Turbidites are deposits of a turbidity current triggered by slope failure, earthquakes and floods. To obtain paleoseismic records using marine sediments, the extent of the turbidite distribution area and age are generally used. Characteristics and sedimentary process of turbidites assumed to be varied by the scale of seismic motion, seafloor topography and composition of sediments. Therefore, understanding and compiling the characteristics of turbidites distributed in each sea region is important to estimate paleoseismic records using turbidites. However, in the Nankai Trough, much less work has been done on paleoseismology using turbidites. This study aims to obtain the fundamental data of fine-grained turbidites, and apply it to reconstruct the seismic history in the Nankai Trough.
Samples are multi-cores and piston cores collected from off Kumano and Hyuga, the Nankai Trough. Main samples are obtained from small slope-basins with pin-point accuracy. Based on its sedimentary structure and magnetic susceptibility, fine-grained turbidites are identified in off Kumano sample and in off Hyuga. In off Kumano sample, coarse silt layer(we named this KL2 unit), silt layer (KL3, KL4) and a thick homogeneous clay layer from the bottom to the top of the upper unit can be identified as fine-grained turbidites. More specifically, KL2 unit shows low CT value, which cannot be shown in X-ray CT image and has Fe peak in XRF core scanner profile. KL3, KL4 unit shows high CT value and has Ca peak in XRF core scanner profile. Although X-ray CT image can be useful tool to identify the fine-grained turbidites, it may lead to misunderstanding the basement of fine-grained turbidites. C-14 radiocarbon dating of the foraminifera, the individual sediment layer interval is 160 years, which is almost agreed with past earthquake recurrence intervals. Also some obtained ages matches with historicalearthaquake age. In off Hyuga sample, characteristics of XRF core scanner profile such as Ca, Fe are different from that of Kumano, which can be affected by volcanic products. Since one of the sampling sites off Hyuga is located at the terrace of the foot of the Oyodo Knoll and topographically isolated from direct sediment path through river, the turbidite deposition is inferred to be triggered by seismic shaking. The youngest C-14 age obtained from this samplewas 11,000 cal yr BP, it cannot be compared to historicalearthquake age. Average earthquake recurrence is estimated to be 700 years, which is longer than other regions in the Nankai Trough.

Flood-induced sediment gravity-flow deposits in varved diatomites

*Hana Sasaki[1], Yoshiro Ishihara[2]

1. Graduate School of Science, Fukuoka University, 2. Department of Science, Fukuoka University

Based on differences between inflows and lake water, lacustrine sediment gravity-flows induced by floods can classified as hyperpycnal flows along the bottom of lakes, homopycnal flows mixed with lake water, and hypopycnal flows that spread along lake surfaces. Lacustrine sediment gravity-flow deposits that show an inversely grading unit overlain by a normally grading unit have been recognized as hyperpycnites. A depositional model is presented where the lower inversely grading unit is deposited during an increasing phase of the flow followed by the upper normally grading unit overlaying in a decreasing phase of the flow. That process based sedimentary model established in marine environments has been applied to sandy inflow deposits of lakes. However, there are only a few reports of fine-grained hyperpycnites, and there is no consideration of lateral facies changes associated with sediment processes of silty hyperpycnites. Also, there is no observation associated with homopycnites and hypopycnites, although these deposits are expected in a depositional setting, including hyperpycnite. In this study, we described detailed sedimentary facies of hyperpycnite, homopycnite, and hypopycnite from lacustrine varved deposits considering their sedimentary processes. We examined several formations including the Hiruzenbara Formation in Maniwa City, Okayama Prefecture, which can easily be used to define flood- and slope-failure deposits. The formation deposited in the paleo-Hiruzenbara Lake includes varved diatomite with more than 95% fossil diatoms. Therefore, inflow materials can be easily identified in the formation. Fine-grained hyperpycnites identified in this study show a set of normally grading and inversely grading units or a normal grading unit. As previously discussed, it is suggested that these deposits are deposited in an increasing phase of inflow followed by a decreasing phase of inflow. The deposit of a normally grading unit is deposited from a flow completely eroding the lower unit. Due to the occurrence of rip-up clasts, the lower inversely grading unit might erode the lower layer; whereas, the upper normally grading unit is suggested to be dominated by more depositional flows that have a higher organic matter content. Hyperpycnites tend to thin out toward the downstream ward and change their sedimentary facies with the occurrence of rip-up clasts and organic matter. Fine-grained homopycnite and hypopycnite are present as structureless thin deposits of less than 1 mm composed of inflows of fine materials with no erosion. These deposits have lower organic matter content than hyperpycnites and do not include rip-up clasts. It is possible that flows of these deposits mixed with the lake water or were spread along the lake surface, after which the materials slowly settled. Thin fine-grained homopycnites and hypopycnites do not exhibit any sedimentary facies change over several kilometers, except in cases where they are pinched out.

Features of parallel lamination in turbidite sandstones in the Upper Cretaceous Izumi Group in the southern part of the Awaji Island, southwest Japan

*Akane Okuda[1], Hajime Naruse[1]

1. Division of Earth and Planetary Sciences, Graduate school of Science, Kyoto University

Parallel lamination is a common structure in sedimentary rocks, which characterizes Bouma T_b division of turbidites. Recent studies of flume experiments suggested that characteristics of parallel lamination vary depending on rates of bed aggradation. That is, the clarity of lamination decreases as rate of bed aggradation increases, and formation of parallel lamination is suppressed under very high bed-aggradation rate (>4 cm/min). However, it has not been examined that variation in features of parallel lamination corresponding to results of flume experiments can be observed in actual turbidite sandstones. In this study, we analyzed microtextures of parallel lamination in the upper part of turbidite sandstones taken from the Upper Cretaceous Izumi Group in soutern part of the Awaji Island, and compared the observed features with the experimental results.

The Izumi Group was subdivided into three lithological parts; the northern marginal part, main part, and southern part. The main part of Izumi Group consists of alternating beds of sandstone, mudstone and conglomerate, and has been interpreted as submarine fan deposits. The turbidite sundstones was sampled from Anaga and Kita-ama formations of the main part of the Izumi Group. The intervals of laminae and oscillation of the grain-size distribution in parallel lamination of turbidite sandstones were measured by automated image analyses.

As a result, it was suggested that parallel lamination in turbidite sandstones can be classified into two types A and B. Type A lamination shows the abrupt change in grain-size at the boundary between laminae, while Type B shows gradual change. In naked eye observation, the former lamination is clearly recognized and the later lamina is unclear. The type B lamination occurs dominantly in turbidites observed in the study area.

Comparing with existing results of flume experiments, we interpret that two types of parallel lamination reflect difference in bed-aggradation rates. In general, the rate of bed-aggradation due to depositti on from turbidity current decreases with time. The fact that the occurrence of Type A lamination is limited in the upper interval of turbidites implies that there is a threshold value of bed-aggradation rate to from Type A parallel lamination. In future, to reconstruct quantitative paleo-flow conditions from characteristics of parallel lamination, we will examine the process and conditions of formation of parallel lamination by the model calculation with further analysis of actual turbidite sandstones.

Sediment wave formation on slope base environments: an example of the Neogene Aoshima Formation, Miyazaki Prefecture, Southwest Japan

Shiori Iwao[1], Yuri Onishi[2], *Yoshiro Ishihara[1], Miwa Yokokawa[3]

1. Department of Earth System Science Faculty of Science, Fukuoka University, 2. OYO Corporation, 3. Lab. of Geoenvironment, Osaka Institute of Technology

Sediment waves with a wavelength of a few hundred meters and an amplitude of a few meters are observed in a turbidite succession of the uppermost part of the Neogene Aoshima Formation, Miyazaki Group. Sediment waves, a type of large sedimentary bedform in deep-sea environments, are frequently observed on levees and in channels of modern, deep-sea floors, and shallow subsurface areas. The Aoshima Formation is suggested to have been deposited on a slope-to-basin area offshore of a fan delta. However, because a turbidite succession of the Aoshima Formation shows a rather monotonous, detailed, and precise depositional setting, the sedimentary waves have not been clarified. To clarify why the sediment waves were in the limited area and horizon of the Aoshima Formation, sedimentary logs were measured at turbidite successions, including upcurrent and downcurrent regions of the sediment waves. Also, the sedimentary logs were carefully correlated together and sedimentary facies of the succession were analysed. The results are as follows: (1) Sediment gravity-flow deposits of the sediment wave horizon have relatively variable thickness. Facies could only be traced between a few hundred meters, even though most sediment gravity-flow deposits of the Aoshima Formation can trace more than 10 km along the paleocurrent directions. In addition, sediment gravity-flow deposits in the sediment wave horizon can trace between the upcurrent and downcurrent sections, except for an interval of the sediment wave formation. (2) Rare, thick sediment gravity-flow deposits including slump-fold beds are observed just under the downcurrent area of the sediment wave horizon. (3) Sediment gravity-flow deposits overlaying the beds, including slump-folds, are relatively thicker than other areas. (4) Sediment gravity-flow deposits in the sediment wave interval show oblique paleocurrent directions against sediment gravity-flow deposits in the upcurrent and downcurrent regions. (5) Small-scale slumping deposits are located at the most downcurrent part of the sediment wave. Results (1) to (3) suggest that the sediment waves of the Aoshima Formation developed on an upcurrent area of a slope change-point near the slope base. Also, results (4) and (5) suggest that the sediment waves were in a depositional channel on the slope base.

A flume experiment on sedimentary structures and grain size distribution of cyclic steps formed by surge-type turbidity currents

*Miwa Yokokawa[1], Kazunori Fujita[1], Isamu Mori[1], Robert Fernandez[2], Matt Czapiga[3], John Berrens[4], Jeffrey Kwang[4], Kensuke Naito[4], Gary Parker[4], Norihiro Izumi[5], Hajime Naruse[6]

1. Osaka Institute of Technology, 2. University of Hull, 3. Technical University of Delft, 4. University of Illinois, 5. Hokkaido University, 6. Kyoto University

In the submarine canyon and the vicinity, continuous step-like morphology is often observed. Many of them are inferred to be formed by turbidity currents. In this study we investigate the sedimentary structures and grain size distribution of cyclic steps formed by surge-type turbidity currents in an experimental flume. Two kinds of plastic particles, whose grain-size distributions differ from each other, were used in this study to observe grain size distribution and sedimentary structures of the cyclic steps, with an eye to application to sediment waves in the modern sea floor and in the rock record.
The experiment was conducted at the Hydrosystems Laboratory of University of Illinois, Urbana-Champaign (UIUC). In the experiment, a flume, which is 14.5 m long, 0.5 m deep and 0.1m wide was suspended in a larger tank, tilted at 2.5 degrees. Salt water (density: 1.17 g/cm^3) and two kinds of plastic particles (specific gravity: 1.5, D_{50}: 68 μm, 206 μm) were mixed at a weight ratio of 20:1:1 in the head tank, and then introduced into the flume as a slurry. In Case A, slurry filling the entire volume of the head tank, 58.7 L (5.87 L/cm), was supplied for single surge, which took 40 seconds to flow out. We repeated 40 such surges. In Case B, slurry filling half the volume of the head tank, 27.4 L (2.74 L/cm), was supplied for each surge, which took 10 seconds to flow out; we repeated 80 surges. The total amount of supplied sediment was about the same in both cases. The flow rate per unit time gradually decreased during a single surge.
At the end of each series, 4 steps were formed in the two series. Those steps moved upstream during the series of pulse runs. The mean values of wave steepness of the resulting steps were 0.06 and 0.05. The sedimentary structures observed in the cyclic steps of these experiments were mainly laminae gently dipping toward the upstream side. These laminae were truncated at the downstream side of the step. Moreover, the grain size analysis of the cyclic steps showed that D_{50} of the surface sediments tended to decrease toward the downstream, with the tendency being more prominent as the total discharge of the surge increased. It was also found that the D_{50} on the downstream side is smaller than on the upstream side of each step. This distribution is inferred to be caused by a hydraulic jump at the upstream side of each step.

The Study of Sky Condition Prediction and Combination Efficiency Estimation about Multi-GNSS

*Chieh-Ting Chou[1], Yi-Shan - Li[2], Yen-Te - Li[1], Wan-Yu - Yu[1]

1. Department of Environmental Information and Engineering, CCIT, National Defense University, Graduate Student,
2. Department of Environmental Information and Engineering, CCIT, National Defense University, Assistant Professor

The Global Navigation Satellite System (GNSS) is widely used in military and civilian applications because of the high-precision services of positioning, velocity and time-of-flight (PVT) at any time and any place. At present, GNSS include the GPS of the United States, the GLONASS of Russia, the Galileo of European Union and the Beidou of China. Due to the rapid development and diversity of GNSS, the positioning efficiency of multi-GNSS is an important information for user reference when surveying.

In this study, the sky condition of the project area is predicted by the STK software. It is expected that the best location and period of observation can be provided to improve the observation efficiency according to simulated calculate the satellite geometric distribution and satellite visible number. Based on mentioned above, the observation efficiency can be improved. In addition, this study conducts a study on the positioning effectiveness of GNSS by actual observation data through different combination of satellite systems, ephemeris and weathers. In the discussion of sky condition prediction, the prediction is successfully carried out. In the discussion of GNSS combination, the results show that the GPS satellite system is relatively stable and highly accurate compared to other satellite systems. The relative positioning accuracy of multi-GNSS with GPS satellite system compared to without GPS system can improve 14ppm. In the discussion of different ephemeris, the short baselines can produce consistent results with relative accuracy in either broadcast or precision ephemeris. In the discussion of weathers, the relative accuracy of observations on a sunny day can be improved by 4ppm compared to a rainy day.

Research on the development of rapid and accurate GNSS routine analysis system (2)

*Hiroyuki Nakagawa[1]

1. The Geospatial Information Authority of Japan

The Geospatial Information Authority of Japan (GSI) routinely analyzes GNSS data obtained by GEONET and monitoring crustal deformation all over Japan. The results are used as fundamental data in the field of such as evaluating earthquake activity or monitoring volcanic activity.

However, depending on the timing of earthquake occurrence or speed of deformation of mountain body, even up-to-date GEONET routine analysis do not always have enough rapidness or time resolution. New analysis method that is more rapid and with higher time resolution are required.

Therefore, we focused on Precise Point Positioning with Ambiguity Resolution, or PPP-AR. With corrective information called Fractional Cycle Bias (FCB) as well as precise orbit and clock information of GNSS satellites, PPP-AR can calculate position for each site as accurate as those derived by interferometric analysis. A key feature is that the position of the stations in every epoch can be calculated rapidly with small calculation load. In addition, PPP-AR does not need fixed reference station. That has advantage when crustal deformation occurs over wide area by large earthquake and it is difficult to find the point that is not subjected to the deformation.

Thus, GSI has started a three-year research project since the April of 2017. In this project, we will develop more rapid and accurate GNSS analysis method based on PPP-AR and make prototype system implementing this method envisioning future GEONET routine analysis. The goal of this research is developing analysis method that can routinely and stably obtain the solution of one-second interval with typical repeatability of about 1cm in horizontal component within about two hours after data acquisition.

In 2018, we perform test analysis of 31 days from Jul. 12 to Aug. 12, 2018 using prototype system under development. Twenty-four hour time series of 1 sec. interval from 0 hour to 0 hour of next day was calculated for al GEONET station once a day, and evaluated estimated satellite orbit and clock, and resulted GEONET time series solutions. First, as an evaluation of quality of estimated satellite orbits and clocks, RMS of estimated orbits with respect to IGS final orbit and RMS of estimated clocks with respect to CODE clock were calculated. As a tentative result, RMS of orbit is about 2.7cm for GPS and about 8.8cm for GLONASS, and RMS of clock is about 4.15ns for GPS and about 6.02ns for GLONASS. Next, as a evaluation of repeatability of GEONET time-series solutions, we calculate a frequency distribution of standard deviation of horizontal coordinate time series. Then, frequency distribution peak is located at a bin from 1.0 to 1.2cm of standard deviation and almost 25% of all time series are fall into this bin. On the other hand, only 21% of time series has standard deviation less than 1cm, which is target of this research project. Time series with standard deviation less than 1.4cm accounts for about 68%.

In this presentation, we will consider the reason and a way to improve the quality of estimated orbit/clock and time series solution.

Characteristics of the Tenryu-Funagira laser extensometer and its detection ability of slow slips

*Akio Katsumata[1], Akiteru Takamori[2], Akito Araya[2]

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Earthquake Research Institute, University of Tokyo

Katsumata et al. (2010) installed a long-baseline laser extensometer in Funagira tunnel in Hamamatsu, Shizuoka Pref. Its baseline length is 400 m. Short-term slow-slips were detected with the extensometer. From spectral analysis, it was shown that a long-term slow-slip can be detected with the laser extensometer earlier than the GNSS network. However. iodine-stabilized He-Ne laser, which was used formerly, had a relatively short life time. It was difficult to continue observation for more than several years. We replaced the stabilized laser with the iodine-stabilized YAG laser developed by Araya et al. (2002), and started observation from March, 2018. The sampling rate was changed from 1 kS/s to 10 kS/s to catch up fast phase change due to quick strain change.
We compared the obtained data with that previously obtained with He-Ne laser. It was found that the atmospheric pressure response and tidal response were not changed. However, trend was changed. Trend of about 10^{-7} strain/year was previously observed. No such trend is observed currently. A trend change was observed before and after the 2011 Tohoku earthquake. The trend might be affected by local condition. We compared spectrum levels of the detrended previous and current data. The spectrum level was almost the same over a period range from 0.1 s to several months.
Ide et al. (2007) presented a scaling law of slow earthquakes, in which seismic moment is proportional to event duration. It is considered that strain rate would be the same level regardless of its seismic moment based on the scaling law. Katsumata et al. (2001) showed that the Tenry-Funagira laser extensometer would detect strain change with strain rate the same as those of short-term slow-slips in a day. If there were a slow-slip of one day duration, the Tenryu-Funagira laser extensometer could detect it.

Performance evaluation of laser strainmeters

*Akiteru Takamori[1], Akito Araya[1], Akio Katsumata[2], Wataru Morii[3], Kouseki Miyo[4], Masatake Ohashi[4]

1. Earthquake Research Institute, University of Tokyo, 2. Meteorological Research Institute, 3. Disaster Prevention Research Institute, Kyoto University, 4. Institute for Cosmic Ray Research, University of Tokyo

We have constructed four laser strainmeters which are in operation to observe Earth’ s strain in underground sites in Japan. The strainmeters are asymmetric Michelson interferometers implemented with a long main arm (ranging from 100 m to 1.5 km, depending on deployment) that follows ground motion and a short reference arm (shorter than 1 m) which is mounted on a stable platform isolated from the ground. The ground strain is observed by detecting phase difference of the two beams that enter and return from these arms. Due to the sensitivity of the phase difference to laser frequency caused by the mismatch of the arm lengths, the laser frequency needs to be stabilized to maintain high resolution of the instruments in long term. For this purpose, we developed a laser frequency stabilization system that locks a Nd:YAG laser to one of the iodine absorption lines, with the designed stability of 10e-13 to 10e-12. In order to evaluate the performance of the strainmeters, we have been studying stability of the lasers by comparing equivalent systems in situ. The details and results of the experiments are presented together with the estimated performance of the strainmeters.

Calculation Method of the Tidal Love Numbers with the Fluid Core Resonance of the Solid Earth

*Yuji Harada[1,2], Shuhei Okubo[3]

1. State Key Laboratory of Lunar and Planetary Science, Space Science Institute, Macau University of Science and Technology, 2. Ocean Hemisphere Research Center, Earthquake Research Institute, University of Tokyo, 3. Center for High Energy Geophysics Research, Earthquake Research Institute, University of Tokyo

Effect of non-rigidity of the solid Earth exerted on the Earth’ s tide and rotation is of importance for understanding dynamical behavior of the core and mantle. The influence of the fluid core on the solid tide is predictable based on Sasao et al.’ s theory (i.e., the SOS theory). In the present study, we show a couple of new ideas so as to simply estimate the Love numbers describing the tidal deformation by means of the SOS theory, and report the results. One of them is how to compute the independent solutions of the radial functions in the solid layer (i.e., the y functions), where we show that it become unnecessary to calculate a part of the solutions in doing numerical integration of the y functions. The other is how to compute those in the liquid layer (i.e., the q functions), where we show that it become unnecessary to calculate the vertical derivative of density in integrating the q functions.

Integrating PSInSAR and Hydrogeophysical Methods for the Characterization of a Earth fissure in the eastern Beijing plain

*Menglin Zhao[1], juan wang[1], wang xu[1], bing hu[1], yisheng chen[1]

1. Capitai Normal University

Modern Earth fissure, ranging from renewed displacement on 1-km-long fault scarps to 9.8-km-long tension cracks, occur in the eastern part of Beijing plain. Most of the failures closely parallel the pre-existing Medio-Pleistocene fault zone. The pattern of earth fissure and the relation to the inferred fault remain controversial. An integrated project, including PSInSAR, geophysical and trenching methods, has been conducted to characterize the formation of earth fissure. The results indicate that this earth fissure was caused by groundwater-level decline rather than natural tectonism. In addition, it is the first time to accurate the initiation and terminal Location of pumping-induced earth fissures within the fault zone.

At present, GNSS include the GPS of the United States, the GLONASS of Russia, the Galileo of European Union and the Beidou of China. Due to the rapid development and diversity of GNSS, the positioning efficiency of multi-GNSS is an important information for user reference when surveying.

In this study, the sky condition of the project area is predicted by the STK software. It is expected that the best location and period of observation can be provided to improve the observation efficiency according to simulated calculate the satellite geometric distribution and satellite visible number. Based on mentioned above, the observation efficiency can be improved. In addition, this study conducts a study on the positioning effectiveness of GNSS by actual observation data through different combination of satellite systems, ephemeris and weathers. In the discussion of sky condition prediction, the prediction is successfully carried out. In the discussion of GNSS combination, the results show that the GPS satellite system is relatively stable and highly accurate compared to other satellite systems. The relative positioning accuracy of multi-GNSS with GPS satellite system compared to without GPS system can improve 14ppm. In the discussion of different ephemeris, the short baselines can produce consistent results with relative accuracy in either broadcast or precision ephemeris. In the discussion of weathers, the relative accuracy of observations on a sunny day can be improved by 4ppm compared to a rainy day.

Research on the development of rapid and accurate GNSS routine analysis system (2)

*Hiroyuki Nakagawa[1]

1. The Geospatial Information Authority of Japan

The Geospatial Information Authority of Japan (GSI) routinely analyzes GNSS data obtained by GEONET and monitoring crustal deformation all over Japan. The results are used as fundamental data in the field of such as evaluating earthquake activity or monitoring volcanic activity.

However, depending on the timing of earthquake occurrence or speed of deformation of mountain body, even up-to-date GEONET routine analysis do not always have enough rapidness or time resolution. New analysis method that is more rapid and with higher time resolution are required.

Therefore, we focused on Precise Point Positioning with Ambiguity Resolution, or PPP-AR. With corrective information called Fractional Cycle Bias (FCB) as well as precise orbit and clock information of GNSS satellites, PPP-AR can calculate position for each site as accurate as those derived by interferometric analysis. A key feature is that the position of the stations in every epoch can be calculated rapidly with small calculation load. In addition, PPP-AR does not need fixed reference station. That has advantage when crustal deformation occurs over wide area by large earthquake and it is difficult to find the point that is not subjected to the deformation.

Thus, GSI has started a three-year research project since the April of 2017. In this project, we will develop more rapid and accurate GNSS analysis method based on PPP-AR and make prototype system implementing this method envisioning future GEONET routine analysis. The goal of this research is developing analysis method that can routinely and stably obtain the solution of one-second interval with typical repeatability of about 1cm in horizontal component within about two hours after data acquisition.

In 2018, we perform test analysis of 31 days from Jul. 12 to Aug. 12, 2018 using prototype system under development. Twenty-four hour time series of 1 sec. interval from 0 hour to 0 hour of next day was calculated for al GEONET station once a day, and evaluated estimated satellite orbit and clock, and resulted GEONET time series solutions. First, as an evaluation of quality of estimated satellite orbits and clocks, RMS of estimated orbits with respect to IGS final orbit and RMS of estimated clocks with respect to CODE clock were calculated. As a tentative result, RMS of orbit is about 2.7cm for GPS and about 8.8cm for GLONASS, and RMS of clock is about 4.15ns for GPS and about 6.02ns for GLONASS. Next, as a evaluation of repeatability of GEONET time-series solutions, we calculate a frequency distribution of standard deviation of horizontal coordinate time series. Then, frequency distribution peak is located at a bin from 1.0 to 1.2cm of standard deviation and almost 25% of all time series are fall into this bin. On the other hand, only 21% of time series has standard deviation less than 1cm, which is target of this research project. Time series with standard deviation less than 1.4cm accounts for about 68%.

In this presentation, we will consider the reason and a way to improve the quality of estimated orbit/clock and time series solution.

Characteristics of the Tenryu-Funagira laser extensometer and its detection ability of slow slips

*Akio Katsumata[1], Akiteru Takamori[2], Akito Araya[2]

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Earthquake Research Institute, University of Tokyo

Katsumata et al. (2010) installed a long-baseline laser extensometer in Funagira tunnel in Hamamatsu, Shizuoka Pref. Its baseline length is 400 m. Short-term slow-slips were detected with the extensometer. From spectral analysis, it was shown that a long-term slow-slip can be detected with the laser extensometer earlier than the GNSS network. However. iodine-stabilized He-Ne laser, which was used formerly, had a relatively short life time. It was difficult to continue observation for more than several years. We replaced the stabilized laser with the iodine-stabilized YAG laser developed by Araya et al. (2002), and started observation from March, 2018. The sampling rate was changed from 1 kS/s to 10 kS/s to catch up fast phase change due to quick strain change.
We compared the obtained data with that previously obtained with He-Ne laser. It was found that the atmospheric pressure response and tidal response were not changed. However, trend was changed. Trend of about 10^{-7} strain/year was previously observed. No such trend is observed currently. A trend change was observed before and after the 2011 Tohoku earthquake. The trend might be affected by local condition. We compared spectrum levels of the detrended previous and current data. The spectrum level was almost the same over a period range from 0.1 s to several months.
Ide et al. (2007) presented a scaling law of slow earthquakes, in which seismic moment is proportional to event duration. It is considered that strain rate would be the same level regardless of its seismic moment based on the scaling law. Katsumata et al. (2001) showed that the Tenry-Funagira laser extensometer would detect strain change with strain rate the same as those of short-term slow-slips in a day. If there were a slow-slip of one day duration, the Tenryu-Funagira laser extensometer could detect it.

Performance evaluation of laser strainmeters

*Akiteru Takamori[1], Akito Araya[1], Akio Katsumata[2], Wataru Morii[3], Kouseki Miyo[4], Masatake Ohashi[4]

1. Earthquake Research Institute, University of Tokyo, 2. Meteorological Research Institute, 3. Disaster Prevention Research Institute, Kyoto University, 4. Institute for Cosmic Ray Research, University of Tokyo

We have constructed four laser strainmeters which are in operation to observe Earth’ s strain in underground sites in Japan. The strainmeters are asymmetric Michelson interferometers implemented with a long main arm (ranging from 100 m to 1.5 km, depending on deployment) that follows ground motion and a short reference arm (shorter than 1 m) which is mounted on a stable platform isolated from the ground. The ground strain is observed by detecting phase difference of the two beams that enter and return from these arms. Due to the sensitivity of the phase difference to laser frequency caused by the mismatch of the arm lengths, the laser frequency needs to be stabilized to maintain high resolution of the instruments in long term. For this purpose, we developed a laser frequency stabilization system that locks a Nd:YAG laser to one of the iodine absorption lines, with the designed stability of 10e-13 to 10e-12. In order to evaluate the performance of the strainmeters, we have been studying stability of the lasers by comparing equivalent systems in situ. The details and results of the experiments are presented together with the estimated performance of the strainmeters.

Calculation Method of the Tidal Love Numbers with the Fluid Core Resonance of the Solid Earth

*Yuji Harada[1,2], Shuhei Okubo[3]

1. State Key Laboratory of Lunar and Planetary Science, Space Science Institute, Macau University of Science and Technology, 2. Ocean Hemisphere Research Center, Earthquake Research Institute, University of Tokyo, 3. Center for High Energy Geophysics Research, Earthquake Research Institute, University of Tokyo

Effect of non-rigidity of the solid Earth exerted on the Earth’ s tide and rotation is of importance for understanding dynamical behavior of the core and mantle. The influence of the fluid core on the solid tide is predictable based on Sasao et al.’ s theory (i.e., the SOS theory). In the present study, we show a couple of new ideas so as to simply estimate the Love numbers describing the tidal deformation by means of the SOS theory, and report the results. One of them is how to compute the independent solutions of the radial functions in the solid layer (i.e., the y functions), where we show that it become unnecessary to calculate a part of the solutions in doing numerical integration of the y functions. The other is how to compute those in the liquid layer (i.e., the q functions), where we show that it become unnecessary to calculate the vertical derivative of density in integrating the q functions.

Integrating PSInSAR and Hydrogeophysical Methods for the Characterization of a Earth fissure in the eastern Beijing plain

*Menglin Zhao[1], juan wang[1], wang xu[1], bing hu[1], yisheng chen[1]

1. Capitai Normal University

Modern Earth fissure, ranging from renewed displacement on 1-km-long fault scarps to 9.8-km-long tension cracks, occur in the eastern part of Beijing plain. Most of the failures closely parallel the pre-existing Medio-Pleistocene fault zone. The pattern of earth fissure and the relation to the inferred fault remain controversial. An integrated project, including PSInSAR, geophysical and trenching methods, has been conducted to characterize the formation of earth fissure. The results indicate that this earth fissure was caused by groundwater-level decline rather than natural tectonism. In addition, it is the first time to accurate the initiation and terminal Location of pumping-induced earth fissures within the fault zone.

[S-GD03] Geodesy General Contributions/Global Geodetic Observing System

convener:Koji Matsuo(Geospatial Information Authority of Japan), Yusuke Yokota(Institute of Industrial Science, The University of Tokyo), Takahiro Wakasugi(Geospatial Information Authority of Japan), Chairperson:Kensuke Kokado(GSI of Japan), Yusuke Yokota

In this session, general contributions from all areas of geodesy are welcomed. Topics of interest will include but not limited to recent advances in measurement techniques, reference frame realization, earth rotation or earth tide. In addition, this session also provides a forum for discussing GGOS (Global Geodetic Observing System) related observation programs, advancement of geodetic techniques, collaboration among various organizations in the world. Topics will include improvements of observing system and data analysis, participations in global programs, global reference frames and geodesy's contributions to society.

Discussion

Activities and future perspective of GGOS Working Group Japan

*Basara Miyahara[1]

1. GSI of Japan

Global Geodetic Observing System (GGOS) is a fundamental framework for integration of global geodetic observations such as GNSS, VLBI, SLR, DORIS, gravity measurements and so on. The main objective of the system is to measure and monitor shape, rotation, gravity field of the earth and its changes. GGOS integrates various international organizations related geodetic observation such as International GNSS Service (IGS), International VLBI Service for Geodesy and Astrometry (IVS), International Laser Ranging Service (ILRS) and so on in order to coordinate and promote global geodetic observations. International Terrestrial Reference Frame (ITRF) which is a de-facto standard for Global Geodetic Reference Frame (GGRF), reference frame for earth’s shape and variation which was endorsed by the United Nations General Assembly in 2015, is also one of the main achievements of GGOS observation. GGOS is essential basic infrastructure for measuring and monitoring of earth’s shape and its change.
The objective of GGOS, that is to continue to measure and monitor earth’s shape and its change can be possible only with continuous global geodetic observation with high quality and enough spatial coverage. Such observation cannot be possible without continuous geodetic observation by countries all over the world. Therefore, several agencies in Japan such as Geospatial Information Authority of Japan (GSI), Japan Coast Guard, National Institute of Information and Communications, National Astronomical Observatory of Japan, National Institute of Polar Research, and Japan Aerospace Exploration Agency have been individually conducting geodetic observation such as GNSS, VLBI and SLR in Japan and Antarctica, and participating in global geodetic observation through international organizations such as IGS, IVS, and ILRS and so on. Several researchers with universities have also participated in the organizations as chairs and board members. In addition, we established a working group on GGOS, GGOS-WG of Japan under IAG Subcommittee in Science Council of Japan in 2013 in order to facilitate information sharing and strengthen collaboration between the agencies for further contribution to GGOS. The WG submitted a status report of geodetic observatories of Japan to GGOS in 2014 and updated it in 2017. The WG has also held a session on GGOS at annual meetings of Japan Geoscience Union (JpGU) since 2015. The theme of GGOS has also added in annual meeting of the Geodetic Society of Japan since 2018. Furthermore, GGOS invited the WG as the first GGOS Affiliate, which is a regional component of GGOS aiming to strengthen regional participation to GGOS and the WG has participated in and contributed to activities of GGOS from regional and national perspectives. As the first GGOS Affiliate, the WG hosted the GGOS annual meeting, GGOS Days 2018 in Tsukuba, Japan and discussed the future activities of GGOS for more strengthened collaboration between GGOS and the WG. In the meeting, current status and issues of network, observation, products and standard were discussed activities of three of four Focus Areas, 1. Unified Height System, 2. Geohazards, 4. Geodetic Space Weather were reported. Some members also reported the possibility of establishment of new GGOS affiliates in DACH countries, Scandinavia, Latin America and North America. The members agreed on the new WG in GGOS which will work on DOI of geodetic data. An update of GGOS guide book was also discussed in the meeting. In addition to the above activities, the WG organized special issue on GGOS in Journal of the Geodetic Society of Japan and also developed a Japanese brochure of GGOS in 2018 to facilitate understanding of the role and significance of GGOS for science and society. In 2018, some members of the WG participated in several international conferences related to GGOS and facilitated exchange of the latest information on geodetic observation. In 2019, we will continue sharing of information and strengthening collaboration in Japan and strengthen collaboration between GGOS and GGOS-WG of Japan.

VLBI-GNSS Co-location Survey at the Ishioka Geodetic Observing Station

*Saho Matsumoto[1], Michiko Umei[1], Haruka Ueshiba[1], Shinobu Kurihara[1], Tadao Kikkawa[1], Takahiro Wakasugi[1]

1. GSI of Japan

The International Terrestrial Reference Frame (ITRF) is realized by a combination of four space geodetic observing techniques (VLBI, SLR, GNSS and DORIS), where VLBI contributes in determining scale and EOP, and SLR contributes in determining scale and the center of mass. To perform this combination, it is necessary that relative coordinates between these space geodetic observing stations are precisely known at co-location sites.

The Ishioka Geodetic Observing Station operates the two space geodetic observing stations, VLBI and GNSS. Ishioka station is a fundamental site on a geodetic perspective since the VLBI station is one of the VGOS (VLBI Global Observing System) stations which is promoted by IVS (International VLBI Service for Geodesy and Astrometry) as the next-generation standards, and the GNSS station "ISHI" is registered as one of the IGS (International GNSS Service) sites. To measure the relative coordinate between the VLBI invariant point (IVP) and the GNSS reference point, we conducted the co-location survey in November 2018 in Ishioka station. In this survey, we adopted two methods to determine the IVP. One is "outside method" where we observe the target attached on the antenna movable part (near the counterweight) with "Total Station" at the reference pillars installed around the antenna. The other is "inside method" where we observe the targets attached near the IVP from the inside of the antenna cabin. "Inside method" was adopted for the first time in Ishioka station so we discussed the way of observation, computation and evaluation of error.

In this talk, we will report a co-location survey result in November 2018 and discuss details on two different methods.

Research of Crustal Deformation Model for Next Version of Japanese Geodetic Datum

*Kensuke Kokado[1]

1. GSI of Japan

Geospatial Information Authority of Japan (GSI) maintains the Japanese horizontal and vertical datum reference system and provides the accurate positions of control points including GNSS CORSs (Continuously Operating Reference Stations) as basic survey result based on the reference system. By utilizing the survey results as the reference position of various surveys and maps, people can receive location information service which positions are aligned with each other nationwide. Along with the progress of Global Navigation Satellite System (GNSS) and the satellite positioning techniques in recent years, it is expected that location information service will be developed using the high accuracy GNSS positioning.

However, there is some gaps due to the crustal deformation between the position of the survey results such as map and the measurement position of the GNSS positioning, which will be used in location information service. Therefore it is necessary to correct the crustal deformation that occurred between the reference date of map and the measurement date of the GNSS positioning in order to match the measurement position by GNSS with the map.

In order to properly correct the above gaps due to the crustal deformation, GSI plans to develop advanced correction system instead of the existing semi-dynamic correction system. For the system development, we have been researching the crustal deformation model considering not only steady crustal deformation but also postseismic deformation of the 2011 Tohoku-Oki earthquake or coseismic deformation of the other earthquakes caused along an active inland faults.

In this presentation, we will focus on the postseismic deformation of 2011 Tohoku-Oki earthquake among the contents of the research, and report the progress of the research to create the crustal deformation model in the Tohoku region.

Construction of a laser-strainmeter network for accurate seismic and geodetic observations

*Akito Araya[1], Akiteru Takamori[1], Wataru Morii[2], Akio Katsumata[3], Akio Kobayashi[3], Takeo Ito[4], Takashi Okuda[4], Makoto Okubo[5]

1. Earthquake Research Institute, University of Tokyo, 2. Disaster Prevention Research Institute, Kyoto University, 3. Meteorological Research Institute, Japan Meteorological Agency, 4. Graduate School of Environmental Studies, Nagoya University, 5. Natural Science Cluster, Kochi University

Laser interferometers are widely used for precise measurements of displacement with reference to wavelength of light. As their geophysical application, a laser strainmeter is used for measuring deformation of the ground by sensing distance between two separated points, enabling to detect small strain changes over wide frequency range [1]. The advantages of the laser strainmeter over conventional strainmeters using mechanical references are high resolution with a long baseline, resonance-free response of optical reference, and low-drift detection using stabilized laser wavelength. Apart from the instrumental detectability, local noise sources, such as changes in temperature, air pressure, and ground water level, will affect both the instrument and the ground, and should be properly evaluated to examine the measured strain data. For this purpose, we constructed a network of laser strainmeters deployed at three underground sites in Japan: Kamioka (Gifu Pref.), Inuyama (Aichi Pref.), and Tenryu-Funagira (Shizuoka Pref.). These strain data are analyzed to evaluate performance of instruments installed at these sites as well as to identify common geophysical signals.

At Kamioka site, two laser strainmeters with baselines of 100m and 1500m are in operation [2, 3]. At Inuyama and Tenryu-Funagira sites, a 30-m strainmeter and a 400-m one are installed, respectively [4]. These strainmeters clearly detect earth tides, and their amplitudes are consistent with the calculation based on the tidal force, the standard Earth's model, and the topographic effects around the sites. Using the site effects, coseismic strain steps observed by the strainmeter network are compared with fault parameters estimated from seismic observations and the detectability of the fault mechanisms using the strainmeter network is estimated. For long-term strain changes, local disturbances of the sites and detectability of the network are estimated using GNSS data. In the presentation, we discuss detectability of the strainmeter network for seismic and geodetic signals and prospects for monitoring crustal activities using long-baseline laser strainmeters.

UNAVCO GNSS Data: Real-time High-rate Streams, Geodetic Earthquake Magnitudes, Cloud Computing and Future Machine Learning Frameworks

*David A Phillips[1], Kathleen Hodgkinson[1], David Mencin[1], Charles Meertens[1], Thomas Herring[2], Walter Szeliga[3], Timothy Melbourne[3], Mark Murray[4], Glen Mattioli[1], Christine Puskas[1]

1. UNAVCO, Inc. Boulder, 2. Massachusetts Institute of Technology, 3. Central Washington University, 4. USGS

UNAVCO provides a diverse suite of geodetic data, derived products and cyberinfrastructure services to support the geodetic community, Earth science research and education. We present here an overview of recent developments related to real-time GNSS data streams, GNSS earthquake magnitude estimation, a new project focusing on machine learning for geoscience and hazards research, and cloud based GNSS data analysis experiments. UNAVCO operates the National Earth Science Geodetic Facility through a cooperative agreement with the U.S. National Science Foundation (NSF) and NASA.

Real-time (<2 seconds) high-rate (1 Hz) GNSS (RT-GNSS) data streams are now provided from ~900 UNAVCO sites. Streams include raw data in BINEX and RTCM3, and PPP solutions in ITRF2008 via Trimble PIVOT RTX software. Most UNAVCO RT-GNSS sites are within the Network of the Americas (NOTA). NOTA, which includes the historic Plate Boundary Observatory (PBO) network, is an extensive network of GNSS reference stations and other geophysical instruments in the United States, Mexico, Central America, the Caribbean and parts of South America. The network advances research into Earth systems from the core to the atmosphere. Recent advances include improved plate tectonic models, understanding earthquakes and slow slip/episodic tremor, measuring surface water load, deciphering ionospheric dynamics and measuring changes in permafrost. Beyond research the network provides information for earthquake and tsunami early warning systems (EWS), severe weather and space weather forecasts, volcanic activity alerts, drought and flood monitoring and other risk assessments. UNAVCO data are open access; an objective of the geodetic community is to enhance data access and data use for global hazard risk reduction.

Following an earthquake, RT-GNSS data streams can record peak ground displacement (PGD) measurements from long-period surface waves and provide a source-scaling relation that does not saturate with event magnitude. “Geodetic magnitudes” derived from RT-GNSS data can be estimated within seconds to minutes after an earthquake, and can improve earthquake and tsunami EWS. Dynamic displacements estimated in real time show reasonable agreement with post-processed estimates. And while individual position estimates have large errors, RT-GNSS solutions offer excellent operational potential for EWS, including the use of PGD to directly invert for finite-fault solutions. We will show PGD and geodetic magnitude estimate results from recent earthquakes including the 2018-11-30 Mw 7.0 Anchorage, Alaska earthquake. PGD’s from this earthquake were calculated automatically from the RT-GNSS displacement traces, which were large enough and recorded by enough sites to determine that, using GNSS data only, the event was ~M7 within 120s.

As the number of RT-GNSS sites increases, the volume of data and the complexity of automated analysis increase as well. When other data streams are factored in, such as seismic, ocean bottom pressure and satellite radar, the shear volume and complexity of these data streams, coupled with the need to model, analyze and assess hazards in a matter of only minutes, makes geophysical applications to hazards early

warning a Big Data problem. To address this, UNAVCO is collaborating in an NSF project called "GeoSCIFramework: Scalable Real-time Streaming Analytics and Machine Learning for Geoscience and Hazards Research." This project unites computer scientists and geoscientists to develop a data framework for generalized real-time streaming analytics and machine learning for geoscience and hazards research. The goals of this project, which was just initiated, will be presented.

In addition to real-time products, UNAVCO also provides post-processed position time series and velocities from 2000+ GNSS stations. These products are based on daily solutions generated using GIPSY PPP and GAMIT/GLOBK double-difference network software. This software is currently run on local computing clusters. As part of an NSF funded project called GeoSciCloud, we are testing our GIPSY and GAMIT workflows in two cloud computing environments: Amazon Web Services and NSF's Extreme Science and Engineering Discovery Environment (XSEDE). The IRIS seismic data facility is a collaborative partner on this project and conducted similar experiments using seismic software and data. We summarize our latest findings from these cloud computing experiments including performance and cost relative to local systems.

On application of GNSS-techniques for early tsunami warning in the Sea of Japan

*Grigorii Viktorovich Nechaev[1,2,3], Nikolai Shestakov[2,3], Hiroaki Takahashi[1], Mako Ohzono[1]

1. Institute of Seismology and Volcanology, Graduate Schooll of Science, Hokkaido University, 2. Far Eastern Federal University, 3. Institute for Applied Mathematics FEB RAS

Tsunami hazard threatens an extensive coastlines located in the seismically active areas. About 250000 persons were killed by tsunami only with the beginning of 21th century. Thus, the problem of reliable early tsunami warning is very important nowadays.
The most of working tsunami early warning systems (TEWS) are based on seismic methods that often cannot provide a reliable and accurate warning due to different reasons. The GNSS-based TEWS recently has been developed and they are free of many shortcomings of seismic methods. Such systems utilize coseismic shifts measured by onshore GNSS-networks for tsunami modeling. The TEWS operating now, for example, REGARD [Kawamoto S. et al., 2017], are mainly focused on detection of huge Mw8-9 class subduction zone earthquakes. They are not designed to process relatively small events, which can produce coseismic displacements less than 10 cm, despite on RTX-techniques or recently developed methods [Fratarcangeli F. et al., 2018], which can detect site position changes of 1-2 cm in horizontal and 3-4 cm in vertical components. However, devastating tsunamis regularly appear in the Japan Sea. They are caused by shallow thrust seismic events with magnitudes Mw6.2-7.8. These quakes generate tsunamis more effectively than Pacific ones with the same magnitude.The epicenters of tsunamigenic earthquakes are distributed along the western coast of Honshu, south-west of Hokkaido and Sakhalin Islands. Nevertheless, tectonics and seismicity of the Japan Seahaven't been sufficiently investigated still and tsunamigenic seismic events can occur along the north-western margin of the sea. For example, the potentially tsunamigenic Mw˜6 shallow seismic event occurred near the northeastern coast of Primorye on Nov. 11, 1990.
In this work we explored: 1) the capacity of GNSS-based TEWS application using data about historical Mw 6.2-7.8 Japan Sea crustal seismic events. The appropriate coseismic displacement fields were calculated and analyzed. Possible hypothetic tsunamigenic seismic sources were also considered; 2) the optimal GNSS-site distribution for earthquake source parameters obtaining based on existing and prospective GNSS-networks configuration in the region.
We obtained, that historical tsunamigenic earthquakes occurred along the eastern margin of the Japan Sea induced coseismic displacements ranging from 1 cm to a few decimeters through the northern Honshu and western Hokkaido. Even 1964 Oga-oki, Mw7.0 event caused up to 4 cm surface offsets on the Honshu Island coast. Southwestern Sakhalin Island are also might be affected by centimeter level coseismic movement invoked by the shallow Mw 6.2-7.3 earthquakes appeared in the north of the Sea of Japan and Tatar strait. Hypothetical events with Mw > 7.5 and located in the north-west of the sea may excite displacement varying from 1 to 4 cm in Russian Primorye and Hokkaido Island. A set of inversion tests lead us to a conclusion that GEONET GNSS-network might be used to model tsunamigenic earthquake sources with Mw>7.0-7.8 distributed along the eastern margin of the Japan Sea. Working and prospective GNSS-networks located along the western coast of the sea and Sakhalin Island might be involved into processing of seismic events with Mw ≧ 7.3 appeared in the northern part of the sea.

Measurements of occurrence of solar conjunction with the orbits of Asian QZSS/IGSO satellites

*Fujinobu Takahashi[1]

1. Yokohama National University

On the space PNT in the 20th century, the MEO satellite system represented by GPS space segment of USA has played a major role. In the 21st century, Japan's QZSS (Michibiki) satellite system and IGSO space segment of China and India are now appearing. The feature of the MEO satellite system is a scheme that the positioning accuracy is determined by randomly selecting MEO satellites above the elevation limit and by the satellites combination of smaller DOP. This is one of the stochastic based on the group of the randomly selected satellites, rather than the orbital theory of the satellite. Meanwhile the orbital motions of QZSS/IGSO of new 21st century are very slow over the respective earth regions. The more theoretical methods using satellite orbit models are available and the more reproducible analytic methods are possible. The author will report the measuring results of the orbital motion and the solar conjunctions of Asian QZSS/IGSO satellites over more than a year.

Sea level evaluation in northern Australian coast

*Yuta Tokui[1], Kosuke Heki[1]

1. Hokkaido University

Sea surface heights (SSH) are observed by satellite ocean altimetry, and it changes by two major causes. They are barystatic changes e.g. inflow of melt water from land ice, and thermal expansion of sea water, and they can be observed by GRACE and Argo floats, respectively. The three quantities behave differently from region to region, and their mutual link is important to understand regional characteristic of oceans. Here we study sea level changes in northern Australian coast (consisting of the Arafura, Timor, and Solomon Seas and the Gulf of Carpentaria). This region is characterized by large seasonal changes in SSH and gravity, and influenced by multiple climate changes such as ENSO (El Nino and Southern Oscillation) and IOD (Indian Ocean Dipole). First, we compare three changes (altimetric, thermosteric and gravity) to evaluate sea level budget. We found that SSH changes mainly come from steric changes excluding Gulf of Carpentaria where barystatic changes prevail. Next, we use the Empirical Orthogonal Functions (EOF) approach to identify the major modes of the seasonal and interannual variability. Seasonal changes in SSH are strong in Gulf of Carpentaria. The 1 st EOF of gravity indicates that main seasonal change occur in phase in the land and the sea. We also found that long-term precipitation variability appears as the 2nd EOF. The EOF analysis further showed that non-seasonal altimetric and gravity changes are driven mainly by climate changes, mainly ENSO in SSH and PDO in gravity.

Implications from geomagnetic observation for the interannual fluctuations of Earth rotation

*Seiki Asari[1], Masanori Kurihara[1], Kenji Morinaga[1], Shingo Nagamachi[1]

1. Kakioka Magnetic Observatory, Japan Meteorological Agency

Kakioka Magnetic Observatory has a history of magnetic observation over as long time as more then a century. It has supported a progress of scietific researches and industry by providing accurate data, developing observation technology, certifying measurement instruments, as well as playing a geodetic role as a magnetic reference station of Japan. The observatory is even increasingly expected to stay as one of world's principal observatories, with the increase of demands for prompt data issuance to serve as reference for the recent satellite magnetic observations.

Geomagnetic variations consist of different components with varying sources and timescales. The accumulation of enormous amount of data from the recent satellite observations in the late years have drawn attentions to the interannual variations of the geomagnetic main field originating in Earth core. These variations had not been well recognised, with their tiny signals hidden by the magnetic perturbations from the magnetosphere. If these signals are resolved more clearly, they can be a precious key to reveal the interannual phenomena in Earth fluid core such as hydromagnetic waves. Imaging of the core fluid flow relies entirely on mangetic observations, as the seismic and gravitational observations do not provide high enough sensitivity, while the net fluctuations of the core may be analysed by using Earth rotation variation.

Currently, monthly mean database for the past half century has been under construction at Kakioka Magnetic Observatory such that they are optimised for better identifying the interannual main field variations. It has been found that approximately 70 percent of the external field perturbations can be eliminated from monthly data at any observatories at low- and mid-latitudes. A better mapping of the fluid core flow may be possible for even longer period. In this presentation, a report for the progress and prospect is given, together with discussion on implications for the interannual Earth rotation fluctuations through the core flow map imaged from magnetic observations. A spatiotemporal features of the westward core fluid jet at the polar region in the northern hemisphere, which may be responsible for both the rapid changes in both the geomagnetic main field and the length-of-day.

[S-SS07] Rigorous Seismicity Modelling and Hypothesis Testing

convener:Jiancang Zhuang(Institute of Statistical Mathematics), Danijel Schorlemmer(GFZ German Research Centre for Geosciences), Matt Gerstenberger(GNS Science), Hiroshi Tsuruoka(Earthquake Research Institute, Tokyo Univ.)

Probabilistic models have been developed for describing, analyzing, and forecasting seismicity since more than 100 years and, with the advent of large-scale digital networks, in high resolution during the last 30 years. These models include recurrence and stress-release models for long-term earthquake hazard assessment, and short-term models describing earthquake clustering, e.g. the ETAS model. Some models have become standard tools in seismic hazard assessment. However, the overall probabilities remain on the low end and the uncertainties of the forecasts are not well described. Rigorous data-based development and testing of models will help further improving forecasting power and accuracy of these models. Similarly, new hypotheses shall be evaluated rigorously using some existing model as the null hypothesis model or in dedicated tests addressing the hypothesis directly. In this context, the Collaboratory for the Study of Earthquake Predictability and its Japan branch provides the necessary testing capabilities for rigorous and unbiased evaluation of models and hypotheses. This session focuses on research that increases information on seismicity, being with respect to a reference model or as an independent hypothesis. We solicit contributions of model developments and hypothesis formulation based on the increased understanding of the physical process of earthquakes, such as the preparation and rupture processes of the earthquake source and the interaction between earthquakes and tectonic environments. We also welcome development and implementation of improved statistical methods for testing and validating physical hypotheses based on observed data. In particular, we welcome contributions about model- or hypothesis-test experiments that could be implemented in the Japan testing center.

Development of Physics-based Ground Motion Simulation in A Hybrid Approach and Applications to Seismic Hazard Assessment in Taiwan

*Ming-Che Hsieh[1], Yin-Tung Yen[1], Kuo-Fong Ma[2,3]

1. Disaster Prevention Technology Research Center, Sinotech Engineering Consultants (Inc.), Taiwan, 2. Department of Earth Sciences, National Central University, Taiwan, 3. Earthquake-Disaster & Risk Evaluation and Management Center, National Central University, Taiwan

Damages to engineering structures by an earthquake depend on the entire time history of the ground motion, which is affected by a number of factors including source-rupture process, seismic-wave velocity structure, topographic relief, and local site condition. To quantitatively assess these effects to ground motion, physics-based ground motion simulation is a powerful tool which enables rigorous modeling of each effect and their coupling. In this study, we present a recent-developed physics-based ground motion simulator in generating broadband seismograms for seismic hazard assessment. The simulator is essentially based on a hybrid approach in which long-period synthetics are calculated by the efficient 3-D strain Green’ s tensor (SGT) and short-period synthetics are modeled by the stochastic method. Physical effects of (1) source slip distribution, (2) seismic wave propagation, (3) surface topography and (4) site amplification are taken into account. This hybrid approach has been validated by the 2016 M_W6.6 Meinong earthquake in southern Taiwan and reveals good potential for engineering applications. We also carried out simulations to model rupture scenarios of seismogenic structure and subduction zone sources. Output full waveform and ground motion parameters, e.g. peak ground acceleration (PGA) and 1.0-s-period spectral acceleration (SA1.0), have been further implemented to risk estimation, and even earthquake drill. Our result shows the ground motion simulator has the potential for earthquake scenario modeling and hazard assessment.

University of California Los Angeles, Los Angeles, USA, 9. University of Shizuoka, Shizuoka, Japan, 10. Institute of Statistical Mathematics, Tachikawa, Japan

The Collaboratory for the Study of Earthquake Predictability (CSEP) has expanded over the years to many different testing areas hosted at multiple testing centers. Hundreds of earthquake forecast models have been submitted to CSEP and are being tested. New testing metrics were developed and implemented and a lot of progress was made to establish CSEP as an institution that cannot be ignored when issuing earthquake forecasts. Its rigor and independence became the standard in evaluating earthquake forecasts and in reporting on the results.

In the framework of the testing activities of the Global Earthquake Model, one line of expanding the capabilities of CSEP was developed at GFZ Potsdam. The group there applied the mechanisms that CSEP introduced to earthquake forecast models to the area of intensity prediction equations (IPEs) and ground-motion prediction equations (GMPEs). The first truly prospective tests were carried out on IPEs for Italy and also on GMPEs for Japan and New Zealand. This new set of tests helped CSEP move into the hazard domain and increase the relevance of its results to the hazard community. Finally, the group at GFZ Potsdam has also conducted the first prospective test of the US national seismic hazard maps.

