 near the bottom, together with the low temperature (< −0.4°C), reflects the spread of CDBW. At the presentation, we will discuss mean age and circulation of CDBW.

Mechanism of sea-ice production variation in Amundsen Sea Polynya

*Sohey Nihashi[1], Kouta Mine[1], Kazuki Nakata[2]

1. National Institute of Technology, Tomakomai College, 2. RESTEC

A coastal polynya is an area of high ice production and dense water formation. This dense water is a major source of the Antarctic Bottom Water. Since winter polynya is a difficult site to observe, the mechanism of polynya formation and variation had not been understood well. About ten years ago, an algorithm was developed that uses satellite passive microwave data to detect polynyas and estimates thin ice thickness on a daily timescale. The satellite data revealed the detailed distribution and variation of polynyas (e.g., Tamura et al., 2007; 2008). Use of AMSR-E/AMSR2 data with a finer spatial resolution (about 5-6 km), can reveal the more detailed spatial distribution of polynyas. For example, it was revealed that most of coastal polynyas form on the west side of landfast ice (fast ice: stationary sea ice attached to coastal features such as shoreline and grounded icebergs). This close relationship indicates a vital role of fast ice for formation and variation of coastal polynyas (Nihashi and Ohshima, 2015; Nihashi et al., 2017). The Amundsen Sea Polynya (ASP), located in West Antarctica, is the third largest ice production area and is formed on the west side of fast ice protruding into the ocean. Thwaites Glacier adjacent to the fast ice has been suggested that a rapid melting occurs in recent decades (Rignot et al., 2008; Milio et al., 2019). Grounded icebergs that act as anchor points play an essential role in the formation of fast ice protruding into the ocean. Since the sources of an iceberg are glacier and ice sheet, the rapid melting possibly affects the formation and distribution of fast ice and accordingly adjacent polynyas.

In this study, we compare the ice production in the ASP with atmospheric parameters and fast ice extent to investigate factors for causing ice production variation. Ice production estimated from heat flux calculation with daily thin ice thickness from AMSR-E/AMSR2 data (Nihashi and Ohshima, 2015; Nihashi et al., 2017) is used. For fast ice, monthly extent detected from AMSR-E/AMSR2 data is used. We also use ice production estimated using thin ice thickness by an improved algorithm in which ice types (active frazil and thin solid ice) are considered (Nakata et al., 2019). As atmospheric data, we use ERA5.

Ice production is positively correlated with wind speed regardless of daily or monthly data with the coefficient of 0.54-0.73. Here, we use a wind component with the highest correlation; components of the wind vector are projected in all directions of every 1˚ from 0˚ (northerly wind) clockwise to 360˚, and then, correlation coefficients are calculated. The wind component is oriented to the west rather than to the offshore (north) against the land. This is a direction towards the offshore against the shoreline defined by both the land and fast ice. This result supports the analysis using only AMSR-E data (Nihashi and Ohshima, 2015). If ice production in which thin ice types are considered is used, the wind component is oriented toward further west when active frazil is dominant. This direction is to the offshore against the fast ice. Further, active frazil tends to form along fast ice. On the other hand, the wind component is northward (to the offshore against land) when thin solid ice is dominant. Multiple regression analysis is performed on the ice production using air temperature, wind speed, and fast ice extent averaged over the freezing season (May-August). Ice production can be explained by these parameters with R=0.77. This indicates that ice production in the ASP before the satellite observation era can be reproduced to some extent from atmospheric data by using this regression line. The results presented in this study suggest that fast ice plays a vital role in the formation and variation of the ASP. Continuous monitoring of Antarctic coastal polynyas and fast ice from passive microwave satellite sensor is quite meaningful understanding climate change.

Estimation of thin ice thickness and discrimination of ice type from AMSR2 passive microwave data

*Kazuki Nakata[1], Tamaru Naoya[1], Sohey Nihashi[2], Kay I. Ohshima[3]

1. Remote Sensing Technology Center of Japan, 2. National Institute of Technology, Tomakomai College, 3. Institute of Low Temperature Science, Hokkaido University

Antarctic coastal polynyas (thin ice and/or low ice concentration area) are areas of high ice production due to huge heat loss to the atmosphere. Dense water formed by the high ice production is a significant source of Antarctic Bottom Water. Thin ice thickness algorithms that use satellite passive microwave data have been developed to detect coastal polynyas and estimates thin ice thickness on a daily timescale. In these algorithms, ice thickness of <20 cm is empirically estimated based on a negative correlation relationship between polarization ratio (PR) of brightness temperatures (TBs) and ice thickness (hi). However, the dispersion of the data points of PR-hi relationship was relatively large. Nakata et al. (2019) revealed that two thin ice types (active frazil and thin solid ice) cause this dispersion using AMSR-E data (2002-2011). They detected these ice types based on a PR-GR (Gradient Ratio) relationship. And thin ice thickness was estimated from PR-hi relationships for each ice type. This new thin ice algorithm can improve the accuracy of the thin-ice thickness estimation. In this study, we have examined whether this new algorithm can apply to data from AMSR2 which the successor of AMSR-E. The footprint size of AMSR2 is improved by about 85% from AMSR-E in spite of the frequency channels are the same. By adding AMSR2 data, thin-ice thickness, ice type, and ice production data set with a higher spatial resolution can be obtained from 2002 to the present.
We use TBs at 36 and 89 GHz from AMSR2 Level 1B data. The footprint sizes are 12 km ×7 km and 5 km × 3 km, respectively. Ice thickness for comparison with AMSR2 PR is derived from clear-sky thermal infrared images by MODIS with a spatial resolution of 1 km. Backscatter images acquired by C-band SAR (C-SAR) on the ESA’s Sentinel-1 satellite with a spatial resolution of 90 m are used to validate two thin ice types. We use these satellite data obtained at Ross Ice Shelf and Cape Darnley polynya areas.
AMSR2 PR-hi relationships for two ice types differs clearly as in Nakata et al. (2019). We estimate ice thickness using lines that best fit into the AMSR-E PR-hi relationships (Nakata et al., 2019) using AMSR2 data. And then, mean bias and root-mean-square error (RMSE) of the data points from the lines are calculated. The errors are slightly larger than the cases of AMSR-E data. When ice thickness is <10 cm, mean bias and RMSE for active frazil are -2.0 and 1.0 cm, respectively, while those for thin solid ice are -6.2 and 9.8 cm, respectively. For ice thickness of 10-20 cm (only for thin solid ice), the bias and RMSE are -5.9 and 9.9 cm, respectively. We also have confirmed that two ice types can be detected using AMSR2 data by a method for AMSR-E data proposed by Nakata et al. (2019). The results of this study indicate that the new thin ice algorithm for AMSR-E data can apply to the AMSR2 data.

[M-IS15] Evolution of Pelagic Realm

convener:Atsushi Matsuoka(Department of Geology, Faculty of Science, Niigata University), Katsunori Kimoto(Japan Agency for Marine-Earth Science and Technology), Toshiyuki Kurihara(Graduate School of Science and Technology, Niigata University), Tetsuji Onoue(Earth and Environmental Sciences, Graduate School of Science and Technology, Kumamoto University)

This session focuses on the evolution of ecosystem in the pelagic realms,
including discussions on all aspects of pelagic biota covering biostratigraphy,
biochronology, evolution, and biogeography, which are important to the
reconstruction of the spatio-temporal framework in the pelagic realm.
Reconstructions of plate configuration through time are included in the scope of
 this session. Biological, geochemical, sedimentological approaches to the
pelagic environments are welcomed.

REY-rich mud, a type of deep-sea sediment containing high concentrations of rare-earth elements and yittrium (REY), is widely distributed in the North and South Pacific Oceans [1]. It is expected to be a new resource of the critical elements that are essential for multiple high-tech devices and environment-friendly technologies. Recently, high-grade REY-rich mud layers have been discovered in the western North Pacific Ocean [2], whereas the formation process of the layers is still unclear.

Clarifying the depositional ages and areas of the high-grade REY-rich mud layers is the key to understanding their formation process. Regarding the North Pacific Ocean, the ages and areas of deposition of the high-grade REY-rich mud layers have been constrained recently [3,4]. In contrast, the ages and areas of deposition of the high-grade REY-rich mud in the South Pacific Ocean have been poorly understood, although high-grade REY-rich mud layers comparable to that in the North Pacific Ocean have been recognized [5,6].

In this study, based on the ichthyolith stratigraphy, we constrained the depositional age of high-grade REY-rich mud layers at the IODP Sites U1366 and U1370 that were drilled in the South Pacific Gyre [7]. Ichthyolith is a type of microfossil of fish teeth and denticles, which remains well even in deep-sea sediments beneath the carbonate compensation depth (CCD). Therefore, it has been used for age determination of pelagic clay with a paucity of typical age-diagnostic microfossils such as foraminifera or radiolaria [8]. We determined the depositional age of the high-grade REY-rich mud layers based on identification of more than 700 ichthyoliths contained in the sediments at Sites U1366 and U1370 and collation of them with the already known taxa associated with the ages. Based on the age data, we also located the depositional area of the layers by backtracking of plate motion. Consequently, we revealed that the depositional area of REY-rich mud during the Paleogene was significantly extended to the south of the present one. Moreover, based on the constrained depositional age, we suggest that the period of high-grade REY-rich mud deposition in the South Pacific Ocean likely continued for up to 50 million years, which is much longer than that in the North Pacific Ocean.

Radiolarian phylogeny around the Jurassic–Cretaceous boundary

*Atsushi Matsuoka[1]

1. Department of Geology, Faculty of Science, Niigata University

The Global Boundary Stratotype Section and Point (GSSP) of the Jurassic–Cretaceous boundary (JKB) is the last among the GSSPs in the Phanerozoic. It is defined as the base of the Berriasian Stage. Radiolarians are good candidates for defining the JKB because they are wide spread and can be found both pelagic and neritic marine environments. Pelagic sequences across the JKB have been reported in ODP/IODP sites in the western Pacific and land sections in Japan, the Philippines, southern Tibet, Iran and others. Evolutionary lineages of several radiolarian taxa across the JKB are reviewed and suitable bioevents, which are approximate to the JKB, are presented. These lineages include the radiolarian genera: *Alievium, Archaeodictyomitra, Cinguloturris, Complexapora, Crococapsa, Doliocapsa, Emiluvia, Eucyrtidiellum, Hemicryptocapsa, Hsuum, Loopus, Mirifusus, Mesovallupus, Neorelumbra, Pantanellium, Protovallupus, Protunuma, Pseudodictyomitra, Ristola, Spinosicapsa, Tethysetta, Thanarla, Vallupus, Xitus,* and *Zhamoidellum*. Among them the *Loopus–Pseudodictyomitra* lineage, the *Protovallupus –Mesovallupus–Vallupus* lineage, and *Complexapora* lineage are important phylogeny for defining the JKB.

Late Silurian and Early Devonian radiolarian assemblages from the Yokokurayama and Konomori areas in the Kurosegawa belt, Southwest Japan

*Toshiyuki Kurihara[1], Kaori Tsuchiya[2]

1. Graduate School of Science and Technology, Niigata University, 2. Faculty of Science, Niigata University

The radiolarian biozonations for the Upper Silurian to Lower Devonian in the Kurosegawa belt, Southwest Japan, were developed by Furutani (1983), Wakamatsu et al. (1990), Aitchison et al. (1996), and Umeda (1998b), based mainly upon the studies of tuffaceous clastic strata in the Yokokurayama and Konomori areas. However, the availability of only sparse data of latest Silurian to Early Devonian radiolarians in the 1990s has hampered age assignments of the radiolarian assemblages. In addition, since most information on radiolarians from this belt has come from spot localities with poor chronostratigraphic control, little is known about faunal transition during this time period.

We recognized three radiolarian assemblages (YK-1 to 3) from fine-grained portion of an alternating tuffaceous sandstone and mudstone sequence of the Nakahata Formation (Umeda, 1998a) in the Yokokurayama area. YK-1 is characterized by diverse species of inaniguttids with a large spherical outer cortical shell (200 to 300 μm), including *Oriundogutta* (?) *kingi*, *Zadrappolus yoshikiensis*, and *Fusalfanus* (?) sp. YK-2 contains *Praespongocoelia* (?) sp. and *Futobari* (?) spp., which are somewhat similar to *Futobari solidus* in their external appearances (but they differ from *F. solidus* in the cortical shell structure and spine morphology). YK-3 is characterized by the occurrences of some inaniguttids, small spherical radiolarians with short bladed spines, and *Deflantrica solidum*. Four radiolarian assemblages (KN-1 to 4) from felsic tuff and fine-grained portion of an alternating tuffaceous sandstone and mudstone in the Konomori area. KN-1 characteristically contains *Pseudospongoprunum sagittatum*. The species compositions of KN-2 and 4 are very similar to those of YK-2 and 3, respectively, and therefore they can be correlated each other. KN-3 is characterized by *Praespongocoelia robusta* and small spherical radiolarians.

The age of KN-1 is Late Silurian based on the occurrence of *P. sagittatum* (Noble, 1994; Umeda, 1998b). Considering the species composition of YK-1, characterized by large inaniguttids, this assemblage is also Late Silurian in age. In the previous study (Umeda, 1998b), the stratigraphic interval yielding YK-2 and 3, and KN-2 to 4 was subdivided into *Futobari solidus* and *Trilonche* (?) sp. A zones; however, YK-2, KN-2, and KN-3 contain no *F. solidus*. Recently, Late Silurian (Ludlovian) chitinozoans have been reported from the type locality of *F. solidus* (Ichinotani of the Yoshiki Formation in the Hida Gaien belt: Vandenbroucke et al., 2019). Therefore, the age of these assemblages is Ludlovian or younger. The palaeoscenidiid-dominated fauna (YK-3 and KN-4) is Early Devonian in age, based on the correlation with a similar fauna of the Hida Gaien belt (Sato and Kurihara, 2018 JpGU). The result of the present study suggests that a gradual faunal change from an inaniguttid-dominated fauna to a palaeoscenidiid-dominated fauna took place some time in latest Silurian to early Devonian.

Environmental changes of the North Pacific Ocean through the Cenozoic era recorded in DSDP/ODP pelagic clay cores

*Kazuhide Mimura[1], Katsushi Yamamoto[1], Kentaro Nakamura[1], Kazutaka Yasukawa[1,2], Junichiro Ohta[2], Koichiro Fujinaga[2,1], Shiki Machida[2], Yoichi Usui[3], Yasuhiro Kato[1,2]

Deep-sea sediment records paleo-environmental changes thorough geologic time. Pelagic clay, one of the most common types of deep-sea sediment, is an important medium recording changes of atmospheric/oceanic circulations and surface ocean productivity that occurred in pelagic realm [1]. Despite its importance, however, less attention has been paid to the pelagic clay than to other sediments, mainly due to the two following reasons: (1) pelagic clay lacks visible features, which hampers clarifying the stratigraphic variations within pelagic clay units, (2) determining the depositional age is very difficult due to lacks of siliceous/calcareous microfossils and difficulties in identifying paleomagnetic reversals.

Our recent studies [2,3] have shown that bulk chemical composition is a very useful tool to characterize apparently homogenous pelagic clay. We previously determined bulk geochemistry of pelagic clay samples obtained from ODP sites 1149 and 1179 in the western North Pacific Ocean [2], and compared with that from LL44-GPC3 in the central North Pacific Ocean [1]. The results indicate that pelagic clay in the North Pacific is composed of common three layers, each having characteristic major- and trace-element composition [2,3]. This suggests that the problem (1) (i.e., difficulty in stratigraphic characterization) can be solved on the basis of geochemistry. Moreover, regarding the problem (2) (i.e., difficulty in age determination), we have applied biostratigraphy of ichthyolith (microfossils of fish teeth) to constraining the depositional ages of pelagic clay at sites 1149 and 1179 [3]. These achievements suggest that the problems in using pelagic clay as a recorder of paleo-environment can be overcome.

Here, we newly determined bulk chemical compositions of pelagic clay cores at DSDP sites 576, 578 and ODP Site 886, whose depositional ages were constrained [4,5]. By combining the results with our previous data, we constructed a dataset of bulk geochemistry and depositional age of pelagic clay covering a broad area in the North Pacific Ocean. The data show that the common chemostratigraphy we have reported [2,3] is truly a general feature of pelagic clay in the North Pacific Ocean. Moreover, the integration of the geochemical features and paleogeographic reconstruction suggests that the common chemostratigraphy in the North Pacific Ocean reflects the global environmental changes through the Cenozoic era.

Reconstruction of oceanic redox conditions in the Lower Jurassic (Pliensbachian–Toarcian) pelagic deep-sea bedded chert sequence of the Mino Belt, central Japan

*Katsuhito Soda[1]

1. Department of Earth and Environmental Sciences, Faculty of Science, Kumamoto University

The Pliensbachian-Toarcian interval in the Early Jurassic is characterized by a second-order marine mass extinction and remarkable worldwide palaeoenvironmental perturbations associated with the early Toarcian oceanic anoxic event (T-OAE). However, oceanic redox conditions and palaeoceanographic processes for redox sensitive elemental accumulation are unclear in the pelagic deep-sea realms of the Panthalassic Ocean. Here we show geochemical and multivariate statistical analyses in the pelagic deep-sea sedimentary rocks of the Panthalassic Ocean during the Pliensbachian-Toarcian. Three principal components (PC1, PC2, and PC3) in the redox sensitive elements explained 88.64% of the total variance. The PC1 represents the comprehensive redox variations, whose stratigraphic variations show euxinic-anoxic conditions across the Pliensbachian/Toarcian (Pl/To) boundary layer and the classical T-OAE. The PC2 depicts the sorption processes of Fe-Mn oxide minerals with transition elements, whose stratigraphic variations suggest few drawdowns of the transition elemental inventory after the Pl/To boundary layer. The PC3 delineates the active particulate shuttles by Fe (-Mn) oxide minerals, whose stratigraphic variations indicate the strong activation between the Pl/To boundary layer and the classical T-OAE. The statistical extraction of both the PC1 and the PC3 support the characteristic phenomena in the pelagic deep-sea realms of the Panthalassic Ocean under the relatively strong reductive conditions.

Conodont biostratigraphy of Anisian pelagic deep-sea sedimentary rocks deposited in the pelagic Panthalassa—Integration with radiolarian biozones—

*Shun Muto[1], Satoshi Takahashi[1], Satoshi Yamakita[2], Katsuhito Soda[3], Tetsuji Onoue[3]

1. Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo, 2. Faculty of Education, University of Miyazaki, 3. Faculty of Advanced Science and Technology

The age of pelagic Panthalassic deep-sea sedimentary rocks such as bedded chert and claystone has been assigned based on radiolarian biozones. However, Middle Triassic radiolarian biozones of pelagic Panthalassic deep-sea strata are not precisely correlated to the standard geological timescale. In order to establish a direct correlation between the pelagic Panthalassic radiolarian biozones and the standard geological timescale, we investigated conodont biostratigraphy in two radiolarian-controlled bedded chert sections of Anisian age: the Ajiro Island section in Oita Prefecture and the Kurusu section in Aichi Prefecture. We recognised six conodont biozones in the studied sections: the upper Olenekian *Novispathodus brevissimus-Icriospathodus collinsoni* and *Triassospathodus homeri* Zones, the lower Anisian *Chiosella timorensis* Zone, the middle Anisian *Paragondolella bulgarica* Zone, the upper Anisian *Paragondolella excelsa* Zone and the uppermost Anisian to lowermost Ladinian *Paragondolella trammeri* Zone. Based on the recognition on these conodont zones, we reassessed the age of the Triassic radiolarian biozones defined by Sugiyama (1997, *Bull. Mizunami Foss. Mus.*, vol. 24, p. 79–193). Sugiyama’ s radiolarian TR 1 Zone, previously considered to be of Olenekian age, extends to the middle Anisian. The TR 2A Zone, the TR 2B Zone and the lower part of the TR 2C Zone are correlated to the middle Anisian, while the upper part of the TR 2C Zone and the lower part of the TR 3A Zone are correlated to the upper Anisian. The upper part of the TR 3A Zone and the lower part of the TR 3B Zone are probably correlative to the uppermost Anisian, but the possibility that they are correlative to the lowermost Ladinian cannot be ruled out.

Pelagic cherts preserved in accretionary complexes represent former seafloor sediment that can retain geochemical evidence of paleoceanographic conditions that predate the oldest extant oceanic crust. The ratio of Os isotopes in seawater, in particular, is of wide interest as a source of insight into notable geologic events such as oceanic anoxic events, rapid global warming episodes, and eruption of large igneous provinces, but marine Os isotope records from before 80 Ma are scarce. We present a record of secular variations of marine Os isotope ratios from a thick, continuous succession of Middle and Upper Triassic pelagic chert in the Sakahogi section of the Mino Belt accretionary complex.

The preservation of radiolarians across the Jurassic-Cretaceous (J/K) boundary in the Bosso Valley section, Central Italy

*XIN LI[1], Atsushi Matsuoka[2], Angela Bertinelli[3], Marco Chiari[4]

1. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, 2. Niigata University, 3. Università degli Studi di Perugia, 4. Istituto di Geoscienze e Georisorse

The Bosso Valley section is located near the Pianello-Cagli road and follows the Bosso River in the Umbria-Marche area of the Central Italy. The pronounced increase in abundance of *Calpionella alpina* documented at the base of *Calpionella* zone was accepted as the Jurassic–Cretaceous boundary (JKB) indicator in the Bosso Valley section. The magnetostratigraphical record of the JKB has been correlated with the *Calpionella* zone. The JKB is placed between Beds 77 and 78 (Housa et al. 2004). The Maiolica Formation, which crosses the JKB, is characterized by whitish, beige to gray colored, well-bedded limestones with abundant black to gray chert layers and chert nodules and marly intervals. Certain horizons in the Bosso Valley section yield well-preserved radiolarians, significant for the correlation of deep marine sediments. In order to establish radiolarian biostratigraphy across the JKB, detailed study was conducted to elucidate relationship between lithology and preservation of radiolarians in the Bosso Valley section.

Thin sections of 19 samples were observed to elucidate the relationship between lithology and preservation of radiolarians. Three samples of micritic limestone below the JKB (Beds 73, 75, and 77) and two samples above the JKB were collected for analyzing. The limestone samples were immersed in 10% hydrochloric acid for 30 to 60 minutes, then washed, dried and examined under a binocular microscope and a scanning electron microscope.

Radiolarians are abundant both in the chert bands or nodules and in the limestone. Preservation of radiolarians varies in different parts because of the diagenesis. Surfaces of etched limestone are observed and divided into different parts, based on the preservation of radiolarians. Radiolarians are generally calcified in the pure lime beds. Radiolarians are generally bad preserved in the chert bands or nodules. Well-preserved radiolarians are located inside the lime part near the chert bands or nodules. Primary results of radiolarian assemblages near the JKB are proposed. Limestones near chert layers or nodules in the Bosso Valley section enable radiolarian biostratigraphic study across the JKB.

Radiolarian faunas around the Jurassic-Cretaceous boundary in the Bosso Valley section, central Italy

*Atsushi Matsuoka[1], XIN LI[2], Marco Chiari[3], Angela Bertinelli[4]

1. Department of Geology, Faculty of Science, Niigata University, 2. Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciense, 3. C.N.R., Istituto di Geoscienze e Georisorse, sede secondaria di Firenze, 4. Dipartimento di Fisica e Geologia, Università degli Studi di Perugia

The Global Boundary Stratotype Section and Point (GSSP) of the Jurassic–Cretaceous boundary (JKB) is the last among the GSSPs in the Phanerozoic. It is defined as the base of the Berriasian Stage. The formal definition was decided in 2016 to use the base of the *Calpionella alpina* Subzone as the primary marker by the Berriasian Working Group in the International Subcommission on Cretaceous Stratigraphy. The definition is satisfactorily applicable for shallow marine deposits within the western Tethys, north Atlantic and central-south America. Unfortunately, the primary marker taxon cannot be found in the Pacific and circum-Pacific regions because of the limited distribution of *Calpionella*. To determine the base of the Berriasian outside of the *Calpionella* territory, alternative markers are needed.

Radiolarians are good candidates for defining the JKB because they are wide spread and can be found both shallow and deep sedimentary facies. Pelagic sequences across the JKB have been reported in ODP/IODP sites in the western Pacific and land sections in Japan, the Philippines, southern Tibet, Iran and others. Evolutionary lineages of several radiolarian taxa across the JKB are reviewed and suitable bioevents, which are approximate to the JKB, are presented. The *Loopus–Pseudodictyomitra* lineage can be the most important phylogeny for defining the JKB.

The Bosso Valley section in Umbria–Marche, central Italy, is one of potential candidates for GSSP of the JKB. The Maiolica Formation, which crosses the JKB, is characterized by whitish, beige to gray colored, well-bedded micritic limestones with abundant black to gray chert layers and nodules. Calpionellid stratigraphy and magnetostratigraphy have been studied sufficiently in the section. The base of the *Calpionella alpina* Subzone, i.e. the JKB, is placed between Beds 77 and 78. We carried out detailed field observations and careful sample collections in a 4-m interval across the JKB. Acid-etched examination of rock samples revealed that well-preserved radiolarians are recognized inside the lime part near the chert layers or nodules. Several samples of micritic limestone below and above the JKB yield well-preserved radiolarians. The result of radiolarian faunal analysis in the Bosso Valley section is presented.

[M-IS17] History X Earth and Planetary Science

convener:Yasuyuki Kano(Earthquake Research Institute, The University of Tokyo), Kei Yoshimura(Institute of Industrial Science, The University of Tokyo), Hiroaki Isobe(Faculty of Fine Arts, Kyoto City University of Arts), kiyomi iwahashi(National Institute of Japanese Literature), Chairperson:Yasuyuki Kano(東京大学 地震研究所), Kiyomi Iwahashi, Hiroaki Isobe, Kei Yoshimura, Harufumi Tamazawa

The history of modern observation in earth and planetary sciences is often far shorter compared with the timescales of their interests. Investigation of the long-term variations and occurrences of extremely rare events requires effective use of information before modern observations. Historical documents recorded by diverse kinds of authors in various situations are the important sources of such information.

Thus, historical documents have been referred in various fields of earth and planetary sciences such as seismology, climatology, meteorology and astronomy. Sharing their records, methods and experiences will be beneficial for each field and bring new insights. It is also essential to involve experienced scholars in history because one needs to carefully investigate the reliability and the context of each document in order to use it as scientific data. On the other hand, analyzing the record in the historical documents with the eyes of modern science may also bring new insights to the history scholars.

In this session we overview the studies using the historical documents in various fields of the earth and planetary sciences as well as the recent advances in related topics such as digital humanities and historical-data assimilation. The aim is to promote the communication and dialogues among the researchers in various background, and thus foster the new ideas and collaborations in the study of "History X EPS."

Document based reconstruction of environment of forests in the Edo period

*SATOSHI SHIROUZU[1]

1. Chuogakuin University

Edo period is sometimes praised as the people had lived sustainably in harmony with nature. However, the people not necessarily lived sustainably. For example, excess usage of natural resources leaded to exhaustion of the resources.

There is a category of historical document called “O-Hayahi-Kakiage-Cho” or register of official forests. The “O-Hayashi” or the official forest is a forest controlled by Tokugawa shogunate or local feudal government, which could not be used by ordinary people. Maintenance of the forest was assigned to local people, “O-Hayashi-Mori” who made the register. The register contains the data such as kind or name, thickness, highlight, and number of woods. While the register itself is boring document for historians, it is a mine of data for dendrologists. The register describes a condition of the forest over a few hundred years ago, which helps dendrologists to reconstruct the environment of the forests. Dr. Yasuhiro Koyama showed that most of the official forest in northern part of Shinano province, or Nagano Prefecture, were sparse woods with Japanese red pine of 20-30 cm diameter. The official forests in the region were not green nor rich. By contrast, “Sendou-O-Hayashi” in the same region corresponds to Sakae village showed totally different environment. The forest had a spread of 13.5 ha. 70% of the woods were Japanese oak and beech. There were over 56 woods with diameter of 2 m. 1615 of woods had circumference over 3 m which corresponds the definition of “giant tree” by Ministry of the Environment. The forest was the one with a grade of Natural monuments today. It is surprising that there was such a rich forest in Japan only 200 years ago. Natural environment of Japan seemed to foster the rich forests. The rich forests have been lost because of deforestation by human. This is a good example to show the importance of human activities on condition of natural environment.

Rapid deforestation at nonofficial forests leads to exhaustion of useful woods. All the useful woods such as Japanese cedar and arborvitae had been cut down around Akiyama district until late 19 century. A historical document reported that only useless woods such as Japanese beech, oak, or chestnut remained. The people of Akiyama district demanded conifers to make wooden products such as bucket. After difficulty to obtain material, people changed their mind to use broadleaf trees and started to make bowl and plow etc. The useless woods turned to main material for production. Although they overcame the difficulty, they continued deforestation as they wrote on a document that the desire of human was limitless.

Incorrect or false descriptions are found from the close examination of the registers. There are same numbers of woods on registers recorded at different time. The person in charge seemed to alter the number for fear of meeting criticism for insufficient management. This example shows that historical records are product of “human.” The true value of historical science is to reveal the activity and society of human. The examination of historical documents on the assumption of the human nature or the procedure of information evaluation increase the value of the historical documents as data.

Studies of Babylonian Astronomical Diaries: Today and the Future

*Yasuyuki Mitsuma[1]

1. The University of Tokyo

The presenter uses a large group of Akkadian cuneiform texts on clay tablets, the Astronomical Diaries from ancient Babylonia (mainly from Babylon) as the main source of his presentation. The text group is called ADB in this presentation. ADB is a large series of clay tablets recording astronomical and meteorological phenomena, commodity prices, level of the Euphrates, and historical events from the seventh to the first centuries BC. The clay tablets of ADB count up to over 1500, but only about 400 tablets have been published for the use of researchers. The presenter stayed in London for two years and consulted and photographed most of the unpublished tablets of ADB, which are now preserved in the British Museum. He also took photos of a considerable amount of published ADB tablets. Basesd on the photos and additional data of ADB tablets, the presenter will publish the (new and more exact) texts of published and unpublished ADB tablets. The presenter will also colloborate with some researchers and provide them with the astronomical and meteorological data of ADB, which are useful for the restoration of the ancient astronomical phenomena and climate.

Characteristics of the Sunspots that Produce Large Solar Flares and the Possibility to Investigate these Events Utilizing Historical Observational Records

*Shin Toriumi[1]

1. National Astronomical Observatory of Japan

Solar flares are the sudden releasing of magnetic energy and, among them, the energetic ones that occur around the sunspot regions may directly and indirectly affect the Earth through the enhancement of electromagnetic waves, releasing of high energy particles, and coronal mass ejection. While it is accepted that the strongest flare activity ever observed is the "Carrington event" in September 1859, in order to understand the mechanisms and trends of such extreme space-weather events, it is crucial to increase the sample number of the events with enough observational data and conduct statistical investigations. Although often these events do not have observations of sufficient data quality for modern scientific analysis, there are several ways to elucidate how and why the strong events occurred. In this presentation, we first show the morphological and magnetic characteristics of flare-productive sunspots that are revealed by observational data analysis of sunspots in Solar Cycle 24 (especially for six years from 2010) and by magnetohydrodynamic simulations to model these sunspots. Then, we introduce several research attempts to reconstruct magnetic activities by using historical documents such as sunspot drawings. Finally, we discuss the the possibility to investigate extreme space-weather events by applying our modern knowledge of flare-productive sunspots to extreme events in history.

An Approach of Environmental History to the "14th Century Crisis"

*Isahaya Yoichi[1]

1. Slavic-Eurasian Research Center, Hokkaido University

This paper is an introduction to an approach of environmental history to the “14th Century Crisis.” The “14th Century Crisis” is the term for collective peril in the 14th century which is considered to be the time of transition from the Medieval Warm Period (ca. 1000–1300) to the Little Ice Age. The peril consists of cooling, natural disasters, epidemics and political upheaval such as the fall of the Mongol Empire (1206–1368). Our project embarks upon interdisciplinary collaboration between sciences (astronomy, meteorology, and seismology) and humanities (history and archival science) to elucidate an actual phase of the crisis. In the context of world history, the “14th Century Crisis” has attracted scholarly attention as the pivot that closed the multi-centered “13th Century System” across Afro-Eurasia, and paved the way for the European-centered “Modern World-System.” The grand shift, however, could not be calibrated properly without taking account of the environmental transition to the Little Ice Age. This is an introductory remark of our project aiming to shed some new light upon entangled relationships between human development and environment.

Hokkaido University, 7. Senshu University, 8. Meteorological Research Institute, 9. NARO/NIAES, 10. Yamaguchi University, 11. Osaka University, 12. EScoT

In most of the countries in monsoon Asia, the meteorological observations by modern instruments started during their colonial period before the World War II. However, most of these old meteorological data have not been digitized yet, and have not been utilized in the past climatic change researches. Here, we will briefly introduce our recent data rescue activities mainly for the daily precipitation data in the Former British India, China, Philippines, Vietnam, and Japan for the recovery of the past Asian monsoon variations since the late 19th century as one of the activities in the ACRE (Atmospheric Circulation Reconstruction over the Earth) project. Although with the aid of the World Meteorological Organization, the National Oceanic and Atmospheric Administration archived the scanned images of huge data books all over the world, it was sometimes very difficult to read the numerals in the scanned data. The original data books/sheets are needed for the accurate digitization of the old data. Acknowledgments: Part of this study was supported by The JSPS KAKENHI (25282085,26220202,15K16283,18K19951, 18H01681), The GRENE program of the MEXT. Discussion

Historical big data: integrated analysis of the past world by the workflow that bridges data structuring gaps

*Asanobu Kitamoto[1,2,3], Mika Ichino[1,2]

1. National Institute of Informatics, 2. ROIS-DS Center for Open Data in the Humanities, 3. SOKENDAI

1. Introduction

Reconstruct and analyze the past world through the extraction and integration of information from the past books and documents –we call this type of historical research as “historical big data.” This is because this approach has the same structure and purpose with “modern big data” on the current world, and it is meaningful to extend this approach into the past world. A big obstacle, however, is in data structuring. We start from data written in Kuzushiji (cursive scripts) on historical documents to high quality data usable for computaitonal analysis of the past world. For this purpose, we need information infrastructure to support this long data structuring workflow from digitzation to quality control. Because this is difficult to automate, we need efficient data structuring workflow based on human-machine collaboration. We therefore design a workflow to convert non-structured data (e.g. image and text) to structured data (analysis-ready data) and develop information platform for humanities dataset that is reusable and verifiable.

A similar but bigger project has started in EU called “Time Machine Flagship” involving more than 200 organizations. The project is building “time machine” to move freely within spatio-temporal space, especially within the big data of cities such as Venice in Italy and Amsterdam in the Netherlands. This trend has not been incorporated in Japan and Asia, so our platform may also be an entry point for this global initiative.

2. Issues

Many research projects for reconstructing the past have been carried out, but historical big data is a different approach in terms of the following.

First, the type of data is different. For example, paleoclimate research uses any data related to climate; not only books and documents, but also traces in the nature (proxy data such as ice core and growth ring). On the other hand, historical big data limits its scope on records written by human, and focuses on developing new data structuring workflow including the interpretation of textual records.

Second, the target of discipline is different. Research in one discipline had a tendency of focusing only on a limited type of phenomena, and did not pay attention to other phenomena. Even when researchers are studying the same diary, bibliographic data or extracted data were not shared across research groups, and many researchers repeated similar tasks again and again. To solve this problem, historical big data offers data structuring workflow that is effective across disciplines, and enables research that takes advantage of data sharing.

3. Data crossing and re-interpretation

To extend the modern big data into the past, relevant issues are not only the extension of technologies

©2019. Japan Geoscience Union. All Right Reserved.

but also concepts and methodologies.

First, data crossing is a methodology to overlay different data to find unexpected relationship. A typical example is a map. By registering and overlaying data from different sources, we can take actions based on insights obtained from data. Here important challenges include the interoperability of API and sharing of terminology. To solve this challenge, we share future challenges within our research group, take advantage of the strength of each member without overlapping tasks, and develop information infrastructure maximizing the outcome within limited resources.

Second, data re-interpretation is a methodology to find effective reuse of data collected for one purpose into another purpose. A famous example in the modern big data is the case of reusing car probe data for the map showing passed routes after earthquake disasters. A same approach should be effective for historical big data. For example, is it possible to use the change of bureaucrat's directories for evaluating societal impact by climate change? Flexible imagination may lead to the creative usage of data.

4. Beyond “One Bed Multiple Dreams”

Historical big data is a multidisciplinary research. Of course, a big gap exists between humanities and science/technology, but difference within science and technology disciplines are not negligible. How to go beyond these gaps? Our basic idea is to recognize that we are in “one bed multiple dreams” situation in the sense that each member in the research group has a different dream. But at the same time, we recognize the advantages of being in one bed. For example, data and tools can be shared even if we have different dreams. After maximizing the advantages of sharing, an individual researcher tackles the reconstruction of a different part of the past world –this is the concept of historical big data research.

Felt earthquakes in Tokyo (Edo) based on historical daily records and seismic intensity data

*Kenji Satake[1]

1. Earthquake Research Institute, University of Tokyo

There have been three generations of collection and publication of historical materials on earthquakes. They are “Dai-Nihon Jishin Shiryo (Collection of Historical Documents on Earthquakes in Great Japan)” in 1904, “Zotei Dai-Nihon Jishin Shiryo” and “Nihon Jishin Shiryo” in 1941-1951, and “Shinshu Nihon Jishin Shiryo” in 1981-1991. On the basis of these collected materials, annual number of felt earthquakes in Tokyo (formerly Edo) was examined by Usami (1979, CCERP report) and Usami and Watanabe (2005, 2006, Historical Earthquakes). Number of felt earthquakes strongly depends on the available materials. The above collections contains some daily records of clans which documented daily weather and earthquakes, and the recorded earthquakes include small shocks or aftershocks of large damaging earthquakes. In order to discuss temporal changes of seismicity, such homogeneous records should be used. In this study, number of yearly earthquakes in several daily records are counted, and compared with seismic intensity data of Japan Meteorological Agency since 1885.

Among the daily records during the Edo period (1603-1867), “Tsugaru-han On-nikki” recorded the largest number of felt earthquakes; approximately 1550 events during 200 year period between 1668 and 1866. However, there are several years during which no earthquake was documented. The next one is “Sakaki-bara Nikki”, which documented approximately 700 events during 200 year period between 1651 and 1859. This record also contains years without any earthquake, but such years are different from those of the previous record. By merging these two daily records, there are only few years without felt earthquakes. For the earlier Edo period, “Edo-bakufu Nikki” (two different sources) cover more or less continuously from 1631 to 1707 with 680 earthquakes. In addition, several other records such as “Tsushima-han Mainichiki”, “Inaba-shi Eidai Nikki” or “Sakai-ke Shiryo” each documented more than 100 earthquakes. Yearly number of earthquakes were counted for each record, and the largest number for each year was selected. The dataset thus made contain nearly 2500 earthquakes for 241 year period (1628-1868) with annual average of about 10 events. The yearly record has several peaks in 1704 (about 60 events), in 1855 (about 50 events) and in 1649 (about 50 events). These represent aftershocks of the 1703 (31 December) Kanto earthquake, 1855 Edo earthquake and two M7 earthquakes in 1649.

Seismic intensity data since 1885 has been complied by JMA (Ishigaki and Takagi, 2000, Quarterly J. Seismology; Ishigaki, 2007, ibid), which shows that the annual number of earthquakes with intensity 1 or larger, 2 or larger, 3 or larger are 52, 16 and 5, respectively. If we assume that the seismic intensity rate is constant in the last 400 years, then the above merged historical daily data recorded felt earthquakes with intensity 2 or larger. The JMA data show that the largest number of felt earthquakes was recorded in 2011, with 148 events with intensity 2 or larger, representing aftershocks and triggered seismicity by the Tohoku earthquake. Numbers of earthquakes with intensity 2 or larger were 36 and 35 in 1923 and 1924, following the Taisho Kanto earthquake. Combining the historical data from daily records, it is concluded that the number of felt earthquakes was largest in 2011 in the last 400 years.

Climate and social changes in ancient Japan construed by use of high resolution reconstruction of the Climate in Historical Time

*Katsunori IMAZU[1], Takeshi Nakatsuka[2]

1. OKAYAMA University Graduate School of Humanities and Social Sciences, 2. Research Institute for Humanity and Nature

This study focuses on ancient times of Japan, specifically the 8th and 9th Century in an attempt to clarify how the weather impacted societies then. Takeshi Nakatsuka developed per-annum reconstruction of climate for that period of time, which revealed that the 8th Century was, in general, relatively dry but stable, whereas the second half of the 9th Century turned to be unstable and wet, then in the 10th Century the weather changed to dry. Historical literature including Shoku Nihongi (second of the six classical Japanese history texts)、Nihon Kouki (third of the six classical Japanese history texts), Shoku Nihon Kouki (fourth of the six classical Japanese history texts), Nihon Montoku Tenno Jitsuroku (fifth of the six classical Japanese history texts), and Nihon Sandai Jitsuroku (sixth of the six classical Japanese history texts) described history of said period and included the description of the weather then. However, they are very brief and do not provide precise details as to the severity of drought, spells of rain or torrential rain. At long last, high-resolution weather reconstruction helps to bring clarity to the level of extreme dryness and humidity of summer and the damage they brought about, when we review historical documents. Additionally, the deeper understanding of the mid- to long-term weather pattern changes helps to visualize the interrelationship between the climate change and changes in the state and societies.

In this research, our interest, in particular, lies on demographic change and social system transformation in ancient times. In the early 8th Century Taiho Code was enacted and a centralized government established a political system based on the Ritsuryo Codes, which demonstrated their intent to emulate the system in China. The systems set forth by the Ritsuryo-Code-based-nation laid the foundation for the framework of Japan and played an essential role in defining the subsequent development of its history. The population that the state of the Ritsuryo Codes ruled is estimated to be around 4.5 million at the beginning of the 8th Century and approximately 5.5 million at the beginning of the 9th Century, with the average population growth rate from the 8th to 9th Century being 0.2% per annum. The population in the 17th Century, the beginning of the Edo era, is estimated as 12-18 million. The population slightly increased from the ancient times to early modern times. The yearly population increase over a course of 800 years from the mediaeval to early modern times was only 0.1-0.15% at best. Ancient Japan was frequently visited with plague and famine, which kept the nation highly fluid and vulnerable. Despite this situation, yet the population growth was at a higher rate comparing to the middle ages. This is considered due in part to a high functioning reproductive system set forth by the Ritsuryo system in which the central government exercised control over the people's lives and rice paddies and also by a relatively stable weather in the 8th Century.

Changes in Tang dynasty and Shilla, the neighboring countries of Japan, affected the Ritsuryo system in Japan, which collapsed little by little. The Ritsuryo-based-nation considerably changed from the late 9th Century to late 10th Century. These social changes were triggered by the changes in the overseas political landscape in its vicinity as well as the climate change. In the second half of the 9th Century they faced problems of the rise of non-arable rice paddies and flooding of rice fields. We are convinced that the climate change resulting in the humidity level increase of the land was at the root of these problems at that time. The Ritsuryo system started to give up on its exercise of control over its people and rice fields, thereby the reproductive system of the Ritsuryo state broke down. It was exacerbated by frequent

©2019. Japan Geoscience Union. All Right Reserved.

earthquakes, a volcano eruption, famine and pandemic, all of which occurred during the same time frame. It was a time of crisis for ancient Japan as a whole. The nation under the Ritsuryo codes established a centralized government at the beginning of the 8th Century, but in the late 9th Century and onwards it started to collapse and the central government was contracted into a dynastic state in the capital of Heiankyo.

Absolute ages for huge eruptions of Towada Caldera and Baitoushan volcano in the 10th century as seen from dendrochronological studies and historical documents

*Masataka Hakozaki[1], Fusa Miyake[2], Masaki Sano[3], Katsuhiko Kimura[4], Toshio Nakamura[2], Mitsuru Okuno[5], Minoru Sakamoto[1], Takeshi Nakatsuka[6,2]

1. National Museum of Japanese History, 2. Nagoya University, 3. Waseda University, 4. Fukushima University, 5. Fukuoka University, 6. Research Institute for Humanity and Nature

The Towada Caldera (Aomori Prefecture / Akita Prefecture) and Baitoushan volcano (China / North Korea) each caused a huge eruption in the 10th century, respectively. These traces are clearly left behind in the stratum of the northern Japan as To-a tephra and B-Tm tephra. These two eruptions are estimated to be one of the largest in Japan and the world in the past 2000 years, respectively (Hayakawa & Koyama 1998). However, direct document records of these eruptions have not been found from any countries around the volcano. For that reason, these absolute ages had long been unknown. Also, due to uncertain age, the impact on human society and the global environment of these eruptions has not been evaluated.

Recently, the absolute age of the 10th century eruption of Baitoushan volcano was decided in AD946(Oppenheimer et al. 2017, Hakozaki et al. 2018). It was achieved by "^{14}C-spike matching" which is applied a rapidly carbon-14 increase event in AD775 discovered from tree-rings of Japanese trees (Miyake et al. 2012). And this age was also verified by the result of the oxygen isotopic dendrochronology (Kimura et al. 2017). Hayakawa and Koyama (1998) picked up this age (AD946) from descriptions suggesting distant eruptions written in a few old documents of Japan and Korea (ex. "Kofukuji-nendaiki", "Goryeosa") .

On the other hand, due to fixed in AD946 the absolute age of B-Tm, doubts occurred in the age of 10th century eruption of the Towada caldera. The 10th century eruption of Towada caldera had been estimated to be AD915 according to the description on the "Fuso Ryakuki" suggesting the eruption, and the dates of archaeological timbers buried in the lahar at Akita prefecture. Based on this age, the varves at lakes in Akita prefecture counted between To-a and B-Tm to be 14 layers, Kamite et al(2010) estimated the eruption age of Baitoushan volcano to be AD929. However, since the absolute age of B-Tm was AD946, as described above, it became clear that there was a gap of 17 years from Kamite et al's estimates. In other words, there is a possibility that the 10th century eruption of Towada caldera may be AD932. If this is correct, there is a possibility that the description of AD 915 in the "Fuso Ryakuki" indicates the eruption that occurred in volcanoes other than Towada caldera.

Recently, the oxygen isotopic dendrochronology was applied to the timbers of the fence of Tagajo site of Miyagi prefecture, and the absolute age was decided to be AD917 (Saito et al. 2018). In the archaeological survey, this fence has been thought to be built before the ash fall of To-a tephra (AD915) (Miyagi prefectural research institute of the Tagajo site 2018). The fact that the tree-ring of the AD917 was recognized in the timbers of the fence largely contradicts the estimated age (AD915) of To-a tephra. Furthermore, neither bark nor sapwood remained in these timbers, and it is clear that the logging year is later than AD917.

In this presentation, we show how the ages of timbers of Baitoushan volcano and Tagajo site determined

How can we activate collaborations with history and archaeology? –Lesson from Historical Climate Adaptation project

*Takeshi Nakatsuka[1,2]

1. Research Institute for Humanity and Nature, 2. Graduate School of Environmental Studies, Nagoya University

Introduction

Earth and planetary sciences belong to historical sciences dealing with past natural and human phenomena as well as history and archaeology. Although many inter-disciplinary researches have been conducted between them, there are a lot of problems originating from differences of their essential philosophy. Here, I will discuss how to activate collaborations with history and archaeology based on my experiences as the leader of “Historical Climate Adaptation Project” in Research Institute for Humanity and Nature (RIHN) from 2014 to 2018.

Fundamental Strategy of the Project

RIHN is an inter-university research institute, accepting many research proposals aiming to solve a global environmental problem by inter-disciplinary approaches between natural and human sciences. In the framework of RIHN, we created three steps of research strategies. 1) To reconstruct variations in past climate at annual resolution for last several millennia in Japan. 2) To compare paleoclimate data with numerous historical and archaeological archives. 3) To elucidate characteristics of societies resilient or vulnerable to climate changes by comparing many historical cases. Although I initially imaged the unidirectional data provision from paleoclimatology to history and archaeology except for the study of historical climatology, the inter-disciplinary communications actually made unexpected progress in the paleoclimatology, especially in the establishment of super-long chronology of tree-ring cellulose oxygen isotope ratio.

Results of Inter-Disciplinary Collaboration

Tree-ring cellulose oxygen isotope ratio is a novel proxy to reconstruct past summer precipitation precisely even in humid and temperate areas like Japan where traditional dendroclimatology was not very successful. We planned to establish the long-term datasets over Japan. At the beginning, historians and archaeologists were regarded as users of the data, but they actually contributed to the creation and refinement of data by various ways. After receiving the data, they answered to paleoclimatologists as follows. (1) Active provisions of excavated woods and old architectural woods for isotopic analyses. (2) Critical evaluation of the paleoclimate data from the viewpoint of history and archaeology. (3) Request to improve the resolution and extension of paleoclimate data. Paleoclimatologists welcome (1), but it was not easy to answer to (2) and (3) because such criticisms and requests are not usually originating from themselves. However, the request (3) finally made us enable the tree-ring based millennial scales climate reconstruction, by combing the tree-ring oxygen and hydrogen isotope ratios, which were validated by critical evaluations of historians and archaeologists (2). It promoted many studies in paleoclimatology, history and archaeology. However, it was not easy to elucidate “societal systems resilient to climate change” because we had not shared the research purposes between natural and human sciences.

Conclusion

©2019. Japan Geoscience Union. All Right Reserved.

The unprecedented length and precision of paleoclimate data are the results of active inter-disciplinary communications. Although the unidirectional data provision was not successful, the critical interactions improved both the data quantity and quality. On the other hand, the sharing of research philosophy between natural and human sciences was necessary to promote “real inter-disciplinary” research. In the project, I found the fact that historians and archaeologists do not usually study history to solve contemporary problems. Rather, they focus on the difference in people’s sense of values between past and present. Because the future must be different from the present as well as the past, it is very important to promote collaborations between natural scientists who seek the universality in history and human researchers who understand the diversity of history in order to make sustainable society. That was my most important finding in the project.

"History X EPS" is a title of this session as well as the name of the application area proposed for Grant-in-Aid for Scientific Research on Innovative Areas. The application area consists of 4 sub area: “Ten” (astronomy), ”Ki” (climatology and meteorology), ”Chi” (solid earth science), and ”Jin” (human and society).

Historians and researchers of earth and planetary sciences have been collaborated in the preceding projects. There are a number of projects for such interdisciplinary collaboration. Here we present prospects of "History X EPS." The scope of the session is as follows:

The history of modern observation in earth and planetary sciences is often far shorter compared with the timescales of their interests. Investigation of the long-term variations and occurrences of extremely rare events requires effective use of information before modern observations. Historical documents recorded by diverse kinds of authors in various situations are the important sources of such information.

Thus, historical documents have been referred in various fields of earth and planetary sciences such as seismology, climatology, meteorology and astronomy. Sharing their records, methods and experiences will be beneficial for each field and bring new insights. It is also essential to involve experienced scholars in history because one needs to carefully investigate the reliability and the context of each document in order to use it as scientific data. On the other hand, analyzing the record in the historical documents with the eyes of modern science may also bring new insights to the history scholars.

In this session we overview the studies using the historical documents in various fields of the earth and planetary sciences as well as the recent advances in related topics such as digital humanities and historical-data assimilation. The aim is to promote the communication and dialogues among the researchers in various background, and thus foster the new ideas and collaborations in the study of "History X EPS."

Reexamination of intensity distribution of Japanese historical earthquakes using attenuation relation

*Yasuyuki Kano[1], Junzo Ohmura[2]

1. Earthquake Research Institute, The University of Tokyo, 2. Diasaster prevention Research institute, Kyoto University

Sources of historical earthquakes are usually estimated from seismic intensity distributions based on the descriptions on historical documents. Ceaseless efforts to collect historical earthquake documents leads to sourcebooks such as Dai-Nihon Jishin Shiryo (Collection of Historical Documents on Earthquakes in Great Japan) (Tayama, 1904a,b), Zotei Dai-Nihon Jishin Shiryo (Collection of Historical Documents on Earthquakes in Great Japan, Enlarged and Revised Edition) (Musha, 1941, 1943a,b), and Shinshu Nihon Jishin Shiryo (Historical Documents on Earthquakes in Japan, New Collection) (Earthquake Research Institute of the University of Tokyo, 1981-1994) etc. The location of epicenter or hypocenter, origin time, and magnitude of the historical earthquakes are estimated utilizing the descriptions in the sourcebooks. Conversion table from description of damage of building etc. to seismic intensity is used to derive seismic intensity distribution. The location and magnitudes are estimated by drawing isoseismals. The basic procedure for identification of historical earthquakes are: (1) discovery and transcription of historical documents describing earthquake, (2) estimation of intensity distribution from the description, and (3) estimation of epicenter or hypocenter and magnitude. Attenuation relation of seismic intensity can be used to (1)-(3).