Although these tests have been successful and well-received, they have also shown the limitations of the CSEP approach. Many aspects of seismic hazard or earthquake forecasting remain inherently untestable if only the model forecasts are tested and not the model ingredients. We propose to continue along the lines of the GFZ Potsdam developments and create new areas of activity for CSEP, namely targeted experiments that cannot be conducted with the current CSEP software system. As part of the eGSIM (European Ground Shaking Intensity Models) service, we will introduce permanent testing of IPEs and GMPEs to the testing center to establish strong performance records to be used in hazard models. Further targeted experiments include the predictive power of b-values, discrimination of foreshocks for short-term forecasting, as well as a deeper look into precursory
phenomena applying CSEP-style rigorous testing. We support including testability in future hazard models or their components to move to better testable seismic hazard models. Finally, to expand into the risk domain, we will test exposure models against new and independent data.

Precision versus uncertainty in regional seismic hazard mapping

*Matt Gerstenberger[1], Danijel Schorlemmer[2]

1. GNS Science, 2. GFZ-Potsdam

Regional and national seismic hazard mapping efforts have increasingly pursued more detailed and precise models and outputs, particularly in terms of source characterisation and modelling. With increasing precision comes increasing uncertainty. In recent years much attention has been paid to modelling uncertainty in ground-motion models and including this in seismic hazard modelling. However, much less effort has been made to quantify and model uncertainty in seismic source characterisation. This raises two questions: 1) is increasing precision appropriate when uncertainty remains poorly quantified? 2) what is the optimal balance between precision and uncertainty? Ultimately the answer to this depends on the end-uses of the models and the implications of increasing uncertainty with increasing precision. Here we explore some of the main sources of uncertainty in seismic source characterisation such as incomplete and limited records of earthquake occurrence in paleoseismic data and earthquake catalogues, non-stationarity of seismicity and the poisson assumption, fault source characterisation and so-called moment balancing. We pay particular focus to uncertainties in estimating hazard in less seismically active regions and the implications for building design guidance.

An extreme value analysis of seismograms designed for early forecast of aftershocks

*Kaoru Sawazaki[1]

1. National Research Institute for Earth Science and Disaster Resilience

Conventional aftershock forecasting has been operated through applying the Gutenberg-Richter and Omori-Utsu laws to an earthquake catalog. However, catalog's quality is influenced by detectability of earthquake signals (P or S waves), which causes degradation of the catalog in the early stage after a large earthquake and at regions which are sparsely covered by seismograph network. This eventually causes the catalog's nonuniformity and limitation of the forecasting performance.

In this study, we propose a new approach designed for high-performance early aftershock forecasting without using earthquake catalog. Instead, we use a continuous seismogram recorded at each station. First, we pick the maximum amplitude of the seismogram obtained in every assigned time interval (e.g., 1 minute). This picking process can be completely automated and is rarely affected by overlap of multiple seismic signals occurring in approximately the same time. We empirically derive a probability distribution (PD) that accounts for the frequency of the maximum amplitudes. This PD is essentially a non-stationary extreme value distribution derived from the generalized Pareto distribution (GPD) and the Omori-Utsu type temporal decay. We optimize three parameters that control the PD shape (K_a: parameter that controls whole aftershock activity, p_a: parameter that controls temporal decay of the aftershock frequency, m: parameter that controls power-law decay of the maximum amplitude) by applying the maximum likelihood estimation to the observed maximum amplitudes. By extrapolating the optimized PD, we estimate the number of maximum amplitudes that will exceed a threshold value within arbitral time interval in the future. The proposed approach provides forecast of peak ground motion at each station rather than magnitude, which is directly desired for public use. Moreover, the forecasted peak ground motion may automatically incorporate many factors that cannot be described by a simple ground motion attenuation model (e.g., site amplification, radiation pattern, rupture directivity, and so on).

We apply the proposed method to 25 Hi-net seismograms recorded the 2016 Kumamoto earthquakes in Japan. We set the learning periods every one hour after the mainshock (Mj7.3), and set the forecasting period within 24 hours after the end of each learning period. We find that parameters K_a and m become temporally stable within a few hours after the mainshock at many stations. On the other hand, the parameter p_a temporally varies more probably because the induced seismicity at northeast area (Aso and Oita regions) strongly affects the apparent temporal decay rate of the amplitudes. Within 3 hours after the mainshock, the forecasted number of the maximum amplitudes exceeding 10^{-4} m/s is within 0.5 to 2.0 times the actual observation for about 80 % of the used stations. For the threshold amplitude of 10^{-3} m/s, on the other hand, the forecasted number tends to overestimate, probably due to saturation of seismograms by both artificial and physical reasons.

Spatio-temporal clustering of successive earthquakes: data analyses of global data.

*THYSTERE MATONDO BANTIDI[1], Takeshi Nishimura[1]

1. Tohoku University

Spatio-temporal clustering of seismicity is an interesting phenomenon in the earthquake generation process. We investigate the earthquakes closely occurring in space and time, which have been sometimes observed at various regions. A recent example is *Mw*6.5 earthquake at Hinagu active fault on April 14, 2016, followed by a *Mw*7.3 at Futagawa active fault on April 16. The present study analyzes moderate and large earthquakes to clarify characteristics of such successive occurrence of earthquakes.

We use the Global Centroid Moment Tensor catalog for the period from 1976 to 2016. Earthquakes with moment magnitudes (*Mw*) of larger or equal to 5.0 and with depths less than or equal to 70 km are analyzed. The earthquakes that occur within some horizontal distance ranges (Δd*:* from 10 to 500 km*)*, and lapse times (Δt=30, 180 and 365 days*)* from the occurrence of each target earthquake is grouped in a cluster, and the number of clusters are counted.

The results show that cumulative numbers of clusters almost constantly increase in the logarithmic scale with increasing Δt, and the number of clusters increases constantly in general with increasing Δd. For example, for the *Mw* 5.0 –5.5, the cumulative number of clusters at Δd*=100* km are 3177, 4525 and 4808, respectively, for Δt of 30, 180 and 365 days.

To examine whether or not these successive earthquakes occur randomly, in other words, whether or not these successive earthquakes occur under some physical conditions, we compare the observed results with simulations in which earthquakes are set to randomly occur in time. The results show that the observed cumulative numbers of clusters are larger than those of simulation in short distance ranges. The former gradually approach to the latter with increasing the horizontal distance, and merge into a same number at a distance, which is defined as “triggering distance” in the present study. As Δt increases, the occurrence probability decreases and approaches to the normal condition in which the occurrence time intervals of earthquakes obey a Poisson distribution. For example, the triggering distances of Mw5.0-5.5 are 420 km and 66 km, respectively, for Δt*=30* days and *365* days. The results obtained by changing the parameters related to the spatial and temporal distributions of aftershock show no significant difference in the number of clusters and triggering distances.

Kanto 3 month testing class results of CSEP Japan

*Hiroshi Tsuruoka[1], Naoshi Hirata[1]

1. Earthquake Research Institute, Tokyo Univ.

We report about 3 month testing class results of Kanto test region of CSEP Japan. We show the results of three models: RI10K, HISTETAS5PA and HISTETAS5PA1205. HISTETAS5 PA1205 is a model submitted to the Japan test center after the Tohoku-oki earthquake. The test results are about 40 rounds evaluated from 1 November 2009.

From the standard test results of CSEP, RI10K did not pass the S-test in the round of 2017/5 / 1-8 / 1. In addition, there were some rounds that did not pass N-Test in all models when the number of observed earthquakes was relatively small. Calculating the average of information gain values per earthquake for each model in all rounds was 1.419, 1.168, 1.162 for HISTETAS5PA1205, HISTETAS5PA, and RI10K respectively. Regarding the forecast of the number of earthquakes, HISTETA5PA1205 predicts the number of observation earthquakes well.

From the results of multiple rounds, forecast number of earthquakes improvement directly leads to improvement of an earthquake forecast model. Moreover, a model characteristic can be showed well by evaluating the spatial forecast performance and the performance of forecast number of earthquakes.

Long-term earthquake risk in North China estimated from a modern catalogue

Ziyao Xiong[2], *Jiancang Zhuang[1], Shiyong Zhou[2]

1. Institute of Statistical Mathematics, 2. Peking University

In this study, to obtain optimal estimates of the earthquake hazard in North China based on the modern earthquake catalogue, we used two variable kernel function estimation methods and two spatial tessellation methods to calculate the total and background seismic spatial occurrence rates for the study area.

The first problem of this study is to derive the best estimate of the long-term earthquake risk in North China. To address the first problem, we use the kernel function estimation methods of Stock and Smith (2002) and Zhuang et al. (2002), the Bayesian Delaunay-Tessellation Smoothing Method used by Ogata (ODTB) (2003, 2004), and ICVT to estimate the total earthquake hazard for North China. The results were compared and analyzed through the cross-validation method, to ensure accurate reflection of the seismic activity in North China. The sophisticated ODTB method is more stable than the others, but is relatively expensive, in terms of computation demands, while Zhuang et al.’ s kernel estimate and the new ICVT method are able to provide reasonable estimates and easier to implement.

For the second problem, of b-value, we use Ogata’ s method (2004, 2015) based on free nodes, to calculate the *b*-value spatial distribution. We expect that the obtained results of the spatial distribution of seismic risk and *b*-value provide a reference for the evaluation and prediction of large earthquakes and stress distribution in the study area.

For the third problem, we use two methods to estimate background seismic rates, and compare the results. The first method uses the result of the background seismic event probability, calculated by the epidemic-type aftershock sequence (ETAS) model (Zhuang et al., 2002; Zhuang, 2011), to simulate the background seismic risk distribution. The second method is to calculate the spatial distribution of earthquake hazard by using the HIST-ETAS model (Ogata, 2004).

Using comparative analyses and simulation experiments, we show that all of methods give similar spatial patterns of seismic occurrences.

Distributions of focal mechanisms in background seismicity and earthquake clusters in Japan

*Jiancang Zhuang[1,2], Eri Maita[2]

1. Institute of Statistical Mathematics, 2. Graduate University for Advanced Studies

This study tries to find the probability distributions of focal mechanisms in background seismicity and earthquake clusters in Japan by analyzing F-net data. To describe the probability distribution, each focal mechanism is discomposed as the result of a rotation about a particular pole starting from a reference focal mechanism. In this study, DC4 symmetry is considered, i.e., either nodal-plane can be the fault plane and the two sides of the fault plane are distinguishable.

To separate the background and clustering seismicity, we fit the space-time ETAS model (e.g., Zhuang et al, 2011) to the earthquakes with magnitude 4.2+ from 1997 to 2017 in the F-net catalog, and use the stochastic declustering method to estimate the background probabilities that each event is a background event and the triggered probabilities that each event is triggered by other events.

For the background events, the reference focal mechanism is taken as the average focal mechanism in each area, calculated by the method in Kagan (2014). The ration angles between a background event and the mean focal mechanisms at *(x, y)* is reconstructed by

$\zeta(\Delta) \propto \sum_j \phi_j I$(Rotation angle betwen *j* and the mean focal mechanism is within $(\Delta-\delta, \Delta+\delta)$),

where *j* runs over all background events near *x,y,* δ is a small number, and ϕj is the background probability estimated from fitting the space-time ETAS model. For the triggered events, the reference focal mechanism is naturally taken the focal mechanism of the event which triggers it. The rotation angles between the parent event and its direct offspring are reconstructed by

$\xi(\Delta) \propto \sum_{i,j} \rho_{i,j} I$(Rotation angle betwen *i* and *j* is within $(\Delta-\delta, \Delta+\delta)$) .

where *i* and *j* run over all the event pairs in the catalog, ρij is the probability that event *j* is triggered by event *i* estimated based on the ETAS model.

We find that the rotation poles are almost uniformly distributed. The reconstructed results for the rotation angles are shown in Figure 1.

Figure 1 (a) mean focal mechanisms of background seismicity in Japan. (b) Reconstructed distribution of rotation angles for focal mechanisms in the background seismicity and triggered seismicity.

New Ground Motion Prediction Equations for Western Saudi Arabia

*Ryota Kiuchi[1,2], Walter Mooney[1], Hani Zahran[3]

1. U.S. Geological Survey, 2. Disaster Prevenetion Research Institute, Kyoto University, 3. Saudi Geological Survey

We developed Ground Motion Prediction Equations (GMPEs) for western Saudi Arabia using 2770 selected records of PGA and PGV from 177 earthquakes of magnitude 3.0 –5.4, recorded at 58 stations in the distance range from 1 km to 400 km. Our GMPEs are developed based on one of the NGA-West2 Project GMPEs (Boore et al., 2014) by employing a mixed effects regression model.

Saudi Arabia is surrounded by several active tectonic regions, including an extension in the Red Sea and left-lateral strike-slip motion in the Gulf of Aqaba and along the Dead Sea Transform Fault (DSTF). In this area, multiple seismic swarms in and around volcanic fields, also known as harrats, have been detected over the past several decades (El-Isa and Shanti, 1989). The most recent large earthquake swarm in the region, which included more than 30,000 earthquakes, occurred from April to June 2009 beneath the volcanic field of Harrat Lunayyir in northwestern Saudi Arabia. The strongest seismic activity occurred May 13-19, 2009 and consisted of events M > 4 (Pallister et al., 2010). The largest earthquake occurred on May 19th, ML 5.4 as estimated by the SGS (Saudi Geological Survey) and Mw 5.7 by the USGS.

The NGA-West2 project used as a reference model mainly consists of shallow crustal earthquakes in active tectonic regions, rather than extensional earthquakes, such as those observed in Saudi Arabia. This deficiency is corrected by calculating a magnitude scaling of the new Saudi Arabia GMPEs compared to those of Boore et al. (2014). Furthermore, there is a clear difference in distance scaling for the Arabian GMPEs in comparison with the NGA-West2 GMPEs. This difference is especially significant at large distances and is mainly due to lower anelastic attenuation in the crystalline crust of western Saudi Arabia. Our empirical data demonstrate that the GMPEs presented here are in good agreement with observed earthquake ground motions in western Saudi Arabia.

Study on the spatial and temporal change of velocity structure before and after 2003 Chengkung earthquake, Taiwan

*TING YA LIANG[1], Wen-Yen Chang[1,2,3], Strong Wen[4]

1. National DONG HWA University, 2. Eastern Taiwan Earthquake Research Center, 3. National Center for Research on Earthquake Engineering, 4. National Chung Cheng University

Taiwan is located in the plate converge zone, in which the Longitudinal Valley(LV) is the suture zone between the Eurasian Plate and Philippine Sea Plate. The collision process yields two nearly parallel major fault systems: the Central Range fault (CRF) and the Longitudinal Valley fault(LVF). The Chihshang fault is a creeping thrust fault, which is located in the southern section of the LVF in eastern Taiwan. According to geodetic survey, this fault moves to northwest at a rate approximately 2–3 cm/yr. There were two significant earthquakes occurred nearby the Chihshang fault, the 1951 M7.1 Hualien-Taitung earthquake and the 2003 M6.4 Chengkung earthquake. In this study, the spatial and temporal variations of velocity structure before and after 2003 Chengkung earthquake were obtained through the tomography inversion beneath the southern segment of the Longitudinal Valley. The damping least-square technique and 3D ray tracing scheme were adopted to calculate the most appropriate solution and obtain the velocity structures. The results showed that the Vp values exhibit less significant variations than the parameters Vs and Vp/Vs ratio. But the Vs structures show larger variation after the 2003 mainshock. These results imply that Vp/Vs ratios began to increase before the mainshock, at the hanging wall of the Chihshang fault, which may be related to the increasing density of microcracks and fluid. Previous studies has shown that high Vp/Vs ratio may lead to cracks generating and fluid migration, which can result in changing rock volume and produce partial compensation. Therefore, our results not only give better understanding the seismogenic structures in the ES Taiwan, but also allow us to detect variations of physical parameters caused by crack propagating in stratum during the strong earthquake sequence. Hence, this study shows that the results from temporal and spatial variation of Vp/Vs values in the southern segment of the LVF could allow us to assess the seismic hazard potential in this area, and further explore the relationship between the seismicity and the rheology of fault plane. Finally, long-term monitoring of fault activities will contribute to the research of future earthquake early warning.

[S-SS07] Rigorous Seismicity Modelling and Hypothesis Testing

convener:Jiancang Zhuang(Institute of Statistical Mathematics), Danijel Schorlemmer(GFZ German Research Centre for Geosciences), Matt Gerstenberger(GNS Science), Hiroshi Tsuruoka(Earthquake Research Institute, Tokyo Univ.)

Probabilistic models have been developed for describing, analyzing, and forecasting seismicity since more than 100 years and, with the advent of large-scale digital networks, in high resolution during the last 30 years. These models include recurrence and stress-release models for long-term earthquake hazard assessment, and short-term models describing earthquake clustering, e.g. the ETAS model. Some models have become standard tools in seismic hazard assessment. However, the overall probabilities remain on the low end and the uncertainties of the forecasts are not well described. Rigorous data-based development and testing of models will help further improving forecasting power and accuracy of these models. Similarly, new hypotheses shall be evaluated rigorously using some existing model as the null hypothesis model or in dedicated tests addressing the hypothesis directly. In this context, the Collaboratory for the Study of Earthquake Predictability and its Japan branch provides the necessary testing capabilities for rigorous and unbiased evaluation of models and hypotheses. This session focuses on research that increases information on seismicity, being with respect to a reference model or as an independent hypothesis. We solicit contributions of model developments and hypothesis formulation based on the increased understanding of the physical process of earthquakes, such as the preparation and rupture processes of the earthquake source and the interaction between earthquakes and tectonic environments. We also welcome development and implementation of improved statistical methods for testing and validating physical hypotheses based on observed data. In particular, we welcome contributions about model- or hypothesis-test experiments that could be implemented in the Japan testing center.

Development of Physics-based Ground Motion Simulation in A Hybrid Approach and Applications to Seismic Hazard Assessment in Taiwan

*Ming-Che Hsieh[1], Yin-Tung Yen[1], Kuo-Fong Ma[2,3]

1. Disaster Prevention Technology Research Center, Sinotech Engineering Consultants (Inc.), Taiwan, 2. Department of Earth Sciences, National Central University, Taiwan, 3. Earthquake-Disaster & Risk Evaluation and Management Center, National Central University, Taiwan

Damages to engineering structures by an earthquake depend on the entire time history of the ground motion, which is affected by a number of factors including source-rupture process, seismic-wave velocity structure, topographic relief, and local site condition. To quantitatively assess these effects to ground motion, physics-based ground motion simulation is a powerful tool which enables rigorous modeling of each effect and their coupling. In this study, we present a recent-developed physics-based ground motion simulator in generating broadband seismograms for seismic hazard assessment. The simulator is essentially based on a hybrid approach in which long-period synthetics are calculated by the efficient 3-D strain Green’ s tensor (SGT) and short-period synthetics are modeled by the stochastic method. Physical effects of (1) source slip distribution, (2) seismic wave propagation, (3) surface topography and (4) site amplification are taken into account. This hybrid approach has been validated by the 2016 M_W6.6 Meinong earthquake in southern Taiwan and reveals good potential for engineering applications. We also carried out simulations to model rupture scenarios of seismogenic structure and subduction zone sources. Output full waveform and ground motion parameters, e.g. peak ground acceleration (PGA) and 1.0-s-period spectral acceleration (SA1.0), have been further implemented to risk estimation, and even earthquake drill. Our result shows the ground motion simulator has the potential for earthquake scenario modeling and hazard assessment.

The Collaboratory for the Study of Earthquake Predictability (CSEP) has expanded over the years to many different testing areas hosted at multiple testing centers. Hundreds of earthquake forecast models have been submitted to CSEP and are being tested. New testing metrics were developed and implemented and a lot of progress was made to establish CSEP as an institution that cannot be ignored when issuing earthquake forecasts. Its rigor and independence became the standard in evaluating earthquake forecasts and in reporting on the results.

In the framework of the testing activities of the Global Earthquake Model, one line of expanding the capabilities of CSEP was developed at GFZ Potsdam. The group there applied the mechanisms that CSEP introduced to earthquake forecast models to the area of intensity prediction equations (IPEs) and ground-motion prediction equations (GMPEs). The first truly prospective tests were carried out on IPEs for Italy and also on GMPEs for Japan and New Zealand. This new set of tests helped CSEP move into the hazard domain and increase the relevance of its results to the hazard community. Finally, the group at GFZ Potsdam has also conducted the first prospective test of the US national seismic hazard maps.

Although these tests have been successful and well-received, they have also shown the limitations of the CSEP approach. Many aspects of seismic hazard or earthquake forecasting remain inherently untestable if only the model forecasts are tested and not the model ingredients. We propose to continue along the lines of the GFZ Potsdam developments and create new areas of activity for CSEP, namely targeted experiments that cannot be conducted with the current CSEP software system. As part of the eGSIM (European Ground Shaking Intensity Models) service, we will introduce permanent testing of IPEs and GMPEs to the testing center to establish strong performance records to be used in hazard models. Further targeted experiments include the predictive power of b-values, discrimination of foreshocks for short-term forecasting, as well as a deeper look into precursory
phenomena applying CSEP-style rigorous testing. We support including testability in future hazard models or their components to move to better testable seismic hazard models. Finally, to expand into the risk domain, we will test exposure models against new and independent data.

Precision versus uncertainty in regional seismic hazard mapping

*Matt Gerstenberger[1], Danijel Schorlemmer[2]

1. GNS Science, 2. GFZ-Potsdam

Regional and national seismic hazard mapping efforts have increasingly pursued more detailed and precise models and outputs, particularly in terms of source characterisation and modelling. With increasing precision comes increasing uncertainty. In recent years much attention has been paid to modelling uncertainty in ground-motion models and including this in seismic hazard modelling. However, much less effort has been made to quantify and model uncertainty in seismic source characterisation. This raises two questions: 1) is increasing precision appropriate when uncertainty remains poorly quantified? 2) what is the optimal balance between precision and uncertainty? Ultimately the answer to this depends on the end-uses of the models and the implications of increasing uncertainty with increasing precision. Here we explore some of the main sources of uncertainty in seismic source characterisation such as incomplete and limited records of earthquake occurrence in paleoseismic data and earthquake catalogues, non-stationarity of seismicity and the poisson assumption, fault source characterisation and so-called moment balancing. We pay particular focus to uncertainties in estimating hazard in less seismically active regions and the implications for building design guidance.

An extreme value analysis of seismograms designed for early forecast of aftershocks

*Kaoru Sawazaki[1]

1. National Research Institute for Earth Science and Disaster Resilience

Conventional aftershock forecasting has been operated through applying the Gutenberg-Richter and Omori-Utsu laws to an earthquake catalog. However, catalog's quality is influenced by detectability of earthquake signals (P or S waves), which causes degradation of the catalog in the early stage after a large earthquake and at regions which are sparsely covered by seismograph network. This eventually causes the catalog's nonuniformity and limitation of the forecasting performance.

In this study, we propose a new approach designed for high-performance early aftershock forecasting without using earthquake catalog. Instead, we use a continuous seismogram recorded at each station. First, we pick the maximum amplitude of the seismogram obtained in every assigned time interval (e.g., 1 minute). This picking process can be completely automated and is rarely affected by overlap of multiple seismic signals occurring in approximately the same time. We empirically derive a probability distribution (PD) that accounts for the frequency of the maximum amplitudes. This PD is essentially a non-stationary extreme value distribution derived from the generalized Pareto distribution (GPD) and the Omori-Utsu type temporal decay. We optimize three parameters that control the PD shape (K_a: parameter that controls whole aftershock activity, p_a: parameter that controls temporal decay of the aftershock frequency, m: parameter that controls power-law decay of the maximum amplitude) by applying the maximum likelihood estimation to the observed maximum amplitudes. By extrapolating the optimized PD, we estimate the number of maximum amplitudes that will exceed a threshold value within arbitral time interval in the future. The proposed approach provides forecast of peak ground motion at each station rather than magnitude, which is directly desired for public use. Moreover, the forecasted peak ground motion may automatically incorporate many factors that cannot be described by a simple ground motion attenuation model (e.g., site amplification, radiation pattern, rupture directivity, and so on).

We apply the proposed method to 25 Hi-net seismograms recorded the 2016 Kumamoto earthquakes in Japan. We set the learning periods every one hour after the mainshock (Mj7.3), and set the forecasting period within 24 hours after the end of each learning period. We find that parameters K_a and m become temporally stable within a few hours after the mainshock at many stations. On the other hand, the parameter p_a temporally varies more probably because the induced seismicity at northeast area (Aso and Oita regions) strongly affects the apparent temporal decay rate of the amplitudes. Within 3 hours after the mainshock, the forecasted number of the maximum amplitudes exceeding 10^{-4} m/s is within 0.5 to 2.0 times the actual observation for about 80 % of the used stations. For the threshold amplitude of 10^{-3} m/s, on the other hand, the forecasted number tends to overestimate, probably due to saturation of seismograms by both artificial and physical reasons.

Spatio-temporal clustering of successive earthquakes: data analyses of global data.

*THYSTERE MATONDO BANTIDI[1], Takeshi Nishimura[1]

1. Tohoku University

Spatio-temporal clustering of seismicity is an interesting phenomenon in the earthquake generation process. We investigate the earthquakes closely occurring in space and time, which have been sometimes observed at various regions. A recent example is *Mw*6.5 earthquake at Hinagu active fault on April 14, 2016, followed by a *Mw*7.3 at Futagawa active fault on April 16. The present study analyzes moderate and large earthquakes to clarify characteristics of such successive occurrence of earthquakes.

We use the Global Centroid Moment Tensor catalog for the period from 1976 to 2016. Earthquakes with moment magnitudes (*Mw*) of larger or equal to 5.0 and with depths less than or equal to 70 km are analyzed. The earthquakes that occur within some horizontal distance ranges (Δd*:* from 10 to 500 km*)*, and lapse times (Δt=30, 180 and 365 days*)* from the occurrence of each target earthquake is grouped in a cluster, and the number of clusters are counted.

The results show that cumulative numbers of clusters almost constantly increase in the logarithmic scale with increasing Δt, and the number of clusters increases constantly in general with increasing Δd. For example, for the *Mw* 5.0 –5.5, the cumulative number of clusters at Δd*=100* km are 3177, 4525 and 4808, respectively, for Δt of 30, 180 and 365 days.

To examine whether or not these successive earthquakes occur randomly, in other words, whether or not these successive earthquakes occur under some physical conditions, we compare the observed results with simulations in which earthquakes are set to randomly occur in time. The results show that the observed cumulative numbers of clusters are larger than those of simulation in short distance ranges. The former gradually approach to the latter with increasing the horizontal distance, and merge into a same number at a distance, which is defined as “triggering distance” in the present study. As Δt increases, the occurrence probability decreases and approaches to the normal condition in which the occurrence time intervals of earthquakes obey a Poisson distribution. For example, the triggering distances of Mw5.0-5.5 are 420 km and 66 km, respectively, for Δt*=30* days and *365* days. The results obtained by changing the parameters related to the spatial and temporal distributions of aftershock show no significant difference in the number of clusters and triggering distances.

Kanto 3 month testing class results of CSEP Japan

*Hiroshi Tsuruoka[1], Naoshi Hirata[1]

1. Earthquake Research Institute, Tokyo Univ.

We report about 3 month testing class results of Kanto test region of CSEP Japan. We show the results of three models: RI10K, HISTETAS5PA and HISTETAS5PA1205. HISTETAS5 PA1205 is a model submitted to the Japan test center after the Tohoku-oki earthquake. The test results are about 40 rounds evaluated from 1 November 2009.

From the standard test results of CSEP, RI10K did not pass the S-test in the round of 2017/5 / 1-8 / 1. In addition, there were some rounds that did not pass N-Test in all models when the number of observed earthquakes was relatively small. Calculating the average of information gain values per earthquake for each model in all rounds was 1.419, 1.168, 1.162 for HISTETAS5PA1205, HISTETAS5PA, and RI10K respectively. Regarding the forecast of the number of earthquakes, HISTETA5PA1205 predicts the number of observation earthquakes well.

From the results of multiple rounds, forecast number of earthquakes improvement directly leads to improvement of an earthquake forecast model. Moreover, a model characteristic can be showed well by evaluating the spatial forecast performance and the performance of forecast number of earthquakes.

Long-term earthquake risk in North China estimated from a modern catalogue

Ziyao Xiong[2], *Jiancang Zhuang[1], Shiyong Zhou[2]

1. Institute of Statistical Mathematics, 2. Peking University

In this study, to obtain optimal estimates of the earthquake hazard in North China based on the modern earthquake catalogue, we used two variable kernel function estimation methods and two spatial tessellation methods to calculate the total and background seismic spatial occurrence rates for the study area.

The first problem of this study is to derive the best estimate of the long-term earthquake risk in North China. To address the first problem, we use the kernel function estimation methods of Stock and Smith (2002) and Zhuang et al. (2002), the Bayesian Delaunay-Tessellation Smoothing Method used by Ogata (ODTB) (2003, 2004), and ICVT to estimate the total earthquake hazard for North China. The results were compared and analyzed through the cross-validation method, to ensure accurate reflection of the seismic activity in North China. The sophisticated ODTB method is more stable than the others, but is relatively expensive, in terms of computation demands, while Zhuang et al.’ s kernel estimate and the new ICVT method are able to provide reasonable estimates and easier to implement.

For the second problem, of b-value, we use Ogata’ s method (2004, 2015) based on free nodes, to calculate the *b*-value spatial distribution. We expect that the obtained results of the spatial distribution of seismic risk and *b*-value provide a reference for the evaluation and prediction of large earthquakes and stress distribution in the study area.

For the third problem, we use two methods to estimate background seismic rates, and compare the results. The first method uses the result of the background seismic event probability, calculated by the epidemic-type aftershock sequence (ETAS) model (Zhuang et al., 2002; Zhuang, 2011), to simulate the background seismic risk distribution. The second method is to calculate the spatial distribution of earthquake hazard by using the HIST-ETAS model (Ogata, 2004).

Using comparative analyses and simulation experiments, we show that all of methods give similar spatial patterns of seismic occurrences.

Distributions of focal mechanisms in background seismicity and earthquake clusters in Japan

*Jiancang Zhuang[1,2], Eri Maita[2]

1. Institute of Statistical Mathematics, 2. Graduate University for Advanced Studies

This study tries to find the probability distributions of focal mechanisms in background seismicity and earthquake clusters in Japan by analyzing F-net data. To describe the probability distribution, each focal mechanism is discomposed as the result of a rotation about a particular pole starting from a reference focal mechanism. In this study, DC4 symmetry is considered, i.e., either nodal-plane can be the fault plane and the two sides of the fault plane are distinguishable.

To separate the background and clustering seismicity, we fit the space-time ETAS model (e.g., Zhuang et al, 2011) to the earthquakes with magnitude 4.2+ from 1997 to 2017 in the F-net catalog, and use the stochastic declustering method to estimate the background probabilities that each event is a background event and the triggered probabilities that each event is triggered by other events.

For the background events, the reference focal mechanism is taken as the average focal mechanism in each area, calculated by the method in Kagan (2014). The ration angles between a background event and the mean focal mechanisms at *(x, y)* is reconstructed by

$\zeta(\Delta) \propto \sum_j \phi_j I$(Rotation angle betwen *j* and the mean focal mechanism is within $(\Delta-\delta, \Delta+\delta)$),

where *j* runs over all background events near *x,y,* δ is a small number, and ϕj is the background probability estimated from fitting the space-time ETAS model. For the triggered events, the reference focal mechanism is naturally taken the focal mechanism of the event which triggers it. The rotation angles between the parent event and its direct offspring are reconstructed by

$\xi(\Delta) \propto \sum_{i,j} \rho_{i,j} I$(Rotation angle betwen *i* and *j* is within $(\Delta-\delta, \Delta+\delta)$) .

where *i* and *j* run over all the event pairs in the catalog, ρij is the probability that event *j* is triggered by event *i* estimated based on the ETAS model.

We find that the rotation poles are almost uniformly distributed. The reconstructed results for the rotation angles are shown in Figure 1.

Figure 1 (a) mean focal mechanisms of background seismicity in Japan. (b) Reconstructed distribution of rotation angles for focal mechanisms in the background seismicity and triggered seismicity.

New Ground Motion Prediction Equations for Western Saudi Arabia

*Ryota Kiuchi[1,2], Walter Mooney[1], Hani Zahran[3]

1. U.S. Geological Survey, 2. Disaster Prevenetion Research Institute, Kyoto University, 3. Saudi Geological Survey

We developed Ground Motion Prediction Equations (GMPEs) for western Saudi Arabia using 2770 selected records of PGA and PGV from 177 earthquakes of magnitude 3.0 –5.4, recorded at 58 stations in the distance range from 1 km to 400 km. Our GMPEs are developed based on one of the NGA-West2 Project GMPEs (Boore et al., 2014) by employing a mixed effects regression model.

Saudi Arabia is surrounded by several active tectonic regions, including an extension in the Red Sea and left-lateral strike-slip motion in the Gulf of Aqaba and along the Dead Sea Transform Fault (DSTF). In this area, multiple seismic swarms in and around volcanic fields, also known as harrats, have been detected over the past several decades (El-Isa and Shanti, 1989). The most recent large earthquake swarm in the region, which included more than 30,000 earthquakes, occurred from April to June 2009 beneath the volcanic field of Harrat Lunayyir in northwestern Saudi Arabia. The strongest seismic activity occurred May 13-19, 2009 and consisted of events M > 4 (Pallister et al., 2010). The largest earthquake occurred on May 19th, ML 5.4 as estimated by the SGS (Saudi Geological Survey) and Mw 5.7 by the USGS.

The NGA-West2 project used as a reference model mainly consists of shallow crustal earthquakes in active tectonic regions, rather than extensional earthquakes, such as those observed in Saudi Arabia. This deficiency is corrected by calculating a magnitude scaling of the new Saudi Arabia GMPEs compared to those of Boore et al. (2014). Furthermore, there is a clear difference in distance scaling for the Arabian GMPEs in comparison with the NGA-West2 GMPEs. This difference is especially significant at large distances and is mainly due to lower anelastic attenuation in the crystalline crust of western Saudi Arabia. Our empirical data demonstrate that the GMPEs presented here are in good agreement with observed earthquake ground motions in western Saudi Arabia.

Study on the spatial and temporal change of velocity structure before and after 2003 Chengkung earthquake, Taiwan

*TING YA LIANG[1], Wen-Yen Chang[1,2,3], Strong Wen[4]

1. National DONG HWA University, 2. Eastern Taiwan Earthquake Research Center, 3. National Center for Research on Earthquake Engineering, 4. National Chung Cheng University

Taiwan is located in the plate converge zone, in which the Longitudinal Valley(LV) is the suture zone between the Eurasian Plate and Philippine Sea Plate. The collision process yields two nearly parallel major fault systems: the Central Range fault (CRF) and the Longitudinal Valley fault(LVF). The Chihshang fault is a creeping thrust fault, which is located in the southern section of the LVF in eastern Taiwan. According to geodetic survey, this fault moves to northwest at a rate approximately 2–3 cm/yr. There were two significant earthquakes occurred nearby the Chihshang fault, the 1951 M7.1 Hualien-Taitung earthquake and the 2003 M6.4 Chengkung earthquake. In this study, the spatial and temporal variations of velocity structure before and after 2003 Chengkung earthquake were obtained through the tomography inversion beneath the southern segment of the Longitudinal Valley. The damping least-square technique and 3D ray tracing scheme were adopted to calculate the most appropriate solution and obtain the velocity structures. The results showed that the Vp values exhibit less significant variations than the parameters Vs and Vp/Vs ratio. But the Vs structures show larger variation after the 2003 mainshock. These results imply that Vp/Vs ratios began to increase before the mainshock, at the hanging wall of the Chihshang fault, which may be related to the increasing density of microcracks and fluid. Previous studies has shown that high Vp/Vs ratio may lead to cracks generating and fluid migration, which can result in changing rock volume and produce partial compensation. Therefore, our results not only give better understanding the seismogenic structures in the ES Taiwan, but also allow us to detect variations of physical parameters caused by crack propagating in stratum during the strong earthquake sequence. Hence, this study shows that the results from temporal and spatial variation of Vp/Vs values in the southern segment of the LVF could allow us to assess the seismic hazard potential in this area, and further explore the relationship between the seismicity and the rheology of fault plane. Finally, long-term monitoring of fault activities will contribute to the research of future earthquake early warning.

[S-SS07] Rigorous Seismicity Modelling and Hypothesis Testing

convener:Jiancang Zhuang(Institute of Statistical Mathematics), Danijel Schorlemmer(GFZ German Research Centre for Geosciences), Matt Gerstenberger(GNS Science), Hiroshi Tsuruoka(Earthquake Research Institute, Tokyo Univ.), Chairperson:Matthew Gerstenberger(GNS Science, New Zealand), Danijel Schorlemmer(GFZ-Potsdam, Germany)

Probabilistic models have been developed for describing, analyzing, and forecasting seismicity since more than 100 years and, with the advent of large-scale digital networks, in high resolution during the last 30 years. These models include recurrence and stress-release models for long-term earthquake hazard assessment, and short-term models describing earthquake clustering, e.g. the ETAS model. Some models have become standard tools in seismic hazard assessment. However, the overall probabilities remain on the low end and the uncertainties of the forecasts are not well described. Rigorous data-based development and testing of models will help further improving forecasting power and accuracy of these models. Similarly, new hypotheses shall be evaluated rigorously using some existing model as the null hypothesis model or in dedicated tests addressing the hypothesis directly. In this context, the Collaboratory for the Study of Earthquake Predictability and its Japan branch provides the necessary testing capabilities for rigorous and unbiased evaluation of models and hypotheses. This session focuses on research that increases information on seismicity, being with respect to a reference model or as an independent hypothesis. We solicit contributions of model developments and hypothesis formulation based on the increased understanding of the physical process of earthquakes, such as the preparation and rupture processes of the earthquake source and the interaction between earthquakes and tectonic environments. We also welcome development and implementation of improved statistical methods for testing and validating physical hypotheses based on observed data. In particular, we welcome contributions about model- or hypothesis-test experiments that could be implemented in the Japan testing center.

Improving medium-term earthquake forecasts by compensating the EEPAS model for the time-lag

David Rhoades[1], Christophersen Annemarie[1], *Matt Gerstenberger[1]

1. GNS Science

The “Every Earthquake a Precursor According to Scale” (EEPAS) model treats every earthquake as a precursor of larger earthquakes to follow it in the medium term. Each earthquake contributes a transient increment to the expected rate of earthquake occurrence in its vicinity, based on empirical predictive scaling relations associated with the precursory scale increase phenomenon. Incomplete information on precursory earthquakes causes the EEPAS model to under-predict the expected number of earthquakes when forecasting across a time-lag. We modify EEPAS to compensate for the time-lag when calculating future forecasts. Given a set of model parameters, the completeness of precursory information can be expressed as a function of the target earthquake magnitude and the time-lag. The EEPAS model has a time-varying component and a background component. We consider two end-members for compensating the model for incompleteness: one entirely in the background component, and the other entirely in the time-varying component. We estimate an optimal mixture of these two end-members for time-lags out to 12 years using several different versions of the EEPAS model and subsets of the New Zealand earthquake catalogue to which EEPAS was previously fitted. Performance is checked on an independent test period. The optimal compensated model having increasingly high information gains over the original EEPAS model with increasing time-lags. Using catalogue data complete to 2018, the compensated models forecast increased annual probabilities of earthquake occurrence above magnitude thresholds from 6.0 to 8.0 in central New Zealand in the period 2019-2030 relative to the preceding period 2008-2018.

Earthquake probability forecast incorporating non-seismic data

*Peng Han[1], Jiancang Zhuang[2], Yosihiko Ogata[2], Katsumi Hattori[3]

1. Southern University of Science and Technology, Shenzhen, China, 2. The Institute of Statistical Mathematics, Tokyo, Japan , 3. Chiba University, Chiba, Japan

This study aims to develop statistical models for earthquake temporal occurrences based on both earthquake catalogs and other geophysical observations. As an example, the seismomagnetic signals at Kakioka (KAK) station are utilized to illustrate the modeling strategies, because previous studies suggest they might contain certain precursory information of local sizable earthquakes. Self-exciting, external-exciting, and combined models modified from Ogata’ s LIN-LIN algorithm have been applied to forecast the occurrences of M>4.05 earthquakes within 100 km from the KAK station. The self-exciting and external-exciting models perform significantly better than the Poisson Model, implying there are explanatory power in earthquake catalogs and magnetic anomalies, respectively. The combined model, which integrates information from catalogs and magnetic observations, is greatly superior to any of the other three models. Additional tests show that external exciting component derived from the magnetic data is not post-seismic in character, and is more likely to cooperate with large earthquakes. The combined model proposed in this study could also be useful to incorporate other non-catalog observations and may have potential value in improving Time-dependent hazard maps for operational forecasting.

Extended versions of the space-time ETAS model and application to the 2016 Kumamoto earthquake sequence

*YICUN GUO[1], Jiancang Zhuang[1], Yosihiko Ogata[1]

1. The Institute of Statistical Mathematics, Tokyo, Japan

We proposed an extended version of the space-time ETAS model which simultaneously incorporates focal depths and rupture geometries of large earthquakes. The depth component is decoupled from earthquake hypocenters and assumed to follow the Beta distribution. This 3D-hypocenter finite-source ETAS model is applied to the 2016 Kumamoto earthquake sequence. Results from other versions of ETAS models are also obtained as comparisons. To model the dynamically triggered seismicity in Yufuin-Beppu region, an extended source which is more than two times' length of the ruptured fault of the Kumamoto mainshock is taken as its triggering source. Our results show that about 11.2% of the total seismicity is the background rate. Within the triggering source of mainshock, proportions of earthquakes being recognized as direct aftershocks of two foreshocks and the mainshock are 3.6%, 2.7%, and 23.3%, respectively. The reconstructed patterns of aftershock productivity show significant migrations in space and time. In near field (10km from slip > 1m areas), the decay of aftershock productivity follows an inverse power law of distance, verifying that aftershocks occur as an effect of stress changes imparted by the mainshock. Areas of high aftershock productivity form complementary patterns for coseismic slips, meaning that aftershocks contribute to the postseismic relaxation process.

CSEP Japan results and future developments

*Naoshi Hirata[1], Hiroshi Tsuruoka[1], Danijel Schorlemmer[3], Jiancang Zhuang[2]

1. Earthquake Research Institute, the University of Tokyo, 2. Institute of Statistical Mathematics, 3. GFZ German Research Centre for Geosciences

An earthquake predictability experiment based on the Collaboratory for the Study of Earthquake Predictability (CSEP) had started in Japan in November 2009 and ten years have passed. In Japan, three test regions and four testing classes were set up, and more than 160 models are evaluated at the Japan test center operated by Earthquake Research Institute.

Tohoku-oki earthquake occurred immediately after the start of the experiment, and the results of the model’ s forecast were not good, but after that there was a recovery trend. However, it was also found that the model performance improved by model modification considering the influence of the Tohoku-oki earthquake. We also found that the forecast of the number of earthquakes is relatively difficult in many models.

Evaluation of the forecast result is carried out by N-test, M-Test, S-Test, L-test which are the CSEP standard tests, but for comparison between models, log likelihood and information gain (or probability gain) is direct and effective.

Ten years have passed since the experiment was started, testing center hardware replacement are required and some models are required modification about dimension of array according to increase of learning data. In addition, test classes in the current experiment forecasting magnitude 4 or 5 are set, it is necessary to set test classes to forecast larger magnitude such as 6 or 7.

From the studies of historical earthquakes to the implication of single fault to multiple fault segments ruptures in seismic hazard analysis

*Kuo-Fong Ma[1,2,3], Mingshen Yen[1], Yiwun Liao[1], Henyi Su[2]

1. Earthquake - Disaster & Risk Evaluation and Managment (E-DREaM) Center, National Central University, Taiwan, ROC, 2. Department of Earth Sciences, National Central University, Taiwan, ROC, 3. Institute of Earth Sciences, Academia Sinica, Taiwan, ROC

Historically, significant crustal damaging earthquakes in Taiwan mostly were from complicated fault system rather than from a single fault segment, which was not incorporated in the seismic hazard analysis of TEM PSHA2015, but, included in current developed new seismic hazard map of TEM PSHA2019. The 1906 M7.1 Meishan earthquake, recently, had been resolved to be from a fault system of blind NE strike thrust with EW surface breaching fault (one of the identified seismogenic structures). And, the 1935 M7.1 was occurred with bilateral rupture from a blind fault to strike-slip mechanism to the south and thrusting mechanism to the north. We employed the rupture kinematic modeling to the historical geodetic data with comparison to the intensity pattern to understand the possible involvement of the fault system. In addition to the damaging earthquakes from seismic active region, an ancient 1604 M7.5-M8.0 Quanchao damaging Earthquake in southeastern coast China region was also explored from literature intensity to understand the seismic potential of less seismic active regime in Taiwan strait. These historical and past events suggest that a single fault segment evaluation for seismic hazard might be inadequate. But, we have not yet had solution to solve this inadequacy to pin down the partition of slip rate within an identified fault system. We examined the fault rupture system from kinematic and dynamic modeling of the historical events, and examined the possible partition in slip rate for the fault segments in this identified fault system. We, further then compare its influence to the estimation of seismic hazard analysis. For development in PSHA and its application, we suggest the importance of resolving historical damaging earthquakes from modern developed seismology to seismic hazard assessment and risk management.

High resolution space-time models forecasting 3D seismicity beneath the Greater Tokyo Area

*Yosihiko Ogata[1,2], Koichi Katsura, Hiroshi Tsuruoka[2], Naoshi Hirata[2]

1. Research Organization of Information and Systems, The Institute of Statistical Mathematics, 2. Earthquake Research Institute, The University of Tokyo

We propose an extended 3D epidemic-type aftershock sequence (ETAS) models of longitude, latitude and depth for short-term forecasts beneath the Metropolitan area (south Kanto region), Japan; this model also takes account of the induced effects by the 2011 Tohoku-Oki earthquake of magnitude 9.0 (M9). Specifically, we use some location-dependent coefficients in the 3D space; which is called as a hierarchical model. Similarly, we consider 3D location-dependent b-value for the Gutenberg-Richter law. In such modeling, we use linear interpolation on each of the 3D Delaunay tetrahedra of the hypocenters to estimate high resolution images in zones where hypocenters are dense. Based on the hypocenter catalog for a century period, we solve the location dependent parameters including the background seismicity rates, the self-exciting (aftershock) productivity rates, and the M9 induced productivity rate. The optimally inverted 3D spatial images of such characteristic parameters represent quite informative seismicity patterns such as in shallow crust and on the surface of subducting plates. In particular, the location-dependent external triggering factor shows the zones where the induced effect took place intensely by the M9 earthquake beneath the region.

[S-SS11] Seismic wave propagation: Theory and Application

convener:Kiwamu Nishida(Earthquake Research Institute, University of Tokyo), Kazuya Shiraishi(Japan Agency for Marine-Earth Science and Technology), Takao Nibe(JAPEX), Kaoru Sawazaki(National Research Institute for Earth Science and Disaster Resilience), Chairperson:Tsutomu Takahashi(JAMSTEC)

Seismic wave propagation provides rich information of earth's heterogeneities and the excitation sources. In order to extract the information, integrated studies are needed among mathematical/numerical studies based on the wave theory, miniature physical experiments using rock specimens, and practical data analyses. Furthermore, it is greatly beneficial to conduct comparative studies of various kinds of waves, such as elastic, acoustic, traveling ionospheric disturbances, and oceanic waves. This session widely invites presentations about the theories and applications related to seismic and other geophysical waves.

Power Spectrum of Random Heterogeneity of the Solid Earth

*Haruo Sato[1]

1. Tohoku Unvieristy

Recent observations focusing on scattering of seismic waves revealed the existence of random heterogeneities in the solid earth medium. The radiative transfer theory (RTT) has been often used for the study of the propagation and scattering of wavelet intensities. For the statistical characterization of the power spectral density function (PSDF) of the random fractional fluctuation of velocity inhomogeneities in a 3-D space, we use von Karman type with three parameters: the RMS fractional velocity fluctuation, the characteristic length, and the order of the modified Bessel function of the second kind. This model leads to a power-law decay of PSDF at wavenumbers higher than the corner.

We compile reported statistical parameters of the lithosphere and the mantle based on various types of measurements. Reported exponents of wavenumber are distributed between -3 and -4, where many of them are close to -3. Reported RMS fractional fluctuations are of the order of 0.01 -- 0.1 in the crust and the upper mantle. Reported characteristic lengths distribute very widely. In order to grasp the spectral characteristics, eliminating strong heterogeneity data and the lower mantle data, we have plotted all the reported PSDFs of the crust and the upper mantle against wavenumber for a very wide range.

We find that the envelope of those PSDFs is well approximated by the -3rd power of wavenumber. In theory, we need to re-examine the applicable range of the Born approximation in the RTT when the wavenumber of a wavelet is much higher than the corner. In observation, we will have to measure carefully the PSDF on both sides of the corner. It is interesting to study what kinds of geophysical processes created the observed power-law spectral envelope in different scales and in different portions of the solid earth medium.

Estimation of spatio-temporal changes of seismic scattering property associated with the 2008 Iwate-Miyagi Nairiku earthquake from sparse modeling of seismic ambient noise CCFs

*Takashi Hirose[1], Hisashi Nakahara[1], Takeshi Nishimura[1], Michel Campillo[2]

1. Graduate School of Science, Tohoku University, 2. University Grenoble Alpes, CNRS, ISTerre

In recent years, spatial distributions of seismic velocity and/or seismic scattering property changes associated with volcanic activities and earthquakes have been investigated by linear least-squares inversions using seismic ambient noise cross-correlation functions (CCFs) and sensitivity kernels (e.g., Obermann et al., 2013; Obermann et al., 2014). However, spatial distributions of medium changes are not easily estimated in the regions where only a small number of stations are set up. Here, we use sparse modeling (L_1 norm regularization) to estimate model parameters for a small data set (e.g., Tibshirani, 1996), and evaluate the minimum number of stations for these studies. We apply the sparse modeling to the 2008 M_w 6.9 Iwate-Miyagi Nairiku earthquake that occurred on 14 June 2008, and estimate the spatial distribution of seismic scattering property changes from decoherence (waveform changes) data of seismic ambient noise CCFs. Since we have enough seismic stations, we can compare the results from the sparse modeling and those from an ordinary linear least-squares inversion with L_2 norm regularization which has been widely used to solve linearized problems.

Seismic ambient noise CCFs were calculated at 0.5-1 Hz band for the pairs among 17 Hi-net stations during the years of 2007 and 2008. We firstly calculate decoherence values between reference CCFs (Jan-Dec, 2007) and target CCFs in two time periods of May 1 to June 13 (Period I) and June 15 to July 31 (Period II) in 2008, respectively. We then calculate the differences of decoherence values of Period I and Period II, and use them as observed decoherences. Totally, 450 observed decoherence values are analyzed. Finally, we divide the study area into 63 small cells with a size of $0.15^\circ \times 0.15^\circ$ and estimate scattering coefficient changes, Δg, for each small cell by comparing the observed and synthesized decoherence values. Here, we estimate synthesized decoherence values using 2-D decorrelation kernels (Margerin et al., 2016).

The result from the linear least-squares inversion with L_2 norm regularization shows that large Δg values are estimated around the epicenter of the main shock. The region of the largest Δg value is located at the south of the epicenter also from the sparse modeling. The maximum Δg value is about 0.035 km^{-1}, which is almost equivalent to the total scattering coefficient at this region. To know a minimum number of stations for the estimation, we selected the stations which locate within 30 km, 40 km, and 50 km from the epicenter (5, 7, and 13 stations, respectively), and conducted the same estimations for each case using the sparse modeling. We confirmed that 7 stations were necessary to recover the similar result.

The regions with large Δg values are well correlated with the region where large peak ground acceleration and large seismic velocity decreases are obtained (Takagi et al., 2012; Hobiger et al., 2014). This consistency suggests that strong motion by the main shock introduce not only large seismic velocity decreases but also large seismic scattering property changes in the shallow medium at the south of the epicenter. The sparse modeling will be useful to locate a change region of seismic scattering property changes from a sparse seismic network with several seismic stations.

Surface roughness of the Philippine Sea plate at Nankai subduction zone

*Tsutomu Takahashi[1], Ayako Nakanishi[1], Shuichi Kodaira[1], Yoshiyuki Kaneda[2]

1. JAMSTEC, 2. Kagawa University

Seismic fault surfaces have roughness over a broad spatial scale range. In this study, we measured surface roughness of subducting Philippine Sea plate along several seismic survey lines at Nankai trough. Surface geometry of the subducting plate have been estimated by analyzing both the wide-angle refraction and high-resolution seismic-reflection surveys by Nakanishi et al. (2018). They estimated velocity structures from the former data with consideration for travel times of reflected waves from the top of the Philippine Sea plate of the latter data. Uncertainties of their geometry of the Philippine Sea plate can be examined by the uncertainties of velocity structures in the overriding continental plate.
First, we examined the P-wave velocity structures in the continental plate. Power spectra of the velocity fluctuations obey a power-law at small wavenumbers. We also find a clear decrease of power spectral density at larger wavenumbers. Cutoff wavenumber of this change almost corresponds to the inverse of receiver interval. Such decrease of power spectral density is probably caused by a spatial smoothness constraint of velocity estimation. Then, we examined the surface geometries at wavenumbers smaller than the cutoff wavenumber. Power spectra of surface geometries shows self-affine property. We applied bandpass filters for geometry data and mapped the root mean squared amplitudes of filtered geometries as surface roughness. Roughness is large at Hyuga-nada, and becomes small near the trough-axis off south of Shikoku. The small roughness area off Shikoku shows low activity of regular and slow earthquakes. Meanwhile, Hyuga-nada area shows high activity of low frequency earthquakes (Yamashita et al. 2015). Since surface roughness is relevant to a small-scale stress concentration on faults, this result implies an importance of surface roughness for seismicity.

Source location of volcanic earthquakes and tremors at Sakurajima volcano based on seismic correlation

*Theodorus Permana[1], Takeshi Nishimura[1], Hisashi Nakahara[1]

1. Solid Earth Physics Laboratory, Department of Geophysics, Graduate School of Science, Tohoku University

Precise source locations of volcanic tremors and earthquakes are one of the most basic information that is important to understand the volcanic process. The spatio-temporal changes of these source locations may provide insights into the eruption mechanism and the movement of volcanic fluids. However, the determination of those source locations is quite challenging due to the difficulties to distinguish their seismic phases and precisely measure the arrival times. Recently, we developed a hypocenter determination method for volcanic earthquakes and tremor, which adopts seismic interferometry processing technique for calculating cross-correlation functions (CCFs) and the source-scanning algorithm (SSA) (Permana et al., in preparation). Here, we apply our method to observed data recorded at Sakurajima volcano. We first locate volcano-tectonic earthquakes (VTs) and evaluate the location errors by comparing the results with the hypocenters determined by a phase-picking method. Then, we locate volcanic tremors and discuss their source locations, which cannot be obtained from phase-picking methods due to indistinguishable phase arrivals.