Although plenty of historical earthquake documents are published as the sourcebooks mentioned above and used for preceded researches, more historical documents are necessary to know details of historical earthquakes. One possible collaboration between historians and seismologists is search for historical documents related to earthquakes. An exhaustive search for large earthquakes is sometimes hard to be done, because damaged or felt area become wide for the large earthquakes. Seismic intensity of historical earthquake can be estimated assuming attenuation relation and location and magnitude of the earthquake. We can make an effective search plan for historical documents based on the estimated seismic intensity distribution.

Various conversion tables are suggested to estimate seismic intensity of historical earthquake from damage description in historical documents. The tables correlate, for example, the extent of building damage or rate of the damage to seismic intensity. We examined the validity of a conversion table using the damage of cultural property by the earthquakes including the one occurred in northern part of Osaka. Based on the conversion table, the damage of cultural properties was converted to seismic intensity. The estimated seismic intensity is consistent with distribution of seismic intensity at the locations of the cultural properties predicted by attenuation relations.

Attenuation relation of seismic intensity can be used for estimation for location of epicenter or hypocenter. The magnitude of an earthquake can be estimated by fitting attenuation relation to spatial distribution of seismic intensity. The location and magnitude of Japanese historical earthquake are estimated using attenuation relation, which is consistent with the location and magnitude obtained by preceded studies.

Rekisuke: a system for sharing bibliographic information of historical documents through Interdisciplinary collaboration

*Mika Ichino[1,2], Yukie Hashimoto, Kooiti Masuda[3], Asanobu Kitamoto[2,1], Junpei Hirano[4]

1. Center for Open Data in the Humanities, Joint Support-Center for Data Science Research, Research Organization of Information and Systems , 2. National Institute of Informatics, 3. Tokyo Metropolitan University, 4. Faculty of Liberal Arts, Teikyo University

The records of numerous historical documents in Japan have been used for research in diverse scientific fields ranging from seismology, climatology and astronomy, to humanities, social sciences and historical studies. Unfortunately, when processing and applying information found in historical documents for the purpose of scientific research, the one may encounter certain difficulties despite the instrumental observations and the born digital data which can be accessed and acquired easily. Promoting in interdisciplinary fields is one of the measures used to solve these issues related to historical documents. Even under these circumstances, the cooperation with researchers from various fields relaying on historical documents has started. It will develop into interdisciplinary collaborative research to facilitate understanding of spacio-temporal association between nature and human society with a potential to become a novel scientific field.

The processes not only include the finding, obtaining, transcribing and reading the descriptions in the documents, but also structuring, analyzing and integrating, and sharing the data. Transcribing is most difficult for scientists and engineers, because they are not always familiar with historical documents. In the first place, finding the historical documents relevant for research is not always an easy task. It might be a real challenge to identify the best one that suits our needs.

Until now, the research studies using historical documents have been progressing in separate fields, but sometimes researchers extract data from the same materials. For example, Diaries contains not only daily weather conditions, but also important records such as meteorite and earthquake events. Over the years, individual research groups have extracted and digitized the data necessary for their research field only. Sharing that data is more difficult than the information about their existence, due to the secrecy of research and intellectual property legislation.

Hence, we are focused on developing “Rekisuke”, which is a system for interdisciplinary sharing of the variety of information, experience and knowledge obtained from each individual research field. Moreover, any improvements of increasing usability, linking sources, displaying the results, user interface, and increasing the data number towards the release are in great need.

The system can thus help researchers to avoid repeating the same processes/tasks that have been already done by others. An important role of the system is to provide information about the existence and the status of the various material and data. Users can help each other in during the different phases of the process, not only finding and obtaining the data but also reading and structuring them, because it can contain descriptions of various information, such as the state of the materials (paper material, image, transcribed text data, published book, digital text data, structuring data, etc.).

It has some functions enabling the search based on particular keywords, such as weather, earthquake. One of them is a notable function to search by temporal and spatial range by using APIs developed for historical temporal and spatial. It is also helpful for libraries which need to promote their historical documents. We started the collaboration with a local library for promotion of their documents and utilization of our system.

Analysis of reconstruction processes after the 1707 Hoei eruption of Fuji Volcano based on old maps

*Junzo Ohmura[1]

1. Research Institute for Earthquake Prediction, Disaster Prevention Research Institute, Kyoto University

Fuji erupted in 1707, and a large amount of volcanic ash was deposited at its foot. The villages in the eastern part of the Shizuoka prefecture were covered with volcanic ash of about 1 m, so the residents began removing volcanic ash. In this study, we clarified how the volcanic ash removal was carried out by using an old map. On the old map are drawn the plots filled with ash fall due to the eruption. Compared to current maps, many of the plots are found to have been in the marginal areas of slightly elevated lands and villages away from the river.

Workshop of Word Survey about Earth and Planetary Phenomena by Citizen

*Harufumi Tamazawa[1,2], kiyomi iwahashi[3]

1. Disaster Prevention Research Institute Kyoto University, 2. Faculty of Fine Arts, Kyoto City University of Arts, 3. National Institute of Japanese Literature

In order to find phenomena related to earth and planetary sciences such as natural disasters, weather, or astronomical phenomena from historical materials and use them, it is necessary first to read the historical materials and to accurately extract words and phrases. In particular, there are a large amount of Japanese historical materials written in "kuzushi-ji" (cursive hand), and it is indispensable how to extract accurate information from a large amount of data. In handling a large amount of data, in addition to experts, cooperation of citizens who are interested and interested in contents can not be lacked, and interest in citizen participatory research in open science in recent years is also increasing. One example of such citizen participatory research is a preceding example project called "Minna-de-Honkoku" that citizens who are interested in historical disaster histories are widely asked to interpret the historical documents using the Internet. (Kano 2017).

At the National Institute of Japaneses Literature (NIJL), as part of space weather research using historical materials, we have held a citizen participatory workshop "Aurora Hunter from History" three times from 2016 (Iwahashi & Tamazawa 2018). In the workshop, Participants survered actually seek astronomical phenomena by touching classical ceremonies and old records is with reseachers of history and astronomy. This workshop is not only a mere outreach event but also a testcase of research on natural sciences using historical document with citizen. In this report, we will present the results of the efforts and think about the possibility and meaning of citizen participation in future planetary science.

In November 2018, under the full cooperation of the Kyoto University Library, this project, which will be the 4th event, was held under the name "Aurora Hunter from History IN Kyoto" at Kyoto University. There, not only astronomical phenomena but also phenomena such as earthquakes, floods and droughts were extended to the phenomenon of natural disasters, and the research was expanded to research on earth planetary science and disaster prevention. In addition, on the day we also made a lecture on the latest research on aurora and earthquakes using historical materials and demonstrated "Minna-de-Honkoku". Also, as a new attempt, we extracted the weather information from the diary historical materials and worked on data.

Looking at the questionnaire of the participants on the day, there are a lot of participants who are interested in astronomy interest more than in the past three participants. Recruitment has been reaffirmed that the participation was triggered by many lecturers and that daily social contribution activities such as researchers' lectures are important for deepening their interest in scientific research by citizens.

From the free written part of the questionnaire, it became clear that for those with less opportunities to touch historical materials usually, they were interested in reading the historical materials written in Japanese and Chinese. On the contrary, from the people who are interested in history, I found that I was attracted by the unexpectedness that I could discover newly by reading from a different viewpoint from the viewpoint I have read so far. In other words, in a workshop with a different field collaboration type, even if it is an aggregation of citizens with different interests and interests, each interest can be found in

©2019. Japan Geoscience Union. All Right Reserved.

other fields by ingenuity of the organizer side, cooperation is obtained from a wide range It suggests the possibility.

Given the aspect of citizen participation research, the so-called open science, of citizen participatory research, in order to improve the accuracy of data extracted from citizens as natural science data, cooperation among participating experts is indispensable Being able to be accurate as data by discussing beyond its own expertise. Also, in order to capture permanent participation, we aimed for a synergistic effect of both on-line work like "reprinting at everyone" and offline workshops like "classical aurora hunter", both young and senior It is the future goal to approach approach.

This work is supported by JSPS KAKENHI Grant numbers JP18H01254 and JP18H05319.

Observational Data in the first half of 20th century to join modern scientific Observation and historical documents: A Usage example ob Photographic Plate of Kwasan Observatory

*Harufumi Tamazawa[1], Reizaburo Kitai[4], Hiroaki Isobe[2], Satoru UeNo[3], Takahito Sakaue[3]

1. Disaster Prevention Research Institute Kyoto University, 2. Faculty of Fine Arts, Kyoto City University of Arts, 3. Astronomical Observatory, Graduate School of Science, Kyoto University, 4. Bukkyo University

When surveying records of natural phenomena from historical documents and using them as scientific and academic data, it is important to understand how to compare with modern observation parameters. In order to investigate long-term fluctuations of natural phenomena seamlessly linking research using historical documents with observational data of modern science, it is also important to utilize observation data in early modern observation. In the solar observation, there are solar image data recorded by photographic plates etc from the end of the 19th century to the first half of the 20th century, and archivalization is progressing little by little.

In this report, as an example of utilizing such data, we will look at sunspot images and collation of images of chromosphere, CaK line heliograms by spectroheliography, and geomagnetism observation data in the first half of the 20th century .

Regarding the decades of the 1930s, when comparing photographic plate data of the solar CaK line heliogram photographed at Kwasan Observatory, Kyoto University, and the aa index which is one of the indicators of geomagnetic storms, it was found that geomagnetic storm of a scale exceeding -100 nT even when it occurred, it was recorded that none of sunspots, existed in nine cases. As an example, at the end of April 1933, sunspots were not seen in the Kwasan Observatory's CaK line heliogram and sunspot sketches in various places, but on May 1, a geomagnetic storm was observed in Kakioka, the aa index was about -200 nT. The advantage of the CaK line heliogram is that not only sunspots but also regions where relatively weak magnetic fields such as plague that is not visible with continuous light are distributed are visualized. This makes it possible to obtain information on the global magnetic neutral line where filaments causing coronal mass ejection can exist.

Climate changes and lords' control in the early modern period in Japan

*Kaoru kamatani[1], Masaki Sano[2], Takeshi Nakatsuka[3]

1. Ritsumeikan University, 2. Waseda University, 3. Research Institute for Humanity and Nature

Recent progress in isotope dendrochronology makes it possible to precisely reconstruct summer precipitation at an annual resolution, enabling us to study the relationship between climate changes and societal responses in the past. Our earlier study revealed that rice yields estimated from historical documents in several villages near Lake Biwa suffered from frequent flood events, which were reconstructed from tree rings. In the present study, we explore how climate changes affected governmental system of tax collection in the early modern period in Japan, by comparing the methods in tax collection between two local loads of central Japan.

Intense geomagnetic storm during Maunder minimum possibly by quiescent filament eruption

*Hiroaki Isobe[1], Yusuke Ebihara[2], Harufumi Tamazawa[1], Akito Davis Kawamura[3], Hisashi Hayakawa[4]

1. Faculty of Fine Arts, Kyoto City University of Arts, 2. Research Institute for Sustainable Humanosphere, Kyoto University, 3. Graduate School of Science, Kyoto University, 4. Graduate School of Letters, Osaka University

The sun occasionally undergoes the so-called grand minima, in which its magnetic activity, measured by the number of sunspots, is suppressed for decades. The most prominent grand minima, since the beginning of telescopic observations of sunspots, is the Maunder minimum (1645--1715), when the sunspots became rather scarce. The mechanism underlying the grand minima remains poorly understood as there is little observational information of the solar magnetic field at that time. In this study, we examine the records of one candidate aurora display in China and Japan during the Maunder minimum. The presence of auroras in such mid magnetic latitudes indicates the occurrence of great geomagnetic storms that are usually produced by strong solar flares. However, the records of contemporary sunspot observations from Europe suggest that, at least for the likely aurora event, there was no large sunspot that could produce a strong flare. Through simple theoretical arguments, we show that this geomagnetic storm could have been generated by a giant eruption from the spotless sun.

Keywords: magnetic storm, aurora, coronal mass ejection, solar flare, Maunder minimum, historical documents

Reconstructing 1931 flood in Yangtze River basin and its application to Chinese economic history

*CHANG LIU[1], Akiyuki Kawasaki[1], Tomoko Shiroyama[2]

1. Department of Civil Engineering, Graduate School of Engineering, the University of Tokyo, 2. Department of Economics, Graduate School of Economics, the University of Tokyo

Historical floods are receiving increased attention in flood research and in applied flood protection. One of the reasons is that they can be taken into account for the improvement of long-term data series and their statistical validation as well as for the analysis of return periods. Apart from that, analyzing the interaction between historical floods and socio-economic activities has attracted more and more interests as well. Previous research has focused on rebuilding temperature, precipitation, discharge and water level of historical floods, however, more detailed information like inundation depth and area is still required for more advanced analysis. In this research, we reconstructed the inundation condition and flood propagation process of 1931 flood in Yangtze River basin using Rainfall-Runoff-Inundation (RRI) model and carried out some primary analysis on Chinese economic history. Although the 1931 flood in Yangtze River basin is recognized as the deadliest flood ever recorded for its damage to more than 25.2 million people and 58.7 billion m^2 farmland, it is considered to be simulated by a distributed hydrological model for the first time because of data scarcity in 1930s and document loss afterwards. However, with the help from many historians, lots of valuable historical documents were found and collected, which makes the model simulation possible. For the preparation of input data of RRI model, a) 24 stations' daily precipitation data from Jan 1^{st} to Dec 31^{st} were digitized from *Monthly Meteorological Bulletin* and *Hydrological Data of Yangtze River Basin*, b) land use classification data of 2015, 2005, 1995, 1985, 1975 were collected and land use classification data of 1955, 1935 and 1915 were simulated using Artificial-Neural-Network-based-Cellular-Automata (ANN-CA) scheme. Dataset b) is further validated by military map with similarity over 60%. The model was calibrated for the discharge at Chongqing gauge station by varying the land use, soil, geometry and precipitation related parameters and then evaluated using flood investigation map. We expect that the simulation result from RRI model is especially suitable for economic history study, because the inundation depth & area were generated daily for the whole year by a 2D diffusive scheme, with which historians can analyze flood impact in more detailed time and space scale. To demonstrate this point, some primary studies were also carried out: a) validation of the number of farmers influenced by 1931 flood with inundation severity, b) analysis of the rice price fluctuation in Hunan province with the inundation time and depth. From study b), one interesting finding is that places where navigation channel was limited and blocked tended to have higher rice price, which indicated the transportation mainly to be shipping in 1930s.

Keywords: Yangtze River basin, historical flood, hydrological modeling

Seismicity Analysis Using Felt Reports and Attenuation Relation of Seismic Intensity

*Takeo Ishibe[1], Koji Iwasa[1], Mitsuko Furumura[1], Ritsuko S. Matsu'ura[1]

1. Association for the Development of Earthquake Prediction

Can felt reports of historical documents be used to estimate the source of large earthquakes or seismicity analysis during the historical period? To explore the possibility of new historical earthquake studies using felt reports, we validated the reproducibility of the spatial distribution of felt report number by using the Japan Meteorological Agency (JMA) seismic intensity database and recently-constructed attenuation relation of seismic intensity. We then established a new methodology to estimate the source area of large earthquakes based on the spatial distribution of felt report number and attenuation relation and applied it to the recent three earthquakes (2004 Niigata-Ken Chuetsu, 2008 Iwate-Miyagi, and 2011 Fukushima-Hamadori earthquakes) in order to investigate the performance of the new method. The method could successfully image the source area of these earthquakes, suggesting the possibility that the source area of historical large earthquakes can be constrained from the distribution of felt reports.

We first validated the reproducibility of felt report number using the JMA seismic intensity database and newly-constructed attenuation relation of seismic intensity by Tanaka *et al*. (2017) for approximately 2,300 shallow crustal earthquakes in 2000-2010 with the maximum intensity >3. As a result, the histogram of residuals between the calculated and observed seismic intensity showed the normal distribution with the center of approximately zero. Furthermore, the attenuation relation successfully reproduced the spatial distribution of felt report number.

We then constructed a new method imaging the source area of large earthquakes and applied it to the recent three large earthquakes. We calculated the normalized residuals between the observed and calculated number of felt reports (seismic intensity >1.5) at each grid uniformly spaced in Tohoku area, by randomly generating the earthquakes in accordance with the Gutenberg-Richter law. As for the two earthquakes (2004 and 2008 events), the source areas were successfully constrained by normalized residuals and the grids with the minimum normalized residual are well matched with the mainshock epicenters. On the other hand, the source area of the 2011 event was less imaged due to the intensive aftershocks following the 2011 Tohoku-oki earthquake. The source areas of these earthquakes were also imaged even after thinning out the observation stations.

In Japan, abundant historical documents spanning over the 1000 years remain and the source area of historical earthquakes have been traditionally estimated from the distribution of damage and casualties recorded in historical literature. However, the damage could be caused by not only a ground shaking but also tsunami, massive fire and/or landslide. In addition, the distribution of building damage is strongly controlled by the population density and elapsed years since constructed.

In some historical literature, earthquakes that were felt without any damage are also reported as well as damage description from major earthquakes, whereas these were not fully utilized except for several previous studies. The number of felt reports are strongly controlled by the elapsed time since the mainshock and distance from the source area, suggesting the possibility that the source area of these earthquakes can be constrained by the spatiotemporal distribution of felt report number. Furthermore, changes in the number of felt reports may suggest the changes in seismic activity including an occurrence

©2019. Japan Geoscience Union. All Right Reserved.

of swarm-like or triggered activity and seismic quiescence. By constructing the methodology imaging the seismicity based on felt reports in historical literature, a new development of historical earthquake studies including small to moderate earthquakes is expected.

Keywords: Felt Report, Attenuation Relation of Seismic Intensity, Seismicity Analysis

Radiocarbon dating of Japanese tree rings –chronological research and Japanese calibration curve

*Minoru Sakamoto[1,2], Masataka Hakozaki[1], Takumi Mitsutani[3], Takeshi Nakatsuka[4,5]

1. National Museum of Japanese History, 2. The Graduate University for Advanced Studies, 3. Nara National Research Institute for Cultural Properties, 4. Research Institute for Humanity and Nature, 5. Nagoya University

In order to revise radiocarbon age to calendar age, a calibration curve based on the radiocarbon ages of known age sample such as tree rings is used. Calibration curve for the northern hemisphere, IntCal, mainly depended on tree rings which had been growing in the high latitude region of the West so far. However, the latest version “IntCal19” is called upon to reflect radiocarbon ages of various regions. The authors have continued radiocarbon dating of Japanese tree rings of the past 3,000 years. Recently, from a demand for chronological research on wooden buildings as cultural properties using ^{14}C-wiggle matching, we are also focusing on the tree rings of middle to early-modern ages. In the background, there is a practical application of a new method, oxygen-isotope dendrochronology, that can be implemented in several tree species. It becomes easier to obtain tree rings with known age and accumulation of radiocarbon age is progressing rapidly.

There are some periods showing certain offset on radiocarbon ages of Japanese tree ring from IntCal. One of the regional effects is remarkable during the end of the Yayoi to the beginning of the Kofun period, and calibrated age based on IntCal shows older age than the actual age. Also, since IntCal is versatile and smooth, it is sometimes insufficient for the historic chronological research that requires high precision and accuracy. It has an obligation to reveal the behavior of the radiocarbon age of Japanese tree ring and develop domestic calibration curve to promote chronological research.

This work was one of the results of the Collaborative Research Program of the NMJH and the RIHN Research Project of the Ecohistory Program (H-05). JSPS Grant in Aid (#25282075, #18H03594) also supported our research.

Keywords: radiocarbon dating, dendrochronology, calibrated age, regional effect

Usage of Historical Documents with Scientific Understandings in the field of Solar Physics

*Akito Davis Kawamura[1], Hisashi Hayakawa[2], Harufumi Tamazawa[3], Hiroaki Isobe[3], Kazunari Shibata[1]

1. Astronomical Observatory, Kyoto University, 2. Graduate School of Letters, Osaka University, 3. Faculty of Fine Arts, Kyoto City University of Arts

The sun is the most studied star by mankind, yet our knowledge on our parent star is based on the observation of limited time scale. Solar activities have been scientifically recorded for ~400 years with sunspot and ~160 years with flares (sudden increment of light emission with energy release). Meanwhile, people have witnessed and recorded the traces of solar activities for thousands of years, which we nowadays call as aurora. By combining scientific sunspot observations and historical records of aurora, first goal of our study is to decode solar flare activities for last ~400 years.

The physical variable of interest is the flare magnitude, and we have developed an estimation method with the statistics based on modern-day solar observations. The key of this method is an observation of low latitude aurora, which is a strong indication of coronal mass ejection at the flare. By knowing the size of sunspot and the existence of coronal mass ejection, our statistical method could estimate the magnitude of the flare.

At our poster, we will discuss the potentiality and difficulty of solar physics with historical documents. We hope this poster could be a demonstration of successful collaboration of science and history.

Reconstruction of Historical Weather with Data Assimilation Using Old Diaries

*Kei Yoshimura[1], Panduka Neluwala[2], Mika Ichino[3], Kooiti Masuda[4], Junpei Hirano[5]

1. Institute of Industrial Science, The University of Tokyo, 2. University of Peradeniya , 3. National Institute of Informatics, 4. Tokyo Metropolitan University, 5. Teikyo University

Long-term atmospheric reanalysis data is indispensable for understanding the mechanism of climate change, but the current longest data is over 130 years only. The cause of not going back further to the past is largely due to lack of direct weather observation data. However, even in the past where modern weather observation data does not exist, the daily weather information described in the ancient document may exist for a longer time. In this regard, Japan is ideal country that has kept such old weather information. In this research, we developed a method to introduce old weather information into the latest data assimilation system, investigated the effect as the constraint condition of atmospheric condition, and proposed a method to extend existing reanalysis data in the past. We constructed a system using historical weather database, global spectrum model, local ensemble transform Kalman filter as observation data, prediction model and data assimilation scheme respectively. Analog information indicating weather should be classified into about 3 to 5 categories and it is better to correspond to the cloud amount ratio and the short wave downward radiation on the ground surface. Furthermore, it is appropriate that the ensemble number is about 30 from the balance of calculation efficiency and accuracy. Using the above setting, the data assimilation result given the weather information obtained at the meteorological observatory at 18 sites, for the modern era (1990 's), is closer to the modern reanalysis than the result without any weather information. As a result, significant improvements were observed in shortwave radiation and cloud cover, and significant improvement in precipitation was confirmed. These improvements are thought to have been brought by synchronizing the modeled synoptic-scale weather patterns to the reality. Furthermore, it was confirmed that the skill of rainfall estimation was improved by adding information of “no precipitation day” to data assimilation as an observation item. Then we conducted the experiments of the 1830s and 1860s using actual ancient diary data. It was confirmed that similar seasonal change and interannual variations can be obtained compared with temperature and precipitation in the 1860s which was actually observed in Yokohama.

Keywords: old diaries, data assimilation, weather reconstruction

Examination of data range for fitting Omori-Utsu law to temporal decay of aftershocks presented in historical materials on the 1830 Kyoto earthquake: Reason for the difference of numbers of aftershocks in the same place

*Kentaro Hattori[1], Junzo Ohmura[2], Ichiro Nakanishi[1]

1. Kyoto Univ., 2. Bukkyo Univ.

We study the temporal decay of aftershock sequences of the 1830 Kyoto earthquake. Omori(1908) examined aftershock sequences including that of the 1830 Kyoto earthquake. Matsui and Oike (1997) attempted to determine epicenter of the 1830 Kyoto earthquake by using the number of felt aftershocks in time range from the main shock to the next morning in several observational areas including Kyoto. They used two different numbers as the number of felt aftershocks for Kyoto: 100 written in Banzai Rakki and 4 written in Tansui Nikki. In the case using the former number, they obtained the epicenter consistent with that obtained by Usami (1996). However, in the case using the latter number, they obtained an epicenter near the northern shore of the lake Biwa, and the epicenter is inconsistent with distribution of damage caused by the earthquake. They did not pursue the reason of the discrepancy between two numbers for Kyoto.

In order to solve the above mentioned discrepancy among the earthquake records for Kyoto, we include another record Tenpo Zakki in addition to Banzai Rakki.Both records show quite different numbers of daily aftershocks during several days, though they were written in the same place. Kitahara and Ohmura (2012) suggest that the original record was written by an officer in Nijo-jo Castle and was copied many times. They made a graph of temporal decay of daily numbers of aftershocks for a period of one month after the main shock. However, they made neither analysis of the aftershock sequences nor information evaluation of the records.

We examined carefully description of daily aftershocks in both records to know the reason for the differences of the numbers of felt aftershocks. The records show the sizes of earthquakes by the diameters of handwritten circles for each day. Comparing the diameter of standard circle for every day, we infer that writers of the records used different criterion to count the numbers of felt aftershocks.

We measure the diameter of standard circle for every day, and find the diameter changes with day. Fig.1 shows the daily variation of diameter of standard circle in the both records. The vertical axis shows the count threshold of circle diameter (arbitrary unit), and horizontal axis shows the date. Fig.1 suggests that the threshold count level used in Banzai Rakki is larger than that used in Tenpo Zakki. This result means that the number of counted aftershocks becomes smaller in Banzai Rakki than in Tenpo Zakki. The interpretation is consistent with the actual difference of the number of aftershocks in the both records. The threshold level for counting used in Banzai Rakki changes more rapidly with time than that used in Tenpo Zakki (Fig.1). Especially, the change of the threshold level from 7/3 to 7/5 is not negligible in Banzai Rakki.

The above information evaluation of the two records reveals the difference of the two records written in the same place. We fit Omori-Utsu law (Utsu, 1961) to the aftershock sequences after 7/5. We assume that the c value is 0.1 and the p values fall in about 1.2. We obtain a better fit in Tenpo Zakki (Fig.2). Our study may suggest that Tenpo Zakki may have better information quality than Banzai Rakki and the numbers of aftershocks after 7/5 should be used for study of the 1830 Kyoto earthquake.

Tsunami trace height of the AD 1854 Ansei Tokai tsunami around the lake Hamanako inferred from historical maps

*ebina yuichi[1], Kentaro Imai[2], Yoshinobu Tsuji[3], hiroyuki iwase[4]

1. International Research Institute of Disaster Science, 2. JAMSTEC, 3. Fukuda Geological Instite, 4. (C)ECOH CORPORATION

We analyzed the trace of tsunami from historical maps "Maisaka-syuku tsunamizu" and “Ansei Tsunami saigai ezu" (in Hamamatsu museum) drawn about the tsunami damages around Hamanako in the Ansei Tokai earthquake occurred in 1854.

“Maisaka” (present Maisaka-cho Nishi-ku, Hamamatsu-shi, Shizuoka-ken) located in the “Hamanako” east shore is the area which prospered as a post town in “Tokaido”. According to "the history of Shizuoka" (1996), which was drawn by Hachiro Watanabe, who was a resident of “Maisaka” and drew the " Maisaka” tsunami figure. This picture shows that the appearance of Maisaka inundated by tsunami, or people who evacuated. On the east side of a highway, tsunami has reached to near night-lights. Moreover, in the west side, stairs around "Shigetuin" were inundated. This is a place called "Ohkonoboriba" by "Toukaido-bungen-nobe-ezu". It becomes clear that from here to several east sides of a subsidiary inn or an administration office were inundated by tsunami.

“Ansei zisin tsunami saigai ezu“ shows the time when the tsunami hits “Okuhamanako and Kiga” area and after the situation of the tsunami. Here, we can find some points reaching tsunami by considering “Himekaido” north side passes as a mark. Although seeing from the historical map, tsunami reached the front of “Kigasekisyo” but tsunami was not flooded in the barrier main part. Moreover, "Komorisawa" near "Ninomiyasya", and "Iwanesawa", near "Himekaido" were drawn as reaching points of the tsunami. Furthermore, signs that the circumference of a mountain where "Daienzi-temple" located in “Ikutagawa-river mouth-of-a-river part which flows into “Okuhama” name lake serves as a cemetery in the case of tsunami has sunk are drawn. “Dainenji Temple” in the area of mouth of “Ikutagawa River” was inundated by tsunami but only the hill used as the “Dainenji Temple Cemetery” was not. There are few documents described accurate places which was reached by the tsunami around Lake Hamanako, especially Lake Okuhamanako. However, we identified those based on historical maps. We hope that our results will contribute to future interdisciplinary research including tsunami engineering on the past great earthquakes along the Nankai Trough.

Acknowledgement
This research was supported by MEXT (“Research project for compound disaster mitigation on the great earthquakes and tsunamis around the Nankai Trough region”).

[J] Poster | M (Multidisciplinary and Interdisciplinary)：M-IS Intersection

Mon. May 27, 2019 5:15 PM - 6:30 PM JST | Mon. May 27, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_37

[M-IS17] History X Earth and Planetary Science

convener:Yasuyuki Kano(Earthquake Research Institute, The University of Tokyo), Kei Yoshimura(Institute of Industrial Science, The University of Tokyo), Hiroaki Isobe(Faculty of Fine Arts, Kyoto City University of Arts), kiyomi iwahashi(National Institute of Japanese Literature)

The history of modern observation in earth and planetary sciences is often far shorter compared with the timescales of their interests. Investigation of the long-term variations and occurrences of extremely rare events requires effective use of information before modern observations. Historical documents recorded by diverse kinds of authors in various situations are the important sources of such information.

Thus, historical documents have been referred in various fields of earth and planetary sciences such as seismology, climatology, meteorology and astronomy. Sharing their records, methods and experiences will be beneficial for each field and bring new insights. It is also essential to involve experienced scholars in history because one needs to carefully investigate the reliability and the context of each document in order to use it as scientific data. On the other hand, analyzing the record in the historical documents with the eyes of modern science may also bring new insights to the history scholars.

In this session we overview the studies using the historical documents in various fields of the earth and planetary sciences as well as the recent advances in related topics such as digital humanities and historical-data assimilation. The aim is to promote the communication and dialogues among the researchers in various background, and thus foster the new ideas and collaborations in the study of "History X EPS."

"History X EPS" is a title of this session as well as the name of the application area proposed for Grant-in-Aid for Scientific Research on Innovative Areas. The application area consists of 4 sub area: “Ten” (astronomy), ”Ki” (climatology and meteorology), ”Chi” (solid earth science), and ”Jin” (human and society).

Historians and researchers of earth and planetary sciences have been collaborated in the preceding projects. There are a number of projects for such interdisciplinary collaboration. Here we present prospects of "History X EPS." The scope of the session is as follows:

The history of modern observation in earth and planetary sciences is often far shorter compared with the timescales of their interests. Investigation of the long-term variations and occurrences of extremely rare events requires effective use of information before modern observations. Historical documents recorded by diverse kinds of authors in various situations are the important sources of such information.

Thus, historical documents have been referred in various fields of earth and planetary sciences such as seismology, climatology, meteorology and astronomy. Sharing their records, methods and experiences will be beneficial for each field and bring new insights. It is also essential to involve experienced scholars in history because one needs to carefully investigate the reliability and the context of each document in order to use it as scientific data. On the other hand, analyzing the record in the historical documents with the eyes of modern science may also bring new insights to the history scholars.

In this session we overview the studies using the historical documents in various fields of the earth and planetary sciences as well as the recent advances in related topics such as digital humanities and historical-data assimilation. The aim is to promote the communication and dialogues among the researchers in various background, and thus foster the new ideas and collaborations in the study of "History X EPS."

Reexamination of intensity distribution of Japanese historical earthquakes using attenuation relation

*Yasuyuki Kano[1], Junzo Ohmura[2]

1. Earthquake Research Institute, The University of Tokyo, 2. Diasaster prevention Research institute, Kyoto University

Sources of historical earthquakes are usually estimated from seismic intensity distributions based on the descriptions on historical documents. Ceaseless efforts to collect historical earthquake documents leads to sourcebooks such as Dai-Nihon Jishin Shiryo (Collection of Historical Documents on Earthquakes in Great Japan) (Tayama, 1904a,b), Zotei Dai-Nihon Jishin Shiryo (Collection of Historical Documents on Earthquakes in Great Japan, Enlarged and Revised Edition) (Musha, 1941, 1943a,b), and Shinshu Nihon Jishin Shiryo (Historical Documents on Earthquakes in Japan, New Collection) (Earthquake Research Institute of the University of Tokyo, 1981-1994) etc. The location of epicenter or hypocenter, origin time, and magnitude of the historical earthquakes are estimated utilizing the descriptions in the sourcebooks. Conversion table from description of damage of building etc. to seismic intensity is used to derive seismic intensity distribution. The location and magnitudes are estimated by drawing isoseismals. The basic procedure for identification of historical earthquakes are: (1) discovery and transcription of historical documents describing earthquake, (2) estimation of intensity distribution from the description, and (3) estimation of epicenter or hypocenter and magnitude. Attenuation relation of seismic intensity can be used to (1)-(3).

Although plenty of historical earthquake documents are published as the sourcebooks mentioned above and used for preceded researches, more historical documents are necessary to know details of historical earthquakes. One possible collaboration between historians and seismologists is search for historical documents related to earthquakes. An exhaustive search for large earthquakes is sometimes hard to be done, because damaged or felt area become wide for the large earthquakes. Seismic intensity of historical earthquake can be estimated assuming attenuation relation and location and magnitude of the earthquake. We can make an effective search plan for historical documents based on the estimated seismic intensity distribution.

Various conversion tables are suggested to estimate seismic intensity of historical earthquake from damage description in historical documents. The tables correlate, for example, the extent of building damage or rate of the damage to seismic intensity. We examined the validity of a conversion table using the damage of cultural property by the earthquakes including the one occurred in northern part of Osaka. Based on the conversion table, the damage of cultural properties was converted to seismic intensity. The estimated seismic intensity is consistent with distribution of seismic intensity at the locations of the cultural properties predicted by attenuation relations.

Attenuation relation of seismic intensity can be used for estimation for location of epicenter or hypocenter. The magnitude of an earthquake can be estimated by fitting attenuation relation to spatial distribution of seismic intensity. The location and magnitude of Japanese historical earthquake are estimated using attenuation relation, which is consistent with the location and magnitude obtained by preceded studies.

Rekisuke: a system for sharing bibliographic information of historical documents through Interdisciplinary collaboration

*Mika Ichino[1,2], Yukie Hashimoto, Kooiti Masuda[3], Asanobu Kitamoto[2,1], Junpei Hirano[4]

1. Center for Open Data in the Humanities, Joint Support-Center for Data Science Research, Research Organization of Information and Systems , 2. National Institute of Informatics, 3. Tokyo Metropolitan University, 4. Faculty of Liberal Arts, Teikyo University

The records of numerous historical documents in Japan have been used for research in diverse scientific fields ranging from seismology, climatology and astronomy, to humanities, social sciences and historical studies. Unfortunately, when processing and applying information found in historical documents for the purpose of scientific research, the one may encounter certain difficulties despite the instrumental observations and the born digital data which can be accessed and acquired easily. Promoting in interdisciplinary fields is one of the measures used to solve these issues related to historical documents. Even under these circumstances, the cooperation with researchers from various fields relaying on historical documents has started. It will develop into interdisciplinary collaborative research to facilitate understanding of spacio-temporal association between nature and human society with a potential to become a novel scientific field.

The processes not only include the finding, obtaining, transcribing and reading the descriptions in the documents, but also structuring, analyzing and integrating, and sharing the data. Transcribing is most difficult for scientists and engineers, because they are not always familiar with historical documents. In the first place, finding the historical documents relevant for research is not always an easy task. It might be a real challenge to identify the best one that suits our needs.

Until now, the research studies using historical documents have been progressing in separate fields, but sometimes researchers extract data from the same materials. For example, Diaries contains not only daily weather conditions, but also important records such as meteorite and earthquake events. Over the years, individual research groups have extracted and digitized the data necessary for their research field only. Sharing that data is more difficult than the information about their existence, due to the secrecy of research and intellectual property legislation.

Hence, we are focused on developing “Rekisuke”, which is a system for interdisciplinary sharing of the variety of information, experience and knowledge obtained from each individual research field. Moreover, any improvements of increasing usability, linking sources, displaying the results, user interface, and increasing the data number towards the release are in great need.

The system can thus help researchers to avoid repeating the same processes/tasks that have been already done by others. An important role of the system is to provide information about the existence and the status of the various material and data. Users can help each other in during the different phases of the process, not only finding and obtaining the data but also reading and structuring them, because it can contain descriptions of various information, such as the state of the materials (paper material, image, transcribed text data, published book, digital text data, structuring data, etc.).

It has some functions enabling the search based on particular keywords, such as weather, earthquake. One of them is a notable function to search by temporal and spatial range by using APIs developed for historical temporal and spatial. It is also helpful for libraries which need to promote their historical documents. We started the collaboration with a local library for promotion of their documents and utilization of our system.

Analysis of reconstruction processes after the 1707 Hoei eruption of Fuji Volcano based on old maps

*Junzo Ohmura[1]

1. Research Institute for Earthquake Prediction, Disaster Prevention Research Institute, Kyoto University

Fuji erupted in 1707, and a large amount of volcanic ash was deposited at its foot. The villages in the eastern part of the Shizuoka prefecture were covered with volcanic ash of about 1 m, so the residents began removing volcanic ash. In this study, we clarified how the volcanic ash removal was carried out by using an old map. On the old map are drawn the plots filled with ash fall due to the eruption. Compared to current maps, many of the plots are found to have been in the marginal areas of slightly elevated lands and villages away from the river.

Workshop of Word Survey about Earth and Planetary Phenomena by Citizen

*Harufumi Tamazawa[1,2], kiyomi iwahashi[3]

1. Disaster Prevention Research Institute Kyoto University, 2. Faculty of Fine Arts, Kyoto City University of Arts, 3. National Institute of Japanese Literature

In order to find phenomena related to earth and planetary sciences such as natural disasters, weather, or astronomical phenomena from historical materials and use them, it is necessary first to read the historical materials and to accurately extract words and phrases. In particular, there are a large amount of Japanese historical materials written in "kuzushi-ji" (cursive hand), and it is indispensable how to extract accurate information from a large amount of data. In handling a large amount of data, in addition to experts, cooperation of citizens who are interested and interested in contents can not be lacked, and interest in citizen participatory research in open science in recent years is also increasing. One example of such citizen participatory research is a preceding example project called "Minna-de-Honkoku" that citizens who are interested in historical disaster histories are widely asked to interpret the historical documents using the Internet. (Kano 2017).

At the National Institute of Japaneses Literature (NIJL), as part of space weather research using historical materials, we have held a citizen participatory workshop "Aurora Hunter from History" three times from 2016 (Iwahashi & Tamazawa 2018). In the workshop, Participants survered actually seek astronomical phenomena by touching classical ceremonies and old records is with reseachers of history and astronomy. This workshop is not only a mere outreach event but also a testcase of research on natural sciences using historical document with citizen. In this report, we will present the results of the efforts and think about the possibility and meaning of citizen participation in future planetary science.

In November 2018, under the full cooperation of the Kyoto University Library, this project, which will be the 4th event, was held under the name "Aurora Hunter from History IN Kyoto" at Kyoto University. There, not only astronomical phenomena but also phenomena such as earthquakes, floods and droughts were extended to the phenomenon of natural disasters, and the research was expanded to research on earth planetary science and disaster prevention. In addition, on the day we also made a lecture on the latest research on aurora and earthquakes using historical materials and demonstrated "Minna-de-Honkoku". Also, as a new attempt, we extracted the weather information from the diary historical materials and worked on data.

Looking at the questionnaire of the participants on the day, there are a lot of participants who are interested in astronomy interest more than in the past three participants. Recruitment has been reaffirmed that the participation was triggered by many lecturers and that daily social contribution activities such as researchers' lectures are important for deepening their interest in scientific research by citizens.

From the free written part of the questionnaire, it became clear that for those with less opportunities to touch historical materials usually, they were interested in reading the historical materials written in Japanese and Chinese. On the contrary, from the people who are interested in history, I found that I was attracted by the unexpectedness that I could discover newly by reading from a different viewpoint from the viewpoint I have read so far. In other words, in a workshop with a different field collaboration type, even if it is an aggregation of citizens with different interests and interests, each interest can be found in

©2019. Japan Geoscience Union. All Right Reserved.

other fields by ingenuity of the organizer side, cooperation is obtained from a wide range It suggests the possibility.

Given the aspect of citizen participation research, the so-called open science, of citizen participatory research, in order to improve the accuracy of data extracted from citizens as natural science data, cooperation among participating experts is indispensable Being able to be accurate as data by discussing beyond its own expertise. Also, in order to capture permanent participation, we aimed for a synergistic effect of both on-line work like "reprinting at everyone" and offline workshops like "classical aurora hunter", both young and senior It is the future goal to approach approach.

This work is supported by JSPS KAKENHI Grant numbers JP18H01254 and JP18H05319.

Observational Data in the first half of 20th century to join modern scientific Observation and historical documents: A Usage example ob Photographic Plate of Kwasan Observatory

*Harufumi Tamazawa[1], Reizaburo Kitai[4], Hiroaki Isobe[2], Satoru UeNo[3], Takahito Sakaue[3]

1. Disaster Prevention Research Institute Kyoto University, 2. Faculty of Fine Arts, Kyoto City University of Arts, 3. Astronomical Observatory, Graduate School of Science, Kyoto University, 4. Bukkyo University

When surveying records of natural phenomena from historical documents and using them as scientific and academic data, it is important to understand how to compare with modern observation parameters. In order to investigate long-term fluctuations of natural phenomena seamlessly linking research using historical documents with observational data of modern science, it is also important to utilize observation data in early modern observation. In the solar observation, there are solar image data recorded by photographic plates etc from the end of the 19th century to the first half of the 20th century, and archivalization is progressing little by little.

In this report, as an example of utilizing such data, we will look at sunspot images and collation of images of chromosphere, CaK line heliograms by spectroheliography, and geomagnetism observation data in the first half of the 20th century .

Regarding the decades of the 1930s, when comparing photographic plate data of the solar CaK line heliogram photographed at Kwasan Observatory, Kyoto University, and the aa index which is one of the indicators of geomagnetic storms, it was found that geomagnetic storm of a scale exceeding -100 nT even when it occurred, it was recorded that none of sunspots, existed in nine cases. As an example, at the end of April 1933, sunspots were not seen in the Kwasan Observatory's CaK line heliogram and sunspot sketches in various places, but on May 1, a geomagnetic storm was observed in Kakioka, the aa index was about -200 nT. The advantage of the CaK line heliogram is that not only sunspots but also regions where relatively weak magnetic fields such as plague that is not visible with continuous light are distributed are visualized. This makes it possible to obtain information on the global magnetic neutral line where filaments causing coronal mass ejection can exist.

Climate changes and lords' control in the early modern period in Japan

*Kaoru kamatani[1], Masaki Sano[2], Takeshi Nakatsuka[3]

1. Ritsumeikan University, 2. Waseda University, 3. Research Institute for Humanity and Nature

Recent progress in isotope dendrochronology makes it possible to precisely reconstruct summer precipitation at an annual resolution, enabling us to study the relationship between climate changes and societal responses in the past. Our earlier study revealed that rice yields estimated from historical documents in several villages near Lake Biwa suffered from frequent flood events, which were reconstructed from tree rings. In the present study, we explore how climate changes affected governmental system of tax collection in the early modern period in Japan, by comparing the methods in tax collection between two local loads of central Japan.

Intense geomagnetic storm during Maunder minimum possibly by quiescent filament eruption

*Hiroaki Isobe[1], Yusuke Ebihara[2], Harufumi Tamazawa[1], Akito Davis Kawamura[3], Hisashi Hayakawa[4]

1. Faculty of Fine Arts, Kyoto City University of Arts, 2. Research Institute for Sustainable Humanosphere, Kyoto University, 3. Graduate School of Science, Kyoto University, 4. Graduate School of Letters, Osaka University

The sun occasionally undergoes the so-called grand minima, in which its magnetic activity, measured by the number of sunspots, is suppressed for decades. The most prominent grand minima, since the beginning of telescopic observations of sunspots, is the Maunder minimum (1645--1715), when the sunspots became rather scarce. The mechanism underlying the grand minima remains poorly understood as there is little observational information of the solar magnetic field at that time. In this study, we examine the records of one candidate aurora display in China and Japan during the Maunder minimum. The presence of auroras in such mid magnetic latitudes indicates the occurrence of great geomagnetic storms that are usually produced by strong solar flares. However, the records of contemporary sunspot observations from Europe suggest that, at least for the likely aurora event, there was no large sunspot that could produce a strong flare. Through simple theoretical arguments, we show that this geomagnetic storm could have been generated by a giant eruption from the spotless sun.

Keywords: magnetic storm, aurora, coronal mass ejection, solar flare, Maunder minimum, historical documents

Reconstructing 1931 flood in Yangtze River basin and its application to Chinese economic history

*CHANG LIU[1], Akiyuki Kawasaki[1], Tomoko Shiroyama[2]

1. Department of Civil Engineering, Graduate School of Engineering, the University of Tokyo, 2. Department of Economics, Graduate School of Economics, the University of Tokyo

Historical floods are receiving increased attention in flood research and in applied flood protection. One of the reasons is that they can be taken into account for the improvement of long-term data series and their statistical validation as well as for the analysis of return periods. Apart from that, analyzing the interaction between historical floods and socio-economic activities has attracted more and more interests as well. Previous research has focused on rebuilding temperature, precipitation, discharge and water level of historical floods, however, more detailed information like inundation depth and area is still required for more advanced analysis. In this research, we reconstructed the inundation condition and flood propagation process of 1931 flood in Yangtze River basin using Rainfall-Runoff-Inundation (RRI) model and carried out some primary analysis on Chinese economic history. Although the 1931 flood in Yangtze River basin is recognized as the deadliest flood ever recorded for its damage to more than 25.2 million people and 58.7 billion m^2 farmland, it is considered to be simulated by a distributed hydrological model for the first time because of data scarcity in 1930s and document loss afterwards. However, with the help from many historians, lots of valuable historical documents were found and collected, which makes the model simulation possible. For the preparation of input data of RRI model, a) 24 stations' daily precipitation data from Jan 1^{st} to Dec 31^{st} were digitized from *Monthly Meteorological Bulletin* and *Hydrological Data of Yangtze River Basin*, b) land use classification data of 2015, 2005, 1995, 1985, 1975 were collected and land use classification data of 1955, 1935 and 1915 were simulated using Artificial-Neural-Network-based-Cellular-Automata (ANN-CA) scheme. Dataset b) is further validated by military map with similarity over 60%. The model was calibrated for the discharge at Chongqing gauge station by varying the land use, soil, geometry and precipitation related parameters and then evaluated using flood investigation map. We expect that the simulation result from RRI model is especially suitable for economic history study, because the inundation depth & area were generated daily for the whole year by a 2D diffusive scheme, with which historians can analyze flood impact in more detailed time and space scale. To demonstrate this point, some primary studies were also carried out: a) validation of the number of farmers influenced by 1931 flood with inundation severity, b) analysis of the rice price fluctuation in Hunan province with the inundation time and depth. From study b), one interesting finding is that places where navigation channel was limited and blocked tended to have higher rice price, which indicated the transportation mainly to be shipping in 1930s.

Seismicity Analysis Using Felt Reports and Attenuation Relation of Seismic Intensity

*Takeo Ishibe[1], Koji Iwasa[1], Mitsuko Furumura[1], Ritsuko S. Matsu'ura[1]

1. Association for the Development of Earthquake Prediction

Can felt reports of historical documents be used to estimate the source of large earthquakes or seismicity analysis during the historical period? To explore the possibility of new historical earthquake studies using felt reports, we validated the reproducibility of the spatial distribution of felt report number by using the Japan Meteorological Agency (JMA) seismic intensity database and recently-constructed attenuation relation of seismic intensity. We then established a new methodology to estimate the source area of large earthquakes based on the spatial distribution of felt report number and attenuation relation and applied it to the recent three earthquakes (2004 Niigata-Ken Chuetsu, 2008 Iwate-Miyagi, and 2011 Fukushima-Hamadori earthquakes) in order to investigate the performance of the new method. The method could successfully image the source area of these earthquakes, suggesting the possibility that the source area of historical large earthquakes can be constrained from the distribution of felt reports.

We first validated the reproducibility of felt report number using the JMA seismic intensity database and newly-constructed attenuation relation of seismic intensity by Tanaka *et al*. (2017) for approximately 2,300 shallow crustal earthquakes in 2000-2010 with the maximum intensity >3. As a result, the histogram of residuals between the calculated and observed seismic intensity showed the normal distribution with the center of approximately zero. Furthermore, the attenuation relation successfully reproduced the spatial distribution of felt report number.

We then constructed a new method imaging the source area of large earthquakes and applied it to the recent three large earthquakes. We calculated the normalized residuals between the observed and calculated number of felt reports (seismic intensity >1.5) at each grid uniformly spaced in Tohoku area, by randomly generating the earthquakes in accordance with the Gutenberg-Richter law. As for the two earthquakes (2004 and 2008 events), the source areas were successfully constrained by normalized residuals and the grids with the minimum normalized residual are well matched with the mainshock epicenters. On the other hand, the source area of the 2011 event was less imaged due to the intensive aftershocks following the 2011 Tohoku-oki earthquake. The source areas of these earthquakes were also imaged even after thinning out the observation stations.

In Japan, abundant historical documents spanning over the 1000 years remain and the source area of historical earthquakes have been traditionally estimated from the distribution of damage and casualties recorded in historical literature. However, the damage could be caused by not only a ground shaking but also tsunami, massive fire and/or landslide. In addition, the distribution of building damage is strongly controlled by the population density and elapsed years since constructed.

In some historical literature, earthquakes that were felt without any damage are also reported as well as damage description from major earthquakes, whereas these were not fully utilized except for several previous studies. The number of felt reports are strongly controlled by the elapsed time since the mainshock and distance from the source area, suggesting the possibility that the source area of these earthquakes can be constrained by the spatiotemporal distribution of felt report number. Furthermore, changes in the number of felt reports may suggest the changes in seismic activity including an occurrence

©2019. Japan Geoscience Union. All Right Reserved.

of swarm-like or triggered activity and seismic quiescence. By constructing the methodology imaging the seismicity based on felt reports in historical literature, a new development of historical earthquake studies including small to moderate earthquakes is expected.

Radiocarbon dating of Japanese tree rings –chronological research and Japanese calibration curve

*Minoru Sakamoto[1,2], Masataka Hakozaki[1], Takumi Mitsutani[3], Takeshi Nakatsuka[4,5]

1. National Museum of Japanese History, 2. The Graduate University for Advanced Studies, 3. Nara National Research Institute for Cultural Properties, 4. Research Institute for Humanity and Nature, 5. Nagoya University

In order to revise radiocarbon age to calendar age, a calibration curve based on the radiocarbon ages of known age sample such as tree rings is used. Calibration curve for the northern hemisphere, IntCal, mainly depended on tree rings which had been growing in the high latitude region of the West so far. However, the latest version “IntCal19” is called upon to reflect radiocarbon ages of various regions. The authors have continued radiocarbon dating of Japanese tree rings of the past 3,000 years. Recently, from a demand for chronological research on wooden buildings as cultural properties using ^{14}C-wiggle matching, we are also focusing on the tree rings of middle to early-modern ages. In the background, there is a practical application of a new method, oxygen-isotope dendrochronology, that can be implemented in several tree species. It becomes easier to obtain tree rings with known age and accumulation of radiocarbon age is progressing rapidly.

There are some periods showing certain offset on radiocarbon ages of Japanese tree ring from IntCal. One of the regional effects is remarkable during the end of the Yayoi to the beginning of the Kofun period, and calibrated age based on IntCal shows older age than the actual age. Also, since IntCal is versatile and smooth, it is sometimes insufficient for the historic chronological research that requires high precision and accuracy. It has an obligation to reveal the behavior of the radiocarbon age of Japanese tree ring and develop domestic calibration curve to promote chronological research.

This work was one of the results of the Collaborative Research Program of the NMJH and the RIHN Research Project of the Ecohistory Program (H-05). JSPS Grant in Aid (#25282075, #18H03594) also supported our research.

Usage of Historical Documents with Scientific Understandings in the field of Solar Physics

*Akito Davis Kawamura[1], Hisashi Hayakawa[2], Harufumi Tamazawa[3], Hiroaki Isobe[3], Kazunari Shibata[1]

1. Astronomical Observatory, Kyoto University, 2. Graduate School of Letters, Osaka University, 3. Faculty of Fine Arts, Kyoto City University of Arts

The sun is the most studied star by mankind, yet our knowledge on our parent star is based on the observation of limited time scale. Solar activities have been scientifically recorded for ~400 years with sunspot and ~160 years with flares (sudden increment of light emission with energy release). Meanwhile, people have witnessed and recorded the traces of solar activities for thousands of years, which we nowadays call as aurora. By combining scientific sunspot observations and historical records of aurora, first goal of our study is to decode solar flare activities for last ~400 years.

The physical variable of interest is the flare magnitude, and we have developed an estimation method with the statistics based on modern-day solar observations. The key of this method is an observation of low latitude aurora, which is a strong indication of coronal mass ejection at the flare. By knowing the size of sunspot and the existence of coronal mass ejection, our statistical method could estimate the magnitude of the flare.

At our poster, we will discuss the potentiality and difficulty of solar physics with historical documents. We hope this poster could be a demonstration of successful collaboration of science and history.

Reconstruction of Historical Weather with Data Assimilation Using Old Diaries

*Kei Yoshimura[1], Panduka Neluwala[2], Mika Ichino[3], Kooiti Masuda[4], Junpei Hirano[5]

1. Institute of Industrial Science, The University of Tokyo, 2. University of Peradeniya , 3. National Institute of Informatics, 4. Tokyo Metropolitan University, 5. Teikyo University

Long-term atmospheric reanalysis data is indispensable for understanding the mechanism of climate change, but the current longest data is over 130 years only. The cause of not going back further to the past is largely due to lack of direct weather observation data. However, even in the past where modern weather observation data does not exist, the daily weather information described in the ancient document may exist for a longer time. In this regard, Japan is ideal country that has kept such old weather information. In this research, we developed a method to introduce old weather information into the latest data assimilation system, investigated the effect as the constraint condition of atmospheric condition, and proposed a method to extend existing reanalysis data in the past. We constructed a system using historical weather database, global spectrum model, local ensemble transform Kalman filter as observation data, prediction model and data assimilation scheme respectively. Analog information indicating weather should be classified into about 3 to 5 categories and it is better to correspond to the cloud amount ratio and the short wave downward radiation on the ground surface. Furthermore, it is appropriate that the ensemble number is about 30 from the balance of calculation efficiency and accuracy. Using the above setting, the data assimilation result given the weather information obtained at the meteorological observatory at 18 sites, for the modern era (1990 's), is closer to the modern reanalysis than the result without any weather information. As a result, significant improvements were observed in shortwave radiation and cloud cover, and significant improvement in precipitation was confirmed. These improvements are thought to have been brought by synchronizing the modeled synoptic-scale weather patterns to the reality. Furthermore, it was confirmed that the skill of rainfall estimation was improved by adding information of “no precipitation day” to data assimilation as an observation item. Then we conducted the experiments of the 1830s and 1860s using actual ancient diary data. It was confirmed that similar seasonal change and interannual variations can be obtained compared with temperature and precipitation in the 1860s which was actually observed in Yokohama.

Examination of data range for fitting Omori-Utsu law to temporal decay of aftershocks presented in historical materials on the 1830 Kyoto earthquake: Reason for the difference of numbers of aftershocks in the same place

*Kentaro Hattori[1], Junzo Ohmura[2], Ichiro Nakanishi[1]

1. Kyoto Univ., 2. Bukkyo Univ.

We study the temporal decay of aftershock sequences of the 1830 Kyoto earthquake. Omori(1908) examined aftershock sequences including that of the 1830 Kyoto earthquake. Matsui and Oike (1997) attempted to determine epicenter of the 1830 Kyoto earthquake by using the number of felt aftershocks in time range from the main shock to the next morning in several observational areas including Kyoto. They used two different numbers as the number of felt aftershocks for Kyoto: 100 written in Banzai Rakki and 4 written in Tansui Nikki. In the case using the former number, they obtained the epicenter consistent with that obtained by Usami (1996). However, in the case using the latter number, they obtained an epicenter near the northern shore of the lake Biwa, and the epicenter is inconsistent with distribution of damage caused by the earthquake. They did not pursue the reason of the discrepancy between two numbers for Kyoto.

In order to solve the above mentioned discrepancy among the earthquake records for Kyoto, we include another record Tenpo Zakki in addition to Banzai Rakki.Both records show quite different numbers of daily aftershocks during several days, though they were written in the same place. Kitahara and Ohmura (2012) suggest that the original record was written by an officer in Nijo-jo Castle and was copied many times. They made a graph of temporal decay of daily numbers of aftershocks for a period of one month after the main shock. However, they made neither analysis of the aftershock sequences nor information evaluation of the records.

We examined carefully description of daily aftershocks in both records to know the reason for the differences of the numbers of felt aftershocks. The records show the sizes of earthquakes by the diameters of handwritten circles for each day. Comparing the diameter of standard circle for every day, we infer that writers of the records used different criterion to count the numbers of felt aftershocks.

We measure the diameter of standard circle for every day, and find the diameter changes with day. Fig.1 shows the daily variation of diameter of standard circle in the both records. The vertical axis shows the count threshold of circle diameter (arbitrary unit), and horizontal axis shows the date. Fig.1 suggests that the threshold count level used in Banzai Rakki is larger than that used in Tenpo Zakki. This result means that the number of counted aftershocks becomes smaller in Banzai Rakki than in Tenpo Zakki. The interpretation is consistent with the actual difference of the number of aftershocks in the both records. The threshold level for counting used in Banzai Rakki changes more rapidly with time than that used in Tenpo Zakki (Fig.1). Especially, the change of the threshold level from 7/3 to 7/5 is not negligible in Banzai Rakki.

The above information evaluation of the two records reveals the difference of the two records written in the same place. We fit Omori-Utsu law (Utsu, 1961) to the aftershock sequences after 7/5. We assume that the c value is 0.1 and the p values fall in about 1.2. We obtain a better fit in Tenpo Zakki (Fig.2). Our study may suggest that Tenpo Zakki may have better information quality than Banzai Rakki and the numbers of aftershocks after 7/5 should be used for study of the 1830 Kyoto earthquake.

Tsunami trace height of the AD 1854 Ansei Tokai tsunami around the lake Hamanako inferred from historical maps

*ebina yuichi[1], Kentaro Imai[2], Yoshinobu Tsuji[3], hiroyuki iwase[4]

1. International Research Institute of Disaster Science, 2. JAMSTEC, 3. Fukuda Geological Instite, 4. (C)ECOH CORPORATION

We analyzed the trace of tsunami from historical maps "Maisaka-syuku tsunamizu" and “Ansei Tsunami saigai ezu" (in Hamamatsu museum) drawn about the tsunami damages around Hamanako in the Ansei Tokai earthquake occurred in 1854.

“Maisaka” (present Maisaka-cho Nishi-ku, Hamamatsu-shi, Shizuoka-ken) located in the “Hamanako” east shore is the area which prospered as a post town in “Tokaido”. According to "the history of Shizuoka" (1996), which was drawn by Hachiro Watanabe, who was a resident of “Maisaka” and drew the " Maisaka” tsunami figure. This picture shows that the appearance of Maisaka inundated by tsunami, or people who evacuated. On the east side of a highway, tsunami has reached to near night-lights. Moreover, in the west side, stairs around "Shigetuin" were inundated. This is a place called "Ohkonoboriba" by "Toukaido-bungen-nobe-ezu". It becomes clear that from here to several east sides of a subsidiary inn or an administration office were inundated by tsunami.

“Ansei zisin tsunami saigai ezu“ shows the time when the tsunami hits “Okuhamanako and Kiga” area and after the situation of the tsunami. Here, we can find some points reaching tsunami by considering “Himekaido” north side passes as a mark. Although seeing from the historical map, tsunami reached the front of “Kigasekisyo” but tsunami was not flooded in the barrier main part. Moreover, "Komorisawa" near "Ninomiyasya", and "Iwanesawa", near "Himekaido" were drawn as reaching points of the tsunami. Furthermore, signs that the circumference of a mountain where "Daienzi-temple" located in “Ikutagawa-river mouth-of-a-river part which flows into “Okuhama” name lake serves as a cemetery in the case of tsunami has sunk are drawn. “Dainenji Temple” in the area of mouth of “Ikutagawa River” was inundated by tsunami but only the hill used as the “Dainenji Temple Cemetery” was not. There are few documents described accurate places which was reached by the tsunami around Lake Hamanako, especially Lake Okuhamanako. However, we identified those based on historical maps. We hope that our results will contribute to future interdisciplinary research including tsunami engineering on the past great earthquakes along the Nankai Trough.

Acknowledgement

Discussion

Axisymmetric disturbance on an axisymmetric shallow water vortex

*Toshihisa Itano[1]

1. National Defense Academy

The air in an eye of a typhoon is often considered to be stratospheric origin. Indeed, the region of high equivalent potential temperature invading eyes from stratosphere can be seen in most of tropical cyclones. Therefore, we can recognize tropical cyclones are vortices where the air with low potential temperature revolves around the warm air sucked from stratosphere. Also, elliptical or polygonal deformation of an eye of a tropical cyclone can be attributed to the oscillation of the interface between such two kinds of fluids. Thus, in this study, a tropical cyclone is modeled with two layer fluids where the upper fluid touches the ground surface at the core region of the vortex, and the motion on the interface is investigated with the shallow water equations described in polar coordinate by assuming the upper fluid at rest.
An axisymmetric swirling fluid whose center is completely dried up is adopted as the basic state, where the tangential speed is assumed to be inversely proportional to the α-th power of radius. Perturbations are again set to be axisymmetric. Under these settings, the governing equations are linearized, and an eigenvalue problem is formulated after hypothesizing sinusoidal time variation with the angular frequency ω. The eigenvalues are, at first, obtained numerically by discretizing the variables with a standard staggered grid. Then, in the case of no ambient rotation, the problem is solved analytically, by applying a series expansion to the governing equations.
Results reveal the existence of modes like gravity waves. Since the amplitudes of the modes are non-zero at the inner boundary corresponding to the outer edge of the dry core, they would be responsible for the periodic expansion and contraction of an eye in an actual tropical cyclone. Moreover, quasi-steady modes with no nodes in the radial direction emerge in the case of no ambient rotation. Although numerical and analytic solutions roughly coincide with each other, a definite discrepancy is found near the dry core of the basic vortex: radial cross sections reveal that the numerical solutions tend to swing once more against the analytic solutions around there.

Numerical studies on the classification of flow regimes of the 3-D thermal convection of rotating fluids

*Masanori Kameyama[1,2]

1. Geodynamics Research Center, Ehime University, 2. Japan Agency for Marine-Earth Science and Technology

In this study we made a series of statistical analysis for a thermal convection in a three-dimensional Cartesian box rotating about a vertical axis, aiming at obtaining clues to readily understand the flow regimes of rotating convection. First we conducted numerical calculations of 20 cases where the values of Rayleigh number (Ra), Ekman number (Ek) and Prandtl number are systematically varied in the range of earlier studies. We confirmed that, based on the efficiency of convecting heat transfer, the flow patterns of these cases are classified into three regimes mainly depending on Ra and Ek: (i) no-rotating convection, (ii) the regime with strong effect of rotation, and (iii) that with moderate effect of rotation. In particular, we found that the change between the regimes with strong and moderate effect of rotation is associated with the change in the pattern and occurrence of Ekman pumping near the top and bottom boundaries, which can be clearly seen from the correlation between the vertical components of velocity and vorticity there. In the regime with strong effect of rotation, a strong correlation is observed in the vertical flows both away from and toward the horizontal boundaries. In the regime with moderate effect of rotation, in contrast, it is observed only in the flows departing from the boundaries. Our findings suggest that, from the viewpoint of rotating convection, the flow regime the Earth's outer core can be well identified from the observation of the correlation between the radial components of velocity and vorticity.

Diffusive behavior of columnar vortices in rotating thermal convection

*Daisuke Noto[1], Yuji Tasaka[2], Takatoshi Yanagisawa[3], Yuichi Murai[2]

1. Graduate School of Engineering, Hokkaido University, 2. Faculty of Engineering, Hokkaido University, 3. Japan Agency for Marine-Earth Science and Technology

Rotation effect on thermal convections in a fluid layer driven between two parallel plates with temperature difference, i.e., Rayleigh-Bénard convection (RBC) is a ubiquitous to explain large scale fluid motions observed on the Earth, such as typhoon, tornadoes, and liquid metal convection inside outer core. Various approaches so far have revealed its interesting features, e.g. heat transfer enhancement at moderate rotation rate, rotation dependent flow morphologies, and so on. Especially in them, formation of vertically aligned columnar vortices is one of the most curious phenomenon. Early experimental works mentioned those chaotic behavior like vortex-vortex interactions, however, little is known about this complicated vortex dynamics.

The present study is paying attention to such vortex dynamics observable in rotating RBC. With using encapsulated thermochromic liquid crystals, long-time $O(10^3$ s) experimental visualizations of the vortices on time variations of a temperature field were conducted, and we reached two novel insights. One is horizontal diffusive motion like Brownian motion of the columnar vortices. Statistical analyses on motions of the columnar vortices elucidated various kinds of diffusive motion. Such diffusive motions strongly depend on observation timescale (vortex lifetime) and columnar vortices present anomalous diffusive motion. Another is the effect of centrifugal force even under conditions for empirically negligible small effects of centrifugal force. This is the first found thanks to our long-time observations and might give a new caution to rotating RBC studies.

Liquid metal flows driven by a rotating magnetic field

*Koki Sawada[1], Vladimir Galindo[2], Tobias Vogt[2], Sven Eckert[2], Yuji Tasaka[3], Yuichi Murai[3]

1. Graduate School of Engineering, Hokkaido University , 2. Helmholtz-Zentrum Dresden-Rossendorf, 3. Faculty of Engineering, Hokkaido University,

Doing experimental studies on liquid metal flows under interactions with magnetic fields is of great importance for understanding fluid dynamical phenomena including flows in planetary cores. In this research, liquid metal flows driven by a rotating magnetic field (RMF) were examined experimentally. The RMF generates eddy currents in liquid metal layers, and thus Lorentz force as the results of the interaction between the magnetic field and the current achieves the rotating flows. The fluid motions are dominated by angular velocity and magnetic strength of the RMF. In cases at which the skin effect is negligible small because of moderate angular velocity, modal transitions of the flow occur with increase of magnetic Taylor number (Ta_m), which is a dimensionless number including the angular velocity and the magnetic strength. For sufficiently small Ta_m, a quasi-two-dimensional, axisymmetric steady flow is formed. With increase of Ta_m, then, unsteady flows emerge by collapsing the symmetry. For this transition problem, theory and numerical calculation have been preceded. On the other hand, experimental approaches have essential unknows, even though there are quired to uncover the phenomena especially at higher Ta_m with stronger nonlinearity; namely, how to realize the RMF by experiment, and whether the experiment system can reproduce the flows expected by numerical simulations.

In the present experiment, we tried to produce the RMF by switching electric current in six-pair coils. A square container with aspect ratio 2 filled with eutectic of GaInSn, a liquid metal having low melting point, was arranged at the center of the coil. The GaInSn is an opaque fluid and it is impossible to be optically visualized. Ultrasonic Doppler velocimetry was used to obtain information of the flow fields. The switching frequency of the RMF was set at 50 Hz at which the skin effect did not appear, and Ta_m was modified by changing the magnetic strength. A long these methods, the flow transition depending on Ta_m was observed. As the measurement results, a stationary axial symmetric flow, that is in good agreement with the numerical simulation results, was observed under relatively small Ta_m. The increase in Reynolds number with respect to Ta_m also show reasonable agreement with the numerical simulations. Furthermore, the process of unsteady and turbulent transition in the increase of Ta_m was discussed and was compared with the numerical simulations.

A symmetry-breaking self-regulating dynamo generating Mercury's anomalous magnetic field

*Futoshi Takahashi[1], Hisayoshi Shimizu[2], Hideo Tsunakawa[3]

1. Faculty of Sciences, Kyushu University, 2. Earthquake Research Institute, University of Tokyo , 3. Department of Earth and Planetary Sciences, School of Science, Tokyo Institute of Technology

The discovery of Mercury's unusually axisymmetric, anomalously axially offset dipolar magnetic field shows a new regime of planetary magnetic fields. The cause of the offset dipole remains to be resolved, although some exotic models have been proposed. Since the magnetic fields of the terrestrial planets are generated by fluid motions in the liquid iron core through dynamo action, which is inevitably linked to the structure and evolution of planetary interiors, untangling why Mercury has such an anomalous field is not only crucial for understanding the internal dynamics, evolution history and origin of the planet, but also essential for establishing the general theory of planetary magnetic fields by extending our knowledge to small bodies in our solar system such as Ganymede, Moon and asteroids. In this study, we use numerical dynamo models. Convection is driven as thermo-compositional convection. A thermally stably stratified layer is imposed in the outer part of the core. It is found that the magnetic fields similar in morphology as well as strength to that of Mercury are reproduced. Also, the dynamo-generated magnetic fields act on the flow to induce interaction between equatorially symmetric and antisymmetric components, and resultantly to yield north-south asymmetric helicity. Additional runs demonstrate that the offset dipolar field cannot be maintained without the magnetic self-regulating effect. Thus, it is concluded that the symmetry breaking self-regulating effect causes the flow to generate and maintain the Mercury-like offset dipolar field.

Numerical experiments on climate of the Earth-like extrasolar planets using one-dimensional energy balance model

*Tomohiro Oonaka[1], Toru Nozawa[2]

1. Faculty of Science, Okayama University, 2. Graduate School of Natural Science and Technology,Okayama University

Recently, extrasolar planets with a mass similar to the Earth were discovered by observations. It is an important question that what kind of climate could have such an Earth-like extrasolar planet. In this study, we performed a series of numerical experiments using one-dimensional Energy Balance Model (EBM), and investigated dependence of climate of the planet on parameters such as orbital radius, obliquity angle, and rotation rate of the planets.

Assuming that the efficiency of north-south heat transport of the planet is inversely proportional to the square of its rotation rate, the steady climate state of the planet at the obliquity angle of 23.5 degrees was calculated by changing two parameters of the heat transport efficiency (that is, the rotational rate) and the orbital radius.

In the range where the heat transport efficiency is large, the orbital radius leading to the global freezing decreases with a decrease in the heat transport efficiency. On the other hand, in the range where the heat transport efficiency is small, the orbital radius leading to the global freezing increases conversely with a decrease in the heat transport efficiency. In the range where the heat transport efficiency is large, heat is efficiently transported from the equator to the pole, so the temperature difference between the equator and the pole becomes small. In this case, since the temperature in the polar region rises, it is possible to maintain the ice-free climate condition even with a smaller stellar radiation. Therefore, in this range, the orbital radius leading to global freezing decreases as the heat transport efficiency decreases. On the other hand, since heat is difficult to be transported from the equator to the pole in a range where the heat transport efficiency is small, the temperature does not rise except for the low latitude and freezes. The amount of heat accumulated in low latitude increases as the heat transport efficiency decreases. That is, the lower the heat transport efficiency, the higher the temperature at the equator. Therefore, in the range where the heat transport efficiency is small, the orbital radius leading to the global freezing increases with a decrease in the heat transport efficiency.

A study on disturbances with wavenumber 2 in inner-core region of tropical cyclones.

*Yuki Kawata[1], Keita Iga[1], Sho Yokota[2], Eigo Tochimoto[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Meteorological Reseach Institute, Japan Meteorological Agency

While the development mechanisms of tropical cyclones (TCs) have been investigated based on axisymmetric theories, asymmetric structures such as spiral rainbands are also observed inside them. Such asymmetric structures are explained using vortex Rossby waves (Montgomery and Kallenbach, 1997).
Wang (2002) performed idealized numerical experiments, and indicated that these asymmetric structures can be understood as convectively coupled vortex Rossby waves and that the disturbances with wavenumber 1 and 2 are important. Some previous studies have suggested that asymmetric structures have an important role in intensity changes in TCs (e.g. Yang et al., 2007). While the disturbances with wavenumber 1 have been discussed using analytic models (e.g. Ito and Kanehisa, 2013; Nishimoto and Kanehisa, 2018), disturbances with wavenumber 2, which can be observed as elliptical vortices, have been analyzed only using radar reflectivity data (e.g. Kuo, 1999) observations; dynamic environments are not examined nor sufficient numerical experiments using non-hydrostatic mesoscale models.
In this study, we focused especially on the disturbances with azimuthal wavenumber 2, and the mechanisms of its generation and maintenance processes were examined by observational data analysis, and numerical simulations with idealized settings using a non-hydrostatic mesoscale model.
First, the observational data of Typhoon Maria (TC1808) was analyzed in order to investigate asymmetric structure of the actual case. This typhoon kept its inner eyewall with an elliptic structure for a long time, whose inner-core region was observed in detail with a Doppler radar in Ishigakijima, Japan. Retrieving the wind field at 2 km altitude of the TC from the Doppler velocity data using the GBVTD analysis (Lee et al., 1999), it was confirmed that the local region of the tangential wind maximum was formed around the long axis of the ellipse. A vorticity disturbance with wavenumber 2 persisted and from the local maximum regions extended the vorticity disturbance with a filament structure to the outer direction. The results of analyses of these observational data show that this disturbance satisfies the characteristics of vortex Rossby waves.
Second, idealized numerical experiments using JMA-NHM were performed in order to investigate the formation mechanism of the asymmetric structure of TCs, which reproduced successfully a long-lasting elliptical vortex similar to Typhoon Maria. The energy budget analysis using anelastic equations revealed that the shear production and convergence terms contributed mainly to generate the asymmetric structure in the lower layer, and the buoyancy term in the middle layer. Subdividing these effective terms, it was also shown that the term of asymmetric convergence due to radial wind in the boundary layer was dominant. For a period of elliptical vortex, the convergence in the boundary layer was strong at the long axis regions of the elliptical vortex, and the mixing ratio of rainwater was large there. From these results, it is suggested that the persistent horizontal convergence in the long axis regions and the PV generation caused by the latent heat release through the vertical wind due to this convergence are important to maintain the elliptical vortex.

Typhoon-induced vertical mixing measured by the Kuroshio Extension Observatory buoy

*Hidenori AIKI[1], Kohei Kameyama[2]

1. Institute for Space Earth Environmental Research, Nagoya University, 2. Graduate School for Environmental Studies, Nagoya University

We have analyzed the consistency of the vertical profiles of temperature and salinity and air-sea fluxes as observed by the Kuroshio Extension Observatory (KEO) buoy, with an intent to improve one-dimensional turbulence closure models used in OGCMs. The advantage of the KEO buoy data is the successful measurement of extreme weather events, such as typhoons and bomb cyclones with hourly time-resolution in the past 14 years. We have selected 7 typhoons in summer-autumn and 20 bomb cyclones in winter-spring, and compared with the results of the 1D-model experiments. In our buoy-model comparison system, the effect of mesoscale eddies and internal waves has been included by referring to the observed undulation of the seasonal thermocline. Both the timing and strength of the buoy precipitation data are well reproduced by the satellite precipitation data (GSMaP). Salinity profile in the 1D-model is yet to be improved by processes other than precipitation.

A comparison between top-down and bottom-up type convective flows in a rotating spherical shell with stress-free boundaries

*Hinami Taniguchi[1], Futoshi Takahashi[1], Shin-ichi Takehiro[2]

1. Kyushu University, 2. Kyoto University

The terrestrial bodies that maintain their intrinsic magnetic fields have dynamos in the fluid cores, in which convection is developed by a certain kind of compositional/thermal buoyancy sources. In the Earth´s core, compositional buoyancy is given by light element ejection into the outer core caused by inner core growth. In other words, compositional convection occurs as a "bottom-up" type convection. In other celestial bodies, iron ejection due to solidification of iron could occur at different depth, strongly depending on temperature-pressure conditions and bulk sulfur content within the core. When iron solidification occurs at or around the core-mantle boundary, the solid iron falls downward like snow drop, that is, so-called "iron snow". The iron snow can remelt, and then the fluid motion is driven as "top-down" type convection. In this study, basic features of the flows driven by these two types of buoyancy are investigated.

For this purpose, onsets of top-down and bottom-up compositional convection in a rotating spherical shell are studied as a linear stability problem. We consider the Boussinesq fluid contained in the rotating spherical shell, of which radius ratio is 0.2. The linearized governing equations, that is, conservation equations of the momentum and mass, and the transport equation of composition, are solved as an eigenvalue problem. The adopted values of the Ekman number, Ek range from 10^{-4} to 10^{-3}. Boundary conditions are stress-free and impermeable for the velocity field, and fixed flux for composition. It is found that the critical Rayleigh numbers Rac shows an Ekman-number-dependence of $Ra_c \propto Ek^{-1.26}$ for the top-down case and $Ra_c \propto Ek^{-1.09}$ for the bottom-up one. The flows at the onsets for both the types have columnar convection owing to the effect of rotation. Motion in the top-down case is dominated by the convection outside the tangent cylinder, which is an imaginary cylinder co-axial with the rotation axis touching the inner sphere at the equator. On the other hand, the axially elongated flow structure around the surface of the tangent cylinder is formed in the bottom-up case as well as columnar flows outside the tangent cylinder. In decreasing the Ekman number, it repeats that the structure inside the cylinder appears and vanishes, and depends on the transition of critical horizontal wavenumber.

Oscillation of two-dimensional roll-like convection under a strong horizontal magnetic field

*Takatoshi Yanagisawa[1], Yuji Tasaka[2], Takehiro Miyagoshi[1], Ataru Sakuraba[3]

1. Department of Deep Earth Structure and Dynamics Research, Japan Agency for Marine-Earth Science and Technology, 2. Faculty of Engineering, Hokkaido University, 3. Faculty of Science, University of Tokyo

Effects of the magnetic field, together with effects of the rotation, are important to understand coherent flow structures that should be generated in the Earth’ s outer core. To investigate the nature of liquid metal flow where a strong magnetic field exists, we studied magnetoconvection on the Rayleigh-Benard setting in which flows are driven by the temperature difference between the top and bottom boundaries, by laboratory experiments and numerical simulations. The control parameters for this setting are the Rayleigh number (Ra) and the Chandrasekhar number (Q). Ra represents the relative intensity of the buoyancy to the viscous force, while Q represents that of the Lorentz force. In applying a homogeneous magnetic field in the horizontal direction, the flow pattern tends to be a roll-like one whose axes are aligned to the direction of the magnetic field. Under a sufficiently strong magnetic field, that means high Q/Ra, an almost steady two-dimensional flow is observed even at high Ra far from the critical Ra for the onset of convective motion. The Ra corresponds to a state of developed turbulence when Q is zero or small, but significant reduction of fluctuations is observed under high Q. With reducing Q from this steady roll flow regime, an oscillatory motion of rolls is observed. The style of the oscillation shows two-dimensional signatures, that is, little difference of motion is observed in the direction of the magnetic field. On the other hand, the circulation style of rolls shows various interesting features those never observed for the well-known roll type convection near the critical Ra. It is due to the large circulation velocities of the roll-like flow. We can get to this new regime of convection by applying a strong magnetic field in the experiment, and make details of the regime clear by our numerical simulation with high resolutions.

Two-dimensional or shallow water MHD waves on a rotating sphere with an imposed azimuthal magnetic field

*Ryosuke Nakashima[1], Shigeo Yoshida[2]

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University, 2. Department of Earth and Planetary Sciences, Faculty of Science, Kyushu University

Magnetohydrodynamic (MHD) waves in a thin layer on a rotating sphere with an imposed toroidal magnetic field are investigated. The system is often considered as a model of the stably stratified outermost Earth's outer core or the tachocline of the Sun. The stratification of the outermost core is suggested on the basis of seismological evidence (e.g. Helffrich and Kaneshima, 2010; Kaneshima, 2018) and interpretations of the geomagnetic variations with MHD waves (e.g. Braginsky, 1993; Buffett, 2014; Chulliat et al., 2015). In order to provide constraints on the obscure stratified layer by comparing with wavy variations in the geomagnetic field, we studied the linear waves of the two-dimensional MHD and the MHD shallow water system over a rotating sphere.

We adopt an azimuthal equatorially antisymmetric field ($B_\Phi(\theta) = B_0 \sin\theta\cos\theta$, where θ is colatitude, Φ is azimuth) as a background magnetic field. On the other hand, an equatorially symmetric field ($B_\Phi(\theta) = B_0 \sin\theta$) was assumed in Márquez-Artavia et al.(2017), whose results we replicated and reported in JpGU 2018.

Compared with previous results, the dispersion diagrams obtained with the toroidal equatorially antisymmetric field show that some fast magnetic Rossby branches remain, while slow magnetic Rossby waves disappear. Besides, a continuous spectrum is found in the range where an azimuthal phase velocity is coincident with a local Alfvén velocity divided by $\sin\theta$. Similar continuous spectra are also seen in various physical situations, including inviscid shear flow (e.g. Case, 1960; Balmforth and Morrison, 1995; Iga, 2013) and plasma oscillations (e.g. Van Kampen, 1955; Case, 1959; Barston, 1964; Sedláček, 1971). The continuous spectra are accompanied by a singular eigenfunction, which is physically meaningful only when they are integrated over the continuous spectra. Its integrated solutions generally decay with time, which is referred to as phase mixing. Unlike exponentially damped discrete modes, this decaying is proportional to negative powers of time.

In the case of the shallow water system with the antisymmetric field, discrete eigenvalues buried in the continuous spectrum is found, which include unstable modes. For the Earth-like parameters, polar trapped modes with decadal period and equatorial trapped Rossby waves with a few years period are found when the stratification is weak.

Early Holocene landslide deposits found from Mount Honita, the upper Tama River basin, west of Tokyo

*Yoshihiko Kariya[1], Koichiro Sawabe[2]

1. Department of Environmental Geography, Senshu University, 2. Japan Conservation Engineers

Landslide features are common in the upper Tama River basin west of Tokyo Metropolis where sedimentary rocks derived from Mesozoic accretionary prisms are widespread. We obtained two wood fragments from landslide deposits on the northeast side of Mount Honita (710 m ASL). Radiocarbon ages of those fossils showed 10250-10189 cal BP and 10150-10057/10042-9987/9959-9704 cal BP (2sigma; OxCal4.3 with IntCal13). This result indicates that landslide occurred in the early Holocene when precipitation had increased and the elevation of riverbed had decreased in central Japan due to global changes. This situation would create morphogenetic environments prone to landslide occurrence. Although the Tachikawa Fault zone is close to Mount Honita, the age of latest paleoseismic event revealed by a trenching survey does not coincide with ages of the landslide event shown here.

The effect of understanding of mountainous terrain using 3D maps and solid model

*Jiro Komori[1]

1. Teikyo Heisei University

The topography shows various forms by a background of the formation of the place, i.e history of geology and structural development, weathering, erosion and deposition. However, for a person without an interest and opportunity for geoscience study, it is difficult to understand the relation between the topography and background. On the other hand, it became easy to see a stereoimage of the topography without difficulty using a special relief map, 3D view on the screen and hands-on model by 3D printer. This presentation will introduce practical example and reaction of the students for understanding mountain topography.

Development process of Lake Naganuma in a large-scale landslide on Hachimantai Volcano

*Natsuki Sasaki[1], Toshihiko Sugai[1]

1. Graduate School of Frontier Science, the University of Tokyo

In the Hachimantai volcanic group, landslide is one of the most important origins of wetland, and various types of wetlands, including lakes and peatlands, tend to coexist in a large-scale landslide (Sasaki and Sugai, 2015). Landslide wetlands commonly develop from lakes to peatlands, so the wetland types are considered to reflect their developmental stage. This study analyzed sediment cores to reconstruct the development history of Lake Naganuma formed in a large landslide of the Hachimantai volcanic group, and discussed the difference in the developmental history with Oyachi, a large peatland in the same landslide.

Lake Naganuma, which is formed in the upper part of the Komonomori landslide in the northwest of Hachimantai volcano, has an elliptical shape with a long axis in the north-south direction parallel to the scarp of the landslide, and its southern part is peatland. Drilling surveys were conducted at two sites on the long axis, and each sediment core was designated as NN1 and NN 2 from near to the water area. In NN1 core, we identified two lithostratigraphic units: NN1-Unit 1 (3.40–2.64 m depth) was organic silt; NN1-Unit 2 (2.64–0.00 m depth) was peat. In NN2 core, we recognized three lithostratigraphic units: NN2-Unit 1 (4.50–4.20 m depth) was silt with low organic content showing parallel lamination; NN2-Unit 2 (4.20–1.57 m depth) was organic silt; NN2-Unit 3 (1.57–0.00 m depth) was peat. The boundary between each unit was unclear, and their organic content gradually changed. We visually identified 5 tephra layers in NN1 core and 4 layers in NN2 core. From the result of chemical composition analysis of volcanic glasses, pumice layers at 1.05 m depth in NN1 core and at 1.10 m depth in NN2 core 2 were correlated with the To-a tephra, which is widely distributed over the northern Tohoku region as a result of the 915 AD eruption of Towada volcano. And the chemical composition of volcanic glasses at 2.22 m depth in NN1 core and at 2.87 m depth in NN2 were similar to that of the To-Cu tephra, erupted by Towada volcano at 6.2 ka.

The southern part of Lake Naganuma had developed from lake to peatland, because the organic silt layer changed to the peat layer upward in both sediment cores, and because the lower part of the organic silt layer in NN1 and the silt layer in NN2 showed parallel lamination. The lake changed to peatland before 6.2 ka, since the peat layer of NN1 contained To-Cu tephra. However, in NN2 far from the water area, To-Cu was contained in the organic silt layer below the peat layer. Moreover, the organic silt layer of NN2 was thicker, and the deposition rate between To-a and To-Cu layer was estimated about 0.35 mm/yr for NN2, while that of NN1 was about 0.27 mm/year. These suggest that fine grained soil continuously and slightly flowed into peatland around NN2 from the surrounding slopes even after terrestrialization. From the above, we concluded that Lake Naganuma had gradually filled from the upstream part and then been stable in the present state at least for over a thousand years, while peat layer formed.

Many wetlands are formed in the Komonomori landslide, and the development process of Oyachi peatland in the landslide, located about 800 m southwest of Lake Naganuma, is different from that of Lake Naganuma. Oyachi wetland was in the depression formed by a landslide activity before 8600 cal BP, and its transition from peatland to forest was interrupted at about 5500 cal BP by slope movement leading to the development of a lake that was drained by streams at about 3300 cal BP, after which a peatland environment has persisted until the present (Sasaki and Sugai, 2018). On the other hand, Lake Naganuma is more stable for a long period. These suggested that development processes and rates of wetlands are various even in a same landslide, probably depending on local slope stability rather than regional climatic

Air and ground temperature conditions on alpine and sub-apline zone of Norikura Volcano, Northern Japanese Alps

*Akihiko SASAKI[1], Motoshi NISHIMURA[2], Keisuke Suzuki[3]

1. Department of Geography and Environmental Studies, Kokushikan University, 2. Interdisciplinary Graduate school of Science and Technology, Shinshu University, 3. Faculty of Science, Shinshu University

In Japanese mountains, the alpine zone above the forest limit coincides with the periglacial zone, therefore the position of the forest limit and its genesis are important. The forest limit is thought to control by factors such as thermal conditions, prevailing wind, snow cover, and form and deposit of slope surfaces. We observe the air temperatures on the two sites of forest zone, where are forest limit and under limit of subalpine zone of Norikura volcano. In addition, we also observe the air temperature on an alpine zone of Fujimi-dake in Norikura volcano.
The annual mean air temperatures on the forest limit were 0.1 ℃ in 2014 and -0.3 ℃ in 2017. The warmth index (WI) on the forest limit were 19.7 ℃・months in 2014, 21.8 ℃・months in 2015, and 19.8 ℃・months in 2017, respectively. This WI value exceeds 15℃・months of Kira's WI for the forest line in Japan. This result supports the proposal that the forest line of Norikura volcano is controlled not by thermal conditions but by other factors such as the prevailing wind or snow cover.

Initiation and flow characteristics of debris flows on a sediment deposition zone in a mountain area

*Fumitoshi Imaizumi[1], Yuichi S. Hayakawa[2], Haruka Tsunetaka[3], Norifumi Hotta[4]

1. Faculty of Agriculture, Shizuoka University, 2. Faculty of Environmental Earth Sciences, 3. Forestry and Forest Products Research Institute, 4. Graduate School of Agricultural and Life Sciences

Debris flows is a geomorphic process, which is extremely hazardous as a result of their high velocity, long travel distance, and destructive power. However, debris flow characteristics in the initiation zones, which could possibly be affected by accumulation conditions of the storage (i.e., channel gradient and volume of storage) associated with sediment supply from hillslopes and the evacuation of sediment by debris flows, are poorly understood because of the difficulty in access. Thus, we studied the influence of accumulation condition of the storage on initiation and flow characteristics of debris flow at the Ohya landslide body in Japan by periodical terrestrial laser scanning (TLS) and UAV surveys, and field monitoring. In the Ohya landslide, debris flow occurs frequently (about three or four events per year) due to the mobilization of storage Our study clarified that initiation location of the debris flow is highly affected by depth of the storage and water supply from tributaries. Partly saturated debris flow is an important hydrogeomorphic processes in the initiation zones of debris flow because of the steep terrain. The flow characteristics were affected by the volume of storage and rainfall patterns. Partly saturated flow dominated when total of the storage > 15,000 m^3, while fully saturated flow dominated when total volume of the storage < 10,000 m^3. Transition of the flow type from partly saturated flow to fully saturated flow as the surges flow down was monitored by the time lapse cameras. Therefore, debris flow characteristics in the initiation zone, which is highly affected by accumulation conditions of the storage, are sometimes different from that in the transportation and deposition zones.

Relationships between annual landform changes of the riverbed and vegetation dynamics during recent 10 years in the upper Asusa River in Kamikochi valley in the Japan Alps

*Hiroshi Shimazu[1]

1. Department of Geography, Faculty of Geo-Environmental Science, Rissho University

The Azusa river is originated from Mt. Yarigatake and runs through the Kamikochi valley, whichi has the wide valley bottom instead of the mountain region. The Azusa river forms multi bar with gravelbed braided channel in the Kamikochi valley. There are patchy willow communities of *Salix arbutifolia* and *Salix rorida* in the riverbed. Kamikochi Natural History Research Group has made geomorphological maps more than 25 years, recorded annual landform changes and dynamics of vegetation. This paper discusses the relationships between landform changes and germination and destruction of willow communities.

After 2008 major channel pattern changes occurred in 2009, 2010, 2011, 2013, 2017 and 2018. Except 2009 there were heavy rain event whose daily rain fall was over 110mm in the Baiu rainy season (from June to July). In July 2009 rain observed 29 days and maximum 3 days rainfall was excess 170mm. Based on the overview images taken by interval shooting cameras placed in the study area between July 2011 and October 2016, one or two hours after beginning of rain water level rises and in heave rainfall events occurred not in the Baiu maximum water level was not high as in the event in the Baiu.

Observation of surveyed cross sections of the riverbed and distribution of vegetated area on the gravel bars shows that the channels do not move laterally. Former channels were buried by transported sediments and new channels were excavated. Although the most bars were covered with water and sediments, their surfaces were not eroded. Thus, most vegetation on the bars survived the food event. By slight lateral erosion patchy communities of willow were gradually destructed and reduction of the area. During recent ten years a new willow community germinated in a shallow ditch continues growing. The Height of the community reaches 3 meters. Another willow community germinated in 1998 and more than 20m in height continues growing, reducing its area by lateral erosion in several flood events. Isolated willow trees on the bar in the center of the riverbed survived more than 20 years impact of yearly flood flows. But some of them were washed away in the 2017 and 2018 flood events.

The landform of the riverbed of the Azusa River in Kamikochi region considerably changed by burying former channels and excavating new channels, which occurred in once in several years during heavy rainfall events in the Baiu season. After these flood events *Salix arbutifolia* germinated and form new patchy communities. Although these communities were destructed partly, they have continued growing and some of them form communities of isolated large trees. These processes form the peculiar alpine river landscape in Kamikochi area.

Groundwater age is crucial information for understanding the continuum groundwater flow system from mountain to ocean. Headwaters are origins of the terrestrial hydrological cycle and therefore important areas to understand the water resources management, material cycle, and disaster prevention. After the Fukushima Dai-ichi Nuclear Power Plant accident, concerns of radionuclide contamination of water resources have been elevated. However, the groundwater flow system including age information in radionuclide-contaminated headwaters in Japan has not been well clarified. Therefore, the objective of this study is to investigate the groundwater age and related radionuclide effect on the water resources by using multi-tracer approach in headwater catchments approximately 30 km north-west apart from the Fukushima Dai-ichi Nuclear Power Plant. Periodical field surveys were conducted from May 2011 (2 months after the disaster) to November 2012. Tritium, chlorofluorocarbon (CFCs), and stable isotopes (oxygen and hydrogen) were used as environmental tracers.
Mean groundwater age in the study areas was estimated to be ranging from 10 to 26 years by combined use of multiple CFCs concentrations. The tritium concentration in groundwater was between 1.3 TU and 6.0 TU, which supported the estimated CFCs-based groundwater age. In addition, the governing groundwater flow system was approximated by a piston flow model; however, a modern water fraction was also suggested based on the relationship between CFC-11 and CFC-12. The estimated water age and isotopic signals among the stream water, spring water, and groundwater suggested an indication of the radionuclide intrusion into the groundwater. This is consistent with the monitored ^{137}Cs concentration in the groundwater (Iwagami et al., 2017). Modern water fractions with relatively high radionuclide concentrations into groundwater possibly cause the prolonged contamination of water resources.

Hydraulic adaptation for tree height growth in tall tree species

*Wakana Azuma[1]

1. Kyoto University

Forest ecosystems, one of the major elements of the mountainous area, are characterized by its complicated three-dimensional structure which is 95% occupied by canopy where cannot be reached from the ground, compared to grasslands, deserts and rocky areas (Lowman and Rinker 2004). Various life activities such as photosynthesis, transpiration, breeding, and interaction with various organisms are performed on the canopy. Canopy researches have been progressed rapidly by the development of methods for accessing treetop in recent years (Nakanishi et al. 2018).

The question of why trees can grow up so tall is simple but its discussion has continued for a long time among ecophysiological studies. Among some factors related to tree height growth being pointed out, a main factor is considered that the limitation of water transport from root to leaves at the far end (e.g. Ryan et al. 2006). While this is the beginning of theoretical research, it has not been directly measured how much actual leaves are affected by the water transport limitation in tall trees. Therefore, we accessed to crown for 100 m tall of *Sequoia sempervirens* and 50 m tall *Cryptomeria japonica* by tree climbing, and directly evaluated water relations characteristics of leaves at various heights. As a result, although the supposed influence by water limitation was not observed, the high water capacitance of treetop leaf was revealed. This results suggested that the high water capacitance of treetop leaf would compensate for the physical water transport limit at treetop (Ishii et al. 2014).

How can treetop leaves perform high water capacity? To investigate a relationship between leaf anatomy and water relations, leaves of 50 m tall C. japonica were freeze by liquid nitrogen in situ of crown before dawn and at midday, then took it back to the laboratory and sectioned with cryo-SEM for observations. As a result, it was revealed that the transfusion tissue specific to the gymnosperm, which is located between the vascular bundle and the mesophyll, reversibly stored water and shrink like a sponge. At the treetop, large number of transfusion cells contributed to maintain the physiological function by the tissue structure giving priority to the water limit compensation, and as a result, maximum tree height could be regulated by tradeoff of the resource allocation with photosynthetic structure (Azuma et al. 2016).

To elucidate the mechanism of water retention within leaves focusing on the physicochemical properties, infrared spectroscopy is conducted. By applying it to leaf cross-sections in combination with a microscope, it is possible to quantify and visualize the distribution of water and sugars which were difficult to evaluate by an anatomical method alone. Although water is treated as one kind in the present plant physiology, in actual, physicochemical studies are known that various water components exists due to a difference in hydrogen bonding. In this study, working hypothesis that water with short hydrogen bonding component could be retained to polysaccharides within leaves was discussed. (Azuma et al. 2017).

These results suggest the one of a mechanism for tree height growth in tall conifer species with a new insight that “adaptation” to the water transport limit at treetop. To elucidate the actual ecophysiological characteristics in such huge trees, more comprehensive understanding from multiple perspectives would be necessary.

The molecular phylogenetic structure and biogeographic history of a alpine gravel environment specific plant *Dicentra peregrina* (Papaveraceae) in Japan

*Takahisa Ozaki[1], Hirokazu Matsuda, Koji Tojo[2]

1. Graduate School of Science and Technology, Shinshu University, 2. Biology Department, Faculty of Science, Shinshu University

In determining the distribution area of an organism, meteorology, climate, geography, topography and geology are important factors. In particular plants are more susceptible to climate change by limitations on dispersion compared with animals, thus the relationship between climate change and geographical distributional history in the glacial-interglacial cycles have been discussed a lot. For example, a hypotheses and a pattern have been proposed about the distribution history of alpine plants in the Japanese Archipelago. During the glacial periods, their distribution area was expanded (to the more southern region), on the other hand, the distribution area shrank (to the more northern region) during the interglacial periods and survived only in the alpine areas. Regarding the geological conditions, soil nutrition, size and stability of gravels influence species composition and population dynamics. Not only environmental factors but also biological interactions play an important role. If the weather, geography and geological conditions are severe, it will be a major barrier to plants' lives. However, few cases have established the effects of habitats' environments on their distributional histories. *Dicentra peregrina* inhabiting the alpine gravel lands and represent the alpine desert plants' community. In Japan, *D. peregrina* is also called "queen of alpine plants". Such alpine gravel lands distribute scattered around the volcanoes, and also around the ridgeline areas of high altitude mountains with strong disturbances: harsh weathering and/or unstable lands' surface. Therefore, migration is strongly restricted and highly influenced by weather, geography, topography and geology, compared with other alpine plants. Thus, *D. peregrina* is a suitable targeted alpine plant to investigate the relationship between the habitat environments and the distributional history. In order to estimate their distributional history, we have conducted phylogenetic analyses of *D. peregrina* in the Japanese Archipelago. Additionally, we have also conducted the "Ecological niche modeling" to estimate distributional changes by climate changes. As a result of our phylogenetic analyses, we observed two major genetic lineages within *D. peregrina*: one is endemic to Hokkaido (Group 1), and the other was observed from wide-areas in the Japanese Archipelago (Group 2). The boundary between the two lineages was recognized within the Daisetsu Mountain Range at Central Hokkaido. In Hokkaido, Group 2 was only observed in Mt. Kaundake and Mt. Furanodake. According to some geological studies, both Mt. Kaundake and Mt. Furanodake having comparatively old origin, it is considered that they were formed before 700,000 years ago. In contrast, regarding mountains where observed the Group 1, it is considered that they were formed around 150,000 years ago. Such differences of the mountain formation ages might be affected the population dynamics of *D. peregrina* in the glacial-interglacial climate changes. The Group 2 of *D. peregrina* is highly likely migrated to the Japanese Archipelago during the last glacial period. On the other hand, the Group 1 was dispersed to the Japanese Archipelago in older period and it is considered that their distribution spread more widely in the last glacial period. Thus, these old originated mountains served as refugia during inter-glacial periods. In addition, the genetic structure of *D. peregrina* was largely different from other alpine plants, and such difference suggests the distributional history of *D. peregrina* is strongly related to geological history rather than other alpine plants.

Formation process of small stands of *Abies mariesii* forest in pseudo-alpine zone on Mt. Akita-komagatake, northern Japan

*Asaka Konno[1]

1. International Research Institute of Disaster Science, Tohoku University

The coniferous forest (largely composed of *Abies mariesii*) is presently the typical vegetation of the subalpine zone in Japan. However, around Mt. Akita-komagatake, in northern Japan, the expected predominance of *A. mariesii* is not extensively observed, and the predominant vegetation is instead the dwarf bamboo (Sasa kurilensis) grasslands and broad leaf forests. It' s called Pseudo-Alpine zone. According to pollen analysis, this vegetation is assumed to be attributed to unsatisfactory expansion of *A. mariesii* forest.

Here we clarify the formation process of small stand of the *A. mariesii* forest by its size structure and process of regeneration.

The surveyed area is located in the northern Mt. Akita-komagatake. We classified the vegetation and measured DBH (diameter at breast height) and created frequency histograms of size structure on each vegetation.

The both histograms of *A. mariesii* thick and thin forest display gradual decreasing on the small classes on the *X* axis (DBH). The maximum classes of DBH are the class of 20-30 cm on the both histograms. The decreasing is considered to be brought about by two reasons: the second generation of *A. mariesii* on 20-30 cm DBH class is not enough equipped to propagate, and there is less numbers of first generation. These results are indicated that the small stands of *A. mariesii* forest rapidly formed by second generations.

Natural cedar grows in the area of southeastern part of Aizu area to Higashi Kanbara gun.
This cedar is known as the real name Cryptomeria japonica or Sanjo Sugi, a famous cultivar called Sugi or Sanjo Sugi. On a gentle slope it forms a forest that intermixes with beech and on the ridge it forms a mixed forest with the Chitose or Pinus densiflora.
Forests mixed with sugi and beech are recognized on the Sea of Japan side mainly in Akita prefecture (2018 Echigo valley), whereas forests mixed with sugi and Kitakagoyo or Pinus densiflora are not well recognized in other areas, .
Regarding vegetation in this area Matsuura (2010) says, "The most characteristic of vegetation in this area is avalanche vegetation consisting of shrub forests and grasslands formed by frequent avalanche due to heavy snow.The upper slope of the ridge An avalanche vegetation in a shrub forest from both sides, formed as a result of snow accumulation as a pine forest (Mainly for Kita gobo and Mixed Pinus densiflora in a low altitude) on a Yase ridge remains linear (Mohegan cut) It shows that it is vegetation.
By the way, the author made a survey in this area around the autumn of last year, and found that the pine forest including this cedar has relevance to snow accumulation gradient. In addition, from the viewpoint of the combination of plants, that is, from the viewpoint of plant sociology, it was also found to be strongly related to "Crobe - Kita - gobay Forest" distributed in the sub - alpine region of Japan.
We analyze these relationships, that is, the plant sociological features and the geographical relevance of the environment such as snow cover by using existing vegetation survey database and mesh climate value and report the results.

Roles of glacier microbes in alpine ecosystems of Asian high mountains: effect of cryoconite outflow on soil development in glacier forefields

*Nozomu Takeuchi[1], Masato Shiomuki[1]

1. Chiba University

The Tien Shan Mountains are one of the major mountain systems in Central Asia, extending over 2000 km, from east Uzbekistan to northeast of the Taklamakan Desert in China. The major Tien Shan peaks rise from over 4000 to 7000 m above sea level (a.s.l.). Glaciers presently exist in mountains mainly above 3500 m a.s.l. and most rivers originating from the Tien Shan glaciers flow down through the steppes and deserts surrounding the mountains. Water from the mountains has sustained the local inhabitants and ecosystems of this arid area. Recent studies revealed that there are diverse microbes living on the Tien Shan glaciers and they produce significant amounts of cryoconite, which is a small granular aggregation of microbial organic matter on the glacier ice. We found abundant cryoconite deposit along a river from glaciers, which is likely to contribute development of organic soil in the glacier forefields. Thus, biological communities living on the glaciers also play a role to maintain the alpine ecosystems and regional environments in the Tien Shan Mountains.

Comparison of surface energy balance of seasonal snowcover for three sites in Japanese alpine region

*Motoshi NISHIMURA[1], Akihiko SASAKI[2], Keisuke Suzuki[3]

1. Interdisciplinary Graduate school of Science and Technology, Shinshu University, 2. Department of Geography and environmental Studies, Kokushikan University, 3. Faculty of Science, Shinshu University

Process of snow and glacier ablation is one of the indicator of global climate change, so is of interest as understanding earth system. In the discussion of snow ablation process, calculating surface energy balance (SEB) is one effective method, and it is generally analysed with local meteorological observation data. SEB is sensitive to regional atmospheric conditions, therefore it often reflects in situ regional climate and surrounding environment. This presentation offers the result of regional SEB analysis in central Japanese alpine region, Kamikochi (1490 m a.s.l.), Norikura highland (1590 m a.s.l.) and Nishi-Hodaka (2355 m a.s.l.) to reveal the characteristic of SEB of seasonal snowcover in Japanese sub-alpine region. Three automatic weather stations, operated by Shinshu University, were located each targeted region in snow covered period of 2016/17 (Hydrological year). SEB analysis was conducted using surface energy balance method, and an analysis of turbulent heat flux was done using the bulk aerodynamic method. SEB analysis were conducted only snow covered period from October, 2016 to June, 2017.
The most major energy source was net shortwave radiation and negative energy flux was offered by net longwave radiation and latent heat flux in every site. Those characteristics were often reported in continental regions and high elevation areas, such as alpine region, because atmospheric condition in those regions are often cold and dry so that incoming turbulent enegy flux were restrained. The most atrractive characteristic resulted in SEB comparison is that the behavior of snowmelt energy flux in later ablation period is different in three sites. Snowpack in Nishi-Hodaka is persisted longer (untill June) than other two sites due to a lot of snowfall offered in winter, so that atmospheric condition (e.g. air temperature, specific humidity) and radiation components in later ablation period have been different from other two sites. Threrfore the different SEB properties in each site were also discovered.
Similar and diference SEB properties, which are resulted from regional climate condition and local topographic environment, among the three target sites were revealed. It is interesting that the target sites, relatively near but diferent (or same) elevation band, have each different SEB properties, so more detailed analysis of regional SEB properties are required.Comparison of surface energy balance of seasonal snowcover for three sites in Japanese alpine regionComparison of surface energy balance of seasonal snowcover for three sites in Japanese alpine region

The influence of snow for the local wind system on the east slope of Mt.Norikura

*Genki Uehara[1], Keisuke Suzuki[2]

1. Graduate School of Science and Technology, Shinshu University, 2. Department of Environmental Science, Faculty of Science, Shinshu University

On the east slope of Mt.Norikura (3026 m), there is a unique local wind system, which is thought to be influenced by the snow on the slope. In general, on the mountain regions, the nocturnal flows are down-slope and down-valley wind, while the daytime flow are up-slope and up-valley wind. However, in the Mt.Norikura on the winter-spring, the down-slope wind develop afternoon even though daytime. It is a unique local wind system. The snow on the slope of mountain is possible to play a role in the development of the unique wind system. Because a temperature of a snow surface is always near or below 0 ˚C, a downward sensible heat be formed whenever the air temperature is above 0 ˚C. The air over snow that has been cooled by a downward flux of sensible heat produce the down-slope wind in especially the late afternoon of warm, sunny days (Whiteman, 1999). We consider that the unique wind system is formed with the result of the interaction between “down-slope wind on the snow” and “up-slope wind on the no-snow surface“.