We analyze VTs that occurred during a rapid dike intrusion on August 15, 2015. Our result shows the hypocenters are distributed beneath the Mt. Minamidake mainly at 0-4 km depths. Our source locations are consistent with the hypocenters obtained by using the method of Hirata and Matsuura (1987), and the errors are estimated to be 2 km or less.

We determine the source locations of two kinds of tremors occurred on August 22-25, 2017. The first is a 13.5 hours long continuous tremor accompanying Strombolian eruptions on August 22-23. The second is a series of intermittent tremors that are recorded following the explosion earthquakes associated with Vulcanian eruptions which followed the continuous tremor. We calculate the CCFs at 1-3 Hz by using 20 s time windows with 19 s overlap for these tremors and stacked them to obtain average CCFs. Our results show that the source locations of the first 6 hours of continuous tremor, which are determined every 10 minutes, are located beneath Mt. Minamidake at depths from about 3 km to below the active crater. The sources of the following continuous tremor are located at shallower depths, from about 2 km depth to the ground surface on the southern flank of Mt. Minamidake. The sources of 61 segments of the intermittent tremors are densely distributed at 0-2 km depth beneath Mt. Minamidake.

The observed tremors are related to the eruptive activities at Sakurajima volcano and their sources are expected to be located at the eruptive conduit. Our estimated sources are distributed at the shallow depths beneath the active craters within the estimated errors. Therefore, our results show the prospect of our method as an alternative for tremor source location determination and volcano monitoring. The depth range of our results for continuous tremor also coincides with the previous studies on the generation depth of volcanic earthquakes.

Crustal Structure Investigation in Northern Taiwan - Localized Wavefield Inversion of TAIGER T6 Wide Angle Refraction/Reflection Data

*Fandy Adji Fachtony[1], How-wei Chen[1]

1. Institute of Geophysics, National Central University

TAIGER T6 transects is one of the four crustal-scale Wide Angle Refraction/Reflection (WARR) survey lines under **TA**iwan **I**ntegrated **GE**odynamics **R**esearch (TAIGER) project conducted in 2008 in Taiwan. The north main array consist of four shot points (N1, N2, N3, and N4) across northern Taiwan from west to east. A total of 456 geophones deployed with receiver interval of ~200m on average. However, the recorded data suffers from crooked survey line geometry, uneven shot energy, noise level and currently available poorly defined 3D reference velocity model. Near-surface static effects caused by the irregular source and receiver spacing, strong lateral velocity variations and rapid topography changes produce apparent 3D wave propagation so that the standard seismic data processing or travel-time inversion could not be fully applied. To compensate above-mentioned drawbacks, Localized Slant Stack Transformation (LSST) for data pre-processing was applied to separate signal from interfering noise that has big amplitude and minor T-X curve difference. LSST is slowness and offset range-based plane wave destruction and construction techniques. The pros and cons of LSST will be discussed for TAIGER-T6 line.
For stable wavefield inversion, sufficient spatial sampling and events enhancement is essential. Wavefield inversion utilize the complete-cycle of wavelet information without picking compared to tomography study that rely on the travel time picks with potential reading errors. Velocity estimation is performed via wavefield transformation from τ-p data domain to τ-p-z solution domain through downward continuation and the application of imaging condition ($\tau = 0$). Ray tracing is performed for quality control and to quantify the separated static effects produced from source, receiver and velocity changes. Feasibility studies of three crustal scale synthetic models containing: (1) flat layers without topographic, (2) flat layers with topographic, (3) laterally varying topographic velocity models. Synthetic data is produced from Specfem2D computations. Effects of source and/or receiver static, velocity variation, and the combination of all were studied. Wavefield inversion is stable for all test models. Inverted 1D velocity becomes less smooth when static effects are included with and without static corrections. Real data implementation for all shots were cross-checked through numerical travel-time curve with acceptable error bound. Furthermore, the bottoming point of each ray through seismic ray tracing can be mapped along with the velocity information to construct quasi-2D velocity model. Inverted velocity depth profile from wavefield inversion provide higher resolution compared to the existing tomography velocity model across northern Taiwan area.

Self-organized criticality induced by randomness in block-spring models and the Gutenberg=Richter law

*Hidetsugu Sakaguchi [1]

1. Kyushi University

The Block-spring model is a simple mathematical model for earthquakes proposed by Burridge and Knopoff. Later, Carlson and Langer performed numerical simulations of a uniform block-spring model with velocity-weakening friction. They found that the slip-size distribution obeys a power law in a small scale. Their model exhibits a kind of spatio-temporal chaos and the slip size distribution is dur to the chaotic behavior. Many authors studied a variety of block-spring models. In this presentation, we will show numerical results of a block-spring model with quenched randomness in the velocity-strengthening friction. When the pulling force is stationary, there is a continuous transition from a state pinned by the quenched randomness to a sliding state. When the external force is applied through a spring, the pinning and sliding repeat randomly. The effective pulling force fluctuates around the critical value of the pinning-depinning transition. The phase transition is self-organiized even if the parameter is not controlled. As a result of the criticality, the slip size distribution obeys a power law. We consider that the power law is caused by the self-organized criticality to the pinning-depinning transition in the random media. Our model is related to the asperity theory in that the spatial inhomogeneity is important.

[S-SS11] Seismic wave propagation: Theory and Application

convener:Kiwamu Nishida(Earthquake Research Institute, University of Tokyo), Kazuya Shiraishi(Japan Agency for Marine-Earth Science and Technology), Takao Nibe(JAPEX), Kaoru Sawazaki(National Research Institute for Earth Science and Disaster Resilience), Chairperson:Kiwamu Nishida(東京大学地震研究所)

Seismic wave propagation provides rich information of earth's heterogeneities and the excitation sources. In order to extract the information, integrated studies are needed among mathematical/numerical studies based on the wave theory, miniature physical experiments using rock specimens, and practical data analyses. Furthermore, it is greatly beneficial to conduct comparative studies of various kinds of waves, such as elastic, acoustic, traveling ionospheric disturbances, and oceanic waves. This session widely invites presentations about the theories and applications related to seismic and other geophysical waves.

Land-Atmosphere Interaction in the low-frequency seismic band and inversion for shallow elasticity structure

*Toshiro Tanimoto[1], Jiong Wang[1]

1. Department of Earth Science, University of California, Santa Barbara, CA93106, USA

For frequencies below 0.05 Hz, except for the hum signals generated by ocean waves, the atmosphere is the main source of seismic noise. Some characteristics of atmosphere-generated seismic noise have been reported (e.g., Zürn et al., 2007; Zürn and Wielandt, 2007) but recent data from co-located pressure and seismic sensors allow us to improve our understanding of this interaction. We report our analysis of data from the EarthScope Transportable Array (TA) and some global permanent stations that are equipped with pressure and seismic sensors.

We first point out that coherence between surface pressure and vertical seismic data shows two broad peaks, a lower frequency one that rises below about 0.002 Hz and a higher frequency peak that reaches its maximum about 0.02 Hz. There is a minimum of coherence between them at about 0.003-0.004 Hz.

We noted that there is basically no phase-shift between pressure and vertical seismic displacement for the lower frequency peak while there is a 180-degree phase shift between pressure and vertical displacement for the higher frequency peak at about 0.02 Hz. Two peaks show a completely opposite relationship between pressure and vertical displacement. The zero phase-shift for the lower frequency peak is consistent with the mass-attraction effect due to density perturbations in the atmosphere and the 180-degree phase shift for the peak about 0.02 Hz is consistent with elastic deformation caused by surface pressure.

They suggest that these are two competing forces generated by the atmosphere, one that tends to attract the sensor mass upward by density perturbations in the atmosphere and the other that tends to push down the ground due to high pressure. The mass-attraction effect wins for the lower frequency peak and the ground deformation effect wins for frequencies above 0.01 Hz. The existence of the minimum between the two peaks indicates that relative size of these forces switches at about 0.003-0.004 Hz (already pointed out by Zürn and Wielandt, 2007).

The size of the higher frequency peak (at about 0.02 Hz) is strongly influenced by the elasticity of near-surface materials; at many sites with STS-1 sensors, this high frequency peak is often hard to identify as the sites are mostly at hard-rock sites, meaning there is little deformation due to atmospheric pressure. On the other hand, some EarthScope TA sites are at soft sediment sites and show a large (and dominant) peak at about 0.02 Hz. For such soft sites, we can derive shallow structure from pressure and seismic data.

We will present an inversion scheme to invert data from this higher frequency peak. Basic data are the ratios between vertical seismic data to pressure data and also between horizontal seismic data to pressure data for frequencies between 0.005 Hz and 0.05 Hz. The method is an iterative nonlinear inversion from a starting model using depth sensitivity kernels that are computed at each iteration step. The framework of inversion is similar to surface-wave phase velocity inversion. The product is a layered elasticity structure beneath a co-located station.

Noise correlation analysis of S-net records

*Ryota Takagi[1], Genti Toyokuni[1], Mare Yamamoto[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

We applied noise correlation analysis to continuous records of Seafloor Observation Network for Earthquakes and Tsunamis along the Japan Trench (S-net) to estimate crustal structure beneath the offshore region of northeast Japan. We used three-component records from 2017 to 2018 provided by National Research Institute for Earth Science and Disaster Resilience (NIED) and converted wavefoms from XYZ to UNE components. We analyzed accelerometer records because signal-to-noise ratio of accelerometer is higher than that of velocity sensor in the periods longer than a few seconds. The noise cross-correlation functions show periodic pulses every 60 seconds and a single pulse at zero lag. The periodic pulses and zero lag pulse can be attributed to coherent periodic noise and random noise, respectively, due to electric perturbation in instruments. The periodic noise depends on station, component, and time period. The random noise appears to be common only within stations along the same cable lines. We removed the periodic noise by computing cross-correlation functions of the difference waveforms between the records of one day and the records of one day before. The cable-dependent random noise was removed by fitting an empirical function to cross-correlation functions in the frequency domain. The noise reduction and staking within station separation bins enable us to extract Rayleigh and Love waves up to about 30 seconds. In the shorter period than 10 seconds, we found multiple modes of Rayleigh waves with group velocities of about 1.5 km/s and 0.3 km/s, which may have energy in ocean layer and sediment. In addition, we found Rayleigh waves propagating from coastal stations to deep offshore stations at the period around 4 seconds, whereas Rayleigh waves mainly propagate from deep offshore stations to coastal stations at the period around 8 seconds. The extracted surface waves may be useful to estimate crustal structure beneath the offshore region along the Japan trench.

Acknowledgement: We used continuous records of S-net managed by NIED. We thank NIED for providing the data.

Atmospheric waves from the gas explosion in Sapporo on December 16, 2018, recorded by seismometers

*Kazunori Yoshizawa[1]

1. Faculty of Science, Hokkaido University

A large gas explosion occurred in Hiragishi, Sapporo, on December 16, 2018, which blew up a two-story building in the hypocenter with more than 50 injured, although no casualty was reported miraculously. Damages to window glasses of neighboring buildings were reported in the radius of about 100 meters around the hypocenter due to strong blast waves from the explosion.

The infrasound waves from this explosion have been recorded in several seismometers installed on the ground surface of Ishikari Lowland (including the one in the campus of Hokkaido University) even at stations more than 60 kilometers away from the hypocenter, which has traveled with a speed of about 330 m/s. It is well known that atmospheric infrasound waves from large volcanic eruptions and/or meteor blast can travel very long distances, which can be observed with broad-band seismometers. Although this explosion in Sapporo is much smaller than such natural phenomena, the observed seismic records are likely to be caused by the air-earth coupled ground motions due to the infrasound waves from the explosion.

The observed infrasound/acoustic signals from this explosion cannot be observed in seismometers installed underground in and around Sapporo. Also, we cannot see any clear elastic wave (P-wave or surface waves) from this explosion. Only several seismometers installed on the ground surface have recorded the infrasound signals that are characterized by strong spectral peaks in a frequency range between 5 and 30 Hz. We can also identify the directional dependence of the observed waveforms; i.e., the amplitudes of infrasound signals are more attenuated and scattered in the north of hypocenter. This may be affected by winds and/or propagation paths, in particular, the urban area of Sapporo with tall buildings spared over the north of hypocenter.

Time-lapse monitoring of seismic velocity associated with the 2011 Shinmoedake eruption using seismic interferometry

*Kiwamu Nishida[1], Yuta Mizutani[1]

1. Earthquake Research Institute, University of Tokyo

In recent years, the number of applications of seismic interferometry is increasing. In the analysis, the cross-correlation function between ambient noise records of a pair of stations can be regarded as a virtual seismic waveform recorded at one station when the source is placed at the other station. Since, in any time period, the seismic velocity around the station pair can be estimated from the cross-correlation function calculated without an earthquake, the seismic interferometry has been applied in many studies to monitor the temporal change of the seismic velocity. A number of studies have monitored the seismic velocity change in the volcanic region with seismic interferometry and detected the temporal change in seismic velocity associated with the eruption (Brenguier et al., 2008; Rivet et al., 2015). Inferred seismic velocity changes in the volcanic region frequently show the seasonal variations, which were caused by precipitation. The amplitude of seasonal fluctuation has the same order of magnitude of velocity change associated with the eruption. Therefore, in order to detect the transient velocity change accompanying the eruption, it is important to evaluate the seasonal fluctuation due to precipitation quantitatively and remove it appropriately from the estimated seismic velocity change. In this study, seismic interferometry was applied to a seismic array around Shinmoedake to monitor the seismic velocity change, aiming at detecting the velocity change associated with the Shinmoedake eruption in 2011. First, a cross-correlation function was calculated for each pair of stations using continuous ambient noise data for 8 years from May 2010 to April 2018. The stretching method (Sens-Schönfelder and Wegler, 2006) was applied to the calculated cross-correlation function to estimate the temporal change of the seismic velocity. From the estimated seismic velocity change by the stretching method, the seasonal variation affected by precipitation was detected as in the previous study (Wang et al., 2017). Therefore, the effect of precipitation was quantitatively evaluated using pore pressure model (Roeloffs, 1988; Talwani et al., 2007). After the effect of precipitation was subtracted, the seismic velocity change associated with the eruption was detected in several pairs. In order to constrain locations of the seismic velocity change in space, the horizontal and depth sensitivity kernel was calculated. The kernels suggested that structural changes would not occur in the depth of 1-3 km in the southeastern side and in the depth of 1-2 km in the northwestern side of Shinmoedake.

Temporal variations of seismic velocity and azimuthal anisotropy in near-surface rock and soil at KiK-net downhole array sites

*Taka'aki Taira[1], Li-Wei Chen[1], Hiroe Miyake[2]

1. Berkeley Seismological Laboratory, University of California, Berkeley, 2. The University of Tokyo

Measuring stress and damage induced seismic velocity and anisotropy in crustal structure and their temporal behaviors provide insights into the underlying mechanisms of healing processes and its evolution, which would lead to a better understanding of earthquake cycle. We analyze three-component surface and borehole seismic data collected by KiK-net (Kiban-Kyoshin Net) to explore temporal variations in P- and S-wave velocity and S-wave azimuthal anisotropy (strength of anisotropy and polarization direction of the fast S wave) through coda wave interferometry. Our preliminary focus is on Hokkaido sites that experienced ground motion from the 2003 magnitude (M) 8.3 Tokachi-Oki and the 2018 M 6.0 Hokkaido Eastern Iburi earthquakes. Following Chen et al. (2017, EPSL), we analyzed all available KiK-net seismic waveforms in a frequency band of 1-15 Hz from 1997 through 2018 (more than 700 events) and evaluated seismic velocity and azimuthal anisotropy between surface and borehole sensors at 22 KiK-net sites. Median P- and S-wave velocity stacked by all measurements at each site are good agreement with them obtained from borehole logging data provided by NIED (National Research Institute for Earth Science and Disaster Resilience). We find that a number of KiK-net sites recording peak ground acceleration (PGA) higher than ~500 cm/s^2 (at surface sensor) exhibit clear S-wave velocity reductions following the 2018 Hokkaido Eastern Iburi mainshock. Station IBUH03 (located at Atuma town) also shows a sudden decrease of S-wave velocity following the 2003 Tokachi-Oki earthquake (PGA = ~350 cm cm/s^2 at station IBUH03). Reductions of S-wave velocity were about 6.5% for both mainshocks. However, there are a number of differences between two earthquakes. Our preliminary analysis suggests that the polarization direction of fast S-wave was systematically changed from 50 degrees to 10 degrees (measured clockwise from the north) following the 2018 earthquake and no notable change of P-wave velocity was observed. On the other hand, for the Hokkaido earthquake case, station IBUH03 appears to have a large variability in the polarization direction and displays a P-wave velocity reduction of about 4.5%. Our observation suggests a temporally increase of randomly oriented fractures following the 2003 Tokachi-Oki earthquake and also may suggest that the stress changes from the 2018 Hokkaido Eastern Iburi earthquake created water-saturated cracks oriented at ~10 degrees from north.

Denoising Ambient Seismic Field Correlation Functions with Deep Autoencoders

*Loic Viens[1], Chris Van Houtte[2]

1. Disaster Prevention Research Institute, Kyoto University, 2. GNS Science

In the last decade, seismic interferometry has become an established technique for monitoring the temporal changes of the Earth’s physical properties. This technique relies on measuring time shifts of seismic waves present in Green’s functions, which are generally approximated by cross-correlating 1-h long ambient seismic field records at two stations. To increase the accuracy of the phase information of hourly cross-correlation functions, pre-processing is generally applied to the recorded ambient seismic field, such as 1-bit normalization and/or pre-whitening. Despite this, hourly cross correlation functions often need to be stacked over a few hours/days to increase their signal-to-noise ratio and measure reliable phase shifts. We introduce a new technique for improving the time resolution of seismic monitoring, which denoises cross-correlation functions using deep autoencoders. Autoencoders are composed of an encoding function, which computes a compressed representation of the input data, and a decoding function which reconstructs a simplified representation of the input data. Both the encoder and decoder parts are composed of a stack of densely-connected neural network layers. Such an algorithm can be trained to denoise corrupted versions of their inputs, which in our case are correlation functions with low signal-to-noise ratio. We apply our deep denoising autoencoder on synthetic and real single-station cross-correlation functions computed from a few MeSO-net stations located in the Tokyo Metropolitan area. The denoised waveforms allow us to compute more precise relative velocity change (dv/v) than with the raw waveforms. The great advantage of this technique is that the algorithm can be trained within a few seconds and can be used to denoise near-real-time data, which could be useful for volcano monitoring.

Determination of dynamic characteristics of existing buildings at various site conditions in Eskisehir, Turkey

*Onur Kaplan[1], Seiji Tsuno[2], Hiroaki Yamanaka[3], Mehmet Safa Arslan[4], Oguz Ozel[4]

1. Eskisehir Technical University, 2. Railway Technical Research Institute , 3. Tokyo Institute of Technology , 4. Istanbul University

The fundamental vibration period of a building is a crucial parameter for earthquake engineering. The equivalent seismic lateral force is determined from a design spectrum in most static design methods. Accordingly, the earthquake force is a function of the fundamental vibration period of the building. The fundamental period of an existing building can be determined by both forced and ambient vibration measurements. In this study, ambient vibration measurements were conducted at 17 existing buildings including different structural styles (masonry and reinforced concrete) and heights (7 to about 65 meters) which are located at different site conditions in Eskisehir, Turkey. In ambient vibration measurements, two accelerometers were placed on the top of the buildings and one accelerometer was placed on the ground. The fundamental vibration periods and the dampings of the measured buildings were evaluated. The fundamental vibration periods of the buildings were evaluated by picking the peaks of the spectral ratios of Fourier spectra on the top floor of buildings to those on the ground. The dampings of the measured buildings were estimated by fitting the spectral ratios calculated using a single degree of freedom system to the spectral ratios observed, in the process of trial and error (Iwata and Tsuno, 2013). In order to understand the site conditions near the buildings, array microtremor observations by small-scale arrays of 1.5 to 16 meters were performed on the free field. SPAC method was used to obtain the phase velocities of Rayleigh waves and the S-wave velocity profiles were estimated using those phase velocities in the inversion technique. Tsuno et al. (2018) derived an equation of T=0.016H from 10 building measurements carried out in Eskisehir, Turkey. In this study, 7 more measurements were added to the previous measurements of Tsuno et al. (2018) thus, according to findings of this study, the equation of T=0.0165H was proposed to estimate the fundamental vibration period (T, in seconds) of an existing building in Eskisehir, Turkey with respect to its height (H, in meters). This equation is still in need to improve with additional measurements, which could represent most of the building heights in the Eskisehir building inventory. The calculated dampings of the measured buildings have a general tendency that the higher the buildings, the smaller the dampings.

ICDP DSeis 10: Near-field Observations for the M5.5 Orkney, South Africa Earthquake

Tatsunari Yasutomi[1], *James Mori[1], Hiroshi Ogasawara[2]

1. Earthquake Hazards Division, Disaster Prevention Research Institute, Kyoto University, 2. Ritsumeikan University

We examined the near-field records for the 2014 Orkney earthquake (M5.5) to infer source properties for this moderate-sized earthquake. The event was the largest recent earthquake associated with the deep gold mines of the region. Different from usual normal-faulting events that are induced on known structures of the mines, the M5.5 earthquake took place significantly below the mining horizon with a strike-slip mechanism on an unknown geologic structure. Seismic activity close to the Moab Khotsong and Great Noligwa mines is very well monitored by instruments installed on the surface and in the mine tunnels. The high sample-rate (6 khz) geophones installed in the mine at depths of 1 to 3 km provide high-quality recordings of the mainshock and aftershocks.

The waveforms show that there is a small foreshock (about M1.8) located 1.6 km south of the mainshock hypocenter and at 0.6 sec before the mainshock. There is no evidence of any unusual character of the foreshock, or any significant deformation between the foreshock and mainshock.

Using lower frequency (<2.0 hz) data, the nearfield waveforms can be modeled using a finite fault slip inversion. The results show a slip distribution with two main patches of larger slip, which are located a few kilometers to the north and to the south of the hypocenter. The area of the fault plane is relatively large for a M5 earthquake and this gives a rather small static stress drop.

Number of earthquakes from seismic activity model of the national seismic hazard maps for Japan

*Nobuyuki Morikawa[1], Junichi Miyakoshi[2], Hiroyuki Fujiwara[1]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Ohsaki Research Institute, Inc.

In this paper, as a part of the verification of the probabilistic national seismic hazard maps for Japan, we compare the earthquake occurrence ratio from seismic activity model in the national seismic hazard maps for Japan and that from earthquake catalog data.
As the number of earthquakes from seismic activity model of the national seismic hazard maps for Japan 2018 version, the expected value in 30 years is calculated for each magnitude and expressed by the cumulative number of earthquakes. The procedure is as follows.
1. For earthquakes with nonstationary seismic activity model adopted, set the probability of occurrence of earthquake in 30 years from January 2018 as the expected value of the number of earthquakes.
2. Earthquakes in Nankai Trough (M8-9 class), in Sagami Trough (M8-class), Mega-earthquake along the Kuril trench, and large plate-boundary earthquakes in Tokachi-oki and Nemruo-oki, the whole 30 years of the earthquake occurrence probability by the weight of each occurrence pattern as the expected value of the earthquake number in 30 years, respectively.
3. For the earthquakes in which the Poisson process is adopted, use the 30 year earthquake number based on the occurrence frequency of earthquakes.
Here, we prepare three datasets of cumulative earthquake number. The first is based on the “average case”, the second is based on the “maximum case”, and the third is based on the “averaged hazard” models.
For the earthquake catalog to be compared, we combine earthquakes with M 6.0 or more from 1885 to 1925 by Utsu (1982) and Japan Meteorological Agency earthquake data of M 5.0 or more from 1926 to 2010. At this time, aftershocks are removed according to the same rules as the national seismic hazard maps for Japan.
For shallow crustal earthquakes, the number of earthquakes from the model and the catalog are consistent at less than M 7.0 for the “average case”, and are consistent at less than M 7.7 for the “maximum case”. However, on a larger magnitude, there is a tendency for the model to have a smaller number of earthquakes. For earthquakes in Philippine Sea Plate, the number of earthquakes from the model and the catalog are consistent at M 8.0 and below. However, on a larger magnitude, the number of earthquakes in the model is extremely large. This is caused by the modeling of the large occurrence probability based on the time predictable model for the Nankai Trough earthquake. The number of earthquakes from the “average hazard” model decreases at M 8.0 or more. For earthquakes in the Pacific plate, the number of earthquakes from the model and the catalog are consistent at less than M 7.0. However, on a larger magnitude, the number of earthquakes from the model is somewhat larger. For M 7.8 and more, the model has changed based on the new long-term evaluation of earthquakes along the Kuril Trench by Headquarters for Earthquake Research Promotion of Japan, and the increase in number of earthquakes is also affecting.
On the other hand, when the period of the earthquake catalog is expanded until 2015, after the 2011 great Tohoku earthquake, the number of earthquakes from the model becomes smaller than that from the catalog for earthquakes in the Pacific and Philippine Sea plates. This is due to a large number of aftershocks and induced earthquakes of the 2011 Tohoku earthquake. How to incorporate the earthquake catalog after the great Tohoku earthquake into the seismic activity model in the seismic hazard assessment is a very important task.

Comparative examination of the Probabilistic Seismic Hazard Maps in Japan with observed maximum seismic intensities for various periods

*Takamoto Muneta[1], Kazuki Koketsu[1]

1. Earthquake Research Institute, The University of Tokyo

The accuracy of the Probabilistic Seismic Hazard Maps in Japan (PSHMJ), which is being published by the Headquarters for Earthquake Research Promotion of the Japanese government, was examined by comparing the observed maximum seismic intensities with the PSHMJ. Miyazawa and Mori (2009) compared those only for about 500 years from 1498, and Kondo (2017) compared those for 30 years from 1890, 1920, 1950, or 1980. However, in this study, we compared those for 30, 60, 90, and 120 years from 1890, to show how the accuracy varies for various periods.

Following Kondo (2017), for synthetic seismic intensities, we combined the hazard curves in the engineering bedrocks for PSHMJ (Miyakoshi et al., 2016), the site amplification factors (Wakamatsu and Matsuoka, 2013), and the relationship of seismic intensities and peak ground velocities (Midorikawa et al., 1999; Fujimoto and Midorikawa, 2005). As in Miyazawa and Mori (2009), the Poisson distribution was assumed, and phenomena of return periods of 30, 60, 90, and 120 years were related to those with probabilities of exceedance in 30 years of 64, 45, 28, and 22%, respectively. Observed seismic intensities were derived from the JMA seismic intensity database (Ishigaki and Takagi, 2000; Ishigaki, 2007) and the reports of large earthquakes between 1944 and 1964 (Usami, 1985; Harada et al., 2016). The derived dataset consists of observed seismic intensities at 110 points. This observed dataset was compared with the synthetic seismic intensities at the corresponding points in PSHMJ.

As an index of the comparison, we first calculated the root mean square of differences between observed and synthetic seismic intensities. The results are 1.2, 0.8, 0.7, and 0.7 for return periods of 30, 60, 90, and 120 years, respectively. Since large earthquakes, which can lead to large seismic intensities, are phenomena happening once in several hundred years (plate boundary earthquakes) or once in several thousand years, it is expected that a smaller root mean square is obtained for a longer return period. The above results mostly meet this expectation, but they do not approach 0.4 to 0.5 for a return period of 500 years (Miyazawa and Mori, 2009) being saturated at 0.7 for 90 and 120 years. We secondly performed regression analyses, and similar saturation was also found. For example, the small number of observed seismic intensities can cause this problem, and therefore it will be considered further.

Acknowledgments: J. Miyakoshi provided the hazard curves, and T. Kondo provided computer codes etc. Discussion with J. Miyakoshi and H. Fujiwara is helpful for this study.

A Study on the Ground Motion Characteristics close to the Basin Edge

Ryota Hamabe[2], *Shinichi Matsushima[1], Takashi Azuma[3], Florent De Martin[4]

1. Disaster Prevention Research Institute, Kyoto University, 2. Graduate School of Engineering, Kyoto University, 3. National Institute of Advanced Industrial Science and Technology, 4. French Geological Survey

The 1995 Kobe Earthquake brought significant damage around the Kobe area in Japan. It was notable that a “Damage Belt” with an area with a width of 1km and length of 20km was formed. The main cause of this phenomenon was called the “Basin-Edge Effect”, which is a result of the constructive interference of seismic waves owing to the basin edge structure, i.e. the interference between the direct S-wave propagating upward and the basin-induced/diffracted surface waves propagating laterally. Therefore, this phenomenon should not limited to the Kobe area. In this study, we conduct a ground response analysis at sites close to the basin edge, assuming various types of basin structures, to understand the influence of the subsurface structure to the characteristics of the ground motion close to the basin edge. Also, the observed microtremor Horizontal-to-Vertical spectral ratio (MHVR) will be used to understand the relation between the shape of the MHVR and the basin edge shape. A method to estimate the region of amplification of ground motion due to the Basin-Edge effect at the basin edge estimated from MHVRs will be introduced.

Spectrum Characteristics of MeSO-net seismograms –Effect of Underground Installation -

*Ryoichi Nakamura[1], Hiroshi Tsuruoka[1], Aitaro Kato[1], Shin'ichi Sakai[1], Naoshi Hirata[1], Takahiro Shiina[1]

1. Earthquake Research Institute, The University of Tokyo

1. Introduction

In the Kanto district, high-density seismographs with about 300 accelerometers by MeSO-net have been deployed, and records from 2008 have been accumulated. By analyzing the MeSO-net records integrating with those obtained in K-NET and KiK-net, which is operated near the ground surface, it will able to largely improve structural images in seismic attenuation. However, MeSO-net is installed at a depth of 20 m and there is a problem to integrate records obtained at the surface. In this study, we investigated relative amplification factors among MeSO-net sites and compared the factors to those estimated at the surface sites, K-NET and KiK-net.

2. Method and Data

Observation records which are obtained at two closely located sites by the same earthquake have almost the same propagation paths, so the difference of the two site records can represent a difference of site amplifications because effects of source radiation and attenuation along paths are canceled out. Based on this idea, some studies have been investigated relative amplification factors between the sites. Recently, Ikeura and Kato (2011) proposed a new method that regards site pairs as a network and estimates relative ground amplification factors by using least squares method within the network.

In this study, the relative amplification factors in MeSO-net was examined by using the Ikeura and Kato's method. In order to compare with the amplification factors on the surface, the ground record of K-NET and KiK-net was also included in the analysis. The ARTB method (Herman, 1980) was used for least squares estimation. A distance between sites to pair is 10 km or short. The Fourier spectrum of every 1 Hz from 1 Hz to 10 Hz were used for the data. The strong motion records of MeSO-net from 2011 to 2015 and K-NET/KiK-net from 1996 to July 2016 were selected. Earthquakes with Mj 4 or more and depths less than 200 km were used. We only adopted records which the maximum acceleration amplitude is 100 Gal or less to exclude the nonlinearity effects resulted in strong ground motion. Finally, we used site pairs of 962,422 with 394 observation sites of 394, which include MeSO-net site of 297.

3. Results

In this study, first, we performed numerical experiments to vilify the validity of results given by the ARTB. The geometries of site and earthquake used in the experiments are the same to the actual investigation. After 50 times iteration, it is confirmed that synthesized dataset well reproduce the relative site amplifications assumed in artificially.

Then, we conducted 100 times iteration for the actual observation records to obtain the relative ground amplification. Fig.1 shows an example of the result at 5 Hz. Here we compare the relationship with the average S wave velocity to 30m depth (AVS 30) provided from the JSHIS. The amplification factors at the

©2019. Japan Geoscience Union. All Right Reserved.

ground surface (K-NET and KiK-net) is about 3 times larger than that at the underground (MeSO-net) on average. The amplification rate tends to decrease with increasing velocities of the AVS 30. This trend is consistent with the relationship for the PGV data expected based on Fujimoto and Midorikawa (2006) (black solid line in Fig. 1).

We confirmed that the residuals in the attenuation tomographic inversion can be greatly reduced by giving the relative amplification factors obtained in this study as a priori information.

4. Conclusions

Relative amplifications of ground motion were investigated for observation sites of the MeSO-net, K-NET and KiK-net by using the site-pair network and the least squares method. As a result, it was found that amplification factor in the MeSO-net of which seismographs are deployed at the underground, 20 m depth, is about 1/3 comparing with those of ground surface recorded in the K-NET and KiK -net on average.

Discussion

Interpretation of attenuation of high-frequency waves from the intraslab, interplate, and outer-rise earthqukakes of Northeastern Japan

*Yasumaro Kakehi[1], Yu Ogasawara[1]

1. Graduate School of Science, Kobe University

Previous studies (e.g. Tsumura et al., 2000) have shown the backarc side of Northeastern Japan has lower Q-value than the forearc side and remarkably low-Q zones exist just beneath and slightly backarc-side of the volcanic front. On the backarc side, high-frequency seismic waves attenuate due to the low-Q medium, and the contrast is seen between the high-frequency wave amplitudes on the backarc side and those of the forearc side, where such attenuation does not occur. In this study, characteristics of the spatial distribution of peak ground acceleration and the attenuation relation from 3 types of earthquakes: intraslab, interplate, and outer-rise earthquakes, are investigated using high-density strong motion data of NIED K-NET and KiK-net. The number of studied earthquakes is 15 in total. The most clear contrast between the forearc and backarc sides is seen in the intraslab earthquakes with deep focal depths, and the contrast is also clear in the outer-rise earthquakes though the contrast is not so clear as that in the intraslab earthquakes. On the other hand, the contrast is observed also in the interplate earthquakes, but it is less clear than that in the outer-rise earthquakes. The length of seismic wave path propagating in the low-Q region on the backarc side is long in the case of intraslab earthquakes with deep focal depths, and in the case of interplate and outer-rise earthquakes, both of which have shallow focal depths, the lengths of seismic wave path are shorter than the case of intraslab earthqukaes and are approximately the same. Therefore, it is reasonable that the contrast in outer-rise earthquakes is less clear than that in intraslab eartgquake. It is incomprehensible, however, that the contrast in interplate earthquakes is less clear than that in outer-rise earthquakes. To understand this mystery, we newly take the contribution of the attenuation due to the geometrical spreading factor into consideration. In case of interplate earthquakes whose epicenters are close to the land, the curvature of hypocentral distance contors in the land area (where the observation stations are located) is large. Therefore, attenuation due to the geometric spreading factor is large at the northern and southern ends of the Northeastern Japan arc, where hypocentral distances are large than those in the central part of the island arc, the amplitude difference between the forearch and backarc sides is masked. On the other hand, in case of outer-rise earthquake whose epicenter is far away from the land, the curvature of hypocentral distance contors in the land area is very small and the geometrical spreading factor hardly varies throughout the Northeastern Japan arc. Therefore, the mask effect due to the geometric spreading factor at the norther and southern ends of the Northeastern Japan arc does not work effectively. That is, due to the mask effect of the geometric spreading factor, the contrast between the forearc and backarc sides in interplate earthquakes becomes less clear than that in outer-rise earthquakes, where the mask effect does not work. Furthermore, as to the PGA attenuation relation, an apparent effect appears in the case of outer-rise earthquakes that makes the amplitude difference between the forearc and the backarc sides apparently emphasized than it is, as pointed out by Ogasawara and Kakehi (2018, SSJ Fall Meeting). Thus, the difference of the contrast of seismic shaking on the forearc side and that of the backarc side of Northeastern Japan due to the 3 types of earthquakes is interpreted unifiedly by considering the following 3 factors: (1) the length of seismic wave path propagating in the low-Q region, (2) the mask effect due to the geometrical spreading factor, and (3) the apparent effect in the case of outer-rise earthquakes whose hypocentral distances are systematically large.

Effect analysis of soil interlayer on seismic dynamic response and failure mode of metro station structure

*Shuai Huang[1], Yuejun Lyu[1], Yanju Peng[1]

1. Institute of Crustal Dynamics,China Earthquake Administration

When the metro station structure is built in the site with weak interlayer, the metro station structure shows different patterns of destruction. In this article, based on the nonlinear elastic-plastic finite element model for metro station, considering the structure-soil dynamic interaction, the influence laws of the weak interlayer on the dynamic response and failure mode of the metro station structure under near and far-field earthquakes are studied. We found that the weak interlayer in the middle of the metro station has the greatest effect on the displacement, dynamic amplification factor and internal force of the metro station which leads to the poor anti-seismic performance of the metro station structure, and the metro station is more vulnerable to damage under near-field earthquake. When there is a middle interlayer, the maximum horizontal displacement of the metro station increases 63% at most compared to no interlayer under near-field earthquake. The interlayer below the metro station has a minimal impact on the dynamic amplification factor which shows that the existence of the interlayer below the metro station could reduce the vibration of the metro station to a certain extent. At last, indoor shaking table test for metro station was done, through which we determined the position of initial failure and the failure mode of the metro station structure under earthquake, and shaking table test results demonstrate the validation of the numerical simulation results.

Investigation on the Applicability of V_{S30} Estimation Models for the Beijing Plain Area

*Yi Fang, Yanju Peng, Zhijie Jiang

Using three models which respectively are bottom-layer constant velocity model, velocity gradient model and the extrapolation model with the travel-time averaged shear-wave velocities at two different depths, we investigate the data from 460 boreholes in Beijing plain area that the shear-wave velocity profile reaches at least 30 m. Through a detailed research, we found that the last method can estimate V_{S30} with high accuracy. It does not need any regression analysis to derive empirical relations from a large number of data. Meanwhile, this method is not regionally dependent, and has a remarkable improvement in the accuracy, therefore, it is potentially useful for many parts of the world including Beijing. It provides a basis for site classification, and then extends its application to evaluation of site effect in a rapid assessment of earthquake damage, thus being worth to be extensively applied.

Early prediction of PGA and Sa using ANN

*Ting Yu Hsu[1]

1. Taiwan Tech

In order to perform on-site earthquake early warning, in this study, we develop a novel approach to predict the peak ground acceleration (PGA) and pseudo-spectral acceleration (Sa) using the first few seconds of P-wave features. The Fourier spectrum amplitude (FSA) and phase (FSP) are handled separately and then combined together to predict the acceleration time history, then the PGA and Sa can be estimated accordingly. The FSA is predicted using the artificial neural network (ANN) with the predominant period, peak acceleration amplitude, peak velocity amplitude, peak displacement amplitude, cumulative absolute velocity, integral of the squared velocity, and FSA of the first three seconds of P-wave as input. The mean and standard deviation of the group delay time of phase spectrum of each separated frequency range decomposed by wavelet transform is employed as the prediction target, then the FSP can be generated using these mean and standard deviation of the group delay time. The FSP is predicted using another ANN model using similar P-wave features as the FSA ANN model. The earthquake records of the Taiwan Strong Motion Instrumentation Program from 1992 to 2006 were used to train and validate the proposed approach, and the promising accuracy of PGA and Sa prediction is obtained.

Analysis of strong-motion acceleration records based on the Generalized Pareto distribution

*Hisashi Nakahara[1]

1. Solid Earth Physics Laboratory, Department of Geophysics, Graduate School of Science, Tohoku University

Owing to K-NET and KiK-net managed by NIED, high-quality strong ground motion data have been accumulating in Japan in these two decades. Analyzing these data set, I investigate the upper limit of ground accelerations of near-field strong motion records in Japan. I apply the Generalized Pareto distribution (GPD) to amplitude distributions of ground accelerations exceeding given threshold levels, and estimate the parameters of GPD. Especially, the shape parameter of GPD is very important for this purpose. If the shape parameter is negative, an upper limit exists in the distribution. If the shape parameter is greater or equal to 0, there is no upper limit.

Among the strong motion database from K-NET and KiK-net, I select 98 strong motion records whose peak ground accelerations exceed 1g. I finally use 77 strong motion records after eliminating records contaminated by other events like aftershocks and those whose duration times are too short to have enough data. Positive values and negative values of ground accelerations are independently analyzed. I use the absolute value for the negative amplitude. Changing the threshold value of ground acceleration from 10 to 300 gal, I fit GPD to the data exceeding the threshold, and estimate the minimum threshold over which the estimated parameters of GPD (the shape parameter, the scale parameter, and the mean excess) will not change much. I also confirm the goodness of fit of GPD by checking P-P plots and Q-Q plots visually.

GPD explains amplitude distributions of 77 acceleration records. For the positive amplitudes of accelerations, 48 records show the upper limits. For the negative amplitudes of accelerations, 53 records show the limits. In total, about 70 % records show the limit in ground accelerations. The range of the limit is mostly smaller than about 6000gal. However, a few results with very small negative shape parameters suggest much larger limits. These results should be regarded practically as no limits. For the rest of about 30 % records, the existence of the limit is not statistically supported. However, there should be the upper limit in ground accelerations from the viewpoint of physics. So it is necessary to clarify reasons why about 30 % records do not suggest the upper limit in ground acceleration.

Acknowledgment:

I used strong motion records obtained by K-NET and KiK-net, NIED.

To investigate a cause of serious damages of the 2018 Hokkaido Eastern Iburi Earthquake, we observed microtremors and aftershocks at a landslide area and around strong ground motion observation stations. As a result, S-wave velocity structures were estimated at all observation sites. It was found that thickness of the volcanic ash layer (S-wave velocity:75-130 m/s) is 10m. Especially, it is suggested that two layers of volcanic ash layer have caused a landslide in the Shikanuma and Atsuma sites. It was found that the H / V spectral ratio of microtremor corresponds to the thickness of volcanic ash. The spectral amplitude of the H / V of the orthogonal direction component of the mountain ridge line became larger than that of the parallel direction component.

Nonlinear site amplification for high intensity ground motions during the 2018 Mw 6.6 Hokkaido eastern Iburi earthquake

*Yadab Prasad Dhakal[1], Takashi Kunugi[1], Takeshi Kimura[1], Wataru Suzuki[1], Shin Aoi[1]

1. National Research Institute for Earth Science and Disaster Resilience (NIED)

Large peak ground accelerations (PGAs) exceeding 1g on both the horizontal and vertical components were recorded at a fault distance of about 25 km during the September 6, 2018, Mw 6.6 Hokkaido eastern Iburi earthquake. Explaining the large PGAs at the distance for the magnitude of the event requires detailed investigation of the site response and source radiations. At several sedimentary sites, peak ground velocities (PGVs) exceeding 100 cm/s were recorded. Comparison of the observed PGAs and PGVs with the ground motion prediction equations (GMPEs) by Si and Midorikawa (1999) revealed that the observed data, especially the PGVs, were substantially larger at fault distances smaller than about 40-50 km, while the data at longer distances showed little or no trend different from the GMPEs. This motivated us to examine the site response during the earthquake. We processed many small amplitude (PGAs between 5 and 20 cm/s/s) accelerograms from earthquakes that occurred prior to the mainshock (the Mw 6.6 event) at sixteen KiK-net sites, and compared the surface-to-borehole spectral ratios between the small-amplitude ground motions from prior earthquakes and large-amplitude ground motions recorded during the mainshock. The comparison suggested that the sites at short distances where PGVs were underestimated, sustained various degrees of nonlinear site response, and the recovery is still undergoing at some of the sites based on similar analysis of aftershock recordings. Nonlinear site amplification has been known for a long time for the reduction of short-period ground motion amplitudes at a soil site during strong input motions compared with the weak input motions. Another commonly reported effect of nonlinear site response is the shift of predominant frequency to lower one. This second effect was found to be very prominent during the mainshock at soil sites and smaller distances, which caused stronger amplification at relatively longer-periods resulting into large PGVs and large JMA intensities. At the site of largest PGA, the ground motions were amplified by an order of magnitude at the new predominant frequency during the mainshock. We also analyzed the horizontal-to-vertical (H-to-V) spectral ratios at K-NET sites where PGAs were larger than 200 cm/s/s. We found that the K-NET sites also experienced larger degree of nonlinear site response at sites of larger PGAs. Based on the above analysis, the nonlinear site amplification could be one of the major reasons for the high intensity ground motions that were underestimated at the smaller distances by the GMPEs. Moreover, two sites (IBUH01: KiK-net; HKD127: K-NET), which were closely located, recorded vertical PGAs exceeding 1g for the up going motions at the surface, and the recordings showed asymmetric waveforms and amplitudes characteristics to the nonlinear site response reported during a few earthquakes in the past. A few sites having lower vertical PGAs were also suspected of being experienced nonlinear site response on vertical motions. Finally, we derived an ad-hoc equation to correct for the nonlinear site amplification in the prediction of horizontal PGVs with respect to the GMPE by Si and Midorikawa (1999). The results indicated that the stronger input motions may induce larger changes in PGVs at the surface than that for a proportional change in the shallow S-wave velocities (Dhakal et al. 2019).

1.Introduction

An earthquake of Mj6.7 occurred at 3:07 on September 6, 2018, in the Eastern part of the Hokkaido Iburi region. High seismic intensities (SI) of upper 6 and 7 were observed during this earthquake, even though the hypocenter of the earthquake was at the depth of 37 km. The amplification of surface ground was considered as one of the main factors that contributed such high SI. In order to estimate the ground amplification of the near surface ground, microtremor array measurements were conducted at six strong motion recording stations that observed SI upper 6 or 7.
In this presentation, we focused on two stations, HKD127 and IBUH01, because there was a difference in SI in spite that the two stations closely located. So we will show the result of analysis for these two sites.

2.Microtremor array measurement

The shape of the microtremor array used was an equilateral triangle. The vertical components were measured at three vertex points as well as the center of the array, in addition to the two horizontal components at the center. The measurements with a radius of 10m or less were made for each station, whereas those with a radius of 25m or more were made once around the two stations and used for both, because the distance between the two is as close as about 100m.

3.Analysis

A dispersion curve was determined from stationary part of microtremor array data based on SPAC method, and calculated H/V spectra from the three component microtremors observed at the center. The shear wave velocity profiles of the two stations were then back-calculated by the genetic algorithm using both observed dispersion curve and H/V spectra. The influence of higher modes of Rayleigh and Love waves was considered for the observed H/V spectra but neglected for the observed dispersion curve.

Subsurface structure model based at diffuse-field theory in Oiwake region: Simultaneous inversion analysis on adjacent two sites

*Moeko Koie[1], Kentaro Motoki[1], Kenichi Kato[1], Takuto Kogawa[2]

1. KOBORI RESEARCH COMPLEX INC., 2. TOKYO SOIL RESEARCH CO., LTD.

During the 2018 Hokkaido Eastern Iburi Earthquake, 6.7 seismic intensity was observed in KiK-net Oiwake. On the other hand, observed seismic intensity at K-NET Oiwake, which is 100m away from the KiK-net, was 6.4. The amplitude of response spectra at KiK-net were higher near the predominant period than those at K-NET. The reason for the difference between their seismic intensity seems to be thought of due to the difference of their subsurface structure. In this study, we deduce subsurface structure models at the two sites by H/V inversion based on diffuse-field theory and estimate amplification factor at the sites.

To select the earthquakes for inversion analysis, we set the conditions such as occurrence before the main shock, less PGA than 100 cm/s^2, and higher ratio of epicentral distance to depth of hypocenter than 2. We used the average H/V of the selected earthquakes for observed H/V. In the calculation of H/V, we use the square-root of sum of squares of NS and EW component for horizontal component. The period at the peak observed H/V at K-NET Oiwake is shorter than that at KiK-net. The difference between their observed H/V is small in longer period range than 2 seconds.

Because of the adjacent of the sites and similarity of observed H/V in the long period, we set the deep part of structure at the 2 sites to be in common and search for shallow part of that individually. In order to make the deep part of structure in common, we adopted simultaneous inversion analysis at the two sites. We used the hybrid heuristic method and set the range of search based on the model of PS logging and J-SHIS. We searched for the thickness for the deep structure and S wave velocity for the shallow structure.

As a result of inversion analysis, we could deduce subsurface structure models which accorded with the observed H/V. The depth up to engineering bedrock of deduced K-NET model is 7m, and that at KiK-net is 20m. AVS30 at K-NET is 278m/s, whereas that at KiK-net is 243m/s. On the whole, S wave velocity at KiK-net in shallow part is lower than that at K-NET. We calculated the amplification factor of the shallow part, which was searched individually. The first natural period of amplification factor at KiK-net is 0.31s and that at K-NET is 0.20s. The predominant period of response spectra at KiK-net’ s (0.53s) is also longer than K-NET (0.48s). Because both of the natural and the predominant period at K-NET are shorter than those at KiK-net, the difference between subsurface structures might cause that of the amplitude of the main shock. However, the predominant period of the main shock is longer than the natural period at both sites, which seems to be influenced by nonlinear effect of the subsurface soil.

We will study about a cause of the difference of seismic intensity considering nonlinear effect of the subsurface soil.

The 2018 Hokkaido eastern Iburi earthquake (M_w 6.6, focal depth=37 km) occurred on 6 September 2018 at the Hidaka arc-arc collision zone, Hokkaido, Japan. The many building damages by strong ground motion were concentrated around K-NET Mukawa strong motion observation station (HKD126). Strong motion records had strong power in 1-2 second periods of the response spectrum to destroy the timber frame buildings. It is an important examination to know the cause of the generation of this destructive strong motion.

To understand the site effects of this strong motion, we estimate the velocity structure models by using the microtremor array and multichannel analysis of surface wave measurements at three sites; around HKD126 site, a hillside site located about 6 km north from HKD126, and midpoint between both sites. We carried out the microtremor array measurements (R=1-2000 m) on 14-16 December 2018. We used servo type velocity sensor (Le-3D/5s) and 24-bit data logger (DATAMARK LS-7000XT) with GPS time calibration. At small arrays (R<~10 m), we used moving coil accelerometer (JEP-6A3, 10V/g). The fundamental Rayleigh wave phase velocity is examined with the spatial autocorrelation method. We also carried out a multichannel analysis of surface wave to emphasize the high-frequency side phase velocity. We set 24 channel 4.5 Hz geophones in interval 1 m with GEODE and 10 kg wood hammer. The phase velocity is examined with the Frequency-wavenumber method. The shear wave velocity structure models are estimated to fit the dispersion curve of the fundamental mode of Rayleigh wave using the genetic algorithm inversion method (Yamanaka and Ishida, 1998). The phase velocity data of the large array (R=2000 m) were used in common to the three sites.

Comparing the velocity structures, the Vs=1300 m/s layer’s depth of HKD126 is shallower than the hillside site ones and midpoint depth is mid of both. This tendency of depth variation is the same as the seismic bedrock and subsurface structure depth variation of AIST model (Yoshida *et al.*, 2007) and J-SHIS V2 model (Fujiwara *et al.*, 2012). On the other hand, about the shallow part, engineering bedrock depth of hillside site is shallower than the HKD126. The midpoint’s seismic bedrock is mid for the others, however, the surface soft soil deposit is detected as richer than the HKD126. These features of the shallow part structure's variation are able to confirm by the surface geology or Vs30 values of J-SHIS.

Source Process of the 2018 Hokkaido Eastern Iburi Earthquake Inferred from Strong Motion Data and Green's Functions Based on Three-Dimensional Velocity Structure Model

*Kimiyuki Asano[1], Tomotaka Iwata[1]

1. Disaster Prevention Research Institute, Kyoto University

The source rupture process of the 2018 Hokkaido Eastern Iburi earthquake (M_{JMA} 6.7) was analyzed by the kinematic waveform inversion using strong motion data. Since this earthquake occurred close to the Hidaka Collision Zone and the Ishikari Lowland, the crustal and sedimentary basin structure of surrounding region is rather complex. Thus, we tried to use a three-dimensional velocity structure model to compute theoretical Green's functions. We used the Japan Integrated Velocity Structure Model (JIVSM; Koketsu *et al.*, 2012), and the Green's functions were computed by the three-dimensional finite difference method. The source fault model with strike-angle variation was set by referring to the spatial distribution of early aftershocks and the Global CMT solution. The source rupture process was estimated by the multiple time-window kinematic waveform inversion method (e.g., Hartzell and Heaton, 1983). The observed data for the inversion was strong-motion velocity waveforms in 0.04–0.5 Hz at K-NET, KiK-net and F-net stations. The rupture starting point was assumed to be at the hypocenter located by JMA at a depth of 37 km. The strong motion stations were selected based on the result of forward ground motion simulation of an Mw 4.1 aftershock occurring on September 14, 2018.
The estimated source model has small slip in the vicinity of the hypocenter, but significant slip is found in the depth range from about 22 km to 32 km. The rupture mainly propagated toward shallow and southwest direction. Considering crustal structure in this region (e.g., Iwasaki et al., 2004; Kita et al., 2012), the large slip area (asperity) is located in the middle-to-lower crust, and its rupture does not reach the upper crust. The depth range of significant slip is consistent with the spatial distribution of early aftershocks. Later aftershocks occurring in shallower depth are thought to occur outside the mainshock's source fault.

Acknowledgements: Strong motion data from K-NET, KiK-net and F-net (NIED) and JMA unified hypocenter catalog were used in this study. This study was supported by the Grant-in-Aid for Special Purposes 18K19952 (PI: Prof. Hiroaki Takahashi at Hokkaido University) from MEXT.

Source process of the 2018 Hokkaido Eastern Iburi earthquake derived from strong motion data

*Hisahiko Kubo[1], Wataru Suzuki[1], Asako Iwaki[1], Shin Aoi[1], Haruko Sekiguchi[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. DPRI, Kyoto University

The 2018 Hokkaido Eastern Iburi earthquake (M_{jma} 6.7) struck southern Hokkaido, Japan on September 6, 2018 (JST). This earthquake caused strong ground motions over southern Hokkaido with a maximum seismic intensity of 7 on the JMA scale and a maximum PGA of over 1500 cm/s/s. In this study, we estimate the source process of this earthquake using strong motion waveforms.
For source-process analysis of this event, we develop a curved fault model based on the spatial distribution of aftershocks. This curved fault model consists of multiple planes, each with a width of 20 km, a common dip angle (65 degree), and a common top depth (approximately 22 km). The common dip angle refers to the moment tensor analysis of F-net. The strike angle of the planes smoothly changes along the strike direction: the strike angle is 15˚ at the north part, 340˚ at the central part, and 40˚ at the south part. The rupture starting point is set to the hypocenter determined by JMA. The curved fault model is divided into 15 subfaults along the strike direction and 10 subfaults along the dip direction.
We use velocity waveforms at 20 stations of K-NET and KiK-net, F-net of NIED. The waveforms are band-pass filtered between 0.05 and 0.5 Hz, resampled to 10 Hz, and windowed from 1 s before S-wave arrival for 25 s.
Green's functions are calculated with the discrete wavenumber method (Bouchon 1981) and the reflection/transmission matrix method (Kennett and Kerry 1979) assuming 1-D velocity structure models. The structure models are obtained for each station from the 3-D structure model (Fujiwara et al. 2009). Logging information is also used for the KiK-net station. To consider the rupture propagation effect, 25 point-sources are uniformly distributed over each subfault in the calculation of Green’ s functions.
The multi-time-window linear waveform inversion method (Olson and Apsel 1982; Hartzell and Heaton 1983) is used in this study. The slip time history of each subfault is discretized using eight smoothed ramp functions (time windows) progressively delayed by 0.4 s and having a duration of 0.8 s each. The triggering velocity of first time window is set to 1.4 km/s to minimize the data-fit residual. Two orthogonal slips of each time window at each subfault are derived by minimizing the difference between the observed and synthetic waveforms using the non-negative least-squares scheme (Lawson and Hanson 1974). The slip angle is allowed to vary centered at 107˚, which is the rake angle of the F-net analysis. In addition, we impose a spatiotemporal smoothing constraint on slips (Sekiguchi et al. 2000).
In the estimated source model, the large slips are found at approximately 30 km depth in the up-dip direction from the hypocenter. In the first 6 s, the rupture grows slowly around the hypocenter with small slips. Then, the rupture developed with the large moment release between 6 s and 12 s in the large slip area. The large slip area does not overlap with the active aftershock area

Broadband ground-motion simulation of the 2018 Hokkaido Eastern Iburi earthquake

*Asako Iwaki[1], Nobuyuki Morikawa[1], Takahiro Maeda[1], Hisahiko Kubo[1], Hiroyuki Fujiwara[1]

1. National Research Institute for Earth Science and Disaster Resilience

1. Introduction

The 2018 Hokkaido Eastern Iburi earthquake (M_{JMA}6.7) was an inland crustal earthquake at a focal depth of approximately 35 km. This earthquake brought strong ground motion to the southern Hokkaido, causing JMA seismic intensity of 6+ and 7 above the fault and nearby, and 6- in the city of Sapporo. The seismicity around the source region reaches to deeper region compared to other inland areas in Japan (HERP 2018). Inland crustal earthquakes at this depth have not been considered by the current ground-motion prediction procedure in Japan. Therefore it is necessary to examine whether the strong ground motion from this earthquake can be modeled by the conventional procedure.