Japanese Alps including the Mt.Norikura is known as a heavy snow region, a lot of snow falls on the mountain region in winter (Suzuki, 2013). The snow surface forms a characteristic thermodynamically structure and plays important roles in the atmospheric environmental of mountain regions. However the atmospheric environment of mountain regions have not been understood sufficiently due to insufficiency of meteorological observation. In this research, We will report the relevance between a local wind system and snow on the mountain region with using the data of meteorological observation.

Mass balance of "Avalanche-accumulation type"glaciers and perennial snow patches in Hida mountain range.

*Kenshiro Arie[1], Chiyuki Narama[2], Kotaro FUKUI[3], Hajime IIDA[3]

1. Graduate School of Science and Technology, Niigata University, 2. Faculty of Science, Niigata University, 3. Tateyama Caldera Sabo Museum

In the Hida mountain range, we clarified mass balance of glaciers and perennial snow patches of ” avalanche-accumulation type" by aerial photos and SfM analysis. Comparing mass balance of the "snowdrift-acumulation type" and "avalanche-accumulation type", "avalanche-accumulation type" was more positive.

Pattern of occurrence of sea of clouds and waterfall cloud near Mt.Nishihotakadake

*Toru Awazawa[1]

1. Faculty of Science, Shinshu University National University, Shinshu University Faculty of Science

The mountain ranges of 3000 m class are connected to the spear ·Mt.Yarigatake-Mt.Hotakadake mountain range, and the mountain ranging from Mt.Nishihotakadake located at the southwest end to Mt.Yakedake, Mt.Norikuradake ridgeline is also over 2000 m. Although it is said that the atmospheric boundary layer is within 1000 meters in the temperate region, situations where the atmosphere boundary layer between Gifu prefecture and Nagano prefecture is divided by continuous mountains often occurs in this area. Under such circumstances, when moist air flows into the lower layer from the Sea of Japan side, it becomes a form that can be stopped at Gifu prefecture side. Furthermore, when an event such as subsidence inversion layer due to high pressure occurs, stratocumulus cover the sky with the reversal layer as the boundary, and a sea of clouds occurs. Analysis of the weather conditions at the time of occurrence revealed that there are some patterns in the inflow of moist air in the lower layer. We also verified the supply of lower layer wetness to maintain the generated cloud sea and the influence of solar radiation at the time of disappearance of the sea of clouds.

In addition, waterfall cloud often occurs near Nishiho Sanso, but this is due to the lowest between Nishiho Maruyama and Mt.Yakedake in the ridgeline leading from Mt.Yarigatake-Mt.Hotakadake mountain range to Mt.Yakedake. It was found that there are two patterns in the waterfall cloud seen in this mountain region. Dynamic things, such as weakening of high pressure and strengthening inflow of moist air in the lower layer, are added at the time of the occurrence of the sea of clouds, the altitude of the sea of clouds rise, and from Nishiho Maruyama - Mt.Yakedake to Nagano Prefecture side It occurs by the cloud overflowing. On a small scale, it is caused by the air rising along the slope like the cap cloud and disappearing when it goes down, but in any case, it will be between Nishiho Maruyama and Mt.Yakutake The low altitude is a major factor in the occurrence.

Review and prospect of strong local wind “Matsubori-kaze” blowing at the western foot of Mt. Aso.

*Hiroshi Matsuyama[1]

1. Graduate School of Urban Environmental Sciences, Tokyo Metropolitan University

“Matsubori-kaze” (hereafter referred to as MK) is strong local wind blowing at the western foot of Mt. Aso. It is likely to blow when a depression with warm front is located off the southwestern part of Kyushu. In this presentation, we reviewed the studies on MK and their future.

The first study that investigated MK is Hayamizu and Yamashika (1950). They observed wind speed and temperature at Tateno and Ozu from 10th to 21st November, 1949. Strong local wind blew at night when Kyushu was prevailed by an anticyclone. Because Aso-caldera is located at east, they considered cold air pooled at the caldera flew through Tateno Valley. This study was introduced in the textbook of Yoshino (1961). Yoshino (1968) investigated the distribution of wind breaks around Tateno Valley. They were densely distributed around Tateno Valley, and he estimated MK was the strongest there.

Onodera (1975) opposed to the proposed blowing mechanism of MK . He investigated the diaries of Ozu-higashi elementary school, located at the strongest area of MK. He found MK blew more frequently in spring than in autumn-winter. He also found that a depression with warm front was located at 300 km south of Kyushu when strong MK blew. Onodera (1975) concluded that the inversion layer around the top of Mt. Aso, along with the existence of warm front, was important for the occurrence and intensification of MK.

Ozu-higashi elementary school stopped keeping diaries after October 1971. Because meteorological stations were not located there, we could not know when and how MK blew after October 1971. Yoshino (1986) cited Onodera (1975), however, he still explained MK originated from cold air pooled at Aso-caldera as in Yoshino (1961).

Based on long-term meteorological and mobile observations, Kurose et al. (2002a, b) clearly distinguished two types of winds, i.e., “Aso-oroshi” (hereafter referred to as AO) and MK. Kurose et al. (2002a) found AO was outflow of cold air pooled at Aso-caldera that mainly occurred at calm night in autumn-winter. On the other hand, Kurose et al. (2002b) found MK was airflow over Mt. Aso that occurred in the specific weather condition, i.e., stable stratification was formed at lower part of the troposphere, and southeasterly wind over 10 m/s prevailed at 850 hPa level. Under this condition, the airflow over mountains converged at Tateno Valley, and its wind speed exceeded 10 m/s which usually caused damages in agriculture.

It was speculated that unique topography of Mt. Aso certainly affected MK. By using virtual topographies, Inamura et al. (2009) conducted numerical simulation using meso-scale model (RAMS). They clarified MK was composite wind of downslope wind at the southern slope of Tateno Valley as well as the gap wind through it. They also revealed that a critical layer around 850hPa was important for producing well-mixed stagnant layer and generating the strong wind beneath it.

Matsuyama et al. (2014) conducted questionnaire survey to families of the students at Ozu-higashi elementary school. Keywords in the answer sheets were summarized as “strength and mode of MK,

©2019. Japan Geoscience Union. All Right Reserved.

“agricultural damage in areas with strong winds”, and “surrendering to MK". Matsuyama (2014) also analyzed written descriptions of the students’ impressions to MK. As for children, keywords were summarized as “fear”, “outdoor experiences”, and “intellectual interest”.

Sakamoto et al. (2014) caught MK blowing on 5th to 6th April, 2013. They conducted mobile observations and investigated the spatial extent to which MK reached. They also reproduced the phenomena by RAMS. The wind speed around Ozu town was on average 1.5 times as large as that at Nishihara village, closely located south of Ozu town. RAMS revealed that fluctuation of wind speeds depended on the relation between the position of Nishihara village and hydraulic jump caused by airflow over Mt. Aso.

Based on meteorological observations, Sagawa (2017) investigated the spatial extent to which AO reached. He also compared wind speeds at Tateno and Fuketa/Uchimaki where MK is the strongest. Sagawa (2017) clarified that AO blew from Fuketa to the Kikuchi-minami fire station. Wind speeds were significantly lower at Tateno both for AO and MK. It was clearly evident during the blowing of MK.

So far, characteristics of MK have been clarified fairly well. For the occurrence of MK, wind direction and wind speed at 850 hPa (about 1500 m a.s.l.) are important information. At central cone of Mt. Aso, Aso-san Meteorological Observatory (1142.3 m a.s.l.) had been operated whose data were frequently used. However, it stopped observations on 11th December, 2017, i.e., it is impossible to use these data in the future. This is a serious damage in the study of MK.

Two decades of mountain climate monitoring and research: lessons learned and future challenges.

*Luis Duran[1,2,3], Irene Rodríguez-Muñoz[1]

1. interMET Sistemas y Redes S.L.U. Madrid. Spain, 2. Centro de Investigación, Seguimiento y Evaluación del Parque Nacional Sierra de Guadarrama. Madrid. Spain, 3. Departamento de Física de la Tierra y Astrofísica. Facultad de Ciencias Físicas. Universidad Complutense de Madrid. Spain

During the last two decades several efforts have been made in order to have an accurate assessment of climatic conditions in a mountain area in Central Spain (Peñalara Massif). A combination of in-situ measurements, statistical analysis of historical data, use of re-analyses and high resolution modeling has been done in order to overcome the difficulties inherent in such a complex terrain. The first decade has been focused on the design and operation of a mountain observational network. After some efforts, the performance achieved was satisfactory. As a result, long and homogeneous records are now available for the first time. Also, valuable technical and operational information has been gained which helped in the re-design of the network which is now in operation. In the meantime, connections between mountain meteorological phenomena and synoptic forcing has been found using weather typing methods using total column water vapor flux fields from re-analyses. The interaction between regional scale advection of humidity and orography has been identified as the leading phenomena in terms of precipitation. This finally led to the application of an orographic precipitation model giving a high resolution assessment of precipitation at this mountain area which is coherent with in-situ observations. This database opens new horizons of research since it converts point measurements into spatial fields. This comprehensive approach for researching the climate of a mountain area has proven to be effective but also brings future challenges which will be discussed here.

Development of fluvial terraces and landslides since the late Pleistocene in the Shirata River basin, southeastern side of Amagi Volcano, Izu Peninsula, Japan

*Nao Tokumoto[1], Yoshihiko Kariya[2], Kuniyasu Mokudai[3]

1. Undegraduate, Senshu Univ., 2. Senshu Univ., 3. Japan Geoservice Inc.

This study clarified geomorphic features of debris flow-fluvial terraces and landslide complexes on the southeastern side of Amagi Volcano in Izu Peninsula, central Japan. Terrace forms can be classified into three: H, M, and L surfaces from descending altitude order. Among them, the M surface is common and its geology is unique. The M surface is composed of thick and poorly sorted angular gravel beds associated with debris flow processes. The L surface is an erosion surface of higher terraces. A longitudinal profile of the M surface seems to connect with large landslide bodies in the upper reach of stream on the volcano and to continue below the present seafloor off the mouth of such a stream. Some of large landslides show secondary movement of bodies and dissected headscarps. Furthermore, the M surface is covered by a tephra layer supplied from a nearby monogenetic volcano in 19 ka. These facts show that the M surface had been formed by debris flow events filling the stream in the late Pleistocene when the sea-level was lowered. Then an increase in precipitation in the area and a decrease in bedload supply into the stream, as well as sea level rise, would have caused down cutting of the floor of stream and created a terrace form of the M surface during the period from the latest Pleistocene to the early Holocene. Because of further down cutting, the L surface had been formed. Detailed descrption of the H surface is required in future.

Variation trends of air temperature and snow depth in the Japanese Alps

*Keisuke Suzuki[1], Akihiko SASAKI[2]

1. Faculty of Science, Shinshu University, 2. Faculty of Literature, Kokushikan University

Mountainous areas are quite sensitive to global-scale environmental changes, such as warming. Therefore, the effects of global warming on these meteorological elements is a critical issue. We have developed a network of 14 meteorological observatories in the Japanese Alps, which have already started recording observations. The highest observation site is Mt. Yari, at 3125 m. Observation data from these sites are sent to a computer at the laboratory via a data communication mobile telephone network or phone line throughout the year. These meteorological observation data are available on the laboratory website in quasi-real time. The interannual variability of the air temperature and the snow depth in the Japanese Alps region are discussed.

Keywords: global warming, meteorological observation

Abundant tardigrades found in snow pack in Mt.Gassan in Yamagata Prefecture, Japan

*MASATO ONO[1]

1. Chiba University

Water bears are small invertebrates belonging to the phylum Tardigrada. They are typically 0.1 –1.0 mm in body length, and walk slowly with four pairs of legs. Tardigrades can shrink their body like a tun and become cryptobiosis, which enables to survive in extreme environments, such as low and high temperature, high pressure, under strong radiation. Their physiological mechanism of cryptobiosis is expected to be applied to medical and industry technologies, such as dry preservation of animal cells. They are commonly found on glaciers in polar or alpine regions. They actively live in cryoconite holes on glaciers and spend their entire lives on glaciers. In Japan, there is a heavy snow in mountainous regions due to strong monsoon westerly in winter, On the snow fields in Japan, there are various cold-tolerant organisms such as snow algae and invertebrates. However, no tardigrade has been reported on snow packs in Japan. In this study, we investigated mountain snow packs in Japan to search the presence of tardigrade and tried to reveal their life cycle.

The fieldworks were carried out on snow packs in the forest located in Mt. Gassan in Yamagata prefecture in Japan. Snow and moss samples were collected in a total of four times from April to October 2018, three times in snow season and once in no snow season. Mt. Gassan is an area with heavy snowfall in winter. Microscopic observation revealed that there were many tardigrades of the genus *Hypsibius* in surface snow. While only one species of *Hypsibius* was observed in snow samples, a total of two species including one species of the genus *Macrobiotus* were observed in moss of trees in the forest, and a total of six species were observed in moss of trees collected in no snow season. The species observed in snow is likely cold-tolerant tardigrade and preferably lives in the snow pack. Population density of tardigrades in snow was exceptionally higher on the green coloured snow due to algal blooming, but was little on white snow without algae. It was an average of 7.1×10^{3} ind L^{-1} in green snow samples. The body length distribution of tardigrades shows that the their size increased significantly from April to May in the snow pack, and the small sized larvae were observed only in the moss of trees collected in fall. Therefore, they live preferably in snow packs with green snow algae and grow up. When the snow disappears, they move to moss of trees and reproduce there. This life history seems to adapt to the area where heavy snow seasonally covers.

Variation of stable isotope ratios of precipitation in the Japanese Alps Region

*Tsukasa Katsuragawa[1], Tsutomu Yamanaka[2], Akihiko SASAKI[3], Yuki Kurokumo[1], Motoshi NISHIMURA[1], Shimizu Hironori[1], Keisuke Suzuki[4]

1. Graduate School of Science and Technology,Shinshu University, 2. Faculty of Life and Environmental Sciences, University of Tsukuba, 3. Department of Geography and Environmental Studies, Kokushikan University, 4. Department of Environmental Sciences, Faculty of Science, Shinshu University

We collected precipitation samples and observed meteorological condition every month from January 2011 to December 2016 at nine locations in the Japanese Alps Region (Nagano, Matsumoto, Suwa, Omachi, Sugadaira, Norikura, Kamikochi, Shigakogen, Nishihotaka). The collected water samples were brought back to the laboratory to stable isotope analysis to determineD,^{18}O and calculated d-excess. The ^{18}O in precipitation collected more than once times per month was weighted mean using the amount of precipitation and was taken as the mean monthly value. As a result of examining the seasonal variation of ^{18}O from 2011 to 2016, ^{18}O showed two peaks in spring and summer. In order to investigate the spatial variation, the coefficient of determination between latitude, longitude, altitude and ^{18}O was calculated, it clearly correlated with altitude from April to October. d-excess showed seasonal variation which is high in winter and low in summer. As a spatial variation, correlation with altitude is high in summer and correlation with longitude is high in winter. To investigate the factors that cause such variations, correlation coefficients between temperature, precipitation amount, lifting condensation level (LCL) and precipitation at δ^{18}O and d-excess at each site were calculated. Regarding δ^{18}O, it showed a positive correlation with the temperature at 8 points excluding Nishi Hodaka. Especially at 5 points of Matsumoto, Sugadaira, Omachi, Suwa, Nagano showed relatively high values. Regarding the relationship with precipitation, it showed a weak negative correlation at 6 sites excluding Omachi, Nagano and Nishi Hodaka. Regarding the relationship with LCL, there was a generally positive correlation, and particularly high correlation coefficients were found in Suwa and Nagano. From these results, it is considered that the temperature mainly contributes to δ^{18}O, and the correlation was high in Matsumoto, Sugadaira, Omachi, Suwa and Nagano, so there is a possibility that influence became strong in urban areas. The d-excess showed a negative correlation with temperature and precipitation, and there was no particularly significant relationship with LCL. The strong correlation was observed in relation to the temperature, the contribution to the fluctuation of d-excess was mainly considered to be the temperature.

Probable glacier detritus found at downstream site of the Yokoo moraines in the northern Japanese Alps: its geological characteristics and implications

*Manami Ishibashi[1], Yoshihiko Kariya[2], Kuniyasu Mokudai[3]

1. Undergraduate Senshu Univ., 2. Senshu Univ., 3. Japan Geo serivice Inc.

Around the upper reach of Azusa River in the northern Japanese Alps, the lowest position of a glacier snout during the late Pleistocene was known as the Yokoo-Iwagoya moraines (ca. 1700 m ASL). We revisited this widely-accepted concept of paleoglaciations in the Japanese Alps and newly found poorly-sorted angular to subangular rock clasts from the site lower than Yokoo-Iwagoya moraines (ca. 1400 m longitudinal and 50 m vertical). Rock clasts are composed of Quaternary igneous rocks that are never distributed around Yokoo. We concluded that those rock clasts were transported by a valley glacier from the higher slopes of Mount Yari-Hotaka Massif around 2800–3000 m ASL. Depositional ages of the clasts are still unknown but the Marine Isotope Stage 4 was probable.

Recent Geomorphological changes of rock slopes in Hakuba-Daisekkei

*Hirotaka Sugiyama[1], Chiyuki Narama[2], Hiroshi Inoue[3]

1. Graduate School of Science and Technology, Niigata University, 2. Faculty of Science, Niigata University, 3. National Reserch Institute for Earth Science and Disaster Resilience

To understand the geomorphological characteristics of slope failure points on rock slopes of the Daisekkei valley, we investigated the surface changes of rock slopes using three-dimensional topographic models based on SfM (structure from motion) with digital aerial images from airplane, drone (Phantom4) and Cessna. Slope failure points and these surface changes were extracted by comparing three-dimensional topographic models. For large slope failure in 2005, we clarified the rock mass of 60 m height and 10 m thickness was collapsed.

Behavior of inorganic ions in air deposition and surface runoff water in an alpine headwater catchment of Mt. Norikura

*Hironori Shimizu[1], Akihiko Sasaki[2], Keisuke Suzuki[3]

1. Graduate School of Science and Technology, Shinshu University , 2. Department of Geography and Environmental Studies, Kokushikan University, 3. Faculty of Science, Shinshu University

Meltwater from perennial snow patch lies on alpine catchment play an important role on the lower ecosystems as sources of fresh water during the warm season as well as rainfall, but chemical properties of air deposition and overland flow from a headwater catchment is not revealed in Japan. To characterize chemical behavior follow the rainfall and snowmelt runoff events, we studied chemical properties of stream water and air deposition during warm seasons 2016-2018, using a hydrometric and hydrochemical approaches and stable isotope of water. The study was carried out in the upper Maekawa River catchment on the east slope of Mt. Norikura, central Japan. Using an approximate curve calculated from the scatter diagrams with discharge and inorganic ion concentrations in stream water, we attempted to quantify the amount of inorganic ion dissolved in stream water during the period of August 28 to October 10, 2017.
Overland flow generation time following rainfall events was within several hours and lower surface runoff rate (up to 7%). The hydrological response properties indicate that periglacial slope overlapped by debris mainly have high water permeability and through the ground along the lava structure quickly. From the result that surface runoff rate of inorganic ions is higher than that of water amount, estimation of the amount of inorganic ions included in air deposition and surface runoff water suggest that eluviation from andesite rock contributes surface runoff amount of K^+, Mg^{2+} and Ca^{2+}. In contrast, surface runoff rate of Cl^-, NO_3^-, SO_4^{2-} were 3.9%, 2.7% and 6.5%, respectively, and it implies the dependency on air deposition for these ions dissolved in overland flow. High-frequency sampling during a rainfall event revealed that first runoff components frequently present a lower value (-19.1‰ at lowest) in $\delta^{18}O$ compared with that of stream water (-16.1‰ at lowest) during non-rainfall period. The fact that $\delta^{18}O$ of new snow obtained 2000m a.s.l. on the east slope of Mt. Norikura in January 2017 was approximately -19‰ suggests that meltwater infiltrated into the ground at early snowmelt season contribute overland flow temporarily follow rainfall input in September and October.

Activity of gravity faults in the Tateyama caldera, Hida Mountains, during the past 55 years

*Kotaro FUKUI[1], Hajime IIDA[1]

1. Tateyama Caldera Sabo Museum

Around Mt. Murodo (2668 m) located in the northeast edge of Tateyama caldera, one of the largest collapse sites in Japan, there are several gravity faults of 300-500 m in length which seem to be the precursory phenomena of deep catastrophic collapse. The gravity faults may still move, because the mountain trail which crosses the fault moves to the caldera side year by year, but the investigation has not been carried out. In this study, the precise measurement of the movement of the fault was carried out by installing many GPS observation points around the gravity fault, and it was confirmed whether it is stable or moving at present. We clarified the change of length and width of the gravity fault for the past 55 years from the aerial photograph interpretation.

Community, population and genetic structures of benthic invertebrates in alpine and sub-alpine ponds of the Kamikochi area and the Yari-Hotaka Mountain Ranges

*Keisuke Inoue[1], Koji Tojo[1]

1. Biology Department, Faculty of Science, Shinshu University

Alpine and sub-alpine ponds are considered that they pay some roles as important habitats and /or environments in mountain ecosystem. For example, they have functions as water resources for terrestrial organisms, and habitats for aquatic animals. Alpine and sub-alpine ponds have various origins, and their environments differ greatly for each origin. For aquatic animals inhabiting these ponds, differences in their environments are thought to directly effect in biota, so their environments' diversity may contribute to the creation of mountainous biodiversity. However, despite the importance of alpine and sub-alpine ponds, studies focusing on the relationship between the ponds' environments and their biodiversity have only a few cases even in high mountainous areas of Europe. Especially in the Japanese alpine ponds, there are no yet study cases. There are natural ponds, natural dammed ponds, glacier and volcanic origin ponds, and so on in the Japanese Alps, and there are good research fields for investigating the relationship between diversity of the environments and their biodiversity.

Under these circumstances, in the present study, we focused on the Kamikochi area and the Yari-Hotaka Mountain Ranges in the Japan Alps, and we have conducted analyses for the relationship between their aquatic insect fauna and the ponds' environments in alpine and sub-alpine ponds. In addition to comparing and examining the obtained community, population structure data and environmental data as habitats, the cluster analysis, the NMDS analysis, and the CCA analysis were also performed. As the result of conducting our studies of 23 ponds in total, community structures were categorized into 4 groups largely in all of our analyses. Also it was suggested that the alpine and sub-alpine aquatic insects' fauna is influenced by altitude, abundance of herbaceous plants around the shore, amount of gravels, sands and soil at the bottom of ponds. In addition, the ponds categorized into the same group, tended to be similar environments. Thus, alpine ponds with divergent environments may have important roles in the creation of mountainous biodiversity.

In addition, we also focused on the dispersal of aquatic insects inhabiting the mountain ponds. In alpine and sub-alpine mountain areas, ponds are isolated and scattered distribution. We would like to try to investigate the direction and frequency of movement and dispersion of aquatic insects between these ponds using molecular markers. As the first step, genetic analysis of the mtDNA COI region (DNA barcoding region) was performed on two caddiesflies *Pseudostenophylax ondakensis* and *Oligotricha fluvipes*, and a small diving beetle *Agabus japonicus*. As a result, in addition to that we could understand the genetic relationships in this mountain areas of *P. ondakensis*, the existence of the new haplotype which had not been observe in this area so far has been detected. Also in *A. japonicus*, in addition to that we observed individuals of the same lineage as widely distributed (i.e., from Hokkaido to Nagano), we revealed that individuals of largely genetically different lineage inhabit some alpine ponds.

Water and carbon use of fine root in four tree species at the forest limit

*Hikari Yahara[1], Wakana Azuma[2], Mai Kamakura[2], Naoki Makita[1]

1. Graduate School of Science and Technology Shinshu University, 2. Graduate School of Agriculture Kyoto University

Tree fine roots are the primary organs for nutrient and water acquisition that is necessary for trees to survive. Trees growing at the forest limit are exposed to water stress because of drying, low temperature and soil freezing in winter. Water and carbon use strategies of fine roots may differ among tree species growing at the forest limit since it is suggested that differences in microbial-symbiosis and phylogenetic groups among tree species show a wide variation of root survival strategies. We aimed to examine the root water absorption and transport characteristics of four tree species at the forest limit (2,500 m altitude) on Mt. Norikura in Central Japan. The hydraulic conductivity, daytime water potential, respiration, morphology and anatomical traits of fine roots in deciduous broad-leaved species (*Sorbus commixta* and *Betula ermanii*) and evergreen needle-leaved species (*Abies mariesii* and *Pinus pumila*) were measured. The range of the root hydraulic conductivity was 1.17 to 4.02×10^{-4} m s^{-1} MPa^{-1}, which was significantly differed among species. In particular, *Pinus pumila* showed the highest hydraulic conductivity. The range of daytime root water potential was -0.20 to -0.12 MPa. Although there was no significant difference among species, the lowest daytime root water potential was observed in *Pinus pumila*. As a preliminary experiment, low root osmotic pressure at full turgor was estimated by pressure-volume curves in *Pinus pumila*. Therefore, the root of *Pinus pumila* might be able to absorb water actively by the low daytime water potential. We also discuss how root respiration, root morphology and anatomical traits are related to root water relations.

Keywords: water relations, fine root, hydraulic conductivity, daytime water potential, forest limit

Visible-near infrared spectral reflectance explains variations in fine root traits of woody species

*Natsuko Tanikawa[1], Tatsuro Nakaji[3], Miwa Kobatake[2], Naoki Makita[2]

1. Graduate School of Science and technology, Shinshu University, 2. Faculty of Science, Shinshu University, 3. Field Science Center for Northern Biosphere

The visible and near infrared spectroscopic information can provide powerful tools for identifying and quantifying chemical substances of soil, fruit and leaf, yet less is known about characteristics of reflectance spectroscopy for tree fine roots. In this study, we aimed to examine the effects of tree species on the reflectance of fine roots and to determine the association of the reflectance with respect to morphological, anatomical and chemical traits of fine roots of 20 species. We sampled fine roots in a cool temperate forest in Japan. The fine roots were divided into three diameter classes (0-0.5 mm, 0.5-1.0 mm, 1.0-2.0 mm). We obtained hyperspectral reflectance images at 458-2391 nm (total 376 bands by 4.1-5.8 nm interval) for fresh intact fine root for each three diameter classes. The relationships of reflectance images with average root diameter (mm), specific root length (m g^{-1}), root tissue density (g cm^{-3}), stele: cortex ratio, and carbon and nitrogen concentration (%) as each root trait were analyzed at each specific wavelength. The spectral patterns of the fresh intact root systems showed peak at four wavelength band across all woody species. Spectral reflectances at 458-1400nm were positively related to the root diameter. On the other hand, the reflectances differ among tree species. We will examine relationship the reflectance and root traits which characterized tree species. These results indicate that spectral reflectance at visible-near infrared regions can be an important determinant of species specificity of fine root traits by even fresh intact samples.

Heat Balance Analysis of Cold Air Pool Formation in Kamikochi

*Sayuri Koyama[1], Motoshi NISHIMURA[2], Keisuke Suzuki[3]

1. Graduate school of science and technorogy, Shinshu University, 2. Interdisciplinary Graduate school of Science and Technology, Shinshu university, 3. Department of Environmental Sciences, Faculty of Science, Shinshu University

Meteorological observation and heat balance analysis were conducted in Kamikochi (1490 m), Dakesawa (1600 m, 1700 m, 1800 m) and Nishi-hotakadake (2355 m), and the formation mechanism of cold air pool was clarified. The observation period is the snowy season at Kamikochi from December 6, 2016 to May 4, 2017 and from November 17, 2017 to April 16, 2018.
In this study, with referring to Dorninger et al. (2011), the cold air pools that occurred during the observation period were classified into eight tyes of the cold air pool events, undisturbed evolution, late buildup, early breakup, mixing event, temperature rise of all layers in a short time, upper disturbance, lower disturbance and short time cold air pool.
The cold air pool events occurred 28 times in April 2017 and 27 times in March 2018. However, mixing event, temperature rise of all layers in a short time, upper disturbance and lower disturbance hardly occurred in both 2016/17 and 2017/18. It is thought that Kamikochi is terrain that is difficult to generate turbulence.
The undisturbed evolution, the late buildup, and the early breakup differed in the time when the cold air pools were built and the time when they were destroyed. While the cold air pools were built, the sensible heat flux and latent heat flux were 0 W m^{-2}. The mixing event, the temperature rise of all layers in a short time and upper disturbance were different in depth of rise in temperature generated in the cold air pool and the increase amount in temperature. Regarding the sensible heat flux and latent heat flux amount, the mixing event was 5.0 W m^{-2} or more, the temperature rise of all layer in a short time was 0.5 W m^{-2} or more, and the upper disturbance was 0 W m^{-2}. The lower disturbance is the event in which a short-time increase in temperature occurs near the bottom of the basin. The cold air pools with formation time of less than 6 hours were classified as the short time cold air pool. These cold air pool events are largely responsible for the generation of clouds and the generation of turbulence by the wind, the time of occurrence and duration of clouds and wind, and the strength of turbulence are considered to be the main factors.

Keywords: Cold air pool, Heat balance

A finding of fossil trees buried in dammed-lake deposits formed by the Dondokosawa rock avalanche of the late 9th century in the Akaishi Mountains, and its significance

*Takashi Kimura[1], Ryuji Yamada[1], Yoshihiko Kariya[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Senshu University

The Dondokosawa rock avalanche (DRA) initiated at an east-side slope of Mount Jizo, the Akaishi Mountains, the Southern Japan Alps, and traveled over 3.6 km along the mainstream of the Dondokosawa River. The displaced mass of the DRA completely blocked two parts, the outlet of a right tributary of the Dondokosawa River and the channel of the Ohdanasawa River, forming two dammed-lakes together with floodplain deposits beside the rock avalanche deposit (Kariya, 2012; Kimura *et al.*, 2018a). At these two sites, many fossil trees buried in lacustrine sediments were found by the authors. Yamada *et al.* (2018) applied the dendrochronological analysis using oxygen isotope ratios to tree-ring samples collected from two individuals (Hinoki cypress of >350 years old and Hemlock tree of >300 years old) and estimated death year of one individual to be around AD885 and that of the other to be AD888. These chronological constraints on the DRA strongly indicated that the DRA has occurred at the year of AD887 Ninna earthquake, which was one of the large ocean-trench earthquakes in Japan, or a couple of years later than the earthquake. The finding of fossil trees has a significance for not only estimating the age of the DRA but also reconstructing the paleoenvironment around the Akaishi Mountains. In this study, we present the vegetation characteristics of the Dondokosawa and the Ohdanasawa river catchments in the late 9th century, based on the tree species compositions of 41 samples analyzed in our previous studies (Kimura *et al.*, 2018b, 2019).

The sampling sites were named LLD and ULD, respectively. LLD is located at the confluence of the Dondokosawa and Ohdanasawa rivers, and has a drainage area of 8.81 km^2 with altitudes ranging from 1220 to 2780 m a.s.l. ULD is located at the outlet of the right tributary of the Dondokosawa River, and has a drainage area of 1.17 km^2 with altitudes ranging from 1470 to 2630 m a.s.l. We collected 41 samples (24 samples in LLD and 17 samples in ULD) between April 2012 and October 2017 and identified species or genus of each sample. The 24 samples in LLD include eight of Hinoki cypress (*Chamaecyparis obtusa*), seven of Hemlock tree (*Tsuga*), three of Sawara cypress (*Chamaecyparis pisifera*), two of Birch tree (*Betula*), and one each of Japanese larch (*Larix kaempferi*), Fir tree (*Abies*), Spruce tree (*Picea*) and Japanese Wingnut (*Pterocarya rhoifolia*). The other 17 samples in ULD include eight of *Tsuga*, four of *Abies*, two each of *L. kaempferi* and Willow tree (*Salix*), and one of Azalea tree (*Rhododendron*). The rates of *Tsuga* in LLD and ULD account for approx. 29% and 47%, respectively. Besides, the rate of cypress species (*C. obtusa* and *C. pisifera*) in LLD accounts for approx. 46%, while both of the two species are absent in ULD.

Although the above results are based on a limited number of samples, it is estimated as vegetation characteristics in the late 9th century, when the DRA occurred, as follows. In the Ohdanasawa River catchment, an old-growth forest dominated by Hinoki cypresses of >350 years old and Hemlock trees was established, while another old-growth forest dominated by Hemlock trees of >300 years old was established in the right tributary catchment of the Dondokosawa River. The remarkable difference in the abundance of cypress species in the two adjacent catchments suggests a possibility that the distribution of the two species has been limited within the Ohdanasawa River catchment and has not extended to the upper part of the Dondokozawa River from that time.

What alpine plants attract visitors in the Daisetsuzan national park, northern, Japan?

*Yukihiro Amagai[1], Kota Mameno[1,2], Hiroyuki Oguma[1], Takahiro Kubo[1]

1. National Institute for Environmental Studies, 2. Hokkaido University

The Daisetsuzan National Park in Hokkaido northern Japan is visited by 5 million people every year, because the Taisetsu Mountains have large fields of alpine vegetation. In the alpine zone, many alpine plant species (365 species: including subspecies and variants as well as 27 Japanese endemic species) grow. However, alpine vegetation has remarkably changed, with alpine dwarf-pine (*Pinus pumila*) and dwarf-bamboo (*Sasa kurilensis*) distributions having expanded during the last decade along with significant changes in the vegetation structure. From such a background, selection of protected areas, evaluation of vulnerbility for each plant species and community type, and adaptation manegement, there are urgent problems for the conservation of biodiversity in the alpine zone. Furthermore, change of alpine vegetation can be considered to damage as tourism resources as well. Therefore, purpose of this study is to clarify the preference of visitor to alpine plant species for collecting baseline information of tourism resources as one conservation indicator.

This study was conducted at the Sugatami Station of the Daisetsuzan Asahidake Ropeway which is located at an elevation of 1600 m, and the treeline is located at an elevation of around 1400-1700m. Therefore, visitors can easily hike and watch for alpine plants in alpine area. To clarify visitors preference for alpine plant species, we distributed questionnaires to visitors at the place. Respondents were asked “what flower do you want to see (check the all plants at posted picture of 20 species)”, and socio-demographics including experiences of visiting Daisetsuzan national parks. The number of questionnaires distributed were 1201 in 6 days of August 2018, and a total of 451 respondents participated our survey. The plant pictures which were showed respondents in the questionnaire were selected from 18 typical alpine plants, which considering habitats, plant growth form, and flower color (*Trollius riederianus, Stellaria pterosperma, Primula cuneifolia, Anemone narcissiflora* var. *sachalinensis, Therorhodion camtschaticum, Lagotis yesoensis, Pentstemon frutescens, Nephrophyllidium crista-galli, Pedicularis oederi, Phyllodoce aleutica, Dicentra peregrina, Saxifraga laciniate, Trichophorum cespitosum, Drosera anglica, Gentiana jamesii, Sieversia pentapetala, Campanula chamissonis, Eriophorum*) and *P. pumila* and *S. kurilensis*.

As a result, *S. pentapetala*, *G. jamesii*, and *P. cuneifolia* are high preference, while *T. cespitosum*, *S. kurilensis*, and *P. pumila* are low. From the respondent information, repeaters had high preference to *S. pentapetala* and *D. peregrina* than first time visitor. Furthermore, we analyzed flower (15 species) and whole (20 species) morphological feature by generalized linear model (GLM) for clarify the preferred features. As a result, the high preference to flower features are: the inflorescence was flat, the number was few, and the color tended to be pink > purple > white ≧ yellow plants. And the whole features are: leaves had gloss, leaf size was small, plant height was low.
Therefore, the *S. pentapetala* is the most attractive species for many visitors, which species is necessary for secure repeaters also. The *S. pentapetala* is not a specific species in the Taisetsu Mountains, because it distributes wide area in the alpine, eastern Japan. However, in the Taisetsu Mountains, a large community is formed along the trail, resulting it represents the image of the flower garden. Therefore, as tourism resources, it is important to maintain a large flower garden and suppress the influence of the expansion of *P. pumila* and *S. kurilensis*, which low preference species. Furthermore, the popular plants

©2019. Japan Geoscience Union. All Right Reserved.

have feature that low height and few flowers from ranking based on the preference by GLM, resulting the visitors expect to see the dwarf plants just like image of alpine plants. On the other hand, we also revealed that species considered to be important as tourism resources are not necessarily consistent with rare and preferential conservation. Therefore, it is necessary to consider the balance between tourism resources and biodiversity.

Spatio-temporal variations of algal snow in Mt. Gassan, Yamagata prefecture, Japan

*Suzuki Takumi[1], Nozomu Takeuchi[1], Tsubasa Takahashi[1]

1. Chiba University

Red, yellow or green colored snow due to algal blooming often appeared on the melting snow surface in the forest zone of Mt. Gassan in Yamagata Prefecture, Japan. Their distribution has been reported to be caused by physical and chemical conditions of snow surface. For example, green snow appears on eutrophic snow surfaces whereas red snow appears in poor nutrition snow surface in Antarctica. However, their temporal and spatial distributions and controlling factors are still unknown. Therefore, in this study, to clarify spatio-temporal changes of algal snow and their controlling factors, we investigated the algal biomass, pigment compositions, and nutrient conditions of colored snow of Mt.Gassan.

Snow samples were collected at 7 sites between 800 m and 1500 m above sea level along a ridge of the southern part of Mt.Ubagatake in May and June, 2018. We collected a surface snow sample from randomly selected surface at each site. The sample was preserved in a plastic bag and was melted in a laboratory. The chlorophyll a concentrations in the samples were measured with a fluorophotometer. Absorption spectra of the extracted pigments were measured with a spectrophotometer. The soluble chemical ions concentrations were measured with an ion chromatography. The samples were also observed with a microscoped.

Most of colored snow appeared in May was green snow. In June, red snow was often observed above the timber line, while orange snow was observed below the timber line. As a result of analyzing the absorption spectrum of the dye extracted from the sample, two kinds of waveforms were observed in both May and June. No major absorption was seen at any site in May. In January and June, the waveforms were found above and below the forest limit, both of which showed greater absorption than in May. Algal biomass generally increased from May to June at any sites. In addition, nitrate and phosphate ions, which are essential nutrients for algal growth, did not show any altitudinal trend, but decreased from May to June. The change of snow color from green in May to red or orange in June may be due to decrease of nutrient at the surface snow. The difference of snow color between above and below the timber line may be due to difference of solar radiation conditions.

Feeding of a wingless stonefly living on snow surface in Mt. Gassan, Yamagata prefecture, Japan

*Risako Yonechi[1], Nozomu Takeuchi[1]

1. Chiba University

There is a biological community on snow and ice consisting of cold-tolerant organisms. For examples, photosynthetic microbes (snow algae), heterotrophic invertebrates and bacteria are living on snow packs in Japan. Wingless stoneflies are also snowy insects commonly found in Japan. They are basically aquatic insects spending in streams when they are nymphs, but actively walks on the snow surface in winter and spring when they become adult. Wingless stoneflies in Japan have been classified into thirty species belonging to two genera (Apteroperla and Eocapnia) based on their morphological perspectives. Several species have been reported to appear on a snow surface simultaneously, however, it is still unknown that their feedings and life cycles. In this study, we reported the spatial distribution and feedings of wingless stoneflies found on snow packs in Mt. Gassan, Yamagata prefecture, Japan.
The fieldworks were conducted three times in April, May and June of 2018 in a south slope of Mt. Gassan, where heavy snow covers during winter and spring. We collected wingless stoneflies on snow surface at 13 sites in different elevations from a summit of Mt. Ubagatake (1487 m.a.s.l) down to Shizu camp site (770 m.a.s.l). We identified their species based on their body morphology using a microscope. We also analyzed carbon and nitrogen stable isotopes of the collected stonefly specimens. The stable isotopes were analyzed with an IRMS (Isotope Ratio Mass Spectrometer) at Research Institute for Humanity and Nature.
Fifty male specimens were classified into two genera. Apteroperla stoneflies were mostly found in the area above 1000 m a.s.l., conversely Eocapnia stoneflies were found in the area below 1000 m a.s.l. This suggests that the two genera have different habitats in this mountainous area. The nitrogen stable isotope of the wingless stoneflies was not significantly different between Apteroperla and Eocapnia (1.10 - 0.95‰ versus -1.63 - 1.05‰), indicating that the tropic levels of two genera are almost same. Carbon stable isotope also did not differ significantly between the two genera (-26.2‰ versus -25.7‰). However, the variance of the carbon stable isotopes of Apteroperla is smaller than that of Eocapnia (0.29‰ versus 3.00‰). This suggests that Apteroperla stoneflies have limited dietary habits while Eocapnia has broad eating habits.

Drainage from glacial lake in Achinathang village, Ladakh Range on 4 August 2017

Maho Saotome[2], *Chiyuki Narama[1], Naoki Sakurai[2]

1. Niigata University, Program of Field Research in the Environmental Sciences, 2. Graduate School of Science and Technology, Niigata University

In the Achinatan valley of the Ladak Range, located in the northwestern part of India, a large debris flow occurred on August 4, 2017. In this disaster, this debris flow caused four victims and serious damages such as a complete collapse of bridge and field. In this study, we tried to clarify the details of drainage from glacial lake and development of debris flow in the Achinatan valley from field survey (2017-2018) and satellite image analysis.

Recent glacier variations at Mt. Kenya using aerial digital image

*Chiyuki Narama[1], kenshiro Arie[2], MIZUNO KAZUHARU[3]

1. Program of Field Research in the Environmental Sciences, Niigata University , 2. Graduate School of Science and Technology, Niigata University, 3. Graduate School of Letters, Kyoto University

The total glacier area decreased by 121.0 x 10^3 m^2 (44%) during 2004–2016 at Mt. Kenya (Prinz et al., 2018). These glaciers are estimated to extinct before 2030, implying the cessation of the longest glacier monitoring record of the tropics. In this study, we investigated mass balance of all glaciers during 2016-2018 using Pleiades satellite data and aerial digital images from Cessna.

Keywords: glacier variations, mass balance, aerial digital image, Mt. Kenya

[J] Poster | M (Multidisciplinary and Interdisciplinary)：M-IS Intersection

Mon. May 27, 2019 5:15 PM - 6:30 PM JST | Mon. May 27, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_39

[M-IS20] Mountain Science

convener:Keisuke Suzuki(Department of Environmental Sciences, Faculty of Science, Shinshu University), Yoshihiko Kariya(Department of Environmental Geography, Senshu University), Akihiko SASAKI(Department of Geography and Environmental Studies, Kokushikan University), Chiyuki Narama(Niigata University, Department of Science)

Mountainous areas provide water resources to the populated downstream areas, protecting the
 diversity of ecosystem and providing tourism attraction. To access the mountain environment
 changes and mitigate the impacts of global warming influences, a cross-cutting session is
 proposed to share the scientific knowledge among various fields; such as climatology, hydrology, geography, glaciology, water/carbon/material cycle, eco-diversity, etc.

Development of fluvial terraces and landslides since the late Pleistocene in the Shirata River basin, southeastern side of Amagi Volcano, Izu Peninsula, Japan

*Nao Tokumoto[1], Yoshihiko Kariya[2], Kuniyasu Mokudai[3]

1. Undegraduate, Senshu Univ., 2. Senshu Univ., 3. Japan Geoservice Inc.

This study clarified geomorphic features of debris flow-fluvial terraces and landslide complexes on the southeastern side of Amagi Volcano in Izu Peninsula, central Japan. Terrace forms can be classified into three: H, M, and L surfaces from descending altitude order. Among them, the M surface is common and its geology is unique. The M surface is composed of thick and poorly sorted angular gravel beds associated with debris flow processes. The L surface is an erosion surface of higher terraces. A longitudinal profile of the M surface seems to connect with large landslide bodies in the upper reach of stream on the volcano and to continue below the present seafloor off the mouth of such a stream. Some of large landslides show secondary movement of bodies and dissected headscarps. Furthermore, the M surface is covered by a tephra layer supplied from a nearby monogenetic volcano in 19 ka. These facts show that the M surface had been formed by debris flow events filling the stream in the late Pleistocene when the sea-level was lowered. Then an increase in precipitation in the area and a decrease in bedload supply into the stream, as well as sea level rise, would have caused down cutting of the floor of stream and created a terrace form of the M surface during the period from the latest Pleistocene to the early Holocene. Because of further down cutting, the L surface had been formed. Detailed descrption of the H surface is required in future.

Variation trends of air temperature and snow depth in the Japanese Alps

*Keisuke Suzuki[1], Akihiko SASAKI[2]

1. Faculty of Science, Shinshu University, 2. Faculty of Literature, Kokushikan University

Mountainous areas are quite sensitive to global-scale environmental changes, such as warming. Therefore, the effects of global warming on these meteorological elements is a critical issue. We have developed a network of 14 meteorological observatories in the Japanese Alps, which have already started recording observations. The highest observation site is Mt. Yari, at 3125 m. Observation data from these sites are sent to a computer at the laboratory via a data communication mobile telephone network or phone line throughout the year. These meteorological observation data are available on the laboratory website in quasi-real time. The interannual variability of the air temperature and the snow depth in the Japanese Alps region are discussed.

Keywords: global warming, meteorological observation

Abundant tardigrades found in snow pack in Mt.Gassan in Yamagata Prefecture, Japan

*MASATO ONO[1]

1. Chiba University

Water bears are small invertebrates belonging to the phylum Tardigrada. They are typically 0.1 –1.0 mm in body length, and walk slowly with four pairs of legs. Tardigrades can shrink their body like a tun and become cryptobiosis, which enables to survive in extreme environments, such as low and high temperature, high pressure, under strong radiation. Their physiological mechanism of cryptobiosis is expected to be applied to medical and industry technologies, such as dry preservation of animal cells. They are commonly found on glaciers in polar or alpine regions. They actively live in cryoconite holes on glaciers and spend their entire lives on glaciers. In Japan, there is a heavy snow in mountainous regions due to strong monsoon westerly in winter, On the snow fields in Japan, there are various cold-tolerant organisms such as snow algae and invertebrates. However, no tardigrade has been reported on snow packs in Japan. In this study, we investigated mountain snow packs in Japan to search the presence of tardigrade and tried to reveal their life cycle.

The fieldworks were carried out on snow packs in the forest located in Mt. Gassan in Yamagata prefecture in Japan. Snow and moss samples were collected in a total of four times from April to October 2018, three times in snow season and once in no snow season. Mt. Gassan is an area with heavy snowfall in winter. Microscopic observation revealed that there were many tardigrades of the genus *Hypsibius* in surface snow. While only one species of *Hypsibius* was observed in snow samples, a total of two species including one species of the genus *Macrobiotus* were observed in moss of trees in the forest, and a total of six species were observed in moss of trees collected in no snow season. The species observed in snow is likely cold-tolerant tardigrade and preferably lives in the snow pack. Population density of tardigrades in snow was exceptionally higher on the green coloured snow due to algal blooming, but was little on white snow without algae. It was an average of 7.1×10^{3} ind L^{-1} in green snow samples. The body length distribution of tardigrades shows that the their size increased significantly from April to May in the snow pack, and the small sized larvae were observed only in the moss of trees collected in fall. Therefore, they live preferably in snow packs with green snow algae and grow up. When the snow disappears, they move to moss of trees and reproduce there. This life history seems to adapt to the area where heavy snow seasonally covers.

Variation of stable isotope ratios of precipitation in the Japanese Alps Region

*Tsukasa Katsuragawa[1], Tsutomu Yamanaka[2], Akihiko SASAKI[3], Yuki Kurokumo[1], Motoshi NISHIMURA[1], Shimizu Hironori[1], Keisuke Suzuki[4]

1. Graduate School of Science and Technology,Shinshu University, 2. Faculty of Life and Environmental Sciences, University of Tsukuba, 3. Department of Geography and Environmental Studies, Kokushikan University, 4. Department of Environmental Sciences, Faculty of Science, Shinshu University

We collected precipitation samples and observed meteorological condition every month from January 2011 to December 2016 at nine locations in the Japanese Alps Region (Nagano, Matsumoto, Suwa, Omachi, Sugadaira, Norikura, Kamikochi, Shigakogen, Nishihotaka). The collected water samples were brought back to the laboratory to stable isotope analysis to determineD,^{18}O and calculated d-excess. The ^{18}O in precipitation collected more than once times per month was weighted mean using the amount of precipitation and was taken as the mean monthly value. As a result of examining the seasonal variation of ^{18}O from 2011 to 2016, ^{18}O showed two peaks in spring and summer. In order to investigate the spatial variation, the coefficient of determination between latitude, longitude, altitude and ^{18}O was calculated, it clearly correlated with altitude from April to October. d-excess showed seasonal variation which is high in winter and low in summer. As a spatial variation, correlation with altitude is high in summer and correlation with longitude is high in winter. To investigate the factors that cause such variations, correlation coefficients between temperature, precipitation amount, lifting condensation level (LCL) and precipitation at δ^{18}O and d-excess at each site were calculated. Regarding δ^{18}O, it showed a positive correlation with the temperature at 8 points excluding Nishi Hodaka. Especially at 5 points of Matsumoto, Sugadaira, Omachi, Suwa, Nagano showed relatively high values. Regarding the relationship with precipitation, it showed a weak negative correlation at 6 sites excluding Omachi, Nagano and Nishi Hodaka. Regarding the relationship with LCL, there was a generally positive correlation, and particularly high correlation coefficients were found in Suwa and Nagano. From these results, it is considered that the temperature mainly contributes to δ^{18}O, and the correlation was high in Matsumoto, Sugadaira, Omachi, Suwa and Nagano, so there is a possibility that influence became strong in urban areas. The d-excess showed a negative correlation with temperature and precipitation, and there was no particularly significant relationship with LCL. The strong correlation was observed in relation to the temperature, the contribution to the fluctuation of d-excess was mainly considered to be the temperature.

Probable glacier detritus found at downstream site of the Yokoo moraines in the northern Japanese Alps: its geological characteristics and implications

*Manami Ishibashi[1], Yoshihiko Kariya[2], Kuniyasu Mokudai[3]

1. Undergraduate Senshu Univ., 2. Senshu Univ., 3. Japan Geo serivice Inc.

Around the upper reach of Azusa River in the northern Japanese Alps, the lowest position of a glacier snout during the late Pleistocene was known as the Yokoo-Iwagoya moraines (ca. 1700 m ASL). We revisited this widely-accepted concept of paleoglaciations in the Japanese Alps and newly found poorly-sorted angular to subangular rock clasts from the site lower than Yokoo-Iwagoya moraines (ca. 1400 m longitudinal and 50 m vertical). Rock clasts are composed of Quaternary igneous rocks that are never distributed around Yokoo. We concluded that those rock clasts were transported by a valley glacier from the higher slopes of Mount Yari-Hotaka Massif around 2800–3000 m ASL. Depositional ages of the clasts are still unknown but the Marine Isotope Stage 4 was probable.

Recent Geomorphological changes of rock slopes in Hakuba-Daisekkei

*Hirotaka Sugiyama[1], Chiyuki Narama[2], Hiroshi Inoue[3]

1. Graduate School of Science and Technology, Niigata University, 2. Faculty of Science, Niigata University, 3. National Reserch Institute for Earth Science and Disaster Resilience

To understand the geomorphological characteristics of slope failure points on rock slopes of the Daisekkei valley, we investigated the surface changes of rock slopes using three-dimensional topographic models based on SfM (structure from motion) with digital aerial images from airplane, drone (Phantom4) and Cessna. Slope failure points and these surface changes were extracted by comparing three-dimensional topographic models. For large slope failure in 2005, we clarified the rock mass of 60 m height and 10 m thickness was collapsed.

Behavior of inorganic ions in air deposition and surface runoff water in an alpine headwater catchment of Mt. Norikura

*Hironori Shimizu[1], Akihiko Sasaki[2], Keisuke Suzuki[3]

1. Graduate School of Science and Technology, Shinshu University , 2. Department of Geography and Environmental Studies, Kokushikan University, 3. Faculty of Science, Shinshu University

Meltwater from perennial snow patch lies on alpine catchment play an important role on the lower ecosystems as sources of fresh water during the warm season as well as rainfall, but chemical properties of air deposition and overland flow from a headwater catchment is not revealed in Japan. To characterize chemical behavior follow the rainfall and snowmelt runoff events, we studied chemical properties of stream water and air deposition during warm seasons 2016-2018, using a hydrometric and hydrochemical approaches and stable isotope of water. The study was carried out in the upper Maekawa River catchment on the east slope of Mt. Norikura, central Japan. Using an approximate curve calculated from the scatter diagrams with discharge and inorganic ion concentrations in stream water, we attempted to quantify the amount of inorganic ion dissolved in stream water during the period of August 28 to October 10, 2017.
Overland flow generation time following rainfall events was within several hours and lower surface runoff rate (up to 7%). The hydrological response properties indicate that periglacial slope overlapped by debris mainly have high water permeability and through the ground along the lava structure quickly. From the result that surface runoff rate of inorganic ions is higher than that of water amount, estimation of the amount of inorganic ions included in air deposition and surface runoff water suggest that eluviation from andesite rock contributes surface runoff amount of K^+, Mg^{2+} and Ca^{2+}. In contrast, surface runoff rate of Cl^-, NO_3^-, SO_4^{2-} were 3.9%, 2.7% and 6.5%, respectively, and it implies the dependency on air deposition for these ions dissolved in overland flow. High-frequency sampling during a rainfall event revealed that first runoff components frequently present a lower value (-19.1‰ at lowest) in $\delta^{18}O$ compared with that of stream water (-16.1‰ at lowest) during non-rainfall period. The fact that $\delta^{18}O$ of new snow obtained 2000m a.s.l. on the east slope of Mt. Norikura in January 2017 was approximately -19‰ suggests that meltwater infiltrated into the ground at early snowmelt season contribute overland flow temporarily follow rainfall input in September and October.

Activity of gravity faults in the Tateyama caldera, Hida Mountains, during the past 55 years

*Kotaro FUKUI[1], Hajime IIDA[1]

1. Tateyama Caldera Sabo Museum

Around Mt. Murodo (2668 m) located in the northeast edge of Tateyama caldera, one of the largest collapse sites in Japan, there are several gravity faults of 300-500 m in length which seem to be the precursory phenomena of deep catastrophic collapse. The gravity faults may still move, because the mountain trail which crosses the fault moves to the caldera side year by year, but the investigation has not been carried out. In this study, the precise measurement of the movement of the fault was carried out by installing many GPS observation points around the gravity fault, and it was confirmed whether it is stable or moving at present. We clarified the change of length and width of the gravity fault for the past 55 years from the aerial photograph interpretation.

Keywords: gravity fault, Deep-seated landslides, Tateyama Caldera

Community, population and genetic structures of benthic invertebrates in alpine and sub-alpine ponds of the Kamikochi area and the Yari-Hotaka Mountain Ranges

*Keisuke Inoue[1], Koji Tojo[1]

1. Biology Department, Faculty of Science, Shinshu University

Alpine and sub-alpine ponds are considered that they pay some roles as important habitats and /or environments in mountain ecosystem. For example, they have functions as water resources for terrestrial organisms, and habitats for aquatic animals. Alpine and sub-alpine ponds have various origins, and their environments differ greatly for each origin. For aquatic animals inhabiting these ponds, differences in their environments are thought to directly effect in biota, so their environments' diversity may contribute to the creation of mountainous biodiversity. However, despite the importance of alpine and sub-alpine ponds, studies focusing on the relationship between the ponds' environments and their biodiversity have only a few cases even in high mountainous areas of Europe. Especially in the Japanese alpine ponds, there are no yet study cases. There are natural ponds, natural dammed ponds, glacier and volcanic origin ponds, and so on in the Japanese Alps, and there are good research fields for investigating the relationship between diversity of the environments and their biodiversity.

Under these circumstances, in the present study, we focused on the Kamikochi area and the Yari-Hotaka Mountain Ranges in the Japan Alps, and we have conducted analyses for the relationship between their aquatic insect fauna and the ponds' environments in alpine and sub-alpine ponds. In addition to comparing and examining the obtained community, population structure data and environmental data as habitats, the cluster analysis, the NMDS analysis, and the CCA analysis were also performed. As the result of conducting our studies of 23 ponds in total, community structures were categorized into 4 groups largely in all of our analyses. Also it was suggested that the alpine and sub-alpine aquatic insects' fauna is influenced by altitude, abundance of herbaceous plants around the shore, amount of gravels, sands and soil at the bottom of ponds. In addition, the ponds categorized into the same group, tended to be similar environments. Thus, alpine ponds with divergent environments may have important roles in the creation of mountainous biodiversity.

In addition, we also focused on the dispersal of aquatic insects inhabiting the mountain ponds. In alpine and sub-alpine mountain areas, ponds are isolated and scattered distribution. We would like to try to investigate the direction and frequency of movement and dispersion of aquatic insects between these ponds using molecular markers. As the first step, genetic analysis of the mtDNA COI region (DNA barcoding region) was performed on two caddiesflies *Pseudostenophylax ondakensis* and *Oligotricha fluvipes*, and a small diving beetle *Agabus japonicus*. As a result, in addition to that we could understand the genetic relationships in this mountain areas of *P. ondakensis*, the existence of the new haplotype which had not been observe in this area so far has been detected. Also in *A. japonicus*, in addition to that we observed individuals of the same lineage as widely distributed (i.e., from Hokkaido to Nagano), we revealed that individuals of largely genetically different lineage inhabit some alpine ponds.

Water and carbon use of fine root in four tree species at the forest limit

*Hikari Yahara[1], Wakana Azuma[2], Mai Kamakura[2], Naoki Makita[1]

1. Graduate School of Science and Technology Shinshu University, 2. Graduate School of Agriculture Kyoto University

Tree fine roots are the primary organs for nutrient and water acquisition that is necessary for trees to survive. Trees growing at the forest limit are exposed to water stress because of drying, low temperature and soil freezing in winter. Water and carbon use strategies of fine roots may differ among tree species growing at the forest limit since it is suggested that differences in microbial-symbiosis and phylogenetic groups among tree species show a wide variation of root survival strategies. We aimed to examine the root water absorption and transport characteristics of four tree species at the forest limit (2,500 m altitude) on Mt. Norikura in Central Japan. The hydraulic conductivity, daytime water potential, respiration, morphology and anatomical traits of fine roots in deciduous broad-leaved species (*Sorbus commixta* and *Betula ermanii*) and evergreen needle-leaved species (*Abies mariesii* and *Pinus pumila*) were measured. The range of the root hydraulic conductivity was 1.17 to 4.02×10^{-4} m s^{-1} MPa^{-1}, which was significantly differed among species. In particular, *Pinus pumila* showed the highest hydraulic conductivity. The range of daytime root water potential was -0.20 to -0.12 MPa. Although there was no significant difference among species, the lowest daytime root water potential was observed in *Pinus pumila*. As a preliminary experiment, low root osmotic pressure at full turgor was estimated by pressure-volume curves in *Pinus pumila*. Therefore, the root of *Pinus pumila* might be able to absorb water actively by the low daytime water potential. We also discuss how root respiration, root morphology and anatomical traits are related to root water relations.

Keywords: water relations, fine root, hydraulic conductivity, daytime water potential, forest limit

Visible-near infrared spectral reflectance explains variations in fine root traits of woody species

*Natsuko Tanikawa[1], Tatsuro Nakaji[3], Miwa Kobatake[2], Naoki Makita[2]

1. Graduate School of Science and technology, Shinshu University, 2. Faculty of Science, Shinshu University, 3. Field Science Center for Northern Biosphere

The visible and near infrared spectroscopic information can provide powerful tools for identifying and quantifying chemical substances of soil, fruit and leaf, yet less is known about characteristics of reflectance spectroscopy for tree fine roots. In this study, we aimed to examine the effects of tree species on the reflectance of fine roots and to determine the association of the reflectance with respect to morphological, anatomical and chemical traits of fine roots of 20 species. We sampled fine roots in a cool temperate forest in Japan. The fine roots were divided into three diameter classes (0-0.5 mm, 0.5-1.0 mm, 1.0-2.0 mm). We obtained hyperspectral reflectance images at 458-2391 nm (total 376 bands by 4.1-5.8 nm interval) for fresh intact fine root for each three diameter classes. The relationships of reflectance images with average root diameter (mm), specific root length (m g^{-1}), root tissue density (g cm^{-3}), stele: cortex ratio, and carbon and nitrogen concentration (%) as each root trait were analyzed at each specific wavelength. The spectral patterns of the fresh intact root systems showed peak at four wavelength band across all woody species. Spectral reflectances at 458-1400nm were positively related to the root diameter. On the other hand, the reflectances differ among tree species. We will examine relationship the reflectance and root traits which characterized tree species. These results indicate that spectral reflectance at visible-near infrared regions can be an important determinant of species specificity of fine root traits by even fresh intact samples.

Keywords: root diameter, anatomy, morphology, chemistry

Heat Balance Analysis of Cold Air Pool Formation in Kamikochi

*Sayuri Koyama[1], Motoshi NISHIMURA[2], Keisuke Suzuki[3]

1. Graduate school of science and technorogy, Shinshu University, 2. Interdisciplinary Graduate school of Science and Technology, Shinshu university, 3. Department of Environmental Sciences, Faculty of Science, Shinshu University

Meteorological observation and heat balance analysis were conducted in Kamikochi (1490 m), Dakesawa (1600 m, 1700 m, 1800 m) and Nishi-hotakadake (2355 m), and the formation mechanism of cold air pool was clarified. The observation period is the snowy season at Kamikochi from December 6, 2016 to May 4, 2017 and from November 17, 2017 to April 16, 2018.
In this study, with referring to Dorninger et al. (2011), the cold air pools that occurred during the observation period were classified into eight tyes of the cold air pool events, undisturbed evolution, late buildup, early breakup, mixing event, temperature rise of all layers in a short time, upper disturbance, lower disturbance and short time cold air pool.
The cold air pool events occurred 28 times in April 2017 and 27 times in March 2018. However, mixing event, temperature rise of all layers in a short time, upper disturbance and lower disturbance hardly occurred in both 2016/17 and 2017/18. It is thought that Kamikochi is terrain that is difficult to generate turbulence.
The undisturbed evolution, the late buildup, and the early breakup differed in the time when the cold air pools were built and the time when they were destroyed. While the cold air pools were built, the sensible heat flux and latent heat flux were 0 W m^{-2}. The mixing event, the temperature rise of all layers in a short time and upper disturbance were different in depth of rise in temperature generated in the cold air pool and the increase amount in temperature. Regarding the sensible heat flux and latent heat flux amount, the mixing event was 5.0 W m^{-2} or more, the temperature rise of all layer in a short time was 0.5 W m^{-2} or more, and the upper disturbance was 0 W m^{-2}. The lower disturbance is the event in which a short-time increase in temperature occurs near the bottom of the basin. The cold air pools with formation time of less than 6 hours were classified as the short time cold air pool. These cold air pool events are largely responsible for the generation of clouds and the generation of turbulence by the wind, the time of occurrence and duration of clouds and wind, and the strength of turbulence are considered to be the main factors.

Keywords: Cold air pool, Heat balance

A finding of fossil trees buried in dammed-lake deposits formed by the Dondokosawa rock avalanche of the late 9th century in the Akaishi Mountains, and its significance

*Takashi Kimura[1], Ryuji Yamada[1], Yoshihiko Kariya[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Senshu University

The Dondokosawa rock avalanche (DRA) initiated at an east-side slope of Mount Jizo, the Akaishi Mountains, the Southern Japan Alps, and traveled over 3.6 km along the mainstream of the Dondokosawa River. The displaced mass of the DRA completely blocked two parts, the outlet of a right tributary of the Dondokosawa River and the channel of the Ohdanasawa River, forming two dammed-lakes together with floodplain deposits beside the rock avalanche deposit (Kariya, 2012; Kimura *et al.*, 2018a). At these two sites, many fossil trees buried in lacustrine sediments were found by the authors. Yamada *et al.* (2018) applied the dendrochronological analysis using oxygen isotope ratios to tree-ring samples collected from two individuals (Hinoki cypress of >350 years old and Hemlock tree of >300 years old) and estimated death year of one individual to be around AD885 and that of the other to be AD888. These chronological constraints on the DRA strongly indicated that the DRA has occurred at the year of AD887 Ninna earthquake, which was one of the large ocean-trench earthquakes in Japan, or a couple of years later than the earthquake. The finding of fossil trees has a significance for not only estimating the age of the DRA but also reconstructing the paleoenvironment around the Akaishi Mountains. In this study, we present the vegetation characteristics of the Dondokosawa and the Ohdanasawa river catchments in the late 9th century, based on the tree species compositions of 41 samples analyzed in our previous studies (Kimura *et al.*, 2018b, 2019).

The sampling sites were named LLD and ULD, respectively. LLD is located at the confluence of the Dondokosawa and Ohdanasawa rivers, and has a drainage area of 8.81 km^2 with altitudes ranging from 1220 to 2780 m a.s.l. ULD is located at the outlet of the right tributary of the Dondokosawa River, and has a drainage area of 1.17 km^2 with altitudes ranging from 1470 to 2630 m a.s.l. We collected 41 samples (24 samples in LLD and 17 samples in ULD) between April 2012 and October 2017 and identified species or genus of each sample. The 24 samples in LLD include eight of Hinoki cypress (*Chamaecyparis obtusa*), seven of Hemlock tree (*Tsuga*), three of Sawara cypress (*Chamaecyparis pisifera*), two of Birch tree (*Betula*), and one each of Japanese larch (*Larix kaempferi*), Fir tree (*Abies*), Spruce tree (*Picea*) and Japanese Wingnut (*Pterocarya rhoifolia*). The other 17 samples in ULD include eight of *Tsuga*, four of *Abies*, two each of *L. kaempferi* and Willow tree (*Salix*), and one of Azalea tree (*Rhododendron*). The rates of *Tsuga* in LLD and ULD account for approx. 29% and 47%, respectively. Besides, the rate of cypress species (*C. obtusa* and *C. pisifera*) in LLD accounts for approx. 46%, while both of the two species are absent in ULD.

Although the above results are based on a limited number of samples, it is estimated as vegetation characteristics in the late 9th century, when the DRA occurred, as follows. In the Ohdanasawa River catchment, an old-growth forest dominated by Hinoki cypresses of >350 years old and Hemlock trees was established, while another old-growth forest dominated by Hemlock trees of >300 years old was established in the right tributary catchment of the Dondokosawa River. The remarkable difference in the abundance of cypress species in the two adjacent catchments suggests a possibility that the distribution of the two species has been limited within the Ohdanasawa River catchment and has not extended to the upper part of the Dondokozawa River from that time.

What alpine plants attract visitors in the Daisetsuzan national park, northern, Japan?

*Yukihiro Amagai[1], Kota Mameno[1,2], Hiroyuki Oguma[1], Takahiro Kubo[1]

1. National Institute for Environmental Studies, 2. Hokkaido University

The Daisetsuzan National Park in Hokkaido northern Japan is visited by 5 million people every year, because the Taisetsu Mountains have large fields of alpine vegetation. In the alpine zone, many alpine plant species (365 species: including subspecies and variants as well as 27 Japanese endemic species) grow. However, alpine vegetation has remarkably changed, with alpine dwarf-pine (*Pinus pumila*) and dwarf-bamboo (*Sasa kurilensis*) distributions having expanded during the last decade along with significant changes in the vegetation structure. From such a background, selection of protected areas, evaluation of vulnerbility for each plant species and community type, and adaptation manegement, there are urgent problems for the conservation of biodiversity in the alpine zone. Furthermore, change of alpine vegetation can be considered to damage as tourism resources as well. Therefore, purpose of this study is to clarify the preference of visitor to alpine plant species for collecting baseline information of tourism resources as one conservation indicator.

This study was conducted at the Sugatami Station of the Daisetsuzan Asahidake Ropeway which is located at an elevation of 1600 m, and the treeline is located at an elevation of around 1400-1700m. Therefore, visitors can easily hike and watch for alpine plants in alpine area. To clarify visitors preference for alpine plant species, we distributed questionnaires to visitors at the place. Respondents were asked “what flower do you want to see (check the all plants at posted picture of 20 species)”, and socio-demographics including experiences of visiting Daisetsuzan national parks. The number of questionnaires distributed were 1201 in 6 days of August 2018, and a total of 451 respondents participated our survey. The plant pictures which were showed respondents in the questionnaire were selected from 18 typical alpine plants, which considering habitats, plant growth form, and flower color (*Trollius riederianus, Stellaria pterosperma, Primula cuneifolia, Anemone narcissiflora* var. *sachalinensis, Therorhodion camtschaticum, Lagotis yesoensis, Pentstemon frutescens, Nephrophyllidium crista-galli, Pedicularis oederi, Phyllodoce aleutica, Dicentra peregrina, Saxifraga laciniate, Trichophorum cespitosum, Drosera anglica, Gentiana jamesii, Sieversia pentapetala, Campanula chamissonis, Eriophorum*) and *P. pumila* and *S. kurilensis*.

As a result, *S. pentapetala*, *G. jamesii*, and *P. cuneifolia* are high preference, while *T. cespitosum*, *S. kurilensis*, and *P. pumila* are low. From the respondent information, repeaters had high preference to *S. pentapetala* and *D. peregrina* than first time visitor. Furthermore, we analyzed flower (15 species) and whole (20 species) morphological feature by generalized linear model (GLM) for clarify the preferred features. As a result, the high preference to flower features are: the inflorescence was flat, the number was few, and the color tended to be pink > purple > white ≧ yellow plants. And the whole features are: leaves had gloss, leaf size was small, plant height was low.
Therefore, the *S. pentapetala* is the most attractive species for many visitors, which species is necessary for secure repeaters also. The *S. pentapetala* is not a specific species in the Taisetsu Mountains, because it distributes wide area in the alpine, eastern Japan. However, in the Taisetsu Mountains, a large community is formed along the trail, resulting it represents the image of the flower garden. Therefore, as tourism resources, it is important to maintain a large flower garden and suppress the influence of the expansion of *P. pumila* and *S. kurilensis*, which low preference species. Furthermore, the popular plants

©2019. Japan Geoscience Union. All Right Reserved.

have feature that low height and few flowers from ranking based on the preference by GLM, resulting the visitors expect to see the dwarf plants just like image of alpine plants. On the other hand, we also revealed that species considered to be important as tourism resources are not necessarily consistent with rare and preferential conservation. Therefore, it is necessary to consider the balance between tourism resources and biodiversity.

Spatio-temporal variations of algal snow in Mt. Gassan, Yamagata prefecture, Japan

*Suzuki Takumi[1], Nozomu Takeuchi[1], Tsubasa Takahashi[1]

1. Chiba University

Red, yellow or green colored snow due to algal blooming often appeared on the melting snow surface in the forest zone of Mt. Gassan in Yamagata Prefecture, Japan. Their distribution has been reported to be caused by physical and chemical conditions of snow surface. For example, green snow appears on eutrophic snow surfaces whereas red snow appears in poor nutrition snow surface in Antarctica. However, their temporal and spatial distributions and controlling factors are still unknown. Therefore, in this study, to clarify spatio-temporal changes of algal snow and their controlling factors, we investigated the algal biomass, pigment compositions, and nutrient conditions of colored snow of Mt.Gassan.

Snow samples were collected at 7 sites between 800 m and 1500 m above sea level along a ridge of the southern part of Mt.Ubagatake in May and June, 2018. We collected a surface snow sample from randomly selected surface at each site. The sample was preserved in a plastic bag and was melted in a laboratory. The chlorophyll a concentrations in the samples were measured with a fluorophotometer. Absorption spectra of the extracted pigments were measured with a spectrophotometer. The soluble chemical ions concentrations were measured with an ion chromatography. The samples were also observed with a microscoped.

Most of colored snow appeared in May was green snow. In June, red snow was often observed above the timber line, while orange snow was observed below the timber line. As a result of analyzing the absorption spectrum of the dye extracted from the sample, two kinds of waveforms were observed in both May and June. No major absorption was seen at any site in May. In January and June, the waveforms were found above and below the forest limit, both of which showed greater absorption than in May. Algal biomass generally increased from May to June at any sites. In addition, nitrate and phosphate ions, which are essential nutrients for algal growth, did not show any altitudinal trend, but decreased from May to June. The change of snow color from green in May to red or orange in June may be due to decrease of nutrient at the surface snow. The difference of snow color between above and below the timber line may be due to difference of solar radiation conditions.

Feeding of a wingless stonefly living on snow surface in Mt. Gassan, Yamagata prefecture, Japan

*Risako Yonechi[1], Nozomu Takeuchi[1]

1. Chiba University

There is a biological community on snow and ice consisting of cold-tolerant organisms. For examples, photosynthetic microbes (snow algae), heterotrophic invertebrates and bacteria are living on snow packs in Japan. Wingless stoneflies are also snowy insects commonly found in Japan. They are basically aquatic insects spending in streams when they are nymphs, but actively walks on the snow surface in winter and spring when they become adult. Wingless stoneflies in Japan have been classified into thirty species belonging to two genera (Apteroperla and Eocapnia) based on their morphological perspectives. Several species have been reported to appear on a snow surface simultaneously, however, it is still unknown that their feedings and life cycles. In this study, we reported the spatial distribution and feedings of wingless stoneflies found on snow packs in Mt. Gassan, Yamagata prefecture, Japan.
The fieldworks were conducted three times in April, May and June of 2018 in a south slope of Mt. Gassan, where heavy snow covers during winter and spring. We collected wingless stoneflies on snow surface at 13 sites in different elevations from a summit of Mt. Ubagatake (1487 m.a.s.l) down to Shizu camp site (770 m.a.s.l). We identified their species based on their body morphology using a microscope. We also analyzed carbon and nitrogen stable isotopes of the collected stonefly specimens. The stable isotopes were analyzed with an IRMS (Isotope Ratio Mass Spectrometer) at Research Institute for Humanity and Nature.
Fifty male specimens were classified into two genera. Apteroperla stoneflies were mostly found in the area above 1000 m a.s.l., conversely Eocapnia stoneflies were found in the area below 1000 m a.s.l. This suggests that the two genera have different habitats in this mountainous area. The nitrogen stable isotope of the wingless stoneflies was not significantly different between Apteroperla and Eocapnia (1.10 - 0.95‰ versus -1.63 - 1.05‰), indicating that the tropic levels of two genera are almost same. Carbon stable isotope also did not differ significantly between the two genera (-26.2‰ versus -25.7‰). However, the variance of the carbon stable isotopes of Apteroperla is smaller than that of Eocapnia (0.29‰ versus 3.00‰). This suggests that Apteroperla stoneflies have limited dietary habits while Eocapnia has broad eating habits.

Drainage from glacial lake in Achinathang village, Ladakh Range on 4 August 2017

Maho Saotome[2], *Chiyuki Narama[1], Naoki Sakurai[2]

1. Niigata University, Program of Field Research in the Environmental Sciences, 2. Graduate School of Science and Technology, Niigata University

In the Achinatan valley of the Ladak Range, located in the northwestern part of India, a large debris flow occurred on August 4, 2017. In this disaster, this debris flow caused four victims and serious damages such as a complete collapse of bridge and field. In this study, we tried to clarify the details of drainage from glacial lake and development of debris flow in the Achinatan valley from field survey (2017-2018) and satellite image analysis.

Recent glacier variations at Mt. Kenya using aerial digital image

*Chiyuki Narama[1], kenshiro Arie[2], MIZUNO KAZUHARU[3]

1. Program of Field Research in the Environmental Sciences, Niigata University , 2. Graduate School of Science and Technology, Niigata University, 3. Graduate School of Letters, Kyoto University

The total glacier area decreased by 121.0 x 10^3 m^2 (44%) during 2004–2016 at Mt. Kenya (Prinz et al., 2018). These glaciers are estimated to extinct before 2030, implying the cessation of the longest glacier monitoring record of the tropics. In this study, we investigated mass balance of all glaciers during 2016-2018 using Pleiades satellite data and aerial digital images from Cessna.

[M-IS23] Planetary Volcanology

convener:Rina Noguchi(Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency), Tomokatsu Morota(Graduate School of Environmental Studies, Nagoya University), Kyoko S. Kataoka(Research Institute for Natural Hazards and Disaster Recovery, Niigata University), Shizuka Otsuki(Research Institute of Earthquake and Volcano Geology, Geological Survey of Japan, Advanced Industrial Science and Technology), Chairperson:Rina Noguchi(Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency), Nobuo Geshi(GSJ/AIST)

Volcanoes exist on solid planetary surface across the solar system. They tell insight into the interior, and the surface environment when they were formed and subsequent evolution. Recent high-resolution remote sensing data on extraterrestrial body allows us to analyze on outcrop scales. Now we are on the stage to share the research targets beyond fields of general volcanology and planetary science. Because some geomorphological and geological environments
in other planets are similar to those on Earth, research on volcanic geomorphology and geology on Earth will provide good terrestrial analogues to understand planetary volcanology. The aim of this session is to discuss formation history and mechanism of volcanoes across the solar system.

Growth and evolution of isolated volcanic island, Nishinoshima, Ogasawara

*Fukashi Maeno[1]

1. Earthquake Research Institute, University of Tokyo

The process of birth and growth of ocean islands is an interesting phenomenon in the field of geoscience in terms of the creation of new land and the creation of a place for new terrestrial life activities. Nishinoshima is a rare place on the earth that can trace the process of birth, formation and evolution of such ocean islands from various viewpoints of research fields. Meanwhile, since the eruption in the shallow sea can be a factor of maritime hazards, the establishment of investigation/observation method and risk assessment method is also an important subject. Nishinoshima is located in a place deserving to call as an isolated island, 130 km west of Chichijima, Ogasawara Islands. In November 2013, a new island was born by submarine eruption. It gradually covered the preexisted island and increased the land. A series of eruptive activities in Nishinoshima from 2013 to 2018 provided various valuable data on the birth of a new volcanic island and its growth process, and was also important as a place for practical investigation and observation of remote island volcanoes. The eruptive activity of Nishinoshima is divided into November 2013 - December 2015 (first stage), April to August 2017 (second stage), and July 2018 (third stage). Meanwhile, various surveys and observations were conducted to understand the activities of Nishinoshima. Immediately after the beginning of the eruption, the observation data from remote was the only information source, and based on analysis of high-resolution satellite images and direct observation from the airborne, the growth process of Nishinoshima was monitored, focusing on the changes in surface topography and morphology, area, volume, and discharge rate. After that, following the decline in activity at the end of 2015, comprehensive investigation of volcanic activity and biota was carried out in October 2016. In this survey, earth science and ecological scientists collaborated with each other to conduct a landing survey, in order to minimize the risk of bringing invasive species to new Nishinoshima, and lava samples were collected directly for the first time, and the seismometer and the microphone were also installed. In 2017 and 2018, Nishioshima became active again and grew larger, finally its activity ended at the end of July 2018. After 2016, surveys were conducted remotely utilizing drone and unmanned helicopter, taking images and movies of new lavas and craters, sampling eruptive products, installing and collecting loggers for ecological monitoring, magnetic survey and others were carried out, and the result enhancing our understanding of activities and evolution of Nishinoshima is being obtained. Such surveys and observations in Nishinoshima, where it is difficult to access and the perspective of conservation of primitive ecosystem is also necessary, may have common terms with surveys of extraterrestrial body surface. In this presentation, I will introduce the growth and evolution of Nishinoshima, the volcanic activity, and the methods and results of surveys carried out so far, while being conscious of the connection with planetary volcanology.

The style of magmatism on terrestrial planets of various sizes predicted from numerical models of mantle dynamics

*Masaki Ogawa[1]

1. Division of General Systems Studies, Graduate School of Arts and Sciences, University of Tokyo

A series of numerical models of magmatism in the convecting mantle suggest that the vigor and style of mantle magmatism critically depend on the planetary size because of its effects on the elementary processes that exert control over mantle dynamics. On a small planet like the Moon, a mild magmatism continuously occurs for several hundred million years in upwelling limbs of mantle convection and then wanes, because the magmatism extracts heat-producing elements (HPEs) from the mantle. Magmatism, however, often becomes more vigorous and episodic, as observed for the Large Igneous Provinces on Mars and larger planets, because the buoyancy of the generated magma boosts the upwelling flow in the mantle that causes the magmatism itself. The convective stirring enhanced by the MMU feedback keeps the mantle rather homogeneous, despite that the vigorous magmatism due to the feedback differentiates the mantle. The effect of the MMU feedback is particularly important in Venus and the Earth where the lower mantle develops: The solid-solid phase transitions that occur at the top of the lower mantle make mantle upwelling flow pulsating, when the mantle is strongly heated by HPEs and magmatism is vigorous. This pulse or burst of hot materials from the lower mantle causes a vigorous magmatism, especially in the early mantle. Due to this vigorous magmatism, the crust enriched in HPEs recycles back to the mantle to serve as the energy source for the magmatism that continues throughout the history of the mantle. On the Earth, plate tectonics also causes magmatism and recycling of the generated crust. In contrast to Venus, this magmatism differentiates the mantle, because tectonic plates and subducting slabs stir the mantle only mildly.

Lunar and Matian lava tubes and explorations to them through their skylight holes

*Junichi Haruyama[1], Takahiro Iwata[1], Yukio Yamamoto[1], Tetsuya Kaku[2,1], Wataru Miyake[2], Atsushi Kumamoto[3], Ken Ishiyama[1], yokota yasuhiro[4], Takumi Ono[2,1]

1. Japan Aerospace Exploration Agency, 2. Tokai University, 3. Tohoku University, 4. Kochi University

Large and deep hole structures of a few tens to hundreds meter diameter and depth were discovered on Mars in the thermal emission data acquired by Mars Odyssey THEMIS and on the Moon in the SELENE (Kaguya) Terrain Camera visible image data, about 10 years ago. These are probably skylights of underlying caves produced by volcanic activities such as lava tube formation. Later, many hole structures and depression features as "pits" possibly associated to lava tubes have been identified on these celestial bodies in image data of orbiting explores. Intact lava tube existence on the Moon are also suggested by gravity measurements by GRAIL and radar sounding experiments by SELENE (Kaguya).
The role of lava tube on the formation of vast terrains expanding on the Moon and Mars are scientifically interesting, though the study has not been sufficiently done. In addition, lava tubes and their skylight holes offers prominent environments to conduct scientific examination of the history of volcanic activities on the Mars and Moon. Lava tubes on Mars and the Moon are expected to be secure shelters for humans and instruments potentially protecting from micrometeorites bombardments and cosmic ray radiations, In the next decades, therefore, Martian and lunar lava tube exploration will be executed by space agencies of countires and even private companies.
In this presentation, we would introduce recent studies of lava tubes of Mars and the Moon and their explorations.

Volcanic activity on Io, formation of the atmosphere, and escape of atmosphere to the magnetosphere

*Fuminori Tsuchiya[1], Ryoichi Koga[1], Mizuki Yoneda[2], Masato Kagitani[1], Kazuo Yoshioka[4], Reina Hikida[4], Go Murakami[3], Tomoki Kimura[1], Atsushi Yamazaki[3], Hajime Kita[3], Ichiro Yoshikawa[4]

1. Tohoku University, 2. Tadano, 3. ISAS/JAXA, 4. The University of Tokyo

Jupiter's satellite Io is known as the most active volcanically active body in the solar system. The atmosphere of the satellite consists mainly of volcanic gas composed of sulfur dioxide. The molecular escaped becomes primary source of plasma in the magnetosphere of Jupiter. Here, observations of the volcanic gas escaped from satellite with the extreme ultraviolet telescope satellite, Hisaki, and a groundbased visible telescope, and observations of hot spot of Io's volcano with infrared telescopes are presented. We will discuss the formation of the satellite atmosphere, escape process of the atmospheric gas to the magnetosphere, and their relation to volcano types.

Cryovolcanism, a critical review

*Kei Kurita[1]

1. Earthquake Research Inst.,The University of Tokyo

Volcanoes are surface manifestation of internal activity of planets and satellites. In planetary explorations the primarily available data source would be the surface images so that the volcanoes identified on the surface are unique window into the interior. This argument is particularly significant in icy bodies of the outer solar system because exploration data are so limited except for the surface images. Up to now several types of surface morphology have been considered as a product of cryovolcanism. In this presentation I will focus on the general aspects of the cryovolcanism in comparison to the silicate volcanism and would like to emphasize the significant role of hydrate phase in cryovolcanism.

Similarities and dissimilarities between cryovolcanism and silicate volcanism: There exist a lot of similarities between ice and silicate minerals such as the rheological properties and the melting relationship. The depression of the melting point in the existence of accessary components in both systems should play an important role in promoting differentiation. The critical difference is the pressure dependence of the melting temperature and the density contrast between liquid and solid phase. Since water magma is not buoyant in the icy lithosphere this density reversal requires special mechanism for driving water magma to the surface. This situation is, however similar to the continental basalt volcanism. In the icy satellites the stress field in the outer lithosphere plays an important role. Both exogenetic origin such as tidal forcing and endogenous origin such as thermal stress and volume change driven by phase change would be

Significant role of hydrate phase in cryovolcanism: Hydrate is a common phase in the multicomponent system including H2O. It is stable at higher pressure so that it should be an important constituent phase while it decomposes near surface. This may result in explosive behavior because the decomposition is associated with generation of gas phase. Although a lot of combination of the components form various hydrate phases, there exist two planetologically significant end-members, CO2 hydrate and CH4 hydrate. These two have contrasting nature in terms of the density, which would cause different evolution path in the material differentiation.

Keywords: cryovolcanism, hydrate

Cryovolcanisms on Solar System bodies: Observations, importance, and future perspectives

*Yasuhito Sekine[1]

1. Earth-Life Science Insitute, Tokyo Institute of Technology

Cyrovolcanos are volcanos on icy planetary bodies, erupting liquids and vapors of volatiles (e.g., water, ammonia, methane, and carbon dioxide) from subsurface water reservoirs or oceans. In the Solar System, geologically-active icy moons (e.g., Enceladus, Titan, and potentially Europa) and icy dwarf planets (e.g., Ceres and Pluto) are known to possess cryovolcanisms in the past or even today.

Cryovolcanos are unique windows to reveal the physico-chemical states of the subsurface oceans of the icy bodies, which is essential to understand the thermal evolution and habitability. Morphology of cryovolcanos would be a key to constrain the physical properties (e.g., viscosity and density) of liquids in the subsurface water reservoirs. Chemical compositions of erupting materials would provide information on volatile and salt compositions of the liquids. Eruption of volatiles (e.g., methane and nitrogen) could be also a major source of atmospheric gas species and thus could have affected the surface environments.

Despite such importance, the nature of cryovolcanisms, such as formation mechanisms and eruption styles, is largely unknown. Since pure liquid water is denser than that of ice, dissolved gas species in cryolava would play a key role for its eruption through bubbling and a consequent decline in the bulk density. Dissolved gas/salt in the liquids also controls the viscosity of cryolava. Such importance of dissolved species in cryovolcanisms implies a potential similarity in the role of volatiles in silicate volcanisms on rocky planets, such as Earth. Here we review recent observations of cryovolcanos on the Solar System icy bodies by spacecrafts. We then discuss the possibility of and future perspectives for development of comparative researches between cryo- and silicate-volcanisms in the Solar System.

Keywords: icy bodies, Solar System exploration, cryovolcano

[M-IS23] Planetary Volcanology

convener:Rina Noguchi(Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency), Tomokatsu Morota(Graduate School of Environmental Studies, Nagoya University), Kyoko S. Kataoka(Research Institute for Natural Hazards and Disaster Recovery, Niigata University), Shizuka Otsuki(Research Institute of Earthquake and Volcano Geology, Geological Survey of Japan, Advanced Industrial Science and Technology)

Volcanoes exist on solid planetary surface across the solar system. They tell insight into the interior, and the surface environment when they were formed and subsequent evolution. Recent high-resolution remote sensing data on extraterrestrial body allows us to analyze on outcrop scales. Now we are on the stage to share the research targets beyond fields of general volcanology and planetary science. Because some geomorphological and geological environments
in other planets are similar to those on Earth, research on volcanic geomorphology and geology on Earth will provide good terrestrial analogues to understand planetary volcanology. The aim of this session is to discuss formation history and mechanism of volcanoes across the solar system.

A possible method of lava flow temperature estimation by lava tube cave of Earth,Moon and Mars

*Tsutomu Honda[1]

1. Vulcano-speleological Society

[Introduction]In the lava flow of Miharayama of Izu Oshima eruption in 1951, the lava temperature,the lava flow thickness and the flow velocity were directly measured on the site[(1)]. Then, the temperature dependent viscosity coefficient and the yield strength were calculated [(1,2)]. In addition, the temperature dependent surface tension was measured in the laboratory by re-melting the collected sample[(3)]. In 2005, a lava tube cave called Hornito Cave was discovered under the hornito located at the crater edge. The inner and outer structure of the Hornito cave was investigated and lava yield strength and surface tension have been also identified [(4, 5, 6)]. Miharayama Hornito Cave is a representative example where lava temperature, viscosity coefficient, yield value and surface tension are identified. On the other hand, in the universe, vertical holes/pits are found in the lava zone of Moon and Mars and lava tube caves are thought to be present under the vertical hole/pit [(7, 8, 9)]. Based on the example of Mihara yama of Izu Oshima in the Earth, it seems to be possible to identify the lava temperature and viscosity coefficient from lava yield strength and surface tension obtained from lava tube shape and internal structure on the Moon and Mars. It should be considered as an important purpose of future vertical hole/pit exploration.

[Data obtained from Izu Oshima Mihara yama Hornito Cave]For Mihara yama Hornito Cave ,internal observation and the preparation of the survey map of horizontal section and longitudinal section were made [(4)]. Based on the cavity height of the lava tube cave and its slope angle, the lava yield strength f_B is estimated from $f_B = H(\rho g \sin \alpha) / 4$, the flow limitation condition of the Bingham fluid flowing in the inclined circular tube. The obtained lava yield strength was 5000 Pa[(5,6)]. This value is consistent with 4300Pa obtained by field observation of actual lava flow of 1951 of temperature ranging from 1125 to 1038[(2).] From the pitch P of the lava stalactite descending from the ceiling of the cave, the surface tension $\gamma = P^2 g \rho / 4 \pi^2$ is obtained. As the measured pitch is roughly P = 3 to 4 cm, then the surface tension is 600 to 1000 mN / m[(5,6)]. This value is consistent with extrapolated value from the temperature dependent surface tension of Izu Oshima 1951 lava measured by Yokoyama et al.,in his laboratory with the remelted sample[(3)]. This indicates that, if lava tube cave is present. it is possible to estimate the lava temperature of the eruption time, even if lava flow temperature at the past eruption is unknown.

[Application to the Moon,Mars and Future Exploration]

In the vertical hole/pit cross section images of the Moon shown by LRO, the traces such as lava flow layer thickness,lava tube cave height can be seen, so, it seems possible to identify the lava flow temperature using these traces.

For Marius Hills Hole located in the Rille-A, the yield strength can be obtained as 131 Pa from the slope angle with an average lava layer thickness of 6 m and tube cavity height of 18 m[(10)]. If the temperature dependent data of the yield strength is acquired separately, the temperature of the lava flowing through the rill-A can be estimated. Further, if we can find lava stalactite inside of the cave by future moon exploration, the temperature can be identified also by comparing the surface tension obtained from the pitch of the lava stalactite with the temperature dependent surface tension data. The viscosity coefficient can also be fixed by the temperature dependent viscosity coefficient data. Fig.1 shows a concept of estimation.

At the stage where sampling on the Moon and Mars can not be done immediately, the synthetic samples based on the chemical composition will be used to acquire the temperature dependent yield strength and surface tension data.

Process of magma eruption on the Moon

*Tomokatsu Morota[1]

1. Graduate School of Environmental Studies, Nagoya University

Estimates for volumes of mare basalts are essential to understand the thermal conditions of the lunar mantle and its lateral heterogeneity. We have investigated the volumes of mare basalts within farside and nearside basins using topographic and multiband image data obtained by SELENE (Kaguya). Furthermore, using the high-resolution crustal thickness model, we investigated the crustal thickness of major impact basins and its relationship with the mare volumes. Based on these results, we discuss the relationship between the mare volumes and the crustal thickness, differences between magma productions in the farside and nearside mantles, and the processes of magma ascent and eruption.

Statistical analysis of grain morphology generated under hypervelocity impact experiment as an analog of volcanic explosion

*Rina Noguchi[1], Shizuka Otsuki[2], Ayako I Suzuki, Sunao Hasegawa[1]

1. Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency, 2. Geological Survey of Japan, AIST

Natural volcanic ash is formed in several states of magma (i.e., solid or melt) and surrounding conditions (e.g., dry or wet settings). These various factors affect the morphology of ash grain. For example, in a wet setting, moss-like grains are often formed (e.g., Wohletz, 1983). Thus, grain shape of volcanic ash tells us its fragmentation process. This would be useful to estimate eruption mechanism both for on-going and historical eruptions. However, it is difficult to extract the fragmentation mechanism from the grain morphology because of the complex natural system (i.e., not by a single mechanism). Furthermore, manual verification of numbers of ash grains takes a long time and need training. To simplified these issues, we proposed a technique to measure the morphology of volcanic ash grains by using an automatic grain analyzing system (Noguchi et al., in prep.). In this study, we apply the technique to the grains formed by an impact in a laboratory in order to verify the accuracy and applicability of the technique. We used a two-stage light-gas gun in ISAS, JAXA. Grains were collected using a Styrofoam box and segregated with d-limonene. After that, we measured shape parameters and transparency using an automated grain analyzer (Morphologi G3S, Malvern Inst.) of AIST. The measured parameters of grain shape are aspect ratio, high-sensitivity circularity, convexity, and solidity. We also measured transparency of each grain. In this presentation, we show its preliminary result and indicate its applicability to returned sample from other planetary bodies such as Itokawa, Ryugu, and Phobos.

Disequilibrium precipitation of salts during rapid freezing of brine: Implications for cryovolcanisms and formation of sodium carbonate of bright spots on Ceres.

*Masahiro Yoda[1,2], Yasuhito Sekine[2], Shuya Tan[1,2]

1. Department of Earth and Planetary Science, The University of Tokyo, 2. Earth-Life Science Institute, Tokyo Institute of Technology

NASA's Dawn spacecraft has found geological evidence for cryovolcanoes on Ceres, the dwarf planet in the main belt. Erupted materials from Ceres' cryovolcanoes are generally bright and distribute locally over Ceres in association with floor-fractured craters and dome-like features, which have young surface ages (e.g., Buczkowski et al, 2016; Ruesch et al, 2016). The bright materials are considered to be composed mainly of sodium carbonate and ammonium salts, which are different from the average crustal compositions (a mixture of magnesium-calcium carbonates and ammonia phyllosilicates) (De Sanctis, 2016; Zambon et al, 2016). The particular compositions of bright materials could provide unique information on the formation and evolution of liquid reservoirs within Ceres.

Two possible processes have been proposed for the formation of liquid reservoirs that generate Ceres' bright spots: One is remnants of a global subsurface ocean formed in the early history of Ceres (Castillo-Rogez et al, 2018), and the other is impact-induced melting of surface materials in a recent time (Zolotov, 2017). Using thermochemical equilibrium models, Castillo-Rogez et al. (2018) suggest that freezing of an early global ocean on Ceres may not be able to generate salt materials found on bright spots. To account for the abundance and composition of salts on bright spots, Zolotov (2017) suggests extremely high concentrations of dissolved ions in localized liquid reservoirs, possibly generated by re-melting of surface due to a recent impact. These equilibrium models suggest the difficulty to form the salt compositions of the bright spots directly from freezing of an early global ocean. However, Vu et al. (2017) and Thomas et al. (2018) experimentally show the importance of kinetics in salt precipitation from rapidly freezing brine. Thomas et al. (2018) show kinetically preference of precipitation of ammonia-bearing salts upon rapid freezing of Na-NH_4-CO_3-Cl brine despite their thermochemical instability. This implies the disequilibria in salt precipitation may have played a key role to determine the salt composition of bright spots.

In the present study, we compare the results of salt precipitation using thermochemical equilibrium model of FREZCHEM with those formed by rapid freezing in laboratory experiments to evaluate the effects of disequilibria. The starting solutions are prepared based on thermochemical calculations of water-rock reactions within early Ceres. We also measure infrared spectra of the salt precipitates to compare with the observations of bright spots on Ceres.

[M-IS28] Fluid-sediment migration and geo-bio interaction

convener:Robert Jenkins(School of Geosciences and Civil Engineering, College of Science and Engineering, Kanazawa University), Tomohiro Toki(Faculty of Science, University of the Ryukyus), Akira Ijiri(Japan Agency for Marine-Earth Science and Technology), Takami Nobuhara(Science Education (Geology), Faculty of Education, Shizuoka University), Hiromi Kayama WATANABE(Japan Agency for Marine-Earth Science and Technology), Miho Asada(Japan Agency for Marine-Earth Science and Technology), Chairperson:Tomohiro Toki, Robert Jenkins(Kanazawa University)

Chemosynthetic communities are distributed at hydrothermal system and/or cold seep in bathal zone. They gain their energy from chemosynthetic bacteria, a symbiotic life. The chemosynthetic communities have changed in their taxonomic composition and spatial distribution through the Earth history, but the causes and background remain to be unclear.
Mud volcano is one of geological features which derives fluid nd sediment from depth to the Earth's surface and make topographic feature. It plays a role of carbon cycling connecting depth and surface, pipe of life in depth, disaster and civil engineering. Mechanism and activity of mud volcanoes, however, are not enough understood yet. Mud volcano in Japan is mostly active in offshore fields and are frequently accompanying cold seeps at around it.
Here we propose a joint session with Chemosynthetic communities and Mud volcanoes to have cross-cutting discussion between us. Topics relates to mud volcano will help discussion of evolution of communities and chemosynthetic communities will help to understand mud volcano activity along time and space. Study results for usual two sessions, for cross-cutting discussions, and from related settings are absolutely welcome.

Upper Pliocene large lucinid communities with cold-seep carbonates from the Shimajiri Group in the Miyagi-jima Island off the central part of Okinawa-jima Island, Japan

*Takami Nobuhara[1], Robert Jenkins[2], Shin-ichi Nomura[3]

1. Science Education (Geology), Faculty of Education, Shizuoka University, 2. School of Natural System, College of Science and Engineering, Kanazawa University, 3. Chiba Prefectural Kisarazu High School

Fossil chemosynthetic lucinid communities occur with pipe- and burrow-cemented concretions from the Upper Pliocene muddy sand facies of the Shimajiri Group in the Miyagi-jima Island off the central part of Okinawa-jima Island, Japan. The outcrop is a sea-cliff wall along the west coast of Miyagi-jima Island, over 30 m high and 150 m long. The cliff consists of muddy sandstone sporadically yielding outer-shelf to upper-slope molluscan fossils, with intercalation of thin fine-grained sandstone layers. We could directly observe only the lower one-third of the cliff wall, but the fossil-lucinid occurrence seems to be restricted to about a five-meter thick horizon, which is associated with pipe- and burrow-cemented concretions.

Lucioma taiwanensis is dominant and forms shell beds and autochthonous shell clusters in matrix-supported condition. In addition “*Meganodontia*” sp., a gigantic lucinid over 10 cm in diameter, was obtained as floatstones, but all specimens are conjoined valves and maybe fell out from sites with abundant burrow-cemented concretions.

The burrow-cemented concretions look like calianassid nests in shape, irregularly sinuous to vertical to beddings, a few centimeters in diameter and over 1 m long. They amalgamated one another to form network-like clusters. The pipe concretions tend to be recognized below the network clusters of burrow-cemented types. The pipes are cylindrical and straight over 30 cm long, nearly vertical to beddings. They are composed of core calcitic cements (2 cm in diameter, -10 to -15 ‰of δ^{13}C) and surrounding dolomitic coating (4 to 5 cm thick, -20 to lower -40 ‰of δ^{13}C). The δ^{13}C value less than -30 ‰indicates methane seep influence in the sub-bottom of the lucinid community. The pipe concretions are also often recognized 5 m below the fossil lucinid horizons, which suggest that the pipe-like conduits of methane seep supported the lucinid communities.
The fossils of *Lucinoma taiwanensis* often preserve their life positions in matrices apart from the burrows and pipes. Therefore the methane-seep through focused pipe-like conduit were succeeded by into diffusive in sandy surface sediments. But some *Lucinoma* conjoined valves in life position are attached to outer walls of burrow-cemented concretions, which suggests that the burrows made contributions to promoting anaerobic oxidation of methane (AOM) and generating H_2S.

Chemosynthetic fossil community in Early Cretaceous methane seep from Yubari City, Hokkaido

*Nanami Shimazu[1], Robert Jenkins[1]

1. Kanazawa University

Japanese archipelagoes have rich fossil record of the methane-seep communities since the Late Cretaceous, however, the Early Cretaceous record is poorly known. Thus, we have investigated the Early Cretaceous (Albian) carbonate rocks found in Utagoesawa Creek, Yubari City, Hokkaido. The locality was previously mentioned in several papers, but the comprehensive approaches including sedimentary petrological, isotope geochemical and paleontological aspects haven't been done.

Many carbonate boulders were found along the creek and it size distribution along the creek suggest its single origin of outcrop. The carbonate rocks show mosaic textures mainly composed of micritic grayish patchy blocks. Bladed calcite and sparry calcite are filled in void spaces. Detailed observation revealed the micrites and the bladed calcites were precipitated in early diagenetic stages, and its isotopic compositions are -45.8 to -35.8 ‰VPDB for carbon and -25.4 to -17.9 ‰VPDB for oxygen.

The petrological and geochemical features indicate that carbonate rocks were formed under influence anaerobic oxidation of methane(AOM) due to the microbial activity in methane seep.

The carbonate rocks yield many bivalves, such as *Caspiconcha*, lucinids, *Nucinella*, solemyids, and thyasirids, and some hokkaidoconchid species.

Those molluscan species are well known from Cretaceous seeps in the world. No brachiopods were found from the locality. The fossil assemblage indicates that the Utagoesawa seep was fully occupied by chemosynthetic molluscan species whereas the Early Cretaceous seeps in California are characterized to have brachiopods.

Campbell and Bottjer (1995) suggested the faunal composition has been changed mainly from brachiopods to bivalves through transition between Early to Late Cretaceous. The current study indicate the phenomenon occurred only restricted in California.

Marine Snow Hypothesis: What is controling faunal composition of the methane-seep since Mesozoic?

*Robert Jenkins[1]

1. School of Geosciences and Civil Engineering, College of Science and Engineering, Kanazawa University

Fossil record of the methane-seep communities shows several interesting phenomena. One of it is the decreasing of epifaunal bivalve/brachiopod in Late Cretaceous. There are several hypotheses, e.g. “sulfate hypothesis” by Kiel (2015), are proposed to explain the situation. Here, I propose another hypothesis to explain the lacking of epifaunal bivalves/brachiopods in the Late Cretaceous. Occurring pattern of epifaunal bivalves/brachiopods through Paleozoic to Neogene is apparently corresponding to the oil resources in sedimentary rocks in each age. The oil production in the sediments are largely related to the primary production in marine, and the origin of methane is ultimately related to the organic matter in the sediment as almost same as oils. The organic matter, deposited on the sea floor, was subsequently used for the generation of methane in the anoxic condition beneath the sea floor after buried. In the case of increasing organic matter settled onto the sea floor, production of methane would be increasing, and if the organic matter decrease, the production rate of methane would be decrease. These methane is energy source for the chemosynthetic community, thus, the primary production rate at the sea surface level by the photosynthesis may control the presence/absence of epifaunal bivalve/brachiopod in seep environment. I coined this hypothesis as 'Marine Snow Hypothesis', because the particulated organic matter sinking to the sea floor is called marine snow.