2. Broadband ground-motion simulation

We conducted broadband ground-motion simulation using the characterized source model based on the “recipe” for strong motion prediction (HERP 2017), aiming to reproduce the observed ground motion. A planner fault is set referring to the fault slip model by Kubo et al. (2019, this meeting) with the length and width of 28km and 22km, respectively, in the lower crust. Rupture starting point is set to 35 km, and a single asperity is set several km shallower than the rupture starting point on the fault plane. Source parameters are derived by the recipe for inland crustal earthquakes. We call this source model the reference source model.

Broadband ground motion time-series on the engineering bedrock is computed using the J-SHIS v2 3D velocity model (Fujiwara et al. 2009, 2012). We employed a hybrid technique of the 3D finite-difference method (Aoi et al. 2004) and the stochastic Green’s function method (Dan and Sato 1998) superposed in time domain at the period of 1 s. JMA seismic intensity (I_{JMA}) on the ground surface is derived by using the empirical relationships between V_{S30}, PGV and I_{JMA} (Fujimoto and Midorikawa 2005, 2006).

Main features of the velocity waveforms in long-period range (> 1s), amplitude and travel time of the main phases, are found to be consistent with observed records at many observation stations. On the other hand, I_JMA on the ground surface systematically underestimated the observation. Although this underestimation can be attributed to many factors including the source and velocity models, since our simulation results underestimates the observation at all points in short-period component, we first examine the effect of the source parameters that mainly affects the ground-motion level of short-period components. The short-period level, or the source spectral amplitude level at short period, of this earthquake estimated by Tomozawa et al. (2018, SSJ) is 1 –2 times larger, depending on the dataset, than the empirical relation by Dan et al. (2001) which is employed in the recipe. Referring to their result, we set another source model that has smaller size of asperity and consequently higher short-period level, 1.5 times larger than the empirical relation of Dan et al. (2001). I_{JMA} computed with this source model was more consistent with the observation compared to the reference source model.

3. Summary

Broadband ground-motion simulations were conducted for this earthquake using the characterized source models. It was found that the ground motion computed with higher value of short-period level compared to the empirical relation for the ordinary inland crustal earthquake was more consistent with the observed ground motion. It maybe reflecting the feature of the earthquake source characterized by

©2019. Japan Geoscience Union. All Right Reserved.

the depth or the tectonic condition.
We will further study on the source characteristics and site response characteristics in order to better explain the strong ground motion records.

Acknowledgments: We used strong motion data provided by JMA, Hokkaido, the city of Sapporo, and NIED.

Estimation of 1D S-wave velocity structures in Kumamoto plain and Mashiki town using a waveform inversion of S-wave

*Kengo Muroi[1], Hiroaki Yamanaka[1], Kosuke Chimoto[1], Seiji Tsuno[2], Masahiro Korenaga[2], Hiroe Miyake[3], Nobuyuki Yamada[4]

1. Tokyo Institute of Technology, 2. Railway Technical Research Institute, 3. The University of Tokyo, 4. Kochi University

The 2016 Kumamoto earthquakes are crustal earthquakes caused by inland active faults with damage of many wooden houses to the focal area. In this study, we revised the previous subsurface structural model, using the observed ground motion records during aftershocks of the earthquakes, on the purpose of evaluating strong ground motion in damaged area during the main shock. Furthermore, we reproduced the strong motion of main shock, using the revised subsurface structural model.
First, we conducted 3-D finite difference simulations during aftershocks of the 2016 Kumamoto earthquakes, using previous subsurface structural model by Headquarters for Earthquake Research Promotion. We used the aftershock with an Mj of 5.5 and a depth of 10km on April 19 assuming a homogeneous fault model. From the comparison of the observed waveforms and the calculated waveforms in Mashiki, we found that the qualitative characteristics seen in the observed waveforms can be reproduced. However, we found it difficult to reproduce the detailed characteristics, such as the amplitude and phase.
Therefore, we tuned the 1-D subsurface structural models just beneath the observation sites by an inversion analysis, using waveforms of the observed initial S-wave during aftershocks. We estimated a 1-D velocity model minimizing misfit of mean squares between amplitudes of the observed waveforms and the calculated waveforms by a 1-D simulation using the discrete wavenumber method. We estimated the 1-D velocity structures at 36 observation sites in Kumamoto plain and Mashiki town during the aftershocks. We could well explain the characteristics of the observed waveforms, compared with the calculated waveforms using the previous subsurface structural model.
Finally, we conducted a simulation of the ground motion for the main shock, using the revised subsurface structural model. We used the source model by Kubo et al. (2016) and site amplification factors of J-SHIS in order to consider the effect of the amplification of the shallow soil. The calculated J.M.A seismic intensity distribution underestimated the observed seismic intensity at the center of Mashiki town and the calculated waveform at Mashiki town hall was 3 to 4 times smaller than the observed waveform. On the other hand, the calculated waveforms at K-net Kumamoto and KiK-net Mashiki are similar characteristics of the observed waveforms. These results show that the revised subsurface structure was reasonable in the Kumamoto plain, but we need to reconstruct further more the subsurface structural model beneath the center of Mashiki town.

Investigation to estimate high-frequency Empirical Green’s tensor derivatives (EGTD) using aftershocks for the 2016 Kumamoto earthquake

*Sayumi Yoshida[1], Horike Masanori [1], Ken Miyakoshi[2]

1. HANSHIN CONSULTANTS Co., Ltd., 2. Geo-Research Institute

1) Introduction
Green’s tensor derivatives play a key role for evaluation and prediction of strong ground motions and for surveys of the velocity and damping structures. However, it is difficult to generate high-frequency (above 1Hz) Green’s tensor derivatives using numerical approaches for want of fine geological structure models. Plicka and Zahradnik (1998) proposed a method for estimation of Empirical Green’s tensor derivatives (EGTDs) using multiple small earthquakes. EGTDs does not require the structural model along propagation paths for their estimation and is possible to calculate high-frequency ground motions for any focal mechanism. In this study, we investigate the conditions required (focal mechanism, grouping radius, applicable frequency) to obtain high-frequency EGTDs, using aftershocks of the 2016 Kumamoto earthquake.
2) Data and method
The size of the aftershocks ranges between the magnitudes 2 and 4. The focal mechanism, such as the strike, the dip angle, and the rake angle, and the source parameters of radiated spectra, such as the seismic moment and the corner frequency, are required for the estimation of EGTDs. The focal mechanism was obtained from the sign of P-wave first motions and the source parameters were obtained from the Fourier spectra of S-wave motions, assuming the model.
We first set the grouped aftershocks located within a sphere with a certain radius. Then, we estimated 3 EGTDs for 3-component ground motions from the grouped aftershocks by the approach developed by Plicka and Zahradnik (1998). Finally, we evaluated the accuracy of the estimated EGTDs by the correlation coefficients between observed seismic recordings of the grouped aftershocks and those calculated using the estimated EGTD for the 3- component ground motions. We furthermore evaluate the accuracy of EGTDs by investigating whether they can reproduce seismic waveforms of the aftershocks which are not contained in the group.
3) Results
Accurate EGTDs up to 2 Hz can be stably estimated from most groups with the radius of 1km, having the correlation coefficients over 0.8. Also, these EGTDs can reproduce the seismic motions of the aftershock that is not contained in the group. In the meantime, the correlation coefficients calculated from the estimated EGTDs up to 4Hz are not always not high values over 0.8 even for the groups with the radius 0.5 km. These results suggest that estimation of EGTDs up to the frequency higher than 2Hz requires accurate focal mechanism and source parameters of the radiated spectra. Thus, we will improve them, for example, using the Genetic algorithm.
4) Acknowledgement
In this study, we use event waveform data provided by NIED (Hi-net).

Estimation of Site Amplification Characteristics in Kumamoto plain by Spectral Separation Analysis Using Aftershock Records of the 2016 Kumamoto Earthquake

*Tomomi Iida[1], Hiroaki Yamanaka[1], Kosuke Chimoto[1], Daiki Shinoyama[8], Seiji Tsuno[5], Masahiro Korenaga[5], Nobuyuki Yamada[7], Hiroe Miyake[6], Tatsuo Kanno[3], Michiko Shigefuji[3], Masayuki Yoshimi[2], Shinichi Matsushima[4], Hiroshi Kawase[4], Kimiyuki Asano[4], Tomotaka Iwata[4]

The 2016 Kumamoto earthquake contains a foreshock with an Mj of 6.5 on April 14 and the main shock with an Mj of 7.3 on April 16. The earthquakes generated ground motions with a seismic intensity of 7 on the Japan Meteorological Agency scale twice in Mashiki, Kumamoto, Japan and many wooden houses were collapsed. In this study we estimated site amplification characteristics in Kumamoto plain by using ground motion records at strong motion stations of K-NET, KiK-net, seismic intensity-meters stations by local governments and aftershock observation stations by Yamanaka et al. (2016) through a spectral inversion technique. We choose the OITH08 station as the referential site in the inversion. The estimated frequency dependent Q and the source characteristics by the spectral inversion technique show similar features to those from previous studies (e.g. Somei et al, 2018). The site amplifications in the alluvium plain show large values in a frequency range of 0.5-2.0Hz. At high frequency the site amplifications of the mountain are larger than those of the plain area. We estimated S-wave velocity structures in Kumamoto plain by an inverse analysis of the site amplifications. The sediments are large in central area of the Kumamoto plain.

Kinematic and dynamic source models of the 2016 Mj6.4 Kumamoto third large earthquake

*Kunikazu Yoshida[1], Ken Miyakoshi[1]

1. Geo-Research Institute

We make a kinematic source model of the 2016 Mj6.4 earthquake (2016 Apr. 15, 00:03 JST) which is a third large event during the 2016 Kumamoto earthquake sequence and dynamic source models based on the result of the kinematic model.

The kinematic model is made by inverting the strong-motion data obtained from K-NET, KiK-net, JMA and local government were used. The data were windowed for 18 s, starting at P-wave arrival time, and band-pass-filtered between 0.05 to 1.0 Hz (periods of 1-20 s) for waveform inversion. The accelerograms were integrated into ground velocities. Theoretical Green's functions are calculated using the discrete wavenumber method (Bouchon, 1981) and the Reflection/Transmission coefficient matrix method (Kennett and Kerry, 1979) using a stratified medium. We assumed individual one-dimensional velocity structure model for each station by using waveform modelling with small earthquake records (Yoshida et al., 2017). The event locations were relocated using double-difference method by Uchide et al. (2016). We used multi-time-window linear waveform inversion procedure (e.g., Hartzell and Heaton, 1983) in which the moment-release distribution is discretized in both space and time. The length and width of the fault plane was assumed to be 12 km and 10.5 km, respectively. The fault plane is divided into subfaults of 1.5 km ×1.5 km. The moment function of each subfault was represented by a series of six smoothed ramp functions in the 0.4 second interval. The first time-window triggering velocity (V_{FT}) was determined as 2.4 km/s, which was searched between 2.0 and 2.6 km/s based on residual of the waveform fits.

The estimated source model indicated 1.2 ×10^{18} Nm (Mw6.0) of the total moment release and 0.3 m average slip. One rectangular asperity and a high slip/moment rate area (HRA, Yoshida et al., 2017) patches with the average slip of 0.7 m were identified on the shallow part of the fault plane. The slip of the background area is 0.1 m.

We attempt to make dynamic rupture models based on the kinematic model. Stress drop distribution of the kinematic model was calculated (Okada, 1992). The average static stress drops were 3.9 MPa (asperity) or 4.9 MPa (HRA) and 1.0 MPa for the background. Effective stress was taken from the stress parameters estimated from SMGA (Kurahashi et al., 2017). The effective stresses were adjusted as 5.1 MPa (Asperity) or 6.3 MPa (HRA) to rupture over the entire fault. We conducted dynamic rupture simulations using the patched stress drop distribution obtained from the kinematic model (Figure left-bottom). We assumed slip-weakening law with uniform critical distances of 0.1 m, based on Dc’’ (Fukuyama and Mikumo, 2007) of about 0.15 m at KMMH14. The simulation results show that the final slips and total moments well agree with the ones of the kinematic model. Nevertheless, small slips and high slip rate on the top margin of the patches, and supershear rupture propagation on the further of the patch were found. We expect examination of some dynamic parameters, such as critical slip distances, to improve simulation results.

Acknowledgements: We used strong motion data of K-NET, KiK-net, JMA and Mifune town. We thank Dr. Uchide (AIST) to provide the relocated hypocenter location data. This study was based on the 2018 research project ‘Examination for uncertainty of strong ground motion prediction for inland crustal

Source rupture process and strong motion generation area assuming the curved fault model for the 2003 northern Miyagi prefecture earthquake

*Kazuhiro Somei[1], Ken Miyakoshi[1], Yujia Guo[1]

1. Geo-Research Institute

At 07:13 on 26 July 2003 (JST), a shallow inland crustal earthquake (M_{JMA}6.4) with reverse faulting occurred in the northern Miyagi prefecture, north-east Japan. From the strong ground motion records in 0.05-0.5 Hz, the kinematic source rupture processes assuming a two-segment fault model have been estimated by waveform inversion method (e.g., Hikima and Koketsu, 2004). They showed large slips around 1.0 m occurred in a shallow part of the northern segment. However, surface breaks caused by this earthquake were not found along the source area by field surveys (e.g., Imaizumi et al., 2003). Since the shallow large slip area was identified between the north and the south segment, it is reasonable in estimating robust slip distribution to consider the more realistic fault plane with bending zone rather than a simple two-segment fault plane. Actually, the precisely relocated hypocenters of aftershocks were located along a curved plane dipping westward to north-westward (Okada et al., 2003). In this study, we investigate the source rupture process assuming the curved source fault, and estimate the strong motion generation areas (SMGAs; Miyake et al., 2003), in order to discuss the broadband ground motion generation processes during this event.

First, we employed the multi-time window linear waveform inversion method by using the strong motion waveforms (0.1-1.0Hz) recorded by K-NET, KiK-net, and JMA stations around the source area. From the observational information of relocated aftershock distribution and geological structure, the assumed curved fault model was composed of two planar segments (north and south segments) set by Hikima and Koketsu (2004) with transitional part that smoothly connect the north with south segment. The length, width, and shallowest top depth of fault model were 20 km, 11 km, and 0.59 km, respectively. This curved fault model was divided into 220 subfaults of 1.0 ×1.0 km. The temporal moment release history from each subfault was expressed by a series of 6 smoothed ramp functions with a rise time of 1.0 sec separated by 0.5 sec. The first-time window triggering velocity (FTWTV) was 2.8 km/s given by the smallest misfit solution. The theoretical Green’ s function was calculated by using the discrete wavenumber integration method (Bouchon, 1981) with the reflection and transmission matrix (Kennett and Kerry, 1979) assuming a 1D velocity structure model. The velocity structure model of each station was given by referring the Somei et al. (2018) or Petukhin and Miyakoshi (2006).

Second, the SMGAs were constructed based on the forward simulations using the empirical Green’ s function method (Irikura.1986) in the frequency range 0.3-10 Hz. The locations of rupture starting points and rupture times for two SMGAs were fixed by using the onset times of first and second S-wave packets in observations. Scaling parameters N and C were obtained based on the source spectral ratio analysis. The best set of parameters for SMGAs, such as the size, rupture velocity, rise time, and rupture starting point inside the SMGA, were determined by a grid searching to minimize the residual function of waveform fitting between observations and synthetics.

The principal findings from the source inversion and SMGA modeling are following. 1) The large slip area whose maximum slip of 0.93 m was concentrated in the transitional segment, where is north of the

©2019. Japan Geoscience Union. All Right Reserved.

hypocenter. The top depth of characterized asperity area (Somerville et al., 1999) was 3.07 km, which is deeper than that of Hikima and Koketsu (2004) model. The size of asperity area was 35 km^2, which is comparable to that expected by empirical scaling relationship (Somerville et al., 1999). 2) High peak moment ate areas (HRA; Yoshida and Miyakoshi, 2013), which implied the large slip velocity, were characterized with a size of 29 km^2 near the edge of the asperity area. 3) Synthetic ground motions generated from two SMGAs with a size of 24 km^2 identified close to the HRAs explained well the observations in a broadband frequency range. 4) The stress drops of two SMGAs were 13.7 MPa, which are comparable to those estimated for past large inland crustal earthquakes in Japan.

Estimation of source rupture process during the 2018 Shimane-ken seibu earthquake using strong motion data

*Susumu Kurahashi[1], Ken Miyakoshi[2]

1. Aichi Institute of Technology, 2. Geo-Research Institute

1. Introduction

The 2018 Shimane-ken seibu earthquake (Mw5.6) occurred in the western part of Shimane-prefecture, Japan, on April 9, 2018. The maximum seismic intensity with 5 upper was observed at Ohta city. PGA of 564 gal is observed at the SMN006 station. We estimated the source process of this earthquake by the waveform inversion using the strong motion data.

2. Estimation of rupture area from the waveform inversion

We analyzed the slip distribution during this earthquake using the multi-time window linear waveform inversion method (Sekiguchi et al., 2000). The data sets used for the inversion analysis were velocity waveforms of S-waves parts at 13 stations (KiK-net, K-NET). The Green's functions were calculated using the one-dimensional velocity structure models by the discrete wavenumber method (Bouchon, 1981) with the reflection and transmission matrix method (Kennett and Kerry, 1979) at the stations. A fault plane was assumed referring to the aftershock distribution and the moment tensor solution determined by F-net data.

First, in order to estimate the rupture area, we analyzed the waveform inversion in target frequency 0.1-0.5Hz. The fault plane is divided into 36 subfaults of 2.0km×2.0km. The temporal moment release history from each subfault is modeled by a series of 3 smoothed-ramp-functions with a rise time of 1.0 second each separated by 0.5 second. The estimated rupture area was trimmed by criteria of Somerville et al. (1999). The trimming result removes one column of the north edge of rupture area. Seismic moment, area, rupture velocity and average slip are estimated 4.67 $\times 10^{17}$Nm,126km^2, 2.7km/s and 0.11m, respectively. The rupture area was approximately three times larger than the scaling relationship of rupture area vs seismic moment from Irikura and Miyake (2001).

3. Extraction of asperity from the waveform inversion results

Next, in order to extract of asperity from slip distribution, we analyzed the waveform inversion in the frequency range of 0.1-1.0Hz. The rupture area is divided into 56 subfaults of 1.5km×1.5km. The temporal moment release history from each subfault is modeled by a series of 6 smoothed-ramp-functions with a rise time of 0.6 second each separated by 0.3 second. A large slip area is constructed in the proximity of the hypocenter.
The asperity and high rate area (HRA) were extracted from the slip distribution by the criterion of Somerville et al. (1999) and Yoshida et al. (2005), respectively. Seismic moment and area are estimated 2.23×1017Nm and 27km2, respectively. The area and location of the asperity and the HRA are estimated to be almost the same. On the other hands, the asperity was overestimated in comparison with the scaling relationship of asperity are vs seismic moment from Irikura and Miyake (2001).

4. Conclusion

©2019. Japan Geoscience Union. All Right Reserved.

We estimated source process of the 2018 Shimane-ken seibu earthquake (Mw 5.6) form the waveform inversion using the strong motion data. The asperity and the HRA of this earthquake are collocated with nearly the same area. On the other hands, the rupture area and the asperity were overestimated corresponding to scaling law from Irikura and Miyake (2001). The rupture area data of earthquake of Mw6 class vary widely in the scaling law from Irikura and Miyake (2001). Therefore, it is necessary to consider about earthquake of Mw6 class.

Acknowledgements. Seismic waveform data of the K-NET and KiK-net were used. This study was based on the 2018 research project 'Examination for uncertainth of strong ground motion prediction for inland crustal earthquakes').

An estimation of SMGA of M6 class earthquakes based on strong motion records near the source regions

*Kentaro Motoki[1], Kenichi Kato[1], Tetsuo Shiota[2]

1. Kobori Research Complex, 2. Shikoku Electric Power Company

High amplitude earthquake motions exceeding 1 G have been observed when M6 class earthquakes occurred for a couple of decades. In the 2004 Rumoi earthquake (M6.1), two SMGAs in the vicinity of the strong motion station caused high amplitude earthquake motions (Maeda and Sasatani , 2008, Motoki et al., 2015). For M6 class earthquakes, which are difficult to set up fault models to be used for strong ground motion prediction, we thought that accumulating information such as stress drop and area of SMGA gave useful information for setting ground motion level for future earthquakes. In this report, we inverted SMGA for the 2011 Ibaraki-ken Hokubu earthquake.

We used empirical Green's function method (EGF) to invert SMGA. Unknown parameters in this inversion were the location of SMGA trigger point, stress drop ratio c, the number of superposition N, length of SMGA, rupture velocity in SMGA, starting rupture time of SMGA, rise time, and random numbers giving the rupture fluctuation to weaken artificial periodicity. For inverse analysis of SMGA, we used a hybrid heuristic method (Yamanaka, 2007), which could solve nonlinear problems and did not require an initial model.

For an inversion of SMGA, we selected 4 stations (IBRH13, IBRH14, IBR001 and FKS014) where the influence of nonlinearity in subsurface soil during the main shock might be small based on degree of nonlinear site response proposed by Noguchi and Sasatani (2011). We also selected 7 earthquakes as element earthquakes for empirical Green’ s function. We performed 7 inversion analyses using each element earthquake record.

Corner frequencies of the element earthquakes were evaluated by means of genetic algorithm so as to minimize the sum of residuals between the observed source spectral ratio and the source spectrum ratio function assumed ω-square model in the frequency domain. We set the search range for an inversion of SMGA, by referring to the previous source model (JMA, 2017) and c and N expected from the observed source spectral ratio. In this inversion M_0 and A, which means radiant amplitude in a short period range, were constrained not to exceed the value estimated by F-net and the value obtained from the source spectral ratio, respectively. The acceleration envelope shapes, the displacement waveform, and the Fourier amplitude were used as the objective function for an inversion.

Assuming one SMGA, the inverted SMGA could explain the earthquake motions near the source region. The SMGA location were good agreement with the large slip area in the previous models (JMA, 2017 and Hikima, 2017), which were used long period motions for their inversions.

Furthermore, in order to confirm the validity of the inverted SMGA from a theoretical aspect, we performed numerical simulation for the down-hall station at IBRH13 using the theoretical Green’ s function analysis (Hisada and Bielak, 2003). The simulated motions successfully reproduced the pulse wave and the response spectra of the observed motions.

We compared the area of SMGA estimated in this study with the relation of M_0 –area of SMGA according

©2019. Japan Geoscience Union. All Right Reserved.

to Miyake et al. (2003). The result of this study is smaller than that of relation by Miyake et al. One factor that caused this difference is thought to be due to the difference in idea of modeling. As mentioned above, M_0 of the SMGA in this study corresponded to a third of M_0 evaluated by F-net. Meanwhile, the SMGA of Miyake et al. (2003) had set the SMGA to include all of the M_0. It can be consider that the larger M_0 of SMGA has the larger area of SMGA. On this issue, we think that it is important to apply other earthquakes and accumulate data, and we will analyze SMGA of the 2013 Tochigi-ken Hokubu earthquake.

Difference in short-period level between the surface and buried fault rupture crustal earthquake in Japan

*Shohei Yoshida[1], Takao Kagawa[1], Tatsuya Noguchi[1]

1. Graduate School of Engineering, Tottori University

Appearance of surface fault rupture in inland crustal earthquake affects significantly on ground motion characteristics. Somerville(2003) indicated that observed ground motions from buried rupture earthquakes are larger than those from surface fault rupture earthquakes in period range around 1.0 second. Kagawa *et al.*(2004) explained that the differences are mainly caused in seismic source characteristics of fault ruptures, such as peak slip rate and stress drop between shallow and deep region. The Headquarters for Earthquake Research Promotion compiled a method for strong motion prediction (recipe). Short-period level as a parameter of the recipe is an important factor that affects generation of short-period ground motion. Due to the difference in ground motion characteristics between surface and buried fault rupture, the short-period level may also be different between the two rupture types. In this study, we organize short-period levels that evaluated characteristic source models by empirical Green's function method, and investigated empirical relations between short-period level and seismic moment for both surface and buried fault rupture crustal earthquake in Japan.

Probabilistic seismic hazard assessment of response spectra for whole Japan (part 1: Selection of ground motion prediction equations)

*Nobuyuki Morikawa[1], Junichi Miyakoshi[2], Hiroyuki Fujiwara[1]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Ohsaki Research Institute, Inc.

The seismic intensity or peak velocity is used in the probabilistic national seismic hazard maps for Japan. However, seismic hazard assessment of response spectra is useful in seismic risk assessment and engineering field. In this study, we try to assess seismic hazard of the response spectra by using the seismic activity model in the national seismic hazard maps for Japan. In this paper, we mention selection of ground motion prediction equations (GMPEs) used in the assessment, and the results are shown in the next report.
In Douglas (2019), 290 GMPEs for spectral ordinates published after 1973 are summarized, of which about 50 are derived from strong-motion records mainly observed in Japan. The 2003 Tokachi-oki earthquake was the first magnitude 8-class earthquake in the world where strong-motion records observed by the nation-wide dense networks, K-NET and KiK-net. It is very important to use the GMPE obtained using the record of the 2003 earthquake, because the contribution of large subduction earthquakes on seismic hazard assessment in Japan is extremely large. In this study, we carry out the assessment of 5%-damped acceleration response spectra whose period is shorter than 5 seconds all over Japan on the engineering bedrock (Vs=400m/s). So we select GMPEs that satisfy the following conditions.
a. It has been published as a peer-reviewed paper.
b. It was derived from records mainly observed in Japan, including records of the 2003 Tokachi-oki earthquake.
c. It is included peak acceleration and 5% damped acceleration response spectra whose period ranges from 0.1 to 5 seconds and can evaluate on the engineering bedrock.
d. It is possible to consider the difference of source and path characteristics in earthquake type (crustal, subduction plate-boundary, and subduction intra-plate).
e. It is modeled anomalous seismic intensity distribution.
f. It does not target specific earthquakes or observation points only.
g. It is used records of magnitude 9-class mega-earthquake.
As the result, two sets of GMPEs by Morikawa and Fujiwara (2013) and Zhao et al. (2016) were selected. However, with regard to the above condition g, it is inevitable that the uncertainties concerning the applicability to the earthquakes in Nankai trough are large because both GMPEs are used records the 2011 Tohoku great earthquake only for magnitude 9-class. In order to consider such uncertainty, we decide to add the latest GMPE, Goda and Atkinson (2009)’s, that satisfies other conditions.
The difference is large in the short distance or mega-earthquake, which number of records is quite few, among three GMPEs. By the way, the dataset for deriving the GMPE is constructed by each researchers. As the result,
1. Methods of filtering applied to observed waveforms and definition of horizontal maximum amplitude are different each other.
2. The magnitude and fault model selected are different for each other.
3. Indicators related to site amplification, such as site class and Vs30, are not unified.
This situation makes it impossible to compare among GMPEs under exactly the same conditions. This is not limited to the three GMPEs selected here, but is a problem common to all Japanese GMPEs that do not have derived from the same dataset. In seismic hazard assessment including mega-earthquakes and very close distance to the source fault with quite few observation records, it is necessary to use multiple

©2019. Japan Geoscience Union. All Right Reserved.

GMPEs in consideration of epistemic uncertainty. In case of seismic hazard assessment targeting a specific site, there is also the idea that each GMPE is weighted based on consistency with observation records. However, in order to evaluate its consistency, it is necessary to construct a unified standard dataset and to use GMPEs derived based on it that can be compare under the same conditions.

Probabilistic seismic hazard assessment of response spectra for whole Japan (part 2: Probabilistic seismic hazard assessment)

*Junichi Miyakoshi[1], Takeshi Morii[1], Nobuyuki Morikawa[2], Hiroyuki Fujiwara[2]

1. Ohsaki Research Institute, Inc., 2. National Research Institute for Earth Science and Disaster Resilience

The seismic intensity or peak velocity is used in the probabilistic national seismic hazard maps for Japan. However, seismic hazard assessment of response spectra is useful in seismic risk assessment and engineering field. In this study, we try to assess seismic hazard of the response spectra by using the seismic activity model in the national seismic hazard maps for Japan. In this paper, the seismic hazard assessment results of the response spectra are shown using the selected ground motion prediction equations (GMPEs) in the previous report.
Three GMPEs are used: Morikawa and Fujiwara (2013), Goda and Atkinson (2009), Zhao et al. (2016). When evaluating seismic hazards for Japan, it is difficult to evaluate only by one GMPE, so it is necessary to select multiple GMPEs as a branch of the logic tree.
Based on the hazard curve of the response value with respect to the natural period, a uniform hazard spectrum (UHS) is calculated by connecting response spectra that have the same excess probability for each natural period. We calculate UHS at 6 cities (Sapporo, Sendai, Tokyo, Nagoya, Osaka, Fukuoka) by using the seismic activity model in the national seismic hazard maps for Japan.
As an example of the result, we are shown uniform hazard spectra for 39%, 10%, 5%, and 2% probability of exceedance occurring within 50 years from the present for all seismic activity models in Sapporo and Tokyo using GMPE by Morikawa and Fujiwara (2013). In the uniform hazard spectra, we can confirm the difference between the seismic hazard level of Sapporo and Tokyo. Also, the degree of influence of the seismic category for each natural period for a 10% probability of exceedance occurring within 50 years from the present is shown. By using the seismic activity model in the national seismic hazard maps for Japan in this way, it becomes possible to grasp the difference of the seismic hazard in the region for each natural period. In addition, we assess seismic hazard of standard peak acceleration in the world.

Simulation of Long-period Ground Motion around The Fujikawa-kako Fault Zone during the 2018 Northern Osaka Earthquake

*Seina Hashimoto[1], Hiroaki Yamanaka[1], Kosuke Chimoto[1], Masahiro Korenaga[2], Seiji Tsuno[2], Hiroe Miyake[3], Shigeki Senna[4]

1. Tokyo Institute of Technology School of Enviroment and Society, 2. Railway Technical Research Institute, 3. The University of Tokyo, 4. National Research Institute for Earth Science and Disaster Prevention

Abstract

The Fujikawa-kako fault zone is an active fault that is suggested to be associated with the Nankai Trough in Suruga Bay, and the activity interval of this fault is a relatively high as compared to the other general active faults. Furthermore, this area is so important for the transportation network for our lives near this fault zone. A high-reliable prediction of strong ground motion in this area is important in earthquake disaster prevention in the area. In this study, we have installed strong motion observation instruments in Fujinomiya City and Fuji City to acquire strong motion records during small earthquakes since April 2018. From the earthquake records obtained at the observation points, it was found that the duration of the shaking was as long as nearly 2 minutes, and the long period component was dominant in the 2018 Northern Osaka Earthquake with a magnitude of 6.1. Then, using the deep S-wave velocity structure model of J-SHIS, we conducted seismic motion simulation of Northern Osaka Earthquake. We also assumed appoint source model, based on the CMT solution released by the Meteorological Agency. First, we compared the synthetic waveform of the rock site (YMNH10) with the observed one. The calculated waveform had similar characteristics of the observed waveform. By using the snapshots, we found that the major phases observed mainly in this area were surface waves with a north-south oriented wavefront arriving a right after the S wave arrival. We also found the later phases arriving from the southwestern part of Yamanashi Prefecture where the depth of the seismic bedrock is suddenly increases. On the other hand, the reproducibility of the observed frequency characteristics in the vicinity of Shizuoka City was low in a period range of 3-20 seconds. We need further improvement in the S-wave velocity model of the sedimentary layers.

Acknowledgements

A part of this study was carried out as an integrated research project for observation for the Fujikawa estuary fault zone by Ministry of Education, Culture, Sports, Science and Technology-Japan.

Site amplification factors for KiK-net stations in and around Ibaraki Prefecture estimated by the coda normalization method

*Jun Kawahara[1], Takahiro Nakamura[1], Takuji Yamada[1]

1. Graduate School of Science and Engineering, Ibaraki University

It is empirically known that the spatial distribution of the coda wave energy from a local earthquake is nearly uniform for long lapse times. The coda normalization method is a method of separating source, path, and site effects from coda wave records, based on this empirical characteristic (Sato et al., 2012). There are many studies on the evaluation of site amplification factors based on the coda normalization method (e.g., Takahashi et al. 2005; Takemoto et al., 2012). However, little attention has been paid on the magnitude of the variability of amplification factors estimated for different earthquakes in an identical region.

We applied the method to the strong-motion records for 21 KiK-net stations and F-net TSK (Tsukuba) station in and around Ibaraki Prefecture. We used the records of 31 earthquakes with 4.7≦Mw≦6.4, which were classified into four groups depending on their locations. Stations with the epicentral distances less than 100 km were chosen for each earthquake, and the seismograms for lapse times greater than twice the direct S-wave travel time at the farthest station were used in the analysis. We selected TSK as the reference station for which the site amplification is expected to be low, and we obtained the amplification factor for each KiK-net station relative to TSK. We also calculated the geometric mean of the factors for each earthquake group.

We obtained the following results. (1) The low-frequency (0.5 to 1 Hz) amplification factors were apparently correlated with both basement depths and geological ages. It is consistent with previous studies such as Takemoto et al. (2012). (2) At the stations with shallow basement in the northern areas, the variability of the amplification factors among the earthquakes was small irrespectively of frequencies, and the geometric means of the factors for four earthquake groups were nearly the same. (3) At the stations with deep basement in the southern areas, the variability of the amplification factors among the earthquakes was relatively large, and the geometric means of the factors for four earthquake groups were somewhat different. (4) The geometric standard deviations of the amplification factors were apparently correlated with both basement depths and geological ages. (5) There appears no clear relationship between the amplification factors and the hypocentral distances for most stations. It supports the empirical assumption that the spatial distribution of the coda wave energy is nearly uniform.

Acknowledgment.
We used the strong-motion records form KiK-net and F-net and the data of basement depths from J-SHIS (National Research Institute for Earth Science and Disaster Resilience).

Estimation of earthquake ground level in Horinouchi area in the 2014 Northern Nagano earthquake

*RYOTA KAWAI[1], Hiroaki Yamanaka[1], Kosuke Chimoto[1], Seiji Tsuno[2], Masahiro Korenaga[2]

1. Interdisciplinary Graduate School of Science and Engineering,Tokyo institute of Technology, 2. Railway Technical Research Institute

The 2014 Northern Nagano Earthquake with Mj of 6.7 occurred on 22 November 2014. The JMA maximum intensity of 6 lower was observed in Otari village and Ogawa village. However, heavy damage was observed in Horinouchi and Mikkaichiba areas which are 5km away from the strong observation point with intensity of 5 higher. One of the reasons for the heady damage is low seismic performance of the damaged houses as reported in JAEE's team. However, strong motion features of main shock are not fully understood in the area... In this study, we estimated the ground motions in the damaged areas to know the reasons of the damage.

After the main shock, Chimoto et. al (2015) observed aftershock records around the damaged areas In this study, we analyzed these records with records observed at strong motion stations using the spectral inversion technique. This technique can divide ground motion spectra into site, source and propagation effects. We used records from 59 earthquakes including aftershocks between JMA magnitudes of 2.4 and 5.8, and the main shock. During strong shaking like the main shock, nonlinear behavior of soil layers can be observed. Thus, we set three conditions for the data selection in this inversion analysis.

1) For earthquake records with PGAs less than 100 gal except for the main shock,

2) the main shock records with PGAs less than 100 gal have site effects as same to those of weak shock,

3) the main shock records with PGAs more than 100 gal has site effects that are different from those of the weak motions. Under these conditions, different site effects for the weak motion and the main shock are estimated at the observation stations with PGAs more than 100gal during the main shock.

We investigated the relation of the estimated site effect for the weak shaking and the main shock at the observation stations. The differences of these site effects can be caused by the nonlinearity of the soft soil. Therefore, in this study, we defined Ra(f) as an ration of the site effect for the main shock to that of weak shaking. We investigated the relationship between this Ra and the S wave velocity profiles by our microtremor surveys. At the observation stations with PGAs of 400 gal during the main shock, it was found that the Ra is similar for the sites with similar average S wave velocities up to a depth of 10 m (hereafter, Vs 10). The Vs10 in Horinouchi area is 165m/s, and VS10 in Ogawa village is 151m/s. Therefore, it is indicated that Ras in Horinouchi area and Ogawa village are the same.

The spectra characteritics of the main shock at basement was calculated from the source effect of the main shock and the propagation effect, estimated by spectrum inversion. Furthermore, we estimated the site effect of the main shock in Horinouchi area from the site effect of weak shaking and Ra of Ogawa village for estimating the spectral features of the main shock in Horinouchi area by these multiplications of these factors.

As a result, it was found that the estimated earthquake ground motion level was about 2 times stronger

©2019. Japan Geoscience Union. All Right Reserved.

than the strong motion observation stations at a period of 1-1.5 seconds, which has large effects on the wooden houses. We also found that this motion is classified to a seismic intensity of 6 upper on the JMA scale. On the other hand, the estimated spectral power in this study is about 1/4 to 1/2 of the strong motion spectrum of past destructive earthquakes observed in areas with heavy damage of the wooden building.

From these discussions we have concluded that ground motion at periods of 1-1.5 seconds were slightly larger than the surrounding observation stations. However the low earthquake resistance of the damaged building in Horinouchi area must be also included in one of the reasons of the damage.

Ground type classification for strong ground motion prediction based on characteristics of phase-velocity curves from microtremor explorations

*Atsushi Wakai[1], Shigeki Senna[1], Hisanori Matsuyama[2], Yatagai Atsushi[2], Yoshiaki Inagaki[2], Hiroyuki Fujiwara[2]

1. National Research Institute for Earth Science and Disaster Prevention, 2. OYO Corporation

For the purpose of strong ground motion evaluation and prediction, subsurface velocity structures in sedimentary layers have ever been modeled and sophisticated for Kanto, Tokai and Kumamoto region in the national investigation conducted by SIP (Cross-ministerial Strategic Innovation Promotion Program) of Council for Science, Technology and innovation.

There, spatially dense array-microtremor explorations also have been conducted at more than 27,500 sites in the regions, as of February 2019. They consist of miniature and irregular array measurements made at interval of about 1 km and standard-sized array ones made at interval of about 5 km. As a result, shallow S-wave velocity structures were modeled in detail, which can affect ground amplification, building and human damage.

In this study, regarding characteristics of phase-velocity (hereinafter called Pv) curves from array microtremor explorations, it was attempted to investigate relationships with geomorphologic land classification [Wakamatsu et al., 2013] and geological constitution of ground.

Pv curves can be usually obtained 2Hz to 30Hz in frequency from miniature and irregular array microtremor explorations. In general, Pv in higher frequency corresponds to velocity structures in the depth of a few of meters to 10 meters and that in lower frequency corresponds to those in the depth of dozens of meters below ground surface. Here, Pv at wave length of 40 meters or C40 [Konno et al., 2000] was extracted and made use of at each microtremor measurement site. C40 can be regarded as AVS30.

As a result, useful information was able to be acquired to model subsurface velocity structures in addition to new knowledge which was not able to be obtained from only bore-hole exploration data. Also, C40s vary due to different-sized plains and different sedimentary environment despite the same geomorphologic land classification. This presentation will report the results in detail.

Establishment of the Underground Structure Model for Seismic Damage Estimation

*Shigeki Senna[1], Atsushi Wakai[1], Hiroyuki Fujiwara[1]

1. National Research Institute for Earth Science and Disaster Resilience

1.Introduction
To develop subsurface structure models for estimating earthquake damage on a real-time basis, we studied subsurface models capable of evaluating ground motion characteristics at a broad range of frequencies. We combined a shallow subsurface model and a deep subsurface model by collecting boring data and soil property data, which are crucial for explaining the ground motion in the vicinity of each period (0.5 to 2.0s), as such ground motion affects soil both near the surface and deep in the ground. In this study, we developed a widearea subsurface structure model (250m grid cell) and a more detailed subsurface model (50m grid cell), as well as a microtremor measurement system and a subsurface structure information management system to support model development. A brief description of each of the following themes will be provided in the sections below.

(1) Construction of wide-area subsurface models for estimating earthquake damage
(2) Understanding of ground motion characteristics and development of a microtremor observation system
(3) Development of a construction technique for a detailed subsurface model through public-private collaboration

2. Construction of Wide-Area Subsurface Models for Estimating Earthquake Damage
Wide-area subsurface models were constructed for the entire Kanto and Tokai regions. Here, we will mainly report on the progress made with the model for the Kanto and Tokai area. To develop a shallow subsurface model, we primarily used approximately 440,000 sets of boring data gathered by NIED. We created an initial integrated model for shallow and deep subsurfaces by combining this shallow subsurface model with an existing deep subsurface model (J-SHIS) and adjusting the engineering bedrock. Records compiled by K-NET, KiK-net, JMA, and local governments were used as seismic observation records. To gather continuous microtremor data, two types of observation techniques, namely miniature and irregular arrays and large arrays (R = 25 to 800 m), were used at approximately 20,000 and 800 points, respectively.

3. Understanding Ground Motion Characteristics and Development of a Microtremor Observation System
To obtain a large number of microtremor array measurements and ensure that results are managed effectively until the results of analysis are produced, it is necessary to minimize and simplify the steps required to collect observation data, analyze them, and evaluate the results. To achieve these goals, we developed a mechanism that can perform all the steps quickly, including on-site data sorting and analysis while minimizing human error. More specifically, we developed i-Bido, which transmits data between seismometers and computers, tablets, and other computing devices without corrupting the data while preserving its quality, and sends the data to the database described below.

4. Development of a Construction Technique for a Detailed Subsurface Model Through Public-Private Collaboration
Our goal is to construct detailed subsurface models with 50m grid cells capable of predicting liquefaction

and landslides while accounting for factors such as ground irregularity and artificial sites, using both public and private boring data, building confirmation applications, topographical information, old topographic maps, and other data. A slope map developed by the Geospatial Information Man-made structures were excluded. The distribution of small artificial valley fills that could not be identified by topographical maps derived from an algorithm for calculating and comparing slopes was obtained. Finally, the buffer region was applied to the water systems identified from the results of water system analysis to develop a model. The model is consistent with the distribution of large-scale artificial sites and also appears to show small artificial sites.

Consideration of liquefaction damage rate based on liquefaction damage in recent years

*Shigeki Senna[1], Ozawa Kyoko[1]

1. National Research Institute for Earth Science and Disaster Resilience

1. Introduction
In the 2011 off the Pacific coast of Tohoku Earthquake, liquefaction occurred in an extremely large area from the Tohoku region to the Kanto region, and a large number of liquefaction damage was confirmed in Kumamoto City and Aso City in the 2016 Kumamoto earthquake. In The past, the authors examined the rate of liquefaction in recent years of liquefaction and showed that the difference in the rate of liquefaction in the Tohoku-Pacific Ocean earthquake and other earthquakes was explained by the effects of the duration of the seismic motion. However, this creation of anation, liquefaction hazard map is difficult, and there is grouping based on the history of the microtopography of 250 m mesh and the regional classification method for this regionality consideration. the improvement of the high accuracy of the liquefaction rate prediction equation by setting the area ratio of the area and the subdivision of the micro-topography division, etc. by using topography and elevation data. We also collected information on building damage and investigated the rate of liquefaction damage.

2. Collected and maintained data
The 2011 off the Pacific coast of Tohoku Earthquake and the 2016 Kumamoto earthquake liquefaction Point by local surveys and aerial images, A re-reading of the sand point was performed from high sight point of the geographical institute immediately after the earthquake. we have created a detailed data set of about 50 m and about 25 m mesh units as well as the data set of approximate 250 m mesh units that have been prepared so far.
In addition, the following data were also prepared.

(1) Average elevation, average gradient, and ratio of high data for each mesh size (250 m, 50 m, 25 m) based on 10 MDEM data.
(2) Topographic classification data for each mesh size based on land use classification data based on the above data, we investigated the liquefaction incidence and the area ratio from the relationship between the data and the liquefaction point.
(3) We collected damage information such as slope and settlement of buildings in the 2011 off the Pacific coast of Tohoku Earthquake and the 2016 Kumamoto earthquake, and investigated the relationship with the incidence rate.

3. Investigation of liquefaction generation rate and area ratio
With regard to liquefaction incidence, data on liquefaction occurrence rates of the 2011 off the Pacific coast of Tohoku Earthquake and the 2016 Kumamoto Earthquake are summed up and the measured seismic intensity and maximum velocity fragility are calculated for each micro-topography classification using the least squares method and maximum likelihood Method and cluster analysis was carried out to group the micro topographical classification. As a result, it was able to be grouped into four new groups different from the micro topography group classified based on the liability to liquefaction by a previous study. For each group, the possibility of group subdivision was examined by comparing with average elevation, average gradient, specific height data etc. of each mesh. As a result of examination, it was found that the liquefaction occurrence rate has extremely high correlation with the specific height in any of the

©2019. Japan Geoscience Union. All Right Reserved.

micro topography classifications, and it is highly likely that the above four groups can be further subdivided. Regarding the liquefaction area ratio, assuming that 25 m mesh is the minimum unit, if there is even one sand in the mesh, it is assumed that the whole mesh is liquefied. Regarding the areal ratio, because there was no clear correlation with the measured seismic intensity and the maximum velocity in all the micro topographical classifications, the average value of the area ratio was calculated for each micro topographical classification. For the sake of simplicity, this study summarizes the final liquefaction occurrence rate by multiplying the liquefaction occurrence rate and liquefaction area rate shown above. In addition, we examined the relationship between seismic intensity, maximum speed and liquefaction occurrence rate for slope and settlement of building damage caused by liquefaction.

4. Conclusion (future plans)
The liquefaction incidence rate calculation formula (florality) examined in this study will be compared with building damage damage distribution data in the future, and the validity of the results will be verified.

Estimation of surface earthquake record at MeSO-NET observation points

*Shigeki Senna[1], Atsushi Wakai[1]

1. National Research Institute for Earth Science and Disaster Resilience

1. Introduction
In this research, in order to predict the state of shake of the ground surface with high precision from the data of the underground seismometer installed at the depth of 20 m of MeSO-net, microtremor observation at each observation point and temporary observation at the surface By observation, we evaluate the ground amplification characteristics and estimate the S wave velocity structure of the ground. As research and development items for that, 1. Acquisition of surface earthquake record and estimation of amplification characteristics at MeSO-net observation point, 2. Estimation of geophysical properties such as microtremor array observation and S wave velocity structure.The following section introduces efforts for each item.

2. Acquisition of surface earthquake records and estimation of amplification characteristics at MeSO-net observation point
In this item, in order to estimate the ground-to-ground spectral amplification factor for each observation point by temporary seismic observation at the MeSo-net observation point, it was conducted at all MeSO-net observation points (297sites) There. The observation period is 2 to 3 months per point, and observation is completed at 60 points. For each target observation point, one seismometer (JU 310 and JU 410 manufactured by Hakusan Kogyo Co., Ltd.) having the same sensor as the MeSO-net seismograph was used. In addition, the sampling frequency at the time of data acquisition was set to 200 Hz and the range was set to ±4.0G (± 1.0 G for JU 310) for JU410. Amplification characteristics are calculated by calculating the Fourier spectrum for each component from the seismic waveform obtained in the ground and the surface at each observation point, applying a bandpass filter of 0.1 to 10 Hz, smoothing in a logarithmic window, The ratio was taken. As a result, the difference in amplification characteristics between the relatively hard Rohm plateau sites and the soft backward swamp and natural embankment sites.

3. Microtremor array observation and estimation of ground physical property values such as S wave velocity structure
To verify the ground amplification characteristics of the previous section and make it possible to assume the shake even under strong ground motion, microtremor array observation to obtain the S wave velocity structure of about 50 m underground was carried out. Microtremor observation purchased a three component seismometer/ microtremor observation device (JU410) with the same sensor characteristics as the MeSO-net seismograph. Using them, microtremor array observation is carried out just above 296 points of the target MeSO-net observation point. In the fine motion array, we deployed a 4-point extremely small array with an array radius of 60 cm and a 3-point irregular array with about 5 to 15 m on each side, and observation was done for about 15 minutes at the same time. In addition, the ground physical property values such as the S wave velocity structure were estimated using inverse analysis methods such as extraction of amplification characteristics of AVS30 etc. (C40), direct curve transformation method of dispersion curve, inverse analysis and the like. As in the previous section, the difference between the characteristics of the relatively hard Rohm and the soft backward swamp are clear.

©2019. Japan Geoscience Union. All Right Reserved.

4. Conclusion
Based on the seismic observations and microtremor observations carried out up to the previous section, we will consider the ground amplification factor considering the period in the future, but we will consider the past ground model (SIP) of the existing Kanto region We will further improve the S wave velocity structure model using the shallow / deep integrated subsurface structure model of the Kanto region implemented in the real-time earthquake damage estimation) and estimate the highly accurate seismic motion at 250 m mesh interval The goal is to do.

Possibility of estimating phase velocity of Love wave using Horizontal components in microtremor array surveys in the case of Nishio

*Kotoyo Tsuchida[1], Masanori Horike[1], Koji Yamada[1], Masaki Suehiro[1], Sayumi Yoshida[1]

1. HANSHIN CONSULTANTS COMPANY LIMITED

1) Introduction

The S wave velocity structure of sediments is the most important factor for amplification of earthquake motions. In recent years, microtremor array surveys have been popularized because the S wave velocity structures can be estimated by simple measurements and at a low cost. For example, Horike (1985) inferred the S wave velocity from f-k spectra estimated array microtremors and Aki (1957) and Okada (2003) also inferred them from the spatial autocorrelation functions (SPAC). These approaches use vertical microtremor array recordings and discard horizontal-component recordings. As is well known, the phase velocity of Rayleigh waves is influenced not only by the S-wave velocity structure but also by the P-wave velocity structure, while that of Love wave is influenced by the S-wave velocity structure alone. Therefore, it is expected that S wave velocity structure can be obtained clearly by estimating the velocity structure using the dispersion of the Love wave. Several approaches are developed for inference of the phase velocity of Love waves, for example f-k method by Tsuchida et al (2016), SPAC and CCA method by Tada et al (2010; using the microtremor array analysis tool "BIDO 2.0" software). The aim of this study is to compare the phase velocities obtained using the same arrays.

2) Observation and data

For this comparison, we implemented microtremor measurement in Nishio City, Aichi Prefecture, using different-size array composed of 7 stations. At each station 3-component velocity sensors were installed. Microtremor recording were acquired at a sampling interval of 0.005s for 30 minutes. This site is suitable for this comparison, because there is much information about geotechnical and geological property.

3) Results

At the present, the phase velocity by the f-k method is estimated, but it is still in the process of analysis. Therefore, by the day of the presentation, we will proceed with the remains to do.

Enhancement of shallow velocity structure models based on array microtremor explorations for Tokai region, Central Japan

*Atsushi Wakai[1], Shigeki Senna[1], Yatagai Atsushi[2], Yoshiaki Inagaki[2], Hisanori Matsuyama[2], Hiroyuki Fujiwara[1]

1. National Research Institute for Earth Science and Disaster Prevention, 2. OYO Corporation

1. Introduction
For sophistication of strong ground motion prediction, it is important to model subsurface velocity structure so that earthquake ground motions can be evaluated in broadband period from 0.1 s to 10 s. Therefore, it is indispensable to combine shallow and deep velocity structure models which have ever been constructed separately and to constructed subsurface velocity structure models so that earthquake observation records can be reproduced.

We have ever modeled subsurface velocity structure for Kanto, Tokai and Kumamoto region in the national investigation conducted by SIP (Cross-ministerial Strategic Innovation Promotion Program), “reinforcement of resilient disaster prevention and mitigation function” of Council for Science, Technology and innovation.

This study attempted to sophisticate shallow geological and soil structure models in initial subsurface velocity structure ones from seismic bedrock to ground surface which had been constructed for Tokai region (Shizuoka, Gifu, Aichi and Mie pref.) last year. It was based on results of a great number of array microtremor explorations. This report will introduce outline of array microtremor exploration, sophistication process of shallow velocity structure models and characteristics of ground motion.

2. miniature and irregular array microtremor exploration
About microtremor measurements, array observations were conducted in lowland and plateau of Tokai region. It consists of 4-point miniature array with a radius of 60 centi-meters and 3-point irregular array from 5 to more than 10 meters on a side. These measurements were made on the road and near seismic ground-motion stations such as K-NET and KiK-net. The total number of measurement sites has reached about five thousand and nine hundred, as of February in 2019. In addition, the measurement was conducted for around 15 minutes per site at intervals of 1km using JU210/215 or JU410 which was an all-in-one microtremor measurement unit [Senna et al., 2008]. And sampling frequency was set at 200Hz.

About analysis of miniature and irregular array microtremor data, we evaluated one-dimensional S-wave velocity structure using shallow velocity structure exploration method based on microtremor measurements. The method has been proposed and advanced in recent researches [Cho et al., 2013]. The analysis was made using a microtremor analysis tool such as “BIDO” or “Microtremor Array Tools [Cho et al., 2016].”

3. Improvement of initial shallow velocity structure models based on results of array microtremor explorations
Last year, initial shallow velocity structures were modeled using the existing bore-hole data and surface geological data. In basis of results of miniature and irregular array microtremor exploration, 1-dimensional S-wave velocity structures in the initial models were modified at each microtremor measurement point. And then, they were interpolated spatially by means of Kriging method and three-dimensional shallow

©2019. Japan Geoscience Union. All Right Reserved.

velocity structures were modeled.