In situ Sr isotope analysis of methane-seep carbonates: insight into ancient subseafloor fluid circulation

*Yusuke Miyajima[1], Michał Jakubowicz[2,3], Takafumi Hirata[1]

1. Geochemical Research Center, Graduate School of Science, The University of Tokyo, 2. Institute of Geoecology and Geoinformation, Adam Mickiewicz University, Poland, 3. Isotope Laboratory, Adam Mickiewicz University, Poland

Along continental margins, tectonic activities trigger subseafloor migration and seepage of geofluids enriched in methane, which sustain chemosynthesis-based biological communities on the seafloor. Depending on their source and migration pathway, seeping fluids have various elemental and isotopic signatures that provide insights into subseafloor fluid–rock interactions and material cycling. At the methane seeps, precipitation of carbonate is induced by microbial oxidation of methane and resultant production of HCO_3^- ions. The methane-seep carbonates record elemental and isotopic signals of seeping fluids in the geological past, and several studies have aimed to decode the origin and migration pathways of ancient seeping fluids using geochemical signatures of the carbonates (e.g., Jakubowicz et al., 2015, 2019).

Strontium isotope ratio ($^{87}Sr/^{86}Sr$) is one of the common tracers of fluid circulation and fluid–rock interactions, and has been applied to seep carbonates (Peckmann et al., 2001; Joseph et al., 2012; Jakubowicz et al., 2019). Methane-seep carbonates are often characterized by complex textures composed mainly of clay- or detritus-rich matrix and detritus-free void cements, the latter of which could archive Sr isotope signals of subsurface fluids distinct from near-seafloor sediments. However, millimeter- or smaller-scale cement phases are difficult to sample using the conventional microdrills without contamination from the matrix. In this study, we applied a high spatial-resolution Sr isotope analysis to cement phases of seep carbonates using laser ablation multiple collector inductively coupled plasma mass spectrometry (LA-MC-ICP-MS), in order to detect “pure” isotope signals of ancient seeping fluids. We measured the Sr isotope ratios in isopachous cements of fossil seep carbonates collected from the Hollard Mound (Middle Devonian, Morocco) and Baška (Lower Cretaceous, Czech Carpathians). Results obtained by LA-MC-ICP-MS were consistent with the isotope ratios measured previously by thermal ionization mass spectrometry coupled with microdrill sampling technique (Jakubowicz et al., 2019). We also tested the method using radial calcite cements of Upper Cretaceous seep carbonates in Hokkaido that are hosted by forearc basin sediments (Yezo Group). The Yezo Group is underlain by Jurassic to Lower Cretaceous mafic basement rocks and input of deep-sourced fluids from the basement rocks could be recorded as ^{87}Sr-depleted signals in the carbonates. Pilot results from one of the Hokkaido seep carbonates, Gakkonosawa, yielded Sr isotope ratios less-radiogenic than those for the coeval seawater, implying deep-fluid input. Exploring the ^{87}Sr-depleted signals at other Cretaceous seeps in Hokkaido would provide more insights into the deep subseafloor fluid circulation in the Cretaceous subduction zone at the eastern margin of the Eurasian Continent.

Monitoring CH_4 amounts deep inside deep-water mud volcanoes

*A. Kioka[1], T. Tsuji[2], H. Otsuka[3], J. Ashi[3]

1. Universität Innsbruck, Austria, 2. Kyushu University, Japan, 3. The University of Tokyo, Japan

Mud volcanoes are among the largest geological sources releasing CH_4 gas. Numerous studies have revealed their origins and compositions released from submarine mud volcanoes. Yet, quantification of the amount of gas inside submarine mud volcanoes has been challenging due to the difficulty of in situ measurements, which has hampered better evaluation for their contribution to the global methane budget. Here we provide a coupled geochemical and geophysical model that bridges bulk methane concentrations and seismic wave velocities in the mud conduit of submarine mud volcano. This model is applicable to most submarine mud volcanoes, and is able to estimate methane concentration at greater depths where methane hydrate cannot be present, using downhole logging data or seismic data. Our calculation for submarine mud volcanoes in the Eastern Mediterranean and the Nankai plate subduction zones shows that the weight fractions of gaseous and dissolved methane in total weight of sediment are 1,000--3,500 ppm within their mud conduits, which are much higher than previously expected from pore-water evidence from conventional shallow subsurface sampling. Although more definitive calculations cannot be made until the model parameters are better constrained, our approach provides an opportunity for re-estimating the global methane budget in submarine mud volcanoes, shedding new light upon the impact of submarine mud volcanism on carbon cycle.

[M-IS28] Fluid-sediment migration and geo-bio interaction

convener:Robert Jenkins(School of Geosciences and Civil Engineering, College of Science and Engineering, Kanazawa University), Tomohiro Toki(Faculty of Science, University of the Ryukyus), Akira Ijiri(Japan Agency for Marine-Earth Science and Technology), Takami Nobuhara(Science Education (Geology), Faculty of Education, Shizuoka University), Hiromi Kayama WATANABE(Japan Agency for Marine-Earth Science and Technology), Miho Asada(Japan Agency for Marine-Earth Science and Technology)

Chemosynthetic communities are distributed at hydrothermal system and/or cold seep in bathal zone. They gain their energy from chemosynthetic bacteria, a symbiotic life. The chemosynthetic communities have changed in their taxonomic composition and spatial distribution through the Earth history, but the causes and background remain to be unclear.
Mud volcano is one of geological features which derives fluid nd sediment from depth to the Earth's surface and make topographic feature. It plays a role of carbon cycling connecting depth and surface, pipe of life in depth, disaster and civil engineering. Mechanism and activity of mud volcanoes, however, are not enough understood yet. Mud volcano in Japan is mostly active in offshore fields and are frequently accompanying cold seeps at around it.
Here we propose a joint session with Chemosynthetic communities and Mud volcanoes to have cross-cutting discussion between us. Topics relates to mud volcano will help discussion of evolution of communities and chemosynthetic communities will help to understand mud volcano activity along time and space. Study results for usual two sessions, for cross-cutting discussions, and from related settings are absolutely welcome.

An offshore mud volcano that indicates a heterogeneous subseafloor geological environment: a case study along southwest Japan

*Miho Asada[1,2], Kazuya Kitada[2]

1. JSPS Research Fellow, 2. Japan Agency for Marine-Earth Science and Technology

Mud volcanoes (MVs) are geological features that derive fluids and sediments from the depth to surface. Offshore MVs require continuous mud emission to maintain the shape on the seafloor against erosion (Kopf, 2002). Brown and Orange (1993) mentioned that gas is required for sediments moving up from the deep. These necessary conditions for the existence of mud volcanoes restrict the subseafloor environment beneath MV fields.

In Japan, MVs are found both on land and in offshore areas (e.g., Tajika et al., 2009; Kuramoto et al., 2001). A forearc basin, the Kumano Basin, which is bordered by the Nankai Trough along its southern edge, is a representative MV field in Japan. There are at least 14 MVs in the basin (Kuramoto et al., 2001; Morita et al., 2004; Pape et al., 2014; Asada et al., 2017). The recent morphological changes in an MV and the emission of gas bubbles from the top of the MV were discovered through acoustic investigations in the Kumano Basin in 2016 (Menapase et al., 2017), which implies that these MVs actively emit fluid and sediment on the seafloor. Additionally, a group of offshore MVs is known in the off-Tanegashima area in the southeastern part of the Kyusyu Island (Kitada et al., 2018). There are at least 14 MVs, and life moved from the MV to the seawater (Hoshino et al., 2017). Moreover, several MVs have been reported in the off-Miyazaki area of the eastern Kyusyu Island. The Hyuga-nada area, a northeastern part of the Kyusyu Island, probably holds other MVs that exhibit similar bathymetric and acoustic (backscatter) characteristics as MVs in the Kumano Basin and the off-Tanegashima areas. Only one MV candidate feature and the hardened seafloor around it have been recognized in the off-Shikoku Island; however, there are no more MVs in the area. These results indicate that there are discontinuous MV fields along southwest Japan, and there is a vast MV field over the eastern offshore area of Kyusyu Island. This indicates a heterogeneous subseafloor environment in these areas.

Within what type of subseafloor environment can MVs exist? Maintaining a continuous emission of fluid and sediment on the seafloor may restrict the subseafloor environment.
1. A budget of “fluidized mud” or continuous production of “fluidized mud” should exist under the seafloor.
- Large amounts of seawater are trapped when deposits are buried without being drained.
- Dehydration owing to clay minerals collapses the mud rock to form fluidized mud.
- Gathering fluids come along the strata and/or fault to collapse mud rock and make fluidized mud.
2. Gas is required for making intrusions, which can be a root of MVs.
- Sediment can yield enough thermogenic and/or biogenic gas.
- There is an environment for collecting enough fluid coming through the strata and/or fault.
3. Both gas and fluidized mud under the seafloor can be the origin of MVs on the seafloor. Only one of them may not lead to MVs.

The subseafloor temperature of the accretionary prism of the Kumano Basin (e.g., Marcaillow et al., 2012) satisfies the condition for the dehydration of clay minerals. The dehydration may cause the collapse of mud rock, yielding fluidized mud. Gas generation causes sediment intrusion. This fluid may flow along the strata and fault and gather together to cause MVs. As with Hyuga-nada/off-Tanegashima area, there is a

©2019. Japan Geoscience Union. All Right Reserved.

business gas field along the eastern coast of Kyusyu Island, and it may affect the area. However, in the off-Shikoku area, there is not enough subseafloor environment to generate gas and fluidized mud; this may be affected by the high-temperature subduction of the ancient plate-spreading axis in the Shikoku Basin. This subseafloor heterogeneity may be related to other geological phenomena, such as the patchy distribution of the seismogenic zone.

New distribution and implication of dispersal capabililty of a deep-sea chemosymbiotic squat lobster *Shinkaia crosnieri*

*Hiromi Kayama WATANABE[1], Chong Chen[1], Tin-Yam Chan[2], Chien-Hui Yang[2], Chu-Chang Wang[3], Satoshi Mitarai[4], Hiroyuki Yamamoto[1]

1. Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 2. National Taiwan Ocean University, 3. Taiwan Ocean Research Institute (TORI), 4. Okinawa Institute of Science and Technology (OIST)

Distribution range and dispersal capability are important for conservation and understanding changing ocean. A galatheid squat lobster, *Shinkaia crosnieri*, is the dominant animas harboring epibiotic symbionts, in methane-rich deep-sea chemosynthetic environments both of hydrothermal vent and methane seep in the northwestern Pacific. Here we report that a juvenile of *S. crosnieri* inhabits in methane-poor hydrothermal vent field in the northwestern Pacific, with juveniles of another squat lobster species *Munidopsis myojinensis*, which does not have symbiontic microbes. Genetic analysis inferred that the juvenile seemed to migrate from the population in methane seep sites in South China Sea, rather than those in hydrothermal vent fields in Okinawa Trough, East China Sea. The present observation indicates that the range of dispersal of *S. crosnieri* extend north to the Myojin Knoll, while the dispersal capability is not simply correlate to horizontal distance. Furthermore, the present findings may suggest that the settlement of the vent/seep specific animal with symbionts are controlled by phylogenetic constraints rather than environmental specific factors.

Taxonomy and diet of the *Ophryotrocha* (Annelida: Dorvilleidae) from whale- falls in the Tsukumo Bay, Japan

*Midori Suzuki[1], Robert Gwyn Jenkins[1], Shouzo Ogiso[2], Nobuo Suzuki[3]

1. Division of Environmental Science and Engineering, Graduate School of Natural Science and Technology, Kanazawa University, 2. Kanazawa university, 3. Institute of Nature and Environmental Technology, Kanazawa university

Decomposition of large organic-falls, e. g. sunken whale carcasses is a part of nutrient cycle (Smith et al., 2015). The decomposition is performed by not only microbes but also some animals, e. g. the polychaetes. Some polychaetes can be found from inside of decaying bone, however, roles of the polychaetes animals are poorly understood. We examined the organic carbon isotope ratio and DNA(COI) of polychaete *Ophryotrocha* (Annelida: Dorvilleidae), a species lived in the whale bone deployed in the Tsukumo Bay. They are exposed to stress in the form of high levels of hydrogen sulfide but have successfully invaded into the bone. Morphological observation revealed the species is mainly characterized by shape of jaw and we considered as new species. Phylogenetic analyses based on COI suggest that they have independently invaded into whale falls, hydrothermal vent and methane seep from normal environment for each taxon group. The examined *Ophryotrocha* sp. had the broadest $\delta^{13}C$ range (-33.8‰~-19.0‰) among other species lived on/in the bones. It indicates that some of them fed on bacterial mat such as *Beggiatoa* sp. (-37.2‰~-28.5‰) but some of them don’t. These results highlight the role of *Ophryotrocha* has diverse food source, and it would be an advantage to adapt various “extreme environment” such as vent, seep, and whale falls.

Volcanic eruptions often continue for more than a few months or years; the intensity and the style of eruptions remarkably change with time. It is, therefore, desired to forecast such eruption sequences on the basis of field observations during the eruptions. For this purpose, the basic idea of data assimilation is useful. The data assimilation is composed of two mathematical problems: forecasting the system evolution based on forward physical models and determining the model parameters based on inversion analyses of field observations. We are interested in how the mathematical characteristics of the forward models for volcanic eruptions affect those of their inversion problems. In this presentation, we focus on two problems: (1) the estimation of model parameters of magma plumbing system from field observations of magma discharge rate and ground deformation, and (2) the estimation of magma discharge rate of explosive eruptions from tephra-fall deposits.

The inversion problem of magma plumbing system

The eruption sequence is characterized by the evolution of magma discharge rate (Q) and chamber pressure (P) during eruption. To describe the evolution of Q and P, we formulated a model of magma plumbing system composed of a conduit and a magma chamber in elastic rocks. In this model, the effects of gas-exsolution and gas-escape on conduit flow are considered, which leads to complex features of volcanic eruptions such as a transition from a lava-dome forming eruption to an explosive eruption. The eruption style (i.e., evolution of Q and P) is sensitively dependent on model parameters related to geological and petrological conditions (e.g., volume and depth of magma chamber and magma properties). To forecast the eruption sequence, these model parameters need to be estimated from time-varying observations of Q and P through an inverse analysis.

Generally, because of the strong non-linearity of the conduit-flow model, it is mathematically and computationally difficult to investigate the influence of each observation on the estimation of the model parameters. We express the trade-off relationship between the model parameters utilizing analytical solutions of the conduit-flow model (e.g., Koyaguchi, 2005; Kozono and Koyaguchi, 2009), and show that the key parameters that affect the time evolution of P and Q are fundamentally different between explosive and effusive eruptions. Because of this difference, model parameters constrained from the observations of Q and P also depend on whether the eruption is effusive or explosive.

The inversion problem of tephra dispersion

The estimation of magma discharge rate (i.e., Q) is one of the key issues for forecasting volcanic eruption sequence. For explosive eruptions, the value of Q can be estimated from observations of tephra dispersion. The forward model of tephra dispersion is composed of the eruption column dynamics model and the advection-diffusion model. The former describes the supply rate of tephra particles from an eruption column just above the volcano as a function of altitude (referred to as the supply rate function). The latter describes the transportation of tephra particles from the source (i.e., the eruption column just

©2019. Japan Geoscience Union. All Right Reserved.

above the volcano) to the ground surface.
The above two models have distinct features in the inversion problem. The singular value decomposition (SVD) analysis indicate that the inverse problems of the advection-diffusion model is highly ill-conditioned so that the number of basis functions expressing the supply rate function is limited regardless of the number of data of tephra-fall deposits. On the other hand, the eruption column model indicates that the form of the supply rate function is strongly correlated with the eruption conditions such as Q. We, therefore, attempt to develop a method to estimate the value of Q from the supply rate function expressed by the limited number of basis functions. Some preliminary results on this problem will be presented.

Understanding the magma generation processes and characteristic end-members in various tectonic settings is fundamental to understand the material circulation and compositional evolution of the solid Earth. Recent studies based on a machine learning approach revealed that volcanic rocks formed in different tectonic settings have unique geochemical signatures, indicating that both volcanic rock geochemistry and magma generation processes are closely connected to the tectonic setting. We present a result of a feature selection where sparse modeling approach is used. Sparse modeling is an approach in which automatically selects the smallest number of essential variables from high-dimensional data and constructs a succinct model. We used 24 elements and five isotopic ratios of igneous rocks formed in eight different tectonic settings for the feature selection of the settings. In addition to the major and trace element concentrations and isotopic ratios, we also considered combinations of elements, i.e., sum or ratio between two different elements, for the feature selection. This study uses sparse multinomial regression (SMR) approaches for feature selection. Multinomial regression is the classical linear discrimination method. Using the multinomial regression with the sparse modeling approach, a small number of essential geochemical information of tectonic settings are extracted. Based on the automatically selected features, we will discuss the geodynamical and geochemical process to derive various magmas and tectonics.

Automatic Detection of Stationary Gravity Waves in the Venus' Atmosphere Using Deep Generative Models

*Minori Narita[1], Daiki Kimura[2], Atsushi Yamazaki[3], Takeshi Imamura[1]

1. The University of Tokyo, 2. IBM Research AI, 3. ISAS/JAXA

Venus is covered with thick clouds of sulfuric acid, and the entire upper atmosphere rotates much faster than the planet itself. Recently, interhemispheric large bow-shaped structures, remaining fixed above the highland in contrast to background wind fields, were observed in long-infrared and ultraviolet images by Venus Orbiter Akatsuki. These bow-shaped structures are said to be the result of atmospheric gravity waves generated in the lower atmosphere and propagate upwards to the cloud top, which has a significant influence on the Venus' atmospheric system. Not a few bow-shaped, stationary features indicative of topographic gravity waves have been reported so far. However, to unravel where and when these structures appear frequently, we need to analyze the phenomena comprehensively, using much more data. Detection of such characteristic cloud features in images has been done by human eye in Venus research, but to detect many more cases efficiently from massive amounts of image data, we need a framework to do it automatically and robustly. Moreover, most of the bow-shaped structures in ultraviolet images are small, which is almost impossible to find out every case by our eyes.

In this study, we propose a novel approach that detects these stationary features using a deep generative model that has deep neural networks (deep learning). There are various types of such deep models nowadays; we used a variational auto-encoder (VAE) because it has reported good results in dimensionality reduction fields and been a well-known method for image reconstruction. The input and the output of VAE are set to be the same, and the network is divided into two parts, which are the encoder that converts an image to latent representation, and the decoder that reconstructs an image from given latent variables. The detection of stationary features can be seen as an anomaly detection task, which treats images that have stationary features as the anomaly class and the normal cloud image as the normal class.

We used ultraviolet (283 nm) images for this analysis. Firstly, we performed photometric correction using Minnaert Law, and averaged several images taken successively in 24 hours to highlight structures that remains still. Then we extracted features that have scales smaller than 6 degrees by high-pass filtering. Lastly, we extracted image patches from these images. Each patch has the size of 24 degrees both in latitude and longitude. We used images taken in 25 days in 2016 and 2017.

The analysis procedure is as follows. First, we train this network using only normal cloud images that do not include stationary features to let it learn its latent features. When testing, we input test images composed of both normal and anomaly (stationary feature) images, and detect anomalies based on the reconstruction loss that is calculated by the sum of the pixel-wise distance between the original image and the reconstructed image that is output from the last layer in the network. The network has five convolutional layers in the encoder and the decoder, respectively. The latent space has 32 dimensions. We used 4,000 normal cloud images as the training data, and 1,000 normal and 255 anomaly images as the test data.

We evaluated our method by calculating the area under the curve (AUC) of the receiver operating characteristic (ROC) curve. As a result, the AUC was 0.93 (maximum is 1.00), which shows that the

©2019. Japan Geoscience Union. All Right Reserved.

proposed method successfully detects stationary features. The reconstruction error of a stationary structure image is large because the network cannot reconstruct such bow-shaped structure properly. Our method can be easily applied not only to Venus but also various planetary images to detect characteristic structures.

Fracture and mineral distribution analysis using hyper-resolution DEM and hyperspectral satellite imagery for detecting geothermal fluids paths

*Taiki Kubo[1], Hiroaki Gonnokami[1], Arie Naftali Hawu Hede[2], Mohamad Nur Heriawan[2], Irwan Iskandar[2], Katsuaki Koike[1], Sudarto Notosiswoyo[2]

From criteria of power output and temporal stability, geothermal is the most promising renewable energy for electrical generation. However, high introduction cost for geothermal power generation, in particular the cost for exploration to identify the geothermal reservoir is a main issue against the plan. Development of more accurate geothermal-resource exploration is necessary for enhancement of geothermal energy use. Detection of geothermal fluids paths including water and steam from geothermal reservoir is a major target in the exploration stage. Topographic analysis is one of the effective methods for the detection. Thus, we have generated a hyper-resolution DEM (HR-DEM) of the Wayang Windu Geothermal Field (WWGF), situated in West Java, Indonesia using UAV. HR-DEM with high spatial resolution (0.5 m) covers an area of 5 km (E–W) by 10 km (N–S) in WWGF. The lineament density map of WWGF was produced by a topographic analysis through HR-DEM. Moreover, spatial distributions of geothermal alteration minerals such as alunite, calcite, and kaolinite were mapped from an image processing of hyperspectral satellite image, Hyperion. A combination of the lineament and mineral distributions specified highly permeable zones in which the fractures and geothermal alteration minerals were concentrated. The location of high igh radon concentration by in-situ measurements correspond well with these estimated permeable zones. Therefore, the integrated analysis is expected to increase the identification accuracy of fluid paths and clarify the geothermal system in WWGF. This research is supported by JST and JICA through Science and Technology Research Partnership for Sustainable Development (SATREPS).

Geochemical characterization of deep-sea sediments in the western North Pacific Ocean by an integrated multivariate statistical technique

*Kazutaka Yasukawa[1,2], Kentaro Nakamura[1], Koichiro Fujinaga[2,1], Hikaru Iwamori[3,4], Yasuhiro Kato[1,2]

Recently, deep-sea sediments highly enriched in rare-earth elements and yttrium (REY) were discovered within the Japanese exclusive economic zone (EEZ) surrounding Minamitorishima Island [1]. To clarify the distribution of the “extremely REY-rich mud”, eight research cruises (KR13-02, MR13-E02, KR14-02, MR14-E02, MR15-E01 Leg2, MR15-02, MR16-07, and KM17-14C) have collected 71 sediment core samples in total from 2013 to 2018. Now we have constructed a comprehensive dataset of major- and trace-element contents of 1,646 samples by X-ray fluorescence and inductively coupled plasma mass spectrometry analyses [1-8].

Here, in order to depict geochemical features of the deep-sea sediments including the extremely REY-rich mud, we applied an integrated method of k-means cluster analysis (KCA) and independent component analysis (ICA) [9] to the huge (1,646 samples x 41 elements) dataset of the deep-sea sediments in and out of the Minamitorishima EEZ. We demonstrate that the data clusters are distributed not randomly but systematically in the real space; the clusters are vertically aligned from the seafloor to depth in a specific order and thus constitute stratigraphic units defined by geochemical features. In addition, the downhole variation of an extracted independent component (IC) shows a stepwise transition across the extremely REY-enriched layer. This transition is ubiquitous in the studied area of several-hundred-kilometer wide. The geochemical clusters just below the IC transition are variable among the cores, which implies that the IC transition corresponds to an unconformity in the sediment column probably due to erosion [5, 6]. These characteristics of the spatial distributions of the geochemical clusters and ICs support a hypothesis previously proposed by Ohta et al. [10]: an enhanced bottom current caused a physical separation of sedimentary particles, or a winnowing effect, and contributed to form the extremely REY-enriched layer by a selective deposition of relatively coarse and dense grains of biogenic Ca-phosphate that significantly accumulate REY from ambient seawater.

The geochemical database “DODAI” with high-precision location coordinates

*Satoru Haraguchi[1], Kenta Ueki[1], Kenta Yoshida[1], Tatsu Kuwatani[1,3], Mika Mohamed[1], Hikaru Iwamori[1,2,4]

1. Japan Agency for Marine-Earth Science and Technology, 2. Earthquake Research Insititute, the University of Tokyo, 3. PRESTO, 4. Tokyo Institute of Technology

We constructed the geochemical database “DODAI” which compiled data published in the domestic journals and bulletins, and published its details recently (Haraguchi et al., 2018, J. Geol. Soc. Japan, doi: 10.5575/geosoc.2018.0027). This database has converted the sampling position of individual geochemical data into the GPS-familiar location coordinates, i.e. latitude and longitude, by image-based geocoding and improved the positional accuracy drastically compared to the previous databases.

There are some international databases of geochemical data, for example: "GEOROC" mainly involving land samples, "PetDB" mainly involving samples from seafloor. Recent progress on the data-driven science shed a light on a large number of sample data with a multitude of variables. As for heterogeneity of the mantle compositions (e.g. Iwamori et al, 2018), the world-wide scale of the geochemical structure are discussed on the basis of such databases. However, considerable number of data in these international databases provided the location coordinates only as the representative position of the geologic map of the original articles, and thus the resolution of these location data often can represent only the order of degree unit. This precision may have no problem for the discussion of world-wide scale, while interpretation in the detailed spatial scale may not be possible. The precision of location data in the “DODAI” is mostly less than 1 km, some of which have < 10m of errors, based on the spatial resolution of the map provided in the original articles. This precision allows us to correlate sample positions to the correct geological units described in the digital geologic map such as the Seamless Geological Map (AIST). We also defined a standard data format based on the metadata available in the compiled papers covering such as geographical information, sampling, and analytical methods.
In this presentation, we will show the concept and details of DODAI dataset, and discuss the potential of data-driven analysis in the geochemical study.

Keywords: geochemical database, geocoding, normalization of format

Bayesian statistical evaluation method for detrital zircon geochronology

*Tan Furukawa[1], Tatsuki Tsujimori[1]

1. Tohoku University

Over the past two decades, detrital zircon U-Pb geochronology has become an essential method not only in sedimentary provenance analyses but also in characterization of sedimentary and metamorphic strata. Although the age data has been conventionally evaluated by using relative frequency plots (here after called histograms) and density curves, the lack of statistical verification can cause miss reading of data. In order to overcome the statistical issues raised, this study proposes new statistical evaluation method for detrital zircon geochronology.
The new method is based on Bayesian statistics, adapted a theory proposed by Riihimäki and Vehtari (2014) that provides a flexible modeling for density curve using the Logistic Gaussian Process (LGP)
For introducing non-negative consistency for density curve, the logistic density transformation is performed by $p(x)=\exp(f(x))/\int\exp(f(\mathbf{s}))d\mathbf{s}$; x is age, p(x) is density curve, and f(x) is Gaussian Process; $f(x)\sim GP(0, \kappa(x,x'))$. The covariance matrix $\kappa(x,x')$ is calculated by Gaussian kernel with hyperparameters ρ and σ. For the actual computation, the logistic density transformation has integral difficulties, then, M discretized softmax function is used for approximation for it.
The likelihood function is $L(\mathbf{p}|\rho,\sigma)=\mathbf{y}^{T}\mathbf{p}$. $\mathbf{p}$ is M discretized p(x), and $\mathbf{y}$ is vector of y_i, which is the number of observations that fall within the i'th M discretized age subregion.
We have used programming language R and Stan for the MCMC computation of the statistical model above. When the number of detrital zircon data is several hundred or less, the hyperparameters of Gaussian process ρ and σ do not converge, and Bayesian estimation can not be performed. For this reason, the author estimated most plausible ρ and σ by WAIC. Using zircon data from our own data and the literature, in this presentation, we will demonstrate powerfulness of our new statistical evaluation.

Geochemical data processing using machine learning with artificial training data and proposal of environmental evaluation method considering natural background of heavy metals in river water in mining area

*Satoh Kenta[1], Kengo Sawayama[1], Noriyoshi Tsuchiya[1]

1. graduate school of environmental studies, Tohoku University

Acid mining drainage is one of the most important sources of heavy metals in river. Environmental standards are evaluated by the effects on the Ecosystem and human body. However, the current environmental standards do not consider natural background of heavy metals, therefore the method which can evaluate the effects on the environment concerning such heavy metals is needed. Then we propose to apply machine learning to evaluation effects by heavy metals. Using natural soil data and mineral data as training data in machine learning, it will become possible to evaluate the effects concerning heavy metals naturally included in soil. However, it is very important to choose the proper training data set in machine learning. In this study, we created training data artificially. If it can be done that Verifying correctness of this artificial training data, the range of application of machine learning expands. The objective of this study is, firstly, to verify the validity of artificial training data through case study, secondly, to establish the method to evaluate effects on the environment by heavy metals considering natural background of heavy metals. Focusing on the mine area where there are effects by heavy metals has already been confirmed, we digitized the effects by mine as the evaluation score by heavy metals using Support Vector Regression (SVR) and using the element content ratio as attribute. The element content ratio of mine was used as the ore training data and the element content ratio of the area surrounding the mine was used as the training data representing heavy metals naturally included in soil. We created data of the ore training data based on literature data about the mine. Furthermore, we verified validity of the artificial data through comparing three digitized assessment of contamination by the statistical method in the area, by the previous research, and by machine learning. As a result, the evaluation score by each method increased at the same point, and it is verified that the evaluation by machine learning using artificial training data is correct. If we use machine learning using artificial training data, it may improve further development of machine learning in the geochemical data set.

Quantitative Logging Unit Classification with Hidden Markov Model

*Suguru Yabe[1], Rina Fukuchi[2], Kenta Ueki[1], Yohei Hamada[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. UTokyo AORI

International Ocean Discovery Program (IODP) Expeditions have drilled ocean floor to address cores and well logging data for various purposes. Expedition scientists usually define logging units by characterizing logging data, and interpret their geological meaning. Unit classifications and their geological interpretations will be useful to understand the geological formation at the drilling site. The criteria to define such the units are described in the expedition report, which is usually based on the average, the minimum, and the maximum value of logging data. However, there is no mathematical background to support the validity of unit characterization. The motivation of this study is to develop the quantitative method for log unit definition, and to find out overshadowed log-characteristics for detailed geological interpretation.

This study used Hidden Markov Model (HMM) to classify logging data into logging units. HMM is a stochastic model to classify sequential data. In HMM, each sequential step has the unobservable parameter “state”, which corresponds to the logging unit in this case. As the transition probability of the state depends on the state at previous sequential step, HMM considers Markov process. Observable data (logging data in this case) is generated stochastically following the probability distributions defined by the state at each sequential step. Transition probability of the state and data generation probability distributions for each state are parameters to be estimated. We estimated those parameters with Expectation-Maximization (EM) algorithm.

We applied HMM to four drilling sites around Japan. Two sites are located at Nankai subduction zones. In Southwest Japan, Nankai Trough Seismogenic Zone Experiment (NanTroSEIZE) project conducted a series of IODP expeditions, and large amounts of cores and well-logging data have been acquired. Among these expeditions, we used logging data from Holes C0001D and C0004B drilled during IODP Expedition 314. The other two sites are located at Japan Trench. Hole C0019B was drilled during IODP Expedition 343 as Japan Trench Fast Drilling (JFAST) project. Hole C0020A was drilled during IODP Expedition 337 as Deep Coalbed Biosphere off Shimokita. We selected in-situ electric resistivity, gamma ray, and sonic velocity (P- and S- wave) for the analysis.

For each data set, we tested the number of clusters in HMM from two to nine. We compare our results with the logging unit reported by Expedition scientists. Unit classifications with our method are usually consistent with those by Expedition scientists. However, we observed some differences or finer division of units as well. We discuss the geological meaning of our results.

Sparse Modeling of Nonlinear Dynamics in Heterogeneous Reactions

*Masaki Ito[1], Tatsu Kuwatani[2], Ryosuke Oyanagi[2], Toshiaki Omori[1]

1. Kobe University, 2. JAMSTEC

Surface heterogeneous reactions are chemical reactions with conjugation of multiple phases, and they have the intrinsic nonlinearity of their dynamics caused by the effect of surface-area between different phases. We propose a sparse modeling approach for extracting nonlinear dynamics of surface heterogeneous reactions from sparse and noisy observable data. We employ sparse modeling algorithm and sequential Monte Carlo algorithm to partial observation problem, in order to simultaneously extract substantial reaction terms and surface models from a number of candidates. Using our proposed method, we show that the rate constants of dissolution and precipitation reactions, which are typical examples of surface heterogeneous reactions, necessary surface models and reaction terms underlying observable data were successfully estimated only from the observable temporal changes in the concentration of the dissolved intermediate product.

How to obtain a high-SNR EPMA map?: complementary roles of high-resolution imaging and subsequent binning

*Atsushi Yasumoto[1], Kenta Yoshida[2]

1. Hiruzen Institute of Geology and Chronlogy, 2. Japan Agency for Marine-earth Science and Technology

Chemical imaging is a common technique to analyze heterogeneous materials. For example in petrology, X-ray mapping with an electron probe microanalyzer (EPMA) visualizes chemical heterogeneities (so-called texture) in rocks. X-ray mapping measures signals of X-rays, and higher signal-to-noise ratio (SNR) improves clarity of heterogeneities, which is generally achieved by increasing probe current and/or dwell time of pixels (e.g., Hiroi et al., 1997). An appropriate probe current is determined by sample damages, upper limits of the detectors, and dead time. Dwell time is also determined by sample damages and available analysis time. To acquire a high-SNR image at a reasonable time, reducing total number of pixels is one plausible solution; however, spatial resolution shall become low. To overcome this trade-off, this study proposes a complementary use of short dwell time mapping and subsequent binning. The short dwell time mapping generates high-spatial-resolution and low-SNR images for observing fine textures, and the binning treatment converts the raw maps to low-spatial-resolution and high-SNR images for detecting small differences in chemistry. This approach is applicable to any imaging techniques, including EPMA, which count signals under a given dwell time.

Chemical imaging records counts of signals from multiple points, typically as orthogonal pixels. If expected counting rates are fixed for pixels, observed counts follow Poisson distribution. In EPMA mapping, this assumption is valid because counting rates of X-rays depend mostly on (1) chemistry and surface conditions of materials which are constant; and (2) on probe current, accelerating voltage, and sensitivity of detectors which are controlled by analysts. According to the reproducibility of Poisson distribution, an expected counting rate of a certain signal from a large pixel is identical to an arithmetic-mean of counting rates of the signal from pixels dividing the large pixel. In other word, a sum of counts from n-by-n pixels in m seconds each is equivalent to measuring a large pixel composed of the n-by-n pixels in mn^2 seconds. A simulation is performed on a 300-by-300 matrix of Mandelbrot set. Expected counts per second is set to squares of Mandelbrot set timed by 20. Then, a 300-by-300 map with 1 second of dwell time, and a 150-by-150 map with 4 seconds of dwell time are generated by Poisson random numbers. The 300-by-300 map has higher spatial resolutions and lower-SNR than the 150-by-150 maps. Let’s consider a binning treatment of the 300-by-300 map, i.e. combining signal intensity of each 2-by-2 pixels into one superpixel. The binned 150-by-150 map is apparently comparable to the native 150-by-150 map. This means that high-SNR (low-resolution) image can be generated subsequently from high-resolution (low-SNR) image at an arbitrary degree, if necessary. A recommended binning method is sum rather than arithmetic mean so that binned values can be modeled with Poisson distributions. For example, if a pixel value is generated by Poisson distribution, its standard deviation can be approximated as square root of the pixel value.

The proposed approach has advantages in statistical analysis dealing with mapping data. For example, cluster analysis on a map classifies pixels into a given number of groups based on similarity of pixel values. Performance of cluster analysis, such as precision and smoothness, may improve by obtaining high-SNR of pixels through binning which separates signal peaks representing different groups. Note that benefit of sum as a binning method appears in cluster analysis because Poisson-distribution-based clustering algorithm (Witten, 2011) is applicable. If pixel values follow Poisson distributions, this algorism is more

Data-driven estimation of material transfer from bulk compositions

*Tatsu Kuwatani[1,2], Kenta Yoshida[1], Kenta Ueki[1], Ryosuke Oyanagi[1], Masaoki Uno[3], Shotaro Akaho[4]

1. Japan Agency for Marine-Earth Science and Technology, 2. Japan Science and Technology Agency, 3. Graduate School of Environmental Studies, Tohoku University, 4. National Institute of Advanced Industrial Science and Technology

Material transfer of elements is the most important consequences of geological processes. However, it is difficult to estimate it, even if both compositional datasets of before and after are available. This is because the compositional data are not absolute data but relative ratio data. Isocon analysis has been widely applied as a simple and powerful standard tool for quantitative estimation of material transfer to various geoscientific problems. Despite its powerfulness, the method needs to assume the reference frame such as immobile elements or conservation of mass or volume, which relies on the researchers' intuition and experience. We propose a novel data-driven method which determines an appropriate reference frame from compositional data of multiple altered samples. In the proposed method, we use a mathematical framework, called sparse modeling, which can extract essential variables from high-dimensional datasets based on sparsity of the system. By optimizing the evaluation function, the least mobile elements are automatically selected. In this study, the effectiveness is validated and discussed using synthetic and natural sample data. The method seems to be a practical tool for estimate material transfer and it has the potential to be improved for particular problems due to its simple and flexible formulation.

Mon. May 27, 2019 5:15 PM - 6:30 PM JST | Mon. May 27, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_42

[M-GI33] Data-driven geosciences

convener:Tatsu Kuwatani(Japan Agency for Marine-Earth Science and Technology), Hiromichi Nagao(Earthquake Research Institute, The University of Tokyo), Kenta Ueki(Japan Agency for Marine-Earth Science and Technology), Masayuki Kano(Graduate school of science, Tohoku University)

It is important to extract essential processes and structures from observed data sets in order to understand and predict the dynamic behavior of the earth and planetary systems. Recently, many powerful methodologies have been proposed to extract useful information from high-dimensional data sets in information sciences. This session aims to provide an opportunity to gather various geoscientists to have a productive discussion for interdisciplinary collaborations.

We constructed the geochemical database “DODAI” which compiled data published in the domestic journals and bulletins, and published its details recently (Haraguchi et al., 2018, J. Geol. Soc. Japan, doi: 10.5575/geosoc.2018.0027). This database has converted the sampling position of individual geochemical data into the GPS-familiar location coordinates, i.e. latitude and longitude, by image-based geocoding and improved the positional accuracy drastically compared to the previous databases.

There are some international databases of geochemical data, for example: "GEOROC" mainly involving land samples, "PetDB" mainly involving samples from seafloor. Recent progress on the data-driven science shed a light on a large number of sample data with a multitude of variables. As for heterogeneity of the mantle compositions (e.g. Iwamori et al, 2018), the world-wide scale of the geochemical structure are discussed on the basis of such databases. However, considerable number of data in these international databases provided the location coordinates only as the representative position of the geologic map of the original articles, and thus the resolution of these location data often can represent only the order of degree unit. This precision may have no problem for the discussion of world-wide scale, while interpretation in the detailed spatial scale may not be possible. The precision of location data in the “DODAI” is mostly less than 1 km, some of which have < 10m of errors, based on the spatial resolution of the map provided in the original articles. This precision allows us to correlate sample positions to the correct geological units described in the digital geologic map such as the Seamless Geological Map (AIST). We also defined a standard data format based on the metadata available in the compiled papers covering such as geographical information, sampling, and analytical methods.
In this presentation, we will show the concept and details of DODAI dataset, and discuss the potential of data-driven analysis in the geochemical study.

Keywords: geochemical database, geocoding, normalization of format

Bayesian statistical evaluation method for detrital zircon geochronology

*Tan Furukawa[1], Tatsuki Tsujimori[1]

1. Tohoku University

Over the past two decades, detrital zircon U-Pb geochronology has become an essential method not only in sedimentary provenance analyses but also in characterization of sedimentary and metamorphic strata. Although the age data has been conventionally evaluated by using relative frequency plots (here after called histograms) and density curves, the lack of statistical verification can cause miss reading of data. In order to overcome the statistical issues raised, this study proposes new statistical evaluation method for detrital zircon geochronology.
The new method is based on Bayesian statistics, adapted a theory proposed by Riihimäki and Vehtari (2014) that provides a flexible modeling for density curve using the Logistic Gaussian Process (LGP)
For introducing non-negative consistency for density curve, the logistic density transformation is performed by $p(x)=\exp(f(x))/\int\exp(f(\mathbf{s}))d\mathbf{s}$; x is age, p(x) is density curve, and f(x) is Gaussian Process; $f(x)\sim GP(0, \kappa(x,x'))$. The covariance matrix $\kappa(x,x')$ is calculated by Gaussian kernel with hyperparameters ρ and σ. For the actual computation, the logistic density transformation has integral difficulties, then, M discretized softmax function is used for approximation for it.
The likelihood function is $L(\mathbf{p}|\rho,\sigma)=\mathbf{y}^{T}\mathbf{p}$. $\mathbf{p}$ is M discretized p(x), and $\mathbf{y}$ is vector of y_i, which is the number of observations that fall within the i'th M discretized age subregion.
We have used programming language R and Stan for the MCMC computation of the statistical model above. When the number of detrital zircon data is several hundred or less, the hyperparameters of Gaussian process ρ and σ do not converge, and Bayesian estimation can not be performed. For this reason, the author estimated most plausible ρ and σ by WAIC. Using zircon data from our own data and the literature, in this presentation, we will demonstrate powerfulness of our new statistical evaluation.

Geochemical data processing using machine learning with artificial training data and proposal of environmental evaluation method considering natural background of heavy metals in river water in mining area

*Satoh Kenta[1], Kengo Sawayama[1], Noriyoshi Tsuchiya[1]

1. graduate school of environmental studies, Tohoku University

Acid mining drainage is one of the most important sources of heavy metals in river. Environmental standards are evaluated by the effects on the Ecosystem and human body. However, the current environmental standards do not consider natural background of heavy metals, therefore the method which can evaluate the effects on the environment concerning such heavy metals is needed. Then we propose to apply machine learning to evaluation effects by heavy metals. Using natural soil data and mineral data as training data in machine learning, it will become possible to evaluate the effects concerning heavy metals naturally included in soil. However, it is very important to choose the proper training data set in machine learning. In this study, we created training data artificially. If it can be done that Verifying correctness of this artificial training data, the range of application of machine learning expands. The objective of this study is, firstly, to verify the validity of artificial training data through case study, secondly, to establish the method to evaluate effects on the environment by heavy metals considering natural background of heavy metals. Focusing on the mine area where there are effects by heavy metals has already been confirmed, we digitized the effects by mine as the evaluation score by heavy metals using Support Vector Regression (SVR) and using the element content ratio as attribute. The element content ratio of mine was used as the ore training data and the element content ratio of the area surrounding the mine was used as the training data representing heavy metals naturally included in soil. We created data of the ore training data based on literature data about the mine. Furthermore, we verified validity of the artificial data through comparing three digitized assessment of contamination by the statistical method in the area, by the previous research, and by machine learning. As a result, the evaluation score by each method increased at the same point, and it is verified that the evaluation by machine learning using artificial training data is correct. If we use machine learning using artificial training data, it may improve further development of machine learning in the geochemical data set.

Quantitative Logging Unit Classification with Hidden Markov Model

*Suguru Yabe[1], Rina Fukuchi[2], Kenta Ueki[1], Yohei Hamada[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. UTokyo AORI

International Ocean Discovery Program (IODP) Expeditions have drilled ocean floor to address cores and well logging data for various purposes. Expedition scientists usually define logging units by characterizing logging data, and interpret their geological meaning. Unit classifications and their geological interpretations will be useful to understand the geological formation at the drilling site. The criteria to define such the units are described in the expedition report, which is usually based on the average, the minimum, and the maximum value of logging data. However, there is no mathematical background to support the validity of unit characterization. The motivation of this study is to develop the quantitative method for log unit definition, and to find out overshadowed log-characteristics for detailed geological interpretation.

This study used Hidden Markov Model (HMM) to classify logging data into logging units. HMM is a stochastic model to classify sequential data. In HMM, each sequential step has the unobservable parameter “state”, which corresponds to the logging unit in this case. As the transition probability of the state depends on the state at previous sequential step, HMM considers Markov process. Observable data (logging data in this case) is generated stochastically following the probability distributions defined by the state at each sequential step. Transition probability of the state and data generation probability distributions for each state are parameters to be estimated. We estimated those parameters with Expectation-Maximization (EM) algorithm.

We applied HMM to four drilling sites around Japan. Two sites are located at Nankai subduction zones. In Southwest Japan, Nankai Trough Seismogenic Zone Experiment (NanTroSEIZE) project conducted a series of IODP expeditions, and large amounts of cores and well-logging data have been acquired. Among these expeditions, we used logging data from Holes C0001D and C0004B drilled during IODP Expedition 314. The other two sites are located at Japan Trench. Hole C0019B was drilled during IODP Expedition 343 as Japan Trench Fast Drilling (JFAST) project. Hole C0020A was drilled during IODP Expedition 337 as Deep Coalbed Biosphere off Shimokita. We selected in-situ electric resistivity, gamma ray, and sonic velocity (P- and S- wave) for the analysis.

For each data set, we tested the number of clusters in HMM from two to nine. We compare our results with the logging unit reported by Expedition scientists. Unit classifications with our method are usually consistent with those by Expedition scientists. However, we observed some differences or finer division of units as well. We discuss the geological meaning of our results.

Sparse Modeling of Nonlinear Dynamics in Heterogeneous Reactions

*Masaki Ito[1], Tatsu Kuwatani[2], Ryosuke Oyanagi[2], Toshiaki Omori[1]

1. Kobe University, 2. JAMSTEC

Surface heterogeneous reactions are chemical reactions with conjugation of multiple phases, and they have the intrinsic nonlinearity of their dynamics caused by the effect of surface-area between different phases. We propose a sparse modeling approach for extracting nonlinear dynamics of surface heterogeneous reactions from sparse and noisy observable data. We employ sparse modeling algorithm and sequential Monte Carlo algorithm to partial observation problem, in order to simultaneously extract substantial reaction terms and surface models from a number of candidates. Using our proposed method, we show that the rate constants of dissolution and precipitation reactions, which are typical examples of surface heterogeneous reactions, necessary surface models and reaction terms underlying observable data were successfully estimated only from the observable temporal changes in the concentration of the dissolved intermediate product.

How to obtain a high-SNR EPMA map?: complementary roles of high-resolution imaging and subsequent binning

*Atsushi Yasumoto[1], Kenta Yoshida[2]

1. Hiruzen Institute of Geology and Chronlogy, 2. Japan Agency for Marine-earth Science and Technology

Chemical imaging is a common technique to analyze heterogeneous materials. For example in petrology, X-ray mapping with an electron probe microanalyzer (EPMA) visualizes chemical heterogeneities (so-called texture) in rocks. X-ray mapping measures signals of X-rays, and higher signal-to-noise ratio (SNR) improves clarity of heterogeneities, which is generally achieved by increasing probe current and/or dwell time of pixels (e.g., Hiroi et al., 1997). An appropriate probe current is determined by sample damages, upper limits of the detectors, and dead time. Dwell time is also determined by sample damages and available analysis time. To acquire a high-SNR image at a reasonable time, reducing total number of pixels is one plausible solution; however, spatial resolution shall become low. To overcome this trade-off, this study proposes a complementary use of short dwell time mapping and subsequent binning. The short dwell time mapping generates high-spatial-resolution and low-SNR images for observing fine textures, and the binning treatment converts the raw maps to low-spatial-resolution and high-SNR images for detecting small differences in chemistry. This approach is applicable to any imaging techniques, including EPMA, which count signals under a given dwell time.

Chemical imaging records counts of signals from multiple points, typically as orthogonal pixels. If expected counting rates are fixed for pixels, observed counts follow Poisson distribution. In EPMA mapping, this assumption is valid because counting rates of X-rays depend mostly on (1) chemistry and surface conditions of materials which are constant; and (2) on probe current, accelerating voltage, and sensitivity of detectors which are controlled by analysts. According to the reproducibility of Poisson distribution, an expected counting rate of a certain signal from a large pixel is identical to an arithmetic-mean of counting rates of the signal from pixels dividing the large pixel. In other word, a sum of counts from n-by-n pixels in m seconds each is equivalent to measuring a large pixel composed of the n-by-n pixels in mn^2 seconds. A simulation is performed on a 300-by-300 matrix of Mandelbrot set. Expected counts per second is set to squares of Mandelbrot set timed by 20. Then, a 300-by-300 map with 1 second of dwell time, and a 150-by-150 map with 4 seconds of dwell time are generated by Poisson random numbers. The 300-by-300 map has higher spatial resolutions and lower-SNR than the 150-by-150 maps. Let’s consider a binning treatment of the 300-by-300 map, i.e. combining signal intensity of each 2-by-2 pixels into one superpixel. The binned 150-by-150 map is apparently comparable to the native 150-by-150 map. This means that high-SNR (low-resolution) image can be generated subsequently from high-resolution (low-SNR) image at an arbitrary degree, if necessary. A recommended binning method is sum rather than arithmetic mean so that binned values can be modeled with Poisson distributions. For example, if a pixel value is generated by Poisson distribution, its standard deviation can be approximated as square root of the pixel value.

The proposed approach has advantages in statistical analysis dealing with mapping data. For example, cluster analysis on a map classifies pixels into a given number of groups based on similarity of pixel values. Performance of cluster analysis, such as precision and smoothness, may improve by obtaining high-SNR of pixels through binning which separates signal peaks representing different groups. Note that benefit of sum as a binning method appears in cluster analysis because Poisson-distribution-based clustering algorithm (Witten, 2011) is applicable. If pixel values follow Poisson distributions, this algorism is more

Markov Chain Monte Carlo: algorithms for multimodal distribution and their applications

*Yukito iba[1]

1. The Institute of Statistical Mathematics

As introduction, history and software of Markov chain Monte Carlo is briefly discussed. Then, replica exchange method (parallel tempering) is explained as a useful tool for sampling multimodal distributions. It is also stressed that applications of Markov chain Monte Carlo are not rescricted to statistical physics or Bayesian computaion; it can deal with a variety of problems related to high dimensional probability, such as counting the number of discrete structures, sampling rare orbits in nonlinear dynamical systems, statistical testing under complicated null hypothesis.

Specifying rate constants and reaction path on the water-rock chemical reaction based on exchange Monte Carlo method and sparse modeling

*Ryosuke Oyanagi[1], Tatsu Kuwatani[1], Omori Toshiaki[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Kobe University

Water-rock interaction in surface and subsurface environments occurs in complex multicomponent systems and involves several reactions, including element transfer. Such kinetic information is obtained by fitting a forward model into the temporal evolution of solution chemistry or the spatial pattern recorded in the rock samples, although geochemical and petrological data are essentially sparse and noisy. Therefore, the optimization of kinetic parameters sometimes fails to converge toward the global minimum due to being trapped in a local minimum.

In this study, we present a novel framework to estimate multiple reaction-rate constants from the mineral distribution pattern in a rock by using the exchange Monte Carlo method (Hukushima & Nemoto, 1997; Iba, 2001). We applied the method to the synthetic data, which includes nine unknown parameters to be estimated (Oyanagi et al., 2018). As a result, probabilistic distribution of six unknown parameters among them showed normal distributions and the proposed method could find each true parameter. However, the probabilistic distribution of others showed uniform distributions and the proposed method failed to estimate each true value because these parameters did not contribute to the observed dataset. We suggest that effective reaction paths could be extracted from mineral distribution pattern in a rock, by excluding non-effective rate constant using a sparse Modeling.

Superresolution of X-ray CT images of core samples for understanding the multi-scale structures of water-rock interaction

*Toshiaki Omori[1], Atsushi Okamoto[2], Katsuyoshi Michibayashi[3], Oman Drilling Project Phase 2 Science Party -

1. Kobe Univ., 2. Tohoku Univ., 3. Nagoya Univ.

X-ray computed tomography (CT) has become a common tool of earth sciences for the 3D imaging of various structures (layering, fractures, pores etc) of rocks. Recently, several scientific drilling projects has been carried out, and the X-ray CT of such cores provide us the 100 to 1000 m scale continuous data. However, the resolution of such X-ray CT for the cores (for example, ~0.17 mm by the X-ray CT of Drilling Chikyu) is slightly low compare to reveal the shape and geometry of mineral grains and thin fractures. In contrast, the resolution of X-ray CT in usual laboratories is high (~0.01 mm). Therefore, if we can link the high resolution X-ray CT in the lab of the limited samples to the low resolution drilling core CT data, we can obtain the valuable big data for the analyses of multi-scale structures.

For this purpose, we have tried to apply sparse superresolution techniques to the sample of serpentinezed dunite in the Moho transition zone taken by the Oman Drilling project (CM1A). We took the X-ray CT images of the samples with the voxel size of 10, 20, 40 and 80 micrometers. The X-ray CT image reveals that distribution of magnetite and spinel grains and fractures filled with serpentine. In sparse image representation framework, an image is expressed as a sparse linear combination of basis images. In learning phase, basis images are learned from multiple X-ray CT images. In superresolution phase, high resolution X-ray CT image is estimated from low resolution one through common sparse representation of basis images between high and low resolution images. By applying the sparse superresolution technique to the sample of serpentinezed dunite, we obtained results that 2x and 4x sparse superresolutions provide fine structure from low resolution X-ray image.

3-dimensional Fracture Network Analysis by Persistent Homology

*Miyuki Miyazawa[1], Anna Suzuki[2], Atsushi Okamoto[1], Hiroyuki Shimizu[3], Ippei Obayashi[4], Yasuaki Hiraoka[4,5], Takatoshi Ito[2]

1. Graduate School of Environmental Studies, Tohoku University, 2. Institute of Fluid Science, Tohoku University, 3. Kajima Corporation, 4. The Advanced Institute for Materials Research, Tohoku University, 5. Kyoto University

Persistent homology (PH) based on topology is a method for capturing sizes and shapes of “holes”, that is information of connectivity. Because PH enables to quantify complex structures, automatic pattern recognition of fractures can be carried out.

Fluid flow in rocks is dominated by connectivity between fractures, so it can be expected that the relationship between fracture patterns and fluid flow can be obtained by the PH.

In this study, we quantified the images of the results from crack propagations simulation and natural mesh structures in serpentinites. The PH analysis helps to estimate the flow conditions in which the mesh structures in serpentinites were formed. And we can quantify 3D fracture structure by PH. It can be expected that PH is applied to design for geothermal reservoir by coupling PH analysis result of 3D fracture models with feature of fracture (e.g., surface area, volume, connectivity and permeability).

Characteristic patterns and minimal dynamics of correlated seismicity in Japanese island region

*mitsuhiro toriumi[1]

1. Japan agency of marine science and technology

The seismicity rates in this study are defined as the seismic event numbers of the given volume having one degree of longitude and 2.5 degree of latitude from the surface to 30 km depth and 30 to 660km depth in the Japanese islands region. It shows that the characteristic trends of time series of strongly correlated seismicity are possibly obtained as transformed seismicity rates by SVD; the one shows the long term change, second does the periodic time series with various periodicity involving annual variation, and third does nearly Gaussian noise. The first two types of time series can be mapped as five clusters in the diagram of newly transformed seismicity rate coordinates, suggesting existence of stable nodes with annual oscilation and gaussian noises. From these stable nodes, it concludes that the minimal dynamics of the seismicity of the Japanese island region is approximated as the simple low dimensional nonlinear dynamics with semi-periodic variable as is similar to van del Pol equation.

Keywords: spatio-temporal variation of seismicity, correlated seismicity time series, minimal non-linear dynamics

[M-TT46] New phase of GPS/GNSS application as an integrated earth observation system

convener:Yoshinori Shoji(The Second Laboratory of Meteorological Satellite and Observation System Research Department, Meteorological Research Institute), Kaoru Ichikawa(Research Institute for Applied Mechanics, Kyushu University), Yusaku Ohta(Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University), Takuya Tsugawa(National Institute of Information and Communications Technology), Chairperson:Yusaku Ohta

GNSS has become a fundamental tool for studies on atmosphere, ionosphere, and solid earth. Ground and space-based GNSS measurements have operationally contributed to improve global and regional NWP since 2006. In recent years, studies utilizing reflected GNSS signals to derive altimetric height, surface roughness, soil moisture, snow depth, humidity or vegetation index have been evolving. Ocean-platform GNSS observations have been demonstrating their capability of real-time monitoring of maritime water vapor as well as sea level. Increasing observations provided through Multi-GNSS (GPS, GLONASS, BEIDOU, GALILEO, QZSS etc.) enhances capability of the GNSS as an integrated earth observation system.
The purpose of this session is to share the latest development of GNSS researches on monitoring the earth system and to stimulate synergetic interdisciplinary studies. Contributions on atmosphere (troposphere and ionosphere) studies, reflectometry (GNSS-R), and integrations of different observation techniques like GNSS-Acoustic measurement to monitor ocean floor positioning are welcome.

The latest status of Quasi-Zenith Satellite System (QZSS) and its future expansion

*Satoshi Kogure[1]

1. QZSS Straetegy Office, National Space Policy Secretariate, Cabinet Office

The Quasi-Zenith Satellite System (QZSS) is a regional space-based Position, Navigation and Timing (PNT) system developed and operated by Japanese government as their important national infrastructure. Three consecutive launches were successfully conducted in 2017. The official operational service has been launched since November 1, 2018. The expansion to 7 satellite constellation is now being investigated. The presentation shows the latest status of the QZSS program as well as its future expansion.

Application of the GNSS-A for other academic fields and fundamental marine information network

*Yusuke Yokota[1], Tadashi Ishikawa[2], Shun-ichi Watanabe[2]

1. Institute of Industrial Science, The University of Tokyo, 2. Hydrographic and Oceanographic department, Japan Coast Guard

The GNSS-A observation technology had detected coseismic deformation fields just above the megathrust earthquake [Sato et al., 2011, Science; Kido et al., 2011, GRL], postseismic deformations [Watanabe et al., 2014, GRL; Tomita et al., 2017, Sci. Adv.] and interseismic coupling condition [Yokota et al., 2016, Nature]. In addition, we recently upgraded the GNSS-A methodology in aspects of observation frequency and accuracy and detected a longer-term sequence of slow slip events (SSEs). The detected undersea SSEs led a new discussion about a diverse behavior of SEQs and provide many questions, i.e., their stress loading for coupling region and difference of geological condition in the SSE, other SEQs and coupling regions, to be solved by the future seafloor, submarine and onshore geophysical monitoring.

In the development process of this new GNSS-A system, new oceanographic information in km scale region was found to be extractable from the GNSS-A data [Yokota et al., 2018, MGR]. This data has features consistent and inconsistent with the JCOPE2 model [Miyazawa et al., 2009, JO], so the GNSS-A system has a potential to provide new observation data of very narrow marine region.

These observations have extremely high scientific potential from the viewpoint of seismology, earthquake disaster prevention engineering and submarine geology about megathrust subduction zones and unknown potential about new multidisciplinary aspects called the nano-scale GNSS-A oceanography and the marine GNSS meteorology. In order to promote the distribution of data to the earthquake science community and different academic fields, it is necessary to establish a simple data format and manage using doi. In particular, for carrying out long-term and stable observation, we must construct strong management and evaluation system to perform appropriately data collection and observation operation. The realization of such a solid fundamental marine observation network will also have a positive effect on new research and development.

Moreover, it is necessary to enhance the GNSS-A observation system to upgrade the observation density, continuity and real-time property for understanding the subduction zone and disaster prevention. Eventually, we should construct next-generation fundamental network that aggregates the marine information system that utilize total data in real time based on numerical simulation and data assimilation.

Feasibility of the GNSS carrier phase to fault slip approach for the estimation of slip phenomena in subduction zone

*Yusuke Tanaka[1], Yusaku Ohta[1], SHINICHI MIYAZAKI[2]

1. Tohoku University, 2. Kyoto University

Precise detection of coseismic deformation and estimation of its source model are especially important in the case of earthquake occur in subduction zones, because it is directly related to accurate tsunami forecasting. Recent years, many researchers have tried to estimate earthquake source model and/or tsunami wave field in real-time using Global Navigation Satellite System (GNSS). However, conventional GNSS-based monitoring requires huge computational cost for positioning analysis. Using coordinate time series for observation also causes difficulty to evaluate accuracy of separation between deformation and other unknown parameters such as tropospheric delay. Additionally, current positioning analysis strongly depends on precise orbit information which is provided externally.

According to such background, we investigate the feasibility of deformation monitoring based on the GNSS carrier phase to fault slip approach for subduction zone. This method, which we call PTS (Phase To Slip) detects fault slip directly from GNSS carrier phase variation without positioning analysis. As PTS method estimates all unknown parameters in parallel, computational costs for real-time seismic monitoring can be reduced. Moreover, PTS does not require high-quality satellite orbit because it relies only on changes in azimuthal site-to-satellite ranges (Tanaka, Ohta, and Miyazaki, GRL, 2019).

Here we applied the PTS method to the largest aftershock of the 2011 Tohoku-Oki earthquake. In the analysis, we used both precise orbit provided by International GNSS Service (IGS) and broadcast orbit submitted from satellite without any network connection. As a result, we obtained very similar coseismic slip distribution in the two cases. Inferred fault slip showed clear thrust slip and was equivalent to M_w 7.8. These results well agree with the estimation based on conventional GNSS analysis such as Nishimura et al. (EPS, 2011). Calculated surface displacements also agree with independent conventional GNSS analysis result. These results indicate that the PTS method can be useful as a supplementary system of current deformation monitoring, which does not require any external information. Furthermore, once we could obtain slip distribution, we can also convert it into deformation of sea bottom, which is equivalent to initial tsunami source. Thus, our results suggest potential feasibility of PTS method for tsunami forecasting.
In the presentation, we will describe application of the PTS method to whole process of Tohoku-Oki earthquake, including its foreshock, mainshock and following aftershocks. Beside detail of its result, we will also demonstrate quantitative evaluation of parameter separation accuracy inside PTS analysis.

Assimilation experiments of GNSS-derived ZTD and Sentinel-derived products into WRF to improve forecasts of severe rain events in Italy

*Eugenio Realini[1], Martina Lagasio[2], Luca Pulvirenti[2], Antonio Parodi[2], Andrea Gatti[1], Giulio Tagliaferro[1], Giovanna Venuti[3], Stefano Barindelli[3], Emanuele Passera[4], Alessio Rucci[4], Nazzareno Pierdicca[5], Bjorn Rommen[6]

The Italian peninsula is frequently struck by severe floods and flash floods causing losses of lives and significant damages every year. Improving the accuracy of rain forecasts is a fundamental goal to limit social and economic damages. Forecasts based on numerical weather prediction (NWP) models are challenged by the uncertainty related to the initial state of the atmosphere at small spatial-temporal scales. The inevitable model spin-up often results in an inaccurate simulation of the timing, the location and the severity of convective events. This challenge becomes even more relevant when the model grid spacing is approaching the kilometer scale, mainly because of the lack of high spatiotemporal resolution observations. In this scenario the STEAM (SaTellite Earth observation for Atmospheric Modelling) project, funded by the European Space Agency (ESA), has the aim of investigating to what extent GNSS-derived and Sentinel SAR-derived tropospheric delay data, as well as other Sentinel-derived products (i.e. soil moisture, soil and sea temperature, wind over sea) can be used to better understand and predict, with high spatial-temporal resolution, the atmospheric phenomena resulting in severe rain events and intense atmospheric turbulence. About 400 GNSS stations distributed throughout Italy were processed by the precise point positioning (PPP) technique, by means of the free and open source software goGPS, to estimate zenith total delay (ZTD) time series. Atmospheric phase screens (APS) were generated from Sentinel-1 observations, calibrated and converted to absolute tropospheric delays by using data from the Generic Atmospheric Correction Online Service for InSAR (GACOS). Surface soil moisture maps were retrieved from Sentinel-1 observations, by means of a multi-temporal algorithm that uses time series of Sentinel-1 data and ancillary data, such as a plant water content map, as inputs. Soil and sea temperature are directly available from ESA as level-2 products based on Sentinel-3, as well as the wind field over sea, based on Sentinel-1.
The experimental results concern two intense rainfall events and subsequent floods that occurred in Italy in Autumn 2017. The best results were obtained by assimilating the wind field (in the first test case) and the GNSS-derived ZTD (in the second test case). Promising results were achieved also by performing a combined assimilation of wind field and ZTD, and direct insertion of soil moisture. The outcomes of this study seem to confirm the synergy between high-resolution numerical weather models and a set of GNSS-derived and Sentinel-derived Earth Observation products, at least for the forecast of severe rain events.

An analysis of tropospheric delays using goGPS software on all GEONET stations during the passage of Typhoon Jebi in September 2018

*Andrea Gatti[1], Eugenio Realini[1], Giulio Tagliaferro[1]

1. Geomatics Research & Development srl

Nowadays, tropospheric delays estimated from GPS observations are widely used for studying weather events all over the world. Some meteorological agencies already use Zenith Tropospheric Delays (ZTD), or similar observables, by assimilation into numerical weather prediction (NWP) models; however, the increasing number of satellites from newer GNSS constellations (Galileo, QZSS, BeiDou, IRNSS), the advent of low-cost receivers and the advancement of techniques and models left space for further studies on the topic.

The new version of the open-source goGPS MATLAB software has been written to be a simple tool to perform efficient analysis of GNSS data from both geodetic and low-cost receivers. With its capability to download automatically all the resources needed by the selected algorithms, the relative easiness of use, and its flexibility with the possibility of trying different configurations in a fast way, goGPS presents itself as a convenient tool for students or researches who want to prototype new algorithms or perform studies on GNSS data.

To demonstrate the capabilities of the software, 1312 stations of the Japanese GEONET GNSS network are processed from September 2, 2018, to September 5, 2018, during the passage of Typhoon Jebi.

A 32-core machine running MATLAB 2016a and the latest beta version of goGPS 1.0 is used to process in a single parallel run the entire 4 days of the dataset. The execution performs for all the stations a multi-epoch precise point positioning (PPP) least squares (LS) adjustment in about two hours of computation time. Series of tropospheric delays and gradients are generated and used to produce maps and animations in order to observe the development of the event. Different solutions including multi-constellation results are presented and discussed.

A new perspective of the storm-time dynamics of the ionosphere using global GNSS-TEC observation data

*Atsuki Shinbori[1], Yuichi Otsuka[1], Takuya Sori[1], Takuya Tsugawa[2], Michi Nishioka[2]

1. Institute for Space-Earth Environment Research (ISEE), Nagoya University, 2. National Institute of Information and Communications Technology (NICT)

The Earth’ s atmosphere is divided into four regions: troposphere, stratosphere, mesosphere and thermosphere by the temperature structure. A part of neutral gases in the mesosphere and thermosphere is ionized by solar extreme ultraviolet (EUV) radiation in a wavelength of less than 100 nm. The region having the ionized gasses (plasmas) is called the ionosphere. The height profile of the electron density in the ionosphere becomes maximum at a height of 300 km is determined by the chemical and dynamical processes in addition to the solar EUV ionization. Due to the interaction between the ionospheric electrons and electric fields of electromagnetic waves, the ionosphere gives a significant influence on the ionospheric transmissions with satellites for communications, positioning, and navigation. The ionosphere changes greatly in association with the activities of the sun, magnetosphere, and the lower atmosphere, and their ionospheric variations interfere with satellite communication and enhances satellite positioning errors in the Global Navigation Satellite System (GNSS), including GPS. The most major factor of the positioning errors is the propagation delay of GNSS signals in the ionosphere. Therefore, a global total electron content (TEC) map or ionospheric model is required to investigate global ionospheric variations associated with geomagnetic storms and lower atmospheric activities and to evaluate the ionospheric delay for GNSS positioning. A scale of the ionospheric variations (traveling ionospheric disturbances (TIDs), equatorial plasma bubbles (EPB), auroral ionospheric irregularity) is in a range between several 100 km and 1000 km. A storm enhanced density (SED) phenomena observed in the mid- and low-latitude ionosphere during the main phase of geomagnetic storms appears with a wide longitudinal extent. In order to clarify generation and propagation mechanisms of these ionospheric phenomena and to investigate their effects on the GNSS positioning, dense and wide-coverage ionospheric observations and the corresponding TEC data are needed. Under these backgrounds, we have built a global TEC database (absolute TEC, detrended TEC, and ROTI) with high time and spatial resolutions and developed a TEC data analysis system in a corroboration with NICT and the IUGONET (Inter-university Upper atmosphere Global Observation NETwork) and PWING (Study of dynamical variation of particles and waves in the inner magnetosphere using ground-based network observations) projects. For the development of the TEC database, we have collected all the available GNSS receiver data in the world. The number of the GNSS stations reaches more than 8500 in January 2019. These GNSS data are provided by the International Geoscience Services (IGS), the University NAVSTAR Consortium (UNAVCO), Scripps Orbit and Permanent Array Center (SOPAC), and other global and regional data centers (more than 50 data providers in all). In this talk, we introduce an overview of recent new scientific results of temporal and spatial variations in the ionosphere during the development and decay of geomagnetic storms as seen in the global GNSS-TEC variations.

Ionospheric space weather studies for GNSS users

*Takuya Tsugawa[1], Kornyanat Hozumi[1], Punyawi Jamjareegulgarn[2], Supnithi Pornchai [2], Susumu Saito[3], Yuichi Otsuka[3,4], Shinichi Hama[1], Takahiro Naoi[1], Mamoru Ishii[1]

1. NICT, 2. KMITL, 3. ENRI, 4. Nagoya Univ.

NICT has observed ionosphere using Ionosondes and GNSS receiver networks in Japan and Southeast Asia for the nowcast and forecast of the ionospheric condition.Two-dimensional ionospheric total electron content (TEC) maps have been derived from dense ground-based GNSS receiver networks and applied to studies of various ionospheric disturbances since mid-1990s. For the purpose of monitoring and researching ionospheric conditions and ionospheric space weather phenomena, we have developed TEC maps over Japan using GEONET. Currently, we are providing high-resolution two-dimensional maps of absolute TEC, detrended TEC, rate of TEC change index (ROTI), and loss-of-lock on GPS signal over Japan in real-time basis.

We have collected all the available GNSS receiver data in the world to expand the TEC observation area. To expand the two-dimensional TEC observation are with high-resolution, we have conducted Dense Regional And Worldwide International GNSS TEC observation (DRAWING-TEC) project, which consists of the three items: (1) standardizing GNSS-TEC data, (2) developing a new high-resolution TEC mapping technique, and (3) sharing the standardized TEC data or the information of GNSS receiver network. One of other effective methods to expand TEC observation area would be to use the maritime GNSS buoys.

NICT have started a new research project to validate the ionospheric effect of precise positioning technique using GNSS including quasi-zenith satellite (QZSS) since 2017. In this project, we will investigate ionospheric effects on individual positioning techniques (single frequency, DGPS, and RTK-PPP) and consider methods to mitigate and/or prevent the positioning errors under sever ionospheric conditions. We have tried to use multi-GNSS data including GPS and QZSS for routine data collection and processing. In the Southeast Asia, it is important to identify which satellite-receiver path suffers from plasma bubble structures for verifying the ionospheric effects on GNSS positioning. we have a plan to install VHF radar at Chumphon (Thailand) and multi-GNSS receivers at Chumphon, Bac Lieu (Vietnam), and Cebu (Philippines) at the magnetic equator.

QZSS geostationary satellite for ionospheric TEC observations

*Kosuke Heki[1]

1. Department of Earth and Planetary Sciences, Faculty of Science, Hokkaido University

Most Global Navigation Satellite System (GNSS) satellites employ orbital periods with a half sidereal day. This makes the satellites move rapidly in the sky when observed from ground receivers. This is important in relative positioning by observing carrier phases and in estimating zenith tropospheric delays. However, measurement of ionospheric total electron content (TEC) could be done instantaneously by comparing phases of the two carrier waves, and the changes in the satellite azimuth and elevation becomes a nuisance. The change in STEC (slant TEC) comes from (1) temporal change and (2) spatial changes of ionosphere, and (3) apparent U-shaped changes coming from the elevation changes. We can mitigate (3) by using VTEC, i.e. removing the inter-frequency biases and multiplying the bias-free STEC with cosine of the line-of-sight penetration angle. Nevertheless, discrimination of (1) and (2) is difficult and becomes possible only by processing the whole data sets of dense networks. The Japanese Quasi-zenith Satellite System (QZSS) is currently composed of four satellites, 3 satellites with quasi-zenith orbits (PRN01, 02, 03) and 1 satellite with geostationary orbit (PRN07). The latter enables continuous observation of certain points in ionosphere fixed to the Earth, i.e. the changes in TEC come entirely from temporal changes.

The Japanese GEONET network GNSS receivers continuously track GPS, GLONASS, Galileo, and QZSS, and their raw data are available on line as the RINEX (Receiver independent exchange format) Ver.3.02 files. I made a software system to read them and convert the phase data to TEC time series. With TEC observations from the geostationary satellite, we could study temporal changes in ionosphere without being bothered by spatial variations. This implies certain benefits in studying ionospheric disturbances, such as LSTID (Large-Scale TID), MSTID (Medium-scale TID) (Otsuka et al., 2011), Es (sporadic-E) (Maeda & Heki, 2015), artificial ionospheric electron depletion due to launches of satellites and ballistic missiles (Hashimoto & Heki, 2018), and preseismic ionospheric anomalies (Heki, 2019). In contrast, geostationary satellites are not suitable for studying coseismic ionospheric disturbances by acoustic waves (Cahyadi & Heki, 2015) and those by volcanic eruptions (Nakashima et al., 2015). This is because stronger signals always appear in poleward line-of-sights from ground stations located at the equatorward side of the epicenters/volcanoes (Heki, 2019).

Precise estimation of total electron content by double-shell model using local receiver network

*Takashi Maruyama[1,2], Kornyanat Hozumi[1], Guanyi Ma[2], Qingtao Wan[2]

1. National Institute of Information and Communications Technology, 2. National Astronomical Observatories, Chinese Academy of Sciences

The total electron content (TEC) derived from the differential group delay of the code signals of GNSS on two frequencies has been a basic parameter in ionospheric studies. In most applications, the thin-layer approximation is used to convert the measured slant TEC to vertical TEC at the ionosphere pierce point. Usually the thin-layer height is assumed to be constant regardless of the location and time, which is unrealistic and can be a source of error in TEC estimations. This is a serious problem at low latitudes where the ionospheric height greatly varies by the action of the vertical EXB drift due to the zonal electric field and field-aligned transport due to the meridional neutral wind drag. In this paper, we parameterized the ionosphere by two thin-layers (double-shell model) at 250 and 1100 km to avoid this inconvenience. The variation of partial electron content related to each layer was approximated by the spherical harmonics expansion to minimize the error of slant TEC between the measurements and the sum of contribution from the two layers. In the harmonics expansion calculation, the longitude parameter was the sun-fixed longitude or the local time measured in angle. Thus data obtained in a whole day were used. Another problem with the conventional technique is the leveling procedure, where phase measurements with a small noise are leveled to the noisy code signal data. Therefore, noises and multipath effect on the code delay are not resolved by the leveling. To avoid this inconvenience, the leveling to the code data was not applied in our study. Instead, the total bias including instrumental (satellite and receiver) code biases and phase ambiguity for each arc (i.e., total arc bias) was determined in conjunction with TEC.
The technique was applied to datasets obtained by a local receiver network near the magnetic equator. Results were compared with those of the conventional (single) thin-layer model. A significant difference was found in the ratio of TECs at the equatorial anomaly crests and trough. The double-shell model captured the equatorial anomaly more correctly than the conventional method. Another outcome of the double-shell model was the different patterns of TEC variations at the two heights, as expected. Equatorial anomaly crests and the evening TEC bite-out at the equator were prominent in the lower shell. The TEC peak at the higher shell appeared later than the lower shell. Two shells exhibited different features of north-south asymmetry of TEC, depending on the local time. These results provide information on the ionospheric dynamics, such as the ionosphere-thermosphere coupling through the field-aligned transport and variations of the evening enhancement of zonal electric field.

Investigation of sea surface height detection by Global Navigation Satellite System Reflectometry (GNSS-R)

*Osamu Isoguchi[1], Kaoru Ichikawa[2], Yukihito Kitazawa[3]

1. RESTEC, 2. Kyushu Univ., 3. ISAS/JAXA

In recent years, the possibility of detecting ocean parameters such as sea surface height (SSH), ocean wind from the Global Navigation Satellite System reflectometry (GNSS-R) was shown. The Cyclone GNSS (CYGNSS) mission aiming to contribute to the forecast of extreme weather phenomena by observing the sea surface wind in the cyclone is in progress operating eight small satellites and ocean wind speed products are being delivered. In GNSS-R, it is theoretically possible to measure the SSH from the ellipsoid by measuring the delay of the reflected wave and the direct wave. The investigation of SSH detection using TDS-1 which was developed and operated mainly by Surrey Satellite Technology Ltd (SSTL) in the UK has been reported. Even in our group, SSH detection was performed using TDS-1 data observed near Japan and the detected ones was compared with the mean SSH constructed by the altimeter observations. It was confirmed that the SSH can be detected with an error of about 1m at observation with good conditions (antenna gain is 7.5 dBi or more). Regarding CYGNSS, SSH is not calculated as an official product and it is limited to detectability study. In this report, we used CYGNSS data to investigate SSH detection from GNSS-R like TDS-1.

The CYGNSS data used for the present study is a full resolution Delayed Doppler Map (DDM) provided as special data through the GNSS Reflectometry for Ocean Waves, Tides and Height (GROWTH) project, which is a member of NASA CYGNSS External Science Member. The size of DDM is 20 (Doppler) ×128 (Delay) bin. On the other hand, the size of the normal DDM is 11 (Doppler) ×17 (Delay) bin in the Level 1 ver 2.1 data provided by NASA's The Physical Oceanography Distributed Active Archive Center (PO.DAAC). Thus, the data are compressed to 1/2 in the doppler direction and 1/8 in the delay one. Since the resolution in the delay direction affects the range measurement, it is expected that the detection resolution by the full DDM will be improved over the usual L1 data. The data provided was data acquired mainly in the East China Sea and acquired for the purpose of demonstrating the possibility of detecting the SSH related to the large tide amplitude.

Since the provided full resolution data are those in which only a part of data on DDM is stored, L1 ver 2.1 data at the same time were collected and the positions of the transmitting GNSS satellite and the receiving CYGNSS, the position of the reflection point and the delay information of the reflection point corresponding to the full DDM were extracted to calculate the SSH. A random variation of about 6m in standard deviation was confirmed in the delay information of the reflection point, so we with calculated weighed average with the 1/e scale of 75 km after excluding the abnormal values. Based on the above information, the SSH along the reflection point was calculated and compared with the mean SSH data calculated based on the altimeter data. A large spatial error that can be approximated by a linear equation of the distance was confirmed for the difference between the two SSHs, and therefore the relative SSH was evaluated by subtracting the approximate expression. The RMS error along the 4 passes of the observation on April 18, 2018 was about 0.8 m to 1.5 m, which was almost the same accuracy as TDS-1.

In the present study, the possibility of SSH detection as a spatial relative altitude was suggested. However since the large spatial error remains, whether the SSH variation in the East China Sea with O (1 m) can be detected will be a subject for further study. In particular, since corrections to the ionosphere and the

troposphere delays have not been made at the stage of this study, it is considered necessary to estimate their influences from model data.

GNSS has become a fundamental tool for studies on atmosphere, ionosphere, and solid earth. Ground and space-based GNSS measurements have operationally contributed to improve global and regional NWP since 2006. In recent years, studies utilizing reflected GNSS signals to derive altimetric height, surface roughness, soil moisture, snow depth, humidity or vegetation index have been evolving. Ocean-platform GNSS observations have been demonstrating their capability of real-time monitoring of maritime water vapor as well as sea level. Increasing observations provided through Multi-GNSS (GPS, GLONASS, BEIDOU, GALILEO, QZSS etc.) enhances capability of the GNSS as an integrated earth observation system.
The purpose of this session is to share the latest development of GNSS researches on monitoring the earth system and to stimulate synergetic interdisciplinary studies. Contributions on atmosphere (troposphere and ionosphere) studies, reflectometry (GNSS-R), and integrations of different observation techniques like GNSS-Acoustic measurement to monitor ocean floor positioning are welcome.

Continuous acoustic ranging from a GNSS buoy for the new method of seafloor crustal deformation measurements

*Keiichi Tadokoro[1], Natsuki Kinugasa[1], Teruyuki Kato[2], Yukihiro Terada[3], Akira Futamura[4], Kenjiro Matsuhiro[1]

1. Research Center for Seismology, Volcanology and Earthquake and Volcano Research Center, Nagoya University, 2. Hot Springs Research Institute of Kanagawa Prefecture, 3. Kochi National College of Technology, 4. National Institute of Technology, Yuge College

Our research group has been testing a measurement system for the continuous seafloor crustal deformation at a moored buoysite operated by Kochi prefecture, located 32 km off Cape Ashizuri, Japan.An acoustic transducer was fixed at about 1.7 m beneath the sea surface with a pole mounted on the buoy body.Three ocean bottom acoustic transponders had been installed around the moored point of the buoy. The acoustic signals are sequentially transmitted to these three transponders every three minutes. The recorded data on the buoy are planned to transmitted to a ground base station through a commercial communication satellite operated by Thuraya Telecommunications Company.
We performed a test for the continuous acoustic ranging between the buoy and the ocean bottom transponders from March 28 to 31 and from June 2 to July 12 (1st period), and from November 16to December 17 (2nd period) in 2018. The acoustic ranging was continuously possible throughout the above periods when power was supplied whereas it was unexpectedly terminated because of power failure during the winter season. The acoustic signals were transmitted 27,856 times in total, and the buoy-mounted acoustic ranging unit received 23,342 signals from the ocean bottom transponders. However, the acoustic data sent to the ground base station was only 12 % because of some trouble of the satellite communication modem.
The reflected signals from the buoy body and/or the seafloor sometimes contaminated the received acoustic signals; also multiple reflections inside of an anti-reflection cover attached to the buoy-mounted transducer, whose purpose is to cut off the reflection from the sea surface, were remarkable during the 1st period. The multiple reflections caused the misidentification of the direct wave from the sea-bottom units. We, therefore, removed the anti-reflection cover during the 2nd period, which remarkably reduced the confused reflections.
We coded a program for detecting the arrival time of direct acoustic wave automatically on the basis of thresholds of cross-correlation coefficient and energy ratio (the ratio of the squared amplitudes preceding and following a test point) to reduce the capacity of data transferred via satellite communication using the acoustic waveform recorded during the 1st period. The program successfully picked the correct direct wave onset for more than 99 % of the waveforms recorded during the 2nd period.

Accuracy and precision assessment of the real-time kinematic GNSS time series for moored buoy using three-axis programable moving table

*Yusaku Ohta[1], Misae Imano[1], Motoyuki Kido[2]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University, 2. IRIDeS, Tohoku University

Rapid understanding of the magnitude of large earthquakes and their associated fault dimensions are extremely important. Especially, capture of the coseismic deformation in the offshore region will be key information to understand the fault dimensions for the large interplate earthquake. Based on this background, Tohoku University and JAMSTEC are jointly developing the on-demand crustal deformation monitoring system using moored buoy system. The buoy can measure the sea-floor horizontal crustal deformation by GNSS/Acoustic technique and vertical deformation using ocean bottom pressure sensor. One of the key technology in our developed system is the real-time kinematic GNSS which can measure three-dimensional position of the buoy in real-time. In contrast, it is difficult to understand quantitatively the precision and accuracy of estimated buoy position because no reference for the position. Thus, we assess the precision and accuracy of real-time kinematic GNSS time series using programable three-axis movable table.

We have developed the single-axis precise programable movable table (Ohta et al., 2016). We expanded this developed system to three-axis. For the real-time kinematic analysis, we adopted Trimble CenterPoint RTX (hereafter, RTX) with 10Hz sampling interval. The correction message for the analysis was received via a stationary satellite. We also estimated the GNSS antenna position using very short-baseline kinematic analysis as reference solution. The developed movable table can operate single axis horizontal displacement, rotational movement, and tilt deformation. To simulate the actual buoy movement, we gave the motion to the movable table based on the actual buoy movement. We conducted the experiment in 24 hours duration.

We calculated the residual time series between obtain time series by RTX and short-baseline kinematic solution. The difference between averaged absolute position was quite good in the horizontal components which was less than 10mm. In contrast, the vertical component shows the clear discrepancy between them. RTX time series shows systemically higher than the baseline analysis which reached approximately 230mm. In contrast, the precision of the calculated residual time series was good in both of the components. Calculated standard deviations were 10-11mm and 28mm in horizontal components and vertical component, respectively. We will show the more detailed results from our experiment and discuss the ability of the real-time kinematic analysis in our developed buoy.

GNSS-R altimetry using a Geostationary Satellite

*Kaoru Ichikawa[1], Tatsuki Okumura[2], Masanori Konda[3], Yasuyuki Baba[4]

1. Res. Inst. Appl. Mech., Kyushu Univ., 2. Dept. ESST, Interdicipl. Grad. School Eng. Sc., Kyushu Univ., 3. Graduate School of Science, Kyoto Univ., 4. Disaster Prevention Res. Inst., Kyoto Univ.

The GNSS reflectometry (GNSS-R) uses GNSS signals reflected at the sea surface, which are usually eliminated as the multipath error. The reflected GNSS path received at an antenna is always longer than the direct path, so that the height of the antenna from the sea surface is geometrically determined from the excess path length. The excess path length can be either directly determined by measuring the temporal delay of the reflected signals, or indirectly estimated from interferometric cyclic modulations of the received power (often referred as signal-to-noise ratio; SNR) induced by phase differences between the direct and reflected GNSS signals. In the latter method, as the elevation angle of an earth orbiting GNSS satellite changes in time, the geometric reflection point on the sea surface temporally displaces, which results in interferometric changes of the path length during a period while the satellite is in sight. Meanwhile, for a geostationary satellite in BeiDou constellations that are always in sight, the path length changes not by the movement of the satellite but the elevation of the reflection surface, *i.e.* the sea level rise. In this study, we used the three-month time series (2016/09-11) of the 1Hz SNR of the geostationary BeiDou #02 satellite observed by a GNSS-R system deployed to the Shirahama Oceanographic Observatory Tower owned by Kyoto University (33deg, 42’ 32’’ N, 135deg, 19’ 58’’ E) at the height of ~20m. The geostationary GNSS-R altimetry observed significant flood tides when the wind speed is stably low; the 0.6m sea level rise was successfully determined by the SNR interferometry with 0.05m rms difference. However, significant interferometric SNR changes by tides were not recorded at high or low tides since at least 0.25m sea level change is required for the interferometry cycle. Consequently, the cyclic periods of the geostationary GNSS-R altimetry for tides become long (1-4 hours for 0.25m change in Shirahama), the interferometric variations were usually contaminated by SNR changes induced by the other factors such as winds. On the contrary, faster sea level changes by wave motions could be recognized by the geostationary GNSS-R altimetry, although the temporal sampling intervals of the present data were not adequate.

Estimation of typhoon wind speed using CYGNSS observations: A case study of Typhoon Lan in 2017

*Kako Shinichiro[1], Hiroyuki Tomita[2], Kaoru Ichikawa[3]

1. Graduate School of Science and Engineering, Kagoshima University, 2. Institute for Space-Earth Environment, Nagoya University, 3. Research institute for Applied Mechanics, Kyushu University

We conducted a case study of Typhoon Lan, which occurred in 2017, to investigate the impact of the Cyclone Global Navigation Satellite System (CYGNSS) on the estimation of extremely high wind speeds, such as those occurring during typhoons. We studied CYGNSS because it is expected to be capable of observing wind speeds in regions with extremely high wind speeds and heavy rains (i.e., typhoons) where it is difficult to perform measurements using the current microwave instrument. Firstly, we compared CYGNSS-derived wind speeds produced by NASA with those derived from AMSR2 produced by the Japan Aerospace Exploration Agency. CYGNSS was found to underestimate the wind speeds around Typhoon Lan compared with AMSR2. We then attempted to estimate the wind speeds using the leading edge slope (LES) and mean square slope (MSS) derived from the CYGNSS observations. Although the relationship between the MSS and wind speed differs depending on the wave age (Zhao and Tobe, 2003), it is difficult to estimate the wave age because this estimation is required the wind and wave speeds. We used the wave period as a substitute for the wave age since the wave period is expected to be similar to the wave age. We therefore first computed the fourth power of the wave period (T4) in line with Wang and Ichikawa (2016). Next, we classified the ocean into three regions based on T4 to investigate the relationship between the MSS and the wind speed observed by AMSR2 in each region. Finally, we approximated the curves relating the MSS to the wind speed using exponential functions in the three regions and estimated the wind speed using these curves. The comparison between the wind speeds produced by NASA and those estimated in this study demonstrated that our method can estimate high wind speeds more accurate than the CYGNSS wind speeds produced by NASA.

Ionospheric and seismic effects caused by the North Korea nuclear tests realized on 2006-2017

Nataliia Perevalova[2], *Nikolai Shestakov[1], Anna Dobrynina[3,4], Dmitry Kostylev[7], Meng Guojie[5], Wei-Wei Wu[5,6]

1. Institute for Applied Mathematics FEB RAS, Vladivostok, Russia; Far Eastern Federal University, Vladivostok, Russia, 2. Institute of Solar-Terrestrial Physics SB RAS, Irkutsk, Russia, 3. Institute of the Earth's Crust SB RAS, Irkutsk, Russia , 4. Geological institute SB RAS, Ulan-Ude, Russia , 5. Institute of Earthquake Forecasting, China Earthquake Administration, Beijing, China, 6. College of Surveying and Geo-informatics, Tongji University, Shanghai, China, 7. Sakhalin Branch of Federal Research Center Geophysical Survey RAS, Yuzhno_Sakhalinsk, Russia

Using data from GPS/GLONASS receivers and seismic networks, we studied the ionospheric and lithospheric effects caused by six underground nuclear tests realized in North Korea on 2006-2017.
To investigate the ionospheric disturbances, we analyzed data from several continuous GNSS-networks (GPS and GLONASS) operating in Asia - Western Pacific region: IGS, GEONET, FEB RAS and FEFU complex geodynamic network, a set of stations belonging to China and South Korea GNSS-networks. Sites close to the Korean Peninsula were selected for the analysis. Series of total electron content (TEC) in the ionosphere were calculated on the base of dual-frequency phase measurements of GNSS receivers. To detect disturbances caused by the nuclear tests, TEC series were filtered in the range of periods from 1 to 10 minutes. Despite the small magnitudes of seismic events associated with the nuclear tests, we were able to identify ionospheric disturbances which were most likely generated by these explosions. Such disturbances were detected for 4 out of 6 nuclear tests. The main parameters of the disturbances were determined. From our analysis we concluded that characteristics of ionospheric disturbances caused by the underground nuclear tests differed significantly from the parameters of disturbances that are usually observed after earthquakes.
For seismic analysis, we used data from the broadband seismic station networks located at distances up to 23 degrees from the Korean Peninsula: II, IC, IU, TW, JP, G, KS, and KG given by IRIS, and regional seismic network BY. The frequency content of P and surface Rayleigh waves registered by 46 broadband stations was analyzed. For some events, the P-wave frequency content showed the prevalence of low frequencies in spectra (~0.45 Hz). The peak frequencies of the surface Rayleigh waves was in the 0.05-0.45 Hz range. Preliminary analysis of the peak frequencies spatial distribution showed that the continental massive area is characterized by the relatively high frequencies (0.14-0.50 Hz) while for the areas adjacent to marginal seas the low values of peak frequencies are observed (from 0.13 Hz and less).
Acknowledgments. We are deeply indebted to Scripps Orbit and Permanent Array Center (SOPAC) for the IGS-network data, to Geospatial Information Authority of Japan for GEONET network data, to Korea Astronomy & Space Science Institute for access to GNSS data on the Korean Peninsula, CCU CC FEB RAS for access to data from the FEB RAS and FEFU complex geodynamic network; Institute of Earthquake Forecasting, China Earthquake Administration for access to GNSS data in China. The facilities of the IRIS Data Management System, and specifically the IRIS Data Management Center, and Baikal Regional Seismological Center and Sakhalin Branch of Federal Research Center Geophysical Survey RAS were used to get waveform and metadata required in this study. This work was performed with budgetary funding of Basic Research program II.16 and was also partially supported by RFBR grants 17-45-388072_p_a, 17-45-388049_ p_a, 17-55-53110_GFEN_a, 19-05-00889_a.

Relationships between Water Vapor Concentration Index derived from GNSS and Surface Wind Convergence during Localized Heavy Rainfall in Tokyo in Summer

*Yoshihito Seto[1], Yoshinori Shoji[2], Nobumitsu Tsunematsu[3], Hideo Takahashi[1]

1. Department of Geography, Graduate School of Urban Environmental Sciences, Tokyo Metropolitan University, 2. Meteorological Research Institute, 3. Tokyo Metropolitan Research Institute for Environmental Protection

In recent years, short-term heavy-rainfall events that have caused severe damages such as flooding have frequently occurred in the Tokyo Metropolitan area in summer. In view of the development process of cumulonimbus clouds, the convergence of surface winds and the spatial concentration of water vapor are supposed to have taken place prior to the occurrence of heavy rainfall. This study aims to clarify the evolutionary process of short-term heavy rainfall as a contribution to short-range forecasting of heavy rainfall that occurs locally.

The relationships between the occurrence of heavy rainfall and the convergence of surface winds and water vapor concentration for heavy-rainfall cases were examined using data from July to September obtained from high-density meteorological observations in Tokyo, Japan. We used the water vapor concentration (WVC) index derived from the global navigation satellite system (GNSS) analysis as indices for the degree of divergence and convergence of water vapor in the lower troposphere (Shoji 2013).

Corresponding to heavy-rainfall areas, the convergence of surface winds tended to increase for several tens of minutes prior to the heavy rainfall. The peak time of wind convergence was observed 10–30 min before the heavy-rainfall occurrence, and the convergence continued to increase for approximately 30 min until the convergence peak time (Seto et al. 2018). Around the heavy-rainfall area, the increase in the WVC index coincided with the increase in convergence. On the other hand, it was considered that the temporal and spatial scales of the WVC index are larger than those of wind convergence. From these results, by monitoring the temporal variations and distributions of these parameters using a high-density observation network, it should be possible to predict the occurrence of heavy rainfall rapidly and accurately.

We have started to develop a next-generation microwave radiometer to be used in millimeter-wave spectroscopy for the high-resolution and high-precision monitoring of water vapor behavior. The new radiometer will be suitable for not only space geodetic techniques such as VLBI and GNSS, but also field measurements such as monitoring volcanic activities and cumulonimbus cloud generation. The basic design concept of the new radiometer follows the previous version named KUMODeS (KEK Universal Moisture and Oxygen Detection System) developed by the High Energy Accelerator Research Organization (KEK). The KUMODeS can measure spectra using two receivers with frequency bands of 20–30 GHz and 50–60 GHz. The low-noise amplifier (LNA) of the first KUMODeS receiver and a cold calibration source are implemented in a cryostat, which is maintained at 10 K to improve the sensitivity of detecting the characteristic broad peak of water vapor at approximately 22 GHz. The second receiver is used to measure the absorption peaks of oxygen (60 GHz). We have carried out comparative measurements of precipitable water vapor (PWV) to investigate the potential of KUMODeS/PWV measurements. The preliminary results of PWV comparisons imply that KUMODeS technology will be useful for retrieving the accurate behavior of water vapor with high temporal resolution. We will implement a wide bandwidth feed of 20–60 GHz into the new system on the basis of a previous comparison study. A signal is separated into two linear orthogonal polarized signals from the feed, one is in the 20–30 GHz feed and the other in the 50–60 GHz feed, using an orthomode transducer (OMT). The wideband feed, OMT, and the LNA for each signal are cooled at 77 K using a Stirling cryocooler to improve signal-to-noise ratio. The development of a new front-end module will be completed at the end of 2019, and we are planning to implement the module in an existing dish antenna to perform validation measurements.

Refractivity Distributions over the Kanto Plain Obtained by Dual-polarization Radar

*Hiromu Seko[1], Eiichi Sato[1], Hiroshi Yamauchi[2]

1. Meteorological Research Institute, 2. Japan Meteorological Agency

Temperature and water vapor near the surface play crucial roles for the generation of convection cells. However, their variations just before the generations of convection cells still are not understood completely. In this study the temporal variations of refractivity index were obtained by MRI dual-polarization Doppler radar. The features of temperature and water vapor including generation period of convection cells will be shown in this presentation. On 19th August 2017, the sea breeze invaded from Kashima-Nada and the refractivity increased along the front of the sea breeze. The scattered weak echoes that appeared around the front seem to be related with the increase of refractivity. These are the features near the surface. The comparison with other data such as GNSS PWV will be also presented.

Spatial and temporal distribution of tropospheric water vapor observed by a Raman lidar and a GNSS receiver network over Shigaraki, Japan

*Masanori Yabuki[1], Toshitaka Tsuda[1], Yuya Kawano[2], Yusaku Tottori[2], Makoto Tsukamoto[2], Eiji Takeuchi[2]

1. Research Institute for Sustainable Humanosphere, Kyoto University, 2. EKO Instruments Co., Ltd.

Understanding the spatial and temporal distributions of water vapor in the atmosphere is critical for unveiling the fundamental mechanisms of localized extreme weather events. Besides, it is highly beneficial for improving the accuracy of weather forecasts by mesoscale numerical weather prediction models. To achieve the continuous monitoring of water vapor distributions, we performed simultaneous measurements by Raman lidar in the UV-C region and a dense Global Navigation Satellite System (GNSS) network. The former is a novel technology that can be utilized for profiling the vertical distribution of the water vapor mixing ratio for twenty-four hours, while the latter can be used for detecting the horizontal distribution of precipitable water vapor. The Raman lidar employs a laser at a wavelength of 266 nm and detects the light separated into an elastic backscatter signal and vibrational Raman signals of oxygen, nitrogen, and water vapor at wavelengths of 266, 277, 284, and 295 nm, respectively. The use of these wavelengths is convenient because of the low background noise during daytime, since most of the solar radiation in the ultraviolet range below 300 nm is absorbed by the ozone layer in the stratosphere. The lidar was encased in a temperature-controlled compact container, resistant to a variety of environmental conditions. Continuous observation of water vapor profiles by lidar has been conducted at the Shigaraki MU radar observatory (34˚51’ N, 136˚06’ E, 385 m a.s.l.) since November 2017. The dense GNSS receiver network consisted of 10 dual-frequency GNSS stations which were installed with a horizontal spacing of 3-4 km near the observatory on July 2017. In this study, we present our water vapor monitoring system as well as the preliminary results on the spatio-temporal water vapor distributions in 2018.

Study of the Mechanisms of Severe Thunderstorm in Tokyo Metropolitan Area using High Frequent Assimilation of GNSS and Other Ground-based Observations

*Yoshinori Shoji[1], Tetsu Sakai[2], Ahoro Adachi[1], Satoru Yoshida[2], Tomohiro Nagai[2]

Highly urbanized Tokyo metropolitan area is vulnerable to severe storms such as local torrential rainfall, thunder lightning and tornado. Recently, the number of days with thunderstorms has been increasing in Tokyo. Elucidation of the mechanism of extreme weather in Tokyo is urgent matter (Nakatani et al. 2013). To study the rolls of water vapor and wind for the rapid life-cycle (initiation, development and dissipation) of hazardous cumulus convection, we installed a mobile Raman-lidar (Sakai et al. 2018), a wind profiler, and five GNSS stations in and around Tokyo.

Using 3DVAR capability of WRF data assimilation system (WRFDA)(Barker et al. 2012) , three-dimensional atmospheric fields with 1 km horizontal resolution were produced at every 10min throughout the August 2017 and 2018. Background fields were produced by JMA nonhydrostatic model (NHM)(Saito et al. 2007). In addition to the observed data at these campaign observation instruments, Japan Meteorological Agency’ s operational surface meteorological stations, wind-profiler stations and GNSS PWV derived at dense GNSS network of Geospatial Information Authority of Japan are assimilated. We confirmed that the reproduced atmospheric fields (Temperature, humidity, and wind) showed better agreement with observations of radiosonde, lidar derived water vapor mixing ratio, and wind-profiler than background fields at altitudes lower than 2 km. Assimilation of surface meteorological observations (atmospheric pressure, temperature, humidity and wind) introduced better agreement mainly at altitude lower than 0.5 km. Inclusion of GNSS derived PWV resulted better agreement of humidity at altitude higher than 0.5 km and inclusion of wind field from wind-profiler led better agreement of wind field.

We have investigated roles of water vapor for several local heavy rainfall events occurred in Tokyo in August 2017 and 2018 and found that convergence of water vapor flux at 0.5 km altitude had intensified prior to the occurrence of torrential precipitation. Statistical and quantitative results will be discussed at the symposium.

This study is supported by JSPS KAKENHI Grants 17H00852.

[M-TT46] New phase of GPS/GNSS application as an integrated earth observation system

convener:Yoshinori Shoji(The Second Laboratory of Meteorological Satellite and Observation System Research Department, Meteorological Research Institute), Kaoru Ichikawa(Research Institute for Applied Mechanics, Kyushu University), Yusaku Ohta(Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University), Takuya Tsugawa(National Institute of Information and Communications Technology)

GNSS has become a fundamental tool for studies on atmosphere, ionosphere, and solid earth. Ground and space-based GNSS measurements have operationally contributed to improve global and regional NWP since 2006. In recent years, studies utilizing reflected GNSS signals to derive altimetric height, surface roughness, soil moisture, snow depth, humidity or vegetation index have been evolving. Ocean-platform GNSS observations have been demonstrating their capability of real-time monitoring of maritime water vapor as well as sea level. Increasing observations provided through Multi-GNSS (GPS, GLONASS, BEIDOU, GALILEO, QZSS etc.) enhances capability of the GNSS as an integrated earth observation system.
The purpose of this session is to share the latest development of GNSS researches on monitoring the earth system and to stimulate synergetic interdisciplinary studies. Contributions on atmosphere (troposphere and ionosphere) studies, reflectometry (GNSS-R), and integrations of different observation techniques like GNSS-Acoustic measurement to monitor ocean floor positioning are welcome.

Continuous acoustic ranging from a GNSS buoy for the new method of seafloor crustal deformation measurements

*Keiichi Tadokoro[1], Natsuki Kinugasa[1], Teruyuki Kato[2], Yukihiro Terada[3], Akira Futamura[4], Kenjiro Matsuhiro[1]

1. Research Center for Seismology, Volcanology and Earthquake and Volcano Research Center, Nagoya University, 2. Hot Springs Research Institute of Kanagawa Prefecture, 3. Kochi National College of Technology, 4. National Institute of Technology, Yuge College

Our research group has been testing a measurement system for the continuous seafloor crustal deformation at a moored buoysite operated by Kochi prefecture, located 32 km off Cape Ashizuri, Japan.An acoustic transducer was fixed at about 1.7 m beneath the sea surface with a pole mounted on the buoy body.Three ocean bottom acoustic transponders had been installed around the moored point of the buoy. The acoustic signals are sequentially transmitted to these three transponders every three minutes. The recorded data on the buoy are planned to transmitted to a ground base station through a commercial communication satellite operated by Thuraya Telecommunications Company.
We performed a test for the continuous acoustic ranging between the buoy and the ocean bottom transponders from March 28 to 31 and from June 2 to July 12 (1st period), and from November 16to December 17 (2nd period) in 2018. The acoustic ranging was continuously possible throughout the above periods when power was supplied whereas it was unexpectedly terminated because of power failure during the winter season. The acoustic signals were transmitted 27,856 times in total, and the buoy-mounted acoustic ranging unit received 23,342 signals from the ocean bottom transponders. However, the acoustic data sent to the ground base station was only 12 % because of some trouble of the satellite communication modem.
The reflected signals from the buoy body and/or the seafloor sometimes contaminated the received acoustic signals; also multiple reflections inside of an anti-reflection cover attached to the buoy-mounted transducer, whose purpose is to cut off the reflection from the sea surface, were remarkable during the 1st period. The multiple reflections caused the misidentification of the direct wave from the sea-bottom units. We, therefore, removed the anti-reflection cover during the 2nd period, which remarkably reduced the confused reflections.
We coded a program for detecting the arrival time of direct acoustic wave automatically on the basis of thresholds of cross-correlation coefficient and energy ratio (the ratio of the squared amplitudes preceding and following a test point) to reduce the capacity of data transferred via satellite communication using the acoustic waveform recorded during the 1st period. The program successfully picked the correct direct wave onset for more than 99 % of the waveforms recorded during the 2nd period.

Accuracy and precision assessment of the real-time kinematic GNSS time series for moored buoy using three-axis programable moving table

*Yusaku Ohta[1], Misae Imano[1], Motoyuki Kido[2]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University, 2. IRIDeS, Tohoku University

Rapid understanding of the magnitude of large earthquakes and their associated fault dimensions are extremely important. Especially, capture of the coseismic deformation in the offshore region will be key information to understand the fault dimensions for the large interplate earthquake. Based on this background, Tohoku University and JAMSTEC are jointly developing the on-demand crustal deformation monitoring system using moored buoy system. The buoy can measure the sea-floor horizontal crustal deformation by GNSS/Acoustic technique and vertical deformation using ocean bottom pressure sensor. One of the key technology in our developed system is the real-time kinematic GNSS which can measure three-dimensional position of the buoy in real-time. In contrast, it is difficult to understand quantitatively the precision and accuracy of estimated buoy position because no reference for the position. Thus, we assess the precision and accuracy of real-time kinematic GNSS time series using programable three-axis movable table.

We have developed the single-axis precise programable movable table (Ohta et al., 2016). We expanded this developed system to three-axis. For the real-time kinematic analysis, we adopted Trimble CenterPoint RTX (hereafter, RTX) with 10Hz sampling interval. The correction message for the analysis was received via a stationary satellite. We also estimated the GNSS antenna position using very short-baseline kinematic analysis as reference solution. The developed movable table can operate single axis horizontal displacement, rotational movement, and tilt deformation. To simulate the actual buoy movement, we gave the motion to the movable table based on the actual buoy movement. We conducted the experiment in 24 hours duration.