On the improved models in this study and the conventional models based on geomorphologic land classification [Wakamatsu et al., 2013], ground amplification index was compared in spatial distribution. From a general viewpoint, the improved models have wider areas with large amplification in lowlands and they tend to have large local variation in ground amplification. In addition, for the improved models, distribution of ground amplification rates was evaluated by each period in basis of 1-dimensional multiple reflection theory. Amplification rates seem to be larger in different areas by each period.

4. Summary and future challenge
In this study, initial shallow velocity structure models, which were constructed based on a lot of bore-hole and geological data, were enhanced for Tokai region using results of array microtremor explorations. Also, it can be suggested that it is important to evaluate ground motion characteristics using both of amplification and period characteristics. In the close future, improved subsurface velocity structure models will be validated using moderate seismic records at strong-motion stations.

Validation of seismic bedrock structure model in the Shimousa region, Chibe prefecture, Japan using seismic interferometry to strong motion

*Kosuke Chimoto[1], Hiroaki Yamanaka[1]

1. Tokyo Institute of Technology

Green’s function is estimated using autocorrelation of strong motions by seismic interferometry, and the depth to the seismic bedrock is estimated in sedimentary basins (Yoshimoto et al., 2009; Watanabe et al., 2011, Shiraishi et al., 2016). Oren and Nowack (2017) observed clear Reflected waves by applying spectral whitening to the autocorrelation of ambient noise. Chimoto and Yamanaka (2018) applied this method to the autocorrelation of strong motions and observed reflected wave from seismic bedrock by estimating the Green’s function in the sedimentary layers. We apply this method in the Shimousa region, Chiba prefecture, Japan to estimate autocorrelation using strong motions. Validation of 3D S-wave velocity structure model was attempted based on the spatial variation of reflected waves from seismic bedrock in the region.

Number of autocorrelations without the selection of strong motions enhance the clear reflected wave (Chimoto and Yamanaka, 2018). We used all the strong motions observed in the period of January 2008 to Jun 2018 observed at the strong motion stations of K-NET and KiK-net installed in the Shimousa region. After removal of offset of the strong motion, horizontal components are rotated to the transverse component. Spectral whitening is applied to the power spectrum and inverse Fourier transform provides autocorrelation function after the bandpass filtering. The range of bandpass filter is important to estimate the expected reflected waves from sedimentary layers (Chimoto and Yamanaka, 2018). We used the range of 0.5-2.0Hz to estimate the reflected wave from the seismic bedrock. Theoretical Green’s function for the validation of the model was calculated by Haskell method using 1D structure model extracted from the 3D J-SHIS deep structure model.

We observe the distinct reflected waves from the seismic bedrock in the autocorrelation functions estimated in the Shimousa region, Chiba prefecture. Two-way travel time of the reflected wave at KiK-net Narita station is 3 seconds and that is 3.5 seconds at K-NET Narita station. These values are almost consistent to those of the theoretical Green’s functions, while slight faster arrivals are observed. On the other hand, the stations located north and east to Narita exhibit several arrivals in the autocorrelations and the reflected wave from the seismic bedrock becomes weak. The travel time is faster than Narita. The reflected waves from the seismic bedrock at the stations located west to Narita appears later than 4 seconds, meaning the deeper bedrock than Narita. The southern part to Narita, central part of Chiba prefecture, shows the two-way times of later than 6 seconds, suggesting the deepest bedrock structure. This fact is consistent with the previous 3D models in the Kanto basin. We thus captured the spatial variation of the seismic bedrock from the estimation of autocorrelations of the strong motions in the Shimousa region, Chiba prefecture. The characteristics of spatial variation was similar to that of previously proposed 3D models. However, it is highly expected for the accurate modeling by tuning the slight difference between the autocorrelation function and the theoretical Green’s function.
We used the records observed at K-NET and KiK-net by National Research Institute for Earth Science and Disaster Resilience and deep structure model of Japan Seismic Hazard Information Station.

Microtremor survey for subsurface velocity structure of Saga plain

*Masayuki Yoshimi[1], Michiko Shigefuji[2], Tadashi Maruyama[1]

1. Geological Survey of Japan, AIST, 2. Kyushu University

Saga plain, located in northern Kyushu island, is quite flat lowland facing south to the Ariake Sea. An active fault zone is recognized at the northern boundary of the plain. If the fault zone activates, strong ground motion will hit whole the plain. To assess possible earthquake hazards, subsurface structure of the plain has to be revealed.

We conducted microtremor array measurements in the plain to investigate the S-wave velocity of the sediment layers and spatial variation of the bedrock depth. Four locations for the survey are chosen along the P-wave reflection survey line (Maruyama et al. 2017) and its extension toward south. Array aperture of the measurements at each location is set about 10 to 500 meters enabling to estimate the subsurface velocity structure down to about 1 km. Four velocity sensors (Tokyo sokushin, SE-321) are deployed at each array to compose equilateral array with a center point. Phase velocity of the Rayleigh wave are estimated using vertical component data of the microtremor by SAPC and V-method (Cho et al. 2004, Tada et al., 2007). The results will be shown.

Densely microtremor observation to estimation of subsurface structure in Hane and Kute area, Ohda City, Shimane Prefecture, Japan

*Tatsuya Noguchi[1], Yoshito Yamaguchi, Yuhei Morita, Isamu Nishimura[1], Shohei Yoshida[1], Takao Kagawa[1]

1. Department of Management of Social Systems and Civil Engineering, Civil Engineering Course Graduate School of Engineering, Tottori University

An earthquake (Mj6.1) occurred in vicinity Ohda City western Shimane Prefecture in Japan on April 9, 2018. Densely microtremor observations were carried out to estimate the characteristic of ground motion in the damage area, Hane and Kute area, Ohda City. A distribution of the predominant period of microtremor H/V spectra and S-wave velocity structures were obtained from observation data. As a result, it was found that maximum thickness of the weak soil subsurface layer is 40m and a short period component of predominant period about 0.2-0.4 seconds may have influenced structural damage.

Densely microtremor observation to estimation of subsurface structure in Nishizono and Yura area, Hokuei Town, Tottori Prefecture, Japan

*Tatsuya Noguchi[1], Katsuya Tomeoku, Isamu Nishimura[1], Shohei Yoshida[1], Takao Kagawa[1]

1. Department of Management of Social Systems and Civil Engineering, Civil Engineering Course Graduate School of Engineering, Tottori University

Densely microtremor observations were carried out to estimate a characteristic of ground motion and subsurface structure in the damage area due to 2016 central Tottori Prefecture earthquake, Yura and Nishizono area, Hokuei Town, Tottori Prefecutre. Microtremor H/V spectra and a distribution of the predominant period and underground structure models were obtained, and grasped the characteristic of ground motion based on this result. As a result, it was found that a difference of the subsurface structure depth to about 20m and a short period component of predominant period less than 0.5 seconds may have influenced structural damage.

Seismic reflection survey in the Kathmandu Valley, Nepal.

*Kota Koshika[1], Yusuke Kawasaki[1], Om Pradhan[1], Masato Yamamoto[1], Dai Nobuoka[1], Yoshikazu Matsubara[1], Hisanori Matsuyama[1], Monika Jha[2], Chintan Timisina[2], Suresh Shrestha[2], Mukunda Bhattarai[2], Dinesh Nepali[2], Soma Nath Sapkota[2], Hiroe Miyake[3], Kazuki Koketsu[3]

1. OYO Corporation, 2. Department of Mines and Geology, 3. Earthquake Research Institute, University of Tokyo

On the April 25, 2015, earthquake of magnitude 7.8 Mw (USGS, 2015) struck in the 78 km north west of Kathmandu (Gorkha Earthquake) and major after shock of magnitude 7.3 Mw, with epicenter about 80 km north east of Kathmandu cases heavy damage in the Kathmandu Valley (KV). It was thought that the damage in the KV was particularly great, due to the underground structure of the KV.

We conducted gravity survey in the KV as part of the SATREPS projects in 2017. The shape of the gravity basement of the whole KV was estimated (Pradhan et al.,2018).

We conducted seismic reflection survey to clarify the detailed basement of the KV and the upper sedimentary structure in 2018. Survey lines were set up at Tribhuvan International Airport (TIA) where depth of gravity basement greatly changes and Nepal Agricultural Research Council (NARC) where deep gravity basement was estimated. Survey line length is about 4km (TIA) and 1km (NARC). Enviro Vibe (IVI, Inc.) was used as a seismic source.

The shape of the basement obtained by the seismic reflection survey and the shape of the gravity basement match well and the structure of the sedimentary layer in the basin was also revealed. These are the world's first results visually showing the underground structure in the KV and are expected to greatly contribute to future earthquake disaster prevention.

Broadband Microtremor Array Exploration at and around Tribhuvan International Airport, Kathmandu, Nepal

*Toshiaki Yokoi[1], Takumi Hayashida[1], Mukunda Bhattarai[2], Tara Pokharel[2], Suresh Shrestha[2], Chintan Timsina[2], Sunita Bhatarrai[2], Dinesh Nepali[2]

1. International Institute of Seismology and Earthquake Engineering, Building Research Institute, Japan, 2. Department of Mines and Geology, Ministry of Industry, Commerce and Supplies, Nepal

Strong ground motion of long duration and long predominant period around four seconds were observed during the 2015 Gorkha earthquake at the central part of the Kathmandu Valley (KTV), Nepal (Dixit et al. 2015, Bhattarai et al. 2015, Takai et al. 2016, Rajaure et al. 2017), a tectonic basin formed during the Himalayan orogeny due to the collision of the Indian plate to the Eurasian plate (e.g., Sakai et al. 2016). Aimed to reveal the cause of this phenomenon and to make possible the seismic hazard assessment considering on the structure of deep sedimentary layers, the research group to which the authors belong (Group3-SATREPS) has conducted the deep exploration by deploying microtremor arrays (Maximum inter station distance about 1400 m) at few sites using four sets of broadband seismographs (CMG40T, Guralp) for estimating the shear wave velocity structure of deep sediments from Dec. 2016 to Feb. 2018, together with shallow exploration using 2 Hz seismometers (L22D, Sercel) and 4.5 Hz geophones (GS11D, GeoSpace) (Yokoi et al. 2018, SSJ-Fall). In KTV as a whole, the gravity survey had been performed in 2017 by the OYO corp. team which belongs the same research group (Pradhan et al. 2018 (JpGU)) and the reflection survey has been conducted Nov. 2018 by OYO corp. also at the Tribhuvan International Airport (TIA) and at the National Agriculture Research Institute (NARI) located at around 2 km SW of TIA. The deep structure of KTV is gradually getting revealed (Koshika et al. 2019 (JpGU) submitted).
In this poster session, we will report the results of analysis of the microtremor array exploration at and around TIA and NAST, and a hard rock site (Chobar) that we have conducted Dec. 2018 following the above mentioned activities.
The attached figure shows the configuration of observation sites and a summary of the dispersion curves of Rayleigh waves. In the legend, *BDR* (red circles) shows the results given by Hayashida et al. (2018, SSJ-Fall) using tele-seismic surface waves, *CHB* (red “x” s): the phase velocities estimated on the outcropped bedrock of the Chobar hill. *SDB*: Singhadurbar, DMG: Department of Mines and Geology-Narayanhiti Royal Palace Museum, *TEKU*: Teku Gas well of DMG, *KIR*: Kirtipur Campus of the Tribhuvan Univ., *BLJ*: Department of Nepal Bureau of Standard and Metrology at Balaju, *GAU*: Gaucharan, *TIA*: Tribhuvan International Airport, *NAST*: National Academy of Science and Technology-National Agriculture Research Institute.

Distribution of average S-wave velocities by small-scale (5 to 15 meters) microtremor arrays in and around Hue City, Thua Thien-Hue province, Vietnam

*Ikuo Cho[1], Makoto OKUBO[2]

1. National Institute of Advanced Industrial Science and Technology, 2. Kochi University

We are promoting earthquake hazard assessment for safe operation of hydroelectric power generation and protection of world cultural heritage for Hue City, Thua Thien-Hue Province, Vietnam. This is a collaborative research with Dr. Nguyen Anh Duong at Vietnam Academy of Science and Technology (VAST). As a part of this research project, we conducted multiple small-scale microtremor array observations in that area and evaluated the distribution of shallow average S-wave velocities.

We began this microtremor research with providing a technical support to researchers at VAST. First, the authors conducted a microtremor array observation at four sites in and around the Hanoi City on 20th and 21st October, 2017, as a practical training of microtremor observation. On the premise of applying the SPAC method, we deployed linear-shaped arrays with a length of about 30 m using a three-component servo-velocimeter. We recorded microtremors for 1 to 2 hours at each site. Since the authors brought two seismometers (three-component servo-accelerometers) from Japan, we deployed two-point arrays along with their array at intervals of 5 to 30 m, and compared the analysis results with those from the VAST observation apparatuses.

On the next step, the VAST research team and the authors conducted microtremor array observations at seven sites in Hue City on 17-19th March, 2018. At each site we deployed triangle-shaped arrays with side lengths of 5 m and 15 m. We also deployed a linear array with a length of 12 m. Those arrays consisted of 4.5 Hz vertical geophones. In addition to this, we deployed two-point arrays with two seismometers brought from Japan. We set the observation durations from about 30 minutes to 1 hour at each site. There were existing subsurface data by refraction surveys at these sites, and therefore, we compared our analysis results with them. As a result, the analysis results of microtremors were consistent with those existing data.

Through the above preparatory period, the VAST research team conducted microtremor array observations at 126 sites in and around the Hue City (observation area of about 11km x 14 km) in a period from June to July 2018 (19 days in total). More specifically, they deployed triangular arrays with side lengths of 5 m and 15 m at 89 sites and a linear array with a length of 12 m at 37 sites. Vertical 4.5Hz geophones were used to consist seismic arrays. The observation duration was set to 30 minutes at each site.

We applied the SPAC method to the array data thus obtained and identified the Rayleigh-wave phase velocities. We read the phase velocities with the wavelengths of 13 m, 25 m and 40 m and interpreted them as average S-wave velocities to the depths of 10 m, 20 m, and 30 m, respectively. The spatial distribution of average S-wave velocities thus obtained is consistent with the geological map in and around the Hue City. In near future, we will improve the accuracy of soil evaluations by adding H/V spectral data at each site of array observation.

Microtremor Array Exploration in the Syiah Kuala University, Banda Aceh, Indonesia

*Makoto OKUBO[1]

1. Natural Science Cluster, Kochi University

We deployed microtremor array survey at Syiah Kuala University in Banda Aceh, Indonesia to clarify a seismic amplification by subsurface S-wave structure. Banda Aceh, located at northern end of Sumatra island, was seriously damaged by the tsunami caused by the 2004 Sumatra earthquake. At the tsunami evacuation, we first have to consider the safe route that does not corrupted, damaged and flooded. Therefore, we plan to understand the seismic amplification distribution as fundamental material. Our results will be available to make a future plan to reconstruction/renovate architectures.

We visited to Banda Aceh at January, 2019, and carried out microtremor exploration using with linear array and triangle array at 17 sites. We used are three 5 Hz geophones and one 1 kHz sampling GPS synchronised data logger for survey. In the case of triangle array, we always used 1.7 m side length. This side length is corresponding to 1.0 m array radius. In the other case, that is linear array, distances of each sensors (A, B, and C) are, A-B:1.7 m, B-C:2.7 m, and A-C:4.4 m. We Assumed these lengths are the array radius for each exploration, and applied SPAC method (*c.f.* Aki 1957). We used a tool, as known as BIDO2.0 (Cho, 2010) to analyze recorded waveforms and estimate dispersion curves.

By using obtained dispersion curves, we determined 3 averaged S wave velocities and roughly velocity structure. Roughly velocity structure was estimated by simple conversion method by using 1/2 wavelength law with linear array's dispersion curves. And three Averaged S-wave velocities AVS10, AVS20 and AVS30 were estimated from the Rayleigh wave phase velocities corresponding to the wave length of 13 m, 25 m and 40 m, respectively. By a preliminary analysis, we obtained result that a thicker low S-wave velocity layer exists along the river and the coastline. This result implies that plain part of Banda Aceh was developed on the old delta made by river and sea. This situation of subsurface structure will be strongly affect to the seismic amplification.

We will discuss in detail at the presentation.

Acknowledgements:
We thanks to Dr. Muksin Umar, Ms. Wiwik and Mr. Arif, they were attended and cooperated to our microtremor array survey in Syiah Kuala University. This study is supported by JSPS KAKENHI Grant Number 17H0457751.

Turkey-Japan Joint Project on Modeling of Geological Structures for Strong Ground Motion Simulations due to Crustal Earthquakes in Eskisehir Basin, Turkey, by Using Seismic Interferometry Method

*Mehmet Safa Arslan[1], Kosuke Chimoto[2], Asim Oguz Ozel[1], Hiroaki Yamanaka[2]

1. ISTANBUL UNIVERSITY-CERRAHPASA, 2. TOKYO INSTITUTE OF TECHNOLOGY

Understanding the seismic hazard of specific area, depends on the regional 2D/3D underground structure on wave propagation. In the frame of the bilateral project between Turkey and Japan, we aim at observing ground motion parameters, crustal activities, underground structures, and improvement of seismic hazard maps. The seismic interferometry method (SIM) is one of the tools to investigate the surface-wave propagation. The method goals to obtain green’ s function (GF) by using ambient noise data. Cross-correlations (CC) between the two pairs of stations’ continuous records, reveal GF and provide group and phase velocities of surface waves. We analyze one-year vertical component broadband data from 8 stations deployed and affiliated with ANANET (Eskisehir Anadolu University Local Seismic Network). Interstation distances between the designated stations are in the range of ~23-139 km. After getting the CC functions, group velocity dispersion curves will be obtained for selected correlation paths in particular to address the azimuthal dependence of the velocity field. Averaging the dispersion curves, in other saying analyzing the group velocities and waveforms typical of these observations, we attempt to estimate the S-wave velocity structure model inside the Eskisehir basin. This study is supported by the Joint Research Project under the Bilateral Program of the Japan Society for the Promotion of Science (JSPS) and The Scientific and Technological Research Council of Turkey (TUBITAK) under Grant TUBITAK 116Y524.

Nonlinear Ground Motion Response During the 2016 Meinong Taiwan Earthquake

*Kuo-Liang Wen[1], Chun-Te Chen[2]

1. National Central University, Department of Earth Sciences, 2. Academia Sinica, Institute of Earth Sciences

The Meinong Taiwan earthquake occurred on February 6, 2016, at 03:57 (UTC+8) with M_L 6.6. The strong ground motion induced the soil liquefaction in Sinshih and Annan districts. To investigate the nonlinear site response during Meinong mainshock, the degree of nonlinear site response (DNL) which summation of the horizontal to vertical spectral ratios (HVSR) differences between weak-motions and Meinong mainshock records from the Taiwan Strong Motion Instrumentation Program (TSMIP) network are calculated. We compare the DNL values with the ground motion parameters such as peak ground acceleration (PGA), peak ground velocity (PGV), and also the ratio between PGV and Vs30. The DNL shows a positive correlation with ground motion intensity, particular with PGV, and the surface site conditions also leading the DNL strength. We also applied a stochastic method for modeling the ground motion of the Meinong earthquake with site correction by the HVSR of weak and strong motions respectively. The percentage of PGA reduction calculated in this study can be an indicator of the spatial distribution of the degree of nonlinear soil effects of the 2016 Meinong Taiwan earthquake.

Earthquake damage of the 2017 Pohang earthquake in South Korea

*Mikyung Choi[1], Sun-Cheon Park[1], Dong-Hyo Sohn[1], Seolhan You[1], Jongsun Sun[1], Seongheum Cho[1], Duk-Kee Lee[1]

1. Korea Meteorological Administration

Pohang earthquake with a magnitude of ML 5.4 occurred on November 15, 2017. This earthquake caused more damage than the 2016 Gyeongju earthquake (ML 5.8). Modified Mercalli intensities were assigned from residential property damage report in the Pohang area. Major damage type was wall crack of building. Maximum intensity was MMI VIII. Result of damage analysis from damage report reveals that the main damage area was distributed within a radius of about 20 km distance from the epicenter. And sand and mud volcanoes were observed in many places.
Between 16 November and 31 December 2017, 10 temporary seismic stations were deployed to record aftershocks and site effect of the Pohang earthquake. Ground motion generated by an earthquake is controlled by several factors, such as source characteristics, propagation path, surface geology, topography. Using recordings of aftershocks, we analyzed the ground motion at two seismic stations near the epicenter and another two seismic stations located on sedimentary rock and bedrock. We compared amplitude and predominant frequencies of ground motion with damage analysis results. Mapping and characterization of the damage for this earthquake is an opportunity to provide useful information on the damage of future possible earthquake in South Korea.

[J] Poster | S (Solid Earth Sciences)：S-SS Seismology

Mon. May 27, 2019 5:15 PM - 6:30 PM JST | Mon. May 27, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_20

[S-SS13] Strong Ground Motion and Earthquake Disaster

convener:Masayuki Kuriyama(Central Research Institute of Electric Power Industry), Kazuhiro Somei(Geo-Research Institute)

Strong ground motion has social impacts as it induces earthquake disasters. We solicit contribution on any seismological topics related to strong ground motion that includes, but are not limited to, source processes, wave propagation, and site effects. We also welcome contribution on earthquake related disaster mitigation.

To investigate a cause of serious damages of the 2018 Hokkaido Eastern Iburi Earthquake, we observed microtremors and aftershocks at a landslide area and around strong ground motion observation stations. As a result, S-wave velocity structures were estimated at all observation sites. It was found that thickness of the volcanic ash layer (S-wave velocity:75-130 m/s) is 10m. Especially, it is suggested that two layers of volcanic ash layer have caused a landslide in the Shikanuma and Atsuma sites. It was found that the H / V spectral ratio of microtremor corresponds to the thickness of volcanic ash. The spectral amplitude of the H / V of the orthogonal direction component of the mountain ridge line became larger than that of the parallel direction component.

Nonlinear site amplification for high intensity ground motions during the 2018 Mw 6.6 Hokkaido eastern Iburi earthquake

*Yadab Prasad Dhakal[1], Takashi Kunugi[1], Takeshi Kimura[1], Wataru Suzuki[1], Shin Aoi[1]

1. National Research Institute for Earth Science and Disaster Resilience (NIED)

Large peak ground accelerations (PGAs) exceeding 1g on both the horizontal and vertical components were recorded at a fault distance of about 25 km during the September 6, 2018, Mw 6.6 Hokkaido eastern Iburi earthquake. Explaining the large PGAs at the distance for the magnitude of the event requires detailed investigation of the site response and source radiations. At several sedimentary sites, peak ground velocities (PGVs) exceeding 100 cm/s were recorded. Comparison of the observed PGAs and PGVs with the ground motion prediction equations (GMPEs) by Si and Midorikawa (1999) revealed that the observed data, especially the PGVs, were substantially larger at fault distances smaller than about 40-50 km, while the data at longer distances showed little or no trend different from the GMPEs. This motivated us to examine the site response during the earthquake. We processed many small amplitude (PGAs between 5 and 20 cm/s/s) accelerograms from earthquakes that occurred prior to the mainshock (the Mw 6.6 event) at sixteen KiK-net sites, and compared the surface-to-borehole spectral ratios between the small-amplitude ground motions from prior earthquakes and large-amplitude ground motions recorded during the mainshock. The comparison suggested that the sites at short distances where PGVs were underestimated, sustained various degrees of nonlinear site response, and the recovery is still undergoing at some of the sites based on similar analysis of aftershock recordings. Nonlinear site amplification has been known for a long time for the reduction of short-period ground motion amplitudes at a soil site during strong input motions compared with the weak input motions. Another commonly reported effect of nonlinear site response is the shift of predominant frequency to lower one. This second effect was found to be very prominent during the mainshock at soil sites and smaller distances, which caused stronger amplification at relatively longer-periods resulting into large PGVs and large JMA intensities. At the site of largest PGA, the ground motions were amplified by an order of magnitude at the new predominant frequency during the mainshock. We also analyzed the horizontal-to-vertical (H-to-V) spectral ratios at K-NET sites where PGAs were larger than 200 cm/s/s. We found that the K-NET sites also experienced larger degree of nonlinear site response at sites of larger PGAs. Based on the above analysis, the nonlinear site amplification could be one of the major reasons for the high intensity ground motions that were underestimated at the smaller distances by the GMPEs. Moreover, two sites (IBUH01: KiK-net; HKD127: K-NET), which were closely located, recorded vertical PGAs exceeding 1g for the up going motions at the surface, and the recordings showed asymmetric waveforms and amplitudes characteristics to the nonlinear site response reported during a few earthquakes in the past. A few sites having lower vertical PGAs were also suspected of being experienced nonlinear site response on vertical motions. Finally, we derived an ad-hoc equation to correct for the nonlinear site amplification in the prediction of horizontal PGVs with respect to the GMPE by Si and Midorikawa (1999). The results indicated that the stronger input motions may induce larger changes in PGVs at the surface than that for a proportional change in the shallow S-wave velocities (Dhakal et al. 2019).

1.Introduction

An earthquake of Mj6.7 occurred at 3:07 on September 6, 2018, in the Eastern part of the Hokkaido Iburi region. High seismic intensities (SI) of upper 6 and 7 were observed during this earthquake, even though the hypocenter of the earthquake was at the depth of 37 km. The amplification of surface ground was considered as one of the main factors that contributed such high SI. In order to estimate the ground amplification of the near surface ground, microtremor array measurements were conducted at six strong motion recording stations that observed SI upper 6 or 7.
In this presentation, we focused on two stations, HKD127 and IBUH01, because there was a difference in SI in spite that the two stations closely located. So we will show the result of analysis for these two sites.

2.Microtremor array measurement

The shape of the microtremor array used was an equilateral triangle. The vertical components were measured at three vertex points as well as the center of the array, in addition to the two horizontal components at the center. The measurements with a radius of 10m or less were made for each station, whereas those with a radius of 25m or more were made once around the two stations and used for both, because the distance between the two is as close as about 100m.

3.Analysis

A dispersion curve was determined from stationary part of microtremor array data based on SPAC method, and calculated H/V spectra from the three component microtremors observed at the center. The shear wave velocity profiles of the two stations were then back-calculated by the genetic algorithm using both observed dispersion curve and H/V spectra. The influence of higher modes of Rayleigh and Love waves was considered for the observed H/V spectra but neglected for the observed dispersion curve.

Subsurface structure model based at diffuse-field theory in Oiwake region: Simultaneous inversion analysis on adjacent two sites

*Moeko Koie[1], Kentaro Motoki[1], Kenichi Kato[1], Takuto Kogawa[2]

1. KOBORI RESEARCH COMPLEX INC., 2. TOKYO SOIL RESEARCH CO., LTD.

During the 2018 Hokkaido Eastern Iburi Earthquake, 6.7 seismic intensity was observed in KiK-net Oiwake. On the other hand, observed seismic intensity at K-NET Oiwake, which is 100m away from the KiK-net, was 6.4. The amplitude of response spectra at KiK-net were higher near the predominant period than those at K-NET. The reason for the difference between their seismic intensity seems to be thought of due to the difference of their subsurface structure. In this study, we deduce subsurface structure models at the two sites by H/V inversion based on diffuse-field theory and estimate amplification factor at the sites.

To select the earthquakes for inversion analysis, we set the conditions such as occurrence before the main shock, less PGA than 100 cm/s^2, and higher ratio of epicentral distance to depth of hypocenter than 2. We used the average H/V of the selected earthquakes for observed H/V. In the calculation of H/V, we use the square-root of sum of squares of NS and EW component for horizontal component. The period at the peak observed H/V at K-NET Oiwake is shorter than that at KiK-net. The difference between their observed H/V is small in longer period range than 2 seconds.

Because of the adjacent of the sites and similarity of observed H/V in the long period, we set the deep part of structure at the 2 sites to be in common and search for shallow part of that individually. In order to make the deep part of structure in common, we adopted simultaneous inversion analysis at the two sites. We used the hybrid heuristic method and set the range of search based on the model of PS logging and J-SHIS. We searched for the thickness for the deep structure and S wave velocity for the shallow structure.

As a result of inversion analysis, we could deduce subsurface structure models which accorded with the observed H/V. The depth up to engineering bedrock of deduced K-NET model is 7m, and that at KiK-net is 20m. AVS30 at K-NET is 278m/s, whereas that at KiK-net is 243m/s. On the whole, S wave velocity at KiK-net in shallow part is lower than that at K-NET. We calculated the amplification factor of the shallow part, which was searched individually. The first natural period of amplification factor at KiK-net is 0.31s and that at K-NET is 0.20s. The predominant period of response spectra at KiK-net’ s (0.53s) is also longer than K-NET (0.48s). Because both of the natural and the predominant period at K-NET are shorter than those at KiK-net, the difference between subsurface structures might cause that of the amplitude of the main shock. However, the predominant period of the main shock is longer than the natural period at both sites, which seems to be influenced by nonlinear effect of the subsurface soil.

We will study about a cause of the difference of seismic intensity considering nonlinear effect of the subsurface soil.

The 2018 Hokkaido eastern Iburi earthquake (M_w 6.6, focal depth=37 km) occurred on 6 September 2018 at the Hidaka arc-arc collision zone, Hokkaido, Japan. The many building damages by strong ground motion were concentrated around K-NET Mukawa strong motion observation station (HKD126). Strong motion records had strong power in 1-2 second periods of the response spectrum to destroy the timber frame buildings. It is an important examination to know the cause of the generation of this destructive strong motion.

To understand the site effects of this strong motion, we estimate the velocity structure models by using the microtremor array and multichannel analysis of surface wave measurements at three sites; around HKD126 site, a hillside site located about 6 km north from HKD126, and midpoint between both sites. We carried out the microtremor array measurements (R=1-2000 m) on 14-16 December 2018. We used servo type velocity sensor (Le-3D/5s) and 24-bit data logger (DATAMARK LS-7000XT) with GPS time calibration. At small arrays (R<~10 m), we used moving coil accelerometer (JEP-6A3, 10V/g). The fundamental Rayleigh wave phase velocity is examined with the spatial autocorrelation method. We also carried out a multichannel analysis of surface wave to emphasize the high-frequency side phase velocity. We set 24 channel 4.5 Hz geophones in interval 1 m with GEODE and 10 kg wood hammer. The phase velocity is examined with the Frequency-wavenumber method. The shear wave velocity structure models are estimated to fit the dispersion curve of the fundamental mode of Rayleigh wave using the genetic algorithm inversion method (Yamanaka and Ishida, 1998). The phase velocity data of the large array (R=2000 m) were used in common to the three sites.

Comparing the velocity structures, the Vs=1300 m/s layer’s depth of HKD126 is shallower than the hillside site ones and midpoint depth is mid of both. This tendency of depth variation is the same as the seismic bedrock and subsurface structure depth variation of AIST model (Yoshida *et al.*, 2007) and J-SHIS V2 model (Fujiwara *et al.*, 2012). On the other hand, about the shallow part, engineering bedrock depth of hillside site is shallower than the HKD126. The midpoint’s seismic bedrock is mid for the others, however, the surface soft soil deposit is detected as richer than the HKD126. These features of the shallow part structure's variation are able to confirm by the surface geology or Vs30 values of J-SHIS.

Source Process of the 2018 Hokkaido Eastern Iburi Earthquake Inferred from Strong Motion Data and Green's Functions Based on Three-Dimensional Velocity Structure Model

*Kimiyuki Asano[1], Tomotaka Iwata[1]

1. Disaster Prevention Research Institute, Kyoto University

The source rupture process of the 2018 Hokkaido Eastern Iburi earthquake (M_{JMA} 6.7) was analyzed by the kinematic waveform inversion using strong motion data. Since this earthquake occurred close to the Hidaka Collision Zone and the Ishikari Lowland, the crustal and sedimentary basin structure of surrounding region is rather complex. Thus, we tried to use a three-dimensional velocity structure model to compute theoretical Green's functions. We used the Japan Integrated Velocity Structure Model (JIVSM; Koketsu *et al.*, 2012), and the Green's functions were computed by the three-dimensional finite difference method. The source fault model with strike-angle variation was set by referring to the spatial distribution of early aftershocks and the Global CMT solution. The source rupture process was estimated by the multiple time-window kinematic waveform inversion method (e.g., Hartzell and Heaton, 1983). The observed data for the inversion was strong-motion velocity waveforms in 0.04–0.5 Hz at K-NET, KiK-net and F-net stations. The rupture starting point was assumed to be at the hypocenter located by JMA at a depth of 37 km. The strong motion stations were selected based on the result of forward ground motion simulation of an Mw 4.1 aftershock occurring on September 14, 2018.
The estimated source model has small slip in the vicinity of the hypocenter, but significant slip is found in the depth range from about 22 km to 32 km. The rupture mainly propagated toward shallow and southwest direction. Considering crustal structure in this region (e.g., Iwasaki et al., 2004; Kita et al., 2012), the large slip area (asperity) is located in the middle-to-lower crust, and its rupture does not reach the upper crust. The depth range of significant slip is consistent with the spatial distribution of early aftershocks. Later aftershocks occurring in shallower depth are thought to occur outside the mainshock's source fault.

Acknowledgements: Strong motion data from K-NET, KiK-net and F-net (NIED) and JMA unified hypocenter catalog were used in this study. This study was supported by the Grant-in-Aid for Special Purposes 18K19952 (PI: Prof. Hiroaki Takahashi at Hokkaido University) from MEXT.

Source process of the 2018 Hokkaido Eastern Iburi earthquake derived from strong motion data

*Hisahiko Kubo[1], Wataru Suzuki[1], Asako Iwaki[1], Shin Aoi[1], Haruko Sekiguchi[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. DPRI, Kyoto University

The 2018 Hokkaido Eastern Iburi earthquake (M_{jma} 6.7) struck southern Hokkaido, Japan on September 6, 2018 (JST). This earthquake caused strong ground motions over southern Hokkaido with a maximum seismic intensity of 7 on the JMA scale and a maximum PGA of over 1500 cm/s/s. In this study, we estimate the source process of this earthquake using strong motion waveforms.
For source-process analysis of this event, we develop a curved fault model based on the spatial distribution of aftershocks. This curved fault model consists of multiple planes, each with a width of 20 km, a common dip angle (65 degree), and a common top depth (approximately 22 km). The common dip angle refers to the moment tensor analysis of F-net. The strike angle of the planes smoothly changes along the strike direction: the strike angle is 15˚ at the north part, 340˚ at the central part, and 40˚ at the south part. The rupture starting point is set to the hypocenter determined by JMA. The curved fault model is divided into 15 subfaults along the strike direction and 10 subfaults along the dip direction.
We use velocity waveforms at 20 stations of K-NET and KiK-net, F-net of NIED. The waveforms are band-pass filtered between 0.05 and 0.5 Hz, resampled to 10 Hz, and windowed from 1 s before S-wave arrival for 25 s.
Green's functions are calculated with the discrete wavenumber method (Bouchon 1981) and the reflection/transmission matrix method (Kennett and Kerry 1979) assuming 1-D velocity structure models. The structure models are obtained for each station from the 3-D structure model (Fujiwara et al. 2009). Logging information is also used for the KiK-net station. To consider the rupture propagation effect, 25 point-sources are uniformly distributed over each subfault in the calculation of Green’ s functions.
The multi-time-window linear waveform inversion method (Olson and Apsel 1982; Hartzell and Heaton 1983) is used in this study. The slip time history of each subfault is discretized using eight smoothed ramp functions (time windows) progressively delayed by 0.4 s and having a duration of 0.8 s each. The triggering velocity of first time window is set to 1.4 km/s to minimize the data-fit residual. Two orthogonal slips of each time window at each subfault are derived by minimizing the difference between the observed and synthetic waveforms using the non-negative least-squares scheme (Lawson and Hanson 1974). The slip angle is allowed to vary centered at 107˚, which is the rake angle of the F-net analysis. In addition, we impose a spatiotemporal smoothing constraint on slips (Sekiguchi et al. 2000).
In the estimated source model, the large slips are found at approximately 30 km depth in the up-dip direction from the hypocenter. In the first 6 s, the rupture grows slowly around the hypocenter with small slips. Then, the rupture developed with the large moment release between 6 s and 12 s in the large slip area. The large slip area does not overlap with the active aftershock area

Broadband ground-motion simulation of the 2018 Hokkaido Eastern Iburi earthquake

*Asako Iwaki[1], Nobuyuki Morikawa[1], Takahiro Maeda[1], Hisahiko Kubo[1], Hiroyuki Fujiwara[1]

1. National Research Institute for Earth Science and Disaster Resilience

1. Introduction

The 2018 Hokkaido Eastern Iburi earthquake (M_{JMA}6.7) was an inland crustal earthquake at a focal depth of approximately 35 km. This earthquake brought strong ground motion to the southern Hokkaido, causing JMA seismic intensity of 6+ and 7 above the fault and nearby, and 6- in the city of Sapporo. The seismicity around the source region reaches to deeper region compared to other inland areas in Japan (HERP 2018). Inland crustal earthquakes at this depth have not been considered by the current ground-motion prediction procedure in Japan. Therefore it is necessary to examine whether the strong ground motion from this earthquake can be modeled by the conventional procedure.

2. Broadband ground-motion simulation

We conducted broadband ground-motion simulation using the characterized source model based on the “recipe” for strong motion prediction (HERP 2017), aiming to reproduce the observed ground motion. A planner fault is set referring to the fault slip model by Kubo et al. (2019, this meeting) with the length and width of 28km and 22km, respectively, in the lower crust. Rupture starting point is set to 35 km, and a single asperity is set several km shallower than the rupture starting point on the fault plane. Source parameters are derived by the recipe for inland crustal earthquakes. We call this source model the reference source model.

Broadband ground motion time-series on the engineering bedrock is computed using the J-SHIS v2 3D velocity model (Fujiwara et al. 2009, 2012). We employed a hybrid technique of the 3D finite-difference method (Aoi et al. 2004) and the stochastic Green’s function method (Dan and Sato 1998) superposed in time domain at the period of 1 s. JMA seismic intensity (I_{JMA}) on the ground surface is derived by using the empirical relationships between V_{S30}, PGV and I_{JMA} (Fujimoto and Midorikawa 2005, 2006).

Main features of the velocity waveforms in long-period range (> 1s), amplitude and travel time of the main phases, are found to be consistent with observed records at many observation stations. On the other hand, I_JMA on the ground surface systematically underestimated the observation. Although this underestimation can be attributed to many factors including the source and velocity models, since our simulation results underestimates the observation at all points in short-period component, we first examine the effect of the source parameters that mainly affects the ground-motion level of short-period components. The short-period level, or the source spectral amplitude level at short period, of this earthquake estimated by Tomozawa et al. (2018, SSJ) is 1 –2 times larger, depending on the dataset, than the empirical relation by Dan et al. (2001) which is employed in the recipe. Referring to their result, we set another source model that has smaller size of asperity and consequently higher short-period level, 1.5 times larger than the empirical relation of Dan et al. (2001). I_{JMA} computed with this source model was more consistent with the observation compared to the reference source model.

3. Summary

Broadband ground-motion simulations were conducted for this earthquake using the characterized source models. It was found that the ground motion computed with higher value of short-period level compared to the empirical relation for the ordinary inland crustal earthquake was more consistent with the observed ground motion. It maybe reflecting the feature of the earthquake source characterized by

©2019. Japan Geoscience Union. All Right Reserved.

the depth or the tectonic condition.
We will further study on the source characteristics and site response characteristics in order to better explain the strong ground motion records.

Acknowledgments: We used strong motion data provided by JMA, Hokkaido, the city of Sapporo, and NIED.

Estimation of 1D S-wave velocity structures in Kumamoto plain and Mashiki town using a waveform inversion of S-wave

*Kengo Muroi[1], Hiroaki Yamanaka[1], Kosuke Chimoto[1], Seiji Tsuno[2], Masahiro Korenaga[2], Hiroe Miyake[3], Nobuyuki Yamada[4]

1. Tokyo Institute of Technology, 2. Railway Technical Research Institute, 3. The University of Tokyo, 4. Kochi University

The 2016 Kumamoto earthquakes are crustal earthquakes caused by inland active faults with damage of many wooden houses to the focal area. In this study, we revised the previous subsurface structural model, using the observed ground motion records during aftershocks of the earthquakes, on the purpose of evaluating strong ground motion in damaged area during the main shock. Furthermore, we reproduced the strong motion of main shock, using the revised subsurface structural model.
First, we conducted 3-D finite difference simulations during aftershocks of the 2016 Kumamoto earthquakes, using previous subsurface structural model by Headquarters for Earthquake Research Promotion. We used the aftershock with an Mj of 5.5 and a depth of 10km on April 19 assuming a homogeneous fault model. From the comparison of the observed waveforms and the calculated waveforms in Mashiki, we found that the qualitative characteristics seen in the observed waveforms can be reproduced. However, we found it difficult to reproduce the detailed characteristics, such as the amplitude and phase.
Therefore, we tuned the 1-D subsurface structural models just beneath the observation sites by an inversion analysis, using waveforms of the observed initial S-wave during aftershocks. We estimated a 1-D velocity model minimizing misfit of mean squares between amplitudes of the observed waveforms and the calculated waveforms by a 1-D simulation using the discrete wavenumber method. We estimated the 1-D velocity structures at 36 observation sites in Kumamoto plain and Mashiki town during the aftershocks. We could well explain the characteristics of the observed waveforms, compared with the calculated waveforms using the previous subsurface structural model.
Finally, we conducted a simulation of the ground motion for the main shock, using the revised subsurface structural model. We used the source model by Kubo et al. (2016) and site amplification factors of J-SHIS in order to consider the effect of the amplification of the shallow soil. The calculated J.M.A seismic intensity distribution underestimated the observed seismic intensity at the center of Mashiki town and the calculated waveform at Mashiki town hall was 3 to 4 times smaller than the observed waveform. On the other hand, the calculated waveforms at K-net Kumamoto and KiK-net Mashiki are similar characteristics of the observed waveforms. These results show that the revised subsurface structure was reasonable in the Kumamoto plain, but we need to reconstruct further more the subsurface structural model beneath the center of Mashiki town.

Investigation to estimate high-frequency Empirical Green’s tensor derivatives (EGTD) using aftershocks for the 2016 Kumamoto earthquake

*Sayumi Yoshida[1], Horike Masanori [1], Ken Miyakoshi[2]

1. HANSHIN CONSULTANTS Co., Ltd., 2. Geo-Research Institute

1) Introduction
Green’s tensor derivatives play a key role for evaluation and prediction of strong ground motions and for surveys of the velocity and damping structures. However, it is difficult to generate high-frequency (above 1Hz) Green’s tensor derivatives using numerical approaches for want of fine geological structure models. Plicka and Zahradnik (1998) proposed a method for estimation of Empirical Green’s tensor derivatives (EGTDs) using multiple small earthquakes. EGTDs does not require the structural model along propagation paths for their estimation and is possible to calculate high-frequency ground motions for any focal mechanism. In this study, we investigate the conditions required (focal mechanism, grouping radius, applicable frequency) to obtain high-frequency EGTDs, using aftershocks of the 2016 Kumamoto earthquake.
2) Data and method
The size of the aftershocks ranges between the magnitudes 2 and 4. The focal mechanism, such as the strike, the dip angle, and the rake angle, and the source parameters of radiated spectra, such as the seismic moment and the corner frequency, are required for the estimation of EGTDs. The focal mechanism was obtained from the sign of P-wave first motions and the source parameters were obtained from the Fourier spectra of S-wave motions, assuming the model.
We first set the grouped aftershocks located within a sphere with a certain radius. Then, we estimated 3 EGTDs for 3-component ground motions from the grouped aftershocks by the approach developed by Plicka and Zahradnik (1998). Finally, we evaluated the accuracy of the estimated EGTDs by the correlation coefficients between observed seismic recordings of the grouped aftershocks and those calculated using the estimated EGTD for the 3- component ground motions. We furthermore evaluate the accuracy of EGTDs by investigating whether they can reproduce seismic waveforms of the aftershocks which are not contained in the group.
3) Results
Accurate EGTDs up to 2 Hz can be stably estimated from most groups with the radius of 1km, having the correlation coefficients over 0.8. Also, these EGTDs can reproduce the seismic motions of the aftershock that is not contained in the group. In the meantime, the correlation coefficients calculated from the estimated EGTDs up to 4Hz are not always not high values over 0.8 even for the groups with the radius 0.5 km. These results suggest that estimation of EGTDs up to the frequency higher than 2Hz requires accurate focal mechanism and source parameters of the radiated spectra. Thus, we will improve them, for example, using the Genetic algorithm.
4) Acknowledgement
In this study, we use event waveform data provided by NIED (Hi-net).

The 2016 Kumamoto earthquake contains a foreshock with an Mj of 6.5 on April 14 and the main shock with an Mj of 7.3 on April 16. The earthquakes generated ground motions with a seismic intensity of 7 on the Japan Meteorological Agency scale twice in Mashiki, Kumamoto, Japan and many wooden houses were collapsed. In this study we estimated site amplification characteristics in Kumamoto plain by using ground motion records at strong motion stations of K-NET, KiK-net, seismic intensity-meters stations by local governments and aftershock observation stations by Yamanaka et al. (2016) through a spectral inversion technique. We choose the OITH08 station as the referential site in the inversion. The estimated frequency dependent Q and the source characteristics by the spectral inversion technique show similar features to those from previous studies (e.g. Somei et al, 2018). The site amplifications in the alluvium plain show large values in a frequency range of 0.5-2.0Hz. At high frequency the site amplifications of the mountain are larger than those of the plain area. We estimated S-wave velocity structures in Kumamoto plain by an inverse analysis of the site amplifications. The sediments are large in central area of the Kumamoto plain.

Kinematic and dynamic source models of the 2016 Mj6.4 Kumamoto third large earthquake

*Kunikazu Yoshida[1], Ken Miyakoshi[1]

1. Geo-Research Institute

We make a kinematic source model of the 2016 Mj6.4 earthquake (2016 Apr. 15, 00:03 JST) which is a third large event during the 2016 Kumamoto earthquake sequence and dynamic source models based on the result of the kinematic model.

The kinematic model is made by inverting the strong-motion data obtained from K-NET, KiK-net, JMA and local government were used. The data were windowed for 18 s, starting at P-wave arrival time, and band-pass-filtered between 0.05 to 1.0 Hz (periods of 1-20 s) for waveform inversion. The accelerograms were integrated into ground velocities. Theoretical Green's functions are calculated using the discrete wavenumber method (Bouchon, 1981) and the Reflection/Transmission coefficient matrix method (Kennett and Kerry, 1979) using a stratified medium. We assumed individual one-dimensional velocity structure model for each station by using waveform modelling with small earthquake records (Yoshida et al., 2017). The event locations were relocated using double-difference method by Uchide et al. (2016). We used multi-time-window linear waveform inversion procedure (e.g., Hartzell and Heaton, 1983) in which the moment-release distribution is discretized in both space and time. The length and width of the fault plane was assumed to be 12 km and 10.5 km, respectively. The fault plane is divided into subfaults of 1.5 km ×1.5 km. The moment function of each subfault was represented by a series of six smoothed ramp functions in the 0.4 second interval. The first time-window triggering velocity (V_{FT}) was determined as 2.4 km/s, which was searched between 2.0 and 2.6 km/s based on residual of the waveform fits.

The estimated source model indicated 1.2 ×10^{18} Nm (Mw6.0) of the total moment release and 0.3 m average slip. One rectangular asperity and a high slip/moment rate area (HRA, Yoshida et al., 2017) patches with the average slip of 0.7 m were identified on the shallow part of the fault plane. The slip of the background area is 0.1 m.

We attempt to make dynamic rupture models based on the kinematic model. Stress drop distribution of the kinematic model was calculated (Okada, 1992). The average static stress drops were 3.9 MPa (asperity) or 4.9 MPa (HRA) and 1.0 MPa for the background. Effective stress was taken from the stress parameters estimated from SMGA (Kurahashi et al., 2017). The effective stresses were adjusted as 5.1 MPa (Asperity) or 6.3 MPa (HRA) to rupture over the entire fault. We conducted dynamic rupture simulations using the patched stress drop distribution obtained from the kinematic model (Figure left-bottom). We assumed slip-weakening law with uniform critical distances of 0.1 m, based on Dc’’ (Fukuyama and Mikumo, 2007) of about 0.15 m at KMMH14. The simulation results show that the final slips and total moments well agree with the ones of the kinematic model. Nevertheless, small slips and high slip rate on the top margin of the patches, and supershear rupture propagation on the further of the patch were found. We expect examination of some dynamic parameters, such as critical slip distances, to improve simulation results.

Source rupture process and strong motion generation area assuming the curved fault model for the 2003 northern Miyagi prefecture earthquake

*Kazuhiro Somei[1], Ken Miyakoshi[1], Yujia Guo[1]

1. Geo-Research Institute

At 07:13 on 26 July 2003 (JST), a shallow inland crustal earthquake (M_{JMA}6.4) with reverse faulting occurred in the northern Miyagi prefecture, north-east Japan. From the strong ground motion records in 0.05-0.5 Hz, the kinematic source rupture processes assuming a two-segment fault model have been estimated by waveform inversion method (e.g., Hikima and Koketsu, 2004). They showed large slips around 1.0 m occurred in a shallow part of the northern segment. However, surface breaks caused by this earthquake were not found along the source area by field surveys (e.g., Imaizumi et al., 2003). Since the shallow large slip area was identified between the north and the south segment, it is reasonable in estimating robust slip distribution to consider the more realistic fault plane with bending zone rather than a simple two-segment fault plane. Actually, the precisely relocated hypocenters of aftershocks were located along a curved plane dipping westward to north-westward (Okada et al., 2003). In this study, we investigate the source rupture process assuming the curved source fault, and estimate the strong motion generation areas (SMGAs; Miyake et al., 2003), in order to discuss the broadband ground motion generation processes during this event.

First, we employed the multi-time window linear waveform inversion method by using the strong motion waveforms (0.1-1.0Hz) recorded by K-NET, KiK-net, and JMA stations around the source area. From the observational information of relocated aftershock distribution and geological structure, the assumed curved fault model was composed of two planar segments (north and south segments) set by Hikima and Koketsu (2004) with transitional part that smoothly connect the north with south segment. The length, width, and shallowest top depth of fault model were 20 km, 11 km, and 0.59 km, respectively. This curved fault model was divided into 220 subfaults of 1.0 ×1.0 km. The temporal moment release history from each subfault was expressed by a series of 6 smoothed ramp functions with a rise time of 1.0 sec separated by 0.5 sec. The first-time window triggering velocity (FTWTV) was 2.8 km/s given by the smallest misfit solution. The theoretical Green’ s function was calculated by using the discrete wavenumber integration method (Bouchon, 1981) with the reflection and transmission matrix (Kennett and Kerry, 1979) assuming a 1D velocity structure model. The velocity structure model of each station was given by referring the Somei et al. (2018) or Petukhin and Miyakoshi (2006).

Second, the SMGAs were constructed based on the forward simulations using the empirical Green’ s function method (Irikura.1986) in the frequency range 0.3-10 Hz. The locations of rupture starting points and rupture times for two SMGAs were fixed by using the onset times of first and second S-wave packets in observations. Scaling parameters N and C were obtained based on the source spectral ratio analysis. The best set of parameters for SMGAs, such as the size, rupture velocity, rise time, and rupture starting point inside the SMGA, were determined by a grid searching to minimize the residual function of waveform fitting between observations and synthetics.

The principal findings from the source inversion and SMGA modeling are following. 1) The large slip area whose maximum slip of 0.93 m was concentrated in the transitional segment, where is north of the

©2019. Japan Geoscience Union. All Right Reserved.

hypocenter. The top depth of characterized asperity area (Somerville et al., 1999) was 3.07 km, which is deeper than that of Hikima and Koketsu (2004) model. The size of asperity area was 35 km^2, which is comparable to that expected by empirical scaling relationship (Somerville et al., 1999). 2) High peak moment ate areas (HRA; Yoshida and Miyakoshi, 2013), which implied the large slip velocity, were characterized with a size of 29 km^2 near the edge of the asperity area. 3) Synthetic ground motions generated from two SMGAs with a size of 24 km^2 identified close to the HRAs explained well the observations in a broadband frequency range. 4) The stress drops of two SMGAs were 13.7 MPa, which are comparable to those estimated for past large inland crustal earthquakes in Japan.

Estimation of source rupture process during the 2018 Shimane-ken seibu earthquake using strong motion data

*Susumu Kurahashi[1], Ken Miyakoshi[2]

1. Aichi Institute of Technology, 2. Geo-Research Institute

1. Introduction

The 2018 Shimane-ken seibu earthquake (Mw5.6) occurred in the western part of Shimane-prefecture, Japan, on April 9, 2018. The maximum seismic intensity with 5 upper was observed at Ohta city. PGA of 564 gal is observed at the SMN006 station. We estimated the source process of this earthquake by the waveform inversion using the strong motion data.

2. Estimation of rupture area from the waveform inversion

We analyzed the slip distribution during this earthquake using the multi-time window linear waveform inversion method (Sekiguchi et al., 2000). The data sets used for the inversion analysis were velocity waveforms of S-waves parts at 13 stations (KiK-net, K-NET). The Green's functions were calculated using the one-dimensional velocity structure models by the discrete wavenumber method (Bouchon, 1981) with the reflection and transmission matrix method (Kennett and Kerry, 1979) at the stations. A fault plane was assumed referring to the aftershock distribution and the moment tensor solution determined by F-net data.

First, in order to estimate the rupture area, we analyzed the waveform inversion in target frequency 0.1-0.5Hz. The fault plane is divided into 36 subfaults of 2.0km×2.0km. The temporal moment release history from each subfault is modeled by a series of 3 smoothed-ramp-functions with a rise time of 1.0 second each separated by 0.5 second. The estimated rupture area was trimmed by criteria of Somerville et al. (1999). The trimming result removes one column of the north edge of rupture area. Seismic moment, area, rupture velocity and average slip are estimated 4.67 $\times 10^{17}$Nm,126km^2, 2.7km/s and 0.11m, respectively. The rupture area was approximately three times larger than the scaling relationship of rupture area vs seismic moment from Irikura and Miyake (2001).

3. Extraction of asperity from the waveform inversion results

Next, in order to extract of asperity from slip distribution, we analyzed the waveform inversion in the frequency range of 0.1-1.0Hz. The rupture area is divided into 56 subfaults of 1.5km×1.5km. The temporal moment release history from each subfault is modeled by a series of 6 smoothed-ramp-functions with a rise time of 0.6 second each separated by 0.3 second. A large slip area is constructed in the proximity of the hypocenter.
The asperity and high rate area (HRA) were extracted from the slip distribution by the criterion of Somerville et al. (1999) and Yoshida et al. (2005), respectively. Seismic moment and area are estimated 2.23×1017Nm and 27km2, respectively. The area and location of the asperity and the HRA are estimated to be almost the same. On the other hands, the asperity was overestimated in comparison with the scaling relationship of asperity are vs seismic moment from Irikura and Miyake (2001).