We calculated the residual time series between obtain time series by RTX and short-baseline kinematic solution. The difference between averaged absolute position was quite good in the horizontal components which was less than 10mm. In contrast, the vertical component shows the clear discrepancy between them. RTX time series shows systemically higher than the baseline analysis which reached approximately 230mm. In contrast, the precision of the calculated residual time series was good in both of the components. Calculated standard deviations were 10-11mm and 28mm in horizontal components and vertical component, respectively. We will show the more detailed results from our experiment and discuss the ability of the real-time kinematic analysis in our developed buoy.

GNSS-R altimetry using a Geostationary Satellite

*Kaoru Ichikawa[1], Tatsuki Okumura[2], Masanori Konda[3], Yasuyuki Baba[4]

1. Res. Inst. Appl. Mech., Kyushu Univ., 2. Dept. ESST, Interdicipl. Grad. School Eng. Sc., Kyushu Univ., 3. Graduate School of Science, Kyoto Univ., 4. Disaster Prevention Res. Inst., Kyoto Univ.

The GNSS reflectometry (GNSS-R) uses GNSS signals reflected at the sea surface, which are usually eliminated as the multipath error. The reflected GNSS path received at an antenna is always longer than the direct path, so that the height of the antenna from the sea surface is geometrically determined from the excess path length. The excess path length can be either directly determined by measuring the temporal delay of the reflected signals, or indirectly estimated from interferometric cyclic modulations of the received power (often referred as signal-to-noise ratio; SNR) induced by phase differences between the direct and reflected GNSS signals. In the latter method, as the elevation angle of an earth orbiting GNSS satellite changes in time, the geometric reflection point on the sea surface temporally displaces, which results in interferometric changes of the path length during a period while the satellite is in sight. Meanwhile, for a geostationary satellite in BeiDou constellations that are always in sight, the path length changes not by the movement of the satellite but the elevation of the reflection surface, *i.e.* the sea level rise. In this study, we used the three-month time series (2016/09-11) of the 1Hz SNR of the geostationary BeiDou #02 satellite observed by a GNSS-R system deployed to the Shirahama Oceanographic Observatory Tower owned by Kyoto University (33deg, 42’ 32’’ N, 135deg, 19’ 58’’ E) at the height of ~20m. The geostationary GNSS-R altimetry observed significant flood tides when the wind speed is stably low; the 0.6m sea level rise was successfully determined by the SNR interferometry with 0.05m rms difference. However, significant interferometric SNR changes by tides were not recorded at high or low tides since at least 0.25m sea level change is required for the interferometry cycle. Consequently, the cyclic periods of the geostationary GNSS-R altimetry for tides become long (1-4 hours for 0.25m change in Shirahama), the interferometric variations were usually contaminated by SNR changes induced by the other factors such as winds. On the contrary, faster sea level changes by wave motions could be recognized by the geostationary GNSS-R altimetry, although the temporal sampling intervals of the present data were not adequate.

Estimation of typhoon wind speed using CYGNSS observations: A case study of Typhoon Lan in 2017

*Kako Shinichiro[1], Hiroyuki Tomita[2], Kaoru Ichikawa[3]

1. Graduate School of Science and Engineering, Kagoshima University, 2. Institute for Space-Earth Environment, Nagoya University, 3. Research institute for Applied Mechanics, Kyushu University

We conducted a case study of Typhoon Lan, which occurred in 2017, to investigate the impact of the Cyclone Global Navigation Satellite System (CYGNSS) on the estimation of extremely high wind speeds, such as those occurring during typhoons. We studied CYGNSS because it is expected to be capable of observing wind speeds in regions with extremely high wind speeds and heavy rains (i.e., typhoons) where it is difficult to perform measurements using the current microwave instrument. Firstly, we compared CYGNSS-derived wind speeds produced by NASA with those derived from AMSR2 produced by the Japan Aerospace Exploration Agency. CYGNSS was found to underestimate the wind speeds around Typhoon Lan compared with AMSR2. We then attempted to estimate the wind speeds using the leading edge slope (LES) and mean square slope (MSS) derived from the CYGNSS observations. Although the relationship between the MSS and wind speed differs depending on the wave age (Zhao and Tobe, 2003), it is difficult to estimate the wave age because this estimation is required the wind and wave speeds. We used the wave period as a substitute for the wave age since the wave period is expected to be similar to the wave age. We therefore first computed the fourth power of the wave period (T4) in line with Wang and Ichikawa (2016). Next, we classified the ocean into three regions based on T4 to investigate the relationship between the MSS and the wind speed observed by AMSR2 in each region. Finally, we approximated the curves relating the MSS to the wind speed using exponential functions in the three regions and estimated the wind speed using these curves. The comparison between the wind speeds produced by NASA and those estimated in this study demonstrated that our method can estimate high wind speeds more accurate than the CYGNSS wind speeds produced by NASA.

Ionospheric and seismic effects caused by the North Korea nuclear tests realized on 2006-2017

Nataliia Perevalova[2], *Nikolai Shestakov[1], Anna Dobrynina[3,4], Dmitry Kostylev[7], Meng Guojie[5], Wei-Wei Wu[5,6]

1. Institute for Applied Mathematics FEB RAS, Vladivostok, Russia; Far Eastern Federal University, Vladivostok, Russia, 2. Institute of Solar-Terrestrial Physics SB RAS, Irkutsk, Russia, 3. Institute of the Earth's Crust SB RAS, Irkutsk, Russia , 4. Geological institute SB RAS, Ulan-Ude, Russia , 5. Institute of Earthquake Forecasting, China Earthquake Administration, Beijing, China, 6. College of Surveying and Geo-informatics, Tongji University, Shanghai, China, 7. Sakhalin Branch of Federal Research Center Geophysical Survey RAS, Yuzhno_Sakhalinsk, Russia

Using data from GPS/GLONASS receivers and seismic networks, we studied the ionospheric and lithospheric effects caused by six underground nuclear tests realized in North Korea on 2006-2017.
To investigate the ionospheric disturbances, we analyzed data from several continuous GNSS-networks (GPS and GLONASS) operating in Asia - Western Pacific region: IGS, GEONET, FEB RAS and FEFU complex geodynamic network, a set of stations belonging to China and South Korea GNSS-networks. Sites close to the Korean Peninsula were selected for the analysis. Series of total electron content (TEC) in the ionosphere were calculated on the base of dual-frequency phase measurements of GNSS receivers. To detect disturbances caused by the nuclear tests, TEC series were filtered in the range of periods from 1 to 10 minutes. Despite the small magnitudes of seismic events associated with the nuclear tests, we were able to identify ionospheric disturbances which were most likely generated by these explosions. Such disturbances were detected for 4 out of 6 nuclear tests. The main parameters of the disturbances were determined. From our analysis we concluded that characteristics of ionospheric disturbances caused by the underground nuclear tests differed significantly from the parameters of disturbances that are usually observed after earthquakes.
For seismic analysis, we used data from the broadband seismic station networks located at distances up to 23 degrees from the Korean Peninsula: II, IC, IU, TW, JP, G, KS, and KG given by IRIS, and regional seismic network BY. The frequency content of P and surface Rayleigh waves registered by 46 broadband stations was analyzed. For some events, the P-wave frequency content showed the prevalence of low frequencies in spectra (~0.45 Hz). The peak frequencies of the surface Rayleigh waves was in the 0.05-0.45 Hz range. Preliminary analysis of the peak frequencies spatial distribution showed that the continental massive area is characterized by the relatively high frequencies (0.14-0.50 Hz) while for the areas adjacent to marginal seas the low values of peak frequencies are observed (from 0.13 Hz and less).
Acknowledgments. We are deeply indebted to Scripps Orbit and Permanent Array Center (SOPAC) for the IGS-network data, to Geospatial Information Authority of Japan for GEONET network data, to Korea Astronomy & Space Science Institute for access to GNSS data on the Korean Peninsula, CCU CC FEB RAS for access to data from the FEB RAS and FEFU complex geodynamic network; Institute of Earthquake Forecasting, China Earthquake Administration for access to GNSS data in China. The facilities of the IRIS Data Management System, and specifically the IRIS Data Management Center, and Baikal Regional Seismological Center and Sakhalin Branch of Federal Research Center Geophysical Survey RAS were used to get waveform and metadata required in this study. This work was performed with budgetary funding of Basic Research program II.16 and was also partially supported by RFBR grants 17-45-388072_p_a, 17-45-388049_ p_a, 17-55-53110_GFEN_a, 19-05-00889_a.

Relationships between Water Vapor Concentration Index derived from GNSS and Surface Wind Convergence during Localized Heavy Rainfall in Tokyo in Summer

*Yoshihito Seto[1], Yoshinori Shoji[2], Nobumitsu Tsunematsu[3], Hideo Takahashi[1]

1. Department of Geography, Graduate School of Urban Environmental Sciences, Tokyo Metropolitan University, 2. Meteorological Research Institute, 3. Tokyo Metropolitan Research Institute for Environmental Protection

In recent years, short-term heavy-rainfall events that have caused severe damages such as flooding have frequently occurred in the Tokyo Metropolitan area in summer. In view of the development process of cumulonimbus clouds, the convergence of surface winds and the spatial concentration of water vapor are supposed to have taken place prior to the occurrence of heavy rainfall. This study aims to clarify the evolutionary process of short-term heavy rainfall as a contribution to short-range forecasting of heavy rainfall that occurs locally.

The relationships between the occurrence of heavy rainfall and the convergence of surface winds and water vapor concentration for heavy-rainfall cases were examined using data from July to September obtained from high-density meteorological observations in Tokyo, Japan. We used the water vapor concentration (WVC) index derived from the global navigation satellite system (GNSS) analysis as indices for the degree of divergence and convergence of water vapor in the lower troposphere (Shoji 2013).

Corresponding to heavy-rainfall areas, the convergence of surface winds tended to increase for several tens of minutes prior to the heavy rainfall. The peak time of wind convergence was observed 10–30 min before the heavy-rainfall occurrence, and the convergence continued to increase for approximately 30 min until the convergence peak time (Seto et al. 2018). Around the heavy-rainfall area, the increase in the WVC index coincided with the increase in convergence. On the other hand, it was considered that the temporal and spatial scales of the WVC index are larger than those of wind convergence. From these results, by monitoring the temporal variations and distributions of these parameters using a high-density observation network, it should be possible to predict the occurrence of heavy rainfall rapidly and accurately.

Japan Weather Association

We have started to develop a next-generation microwave radiometer to be used in millimeter-wave spectroscopy for the high-resolution and high-precision monitoring of water vapor behavior. The new radiometer will be suitable for not only space geodetic techniques such as VLBI and GNSS, but also field measurements such as monitoring volcanic activities and cumulonimbus cloud generation. The basic design concept of the new radiometer follows the previous version named KUMODeS (KEK Universal Moisture and Oxygen Detection System) developed by the High Energy Accelerator Research Organization (KEK). The KUMODeS can measure spectra using two receivers with frequency bands of 20–30 GHz and 50–60 GHz. The low-noise amplifier (LNA) of the first KUMODeS receiver and a cold calibration source are implemented in a cryostat, which is maintained at 10 K to improve the sensitivity of detecting the characteristic broad peak of water vapor at approximately 22 GHz. The second receiver is used to measure the absorption peaks of oxygen (60 GHz). We have carried out comparative measurements of precipitable water vapor (PWV) to investigate the potential of KUMODeS/PWV measurements. The preliminary results of PWV comparisons imply that KUMODeS technology will be useful for retrieving the accurate behavior of water vapor with high temporal resolution. We will implement a wide bandwidth feed of 20–60 GHz into the new system on the basis of a previous comparison study. A signal is separated into two linear orthogonal polarized signals from the feed, one is in the 20–30 GHz feed and the other in the 50–60 GHz feed, using an orthomode transducer (OMT). The wideband feed, OMT, and the LNA for each signal are cooled at 77 K using a Stirling cryocooler to improve signal-to-noise ratio. The development of a new front-end module will be completed at the end of 2019, and we are planning to implement the module in an existing dish antenna to perform validation measurements.

Refractivity Distributions over the Kanto Plain Obtained by Dual-polarization Radar

*Hiromu Seko[1], Eiichi Sato[1], Hiroshi Yamauchi[2]

1. Meteorological Research Institute, 2. Japan Meteorological Agency

Temperature and water vapor near the surface play crucial roles for the generation of convection cells. However, their variations just before the generations of convection cells still are not understood completely. In this study the temporal variations of refractivity index were obtained by MRI dual-polarization Doppler radar. The features of temperature and water vapor including generation period of convection cells will be shown in this presentation. On 19th August 2017, the sea breeze invaded from Kashima-Nada and the refractivity increased along the front of the sea breeze. The scattered weak echoes that appeared around the front seem to be related with the increase of refractivity. These are the features near the surface. The comparison with other data such as GNSS PWV will be also presented.

Spatial and temporal distribution of tropospheric water vapor observed by a Raman lidar and a GNSS receiver network over Shigaraki, Japan

*Masanori Yabuki[1], Toshitaka Tsuda[1], Yuya Kawano[2], Yusaku Tottori[2], Makoto Tsukamoto[2], Eiji Takeuchi[2]

1. Research Institute for Sustainable Humanosphere, Kyoto University, 2. EKO Instruments Co., Ltd.

Understanding the spatial and temporal distributions of water vapor in the atmosphere is critical for unveiling the fundamental mechanisms of localized extreme weather events. Besides, it is highly beneficial for improving the accuracy of weather forecasts by mesoscale numerical weather prediction models. To achieve the continuous monitoring of water vapor distributions, we performed simultaneous measurements by Raman lidar in the UV-C region and a dense Global Navigation Satellite System (GNSS) network. The former is a novel technology that can be utilized for profiling the vertical distribution of the water vapor mixing ratio for twenty-four hours, while the latter can be used for detecting the horizontal distribution of precipitable water vapor. The Raman lidar employs a laser at a wavelength of 266 nm and detects the light separated into an elastic backscatter signal and vibrational Raman signals of oxygen, nitrogen, and water vapor at wavelengths of 266, 277, 284, and 295 nm, respectively. The use of these wavelengths is convenient because of the low background noise during daytime, since most of the solar radiation in the ultraviolet range below 300 nm is absorbed by the ozone layer in the stratosphere. The lidar was encased in a temperature-controlled compact container, resistant to a variety of environmental conditions. Continuous observation of water vapor profiles by lidar has been conducted at the Shigaraki MU radar observatory (34˚51’ N, 136˚06’ E, 385 m a.s.l.) since November 2017. The dense GNSS receiver network consisted of 10 dual-frequency GNSS stations which were installed with a horizontal spacing of 3-4 km near the observatory on July 2017. In this study, we present our water vapor monitoring system as well as the preliminary results on the spatio-temporal water vapor distributions in 2018.

Study of the Mechanisms of Severe Thunderstorm in Tokyo Metropolitan Area using High Frequent Assimilation of GNSS and Other Ground-based Observations

*Yoshinori Shoji[1], Tetsu Sakai[2], Ahoro Adachi[1], Satoru Yoshida[2], Tomohiro Nagai[2]

1. The Second Laboratory of Meteorological Satellite and Observation System Research Department, Meteorological Research Institute, 2. The Third Laboratory of Meteorological Satellite and Observation System Research Department, Meteorological Research Institute

Highly urbanized Tokyo metropolitan area is vulnerable to severe storms such as local torrential rainfall, thunder lightning and tornado. Recently, the number of days with thunderstorms has been increasing in Tokyo. Elucidation of the mechanism of extreme weather in Tokyo is urgent matter (Nakatani et al. 2013). To study the rolls of water vapor and wind for the rapid life-cycle (initiation, development and dissipation) of hazardous cumulus convection, we installed a mobile Raman-lidar (Sakai et al. 2018), a wind profiler, and five GNSS stations in and around Tokyo.

Using 3DVAR capability of WRF data assimilation system (WRFDA)(Barker et al. 2012) , three-dimensional atmospheric fields with 1 km horizontal resolution were produced at every 10min throughout the August 2017 and 2018. Background fields were produced by JMA nonhydrostatic model (NHM)(Saito et al. 2007). In addition to the observed data at these campaign observation instruments, Japan Meteorological Agency’ s operational surface meteorological stations, wind-profiler stations and GNSS PWV derived at dense GNSS network of Geospatial Information Authority of Japan are assimilated. We confirmed that the reproduced atmospheric fields (Temperature, humidity, and wind) showed better agreement with observations of radiosonde, lidar derived water vapor mixing ratio, and wind-profiler than background fields at altitudes lower than 2 km. Assimilation of surface meteorological observations (atmospheric pressure, temperature, humidity and wind) introduced better agreement mainly at altitude lower than 0.5 km. Inclusion of GNSS derived PWV resulted better agreement of humidity at altitude higher than 0.5 km and inclusion of wind field from wind-profiler led better agreement of wind field.

We have investigated roles of water vapor for several local heavy rainfall events occurred in Tokyo in August 2017 and 2018 and found that convergence of water vapor flux at 0.5 km altitude had intensified prior to the occurrence of torrential precipitation. Statistical and quantitative results will be discussed at the symposium.

This study is supported by JSPS KAKENHI Grants 17H00852.

[M-TT46] New phase of GPS/GNSS application as an integrated earth observation system

convener:Yoshinori Shoji(The Second Laboratory of Meteorological Satellite and Observation System Research Department, Meteorological Research Institute), Kaoru Ichikawa(Research Institute for Applied Mechanics, Kyushu University), Yusaku Ohta(Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University), Takuya Tsugawa(National Institute of Information and Communications Technology), Chairperson:Yoshinori Shoji(Meteorological Research Institute)

GNSS has become a fundamental tool for studies on atmosphere, ionosphere, and solid earth. Ground and space-based GNSS measurements have operationally contributed to improve global and regional NWP since 2006. In recent years, studies utilizing reflected GNSS signals to derive altimetric height, surface roughness, soil moisture, snow depth, humidity or vegetation index have been evolving. Ocean-platform GNSS observations have been demonstrating their capability of real-time monitoring of maritime water vapor as well as sea level. Increasing observations provided through Multi-GNSS (GPS, GLONASS, BEIDOU, GALILEO, QZSS etc.) enhances capability of the GNSS as an integrated earth observation system.
The purpose of this session is to share the latest development of GNSS researches on monitoring the earth system and to stimulate synergetic interdisciplinary studies. Contributions on atmosphere (troposphere and ionosphere) studies, reflectometry (GNSS-R), and integrations of different observation techniques like GNSS-Acoustic measurement to monitor ocean floor positioning are welcome.

Study on tropospheric delay variations extracted from a short baseline analysis and their application to meteorological observation

*Takayuki Yoshihara[1], Susumu Saito[1], Atsushi Kezuka[1], Shinji Saitoh[1]

1. Electronic Navigation Research Institute, National Institute of Maritime, Port and Aviation Technology

This paper discusses variation of 10cm order in tropospheric delay differences between two ground-based GNSS stations, which are located with a horizontal scale of about 2km. This typical value of tropospheric delay differences is represented as a tropospheric delay difference projected to the zenith direction for a common satellite between the two stations. The variation also corresponds to an order of 50 mm/km in tropospheric delay spatial gradient. Such large differences of tropospheric delay with short baselines of several 100m had been reported in safety assessment and validation activities for aircraft high category precision approach and landing system called as GBAS (Ground-Based Augmentation System) [1,2,3]. They also reported that their temporal variations are highly correlated with the surface wind velocities under fine weather conditions.

A GBAS ground station typically has four GNSS stations with separation of several 100m each other. Electronic Navigation Research Institute (ENRI) participated in the safety assessment and validation activities, which were performed to validate draft international standards for high category GBAS. As one of the activities, ENRI developed a prototype system and installed it in New Ishigaki airport (24.40N, 124.25E). The system has the typical four GNSS stations within a horizontal scale of 400m and an additional GNSS station called as ionosphere field monitor (IFM), which is located as about 2km away from the four stations. These GNSS stations consists of dual frequency antenna and receiver and continuously collect GNSS data. Additionally, we set up a different GNSS receiver which can accept multi-RF signal inputs. Combining the receiver with Radio-over-Fiber (RoF) devices, we can use a common clock for signal processing two GNSS signals received at the both ends of the baseline with a length of 2.3km [4]. This additional system enables us to examine a tropospheric difference for each GNSS satellite without correction of difference of receiver clock drift components between two received signals although it is required to distinguish tropospheric delay differences from ionospheric effects and multipath errors using dual frequency measurements and characteristics of multipath variations [5].

In this study, we mainly examine tropospheric delay difference data with the baseline length of 2.3km, including GNSS data collected from the prototype system. Considering geometry of GNSS satellite propagation paths and observational errors, we will discuss candidate meteorological phenomena and application to future meteorological observation.

Water vapor estimation using digital terrestrial broadcasting waves - Field test in Tokyo metropolitan area and trial production of small devices -

*Seiji Kawamura[1], Hiroshi HANADO[1], Hiroki Ohta[1], Yoshinobu Matsumura[2], Ryosuke Mori[2], Kazuyoshi Noda[2], Teruaki Hasegawa[2]

1. National Institute of Information and Communications Technology, 2. Socionext Inc.

We have developed a method to measure water vapor in horizontal direction using digital terrestrial broadcasting waves [1]. Radio waves are delayed due to water vapor through propagation. Water vapor can be estimated using propagation delay of digital terrestrial broadcasting waves. The basic idea of using propagation delay is the same as that of retrieving PWV by using GNSS. In this study, we estimate water vapor near a ground surface from the horizontal propagation delay of digital terrestrial broadcasting waves. The main features of this observation are, no need for transmitters (small and low cost due to receiving only), applicability wherever digital terrestrial broadcasting is available, and its high time resolution. Our target is to improve the accuracy of numerical weather forecast for severe weather phenomena such as localized heavy rainstorms in urban areas through data assimilation.
We have developed a real-time delay measurement system with a software-defined radio (SDR) technique, whose main components are USRP-N210 and PC (prototype). Seven measurement systems are now under operation around Tokyo metropolitan area. Although the main source of digital terrestrial broadcasting waves in Tokyo area is the Tokyo Skytree, some small radio towers that transmit Television Saitama, Chiba Television, Television Kanagawa, and do on can be also available. If plural radio waves from different radio towers are available, we can use plural base-lines to estimate water vapor. Outline of demonstration experiment in Tokyo metropolitan area and its initial results are introduced.
Small devices which can measure propagation delay using digital terrestrial broadcasting waves are now under trial production through a joint research by NICT and Socionext. These devices use FPGA for calculate propagation delay of digital terrestrial broadcasting waves. Their size and electricity consumption is smaller than those of prototype. If many small receivers are deployed, 2-D water vapor variations can be monitored with high time and space resolutions. Such a network system will contribute to increasing the accuracy of numerical weather forecast for severe weather phenomena such as localized heavy rainstorms.

Water vapor estimation via propagation delay of 920MHz wireless communication signal

*Nobuyasu Shiga[1], Satoshi Yasuda[1], Seiji Kawamura[1], Hiroshi HANADO[1], Ryuichi Ichikawa[1], Hironori Iwai[1], Shinsuke Satoh[1]

1. National Institute of Information and communications technology

We have developed a 920MHz wireless communication module that can measure the variation of propagation delay precisely (6mm precision) and frequently (20 times/second). We have monitored the variation of propagation delay between 2 places that are 4.25km apart with line-of-sight. The result agreed well with the estimated propagation delay using the data obtained by meteorological observation equipment. This technique is suited to monitor the distribution of surface water vapor, compared to GNSS that primarily measures the propagation delay in vertical direction.
We are seeking the right path for social impremention of this technology, aiming to provide a mean to measure the surface water vapor with high precision, high frequency and high resolution in a cost-effective way.

Comparison of a water vapor observation with GPS and high sensitivity microwave radiometer, KUMODeS

*Taketo Nagasaki[1], Osamu Tajima[2], Ryuichi Ichikawa[3], Hiroshi Takiguchi[4], Kentaro Araki[5], Hiroshi Ishimoto[5]

1. High Energy Accelerator Research Organization, IPNS, 2. Kyoto University, 3. National Institute of Information and Communications Technology, 4. Japan Aerospace Exploration Agency, 5. Meteorological Research Institute

GPS is one of the useful technique which is using electromagnetic waves in the atmosphere. However, radio waves through the atmosphere and have a delay due to water vapor then. It is a major factor of indeterminacy in some measurement. On the other hand, as a device for identifying the amount of water vapor is a microwave radiometer.
We have developed a new microwave radiometer "KUMODeS" to detect local and sudden natural disasters such as tornadoes. This system observes radiation from water molecules present in the atmosphere (20-30 GHz band) and the emission line from the oxygen molecule (50-60 GHz band) are measured at the same time. As a result, the amount of water vapor in the atmosphere is estimated with high accuracy. As a characteristic of KUMODeS, high sensitivity (low noise) was employed as a cooling receiver by application of radio astronomical observation technology. In order to improve convenience, we employed a low-temperature(45K) calibration source in the cryostat and can be operated by remote control. And we are able to select a higher spatial resolution. We conducted long-term observations for more than half a year in Tsukuba city using KUMODeS. At the same point, we measured the amount of water vapor by GPS antenna and confirmed the validity of the observation result. In addition, we have also developed the second device that aimed at a smaller size and lower power consumption as a development of KUMODeS. In this presentation, we report the outline of the system and the results of atmospheric observation in Tsukuba City.
This research has been funded by “Program for Creating STart-ups from Advance Research and Technology (START Program)” from the Ministry of Education, Culture, Sports, Science and Technology, Japan, http://www.jst.go.jp/start/en/index.html.

Development and Observation of Water Vapor Raman Lidars for Localized Torrential Rainfall Prediction

*Tomohiro Nagai[1], Tetsu Sakai[1], Satoru Yoshida[1], Toshiharu Izumi[2], Sho Yokota[1], Hiromu Seko[1], Yoshinori Shoji[1], Koichi Shiraishi[3]

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Japan Meteorological Agency, 3. Fukuoka University

In recent years, the way of rain has been localized and concentrated, and disasters caused by localized torrential rain are increasing accordingly. One of the causes of these rains is thought to be the continuous supply of water vapor rich air through the lower atmosphere to the area where the rainfall is occurring. Therefore, it is very important to continuously observe the vertical distribution of water vaper in the lower atmosphere on the windward side to predict the localized torrential rainfalls. Water vapor Raman lidars are developed and observations are carried out in the Tokyo metropolitan area during summer time in 2017 and 2018. The lidars are carefully designed to potentiate the measurement of the water vapor near the ground as well as to have the capability on the daytime measurement. One of the lidars has the mobility so that we could make measurement at three observational sites in the seashore of the Tokyo metropolitan area that are located on the windward side of prospective area of the heavy rain in the Tokyo metropolitan area. Feasibility study of the impact of the water vapor mixing ratio profiles taken by the lidars on the numerical experiment for the precipitation prediction was carried out. We conducted water vapor assimilation experiment with use of the water vapor mixing ratio measured with the lidars. The assimilation results indicate that water vapor distribution in the analysis field was greatly changed by water vapor assimilation in the downwind side of the lidar observation site. Furthermore, a new research project has been just started to improve quantitative precipitation forecast for heavy rains in Kyushu island of Japan by means of data assimilation of water vapor lidars.

Study of Water Vapor Monitoring in the Open Ocean using Kinematic Precise Point Positioning

*Yoshinori Shoji[1], Teruyuki Kato[2], Yukihiro Terada[3], Toshitaka Tsuda[4], Masanori Yabuki[4]

1. The Second Laboratory of Meteorological Satellite and Observation System Research Department, Meteorological Research Institute, 2. Hot Springs Research Institute/Kanagawa Prefectural Government, 3. Natinal Institute of Technology, Kochi College, 4. Research Institute for Sustainable Humanosphere/Kyoto Unversity

Japan is an archipelago located easternmost of East Asia and influenced by the East Asian monsoon, which is characterized by moist air inflow coming from the ocean that often causes heavy rainfall (Kato 2006, Tsuguti and Kato 2014, Kato 2018). From June 28 to July 8, 2018, extreme rainfall frequented western Japan to the Tokai region, wherein more than 1,000 mm, at the maximum of 1,852.5 mm, precipitation was recorded in several regions (Tsuguti et al. 2018). A press release of Japan Meteorological Agency (JMA) (JMA, 2018) attributed the event to the concentration of two massively moist air streams over western Japan and persistent upward flow. With the frequency of extreme precipitation events, water vapor monitoring over the ocean becomes one of the important issues in Japan. Shoji et al. 2009 exhibited the improvement of a heavy rainfall prediction method by assimilating precipitable water vapor (PWV) estimated via the Global Positioning System (GPS) observation network in East Asia, as well as Japan’s nationwide dense GPS network. The result insisted the importance of water vapor monitoring upstream.

Unlike ground-based fixed GNSS stations, ocean-platform (ship and buoy) GNSS measurements face difficulties in analyzing the variable antenna position simultaneously with the atmospheric delay. However, recent advancement of kinematic precise point positioning technology is beginning to overcome these difficulties. Shoji et al (2017) installed two GNSS antennas on a research vessel, the RYOFU MARU of the Japan Meteorological Agency (JMA), and conducted experimental observations to assess the GNSS derived precipitable water vapor (PWV) from October 19, 2016, to August 6, 2017. The GNSS derived PWVs showed good agreement with the radiosonde observations on the vessel (1.7 mm root mean square difference, −0.7 mm bias, and 3.6% rejection rate).

Kato et al. (2018) introduced a GNSS buoy system for a synthetic geohazard monitoring. The buoy is located about 40 km south of Cape Ashizuri, west of Shikoku, Japan. We succeeded continuous PWV retrieval from June to September 2018. Retrieved PWVs vividly captured water vapor variations associated with north-south shifting of the “BAIU” seasonal rain front and passages of heavy rainfalls and typhoons. The GNSS buoy PWVs also suggest that, compared to over land, uncertainty of water vapor field in JMA’s objective analysis is larger over the ocean (Shoji et al. 2019).

In the year of 2018, we started a new research project to monitor PWV over the ocean west of Kyushu, Japan, getting supports from eight vessels (six regular line cargo vessels, one fisheries research vessel, and one JMA’s research vessel). The purpose of this study is to assess the impact of water vapor monitoring in upward of west Japan on heavy rainfall prediction. Preliminary PWV analyses show about 3 mm rms with about -1 mm bias against JMA’s operational regional objective analysis.

[M-TT47] GEOSCIENTIFIC APPLICATIONS OF HIGH-DEFINITION TOPOGRAPHY AND GEOPHYSICAL DATA IN THE ANTHROPOCENE

convener:Yuichi S. Hayakawa(Faculty of Environmental Earth Science, Hokkaido University), Shigekazu Kusumoto(Graduate School of Science and Engineering for Research, University of Toyama), Christopher A Gomez(Kobe University Faculty of Maritime Sciences Volcanic Risk at Sea Research Group)

Recent technical developments of high-definition topographic and geophysical data acquisition have enabled us to further investigate geoscientific issues including land surface processes, subsurface structures, submarine and aerial environments, geo-ecological interactions, and disaster mitigation. Such high-definition or high-resolution data are particularly useful for studies in short-term temporal scales, and future predictions such as numerical modelings. In this session, we expect submissions on topics challenging such issues in the Anthropocene, the most recent geological era of the Earth. A range of topics would fit the session framework, including theoretical work, improvements in data acquisition, extensive data preservation and archiving, pre- and post-processing, statistical analysis, modeling, and simulation for geoscientific research and geohazard assessments in the Anthropocene. The methodological approaches may include, but not limited to, laser scanning, SfM-MVS photogrammetry, GNSS precise positioning, SAR interferometry, multi-beam sonar, and electromagnetic sensors, based on terrestrial (fixed or mobile) and aerial (UAV or manned airborne) platforms.

Natural processes of erosion and deposition on riverbeds are generally limited in Japan due to large-scale public constructions including dams and banks. As a result of the construction of dams, sediment transport may dramatically decrease in the downstream area are, and the river ecosystem can also be affected. To make sediment move more vigorously, we cultivated the armored gravel riverbed with heavy machinery. We then explore the effects of riverbed cultivating by monitoring the topographic changes with high-frequency and high-definition measurements (HF-HD measurements), whereas conventional measurement technologies do not compensate spatial resolution and temporal resolution to capture the topographic change. Using UAS (Unmanned Aerial Vehicle) and SfM-MVS (Structure-from-Motion –Multi-view Stereo) photogrammetry, we found the transportation of the fixed gravels were occurring after cultivating the riverbed in 2017. The temporal and spatial resolutions of the HF-HD topographic data was approximately 2 months and 10 cm, respectively. In July 2018, water flow at 130 m^3/s was discharged from the upstream dam, and we confirmed that a part of the gravels in the cultivated area was eroded and replaced with new sediments (Fig. 1). These observations indicate that riverbed monitoring using UAV and SfM - MVS can be a practical tool for proper management of riverbeds. Applying this result, we will further clarify the relationships between the water quantity discharged from the dam and the riverbed topographic changes.

Spatial distribution of land surface displacements in the crater of Tateyama Midagahara Volcano using high-definition topographic data

*Yuichi S. Hayakawa[1], Shigekazu Kusumoto[2], Takuro Ogura[3,4]

1. Faculty of Environmental Earth Science, Hokkaido University, 2. Graduate School of Science and Engineering for Research, University of Toyama, 3. Graduate School of Frontier Science, The University of Tokyo, 4. Graduate School of Environmental Science, Hokkaido University

Detailed monitoring of land surface displacements is crucial for the assessment of activities of a volcano, especially in its crater area. Close-range remote sensing of high-definition topographic data is advantageous in the detection of centimeter-scale ground-surface displacements in a wide spacial extent, whereas the conventional leveling method is capable of detecting millimeter-scale displacements along a measurement line. We investigated the spatial distribution of land surface displacements in the Jigoku-Dani crater area of Mt. Tateyama Midagahara Volcano in Toyama Prefecture, central Japan by high-definition topographic measurements including terrestrial laser scanning and unmanned aerial vehicle-based structure-from-motion photogrammetry. The annual measurements were performed for three years (2015 to 2017). The range of uplift detected by terrestrial laser scanning corresponds with that by leveling. Together with the analytical results of the leveling data, the spatial pattern of the uplift suggests the extent of an underground pressured zone to cause the exhumation. For the prediction of the volcanic activities, further monitoring is required to reveal the spatiotemporal patterns of the displacements.

Primary outflow process of radiocesium, which is released by the TEPCO’ s Fukushima Dai-ichi Nuclear Power Plant accident, from a forested hillslope to a mountain stream is a particulate-bond state transport. A detailed estimation of the riverbed form and sediment volume changing with time is a key issue to assess the radiocesium distribution in the forested environment. Changes in the sediment volume can be calculated from the water depth and the difference between measured water surface and reference water surface levels setting up at the initial. Conventional method for a water depth determination is a direct measurement of the stream water depth by using a scale. But it requires a lot of time and labor to evaluate the change of riverbed form and water depth in detail.
In this study, we attempted an accurate and labor-effective method to evaluate the water depth and three-dimensional (3D) structure of underwater riverbed form by applying the SfM (Structure from Motion) /MVS (Multi View Stereo) techniques and the optical image data collected on consumer-grade-camera. These images were photographed beside of the small stream located at southern part of the Abukuma Mountains, Fukushima. Light propagation properties such as attenuation or reflection influence precise reconstruction of 3D model using underwater images. This was done to reduce influence of light propagation in two steps: 1) to reduce the influence of reflection, photographing at the time of twilight using LED light and Circular PL filter. 2) to reduce the influence of attenuation, installing blue colored film on the LED light and omitting band R, G for SfM/MVS analysis. And we also photographed at the day time and reconstructed 3D model (Day Model: DM) to compare and confirm the model applying two steps (Twilight Model: TM). As a criterion for evaluation of these models, we carried out the direct measurement of water depth. Rate of estimation concordance was calculated by dividing analytical water depth by the direct measurement depth, then convert to percentage.
Discrepancy between measured and analytical results increased with depth, the rate of estimation concordances were 46 % (DM) and 73 % (TM) in the water depth of 20-25 cm, and 62 % (DM) and 93 % (TM) in 10-15 cm, respectively (Figure). Next step is an improvement of the correction and image-capturing methods to reduce the estimation errors by elimination of the light refraction on the stream water surface.

Ground Penetrating Radar Imaging of Moisture and Water movement in volcanic soil

*Christopher A Gomez[1]

1. Kobe University Faculty of Maritime Sciences Volcanic Risk at Sea Research Group

Ground Penetrating Radar is a non-invasive subsurface method that provides results on the dielectric properties of the ground between 0 and 30 m on average in sediments. Working from sediments from Mt Unzen in Japan, tests over the moisture content and the air content change were conducted on the material in order to infer further data during field measurement. The GPR used in the survey is a Ramac Mala mounted with an antenna of 800 Mhz and a stack signal over time. The data were processed using Matlab using data filtering and time-depth conversion, and calculation of the dielectric properties variations. The signal analysis shows that the velocity does change over time depending on the moisture content and the change in air/void ratio. For a given homogeneous material, like at volcanoes, multiplying such analysis is a step forward the development of relatable tables for various environments.

Estimating Eruptive Volumes of Mud Volcano Southwestern Taiwan by Using UAV and SfM-MVS Photogrammetry

*CHIA-YING LIU[1], Ray Y Chuang[1], Horng-Yue Chen[2]

1. Department of Geography, National Taiwan University, 2. Academia Sinica, Institute of Earth Sciences

Mud volcanoes are special geologic features occurred in tectonic areas with horizontal compression. Complete research for mud volcanos can help us to understand the interaction of the crust and surface. In Taiwan, mud volcanoes are present on-land and off-shore southwestern Taiwan around the transitional area from subduction to orogeny. Among all mud volcanoes in Taiwan, the Wandan mud volcano erupts sporadically with significantly large amount of effluent mud. However, the mechanism of the eruption remains unclear because we lack fundamental information such as eruptive volumes, duration of mud eruption, impact factors and recurrence intervals. Therefore, it is important to estimate the eruptive volumes and further to examine the spatiotemporal pattern of the Wandan mud volcano eruption. We first compile literature and newspapers for historic eruption events to estimate two groups of recurrence interval: 150-180 days for highly active period and 300-600 days for less active period.

Since the sporadic eruption make different for rapid survey by using traditional methods, we take advantage of unmanned aerial vehicles (UAV) to design a survey network specifically. Therefore, we estimate the eruptive volumes of recent eruptions for the Wandan mud volcano by using aerial images taken from UAV, and 3D models derived from the structure-from-motion (SfM) photogrammetry technique. We use RTK-GPS and leveling for horizontal and vertical measurements of ground control point, respectively. We use the SfM software to generate DSMs, point clouds, and orthophotos with cm-level accuracy. We estimate the eruptive volume by subtracting the pre-eruption DSM from the post-eruption DSM. Our results show that for the event on 15 May, 2018, the eruptive area is 12,761 m^2 and the volume is 13,106.3625 ±13.0105m^3.

Increasing temporal depth of urban Land-Use Regression Models by wind-data driven dynamic buffer generation

*Tilman Leo Hohenberger[1], King Wai Leung[1]

1. Division of Environment and Sustainability, Hong Kong University of Science and Technology

Land-use regression (LUR) models are commonly used as an inexpensive and easy to set-up way to predict spatial variability in air-pollution. They are successfully applied to regional and, more and more, urban settings, making use of spatial predictors such as land-use, vegetation, morphology and geography. New approaches include an improved use of wind-data for buffer-creation and predictor calculation.

Traditionally, LUR models are used to generate annual or seasonal concentration averages and are not able cover deeper temporal variability. We aim at increasing temporal depth by using a novel approach in generating dynamic buffers for predictor calculation using both monthly wind-speed and wind-direction averages. The traditional circular buffers are replaced by wedges, whose orientation and radius are bound to these meteorological variables.

Here, Hong Kong’ s diverse territory is taken as a study site, and our model is trained with 5 years data from 16 government air quality monitoring stations and deployed portable sensors network. We compare our novel approach to both traditional LUR models and a sophisticated urban chemical transport model (ADMS-Urban).

Results will highlight the opportunities in using LUR models for monthly air-quality pollution concentration as an alternative to chemical transport modelling.

[M-TT47] GEOSCIENTIFIC APPLICATIONS OF HIGH-DEFINITION TOPOGRAPHY AND GEOPHYSICAL DATA IN THE ANTHROPOCENE

convener:Yuichi S. Hayakawa(Faculty of Environmental Earth Science, Hokkaido University), Shigekazu Kusumoto(Graduate School of Science and Engineering for Research, University of Toyama), Christopher A Gomez(Kobe University Faculty of Maritime Sciences Volcanic Risk at Sea Research Group)

Recent technical developments of high-definition topographic and geophysical data acquisition have enabled us to further investigate geoscientific issues including land surface processes, subsurface structures, submarine and aerial environments, geo-ecological interactions, and disaster mitigation. Such high-definition or high-resolution data are particularly useful for studies in short-term temporal scales, and future predictions such as numerical modelings. In this session, we expect submissions on topics challenging such issues in the Anthropocene, the most recent geological era of the Earth. A range of topics would fit the session framework, including theoretical work, improvements in data acquisition, extensive data preservation and archiving, pre- and post-processing, statistical analysis, modeling, and simulation for geoscientific research and geohazard assessments in the Anthropocene. The methodological approaches may include, but not limited to, laser scanning, SfM-MVS photogrammetry, GNSS precise positioning, SAR interferometry, multi-beam sonar, and electromagnetic sensors, based on terrestrial (fixed or mobile) and aerial (UAV or manned airborne) platforms.

Cosmic skepticism on meaning of life

*Shigeyuki Aoki[1]

1. School of Computer Science and Engineering, University of Aizu

“Meaning of life” can be questioned in various dimensions. Most of the arguments in the present literature ask what meaning of life we can find in our individual life. So, this line of question is substantially on “meaning in life” rather than on “meaning of life”. On the contrary, cosmology or life sciences raise another type of question (or skepticism) –what on earth is the meaning of life so short? This presentation will classify various types of skepticism on individualistic meanings of life, and then discuss whether the questions on meaning of life are closed each other in each dimension.

Rethinking 'Stenonian Revolution' in stratigraphy: From *Prodromus* (1669) to 'Anthropocene'

*Toshihiro Yamada[1]

1. Research Fellow, Graduate School of Education, University of Tokyo

When the Danish anatomist Nicolaus Steno (1638-1686) published his *Prodromus de solido* in 1669, it is said that the history of geology saw a revolution in stratigraphy, i.e. 'Stenonian Revolution.' My research on this topic, however, revealed that the revolution implied not only the discovery of the principles of stratigraphy but also the emergence of the concept of 'history of nature' (Spinoza suggested) and 'geo-power' (embodied in Leibniz's practice). The significance of the revolution will be discussed.

How Edmund Naumann made the Geologic Map of Japan in 1885?

*Michiko Yajima[1]

1. College of Humanity and Science, Nihon University

German Edmund Naumann (1854-1927) came to Japan in 1875. He became the first professor of geology in the University of Tokyo, founded the Geological Survey of Japan, and made good geological reconnaissance maps of Japan. In 1885, he returned to Germany and introduced these maps at the third International Geological Congress (IGC) held in Berlin, at which they were greatly admired. The map compares favorably with any present existing geologic map. How Naumann made the good Geologic Map of Japan in 1885? Because he was not a briliant student in university days, and when he came to Japan he worked at no duty museum. And the other reason is that he knew the preliminary paper on geology in Japan writen by Guembel (1874). Guembel got stones of Japan from the International Exhibition held in Vienna in 1873.

"Thyco Brahe" in the Geology; The Compromise Models on the Plate Tectonics Revolution.

*Jun'ichi Chiba[1]

1. O-hara Business College

How the scientific revolutions begin, progress and finish? The plate tectonics (PT after below) revolution is the one of the example of the latest scientific revolutions which had occurred after the first definition of the word “scientific revolutions” by Thomas Kuhn, and to restore the processes of the changing mind of the geoscientists in the PT revolutions is to describe the process in detail of the driving mechanism of the scientific revolutions.

Tomari (2008) had described the PT revolution in detail from the viewpoint of scientific historiographers. He wrote the geoscientists in the PT revolution as the person who converted to new paradigm immediately (for example Seiya Uyeda, Kazuaki Nakamura and Arata Sugimura), continued refusing the new theory (Shoji Ijiri, Yukinori Fujita and Masao Minato) and other geologists who had been under the influential scientists as the way of thinking, but he did not described the processes of the conversion; changing impression and overcoming contradiction of the previous paradigm and new theory in the heart of the individual scientist. Actually, it was not the simple binary opposition such as the “immediate acceptance by the advanced mind” and “completely refusal because under arrested by the former paradigm (geosyncline theory)” but most of the heart of the geologists were “torn up” until finishing of the conversion. The author reports the example of the "compromise model" on the Japanese Islands tectonic development scenario and the orogenic movement which were shown by some geologists, in this presentation.

Toshio Kimura who was the Professor the second course of geology, faculty of science, University of Tokyo, refused that the orogenic movement by the trench subduction but accepted the sea-floor spreading as the formation theory of the surface structure of the earth continued adopting a geosyncline idea about the orogenic movement in the neighborhood of trench in the 1970s. Yujiro Ogawa who was a student of Kimura proposed a model explaining the formation process of the buck ark basin by geosyncline instead of the secondary upwelling current of the mantle wedge which caused by subducting slab. Akira Yao, the biostratigrapher of the Osaka City University had begun to think about the formation model of the lens and block-shaped limestone bed by the thrusting and folding without denying geosyncline theory in the late 1970s. In addition, there were the petrographical studies that showed a change of the magma composition in the crossing direction of island arc and an emplacement processes of ophiolite in island arc without denying geosyncline theory. Its were considered to the examples of the blended models of the PT and previous theory.

The word “compromise model” is giving a bad impression like the “opportunism”, however it may be said that it is the wrestling to adopt a new theory to conventional observation datum carefully. I think it shown the existence of the researchers who can be compared to Tycho Brahe in the Copernicus Revolution, and not a thing indicating the geologic backwardness but it express that geological tradition such as to respect the building up the foundation of by the observation fact.

Contributions of Tatsuro Matsumoto (1913-2009) to plate tectonics, a signifcant paradigm shift in earth sicence

*Hidehisa Mashima[1]

1. Center for Obsidian and Lithic Studies, Meiji University

Tasturo Matsumoto (1913-2009), the professor of stratigraphy of Kyushu University, was a leader of the community of geology, especially that of stratigraphy, in Japan from 1960’s to 1970’s, when the seafloor spreading hypothesis was proposed at first then the plate tectonics theory was established at the end. The paradigm shift of earth science related to plate tectonics in Japan is represented by that from the geosyncline hypothesis to the accretional prism hypothesis. Matsumoto volunteered to be the chair of international and domestic symposiums, a committeeman of an international association, the organizer of a comprehensive research program and an editor of proceedings relating to the paradigm shift in this period, which significantly encouraged Japanese earth scientists. The accretional prism model for the Shimanto Belt was proposed by Sakai, supervised by Matsumoto, and Kammera (1975) from the viewpoint of structural geology. It was the Japanese paleontological society, which Matsumoto had leverage in for a long period, that recognized the importance of studies of foraminifera by Nakaseko and his colleagues. The founding of the accretional prism model for the Shimanto, therefore, was started in the vicinity of Matsumoto. These contributions of Matsumoto were passed into silence since he didn’t like to be applauded (Mashima, 2018). His contributions therefore were not referred in recent studies of history of Japanese geology (Tomari, 2008). In this presentation, I present activities of Matsumoto relating to plate tectonics. His activities reveal that Matsumoto is the person who exerted to realize mutual understanding and collaborative alliance between researchers belonging to different disciplines of earth science.

Online Community Responses to Volcanic Disaster: A Study of Yahoo! News Comments on the 2018 Mt. Kusatsu-Shirane eruption

*Kou Yamada[1]

1. Waseda University

This work aims to summarize public real-time reaction to the publication of the news of volcanic disasters by applying a content analysis. On January 23, 2018, there was an unexpected deadly eruption of Mt. Kusatsu-Shirane, located in the Japanese central area. In order to undertake a content analysis of user-generated comments to media coverage related to this volcanic disaster, this work used 'Netnography' which means “a technique for the socio-cultural analysis of social media and online community data” (Kozinets et al. 2014:Netnographic Analysis: Understanding Culture Through Social Media Data, in The SAGE Handbook of Qualitative Data Analysis).

Online social spaces become increasingly acknowledged as important fields for quantitative and qualitative social scientific investigation because of the openness and richness of its multifarious socio-cultural sites. There are approximately 34.1 million active monthly users on Yahoo in 2016 (https://www.netratings.co.jp/news_release/2016/12/Newsrelease20161220.html). Yahoo! News is a news website and one of the most popular news aggregators in Japan. It has received about 4000 articles offered by more than 300 media companies per a day and selectively published socially-minded news from among them. In the case of Mt. Kusatsu-Shirane disaster, a large number of stories were placed on the top page with the highest priority. Therefore, Yahoo! News readers had chances to express their voice about various topics related to the volcanic disaster by posting comments. In Japan, Yahoo! News would play a huge role in shaping online opinion.

A content analysis of reader comments posted in response to twenty-two articles on Yahoo! News site, published in January 2018, was carried out. Then, about 1000 comments are randomly sampled from 4200 comments. Comments that are critical of the measures for the volcanic eruption prediction are most frequently found. A lot of commenters were commenting with experts and the Japan Meteorological Agency in mind. There is a view among commenters that experts and the Japan Meteorological Agency did not work well for the volcanic disaster. This links to the wondering whether the area around the eruption points is really safe. Approximately 10% of comments assert the belief that such accidents would be beyond human control and humans should obey the nature's activities. Moreover, in comments on whether the eruption prediction is possible, a number of comments supporting and opposing the eruption prediction research are almost equal within the error bar. The relationship between citizens and the government/experts can be severely impaired if the crisis communication is mishandled. Conclusively, the result of this study suggests an aspect of examining the public representation of the volcanic disaster. This study reveals that these comments provide any information about the volcanic risk after the Mt. Kusatsu-Shirane eruption and proposes that netnography may prove useful for building effective volcanic risk communication strategies.

Cosmic skepticism on meaning of life

*Shigeyuki Aoki[1]

1. School of Computer Science and Engineering, University of Aizu

“Meaning of life” can be questioned in various dimensions. Most of the arguments in the present literature ask what meaning of life we can find in our individual life. So, this line of question is substantially on “meaning in life” rather than on “meaning of life”. On the contrary, cosmology or life sciences raise another type of question (or skepticism) –what on earth is the meaning of life so short? This presentation will classify various types of skepticism on individualistic meanings of life, and then discuss whether the questions on meaning of life are closed each other in each dimension.

Rethinking 'Stenonian Revolution' in stratigraphy: From *Prodromus* (1669) to 'Anthropocene'

*Toshihiro Yamada[1]

1. Research Fellow, Graduate School of Education, University of Tokyo

When the Danish anatomist Nicolaus Steno (1638-1686) published his *Prodromus de solido* in 1669, it is said that the history of geology saw a revolution in stratigraphy, i.e. 'Stenonian Revolution.' My research on this topic, however, revealed that the revolution implied not only the discovery of the principles of stratigraphy but also the emergence of the concept of 'history of nature' (Spinoza suggested) and 'geo-power' (embodied in Leibniz's practice). The significance of the revolution will be discussed.

How Edmund Naumann made the Geologic Map of Japan in 1885?

*Michiko Yajima[1]

1. College of Humanity and Science, Nihon University

German Edmund Naumann (1854-1927) came to Japan in 1875. He became the first professor of geology in the University of Tokyo, founded the Geological Survey of Japan, and made good geological reconnaissance maps of Japan. In 1885, he returned to Germany and introduced these maps at the third International Geological Congress (IGC) held in Berlin, at which they were greatly admired. The map compares favorably with any present existing geologic map. How Naumann made the good Geologic Map of Japan in 1885? Because he was not a briliant student in university days, and when he came to Japan he worked at no duty museum. And the other reason is that he knew the preliminary paper on geology in Japan writen by Guembel (1874). Guembel got stones of Japan from the International Exhibition held in Vienna in 1873.
Guembel,1874, Japanesische Gesteine, Ausland,p479, 480.

The role of the private sector in the formation of the meteorological observation network of Japan in the nineteenth century

*Akira Yamamoto[1]

1. Meteorological Research Institute

Three names of women are recognized on the membership lists of the Meteorological Society of Japan (1882-) in the nineteenth century. At the time when the national meteorological services were under developing at the initiative of the central government, all of them are in the private sector. By following their origins and backgrounds, some role of the private sector in the formation process of the meteorological observation network in the Meiji era are described.