4. Conclusion

©2019. Japan Geoscience Union. All Right Reserved.

We estimated source process of the 2018 Shimane-ken seibu earthquake (Mw 5.6) form the waveform inversion using the strong motion data. The asperity and the HRA of this earthquake are collocated with nearly the same area. On the other hands, the rupture area and the asperity were overestimated corresponding to scaling law from Irikura and Miyake (2001). The rupture area data of earthquake of Mw6 class vary widely in the scaling law from Irikura and Miyake (2001). Therefore, it is necessary to consider about earthquake of Mw6 class.

Acknowledgements. Seismic waveform data of the K-NET and KiK-net were used. This study was based on the 2018 research project 'Examination for uncertainth of strong ground motion prediction for inland crustal earthquakes').

An estimation of SMGA of M6 class earthquakes based on strong motion records near the source regions

*Kentaro Motoki[1], Kenichi Kato[1], Tetsuo Shiota[2]

1. Kobori Research Complex, 2. Shikoku Electric Power Company

High amplitude earthquake motions exceeding 1 G have been observed when M6 class earthquakes occurred for a couple of decades. In the 2004 Rumoi earthquake (M6.1), two SMGAs in the vicinity of the strong motion station caused high amplitude earthquake motions (Maeda and Sasatani , 2008, Motoki et al., 2015). For M6 class earthquakes, which are difficult to set up fault models to be used for strong ground motion prediction, we thought that accumulating information such as stress drop and area of SMGA gave useful information for setting ground motion level for future earthquakes. In this report, we inverted SMGA for the 2011 Ibaraki-ken Hokubu earthquake.

We used empirical Green's function method (EGF) to invert SMGA. Unknown parameters in this inversion were the location of SMGA trigger point, stress drop ratio c, the number of superposition N, length of SMGA, rupture velocity in SMGA, starting rupture time of SMGA, rise time, and random numbers giving the rupture fluctuation to weaken artificial periodicity. For inverse analysis of SMGA, we used a hybrid heuristic method (Yamanaka, 2007), which could solve nonlinear problems and did not require an initial model.

For an inversion of SMGA, we selected 4 stations (IBRH13, IBRH14, IBR001 and FKS014) where the influence of nonlinearity in subsurface soil during the main shock might be small based on degree of nonlinear site response proposed by Noguchi and Sasatani (2011). We also selected 7 earthquakes as element earthquakes for empirical Green’ s function. We performed 7 inversion analyses using each element earthquake record.

Corner frequencies of the element earthquakes were evaluated by means of genetic algorithm so as to minimize the sum of residuals between the observed source spectral ratio and the source spectrum ratio function assumed ω-square model in the frequency domain. We set the search range for an inversion of SMGA, by referring to the previous source model (JMA, 2017) and c and N expected from the observed source spectral ratio. In this inversion M_0 and A, which means radiant amplitude in a short period range, were constrained not to exceed the value estimated by F-net and the value obtained from the source spectral ratio, respectively. The acceleration envelope shapes, the displacement waveform, and the Fourier amplitude were used as the objective function for an inversion.

Assuming one SMGA, the inverted SMGA could explain the earthquake motions near the source region. The SMGA location were good agreement with the large slip area in the previous models (JMA, 2017 and Hikima, 2017), which were used long period motions for their inversions.

Furthermore, in order to confirm the validity of the inverted SMGA from a theoretical aspect, we performed numerical simulation for the down-hall station at IBRH13 using the theoretical Green’ s function analysis (Hisada and Bielak, 2003). The simulated motions successfully reproduced the pulse wave and the response spectra of the observed motions.

We compared the area of SMGA estimated in this study with the relation of M_0 –area of SMGA according

©2019. Japan Geoscience Union. All Right Reserved.

to Miyake et al. (2003). The result of this study is smaller than that of relation by Miyake et al. One factor that caused this difference is thought to be due to the difference in idea of modeling. As mentioned above, M_0 of the SMGA in this study corresponded to a third of M_0 evaluated by F-net. Meanwhile, the SMGA of Miyake et al. (2003) had set the SMGA to include all of the M_0. It can be consider that the larger M_0 of SMGA has the larger area of SMGA. On this issue, we think that it is important to apply other earthquakes and accumulate data, and we will analyze SMGA of the 2013 Tochigi-ken Hokubu earthquake.

Difference in short-period level between the surface and buried fault rupture crustal earthquake in Japan

*Shohei Yoshida[1], Takao Kagawa[1], Tatsuya Noguchi[1]

1. Graduate School of Engineering, Tottori University

Appearance of surface fault rupture in inland crustal earthquake affects significantly on ground motion characteristics. Somerville(2003) indicated that observed ground motions from buried rupture earthquakes are larger than those from surface fault rupture earthquakes in period range around 1.0 second. Kagawa *et al.*(2004) explained that the differences are mainly caused in seismic source characteristics of fault ruptures, such as peak slip rate and stress drop between shallow and deep region. The Headquarters for Earthquake Research Promotion compiled a method for strong motion prediction (recipe). Short-period level as a parameter of the recipe is an important factor that affects generation of short-period ground motion. Due to the difference in ground motion characteristics between surface and buried fault rupture, the short-period level may also be different between the two rupture types. In this study, we organize short-period levels that evaluated characteristic source models by empirical Green's function method, and investigated empirical relations between short-period level and seismic moment for both surface and buried fault rupture crustal earthquake in Japan.

Probabilistic seismic hazard assessment of response spectra for whole Japan (part 1: Selection of ground motion prediction equations)

*Nobuyuki Morikawa[1], Junichi Miyakoshi[2], Hiroyuki Fujiwara[1]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Ohsaki Research Institute, Inc.

The seismic intensity or peak velocity is used in the probabilistic national seismic hazard maps for Japan. However, seismic hazard assessment of response spectra is useful in seismic risk assessment and engineering field. In this study, we try to assess seismic hazard of the response spectra by using the seismic activity model in the national seismic hazard maps for Japan. In this paper, we mention selection of ground motion prediction equations (GMPEs) used in the assessment, and the results are shown in the next report.
In Douglas (2019), 290 GMPEs for spectral ordinates published after 1973 are summarized, of which about 50 are derived from strong-motion records mainly observed in Japan. The 2003 Tokachi-oki earthquake was the first magnitude 8-class earthquake in the world where strong-motion records observed by the nation-wide dense networks, K-NET and KiK-net. It is very important to use the GMPE obtained using the record of the 2003 earthquake, because the contribution of large subduction earthquakes on seismic hazard assessment in Japan is extremely large. In this study, we carry out the assessment of 5%-damped acceleration response spectra whose period is shorter than 5 seconds all over Japan on the engineering bedrock (Vs=400m/s). So we select GMPEs that satisfy the following conditions.
a. It has been published as a peer-reviewed paper.
b. It was derived from records mainly observed in Japan, including records of the 2003 Tokachi-oki earthquake.
c. It is included peak acceleration and 5% damped acceleration response spectra whose period ranges from 0.1 to 5 seconds and can evaluate on the engineering bedrock.
d. It is possible to consider the difference of source and path characteristics in earthquake type (crustal, subduction plate-boundary, and subduction intra-plate).
e. It is modeled anomalous seismic intensity distribution.
f. It does not target specific earthquakes or observation points only.
g. It is used records of magnitude 9-class mega-earthquake.
As the result, two sets of GMPEs by Morikawa and Fujiwara (2013) and Zhao et al. (2016) were selected. However, with regard to the above condition g, it is inevitable that the uncertainties concerning the applicability to the earthquakes in Nankai trough are large because both GMPEs are used records the 2011 Tohoku great earthquake only for magnitude 9-class. In order to consider such uncertainty, we decide to add the latest GMPE, Goda and Atkinson (2009)’s, that satisfies other conditions.
The difference is large in the short distance or mega-earthquake, which number of records is quite few, among three GMPEs. By the way, the dataset for deriving the GMPE is constructed by each researchers. As the result,
1. Methods of filtering applied to observed waveforms and definition of horizontal maximum amplitude are different each other.
2. The magnitude and fault model selected are different for each other.
3. Indicators related to site amplification, such as site class and Vs30, are not unified.
This situation makes it impossible to compare among GMPEs under exactly the same conditions. This is not limited to the three GMPEs selected here, but is a problem common to all Japanese GMPEs that do not have derived from the same dataset. In seismic hazard assessment including mega-earthquakes and very close distance to the source fault with quite few observation records, it is necessary to use multiple

©2019. Japan Geoscience Union. All Right Reserved.

GMPEs in consideration of epistemic uncertainty. In case of seismic hazard assessment targeting a specific site, there is also the idea that each GMPE is weighted based on consistency with observation records. However, in order to evaluate its consistency, it is necessary to construct a unified standard dataset and to use GMPEs derived based on it that can be compare under the same conditions.

Probabilistic seismic hazard assessment of response spectra for whole Japan (part 2: Probabilistic seismic hazard assessment)

*Junichi Miyakoshi[1], Takeshi Morii[1], Nobuyuki Morikawa[2], Hiroyuki Fujiwara[2]

1. Ohsaki Research Institute, Inc., 2. National Research Institute for Earth Science and Disaster Resilience

The seismic intensity or peak velocity is used in the probabilistic national seismic hazard maps for Japan. However, seismic hazard assessment of response spectra is useful in seismic risk assessment and engineering field. In this study, we try to assess seismic hazard of the response spectra by using the seismic activity model in the national seismic hazard maps for Japan. In this paper, the seismic hazard assessment results of the response spectra are shown using the selected ground motion prediction equations (GMPEs) in the previous report.
Three GMPEs are used: Morikawa and Fujiwara (2013), Goda and Atkinson (2009), Zhao et al. (2016). When evaluating seismic hazards for Japan, it is difficult to evaluate only by one GMPE, so it is necessary to select multiple GMPEs as a branch of the logic tree.
Based on the hazard curve of the response value with respect to the natural period, a uniform hazard spectrum (UHS) is calculated by connecting response spectra that have the same excess probability for each natural period. We calculate UHS at 6 cities (Sapporo, Sendai, Tokyo, Nagoya, Osaka, Fukuoka) by using the seismic activity model in the national seismic hazard maps for Japan.
As an example of the result, we are shown uniform hazard spectra for 39%, 10%, 5%, and 2% probability of exceedance occurring within 50 years from the present for all seismic activity models in Sapporo and Tokyo using GMPE by Morikawa and Fujiwara (2013). In the uniform hazard spectra, we can confirm the difference between the seismic hazard level of Sapporo and Tokyo. Also, the degree of influence of the seismic category for each natural period for a 10% probability of exceedance occurring within 50 years from the present is shown. By using the seismic activity model in the national seismic hazard maps for Japan in this way, it becomes possible to grasp the difference of the seismic hazard in the region for each natural period. In addition, we assess seismic hazard of standard peak acceleration in the world.

Simulation of Long-period Ground Motion around The Fujikawa-kako Fault Zone during the 2018 Northern Osaka Earthquake

*Seina Hashimoto[1], Hiroaki Yamanaka[1], Kosuke Chimoto[1], Masahiro Korenaga[2], Seiji Tsuno[2], Hiroe Miyake[3], Shigeki Senna[4]

1. Tokyo Institute of Technology School of Enviroment and Society, 2. Railway Technical Research Institute, 3. The University of Tokyo, 4. National Research Institute for Earth Science and Disaster Prevention

Abstract

The Fujikawa-kako fault zone is an active fault that is suggested to be associated with the Nankai Trough in Suruga Bay, and the activity interval of this fault is a relatively high as compared to the other general active faults. Furthermore, this area is so important for the transportation network for our lives near this fault zone. A high-reliable prediction of strong ground motion in this area is important in earthquake disaster prevention in the area. In this study, we have installed strong motion observation instruments in Fujinomiya City and Fuji City to acquire strong motion records during small earthquakes since April 2018. From the earthquake records obtained at the observation points, it was found that the duration of the shaking was as long as nearly 2 minutes, and the long period component was dominant in the 2018 Northern Osaka Earthquake with a magnitude of 6.1. Then, using the deep S-wave velocity structure model of J-SHIS, we conducted seismic motion simulation of Northern Osaka Earthquake. We also assumed appoint source model, based on the CMT solution released by the Meteorological Agency. First, we compared the synthetic waveform of the rock site (YMNH10) with the observed one. The calculated waveform had similar characteristics of the observed waveform. By using the snapshots, we found that the major phases observed mainly in this area were surface waves with a north-south oriented wavefront arriving a right after the S wave arrival. We also found the later phases arriving from the southwestern part of Yamanashi Prefecture where the depth of the seismic bedrock is suddenly increases. On the other hand, the reproducibility of the observed frequency characteristics in the vicinity of Shizuoka City was low in a period range of 3-20 seconds. We need further improvement in the S-wave velocity model of the sedimentary layers.

Acknowledgements

Site amplification factors for KiK-net stations in and around Ibaraki Prefecture estimated by the coda normalization method

*Jun Kawahara[1], Takahiro Nakamura[1], Takuji Yamada[1]

1. Graduate School of Science and Engineering, Ibaraki University

It is empirically known that the spatial distribution of the coda wave energy from a local earthquake is nearly uniform for long lapse times. The coda normalization method is a method of separating source, path, and site effects from coda wave records, based on this empirical characteristic (Sato et al., 2012). There are many studies on the evaluation of site amplification factors based on the coda normalization method (e.g., Takahashi et al. 2005; Takemoto et al., 2012). However, little attention has been paid on the magnitude of the variability of amplification factors estimated for different earthquakes in an identical region.

We applied the method to the strong-motion records for 21 KiK-net stations and F-net TSK (Tsukuba) station in and around Ibaraki Prefecture. We used the records of 31 earthquakes with 4.7≦Mw≦6.4, which were classified into four groups depending on their locations. Stations with the epicentral distances less than 100 km were chosen for each earthquake, and the seismograms for lapse times greater than twice the direct S-wave travel time at the farthest station were used in the analysis. We selected TSK as the reference station for which the site amplification is expected to be low, and we obtained the amplification factor for each KiK-net station relative to TSK. We also calculated the geometric mean of the factors for each earthquake group.

We obtained the following results. (1) The low-frequency (0.5 to 1 Hz) amplification factors were apparently correlated with both basement depths and geological ages. It is consistent with previous studies such as Takemoto et al. (2012). (2) At the stations with shallow basement in the northern areas, the variability of the amplification factors among the earthquakes was small irrespectively of frequencies, and the geometric means of the factors for four earthquake groups were nearly the same. (3) At the stations with deep basement in the southern areas, the variability of the amplification factors among the earthquakes was relatively large, and the geometric means of the factors for four earthquake groups were somewhat different. (4) The geometric standard deviations of the amplification factors were apparently correlated with both basement depths and geological ages. (5) There appears no clear relationship between the amplification factors and the hypocentral distances for most stations. It supports the empirical assumption that the spatial distribution of the coda wave energy is nearly uniform.

Acknowledgment.
We used the strong-motion records form KiK-net and F-net and the data of basement depths from J-SHIS (National Research Institute for Earth Science and Disaster Resilience).

Estimation of earthquake ground level in Horinouchi area in the 2014 Northern Nagano earthquake

*RYOTA KAWAI[1], Hiroaki Yamanaka[1], Kosuke Chimoto[1], Seiji Tsuno[2], Masahiro Korenaga[2]

1. Interdisciplinary Graduate School of Science and Engineering,Tokyo institute of Technology, 2. Railway Technical Research Institute

The 2014 Northern Nagano Earthquake with Mj of 6.7 occurred on 22 November 2014. The JMA maximum intensity of 6 lower was observed in Otari village and Ogawa village. However, heavy damage was observed in Horinouchi and Mikkaichiba areas which are 5km away from the strong observation point with intensity of 5 higher. One of the reasons for the heady damage is low seismic performance of the damaged houses as reported in JAEE's team. However, strong motion features of main shock are not fully understood in the area... In this study, we estimated the ground motions in the damaged areas to know the reasons of the damage.

After the main shock, Chimoto et. al (2015) observed aftershock records around the damaged areas In this study, we analyzed these records with records observed at strong motion stations using the spectral inversion technique. This technique can divide ground motion spectra into site, source and propagation effects. We used records from 59 earthquakes including aftershocks between JMA magnitudes of 2.4 and 5.8, and the main shock. During strong shaking like the main shock, nonlinear behavior of soil layers can be observed. Thus, we set three conditions for the data selection in this inversion analysis.

1) For earthquake records with PGAs less than 100 gal except for the main shock,

2) the main shock records with PGAs less than 100 gal have site effects as same to those of weak shock,

3) the main shock records with PGAs more than 100 gal has site effects that are different from those of the weak motions. Under these conditions, different site effects for the weak motion and the main shock are estimated at the observation stations with PGAs more than 100gal during the main shock.

We investigated the relation of the estimated site effect for the weak shaking and the main shock at the observation stations. The differences of these site effects can be caused by the nonlinearity of the soft soil. Therefore, in this study, we defined Ra(f) as an ration of the site effect for the main shock to that of weak shaking. We investigated the relationship between this Ra and the S wave velocity profiles by our microtremor surveys. At the observation stations with PGAs of 400 gal during the main shock, it was found that the Ra is similar for the sites with similar average S wave velocities up to a depth of 10 m (hereafter, Vs 10). The Vs10 in Horinouchi area is 165m/s, and VS10 in Ogawa village is 151m/s. Therefore, it is indicated that Ras in Horinouchi area and Ogawa village are the same.

The spectra characteritics of the main shock at basement was calculated from the source effect of the main shock and the propagation effect, estimated by spectrum inversion. Furthermore, we estimated the site effect of the main shock in Horinouchi area from the site effect of weak shaking and Ra of Ogawa village for estimating the spectral features of the main shock in Horinouchi area by these multiplications of these factors.

As a result, it was found that the estimated earthquake ground motion level was about 2 times stronger

©2019. Japan Geoscience Union. All Right Reserved.

than the strong motion observation stations at a period of 1-1.5 seconds, which has large effects on the wooden houses. We also found that this motion is classified to a seismic intensity of 6 upper on the JMA scale. On the other hand, the estimated spectral power in this study is about 1/4 to 1/2 of the strong motion spectrum of past destructive earthquakes observed in areas with heavy damage of the wooden building.

From these discussions we have concluded that ground motion at periods of 1-1.5 seconds were slightly larger than the surrounding observation stations. However the low earthquake resistance of the damaged building in Horinouchi area must be also included in one of the reasons of the damage.

Ground type classification for strong ground motion prediction based on characteristics of phase-velocity curves from microtremor explorations

*Atsushi Wakai[1], Shigeki Senna[1], Hisanori Matsuyama[2], Yatagai Atsushi[2], Yoshiaki Inagaki[2], Hiroyuki Fujiwara[2]

1. National Research Institute for Earth Science and Disaster Prevention, 2. OYO Corporation

For the purpose of strong ground motion evaluation and prediction, subsurface velocity structures in sedimentary layers have ever been modeled and sophisticated for Kanto, Tokai and Kumamoto region in the national investigation conducted by SIP (Cross-ministerial Strategic Innovation Promotion Program) of Council for Science, Technology and innovation.

There, spatially dense array-microtremor explorations also have been conducted at more than 27,500 sites in the regions, as of February 2019. They consist of miniature and irregular array measurements made at interval of about 1 km and standard-sized array ones made at interval of about 5 km. As a result, shallow S-wave velocity structures were modeled in detail, which can affect ground amplification, building and human damage.

In this study, regarding characteristics of phase-velocity (hereinafter called Pv) curves from array microtremor explorations, it was attempted to investigate relationships with geomorphologic land classification [Wakamatsu et al., 2013] and geological constitution of ground.

Pv curves can be usually obtained 2Hz to 30Hz in frequency from miniature and irregular array microtremor explorations. In general, Pv in higher frequency corresponds to velocity structures in the depth of a few of meters to 10 meters and that in lower frequency corresponds to those in the depth of dozens of meters below ground surface. Here, Pv at wave length of 40 meters or C40 [Konno et al., 2000] was extracted and made use of at each microtremor measurement site. C40 can be regarded as AVS30.

As a result, useful information was able to be acquired to model subsurface velocity structures in addition to new knowledge which was not able to be obtained from only bore-hole exploration data. Also, C40s vary due to different-sized plains and different sedimentary environment despite the same geomorphologic land classification. This presentation will report the results in detail.

Establishment of the Underground Structure Model for Seismic Damage Estimation

*Shigeki Senna[1], Atsushi Wakai[1], Hiroyuki Fujiwara[1]

1. National Research Institute for Earth Science and Disaster Resilience

1.Introduction
To develop subsurface structure models for estimating earthquake damage on a real-time basis, we studied subsurface models capable of evaluating ground motion characteristics at a broad range of frequencies. We combined a shallow subsurface model and a deep subsurface model by collecting boring data and soil property data, which are crucial for explaining the ground motion in the vicinity of each period (0.5 to 2.0s), as such ground motion affects soil both near the surface and deep in the ground. In this study, we developed a widearea subsurface structure model (250m grid cell) and a more detailed subsurface model (50m grid cell), as well as a microtremor measurement system and a subsurface structure information management system to support model development. A brief description of each of the following themes will be provided in the sections below.

(1) Construction of wide-area subsurface models for estimating earthquake damage
(2) Understanding of ground motion characteristics and development of a microtremor observation system
(3) Development of a construction technique for a detailed subsurface model through public-private collaboration

2. Construction of Wide-Area Subsurface Models for Estimating Earthquake Damage
Wide-area subsurface models were constructed for the entire Kanto and Tokai regions. Here, we will mainly report on the progress made with the model for the Kanto and Tokai area. To develop a shallow subsurface model, we primarily used approximately 440,000 sets of boring data gathered by NIED. We created an initial integrated model for shallow and deep subsurfaces by combining this shallow subsurface model with an existing deep subsurface model (J-SHIS) and adjusting the engineering bedrock. Records compiled by K-NET, KiK-net, JMA, and local governments were used as seismic observation records. To gather continuous microtremor data, two types of observation techniques, namely miniature and irregular arrays and large arrays (R = 25 to 800 m), were used at approximately 20,000 and 800 points, respectively.

3. Understanding Ground Motion Characteristics and Development of a Microtremor Observation System
To obtain a large number of microtremor array measurements and ensure that results are managed effectively until the results of analysis are produced, it is necessary to minimize and simplify the steps required to collect observation data, analyze them, and evaluate the results. To achieve these goals, we developed a mechanism that can perform all the steps quickly, including on-site data sorting and analysis while minimizing human error. More specifically, we developed i-Bido, which transmits data between seismometers and computers, tablets, and other computing devices without corrupting the data while preserving its quality, and sends the data to the database described below.

4. Development of a Construction Technique for a Detailed Subsurface Model Through Public-Private Collaboration
Our goal is to construct detailed subsurface models with 50m grid cells capable of predicting liquefaction

©2019. Japan Geoscience Union. All Right Reserved.

and landslides while accounting for factors such as ground irregularity and artificial sites, using both public and private boring data, building confirmation applications, topographical information, old topographic maps, and other data. A slope map developed by the Geospatial Information Man-made structures were excluded. The distribution of small artificial valley fills that could not be identified by topographical maps derived from an algorithm for calculating and comparing slopes was obtained. Finally, the buffer region was applied to the water systems identified from the results of water system analysis to develop a model. The model is consistent with the distribution of large-scale artificial sites and also appears to show small artificial sites.

Consideration of liquefaction damage rate based on liquefaction damage in recent years

*Shigeki Senna[1], Ozawa Kyoko[1]

1. National Research Institute for Earth Science and Disaster Resilience

1. Introduction
In the 2011 off the Pacific coast of Tohoku Earthquake, liquefaction occurred in an extremely large area from the Tohoku region to the Kanto region, and a large number of liquefaction damage was confirmed in Kumamoto City and Aso City in the 2016 Kumamoto earthquake. In The past, the authors examined the rate of liquefaction in recent years of liquefaction and showed that the difference in the rate of liquefaction in the Tohoku-Pacific Ocean earthquake and other earthquakes was explained by the effects of the duration of the seismic motion. However, this creation of anation, liquefaction hazard map is difficult, and there is grouping based on the history of the microtopography of 250 m mesh and the regional classification method for this regionality consideration. the improvement of the high accuracy of the liquefaction rate prediction equation by setting the area ratio of the area and the subdivision of the micro-topography division, etc. by using topography and elevation data. We also collected information on building damage and investigated the rate of liquefaction damage.

2. Collected and maintained data
The 2011 off the Pacific coast of Tohoku Earthquake and the 2016 Kumamoto earthquake liquefaction Point by local surveys and aerial images, A re-reading of the sand point was performed from high sight point of the geographical institute immediately after the earthquake. we have created a detailed data set of about 50 m and about 25 m mesh units as well as the data set of approximate 250 m mesh units that have been prepared so far.
In addition, the following data were also prepared.

(1) Average elevation, average gradient, and ratio of high data for each mesh size (250 m, 50 m, 25 m) based on 10 MDEM data.
(2) Topographic classification data for each mesh size based on land use classification data based on the above data, we investigated the liquefaction incidence and the area ratio from the relationship between the data and the liquefaction point.
(3) We collected damage information such as slope and settlement of buildings in the 2011 off the Pacific coast of Tohoku Earthquake and the 2016 Kumamoto earthquake, and investigated the relationship with the incidence rate.

3. Investigation of liquefaction generation rate and area ratio
With regard to liquefaction incidence, data on liquefaction occurrence rates of the 2011 off the Pacific coast of Tohoku Earthquake and the 2016 Kumamoto Earthquake are summed up and the measured seismic intensity and maximum velocity fragility are calculated for each micro-topography classification using the least squares method and maximum likelihood Method and cluster analysis was carried out to group the micro topographical classification. As a result, it was able to be grouped into four new groups different from the micro topography group classified based on the liability to liquefaction by a previous study. For each group, the possibility of group subdivision was examined by comparing with average elevation, average gradient, specific height data etc. of each mesh. As a result of examination, it was found that the liquefaction occurrence rate has extremely high correlation with the specific height in any of the

©2019. Japan Geoscience Union. All Right Reserved.

micro topography classifications, and it is highly likely that the above four groups can be further subdivided. Regarding the liquefaction area ratio, assuming that 25 m mesh is the minimum unit, if there is even one sand in the mesh, it is assumed that the whole mesh is liquefied. Regarding the areal ratio, because there was no clear correlation with the measured seismic intensity and the maximum velocity in all the micro topographical classifications, the average value of the area ratio was calculated for each micro topographical classification. For the sake of simplicity, this study summarizes the final liquefaction occurrence rate by multiplying the liquefaction occurrence rate and liquefaction area rate shown above. In addition, we examined the relationship between seismic intensity, maximum speed and liquefaction occurrence rate for slope and settlement of building damage caused by liquefaction.

4. Conclusion (future plans)
The liquefaction incidence rate calculation formula (florality) examined in this study will be compared with building damage damage distribution data in the future, and the validity of the results will be verified.

Estimation of surface earthquake record at MeSO-NET observation points

*Shigeki Senna[1], Atsushi Wakai[1]

1. National Research Institute for Earth Science and Disaster Resilience

1. Introduction
In this research, in order to predict the state of shake of the ground surface with high precision from the data of the underground seismometer installed at the depth of 20 m of MeSO-net, microtremor observation at each observation point and temporary observation at the surface By observation, we evaluate the ground amplification characteristics and estimate the S wave velocity structure of the ground. As research and development items for that, 1. Acquisition of surface earthquake record and estimation of amplification characteristics at MeSO-net observation point, 2. Estimation of geophysical properties such as microtremor array observation and S wave velocity structure.The following section introduces efforts for each item.

2. Acquisition of surface earthquake records and estimation of amplification characteristics at MeSO-net observation point
In this item, in order to estimate the ground-to-ground spectral amplification factor for each observation point by temporary seismic observation at the MeSo-net observation point, it was conducted at all MeSO-net observation points (297sites) There. The observation period is 2 to 3 months per point, and observation is completed at 60 points. For each target observation point, one seismometer (JU 310 and JU 410 manufactured by Hakusan Kogyo Co., Ltd.) having the same sensor as the MeSO-net seismograph was used. In addition, the sampling frequency at the time of data acquisition was set to 200 Hz and the range was set to ±4.0G (± 1.0 G for JU 310) for JU410. Amplification characteristics are calculated by calculating the Fourier spectrum for each component from the seismic waveform obtained in the ground and the surface at each observation point, applying a bandpass filter of 0.1 to 10 Hz, smoothing in a logarithmic window, The ratio was taken. As a result, the difference in amplification characteristics between the relatively hard Rohm plateau sites and the soft backward swamp and natural embankment sites.

3. Microtremor array observation and estimation of ground physical property values such as S wave velocity structure
To verify the ground amplification characteristics of the previous section and make it possible to assume the shake even under strong ground motion, microtremor array observation to obtain the S wave velocity structure of about 50 m underground was carried out. Microtremor observation purchased a three component seismometer/ microtremor observation device (JU410) with the same sensor characteristics as the MeSO-net seismograph. Using them, microtremor array observation is carried out just above 296 points of the target MeSO-net observation point. In the fine motion array, we deployed a 4-point extremely small array with an array radius of 60 cm and a 3-point irregular array with about 5 to 15 m on each side, and observation was done for about 15 minutes at the same time. In addition, the ground physical property values such as the S wave velocity structure were estimated using inverse analysis methods such as extraction of amplification characteristics of AVS30 etc. (C40), direct curve transformation method of dispersion curve, inverse analysis and the like. As in the previous section, the difference between the characteristics of the relatively hard Rohm and the soft backward swamp are clear.

©2019. Japan Geoscience Union. All Right Reserved.

4. Conclusion
Based on the seismic observations and microtremor observations carried out up to the previous section, we will consider the ground amplification factor considering the period in the future, but we will consider the past ground model (SIP) of the existing Kanto region We will further improve the S wave velocity structure model using the shallow / deep integrated subsurface structure model of the Kanto region implemented in the real-time earthquake damage estimation) and estimate the highly accurate seismic motion at 250 m mesh interval The goal is to do.

Possibility of estimating phase velocity of Love wave using Horizontal components in microtremor array surveys in the case of Nishio

*Kotoyo Tsuchida[1], Masanori Horike[1], Koji Yamada[1], Masaki Suehiro[1], Sayumi Yoshida[1]

1. HANSHIN CONSULTANTS COMPANY LIMITED

1) Introduction

The S wave velocity structure of sediments is the most important factor for amplification of earthquake motions. In recent years, microtremor array surveys have been popularized because the S wave velocity structures can be estimated by simple measurements and at a low cost. For example, Horike (1985) inferred the S wave velocity from f-k spectra estimated array microtremors and Aki (1957) and Okada (2003) also inferred them from the spatial autocorrelation functions (SPAC). These approaches use vertical microtremor array recordings and discard horizontal-component recordings. As is well known, the phase velocity of Rayleigh waves is influenced not only by the S-wave velocity structure but also by the P-wave velocity structure, while that of Love wave is influenced by the S-wave velocity structure alone. Therefore, it is expected that S wave velocity structure can be obtained clearly by estimating the velocity structure using the dispersion of the Love wave. Several approaches are developed for inference of the phase velocity of Love waves, for example f-k method by Tsuchida et al (2016), SPAC and CCA method by Tada et al (2010; using the microtremor array analysis tool "BIDO 2.0" software). The aim of this study is to compare the phase velocities obtained using the same arrays.

2) Observation and data

For this comparison, we implemented microtremor measurement in Nishio City, Aichi Prefecture, using different-size array composed of 7 stations. At each station 3-component velocity sensors were installed. Microtremor recording were acquired at a sampling interval of 0.005s for 30 minutes. This site is suitable for this comparison, because there is much information about geotechnical and geological property.

3) Results

At the present, the phase velocity by the f-k method is estimated, but it is still in the process of analysis. Therefore, by the day of the presentation, we will proceed with the remains to do.

Enhancement of shallow velocity structure models based on array microtremor explorations for Tokai region, Central Japan

*Atsushi Wakai[1], Shigeki Senna[1], Yatagai Atsushi[2], Yoshiaki Inagaki[2], Hisanori Matsuyama[2], Hiroyuki Fujiwara[1]

1. National Research Institute for Earth Science and Disaster Prevention, 2. OYO Corporation

1. Introduction
For sophistication of strong ground motion prediction, it is important to model subsurface velocity structure so that earthquake ground motions can be evaluated in broadband period from 0.1 s to 10 s. Therefore, it is indispensable to combine shallow and deep velocity structure models which have ever been constructed separately and to constructed subsurface velocity structure models so that earthquake observation records can be reproduced.

We have ever modeled subsurface velocity structure for Kanto, Tokai and Kumamoto region in the national investigation conducted by SIP (Cross-ministerial Strategic Innovation Promotion Program), “reinforcement of resilient disaster prevention and mitigation function” of Council for Science, Technology and innovation.

This study attempted to sophisticate shallow geological and soil structure models in initial subsurface velocity structure ones from seismic bedrock to ground surface which had been constructed for Tokai region (Shizuoka, Gifu, Aichi and Mie pref.) last year. It was based on results of a great number of array microtremor explorations. This report will introduce outline of array microtremor exploration, sophistication process of shallow velocity structure models and characteristics of ground motion.

2. miniature and irregular array microtremor exploration
About microtremor measurements, array observations were conducted in lowland and plateau of Tokai region. It consists of 4-point miniature array with a radius of 60 centi-meters and 3-point irregular array from 5 to more than 10 meters on a side. These measurements were made on the road and near seismic ground-motion stations such as K-NET and KiK-net. The total number of measurement sites has reached about five thousand and nine hundred, as of February in 2019. In addition, the measurement was conducted for around 15 minutes per site at intervals of 1km using JU210/215 or JU410 which was an all-in-one microtremor measurement unit [Senna et al., 2008]. And sampling frequency was set at 200Hz.

About analysis of miniature and irregular array microtremor data, we evaluated one-dimensional S-wave velocity structure using shallow velocity structure exploration method based on microtremor measurements. The method has been proposed and advanced in recent researches [Cho et al., 2013]. The analysis was made using a microtremor analysis tool such as “BIDO” or “Microtremor Array Tools [Cho et al., 2016].”

3. Improvement of initial shallow velocity structure models based on results of array microtremor explorations
Last year, initial shallow velocity structures were modeled using the existing bore-hole data and surface geological data. In basis of results of miniature and irregular array microtremor exploration, 1-dimensional S-wave velocity structures in the initial models were modified at each microtremor measurement point. And then, they were interpolated spatially by means of Kriging method and three-dimensional shallow

©2019. Japan Geoscience Union. All Right Reserved.

velocity structures were modeled.

On the improved models in this study and the conventional models based on geomorphologic land classification [Wakamatsu et al., 2013], ground amplification index was compared in spatial distribution. From a general viewpoint, the improved models have wider areas with large amplification in lowlands and they tend to have large local variation in ground amplification. In addition, for the improved models, distribution of ground amplification rates was evaluated by each period in basis of 1-dimensional multiple reflection theory. Amplification rates seem to be larger in different areas by each period.

4. Summary and future challenge
In this study, initial shallow velocity structure models, which were constructed based on a lot of bore-hole and geological data, were enhanced for Tokai region using results of array microtremor explorations. Also, it can be suggested that it is important to evaluate ground motion characteristics using both of amplification and period characteristics. In the close future, improved subsurface velocity structure models will be validated using moderate seismic records at strong-motion stations.

Validation of seismic bedrock structure model in the Shimousa region, Chibe prefecture, Japan using seismic interferometry to strong motion

*Kosuke Chimoto[1], Hiroaki Yamanaka[1]

1. Tokyo Institute of Technology

Green’s function is estimated using autocorrelation of strong motions by seismic interferometry, and the depth to the seismic bedrock is estimated in sedimentary basins (Yoshimoto et al., 2009; Watanabe et al., 2011, Shiraishi et al., 2016). Oren and Nowack (2017) observed clear Reflected waves by applying spectral whitening to the autocorrelation of ambient noise. Chimoto and Yamanaka (2018) applied this method to the autocorrelation of strong motions and observed reflected wave from seismic bedrock by estimating the Green’s function in the sedimentary layers. We apply this method in the Shimousa region, Chiba prefecture, Japan to estimate autocorrelation using strong motions. Validation of 3D S-wave velocity structure model was attempted based on the spatial variation of reflected waves from seismic bedrock in the region.

Number of autocorrelations without the selection of strong motions enhance the clear reflected wave (Chimoto and Yamanaka, 2018). We used all the strong motions observed in the period of January 2008 to Jun 2018 observed at the strong motion stations of K-NET and KiK-net installed in the Shimousa region. After removal of offset of the strong motion, horizontal components are rotated to the transverse component. Spectral whitening is applied to the power spectrum and inverse Fourier transform provides autocorrelation function after the bandpass filtering. The range of bandpass filter is important to estimate the expected reflected waves from sedimentary layers (Chimoto and Yamanaka, 2018). We used the range of 0.5-2.0Hz to estimate the reflected wave from the seismic bedrock. Theoretical Green’s function for the validation of the model was calculated by Haskell method using 1D structure model extracted from the 3D J-SHIS deep structure model.

We observe the distinct reflected waves from the seismic bedrock in the autocorrelation functions estimated in the Shimousa region, Chiba prefecture. Two-way travel time of the reflected wave at KiK-net Narita station is 3 seconds and that is 3.5 seconds at K-NET Narita station. These values are almost consistent to those of the theoretical Green’s functions, while slight faster arrivals are observed. On the other hand, the stations located north and east to Narita exhibit several arrivals in the autocorrelations and the reflected wave from the seismic bedrock becomes weak. The travel time is faster than Narita. The reflected waves from the seismic bedrock at the stations located west to Narita appears later than 4 seconds, meaning the deeper bedrock than Narita. The southern part to Narita, central part of Chiba prefecture, shows the two-way times of later than 6 seconds, suggesting the deepest bedrock structure. This fact is consistent with the previous 3D models in the Kanto basin. We thus captured the spatial variation of the seismic bedrock from the estimation of autocorrelations of the strong motions in the Shimousa region, Chiba prefecture. The characteristics of spatial variation was similar to that of previously proposed 3D models. However, it is highly expected for the accurate modeling by tuning the slight difference between the autocorrelation function and the theoretical Green’s function.
We used the records observed at K-NET and KiK-net by National Research Institute for Earth Science and Disaster Resilience and deep structure model of Japan Seismic Hazard Information Station.

Microtremor survey for subsurface velocity structure of Saga plain

*Masayuki Yoshimi[1], Michiko Shigefuji[2], Tadashi Maruyama[1]

1. Geological Survey of Japan, AIST, 2. Kyushu University

Saga plain, located in northern Kyushu island, is quite flat lowland facing south to the Ariake Sea. An active fault zone is recognized at the northern boundary of the plain. If the fault zone activates, strong ground motion will hit whole the plain. To assess possible earthquake hazards, subsurface structure of the plain has to be revealed.

We conducted microtremor array measurements in the plain to investigate the S-wave velocity of the sediment layers and spatial variation of the bedrock depth. Four locations for the survey are chosen along the P-wave reflection survey line (Maruyama et al. 2017) and its extension toward south. Array aperture of the measurements at each location is set about 10 to 500 meters enabling to estimate the subsurface velocity structure down to about 1 km. Four velocity sensors (Tokyo sokushin, SE-321) are deployed at each array to compose equilateral array with a center point. Phase velocity of the Rayleigh wave are estimated using vertical component data of the microtremor by SAPC and V-method (Cho et al. 2004, Tada et al., 2007). The results will be shown.

Densely microtremor observation to estimation of subsurface structure in Hane and Kute area, Ohda City, Shimane Prefecture, Japan

*Tatsuya Noguchi[1], Yoshito Yamaguchi, Yuhei Morita, Isamu Nishimura[1], Shohei Yoshida[1], Takao Kagawa[1]

1. Department of Management of Social Systems and Civil Engineering, Civil Engineering Course Graduate School of Engineering, Tottori University

An earthquake (Mj6.1) occurred in vicinity Ohda City western Shimane Prefecture in Japan on April 9, 2018. Densely microtremor observations were carried out to estimate the characteristic of ground motion in the damage area, Hane and Kute area, Ohda City. A distribution of the predominant period of microtremor H/V spectra and S-wave velocity structures were obtained from observation data. As a result, it was found that maximum thickness of the weak soil subsurface layer is 40m and a short period component of predominant period about 0.2-0.4 seconds may have influenced structural damage.

Keywords: microtremor observation, characteristics of ground motion, subsurface structure, 2018 eastern Shimane prefecture earthquake

Densely microtremor observation to estimation of subsurface structure in Nishizono and Yura area, Hokuei Town, Tottori Prefecture, Japan

*Tatsuya Noguchi[1], Katsuya Tomeoku, Isamu Nishimura[1], Shohei Yoshida[1], Takao Kagawa[1]

1. Department of Management of Social Systems and Civil Engineering, Civil Engineering Course Graduate School of Engineering, Tottori University

Densely microtremor observations were carried out to estimate a characteristic of ground motion and subsurface structure in the damage area due to 2016 central Tottori Prefecture earthquake, Yura and Nishizono area, Hokuei Town, Tottori Prefecutre. Microtremor H/V spectra and a distribution of the predominant period and underground structure models were obtained, and grasped the characteristic of ground motion based on this result. As a result, it was found that a difference of the subsurface structure depth to about 20m and a short period component of predominant period less than 0.5 seconds may have influenced structural damage.

Seismic reflection survey in the Kathmandu Valley, Nepal.

*Kota Koshika[1], Yusuke Kawasaki[1], Om Pradhan[1], Masato Yamamoto[1], Dai Nobuoka[1], Yoshikazu Matsubara[1], Hisanori Matsuyama[1], Monika Jha[2], Chintan Timisina[2], Suresh Shrestha[2], Mukunda Bhattarai[2], Dinesh Nepali[2], Soma Nath Sapkota[2], Hiroe Miyake[3], Kazuki Koketsu[3]

1. OYO Corporation, 2. Department of Mines and Geology, 3. Earthquake Research Institute, University of Tokyo

On the April 25, 2015, earthquake of magnitude 7.8 Mw (USGS, 2015) struck in the 78 km north west of Kathmandu (Gorkha Earthquake) and major after shock of magnitude 7.3 Mw, with epicenter about 80 km north east of Kathmandu cases heavy damage in the Kathmandu Valley (KV). It was thought that the damage in the KV was particularly great, due to the underground structure of the KV.

We conducted gravity survey in the KV as part of the SATREPS projects in 2017. The shape of the gravity basement of the whole KV was estimated (Pradhan et al.,2018).

We conducted seismic reflection survey to clarify the detailed basement of the KV and the upper sedimentary structure in 2018. Survey lines were set up at Tribhuvan International Airport (TIA) where depth of gravity basement greatly changes and Nepal Agricultural Research Council (NARC) where deep gravity basement was estimated. Survey line length is about 4km (TIA) and 1km (NARC). Enviro Vibe (IVI, Inc.) was used as a seismic source.

The shape of the basement obtained by the seismic reflection survey and the shape of the gravity basement match well and the structure of the sedimentary layer in the basin was also revealed. These are the world's first results visually showing the underground structure in the KV and are expected to greatly contribute to future earthquake disaster prevention.

Broadband Microtremor Array Exploration at and around Tribhuvan International Airport, Kathmandu, Nepal

*Toshiaki Yokoi[1], Takumi Hayashida[1], Mukunda Bhattarai[2], Tara Pokharel[2], Suresh Shrestha[2], Chintan Timsina[2], Sunita Bhatarrai[2], Dinesh Nepali[2]

1. International Institute of Seismology and Earthquake Engineering, Building Research Institute, Japan, 2. Department of Mines and Geology, Ministry of Industry, Commerce and Supplies, Nepal

Strong ground motion of long duration and long predominant period around four seconds were observed during the 2015 Gorkha earthquake at the central part of the Kathmandu Valley (KTV), Nepal (Dixit et al. 2015, Bhattarai et al. 2015, Takai et al. 2016, Rajaure et al. 2017), a tectonic basin formed during the Himalayan orogeny due to the collision of the Indian plate to the Eurasian plate (e.g., Sakai et al. 2016). Aimed to reveal the cause of this phenomenon and to make possible the seismic hazard assessment considering on the structure of deep sedimentary layers, the research group to which the authors belong (Group3-SATREPS) has conducted the deep exploration by deploying microtremor arrays (Maximum inter station distance about 1400 m) at few sites using four sets of broadband seismographs (CMG40T, Guralp) for estimating the shear wave velocity structure of deep sediments from Dec. 2016 to Feb. 2018, together with shallow exploration using 2 Hz seismometers (L22D, Sercel) and 4.5 Hz geophones (GS11D, GeoSpace) (Yokoi et al. 2018, SSJ-Fall). In KTV as a whole, the gravity survey had been performed in 2017 by the OYO corp. team which belongs the same research group (Pradhan et al. 2018 (JpGU)) and the reflection survey has been conducted Nov. 2018 by OYO corp. also at the Tribhuvan International Airport (TIA) and at the National Agriculture Research Institute (NARI) located at around 2 km SW of TIA. The deep structure of KTV is gradually getting revealed (Koshika et al. 2019 (JpGU) submitted).
In this poster session, we will report the results of analysis of the microtremor array exploration at and around TIA and NAST, and a hard rock site (Chobar) that we have conducted Dec. 2018 following the above mentioned activities.
The attached figure shows the configuration of observation sites and a summary of the dispersion curves of Rayleigh waves. In the legend, *BDR* (red circles) shows the results given by Hayashida et al. (2018, SSJ-Fall) using tele-seismic surface waves, *CHB* (red “x” s): the phase velocities estimated on the outcropped bedrock of the Chobar hill. *SDB*: Singhadurbar, DMG: Department of Mines and Geology-Narayanhiti Royal Palace Museum, *TEKU*: Teku Gas well of DMG, *KIR*: Kirtipur Campus of the Tribhuvan Univ., *BLJ*: Department of Nepal Bureau of Standard and Metrology at Balaju, *GAU*: Gaucharan, *TIA*: Tribhuvan International Airport, *NAST*: National Academy of Science and Technology-National Agriculture Research Institute.

Distribution of average S-wave velocities by small-scale (5 to 15 meters) microtremor arrays in and around Hue City, Thua Thien-Hue province, Vietnam

*Ikuo Cho[1], Makoto OKUBO[2]

1. National Institute of Advanced Industrial Science and Technology, 2. Kochi University

We are promoting earthquake hazard assessment for safe operation of hydroelectric power generation and protection of world cultural heritage for Hue City, Thua Thien-Hue Province, Vietnam. This is a collaborative research with Dr. Nguyen Anh Duong at Vietnam Academy of Science and Technology (VAST). As a part of this research project, we conducted multiple small-scale microtremor array observations in that area and evaluated the distribution of shallow average S-wave velocities.

We began this microtremor research with providing a technical support to researchers at VAST. First, the authors conducted a microtremor array observation at four sites in and around the Hanoi City on 20th and 21st October, 2017, as a practical training of microtremor observation. On the premise of applying the SPAC method, we deployed linear-shaped arrays with a length of about 30 m using a three-component servo-velocimeter. We recorded microtremors for 1 to 2 hours at each site. Since the authors brought two seismometers (three-component servo-accelerometers) from Japan, we deployed two-point arrays along with their array at intervals of 5 to 30 m, and compared the analysis results with those from the VAST observation apparatuses.

On the next step, the VAST research team and the authors conducted microtremor array observations at seven sites in Hue City on 17-19th March, 2018. At each site we deployed triangle-shaped arrays with side lengths of 5 m and 15 m. We also deployed a linear array with a length of 12 m. Those arrays consisted of 4.5 Hz vertical geophones. In addition to this, we deployed two-point arrays with two seismometers brought from Japan. We set the observation durations from about 30 minutes to 1 hour at each site. There were existing subsurface data by refraction surveys at these sites, and therefore, we compared our analysis results with them. As a result, the analysis results of microtremors were consistent with those existing data.

Through the above preparatory period, the VAST research team conducted microtremor array observations at 126 sites in and around the Hue City (observation area of about 11km x 14 km) in a period from June to July 2018 (19 days in total). More specifically, they deployed triangular arrays with side lengths of 5 m and 15 m at 89 sites and a linear array with a length of 12 m at 37 sites. Vertical 4.5Hz geophones were used to consist seismic arrays. The observation duration was set to 30 minutes at each site.

We applied the SPAC method to the array data thus obtained and identified the Rayleigh-wave phase velocities. We read the phase velocities with the wavelengths of 13 m, 25 m and 40 m and interpreted them as average S-wave velocities to the depths of 10 m, 20 m, and 30 m, respectively. The spatial distribution of average S-wave velocities thus obtained is consistent with the geological map in and around the Hue City. In near future, we will improve the accuracy of soil evaluations by adding H/V spectral data at each site of array observation.

Microtremor Array Exploration in the Syiah Kuala University, Banda Aceh, Indonesia

*Makoto OKUBO[1]

1. Natural Science Cluster, Kochi University

We deployed microtremor array survey at Syiah Kuala University in Banda Aceh, Indonesia to clarify a seismic amplification by subsurface S-wave structure. Banda Aceh, located at northern end of Sumatra island, was seriously damaged by the tsunami caused by the 2004 Sumatra earthquake. At the tsunami evacuation, we first have to consider the safe route that does not corrupted, damaged and flooded. Therefore, we plan to understand the seismic amplification distribution as fundamental material. Our results will be available to make a future plan to reconstruction/renovate architectures.

We visited to Banda Aceh at January, 2019, and carried out microtremor exploration using with linear array and triangle array at 17 sites. We used are three 5 Hz geophones and one 1 kHz sampling GPS synchronised data logger for survey. In the case of triangle array, we always used 1.7 m side length. This side length is corresponding to 1.0 m array radius. In the other case, that is linear array, distances of each sensors (A, B, and C) are, A-B:1.7 m, B-C:2.7 m, and A-C:4.4 m. We Assumed these lengths are the array radius for each exploration, and applied SPAC method (*c.f.* Aki 1957). We used a tool, as known as BIDO2.0 (Cho, 2010) to analyze recorded waveforms and estimate dispersion curves.

By using obtained dispersion curves, we determined 3 averaged S wave velocities and roughly velocity structure. Roughly velocity structure was estimated by simple conversion method by using 1/2 wavelength law with linear array's dispersion curves. And three Averaged S-wave velocities AVS10, AVS20 and AVS30 were estimated from the Rayleigh wave phase velocities corresponding to the wave length of 13 m, 25 m and 40 m, respectively. By a preliminary analysis, we obtained result that a thicker low S-wave velocity layer exists along the river and the coastline. This result implies that plain part of Banda Aceh was developed on the old delta made by river and sea. This situation of subsurface structure will be strongly affect to the seismic amplification.

We will discuss in detail at the presentation.

Acknowledgements:
We thanks to Dr. Muksin Umar, Ms. Wiwik and Mr. Arif, they were attended and cooperated to our microtremor array survey in Syiah Kuala University. This study is supported by JSPS KAKENHI Grant Number 17H0457751.

Turkey-Japan Joint Project on Modeling of Geological Structures for Strong Ground Motion Simulations due to Crustal Earthquakes in Eskisehir Basin, Turkey, by Using Seismic Interferometry Method

*Mehmet Safa Arslan[1], Kosuke Chimoto[2], Asim Oguz Ozel[1], Hiroaki Yamanaka[2]

1. ISTANBUL UNIVERSITY-CERRAHPASA, 2. TOKYO INSTITUTE OF TECHNOLOGY

Understanding the seismic hazard of specific area, depends on the regional 2D/3D underground structure on wave propagation. In the frame of the bilateral project between Turkey and Japan, we aim at observing ground motion parameters, crustal activities, underground structures, and improvement of seismic hazard maps. The seismic interferometry method (SIM) is one of the tools to investigate the surface-wave propagation. The method goals to obtain green’ s function (GF) by using ambient noise data. Cross-correlations (CC) between the two pairs of stations’ continuous records, reveal GF and provide group and phase velocities of surface waves. We analyze one-year vertical component broadband data from 8 stations deployed and affiliated with ANANET (Eskisehir Anadolu University Local Seismic Network). Interstation distances between the designated stations are in the range of ~23-139 km. After getting the CC functions, group velocity dispersion curves will be obtained for selected correlation paths in particular to address the azimuthal dependence of the velocity field. Averaging the dispersion curves, in other saying analyzing the group velocities and waveforms typical of these observations, we attempt to estimate the S-wave velocity structure model inside the Eskisehir basin. This study is supported by the Joint Research Project under the Bilateral Program of the Japan Society for the Promotion of Science (JSPS) and The Scientific and Technological Research Council of Turkey (TUBITAK) under Grant TUBITAK 116Y524.

Nonlinear Ground Motion Response During the 2016 Meinong Taiwan Earthquake

*Kuo-Liang Wen[1], Chun-Te Chen[2]

1. National Central University, Department of Earth Sciences, 2. Academia Sinica, Institute of Earth Sciences

The Meinong Taiwan earthquake occurred on February 6, 2016, at 03:57 (UTC+8) with M_L 6.6. The strong ground motion induced the soil liquefaction in Sinshih and Annan districts. To investigate the nonlinear site response during Meinong mainshock, the degree of nonlinear site response (DNL) which summation of the horizontal to vertical spectral ratios (HVSR) differences between weak-motions and Meinong mainshock records from the Taiwan Strong Motion Instrumentation Program (TSMIP) network are calculated. We compare the DNL values with the ground motion parameters such as peak ground acceleration (PGA), peak ground velocity (PGV), and also the ratio between PGV and Vs30. The DNL shows a positive correlation with ground motion intensity, particular with PGV, and the surface site conditions also leading the DNL strength. We also applied a stochastic method for modeling the ground motion of the Meinong earthquake with site correction by the HVSR of weak and strong motions respectively. The percentage of PGA reduction calculated in this study can be an indicator of the spatial distribution of the degree of nonlinear soil effects of the 2016 Meinong Taiwan earthquake.

Earthquake damage of the 2017 Pohang earthquake in South Korea

*Mikyung Choi[1], Sun-Cheon Park[1], Dong-Hyo Sohn[1], Seolhan You[1], Jongsun Sun[1], Seongheum Cho[1], Duk-Kee Lee[1]

1. Korea Meteorological Administration

Pohang earthquake with a magnitude of ML 5.4 occurred on November 15, 2017. This earthquake caused more damage than the 2016 Gyeongju earthquake (ML 5.8). Modified Mercalli intensities were assigned from residential property damage report in the Pohang area. Major damage type was wall crack of building. Maximum intensity was MMI VIII. Result of damage analysis from damage report reveals that the main damage area was distributed within a radius of about 20 km distance from the epicenter. And sand and mud volcanoes were observed in many places.
Between 16 November and 31 December 2017, 10 temporary seismic stations were deployed to record aftershocks and site effect of the Pohang earthquake. Ground motion generated by an earthquake is controlled by several factors, such as source characteristics, propagation path, surface geology, topography. Using recordings of aftershocks, we analyzed the ground motion at two seismic stations near the epicenter and another two seismic stations located on sedimentary rock and bedrock. We compared amplitude and predominant frequencies of ground motion with damage analysis results. Mapping and characterization of the damage for this earthquake is an opportunity to provide useful information on the damage of future possible earthquake in South Korea.

Repeated measurements of the Self-Potential at Akita-Yakeyama, Iwate and Kurikoma volcanoes

*Shin'ya Sakanaka[1], Yasiaki Sawada[3], Kenta Kato[2], Inoue Yusuke[1], Kobayashi Takuya[1], Ryuichi Takei[1], YUYA TADA[2], Muhammad Faizul Nizam Bin Zainudin[2], Tomoya Moriwaki[2]

1. Graduate school of International Resource Sciences, Akita University, 2. Faculty of International Resource Sciences, Akita University, 3. Faculty of International Resource Sciences, Akita University (gradusted in 2018)

We will report the SP (Self-Potential) anomalies at Akita-Yakeyama, Iwate, and Kurikomayama volcanoes. They are active volcanoes along the boundary of Akita and Iwate prefectures and their volcanic activities are relatively high recently.

SP measurements and SP anomalies at those volcanoes were reported by some researchers. We are still carrying out the SP measurements there repeatedly so as to monitor the activities of the volcanoes.

We conducted the SP measurements along the mountain trail from Tamagawa hot spring to Goshougake hot spring at Akita-Yakeyama in 2007 and 2017. At Mt. Iwate the SP measurements were conducted along the Yakebashiri trail up to the summit in 1999, 2004 and 2017. At northern part of Mt. Kurikoma we walked from the Nagorigahara moor, went through the summit and returned back anti-clockwised along the trail with SP electrodes in 2018. The result of the previous SP measurement in Kurikoma volcano can be found in the part of the Aizawa (2010) and we can investigate the time-lapse SP anomalies on these volcanoes.

We adopted the leap-frog measurement method with a 50 m cable, copper-copper sulfate electrodes, and a digital multi-meter (voltmeter). The latitude and longitude data were recorded by the handy GPS receiver (like as Garmin product). Although in the measurements of the leap-frog method might be easily piled up each error of the measured value at a site, a short cable can be easier handled than a longer cable over the length of a couple of kilometers using by the total-potential measurement method. The long and thin cable is sometimes cut apart by animals or human beings and unfortunately we have to return back to the cut point all the way to fix it.

On the compiling the SP data in different years we draw the SP curves along the cumulated distance. Since the cumulated distances of the SP measurements are sometimes up to several kilometers, the lengths of the cumulated distance are sometimes different by more than 100 m in the data of the respective years. We measure the SP on the same mountain trail but the end of the cable at each measurement is not always at the same point and the SP paths are slightly different in year to year on the measurements. This is the reason why the difference of the cumulated distance in different years. The problem might be happened also with the measurements of the total-potential method. To solve it, we set a model path with the function of the cumulated distance on the trail map in advance and the measured site were relocated (projected) onto the model path referred by GPS locations. After that we successfully and comfortably compare the SP data on the same trails.

At Akita-Yakeyama and Iwate volcanoes, we cannot find out the outstanding time variations of SP anomalies but the acquired SP data can be use the monitor the active volcanoes.

Evaluation of surface conductivity of unsaturated Berea sandstone and porous glasses

*Ryosuke Umezawa[1], Makoto Katsura[1], Satoru Nakashima[1]

1. Department of Earth and Space Science, Graduate School of Science, Osaka University

Electrical conduction of rocks composed of insulating minerals are known to depend on degree of water saturation, distribution of pore water, pore size and pore structure. Electrical conduction in rocks is considered to be composed of conductions in bulk water and on mineral surfaces. The electrical double layer (EDL), a layer with adsorbed ions on mineral surfaces (Stern layer) and gradients of ion concentrations (diffuse layer), has thickness characteristic length of the diffuse layer (Debye length). Surface conduction becomes important, when bulk water in rock pore decreases, such as in unsaturated rocks and less porous rocks with thin grain boundary water. Since quantification of dissolved ions in rocks with thin grain boundaries is difficult, quantitative description of surface conduction remains poor.
In this study, in order to examine surface conduction with known dissolved ion concentrations, electrical conductivity of a sandstone and porous glasses were measured for varying water saturation and ion concentrations. Berea sandstone (predominant pore diameter: about 40 μm) and Shirasu porous glass (SPG) membranes (SPG technology; uniform pore sizes: 1.0, 0.5, and 0.2 μm) were saturated with aqueous solutions having varying NaCl concentrations (0, 0.001, 0.01, 0.1 mol L^{-1}). Electrical conductivity values were measured for frequencies from 0.1 Hz to 1 MHz while drying.
Effects of surface conduction of Berea sandstone and SPG membranes were compared by their specific surface conductivity values, which were evaluated by conduction models using surface complexation model, and were discussed in relation to water film thickness and Debye length.

Keywords: Water saturation, electrical conductivity, ion concentration, Debye length, surface conductivity

Observational and theoretical waveforms of electromagnetic signals generated by the motional induction effect before the arrival of seismic waves

*Ken'ichi Yamazaki[1]

1. Disaster Prevention Research Institute, Kyoto University

Earthquake ruptures and consequent ground motions generates variations in the electromagnetic (EM) field by means of variety of conversion processes in the Earth’s crust. The generated EM signals are referred to as seismo-EM signals. Some of the earlier works have reported seismo-EM signals that are observed prior to the arrival of seismic waves [e.g. Iyemori et al. 1996 (JGG); Honkura et al. 2002 (EPS); Okubo et al. 2011 (EPSL)], which are sometimes referred to as “early seismo-EM signals”. Theoretical calculations have been conducted to identify the generation mechanisms of the observed seismo-EM signals assuming some of candidate conversion mechanisms including the electrokinetic effect [Haartsen and Pride 1997 (JGR)], the motional induction effect [Gao et al. 2014 (JGR)], the piezomagnetic effect [Yamazaki 2016 (GJI)] and the piezoelectric effect [Ogawa and Utada 2000a (PEPI), 2000b (EPS)]. However, definitive answers have not been obtained, particularly for the case of early seismo-EM signals.

The objective of this work is to compare theoretical time-series of seismo-EM signals arising from the motional induction effect with observational one by means of simple numerical models. In an earlier work, Gao et al. [2014] consider the same problem by assuming uniform full-space model with analytical solutions. Their results imply that theoretical early seismo-EM signals in this situation are far smaller than observed ones. In the present work, I consider a model composed from conductive half-space that represents the Earth’s crust and another half-space that represents the air as an insulator. In frequency domain, governing equations in this situation are reduced to ordinary differential equations by applying the Hankel transform, which can be solved analytically. Seismo-EM Solutions of the original equations are then obtained after the inverse Hankel transform. Time-series of seismo-EM signals are then obtained after the inverse Fourier transform.

The comparisons between observed and theoretical seismo-EM variations are performed for two cases: one is the phenomena observed at the time of 1999 Izmit earthquake, Turkey [Honkura et al. 2002], and the other is that observed at the time of 2008 Iwate-Miyagi earthquake, Japan [Okubo et al. 2011]. Early seismo-EM signals observed for these two earthquakes have different characters. For the case of Izmit earthquake, signals appeared only after seismic waves reach close to the observational site. In contrast, for the case of Iwate-Miyagi earthquake, EM signals emerges just after the onset of seismic ruptures. Numerical calculations assuming the motional induction effect reasonably account the feature of signals for the Izmit earthquake, but do not account that for the Iwate-Miyagi earthquake.

Effect of reference data on geomagnetic transfer functions

*Shinya Sato[1], Tada-nori Goto[1]

1. Kyoto Univesity, Graduate School of Engineering

It is well-known that inter-station transfer functions (TFs), which are derived generally using two sites (as following Schmucker 1984; Neska 2006), are effected by source field. Also, we sometimes use three sites for deriving TFs in order to reduce the noises mixed in geomagnetic data. These 2 or 3 sites-based TFs have been used for evaluating the spatial characteristics of source field. However, the 3 sites-based TFs (i.e., using site 1, site 2 and reference site) do not always reflect the source field’s condition between site 1 and site 2, and can possibly be effected by the source field’ characteristics at reference site. Also, the evaluation of source field’s condition at time-frequency domain (i.e., at the stage of spectra or spectrograms) will be more accurate. Therefore, for the evaluation we used Multi-Channel Nonnegative Matrix Factorization (MC-NMF, suggested by Sato and Goto 2018), which can extract components included in several geomagnetic spectrograms. Moreover, we derived the condition of geomagnetic events’ spatial-characteristics, which triggers the effect of reference data on 3 sites-based TFs. In order to verify that the TFs are effected by the reference site, we derived the temporal changes in 3 sites-based TFs replacing the reference sites. As a result, we founded that the TFs changed not only temporally but dependent on the reference site and the interpretation of source field’s spatial characteristics was different dependent on the reference site. For exposing the cause, we evaluated the spatial-characteristics of geomagnetic events using MC-NMF. The evaluated spatial-characteristics of geomagnetic events were corresponding with the condition triggering the effect of reference data on TFs as mentioned above. We succeeded to expose the cause of TFs’ variation triggered by reference data evaluating the spatial-characteristics of geomagnetic events at time-frequency domain. Using TFs together with MC-NMF, the interpretation of source-field’s spatial characteristics will be with high accuracy.

Reliability estimation of magnetotelluric inversion result based on the Principle Component Analysis and Markov Chain Monte-Carlo method

Hisatoshi Koji[1], *Tada-nori Goto[1]

1. Graduate School of Engineering, Kyoto University

Magnetotelluric (MT) method is used for detection of electrical conductive materials such as fluid, clay, partial melt and so on. Subsurface resistivity structure is generally estimated by an inverse algorism, based on the least-square scheme using observed apparent resistivity and phase. The reliability of the optimal model in the inversion procedure should be discussed together with seeking the “better” model having the lower data misfit than the optimal model. However, the sophisticated method is not well developed for the magnetotelluric survey, except for the simple test based on a number of forward modeling, constrained inversions and so on, or simple visualization of sensitivity of model parameters. In this study, for a quantitative visualization of reliability of optimal model parameters, we propose a new way of the numerical test of the model based on the Markov Chain Monte-Carlo (MCMC) methods. Since the MCMC cannot solve a number of unknowns in model parameters, we adopted the principle component analysis (PCA) to reduce unknowns in the model obtained by MT inversion code. First, for testing the PCA ability in subsurface image analysis, various two-dimensional (2-D) resistivity models are decomposed by PCA. As a result, we succeeded to extract the “major features” of 2-D resistivity model, especially by using first to third principle components. Then, we tested the MCMC algorithm with changing parameters of “major features” of 2-D model, such as its resistivity, width, thickness, horizontal and vertical locations. In a case of a simple two-prism model, we confirmed that the reliability of low and high resistive anomalies are shown in the probability density functions obtained by MCMC. We also found that some parameters (e.g., thickness and resistivity of an anomalous body) indicate a tread-off relationship as mentioned in the previous studies, and also found the reliable range of parameters even under the trade-off. We then applied this technique to the magnetotelluric data obtained at a field experiment. In consequence, anomalies in the optimal model are detected properly by PCA, and the reliable range of model parameters based on the MCMC method are similar to those inferred by the conventional forward calculations. We conclude that our proposed method can be widely applied to magnetotelluric exploration, even to the three-dimensional inversion.

Probing one-dimensional electrical anisotropy in the oceanic upper mantle from seafloor magnetotelluric array data

*Tetsuo Matsuno[1], Kiyoshi Baba[2], Hisashi Utada[2]

1. Kobe Ocean Bottom Exploration Center, Kobe University, 2. Earthquake Research Institute, The University of Tokyo

Electrical anisotropy in the oceanic upper mantle provides important clues on mantle structure and dynamics if it is confirmed from seafloor magnetotelluric (MT) data. Here we try to probe electrical (azimuthal) anisotropy in the oceanic upper mantle by analyzing recent seafloor MT array data from the northwestern Pacific at 130-145 Ma seafloor. We propose a method, in which an isotropic 1-D model is first obtained from seafloor MT data through iterative correction for topographic distortion, then anisotropic properties are inferred as deviations from the isotropic 1-D model. We investigate the performance of this method through synthetic forward modeling and inversion, using plausible anisotropic 1-D models and actual 3-D bathymetry and topography for the target area. Synthetic tests reveal that the method can detect the electrical anisotropy in the conductive upper mantle or the electrical asthenosphere. We also compare the performance by using two rotational invariant impedances and two topographic correction equations. An application of the method to two seafloor MT array data in the northwestern Pacific reveal anisotropic inversion models, showing the possible presence of electrical anisotropy in two layers in a conductive mantle of <100 Ω-m at 50-250 km depth. Anisotropic signals are larger in shallower layers for both array areas, while anisotropic azimuths (or most conductive directions) and depths to the two layers are different for two array areas even at similar seafloor ages with the horizontal distance of ~1,000 km. Most conductive directions mostly align rather to directions of past seafloor spreading or their perpendicular directions, than a direction of current plate motion and are inconsistent with fastest directions of seismic azimuthal anisotropy. The electrical anisotropic signals may dominantly result from mantle dynamics in array-scale (~500 km or over), like small-scale convection and the formation of seafloor in the past, over in Pacific basin scale.

The Analysis of magnetotelluric sounding data on Kikai submarine caldera.

*Toki Hirose[1], Tetsuo Matsuno[2,1], Nobukazu Seama[1,2], Yuki Okizono[4], Hiroshi Ichihara[3], Hiroko Sugioka[1,2], Yoshiyuki Tatsumi[2,1]

1. Department of Planetology, Graduate School of Science, Kobe University, 2. Kobe ocean Bottom Exploration Center, Kobe University, 3. Graduate school of environmental studies, Nagoya University, 4. Department of Planetology, Faculty of Science, Kobe University

Kikai submarine caldera locates on the south waters of Kagoshima. The caldera was formed after super eruption on 7.3ka, and have formed huge lava dome since the eruption(Tatsumi et al., 2018). A main aim of this study is to determine the electrical resistivity structure beneath the Kikai caldera, and estimate the distriution of melt, magma chamber and thermal anomaly. As one step to the main aim, this study presents the results of calculations of apparent resistivity and phase, and estimating 1D inversion resistivity structure models after their correction for topographic distortion.
Measurements of the time variations of electric and magnetic fields at the seafloor were conducted at 10 sites with a sample rate of 8 Hz for about 20 days. At the four of those after the surveys, measurements were switched to the sample period of 60 s for about half year. Observed data with sample rate of 8 Hz were processed as followings: (1) downsampled to 1 Hz, (2) corrected by comparing the instrument clocks with GPS time, (3) detrended for longer-periods than 1 day, and (4) corrected instrument inclines. The instrument coordinates were transformed to geographic coordinate system. After these processing, we extracted the data without noises which attribute to the shaking of instrument and calculated magnetotelluric(MT) inpedances, apparent resistivity, and phase using the BIRRP method(Chave and Thomson, 2004). Kanoya magnetic observatory was used as the magnetic remote reference.
Estimated apparent resistivities were characterized with respect to periods and elements, whose characteristics are commonly found at all the sites. With respect to periods, off-diagonal apparent resistivity ranges 1Ωm to 10Ωm at the periods of 21s, and increases to 10Ωm to 100Ωm at a longer periods of 1024s. As for elements, diagonal elements are smaller than non-diagonal elements by a degree of magnitude. Estimated phases were characterized by xy and yx elements that are within the range of the first quadrant and the third quadrant respectively.
Effect of topography on MT impedances are modeled with with FS3D(Baba and Seama, 2002). Using The results of FS3D and the method of removing of topographic distortion(Nolasco et al., 1998), MT impedance are corrected for bathymetry. Using the corrected MT impedance, the 1D electrical resistivity structure models at the observation sites are estimated by OCCAM1D inversion program(Constable et al., 1987). The 1-D structure models are compared to 3-D electrical resistivity structure model(Matsuno et al., presented at this meeting) .

Role of Fluids in the earthquake generation: The Nagamachi-Rifu reverse fault, NE Honshu, Japan

*Sabri Bulent Tank[1], Yasuo Ogawa[2]

1. Bogazici University, 2. Tokyo Institute of Technology

The Japanese island arc was drastically influenced by the occurence of the 2011 Tohoku-Oki earthquake (M9) which also effected the volcanic activity and modified the local seismicity both of which are proven to be related to crustal fluid distribution. Therefore, for understanding the dynamic behavior of the region and for making further comparisons, developing an electrical conductivity model that enables to image the fluid’ s presence and capacity by means of analyses based on high-quality magnetotellurics data collected prior to the Tohoku-Oki earthquake at 61 sounding locations near the Nagamachi-Rifu Fault, Northeast Honshu, Japan, became an important task. Magnetotelluric data collected along three profiles that orthogonally cross the almost NE-SW geo-electric strike were used to image the epicentral region of this active reverse fault and its vicinity. State-of-the-art three-dimensional data-space inversion schemes were applied on the wide-band magnetotellurics data to map the fluid-rich and/or -depleted zones. Inversions included 0.3 Ohmm cells with realistic bathymetry on both sides of the initial model representing the Japan Sea in the west and Pacific Ocean in the east to realize the ocean effect. Resulting models were compared with prior and post seismicity of the main event.

Audio-frequency Magnetotelluric Survey of the Tsuyama-hoppou Fault, Yamasaki Fault Zone, southwest Japan.

*Satoru Yamaguchi[1], Daisuke Takakuwa[2], Akira Mimura[1], Kazuki Fkue[1], Shigehiro Katoh[3], Hideki Murakami[4], Shinichi Takakura[5]

1. Department of Geosciences, Graduate School of Science, Osaka City University, 2. Faculty of Science, Osaka City University, 3. The Museum of Nature and Human Activities, 4. Science and Technology Unit, Research and Education Faculty, Kochi University, 5. Geological Survey of Japan, Institute of Advanced Industrial Science and Technology

The Yamasaki fault zone (YFZ) is a ~80 km long, typical left-lateral strike-slip fault zone extending WNW from eastern part Okayama prefecture to southeastern part of Hyogo prefecture. The YFZ consists of the Nagisen fault zone, the main part of the YFZ, and the Kusadani Fault. The Nagisen fault zone show different features in fault activity (e.g. general strike, mean slip rate, the latest event) and seismic activity. Fewer earthquakes are occurred around the Nagisen fault zone compared with around the main part of the YFZ, and the Kusadani Fault.
Earthquake Research Committee (2013) reported that the Nagisen fault zone consists of the Nagisen Fault and Tsuyama-hoppou Fault (abbreviated as TYN Fault here after) and Okada *et al*. (2016) further divided the Nagisen Fault into the Koegatawa Fault, Nagiike Fault, and Nagisen Fault (we referred to them as Nagisen Fault Group here after) and reported fault displacement is recognized along the Nagisen Fault Group. While the TYN Fault is classified into the fault of Certainty II and Degree of activity C, and is annotated as “no fault activity after Middle Pleistocene is recognized” (The Research Group for Active Faults of Japan, 1991). That is, the TYN Fault is still an unknown fault and further survey is required.
Fukue *et al*. (2018) made a magnetotelluric (MT) survey using an audio-frequency MT (AMT) method, which is suitable for revealing shallow part (0 - 2 km in depth) with high spatial resolution, along the line across the Nagiike and Nagisen Faults, then established the two-dimensional resistivity model (NGS model). They pointed out that the Nagiike Fault is recognized as an clear resistivity boundary but that the Nagisen Fault is not recognized in the model.
Aiming to reveal subsurface structure of the unknow TYN Fault, we made an AMT survey along the line of ~4 km long across the TYN Fault and determined the two-dimensional resistivity model along the line. In this paper, we present outline of observation, procedures of data & model analysis, and the resistivity model, then discuss the subsurface structure of the TYN Fault comparing the NGS model.

In December 2018, we have conducted broad-band magnetotelluric (MT) observation around Hinagu fault and Uto Peninsula, which are close to the focal regions of the 2016 M_{JMA} 7.3 Kumamoto earthquakes. Since the resistivity structure of these regions are not well imaged by the previous 3-D inversion by using the 80 MT sites (Aizawa et al., 2017, Sgepss fall meeting), we acquired the new data by using the Metronix ADU-07 system and the telluric loggers (NT System Design ELOG1K). We will present new 3-D resistivity structure and argue its relationship to the hypocenters that are relocated by using the double difference method and 3-D seismic velocity structure (Shito et al., 2017, GRL).

Acknowledgment

We are greatly indebted to the land owners for their permission for field campaigns. The geomagnetic data used for the remote-reference processing were provided by the Kakioka Geomagnetic Observatory of JMA. This work is partly supported by MEXT KAKENHI Grant Number JP16H06298, the Ministry of Education, Culture, Sports, Science and Technology of Japan under its Earthquake and Volcano Hazards Observation and Research Program, and Earthquake Research Institute, The University of Tokyo under Joint Usage Program.

San'in Kaigan Geopark Museum of the Earth and Sea

In order to contribute to a reduction in damage caused by earthquakes and volcanic eruptions, heterogeneities of crustal and upper mantle structure should be clarified based on fundamental investigations of electrical resistivity structure in Chugoku and Shikoku regions, southwestern Japan arc.
Our research group has shown that there is a clear relationship between resistivity and seismicity in the San'in and Shikoku regions. In the eastern part of San'in region, it was found that a conductive area exists in the deep crust part under the seismic region, which is a resistive area, along with the seismic activity area stretching nearly in the east and west direction. Assuming that inland earthquakes occur because of local stress concentration caused by heterogeneity beneath a seismic activity band(Iio, 2009), it is necessary to improve spatial data and to clarify the heterogeneity in this area hereafter.
On the other hand, in the Shikoku district, it was suggested that the distinctive low resistivity region exists in the upper crust mainly from the survey results in the outer belt, and that there is a clear relation between the low resistivity and low seismicity in the central and the western area. In order to understand the earthquake phenomenon, it is important to clarify the generation environment and the principle as well as the activity style of the slow earthquake (Obara(2017)).
In this background, a Magnitude (M6.6) Earthquake in the Central Tottori Prefecture on October 21, 2016 occurred. In order to elucidate the heterogeneous structure of the lower crust beneath the seisimic region, we set up several survey lines across the central focal region of the Chubu region to carry out wideband MT observation at 12 sites in the observations gap area around this region.
By integrating the existing MT data, we tried model analysis using the program code of Ogawa and Uchida (1996) assuming that this region had a two-dimensional structure of EW strike direction harmonious with the seismic active band. According to the 2D model, we confirmed the southern limit of the low resistivity part existing in the deep crust of the focal region.
In the Chugoku and Shikoku district, we aimed to determine the 3D resistivity structure as a whole, and as in the 2017 research, 1D Occam inversion analysis based on determinant impedance was performed and integrated with existing MT data to estimate the preliminary spatial resistivity structure distribution. As a result, in San'in region, it is generally harmonious with the former studies, the low resistivity region in the deep crust continues to exist in the east-west direction with a certain scale.
In the Shikoku district, the resistivity in the mid crust shows the existence of a relative high/low resistivity boundary in the vicinity of the MTL is prominent, consistent with the existing research. Although there is a observation gap on the Seto Inland Sea side, continuity to the south of the low resistivity region of the San'in region is suggested with respect to the northern extension of the high resistivity crust. Moreover, when we look at the correspondence with the epicentral distribution of the crustal earthquake at this depth, there is clear correspondence with the high resistivity region in the north side of inner zone around

the Median Tectonic Line. This relevance is common knowledge with that in the San'in region.

Fluid distribution beneath central and southern Kyushu imaged by 3-D electrical resistivity model

*Maki Hata[1], Hiroshi Munekane[2], Hisashi Utada[1], Tsuneomi Kagiyama[3]

1. Earthquake Research Institute, the University of Tokyo , 2. Geospatial Information Aurhotiry of Japan, 3. Aso Geopark Promotion Council

The island of Kyushu is characterized by a high concentration of active Quaternary volcanoes along a volcanic front of N30˚E–S30˚W associated with the subduction of the Philippine Sea Plate. Some of the active volcanoes exist in southern Kyushu (the southern volcanic region), whereas no volcano exists in central Kyushu (the non-volcanic region). Most of volcanoes in the southern volcanic region exist in the Kagoshima Graben, whose formation was created with ejecting huge pyroclastic flows by the Quaternary volcanism. The Kirishima volcano group appears in Kakuto-Kobayashi caldera on the northern edge of the graben. Shinmoe-dake of the Kirishima volcano group experienced a magmatic eruption of the VEI 3 in 2011 and ash emissions in March 2018. Moreover, Iwo-yama of the Kirishima volcano group experienced hot material ejections in April 2018. Besides, Sakurajima volcano in the southern part of the graben has experienced 153–1,355 small eruptions per year for the last 10 years (the Japanese Meteorological Agency).
The Philippine Sea Plate, whose subduction involves the formation of the volcanic island of Kyushu, in and around Kyushu is classified into three portions: a younger portion, an older portion, and the other part of the Kyushu–Palau Ridge between the two portions. A non-volcanic region distributes in central Kyushu above a junction where the three portions of the subducting Philippine Sea Plate contact with each other. Owing to the subduction of the Philippine Sea Plate, moment magnitude 7-class thrust earthquakes have repeatedly occurred in the Hyuga-nada, lying offshore of the southeast Kyushu. In addition, recent studies using continuous global-navigation-satellite-system data have revealed that long-term slow slip events and short-term slow slip events occur in the Hyuga-nada. Besides, most of the earthquakes in the land area occur along three tectonic lines: Oita-Kumamoto tectonic line, Usuki-Yatsushiro tectonic line and Butsuzo tectonic line.
Fluid distribution in the mantle wedge is an essential factor for the seismic activity and magmatism leading to volcanic activity. Electromagnetic sounding data have high sensitivity to a few percent of interconnected fluids (aqueous fluid and melt). In this study, we generated a three-dimensional (3-D) electrical resistivity model by inverting magnetotelluric data, which covers the active southern volcanic region and the non-volcanic region, to examine the fluid distribution in the mantle wedge beneath Kyushu. We find three important conductive features in the 3-D model. A magma system and a fluid system imaged as two vertical conductors relating to slab-derived fluid, which exist along the volcanic front beneath the southern volcanic region and the non-volcanic region, respectively. The other conductor, relating to the presence of slab-derived fluid and serpentinite in the mantle wedge, appears at a blank area of the slow slip events.

Effects of absolute humidity on contact resistance between dry rock sample surface and electrodes

*Takeshi Suzuki[1], Ryokei Yoshimura[2], Ken'ichi Yamazaki[2], Naoto Oshiman[2]

1. Graduate School of Science, Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University

Resistivity measurements of rock under various conditions are essential for accurately interpreting geoelectromagnetic survey results. However, the contact resistance between the rock sample and measuring electrodes is a problem in measuring the resistivity of a rock sample. Because the measurement of high contact resistance on the dry rock surface is particularly difficult, its characteristics have not been well studied.
In order to investigate the characteristics of contact resistance, we have developed a measurement method of high contact resistance. By using the method, we measured high contact resistance between the dry granite surface and the electrode made of conductive epoxy. Considering the interaction between atmospheric moisture and rock samples, the contact resistance was repeatedly measured under different humidity conditions.
We confirmed the contact resistance decreased with increasing absolute humidity. A clear relationship exists between contact resistance and absolute humidity, and the relationship was approximated by an exponential function. This result suggests that increasing the contact area between the electrode and the rock surface with rising humidity. Moisture in the atmosphere may have caused improvement of contact condition by filling the microscopic gap in the contact surface.

Japanese geomagnetic field variation model based on the IGRF (2): modeling on the oblique Mercator projection

*Tsutomu Ogawa[1]

1. Earthquake Research Institute, the University of Tokyo

For geomagnetic field variation observations around tectonic areas to detect the variations related to tectonic activities in Japan, geomagnetic field model or geomagnetic field variation model around Japan with high accuracy is indispensable as a reference field. The geomagnetic field variation model around Japan proposed by Abe and Miyahara (2015) using the principal component analysis of geomagnetic data is a statistical model but not a physical model of the field variation, for the vector field model is not in general divergence-free. The model also lacked the error estimation for arbitrary positions. The present study evaluates the new geomagnetic field variation model around Japan which corrects the following two points in the model by Ogawa (2018, JpGU) which attempted to overcome the difficulties in the previous work: 1) the geomagnetic field variation is expressed in the Cartesian coordinate system on the map using the oblique Mercator projection of the Japanese island arc along NE-SW direction with a great ellipse centered and oriented along the direction, instead of the Mercator projection, and 2) annual variations in the model residuals of data which correlate with sensor temperature variations at the geoelectromagnetic continuous measurement stations of GIAJ are removed.

The new geomagnetic field variation model is expressed with the magnetic scalar potential by a cubic polynomial with respect to the coordinates in the coordinate system with its origin on the ground in the SE area of Ishikawa prefecture, expressing the difference of the 1-day geomagnetic data at 5 observatories of JMA and GIAJ and 10 stations of GIAJ from the IGRF, between 2005 and 2014. By obtaining the time series of expansion coefficients using the robust least square technique, the model shows the following features: 1) the mean of the model residuals amounts to 1.28nT, 2) by the leave-one-out cross-validation, the mean of the prediction error amounts to 1.94nT, 3) the mean of the prediction error at all the observation points obtained by the propagation of the jackknife standard error of expansion coefficients amounts to 1.16nT, as large as the mean of the model residuals, and 4) the mean of the prediction errors at Chichijima station of JMA, data of which are unused for the model, because of the large distance of the station from the principal part of the Japanese island arc, amounts to 5.06nT.

The mean prediction error along the principal part of the Japanese island arc estimated using the propagation of the jackknife standard errors of estimated expansion coefficients amounts at most to about 2nT for the horizontal two components and about 3nT for the vertical component, respectively. The present geomagnetic field variation model around Japan has the accuracy of a few nT for the principal part of the Japanese island arc.

Examination of criteria to remove the influence of the Sq-field variations from electromagnetic field spectra for a better estimation of regional electromagnetic responses

*RUIBAI LI[1], Hisayoshi Shimizu[1], Kiyoshi Baba[1], Hisashi Utada[1]

1. Earthquake Research Institute, the University of Tokyo

Electromagnetic (EM) responses such as magnetotelluric (MT) impedance and geomagnetic depth sounding (GDS) response (or tipper) in the period range between several minutes to one day are used to study the electrical conductivity in the upper mantle. Spatially uniform and quasi-random magnetic field variations due to geomagnetic disturbances are considered as the source field in regional EM induction studies using the EM responses. However, the magnetic field variations in the period range from to seconds (mixed excitation band, or ME band) contain those with different spatial structure such as the solar quiet (Sq) daily variations and those induced by the ocean tide. Careful treatment of EM field data is necessary to estimate responses in the ME band that reflect actual conductivity structure. For example, Baba et al. (2010) estimated the EM responses in the period range from to seconds using a method based on Fourier transform after removing line spectra of EM field variations at periods of Sq field variations that include the higher harmonics and constituents of ocean tides. However, it was shown that the estimated responses in the ME band still included the influence of Sq field variations (Shimizu et al., 2011).

In this study we try to estimate EM responses that are less influenced by the Sq field variations. We employed line spectra of EM field obtained by using Sompi method, so called wave element (or namiso) (e.g., Kumazawa et al.,1990, Asakawa eta al.,1988), to estimate the EM responses in order to avoid the influence of the Sq field variations that could be contained in continuous spectra. Also, three conditions are applied to select appropriate wave elements from observed ones for EM response estimations. First is to select wave elements of which eastward component have common phase or that close to each other at two stations. This can avoid wave elements influenced by the Sq field variations since their westward propagation causes systematic phase difference of the magnetic field for supposed longitude difference and apparent period, which is determined by the longitudinal wave number of the variation. Second is to select magnetic field spectra that are linearly polarized in horizontal-vertical plane, because that influenced by the Sq field variations are expected to be more elliptically polarized in the plane than those suitable for regional EM response estimation. Ellipticity of the polarization ellipse is used to apply the condition. Third is to select those which have small ratio of the vertical to the horizontal magnetic field components, because the Sq field variations contain significant vertical magnetic field component that can cause larger amplitude of tipper than those from plane wave. It was confirmed that estimated phase difference, ellipticity, and vertical to horizontal field ratio showed a signature of Sq field variations in the ME band but not at a period shorter than seconds.

In this presentation, we are going to show the characteristics of the observed phase difference, ellipticity, and vertical to horizontal field ratio with respect to the period. Criteria to apply the conditions are assumed based on theoretical estimate of the magnetic field due to Sq principle mode and the induced field in assumed one dimensional Earth. The EM responses obtained by applying each condition are shown and the improvement or influence in the obtained responses, as a result, are discussed quantitatively.

Study on long-term variation of geoelectric field observation

*Ren Ozeki[1], Ikuko Fujii[1]

1. Japan Meteorological Agency

Kakioka Magnetic Observatory, Japan Meteorological Agency, has observed the geomagnetic and geoelectric fields for several decades at Kakioka, Kanoya and Memambetsu. Vitage differences between two electrodes are observed in the geoelectric field observation. The baseline length is about 200-300m and the electrodes are installed at 3m deep. The data of the geoelectric field are used worldwide as a unique data set to investigate induced electric fields for last several decades.It is slightly troublesome for us to use the geoelectric field data set by Kakioka Magnetic Observatory because the geoelectric fields at three sites shows long-term variations and especially the north-south component of the geoelectric field at Kakioka clearly changes.Although some studies (e.g., Morinaga and Toya, 2015; Okawa et al., 1995) reported that this long-term variation is related to rain, details of how this long-term variation occurs are still unknown. This study aims to reveal the cause of the long-term variation.
Based on Morinaga and Toya (2015) and Fujii et al.(2007), we focus on geological structures around the electrode at the south end of the north-south line at Kakioka. We infer the geological structure from the distribution of the electrical resistivity.
The electrical prospecting was applied to an area of 20m x 20m with the south electrode as the center. Observations were conducted in March, May and October giving 7 observation lines around the south electrode, 2 lines around the east electrode, and 1 line around a boring hole (fig.1). Apparent resistivity was estimated from the observed currents and voltage differences.
We assume that the subsurface structure is one-dimensional and three layers are stratified. An optimal model of the resistivity distribution was obtained by inversion. All lines show a high resistivity layer at the surface followed by a low resistivity layer and then a high resistivity layer at the bottom. The thickness of the first layer is increased eastward from the south electrode.
The optimal model was compared with a boring profile obtained near the investigated area. We interpret that the resistive surface layer is permeable top soil and the second conductive layer is impermeable clay(Figure 2).We suspect that rain water flows on the top of clay to the east and the south electrode suffers from larger amount of water than the other electrodes.

Deep electrical conductivity structure of Eastern Marmara, Turkey by long period magnetotellurics

*Sabri Bulent Tank[1], Naoto Oshiman[2], Mustafa Karas[1], Ryokei Yoshimura[2], Yasuo Ogawa[3]

1. Bogazici University, 2. Kyoto University, 3. Tokyo Institute of Technology

The electrical resistivity structure of a 100 km x 100 km region at northwestern Anatolia was examined by using long period magnetotelluric data with the aim to image the geo-electrical features at the lower crust and upper mantle. The electromagnetic impedance tensor elements were obtained for eighteen sounding locations within a period range of 20-13000 seconds. The soundings were distributed over the epicentral region of the 1999 Izmit earthquake and its vicinity including the Pontides in the north, Intra-Pontid transition zone and Sakarya Continent in the south. Three-dimensional data-space inversions of the long period magnetotellurics data were performed iteratively to achieve the electrical resistivity structure. In order to determine and overcome the complexities caused by the coast effect that arise due to presence of the conductive Black Sea, the dimensionality of the magnetotellurics data were examined in detail by means of induction arrows and phase tensor ellipses. These complexities may have transpired due to the seismically active branches of the North Anatolian Fault and presence of the Intra-Pontide Suture, too. The final resistivity models revealed a low resistivity zone trapped between two highly resistive blocks of Istanbul Zone in the north and Sakarya Continent in the south. This low conductivity zone coincides with the two main branches of the North Anatolian Fault and may be promoting the seismic activity in both of the branches.

Audio-frequency magnetotelluric survey on the northern edifice of the Kurikoma volcano, northeast of Japan

*Kobayashi Takuya[1], Shin'ya Sakanaka[1], Tomoki Tsutsui[1], Muhammad Faizul Nizam Bin Zinudin[1], Inoue Yusuke[1], Kenta Kato[1], Tomoya Moriwaki[1], YUYA TADA[1], Ryuichi Takei[1]

1. Akita University

Now we focus the Kurikoma volcano closely at the triple junction of borders of Akita, Iwate and Miyagi prefectures, northeast of Japan. The eruption style of the Kurikoma volcano is magma eruption and phreatic eruption. The Kurikoma volcano is one of important active volcanos and its most recent striking activity was a phreatic eruption in 1944. The site of 1994 eruption is now remained as a crater lake called Lake Showa. Besides the Lake Showa, volcanic gas is even now emitted upstream of a gorge called Jigoku-dani. So far the several researches have reported 2- and 3-dimensional resistivity structures of the crust including the Kurikoma volcano (e.g. Mishina, 2009; Ichihara et al., 2014). Mishina (2009) firstly reported the 2-dimensional resistivity structure targeting the deep volcanic fluid beneath the Kurikoma volcano. The result of Mishina (2009) suggested the existence of volcanic fluid at the depth of several kilometers under the volcanic structure. In this study, we aim to find the structure which becomes the key to the occurrence of the phreatic eruption from the shallow resistivity structure directly under the Kurikoma volcano obtained by AMT survey.

We carried out an AMT survey across a high temperature upstream of a gorge from August to November 2018. This method uses magnetotelluric responses derived from variations in the natural audio-frequency band (approximately 1 to 10^4 Hz) of the electromagnetic field to estimate the resistivity structure in an area down to a depth of a few kilometers. The AMT data were collected at thirteen locations. Two components of the electric field and three components of the magnetic field were recorded for 3 to 24 h overnight using a Phoenix Geophysics MTU-5A system (Phoenix Geophysics Ltd., Toronto, ON, Canada). In this study, the concept of phase tensor (Caldwell et al., 2004) and induction vector (Parkinson, 1962) was used to evaluate the dimensionality of structure and the characteristic of resistivity distribution. From the results of the phase tensor, the skew angle was less than 5 degree and the ellipticity was less than 0.2 in the range of frequencies higher than 10 Hz. Therefore, it is suggested that the structure around 1 km below the subsurface is a relatively homogeneous structure. Also, in the frequency range lower than 10 Hz, the direction of the induction vectors tends to point towards a lava dome called Tsurugi-dake.

The 2D inversion model with TM-mode data was constructed using the inversion code developed by Ogawa and Uchida (1996). Only the data with small phase-tensor skew angles (< 5 degrees) were used in the 2D inversion in this study, because the data with large skew angles are inconsistent with the 2D structure assumed in the area.

The final model has three characteristic features. The first is that the low resistivity region (C1) beneath the fumarolic area and hot spring zone. The second is that high resistivity zone (R1) is distributed in the lower layer of the low resistivity region (C1) immediately below the high temperature fumarolic area (Jigoku-dani, Iwo-yama and Yuge-yama). It is suggested that the high resistivity zone (R1) is a high temperature body or a steam dominant region because high temperature fumarolic area exposes the surface of the ground. The third is the existence of a relatively high resistivity zone (R2) is located in the lower layer of the eastern part of the low resistivity region (C1). Since the phreatic eruption crater traces are distributed in the eastern part of the east west cross section, it is suggested that R2 is a trace of activities of the phreatic eruption in the past.

A three-dimensional crustal electrical resistivity model beneath southern Tohoku district, NE Japan

*Aoi Motoyama[1], Yasuo Ogawa[2], Makoto Uyeshima[3], Koichi Asamori[4], Toshihiro Uchida[5], Hideaki Hase[6], Takao Koyama[3], Shin'ya Sakanaka[7], Yusuke Yamaya[5], Koki Aizawa[8], Masahiro Ichiki[1]

1. Graduate school of science, Tohoku university, 2. Volcanic Fluid Research Center, School of Science, Tokyo Institute of Technology, 3. Earthquake research institute, the university of Tokyo, 4. Japan Atomic Energy Agency, 5. National institute of advanced industrial science and technology, 6. Geothermal Energy Research & Development Co., Ltd, 7. Graduate School of International Resource Sciences Department of Earth Resource Engineering and Environmental Science, Akita University, 8. Graduate school of science, Kyusyu university

On the basis of seismological and geodetic results, Hasegawa et al. (2005) proposed a vertical crustal model profile in the across-arc direction beneath Tohoku district. In the model, the magma and/or fluid reservoir lies in the lower crust beneath Ou backbone range running along the central arc of Tohoku district. On the other hand, Uyeshima et al. (2016) recently modeled a two-dimensional (2-D) crustal electrical resistivity profile in which there are three distinguished conductors in the lower crust, that is, beneath the fore-arc, volcanic front and back-arc of southern Tohoku district. The fore-arc conductor underlies the seismicity beneath around Iwaki city activated after 2011 Tohoku-oki earthquake. However, another 2-D resistivity profile 50 km northwards parallel to the Uyeshima et al’ s one shows no distinguished fore-arc conductor, but volcanic front and back-arc conductors (Motoyama et al., 2018). These results indicate geofluids rise up beneath a part of fore-arc beneath southern Tohoku district. Moreover, a part of back-arc of the southern Tohoku district may have conductive lower crust. Because previous resistivity models are limited to 2-D, we estimated a 3-D resistivity model beneath southern Tohoku district with compiling previous magnetotelluirc (MT) data, and discussed geofluids distribution beneath fore-arc and back-arc.

We compiled electromagnetic data at 118 sites and reassessed all MT responses and geomagnetic transfer functions. The $\Phi_{2,}$ square root of determinant of phase tensor (Caldwell et al., 2004), shows high values in the northern part of back-arc, and in the southern part of fore-arc and of Ou backbone range 10-100 s period range.

To estimate 3-D resistivity model, we used WSINV3D_MPI inversion code (Siripunvaraporn & Egbert, 2009). So far, we have estimated a preliminary model using only MT responses. A vertical model profile in the across-arc direction shows an oblique conductor from deeper crust beneath back-arc to shallower crust beneath Ou backbone range. On the other hand, almost all forearc has high resistivities in the crust. The map view of resistivity profile at 22.5 km depth shows a conductor distributes beneath from Murakami city of back-arc to Koriyama city of Ou backbone range. The calculation is still running by using both MT responses and geomagnetic transfer functions, and we will show the results and discussion in this presentation.

Magnetotelluric survey on the northern foot of Meakandake volcano

*Tomohiro Inoue[1], Takeshi Hashimoto[1]

1. Institute of Seismology and Volcanology, Faculty of Science, Hokkaido University

We performed a broadband MT survey in the northern part of Mt. Meakandake in August and September in 2018. Mt. Meakandake is one of the active volcanoes in the southwestern part of Akan caldera in eastern Hokkaido. Recently, a remarkable ground inflation has been reported on the northeastern foot of Meakandake. We planned a magnetotelluric survey to investigate the electrical structure across the deformation source. In this study, we describe the features of our MT data and show the 1-D models as a preliminary modeling.

The Geospatial Information Authority of Japan (2018) reported a remarkable crustal inflation on the basis of the GNSS observation and InSAR analysis from late 2016 through 2017. They modeled the deformation as an opening of the sill-like crack (about 11 km long and 2 km wide) at a depth of about 6 km on the northeastern foot of Meakandake. As the estimated deformation source was large, we considered that it might be imaged as a low resistivity anomaly, if it was related to magma or hydrothermal system. Investigating the subsurface structure across such an extensive inflation source will also contribute to understanding the magma plumbing system of the Akan area. Around Meakandake, a MT survey was previously conducted in the eastern area as a part of the Geothermal Development Promotion Survey (NEDO, 1992). More recently, an AMT survey was performed across the summit along a NE-SW direction as a part of volcano study of Meakandake (Takahashi et al., 2018). However, because of the limited sounding depths, the electrical structure near the above-mentioned deformation source has not been clarified yet.

Therefore, in this study, we newly deployed twelve broadband-MT sites along a NW-SE trending survey line across the longer side of the inflation source on the northern to eastern foot of the volcano. We used four set of the MTU-5/5A system (Phoenix Geophysics) for the campaign. We acquired the time series of the electric field in two components and the magnetic field in three components for 3 to 7 days for each site. In calculating the response functions, we used the SSMT2000 software and applied the remote reference processing using the magnetic field data Sawauchi in Iwate Prefecture that was provided by Nittetsu Mining Consultants Co., Ltd.

Contrary to our first expectation, the induction vectors and phase tensors suggested an electrical regional strike of N60ºW, which was almost parallel to the survey line. Thus, in this study, we sought a provisional 1-D modelling instead of the 2-D analysis in an unpreferable direction. We estimated 1-D resistivity structures using the Occam’s inversion (Constable et al., 1987), in which we used the ssq impedance (Szarka and Menvielle, 1997; Rung-Arunwan et al., 2016) as the input data. In this inversion, we only used a frequency range, in which the responses showed approximately a 1-D feature.

The inverted 1-D models exhibited a distinct low resistivity layer (1-10 Ωm, hereinafter called, C1) at depths around a few hundred meters at all sites. In addition, at the sites in the SE half of the survey line, another low resistivity layer of approximately 10 Ωm (hereinafter called, C2) was found at a depth around 2-4 km.

According to the NEDO (1992)’s borehole logs that were drilled at about 1 km east of our survey line,

©2019. Japan Geoscience Union. All Right Reserved.

the low resistivity layer C1, which is common to all the sites, is likely to correspond with the volcanic tuff layers in the Miocene indicating weak alteration with montmorillonite and/or chlorite. Meanwhile, the deeper low–resistivity layer C2 is recognized only at the locations near the above–mentioned inflation source. In addition, C2 is shallower at the sites near the inflation source. For this reason, we suspect that C2 has some relation to the inflation source, although their depths are different. We note that the interpretations are tentative since they are based on the 1–D modeling, and further evaluation is needed through a 3–D modeling in the future.

Hydrothermal system of Kuttara Volcanic Group inferred from 3D resistivity modeling (2)

*Ryo Tanaka[1], Midori Hayakawa[2], Takeshi Hashimoto[1], Wataru Kanda[3], Yuichi Morita[4], Hiroshi Aoyama[1], Makoto Uyeshima[4]

1. Institute of Seismology and Volcanology, Hokkaido University, 2. Mitsui Oil Exploration Co., Ltd. Geothermal Business Division, 3. Volcanic Fluid Research Center, School of Science, Tokyo Institute of Technology, 4. Earthquake Research Institute, The University of Tokyo

Estimation of the volcanic hydrothermal system that is composed of an alteration zone, a fluid upflow zone and a heat source, is a key feature in assessing the potential of phreatic eruptions. Magnetotelluric (MT) method is one of the effective ways of estimating such hydrothermal system since it has the sensitivity to hydrothermal fluid and hydrothermal alteration zones. We performed the MT survey at Kuttara Volcano Group, northern Japan, to evaluate imminence of phreatic eruption.

Kuttara Volcanic Group is a basaltic to andesitic volcanic complex in southwestern Hokkaido, northern Japan. Kuttara volcano was formed by several silicic explosive eruptions and construction of an andesitic stratovolcano built up from ca. 80 to 40 ka. Lake Kuttara is a caldera lake formed by a violent explosive eruption at ca. 40 ka (Katsui et al., 1988; Moriizumi,1998). Noboribetsu volcano, post-caldera volcanism on the western foot of the stratovolcano at ca. 15 ka, formed Hiyoriyama cryptodome and Jigokudani geothermal field. We can see weak plumes (110–140 ºC; maximum height of ca. 50 m) near the top of Hiyoriyama cryptdome. We also see hot spring areas around Kuttara volcano at Noboribetsu, Carls, and Kojo-hama.

Although some previous studies (Goto and Johmori, 2011, 2013, 2015) revealed 2-D resistivity cross sections by CSAMT and TDEM methods at Kuttara volcano, they did not image deeper than about 1km. In this study, we carried out a broadband MT survey in 2017 at 49 stations in the area of 20x20 km wide and estimated 3-D resistivity structure of Kuttara Volcanic Group. We used ModEM (Egbert and Kelbert, 2012) as the 3-D inversion code, using a model space containing topography and sea bottom relieves. Responses at twelve periods between 0.00521 and 512 s were selected as the input data of the inversion. Error floors of 5% for the diagonal components of the impedance and 10% for the tippers and non-diagonal components of the impedance were given to avoid too much weighting for these data in the inversion process. Two-step inversion was applied, in which only the tippers were inverted at first, and subsequently, only the impedances were inverted. We already presented preliminary results at JpGU 2018 (Hayakawa et al., 2018). In this presentation, we discuss the results through the sensitivity check. We performed the sensitivity check by measuring the change in RMS due to disturbance of resistivity value in the focusing area.

We summarized the key features of the modeling results as follows. (1) The near-surface resistivity distribution is in good agreement with the surface geology. The resistivity was relatively high (100 to1000 Ωm) on northern and eastern to southern flanks of Kuttara Volcano, where volcanic deposits such as andesite lava flows covered the surface. (2) A low resistivity zone is imaged beneath Noboribetsu hot spring and a columnar low resistivity zone reached to the bottom of Lake Kuttara from the depth. These low resistivity zones indicate hydrothermal system in the Kuttara-Noboribetsu area. Low resistivity layer is also imaged just below Carls hot spring. However, this low resistivity layer is not sensitive in our inversion since this layer is very thin. (3) Relatively high resistivity zone beneath Lake Kuttara also has insufficient

©2019. Japan Geoscience Union. All Right Reserved.

sensitivity. This result indicates we have to perform more dense survey around Lake Kuttara to discuss whether magma or hydrothermal reservoir exist beneath Lake Kuttara or not. Our study is the first 3-D MT modeling for Kuttara Volcanic Group and further detailed comparison to geology, hydrology, drilling data, and hydrothermal simulation is necessary to better understand the current and to assess the potential of phreatic eruptions at Kuttara Volcanic Group.

3D magnetic structure of Aso volcano

*Mitsuru Utsugi[1]

1. Aso Volcanological Laboratory, Institute for Geothermal Sciences, Graduate School of Science, Kyoto University

On Aso volcano, some aeromagnetic survey was conducted in previously to reveal the subsurface magnetic structure of the volcanic bodies, on 2001 (Tanaka et al., 2001), 2004 and 2004 (Tanaka et al., 2006) and 2006 (Utsugi et al., 2007). On this study, we tried to re-analyze these previous data, and tried to obtain detailed subsurface 3D magnetic structure of Aso volcano.

To the previous observed data, the processing of the IGRF correction and trend surface analysis were applied. Further, the process of the upward continuation (Nakatsuka and Okuma, 2005) was applied, and obtained the magnetic data on regular grid above the ground surface. Using this data as an input, the magnetization intensity distribution inside the volcanic bodies was determined by L1 norm regularized magnetic inversion. For this process, we divided the summit area of Aso volcano of about 5 x 5 km and the depth of 2.5 km into small blocks of 80 x 80 x 40, and determined the magnetization of each block. At this time, it was assumed that the magnetization was constant in each block, and the direction of magnetization was parallel to the current direction of the earth's magnetic field. In this presentation, detailed results of our magnetic inversion will be introduced.

The piezomagnetic field produced by an ellipsoidal pressure source: A preliminary result

*Yoichi Sasai[1]

1. Earthquake Prediction Research Center, Institute of Oceanic Research and Development, Tokai University

Sasai (1986) formulated the piezomagnetic potential produced by a single force operative at a point, which was called the fundamental piezomagnetic potential (FPP). As an application example, he obtained the piezomagnetic field associated with a uniform circular load or the dam-magnetic effect. He also suggested that the FPP should be applicable to an ellipsoidal pressure source based on Eshelby's (1957) elastic inclusion theory. However, such an attempt has not been completed yet. Davis (1986) pointed out that the surface deformation observed at Kilauea volcano, Hawaii, could not be fully explained by the simple Mogi model and applied Eshelby's solution to find the best-fit ellipsoidal pressure source. He gave the displacement field only at the ground surface, while we need the one within the entire elastic half-space. Seo and Mura (1979) had formulated the displacement field due to the ellipsoidal inclusions with uniform dilatational eigenstrains, which was useful in some subjects in the metallography. Their model is also applicable to the magma reservoir in a shallow depth. When we consider the piezomagntic effect in the shallow crust, we must take into account the Curie point isotherm, i.e. an elastic half-space with a uniformly magnetized top layer. According to the representation theorem of the piezomagnetic field (Sasai, 1991), the potential is given by the surface integral with respect to the displacement and its normal derivatives. We discriminate three cases, i.e. Case I: the Curie surface (H) lies below the ellipsoid, Case II: H intersects the ellipsoid, and Case III: H lies above the ellipsoid. Here we obtained the solution for the simplist case (III).

Effects of absolute humidity on contact resistance between dry rock sample surface and electrodes

*Takeshi Suzuki[1], Ryokei Yoshimura[2], Ken'ichi Yamazaki[2], Naoto Oshiman[2]

1. Graduate School of Science, Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University

Resistivity measurements of rock under various conditions are essential for accurately interpreting geoelectromagnetic survey results. However, the contact resistance between the rock sample and measuring electrodes is a problem in measuring the resistivity of a rock sample. Because the measurement of high contact resistance on the dry rock surface is particularly difficult, its characteristics have not been well studied.
In order to investigate the characteristics of contact resistance, we have developed a measurement method of high contact resistance. By using the method, we measured high contact resistance between the dry granite surface and the electrode made of conductive epoxy. Considering the interaction between atmospheric moisture and rock samples, the contact resistance was repeatedly measured under different humidity conditions.
We confirmed the contact resistance decreased with increasing absolute humidity. A clear relationship exists between contact resistance and absolute humidity, and the relationship was approximated by an exponential function. This result suggests that increasing the contact area between the electrode and the rock surface with rising humidity. Moisture in the atmosphere may have caused improvement of contact condition by filling the microscopic gap in the contact surface.

Keywords: contact resistance, atmospheric Moisture, absolute humidity, contact area, conductive epoxy, granite

Japanese geomagnetic field variation model based on the IGRF (2): modeling on the oblique Mercator projection

*Tsutomu Ogawa[1]

1. Earthquake Research Institute, the University of Tokyo

For geomagnetic field variation observations around tectonic areas to detect the variations related to tectonic activities in Japan, geomagnetic field model or geomagnetic field variation model around Japan with high accuracy is indispensable as a reference field. The geomagnetic field variation model around Japan proposed by Abe and Miyahara (2015) using the principal component analysis of geomagnetic data is a statistical model but not a physical model of the field variation, for the vector field model is not in general divergence-free. The model also lacked the error estimation for arbitrary positions. The present study evaluates the new geomagnetic field variation model around Japan which corrects the following two points in the model by Ogawa (2018, JpGU) which attempted to overcome the difficulties in the previous work: 1) the geomagnetic field variation is expressed in the Cartesian coordinate system on the map using the oblique Mercator projection of the Japanese island arc along NE-SW direction with a great ellipse centered and oriented along the direction, instead of the Mercator projection, and 2) annual variations in the model residuals of data which correlate with sensor temperature variations at the geoelectromagnetic continuous measurement stations of GIAJ are removed.

The new geomagnetic field variation model is expressed with the magnetic scalar potential by a cubic polynomial with respect to the coordinates in the coordinate system with its origin on the ground in the SE area of Ishikawa prefecture, expressing the difference of the 1-day geomagnetic data at 5 observatories of JMA and GIAJ and 10 stations of GIAJ from the IGRF, between 2005 and 2014. By obtaining the time series of expansion coefficients using the robust least square technique, the model shows the following features: 1) the mean of the model residuals amounts to 1.28nT, 2) by the leave-one-out cross-validation, the mean of the prediction error amounts to 1.94nT, 3) the mean of the prediction error at all the observation points obtained by the propagation of the jackknife standard error of expansion coefficients amounts to 1.16nT, as large as the mean of the model residuals, and 4) the mean of the prediction errors at Chichijima station of JMA, data of which are unused for the model, because of the large distance of the station from the principal part of the Japanese island arc, amounts to 5.06nT.

The mean prediction error along the principal part of the Japanese island arc estimated using the propagation of the jackknife standard errors of estimated expansion coefficients amounts at most to about 2nT for the horizontal two components and about 3nT for the vertical component, respectively. The present geomagnetic field variation model around Japan has the accuracy of a few nT for the principal part of the Japanese island arc.

Examination of criteria to remove the influence of the Sq-field variations from electromagnetic field spectra for a better estimation of regional electromagnetic responses

*RUIBAI LI[1], Hisayoshi Shimizu[1], Kiyoshi Baba[1], Hisashi Utada[1]

1. Earthquake Research Institute, the University of Tokyo

Electromagnetic (EM) responses such as magnetotelluric (MT) impedance and geomagnetic depth sounding (GDS) response (or tipper) in the period range between several minutes to one day are used to study the electrical conductivity in the upper mantle. Spatially uniform and quasi-random magnetic field variations due to geomagnetic disturbances are considered as the source field in regional EM induction studies using the EM responses. However, the magnetic field variations in the period range from to seconds (mixed excitation band, or ME band) contain those with different spatial structure such as the solar quiet (Sq) daily variations and those induced by the ocean tide. Careful treatment of EM field data is necessary to estimate responses in the ME band that reflect actual conductivity structure. For example, Baba et al. (2010) estimated the EM responses in the period range from to seconds using a method based on Fourier transform after removing line spectra of EM field variations at periods of Sq field variations that include the higher harmonics and constituents of ocean tides. However, it was shown that the estimated responses in the ME band still included the influence of Sq field variations (Shimizu et al., 2011).

In this study we try to estimate EM responses that are less influenced by the Sq field variations. We employed line spectra of EM field obtained by using Sompi method, so called wave element (or namiso) (e.g., Kumazawa et al.,1990, Asakawa eta al.,1988), to estimate the EM responses in order to avoid the influence of the Sq field variations that could be contained in continuous spectra. Also, three conditions are applied to select appropriate wave elements from observed ones for EM response estimations. First is to select wave elements of which eastward component have common phase or that close to each other at two stations. This can avoid wave elements influenced by the Sq field variations since their westward propagation causes systematic phase difference of the magnetic field for supposed longitude difference and apparent period, which is determined by the longitudinal wave number of the variation. Second is to select magnetic field spectra that are linearly polarized in horizontal-vertical plane, because that influenced by the Sq field variations are expected to be more elliptically polarized in the plane than those suitable for regional EM response estimation. Ellipticity of the polarization ellipse is used to apply the condition. Third is to select those which have small ratio of the vertical to the horizontal magnetic field components, because the Sq field variations contain significant vertical magnetic field component that can cause larger amplitude of tipper than those from plane wave. It was confirmed that estimated phase difference, ellipticity, and vertical to horizontal field ratio showed a signature of Sq field variations in the ME band but not at a period shorter than seconds.

In this presentation, we are going to show the characteristics of the observed phase difference, ellipticity, and vertical to horizontal field ratio with respect to the period. Criteria to apply the conditions are assumed based on theoretical estimate of the magnetic field due to Sq principle mode and the induced field in assumed one dimensional Earth. The EM responses obtained by applying each condition are shown and the improvement or influence in the obtained responses, as a result, are discussed quantitatively.

Study on long-term variation of geoelectric field observation

*Ren Ozeki[1], Ikuko Fujii[1]

1. Japan Meteorological Agency

Kakioka Magnetic Observatory, Japan Meteorological Agency, has observed the geomagnetic and geoelectric fields for several decades at Kakioka, Kanoya and Memambetsu. Vitage differences between two electrodes are observed in the geoelectric field observation. The baseline length is about 200-300m and the electrodes are installed at 3m deep. The data of the geoelectric field are used worldwide as a unique data set to investigate induced electric fields for last several decades.It is slightly troublesome for us to use the geoelectric field data set by Kakioka Magnetic Observatory because the geoelectric fields at three sites shows long-term variations and especially the north-south component of the geoelectric field at Kakioka clearly changes.Although some studies (e.g., Morinaga and Toya, 2015; Okawa et al., 1995) reported that this long-term variation is related to rain, details of how this long-term variation occurs are still unknown. This study aims to reveal the cause of the long-term variation.
Based on Morinaga and Toya (2015) and Fujii et al.(2007), we focus on geological structures around the electrode at the south end of the north-south line at Kakioka. We infer the geological structure from the distribution of the electrical resistivity.
The electrical prospecting was applied to an area of 20m x 20m with the south electrode as the center. Observations were conducted in March, May and October giving 7 observation lines around the south electrode, 2 lines around the east electrode, and 1 line around a boring hole (fig.1). Apparent resistivity was estimated from the observed currents and voltage differences.
We assume that the subsurface structure is one-dimensional and three layers are stratified. An optimal model of the resistivity distribution was obtained by inversion. All lines show a high resistivity layer at the surface followed by a low resistivity layer and then a high resistivity layer at the bottom. The thickness of the first layer is increased eastward from the south electrode.
The optimal model was compared with a boring profile obtained near the investigated area. We interpret that the resistive surface layer is permeable top soil and the second conductive layer is impermeable clay(Figure 2).We suspect that rain water flows on the top of clay to the east and the south electrode suffers from larger amount of water than the other electrodes.

Deep electrical conductivity structure of Eastern Marmara, Turkey by long period magnetotellurics

*Sabri Bulent Tank[1], Naoto Oshiman[2], Mustafa Karas[1], Ryokei Yoshimura[2], Yasuo Ogawa[3]

1. Bogazici University, 2. Kyoto University, 3. Tokyo Institute of Technology

The electrical resistivity structure of a 100 km x 100 km region at northwestern Anatolia was examined by using long period magnetotelluric data with the aim to image the geo-electrical features at the lower crust and upper mantle. The electromagnetic impedance tensor elements were obtained for eighteen sounding locations within a period range of 20-13000 seconds. The soundings were distributed over the epicentral region of the 1999 Izmit earthquake and its vicinity including the Pontides in the north, Intra-Pontid transition zone and Sakarya Continent in the south. Three-dimensional data-space inversions of the long period magnetotellurics data were performed iteratively to achieve the electrical resistivity structure. In order to determine and overcome the complexities caused by the coast effect that arise due to presence of the conductive Black Sea, the dimensionality of the magnetotellurics data were examined in detail by means of induction arrows and phase tensor ellipses. These complexities may have transpired due to the seismically active branches of the North Anatolian Fault and presence of the Intra-Pontide Suture, too. The final resistivity models revealed a low resistivity zone trapped between two highly resistive blocks of Istanbul Zone in the north and Sakarya Continent in the south. This low conductivity zone coincides with the two main branches of the North Anatolian Fault and may be promoting the seismic activity in both of the branches.

Audio-frequency magnetotelluric survey on the northern edifice of the Kurikoma volcano, northeast of Japan

*Kobayashi Takuya[1], Shin'ya Sakanaka[1], Tomoki Tsutsui[1], Muhammad Faizul Nizam Bin Zinudin[1], Inoue Yusuke[1], Kenta Kato[1], Tomoya Moriwaki[1], YUYA TADA[1], Ryuichi Takei[1]

1. Akita University

Now we focus the Kurikoma volcano closely at the triple junction of borders of Akita, Iwate and Miyagi prefectures, northeast of Japan. The eruption style of the Kurikoma volcano is magma eruption and phreatic eruption. The Kurikoma volcano is one of important active volcanos and its most recent striking activity was a phreatic eruption in 1944. The site of 1994 eruption is now remained as a crater lake called Lake Showa. Besides the Lake Showa, volcanic gas is even now emitted upstream of a gorge called Jigoku-dani. So far the several researches have reported 2- and 3-dimensional resistivity structures of the crust including the Kurikoma volcano (e.g. Mishina, 2009; Ichihara et al., 2014). Mishina (2009) firstly reported the 2-dimensional resistivity structure targeting the deep volcanic fluid beneath the Kurikoma volcano. The result of Mishina (2009) suggested the existence of volcanic fluid at the depth of several kilometers under the volcanic structure. In this study, we aim to find the structure which becomes the key to the occurrence of the phreatic eruption from the shallow resistivity structure directly under the Kurikoma volcano obtained by AMT survey.

We carried out an AMT survey across a high temperature upstream of a gorge from August to November 2018. This method uses magnetotelluric responses derived from variations in the natural audio-frequency band (approximately 1 to 10^4 Hz) of the electromagnetic field to estimate the resistivity structure in an area down to a depth of a few kilometers. The AMT data were collected at thirteen locations. Two components of the electric field and three components of the magnetic field were recorded for 3 to 24 h overnight using a Phoenix Geophysics MTU-5A system (Phoenix Geophysics Ltd., Toronto, ON, Canada). In this study, the concept of phase tensor (Caldwell et al., 2004) and induction vector (Parkinson, 1962) was used to evaluate the dimensionality of structure and the characteristic of resistivity distribution. From the results of the phase tensor, the skew angle was less than 5 degree and the ellipticity was less than 0.2 in the range of frequencies higher than 10 Hz. Therefore, it is suggested that the structure around 1 km below the subsurface is a relatively homogeneous structure. Also, in the frequency range lower than 10 Hz, the direction of the induction vectors tends to point towards a lava dome called Tsurugi-dake.

The 2D inversion model with TM-mode data was constructed using the inversion code developed by Ogawa and Uchida (1996). Only the data with small phase-tensor skew angles (< 5 degrees) were used in the 2D inversion in this study, because the data with large skew angles are inconsistent with the 2D structure assumed in the area.

The final model has three characteristic features. The first is that the low resistivity region (C1) beneath the fumarolic area and hot spring zone. The second is that high resistivity zone (R1) is distributed in the lower layer of the low resistivity region (C1) immediately below the high temperature fumarolic area (Jigoku-dani, Iwo-yama and Yuge-yama). It is suggested that the high resistivity zone (R1) is a high temperature body or a steam dominant region because high temperature fumarolic area exposes the surface of the ground. The third is the existence of a relatively high resistivity zone (R2) is located in the lower layer of the eastern part of the low resistivity region (C1). Since the phreatic eruption crater traces are distributed in the eastern part of the east west cross section, it is suggested that R2 is a trace of activities of the phreatic eruption in the past.

A three-dimensional crustal electrical resistivity model beneath southern Tohoku district, NE Japan

*Aoi Motoyama[1], Yasuo Ogawa[2], Makoto Uyeshima[3], Koichi Asamori[4], Toshihiro Uchida[5], Hideaki Hase[6], Takao Koyama[3], Shin'ya Sakanaka[7], Yusuke Yamaya[5], Koki Aizawa[8], Masahiro Ichiki[1]

1. Graduate school of science, Tohoku university, 2. Volcanic Fluid Research Center, School of Science, Tokyo Institute of Technology, 3. Earthquake research institute, the university of Tokyo, 4. Japan Atomic Energy Agency, 5. National institute of advanced industrial science and technology, 6. Geothermal Energy Research & Development Co., Ltd, 7. Graduate School of International Resource Sciences Department of Earth Resource Engineering and Environmental Science, Akita University, 8. Graduate school of science, Kyusyu university

On the basis of seismological and geodetic results, Hasegawa et al. (2005) proposed a vertical crustal model profile in the across-arc direction beneath Tohoku district. In the model, the magma and/or fluid reservoir lies in the lower crust beneath Ou backbone range running along the central arc of Tohoku district. On the other hand, Uyeshima et al. (2016) recently modeled a two-dimensional (2-D) crustal electrical resistivity profile in which there are three distinguished conductors in the lower crust, that is, beneath the fore-arc, volcanic front and back-arc of southern Tohoku district. The fore-arc conductor underlies the seismicity beneath around Iwaki city activated after 2011 Tohoku-oki earthquake. However, another 2-D resistivity profile 50 km northwards parallel to the Uyeshima et al’ s one shows no distinguished fore-arc conductor, but volcanic front and back-arc conductors (Motoyama et al., 2018). These results indicate geofluids rise up beneath a part of fore-arc beneath southern Tohoku district. Moreover, a part of back-arc of the southern Tohoku district may have conductive lower crust. Because previous resistivity models are limited to 2-D, we estimated a 3-D resistivity model beneath southern Tohoku district with compiling previous magnetotelluirc (MT) data, and discussed geofluids distribution beneath fore-arc and back-arc.

We compiled electromagnetic data at 118 sites and reassessed all MT responses and geomagnetic transfer functions. The $\Phi_{2,}$ square root of determinant of phase tensor (Caldwell et al., 2004), shows high values in the northern part of back-arc, and in the southern part of fore-arc and of Ou backbone range 10-100 s period range.

To estimate 3-D resistivity model, we used WSINV3D_MPI inversion code (Siripunvaraporn & Egbert, 2009). So far, we have estimated a preliminary model using only MT responses. A vertical model profile in the across-arc direction shows an oblique conductor from deeper crust beneath back-arc to shallower crust beneath Ou backbone range. On the other hand, almost all forearc has high resistivities in the crust. The map view of resistivity profile at 22.5 km depth shows a conductor distributes beneath from Murakami city of back-arc to Koriyama city of Ou backbone range. The calculation is still running by using both MT responses and geomagnetic transfer functions, and we will show the results and discussion in this presentation.

Magnetotelluric survey on the northern foot of Meakandake volcano

*Tomohiro Inoue[1], Takeshi Hashimoto[1]

1. Institute of Seismology and Volcanology, Faculty of Science, Hokkaido University

We performed a broadband MT survey in the northern part of Mt. Meakandake in August and September in 2018. Mt. Meakandake is one of the active volcanoes in the southwestern part of Akan caldera in eastern Hokkaido. Recently, a remarkable ground inflation has been reported on the northeastern foot of Meakandake. We planned a magnetotelluric survey to investigate the electrical structure across the deformation source. In this study, we describe the features of our MT data and show the 1-D models as a preliminary modeling.

The Geospatial Information Authority of Japan (2018) reported a remarkable crustal inflation on the basis of the GNSS observation and InSAR analysis from late 2016 through 2017. They modeled the deformation as an opening of the sill-like crack (about 11 km long and 2 km wide) at a depth of about 6 km on the northeastern foot of Meakandake. As the estimated deformation source was large, we considered that it might be imaged as a low resistivity anomaly, if it was related to magma or hydrothermal system. Investigating the subsurface structure across such an extensive inflation source will also contribute to understanding the magma plumbing system of the Akan area. Around Meakandake, a MT survey was previously conducted in the eastern area as a part of the Geothermal Development Promotion Survey (NEDO, 1992). More recently, an AMT survey was performed across the summit along a NE-SW direction as a part of volcano study of Meakandake (Takahashi et al., 2018). However, because of the limited sounding depths, the electrical structure near the above-mentioned deformation source has not been clarified yet.

Therefore, in this study, we newly deployed twelve broadband-MT sites along a NW-SE trending survey line across the longer side of the inflation source on the northern to eastern foot of the volcano. We used four set of the MTU-5/5A system (Phoenix Geophysics) for the campaign. We acquired the time series of the electric field in two components and the magnetic field in three components for 3 to 7 days for each site. In calculating the response functions, we used the SSMT2000 software and applied the remote reference processing using the magnetic field data Sawauchi in Iwate Prefecture that was provided by Nittetsu Mining Consultants Co., Ltd.

Contrary to our first expectation, the induction vectors and phase tensors suggested an electrical regional strike of N60ºW, which was almost parallel to the survey line. Thus, in this study, we sought a provisional 1-D modelling instead of the 2-D analysis in an unpreferable direction. We estimated 1-D resistivity structures using the Occam’s inversion (Constable et al., 1987), in which we used the ssq impedance (Szarka and Menvielle, 1997; Rung-Arunwan et al., 2016) as the input data. In this inversion, we only used a frequency range, in which the responses showed approximately a 1-D feature.

The inverted 1-D models exhibited a distinct low resistivity layer (1-10 Ωm, hereinafter called, C1) at depths around a few hundred meters at all sites. In addition, at the sites in the SE half of the survey line, another low resistivity layer of approximately 10 Ωm (hereinafter called, C2) was found at a depth around 2-4 km.

According to the NEDO (1992)’s borehole logs that were drilled at about 1 km east of our survey line,

©2019. Japan Geoscience Union. All Right Reserved.

the low resistivity layer C1, which is common to all the sites, is likely to correspond with the volcanic tuff layers in the Miocene indicating weak alteration with montmorillonite and/or chlorite. Meanwhile, the deeper low–resistivity layer C2 is recognized only at the locations near the above–mentioned inflation source. In addition, C2 is shallower at the sites near the inflation source. For this reason, we suspect that C2 has some relation to the inflation source, although their depths are different. We note that the interpretations are tentative since they are based on the 1–D modeling, and further evaluation is needed through a 3–D modeling in the future.

Hydrothermal system of Kuttara Volcanic Group inferred from 3D resistivity modeling (2)

*Ryo Tanaka[1], Midori Hayakawa[2], Takeshi Hashimoto[1], Wataru Kanda[3], Yuichi Morita[4], Hiroshi Aoyama[1], Makoto Uyeshima[4]

1. Institute of Seismology and Volcanology, Hokkaido University, 2. Mitsui Oil Exploration Co., Ltd. Geothermal Business Division, 3. Volcanic Fluid Research Center, School of Science, Tokyo Institute of Technology, 4. Earthquake Research Institute, The University of Tokyo

Estimation of the volcanic hydrothermal system that is composed of an alteration zone, a fluid upflow zone and a heat source, is a key feature in assessing the potential of phreatic eruptions. Magnetotelluric (MT) method is one of the effective ways of estimating such hydrothermal system since it has the sensitivity to hydrothermal fluid and hydrothermal alteration zones. We performed the MT survey at Kuttara Volcano Group, northern Japan, to evaluate imminence of phreatic eruption.

Kuttara Volcanic Group is a basaltic to andesitic volcanic complex in southwestern Hokkaido, northern Japan. Kuttara volcano was formed by several silicic explosive eruptions and construction of an andesitic stratovolcano built up from ca. 80 to 40 ka. Lake Kuttara is a caldera lake formed by a violent explosive eruption at ca. 40 ka (Katsui et al., 1988; Moriizumi,1998). Noboribetsu volcano, post-caldera volcanism on the western foot of the stratovolcano at ca. 15 ka, formed Hiyoriyama cryptodome and Jigokudani geothermal field. We can see weak plumes (110–140 ºC; maximum height of ca. 50 m) near the top of Hiyoriyama cryptdome. We also see hot spring areas around Kuttara volcano at Noboribetsu, Carls, and Kojo-hama.

Although some previous studies (Goto and Johmori, 2011, 2013, 2015) revealed 2-D resistivity cross sections by CSAMT and TDEM methods at Kuttara volcano, they did not image deeper than about 1km. In this study, we carried out a broadband MT survey in 2017 at 49 stations in the area of 20x20 km wide and estimated 3-D resistivity structure of Kuttara Volcanic Group. We used ModEM (Egbert and Kelbert, 2012) as the 3-D inversion code, using a model space containing topography and sea bottom relieves. Responses at twelve periods between 0.00521 and 512 s were selected as the input data of the inversion. Error floors of 5% for the diagonal components of the impedance and 10% for the tippers and non-diagonal components of the impedance were given to avoid too much weighting for these data in the inversion process. Two-step inversion was applied, in which only the tippers were inverted at first, and subsequently, only the impedances were inverted. We already presented preliminary results at JpGU 2018 (Hayakawa et al., 2018). In this presentation, we discuss the results through the sensitivity check. We performed the sensitivity check by measuring the change in RMS due to disturbance of resistivity value in the focusing area.

We summarized the key features of the modeling results as follows. (1) The near-surface resistivity distribution is in good agreement with the surface geology. The resistivity was relatively high (100 to1000 Ωm) on northern and eastern to southern flanks of Kuttara Volcano, where volcanic deposits such as andesite lava flows covered the surface. (2) A low resistivity zone is imaged beneath Noboribetsu hot spring and a columnar low resistivity zone reached to the bottom of Lake Kuttara from the depth. These low resistivity zones indicate hydrothermal system in the Kuttara-Noboribetsu area. Low resistivity layer is also imaged just below Carls hot spring. However, this low resistivity layer is not sensitive in our inversion since this layer is very thin. (3) Relatively high resistivity zone beneath Lake Kuttara also has insufficient

©2019. Japan Geoscience Union. All Right Reserved.

sensitivity. This result indicates we have to perform more dense survey around Lake Kuttara to discuss whether magma or hydrothermal reservoir exist beneath Lake Kuttara or not. Our study is the first 3-D MT modeling for Kuttara Volcanic Group and further detailed comparison to geology, hydrology, drilling data, and hydrothermal simulation is necessary to better understand the current and to assess the potential of phreatic eruptions at Kuttara Volcanic Group.

3D magnetic structure of Aso volcano

*Mitsuru Utsugi[1]

1. Aso Volcanological Laboratory, Institute for Geothermal Sciences, Graduate School of Science, Kyoto University

On Aso volcano, some aeromagnetic survey was conducted in previously to reveal the subsurface magnetic structure of the volcanic bodies, on 2001 (Tanaka et al., 2001), 2004 and 2004 (Tanaka et al., 2006) and 2006 (Utsugi et al., 2007). On this study, we tried to re-analyze these previous data, and tried to obtain detailed subsurface 3D magnetic structure of Aso volcano.

To the previous observed data, the processing of the IGRF correction and trend surface analysis were applied. Further, the process of the upward continuation (Nakatsuka and Okuma, 2005) was applied, and obtained the magnetic data on regular grid above the ground surface. Using this data as an input, the magnetization intensity distribution inside the volcanic bodies was determined by L1 norm regularized magnetic inversion. For this process, we divided the summit area of Aso volcano of about 5 x 5 km and the depth of 2.5 km into small blocks of 80 x 80 x 40, and determined the magnetization of each block. At this time, it was assumed that the magnetization was constant in each block, and the direction of magnetization was parallel to the current direction of the earth's magnetic field. In this presentation, detailed results of our magnetic inversion will be introduced.

The piezomagnetic field produced by an ellipsoidal pressure source: A preliminary result

*Yoichi Sasai[1]

1. Earthquake Prediction Research Center, Institute of Oceanic Research and Development, Tokai University

Sasai (1986) formulated the piezomagnetic potential produced by a single force operative at a point, which was called the fundamental piezomagnetic potential (FPP). As an application example, he obtained the piezomagnetic field associated with a uniform circular load or the dam-magnetic effect. He also suggested that the FPP should be applicable to an ellipsoidal pressure source based on Eshelby's (1957) elastic inclusion theory. However, such an attempt has not been completed yet. Davis (1986) pointed out that the surface deformation observed at Kilauea volcano, Hawaii, could not be fully explained by the simple Mogi model and applied Eshelby's solution to find the best-fit ellipsoidal pressure source. He gave the displacement field only at the ground surface, while we need the one within the entire elastic half-space. Seo and Mura (1979) had formulated the displacement field due to the ellipsoidal inclusions with uniform dilatational eigenstrains, which was useful in some subjects in the metallography. Their model is also applicable to the magma reservoir in a shallow depth. When we consider the piezomagntic effect in the shallow crust, we must take into account the Curie point isotherm, i.e. an elastic half-space with a uniformly magnetized top layer. According to the representation theorem of the piezomagnetic field (Sasai, 1991), the potential is given by the surface integral with respect to the displacement and its normal derivatives. We discriminate three cases, i.e. Case I: the Curie surface (H) lies below the ellipsoid, Case II: H intersects the ellipsoid, and Case III: H lies above the ellipsoid. Here we obtained the solution for the simplist case (III).

Nitrogen occupies about 80% in the Earth's atmosphere and is one of essential elements of life. For these reasons, nitrogen is an important volatile element in various aspects of geoscience, including climates (e.g. Goldblatt et al., 2009; Wordsworth and Pierrehumbert, 2013) and the origin of life. However, we couldn't have still understood details of behavior or cycle of nitrogen in the Earth's interior. For example, it is known that the amount of nitrogen in deep Earth is more depleted than that of other volatile elements (Marty, 2012). This is called "missing" nitrogen and suggested to be caused by nitrogen stored in the upper mantle, the mantle transition zone, and the lower mantle through magma ocean from experimental researches (e.g., Li et al., 2013; Yoshioka et al., 2018). However, only two experiments corresponding to the lower mantle were conducted in the previous study (Yoshioka et al., 2018). In addition, subducting slab have played important role for volatile cycle into the deep Earth.

In this research, in order to investigate how much nitrogen is incorporated into stishovite which can carry nitrogen to the lower mantle, we conducted high-pressure and high-temperature experiments using multi-anvil apparatus installed at Geodynamics Research Center, Ehime University. All experimental pressure conditions were 27 GPa and temperature conditions ranged from 1400 ℃ to 1700 ℃. Fe-FeO buffer was used to control the redox state equal to the lower mantle. Nitrogen in recovered samples were analyzed using NanoSIMS installed at Atmosphere and Ocean Research Institute, The University of Tokyo. Nitrogen implanted standard samples were prepared in order to estimate nitrogen solubility in silicate minerals at National Institute for Materials Science.

A series of experimental results revealed that stishovite can incorporate 39-418 ppm nitrogen which is higher than nitrogen solubility in bridgmanite (5-50 ppm nitrogen solubility reported by Yoshioka et al. (2018)). Stishovite is mainly formed by the transition of nitrogen-rich sedimentary rocks transported to the lower mantle via subducting slabs. Our study suggests that nitrogen would continue to be supplied to the lower mantle via subducting slabs since when the plate tectonics had begun. This implies that "hidden" nitrogen reservoir was formed in the lower mantle approximately 4 billion years ago. Furthermore, this " hidden" nitrogen reservoir may play a role in decreasing high-concentration nitrogen which had enhanced greenhouse effect in the early atmosphere (Goldblatt et al., 2009) to the present nitrogen concentration level. Thus, our experimental results support the young faint Sun paradox explained by high-concentration nitrogen in the early Earth (e.g. Goldblatt et al., 2009; Wordsworth and Pierrehumbert, 2013) and suggest that "missing" nitrogen has been caused by forming a "hidden" nitrogen reservoir in the lower mantle.

3-D P- and S-velocity structure of the D″ layer beneath Central America and the Caribbean using waveform inversion

*Anselme F. E. Borgeaud[1,2], Kenji Kawai[1], Robert J. Geller[1]

1. Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo, 2. Institute of Earth Sciences, Academia Sinica

We present 3-D P- and S-velocity models of the lowermost mantle (0–400 km above the core-mantle boundary) beneath Central America and the Caribbean inferred from waveform inversion of a large dataset of ~16,000 USArray waveforms data. The origin of seismic velocity anomalies in the D″ region, e.g., thermal, chemical, or due to the phase transition from Bridgemanite (brg) to post-perovskite (pPv), is still debated. Insights into the origin of velocity anomalies can be obtained by comparison of P- and S-velocity models (Wentzcovitch et al. 2006). Previous tomographic studies have reported large S-to-P velocity ratio in the lowermost mantle based mainly on normal modes, which can constrain the large-scale structure of the mantle (e.g., Masters et al. 2000; Koelemeijer et al. 2018). There are, however, few local high-resolution models of the 3-D P- and S-velocity structure of the lowermost mantle due to the difficulty of measuring the arrival-time of the small-amplitude PcP phase. Since waveform inversion does not require measuring arrival times, it might provide a more robust way of using the PcP phase to constrain the high-resolution structure of the lowermost mantle. In this study, we use ~7000 transverse component and ~7000 vertical component records from ~38 intermediate and deep-focus earthquakes in South-America recorded at USArray stations between 2004–2015. The records are cut ~10 s before the arrival of the P (S) phase, and ~40 s after the arrival of the PcP (ScS) phase. Resolution tests shows that we can resolve separately the P- and S-velocity structure of the lowermost mantle on scales less than ~300 km. Our preliminary results show a relatively good correlation between S- and P-wave anomalies on small-scales, with a large S-to-P velocity ratio in the range 100–300 km above the CMB, and a smaller ratio 0–100 km above the CMB, in general agreement with the results of Koelemeijer et al. (2018).

Uniaxial deformation experiments of bridgmanite using D-111 type high pressure apparatus

*Noriyoshi Tsujino[1], Daisuke Yamazaki[1], Yu Nishihara[2]

1. Institute for Planetary Materials, Okayama University, 2. Geodynamics Research Center, Ehime University

One dimensional viscosity models of the Earth’s mantle proposed by geophysical observations suggested that the lower mantle had the largest viscosity in the Earth’s mantle. In order to understand mantle dynamics in the Earth’s interior, it is important to know the viscosity of the Earth’s lower mantle. However, there are large variations of viscosity in the lower mantle between suggested models because of limitation of locations for geophysical observations. Therefore it is important to determine viscosity of lower mantle minerals by high pressure experiments in order to discuss mantle dynamics. Bridgmanite would be the most abundant mineral in the lower mantle. This mineral could dominate the lower mantle viscosity. In this study, we conducted in-situ stress-strain measurements of uniaxial deformation experiments of bridgmanite aggregate using D-111 type high pressure apparatus.
In-situ measurements were conducted using MAX III with D111 type guide block at PF-AR NE7A beam line. Mg-pure bridgmanite aggregates were used as starting material. Experimental conditions are 1473-1673 K and 24-27 GPa. WC second cubic anvils with cone (6.5˚) to take 2D X-ray diffraction, was used along X-ray path. Two-dimensional X-ray diffraction patterns were corrected for 240 s using flat panel detector. To calculate pressure and the stress magnitude of bridgmanite, (112) X-ray diffraction peaks were used. Strain of bridgmanite was measured by X-ray radiographies taken using an imaging system composed of a YAG crystal and a CMOS camera.
Largest strain was reached to approximately 20 %. It is confirmed that strain rate can be well controlled using stroke speed of differential rams. Steady state creep were observed at 1473 K –1673 K and 5 $\times 10^{-6}$ –3.8 $\times 10^{-5}$ /s. At normalized strain (10^{-5} /s), the creep strength of bridgmanite in this study is the largest in constituent mantle minerals reported by D-DAI apparatus.

Waveform inversion for 3D anisotropic structure in D″ beneath the Northern Pacific: Constraints on mineralogy and flow in the lowermost mantle

*Yuki Suzuki[1], Kenji Kawai[1], Robert J. Geller[1]

1. Department of Earth and Planetary Sciences, School of Science,The University of Tokyo

The D″ region is the lowermost several hundred km of the mantle immediately above the core-mantle boundary (CMB) and its base is in contact with the liquid outer core composed of iron alloy. Since the D″ region is the thermal boundary layer (TBL) at the base of the Earth's mantle, and the solidus of its constituent materials is thought to be close to the mantle geotherm, vertical and lateral variations of temperature and chemical composition associated with the Earth's thermal evolution are expected. Since chemically and thermally distinct subducted slabs would interact with the hot TBL above the CMB, and disturb the lowermost mantle, understanding the thermal and chemical evolution processes of the D″ region under subduction zones is essential to better understand the Earth's evolution.
The D″ region beneath the northern Pacific is of particular geodynamical interest because the paleo-Izanagi and present Pacific plates have been subducting beneath the northwestern margin of Laurentia since ~250 million years ago (Müller et al. 2016), which implies that paleoslabs could have reached the lowermost mantle. Suzuki et al. (2016) inferred the detailed three-dimensional S-velocity structure in the lowermost 400 km of the mantle beneath the northern Pacific. They hypothesized a prominent sheet-like lateral high-velocity, interpreted as paleoslabs, and a prominent low-velocity anomaly block immediately above the CMB below the high-velocity anomalies, which they interpreted as a TBL. In order to verify the above hypothesis and obtain geodynamical information, we infer 3D anisotropic structure beneath the northern Pacific in this study.
We conduct waveform inversion (Kawai et al. 2014) to infer the variation of the values of the TI (transverse isotropic, i.e. radial anisotropic) elastic constants L and N (Note that L is related to V_{SV} and N is related to V_{SH} when the shear wave propagates horizontally) straightforwardly in the lowermost mantle beneath the Northern Pacific, using a total of ~18,000 (~9,000 transverse and ~9,000 radial component) broadband body-wave seismograms. We used deep- and intermediate-focus events recorded at epicentral distances 70 to100 degrees at seismic stations of the USArray. The data are filtered in the period range of 20 to 200 s (i.e. 0.005 to 0.05 Hz) using a Butterworth bandpass filter. By using an S/ScS time window which is sensitive to the D″ structure we could image small-scale structure with finer resolution than previous tomographic studies.
The observed anisotropy is interpreted as due to the deformation-induced alignment of crystal caused by mantle flow for either Mg-perovskite (Mg-Pv), Mg-post-Perovskite (Mg-pPv), Ferro-periclase (Fp) or a combination thereof. In order to relate the flow geometry to the anisotropic geometry, we assume the dominant glide system and elastic constants of each mineral under the lowermost mantle condition based on high pressure experiment and theoretical calculation studies (e.g., Tsujino et al. 2016, Yamazaki et al. 2006 for deformation experiments; Wentzcovich et al. 2006 for ab initio calculation). We interpret the inferred 3D anisotropic structure based on above assumption, and we find the horizontal flow which could be related to subducted paleo-slabs is dominant in this region, and we also find vertical flow which could be related to the plume induced by slab sinking.

Maximum water solubility of bridgmanite under the Earth's lower mantle conditions

*Sho Kakizawa[1], Toru Inoue[1,2,3], Ryotaro Abe[1], Minami Kuroda[4], Naoya Sakamoto[5], Hisayoshi Yurimoto[4,5,6]

The Earth initially contained ~2 wt% H_2O, if it was formed by the mixture of C1 chondrite and enstatite chondrite [Ringwood, 1977]. However, the mass of the Earth's ocean is only 0.02 wt% of that of the Earth. Thus, most of the H_2O or molecular H may have been lost from the Earth since then, or it may still be stored in the Earth's deep interior. Water significantly influences the physical and chemical properties of the mantle minerals and rocks. Therefore, it is important to clarify the effect of water to understand the evolution and dynamics of the Earth. A part of water in the deep mantle can be dissolved in nominally anhydrous minerals. Wadsleyite and ringwoodite which are the major constituent minerals in the mantle transition zone, can contain ~2-3 wt% H_2O [e.g., Inoue et al., 1995; Kohlstedt et al., 1996]. On the other hand, water solubility of bridgmanite which is the most abundant mineral in the lower mantle, is a matter of debate [e.g., Bolfan-Casanova et al., 2004; Murakami et al., 2003]. Recently, Al-bearing hydrous bridgmanite contained ~0.8 wt% water was synthesized by Inoue et al. (under review). This report suggests that lower mantle can become a water reservoir in the Earth. However, the effects of pressure and Fe content on maximum water solubility of Al-bearing bridgmanite have not been clarified yet.
To determine the maximum water solubility of Al-bearing hydrous bridgmanite, high pressure and high temperature experiments were conducted under the conditions of 25-48 GPa and 1600℃. The starting materials were prepared by the mixtures of MgO, SiO_2, $Mg(OH)_2$, and $Al(OH)_3$ reagents with clinochlore [$Mg_5Al_2Si_3O_{10}(OH)_8$], Fe-bearing natural chlorite [$Mg_{4.9}Al_{1.6}Si_{3.2}Fe_{0.3}O_{10}(OH)_8$], and Fe-bearing hydrous pyrolite compositions. The water contents of the recovered run products were measured by SIMS. The water contents of Al-bearing hydrous bridgmanite increased with increasing pressure, at least up to 48 GPa. This is considered to occur the following two hydrous coupling substitutions with increasing pressure: $Si^{4+} = Al^{3+} + H^+$ and $2Mg^{2+} = Al^{3+} + H^+ + V_{Mg}$. These substitutions were dominant at low Al content, and Tschermak substitution ($Mg^{2+} + Si^{4+} = 2Al^{3+}$) became dominant with increasing Al content above Al = ~0.1 per formula unit (pfu, O = 3). The water content decreased as a result of Tschermak substitution, thus the maximum water solubility of bridgmanite is expected to be about 1.0 wt% at Al = ~0.1 pfu. In addition, the water solubility of Al-bearing hydrous bridgmanite decreased in the presence of Fe, and it became clear that it depends on the amount of Al and Fe in bridgmanite. Because of these properties, the maximum water solubility of bridgmanite in pyrolite and MORB are expected to be ~0.1 and ~0.2 wt%, respectively. When ringwoodite with high H_2O content is subducted to the lower mantle, the dehydration would occur at the top of the lower mantle. The dehydrated water should decrease melting temperature of the surrounding rocks and generates magma. Moreover, when chlorite dominant rock with high Al and low Fe content is subducted to the lower mantle, water heterogeneity would be predicted in the lower mantle, because the water content of bridgmanite generated by chlorite is significantly higher than that generated by pyrolite.

Origin and role of lost continents

*Shigenori Maruyama[1], Kenji Kawai[2], Steeve Gréaux[3], Taku Tsuchiya[3], Dapeng Zhao[4]

1. Earth-Life Science Institute, Tokyo Institute of Technology, 2. Department of Earth and Planetary Science, School of Science, University of Tokyo, 3. Ehime University, 4. Department of Geophysics, Tohoku University

<Purpose>

Continental crust had long been regarded that it cannot subduct into mantle forever because of lower density. If so, the Earth must have extraordinary thick continental crust over 300km in thickness. But, of course, not. We elucidate where continental curst has gone?

<Method>

Recently, on-going process of direct subduction of island arcs off Japan was reported (Yamamoto et al., 2007), as well as tectonic erosion of hanging wall of continental crust (von Huene and Scholl, 1991), the physical process by numerical simulation (Ichikawa et al., 2009), the presence of abundant TTG materials in MTZ (Kawai et al., 2013), and spatial distribution of the second continents in the MTZ over the world (Maruyama et al., 2008).

<Result>

We revealed continental curst is subducted into mantle and accumulated as “lost continent”. The estimated mass of the lost continent in MTZ (depth range of 520-660km) is 7.5 times more than total volume of TTG crust on the surface Kawai et al (2009; 2013), and the existing material is expected to be TTG, not MORB or harzuburgite based on seismology. Kawai et al. (2007) also predicted that D” layer ca. 300km thick right above CMB could be another lost continent, which anorthosite and KREEP dominated. However, this idea cannot explain reasonable enough that the density of KREEP basalt is close to that of surrounding peridotites. According to more recent estimate by Greaux et al. (2018), lost continent on CMB is expected to be fractionated KREEP and anorthosite. If KREEP lower crust of the Hadean continent subducted and segregated at 660km depth, these material could be falling preferentially into lower mantle, and they must have been accumulated on the CMB.

<Discussion>

It is pointed out that those lost continents may have played critical role for the thermal history of Earth, because most radiogenic elements such as U, Th, and K were predominantly concentrated into the primordial continents, whereas these elements were rare in the mantle. Radiogenic elements contained in lost continents must have contributed as the heat generator of the inner Earth and controlled thermal history of the Earth. One of the most significant next research targets is to conduct the quantitative estimates of lost continent. The idea of lost continents would change the concept of mantle dynamics.

Thermal conductivity anomaly in spin-crossover ferropericlase under lower mantle conditions

*Zhongqing Wu[1]

1. University of Science and Technology of China

Thermal conductivity of the mantle minerals is one of the key parameters that control mantle convection. The heat flux from the core, which is determined by the heat conductivity of the thin layer overlying the core-mantle boundary (CMB), is critical to the understanding of many processes such as the Earth’s evolution, mantle convection, and geodynamo. Iron in ferropericlase experiences a spin crossover from a high spin to a low spin under lower mantle conditions, which generates anomalies in many properties such as the heat capacity and sound velocity (Wu et al., 2009, 2013). Since the thermal conductivity is proportional to the heat capacity and the square of the sound velocity, the spin-state crossover of iron in the lower mantle minerals may profoundly affect the lattice thermal conductivity of the lower mantle. However, knowledge of the spin-crossover effect on the lattice thermal conductivity is very limited.

Here, I found that the spin crossover completely changes the conventional pressure and temperature dependences of the thermal conductivity. The pressure dependence of the thermal conductivity of ferropericlase will show a double-valley feature across the spin-crossover region. Thermal conductivity of ferropericalse may increase with the temperature in some temperature region. The spin crossover can explain the anomalous reduction in thermal conductivity of ferropericlase observed recently by Ohta et al (2017) in the spin crossover region. The unusual effect of spin crossover on the thermal conductivity can be expected in other minerals with spin crossover. Since the spin-crossover region of ferropericlase covers the CMB conditions, the spin crossover effect needs serious consideration when estimating the thermal conductivity at the core-mantle boundary

Ab initio anharmonic lattice dynamics for Fe-bearing lower mantle minerals

*Haruhiko Dekura[1], Taku Tsuchiya[1]

1. Geodynamics Research Center, Ehime University

Determination of lattice thermal conductivity (κ_{lat}) of lower mantle (LM) minerals is a key to understanding the dynamics and evolution of the earth’ s deep interior. Some recent experimental studies have shown that κ_{lat} of MgO and $MgSiO_3$ bridgmanite (Brg) are substantially reduced by Fe incorporation (Manthilake et al., 2012; Goncharov et al., 2015; Ohta et al., 2017; Hsieh et al., 2017). In contrast, Okuda et al. (2017) reported a very different result on Brg with a marginal effect of Fe. Besides, the effect of Fe on $MgSiO_3$ post-perovskite (PPv) has never been reported. Therefore, in this study, we investigate κ_{lat} of Fe-bearing LM minerals (ferropericlase (FP), Brg, and PPv) in the LM pressure and temperature conditions, based on the *ab initio* anharmonic lattice dynamics techniques with fully solving the phonon Boltzmann transport equation (Dekura and Tsuchiya, 2017) combined with the internally consistent LDA+*U* technique for more precisely describing the Fe-O bond (Wang et al., 2015). Calculations demonstrate strong negative solid solution effects of low-spin Fe on κ_{lat} of FP and high-spin Fe on κ_{lat} of Brg and PPv, as a linear decrease in log κ_{lat} of FP with increasing the Fe concentration. Our detailed analyses indicate that such strong effects occur primarily due to the substantial changes in harmonic properties and are found to be Brg > PPv >FP. The present results improve the conventional estimation of the effective LM conductivity (e.g., Stacey 1992). It is estimated to be ~2-3 $Wm^{-1}K^{-1}$ for the pyrolytic aggregate (FP + Brg) and ~4-5 $Wm^{-1}K^{-1}$ (FP+PPv) at 136 GPa and 4000 K, which are ~60-80% smaller than the conventional value of 10 $Wm^{-1}K^{-1}$.

Measurements of high pressure-temperature thermal conductivity of the Earth's lower mantle minerals in a laser-heated diamond anvil cell

*Kenji Ohta[1], Akira Hasegawa[1,2], Takashi Yagi[2], Yoshiyuki Okuda[1], Koutarou Onga[1], Kei Hirose[3,4], Yasuo Ohishi[5]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. National Metrology Institute of Japan, National Institute of Advanced Industrial Science and Technology, 3. Earth-Life Science Institute, Tokyo Institute of Technology, 4. Department of Earth and Planetary Science, The University of Tokyo, 5. Japan Synchrotron Radiation Research Institute

The thermal transport properties of the Earth's constituents are important information to understand thermal evolution and the heat budget of the Earth. Thus, the experimental determination of thermal conductivity of deep Earth materials are required. The diamond anvil cell (DAC) is capable of accessing the pressure-temperature conditions of the Earth's deep interior, and is compatible with laser optical techniques. The pulsed light heating thermoreflectance (TR) method has been applied to a DAC in order to measure thermal conductivity and diffusivity of condensed material [1,2]. This TR with DAC method successfully obtained the thermal conductivity of the Earth's lower mantle minerals to the pressure condition equal to the Earth's core-mantle boundary (135 GPa) but at room temperature [3]. To extend measurable temperature range, the TR method may be combined with a laser-heated DAC (LHDAC) technique that is able to generate the pressure-temperature condition equivalent to the center of the Earth.

We recently developed a new instrument to measure the thermal diffusivity (and thus thermal conductivity) of sample *in-situ* at high pressure and temperature based on the combination of the TR method and the LHDAC system. We use a double-sided high-power CW laser heating technique to generate stable high temperature conditions of sample in a DAC. A pulsed pump laser and a CW probe laser are also irradiated to the sample to determine heat diffusion time through the sample via the thermoreflectance phenomena. Details of the thermoreflectance technique in a DAC may be found in our previous studies [2]. Using the developed method, we measured the thermal conductivity of the main minerals in the Earth's lower mantle, MgO periclase, $MgSiO_3$ bridgmanite, post-perovskite and $CaSiO_3$ perovskite *in-situ* at high pressures and high temperatures. These are the first experimental demonstrations of thermal conductivity of the lower mantle minerals at the conditions below the mid-part of the Earth's lower mantle. The new thermal conductivity measurement system will shed light on the controversial thermal transport properties of the Earth's deep interior [4].

Is there evidence for a paleo-LLSVP beneath Eurasia?: Implications for the origin of the Siberian Traps

*Tsubasa Ue[1], Yuki Suzuki[1], Kenji Kawai[1]

1. Department of Earth and Planetary Sciences, Graduate School of Science, The University of Tokyo

The massive eruption during the latest Permian, which precipitated the Earth's most severe known extinction event, is one of the largest known volcanic events on Earth. However, the cause of the active volcanism remains incompletely understood. Recent seismological analysis has revealed that currently active volcanoes are related to seismic low-velocity anomalies which are almost vertically continuous from the core-mantle boundary (CMB) to shallow depths. Here we infer the seismic velocity structure beneath Eurasia in order to confirm whether formerly active volcanism is also related to a mantle upwelling.

We apply the 3-D localized waveform inversion methods to about 5,500 transverse-component of broadband body-wave seismograms observed at Japan for 3 intermediate and deep earthquakes occurred in Europe, European stations for 116 events occurred beneath the western Pacific subduction zone and Canadian stations for 5 events occurred beneath the Hindu Kush. We use waveform data obtained from the National Research Institute for Earth Science and Disaster Prevention (NIED), Observation & Research Facilities for European Seismology (ORFEUS) and Canadian National Data Centre (CNDC).

We found a high-velocity anomaly about 100 km above the CMB beneath Lake Baikal and two low-velocity anomalies immediately above the CMB beneath the cities of Perm and Irkutsk, Russia, respectively. Plate reconstructions show there are some large igneous provinces (LIPs) and slab remnants beneath Eurasia. Our results suggest two scenarios: one where two low-velocity anomalies used to be united and larger than present size but divided and weakened by the subducted cold slab and another where two low-velocity anomalies were originally separated with each other and became different LIPs. In either case, our findings suggest that the cause of a massive eruption during the latest Permian was a plume upwelling from the CMB.

Possible compositional region of Al-bearing anhydrous bridgmanite

*Toru Inoue[1,2], Masamichi Noda[2], Sho Kakizawa[2]

1. Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University, 2. Geodynamics Research Center, Ehime University

Bridgmanite should be a major constituent mineral in the Earth's lower mantle, and Irifune (1994) reported that bridgmanite can incorporate almost Al_2O_3 component in lower mantle. The Al substitution mechanism is supposed to be complicated, because there are two types of Al substitution mechanisms in anhydrous bridgmanite, Tschermak and oxygen vacancy substitutions (e.g. Kojitani et al., 2007). However, the pure Tschermak and oxygen vacancy substitutions bridgmanite has not been reported so far in low Al content, when we checked the previous studies carefully (e.g. Irifune et al, 1996; Kubo and Akaogi, 2000). The previous studies have used powder samples as the starting materials, so we considered that the absorbed water may affect the results, because we have a knowledge of the possible existence of hydrous bridgmanite which has a water content of ~0.8 wt%. Therefore, we tried to investigate the possible existence of the Al substitution mechanism in bridgmanite as a function of Al content in extremely anhydrous condition.

The high pressure experiments were conducted at 28 GPa and 1600-1700℃ for 1 hour using a Kawai type apparatus. Some different Al content samples were prepared as the starting materials along the ideal substitution line of Tschermak and oxygen vacancy substitutions, respectively. Glass rods were used as the starting materials to eliminate the absorbed water on the sample surface. Moreover, the glass rods were enclosed in a rhenium capsule to prevent the water incorporation from the surrounding cell assembly. In addition, all parts of the cell assembly were dried just before the synthesis experiments. The chemical compositions of the starting materials were examined by SEM-EDS, and the recovered samples were identified by X-ray and neutron (in J-PARC) diffractions and SEM-EDS.

Our results show that it is possible to exist both Tschermak and oxygen vacancy substitution bridgmanites in low Al content in anhydrous condition. The maximum Al content for pure oxygen vacancy substitution bridgmanite was ~0.025 pfu in total cation of 2, and the existence of oxygen vacancy substitution component was restricted to be less than Al=~0.1 pfu. The present result combining with our previous study in hydrous condition, shows that hydration in Al-bearing bridgmanite should occur easily if hydrogen exists in the system (lower mantle) in pyrolite (MgO-excess) composition. Thus the large deviation from the Tschermak substitution in the previous studies mainly should come from the hydration from the absorbed water.

[S-IT21] Interaction and Coevolution of the Core and Mantle in the Earth and Planets

convener:Kenji Kawai(Department of Earth and Planetary Science, School of Science, University of Tokyo), Tsuyoshi Iizuka(University of Tokyo), Kenji Ohta(Department of Earth and Planetary Sciences, Tokyo Institute of Technology), Taku Tsuchiya(Geodynamics Research Center, Ehime University), Chairperson:Hitoshi Gomi, Tsuyoshi Iizuka

Recent observational and experimental investigations have significantly advanced our understanding of the structure and constituent materials of the deep Earth. Yet, even fundamental properties intimately linked with formation and evolution of the planet, such as details of the chemical heterogeneity in the mantle and light elements dissolved in the core, remained unclear. Seismological evidence has suggested a vigorous convection in the lower mantle, whereas geochemistry has suggested the presence of stable regions there that hold ancient chemical signatures. The amounts of radioactive isotopes that act as heat sources and drive dynamic behaviors of the deep Earth are also still largely unknown. We provide an opportunity to exchange the achievements and ideas, and encourage persons who try to elucidate these unsolved issues of the core-mantle evolution using various methods, including high-pressure and high-temperature experiments, high-precision geochemical and paleomagnetic analyses, high-resolution geophysical observations, geo-neutrino observations, and large-scale numerical simulations. Papers stimulating an interdisciplinary collaboration relating to establishment of the Japan-SEDI community are also welcomed.

The rate and style of mantle convection, as well as production and recycling of crust into the mantle, control the evolution of the Earth. Present knowledge of mantle evolution is mostly restricted to the Phanerozoic, for which fresh mantle-derived lavas and relevant geophysical data are available. Information about the Precambrian mantle comes almost entirely from the compositions of altered rocks, which lack data on the contents of mobile and volatile elements and their isotopes. Such data are crucial for geodynamic reconstructions and understanding of surface rock recycling into the deep mantle. Fortunately, this information is preserved within inclusions of melt in relicts of olivine phenocrysts in komatiites.

In this presentation we will address the compositional evolution of the terrestrial mantle, from the Archean to the Phanerozoic, using compositions and temperatures of primary mantle-derived melts reconstructed from the study of melt inclusions and host olivine. We will report an extensive range of geochemical parameters, including mobile and volatile element (Pb, B, Rb, Ba, Sr, Cl, S, H2O, CO2) concentrations and isotopic compositions of H in homogenized melt inclusions and the elemental compositions of host olivines and inclusions of spinel. We will present data for komatiites and picrites that originated at different depths and cratons between 3.3 and 0.09 Ga. We will apply published and new models to constrain the temperatures and compositions of their mantle sources to relate our observations to the evolution of mantle convection and plate tectonics. We will, therefore, address the following issues: the rate of crustal growth and recycling through time; the timing of the onset of large-scale subduction and plate tectonics; the concentration and origin of H2O and halogens in the deep mantle, and the extent (if any) of core-mantle interaction.

We will present evidence of the significant excess of H2O and Cl in the mantle sources of komatiites and will show that hydrogen isotope composition of komatiites is significantly more depleted in deuterium than all surface reservoirs and typical mantle but resembles that in dehydrated subducted slabs. We will demonstrate temporal trends of Pb/Ce and oxygen fugacity of primary komatiite melts.

Our results suggest that lithosphere recycling into the deep mantle, arguably via subduction, started before 3.3 Ga and interaction of mantle and core probably took place all this time.

The core–mantle boundary (CMB) is the most fundamental chemical discontinuity in the Earth. Recent experiments showed that, when water meets iron at the CMB, hydrogen-bearing iron peroxide FeO_2H_x can be produced. The results indicate that water can interact with iron metal very differently than it does on the surface of the earth. Seismic waves speeds in this hydrogen bearing iron peroxide are much slower compared with lower-mantle silicate solid phases, and therefore it may help explain the seismic anomalies at the CMB.

Given the steep geothermal gradient across the CMB, the hydrogen-bearing iron peroxide FeO_2H_x likely undergoes high-temperature decomposition into anhydrous iron oxides (e.g., Fe_2O_3) and fluids. We measured the sound velocity of Fe_2O_3 post-perovskite (ppv) through inelastic X-ray scattering up to 132 GPa and 1,800 K, relevant to the lowermost mantle. Combined with first-principles investigations, we are able to show that Fe_2O_3 ppv has very low sound velocities and strong anisotropy with respect to lower-mantle silicates. Therefore, both hydrogen-bearing iron peroxide FeO_2H_x and post-perovskite Fe_2O_3 are candidate phases for ultralow-velocity zones at the CMB.

Funding acknowledgment: This work was supported by the JSPS Japanese–German Graduate Externship.

High-precision $^{142}W/^{144}W$ ratios of oceanic island basalts and Large Igneous Province basalts.

Asako Takamasa[1], *Katsuhiko Suzuki[1], Yusuke Fukami[2], Tsuyoshi Iizuka[3]

1. Research and Development Center for Submarine Resources, Japan Agency for Marine-Earth Science and Technology, 2. Department of Subsurface Geobiological Analysis and Research, Japan Agency for Marine-Earth Science and Technology, 3. Graduate School of Science, The University of Tokyo

Among five W isotopes, ^{182}W is a product of b-decay of ^{182}Hf with the relatively short half life of 8.9 m.y. As Hf and W are lithophile and siderophile, respectively, the ^{182}Hf-^{182}W radiometric system could constrain metal-silicate (core-mantle) differentiation, especially core segregation, in the very early Earth system because of its large fractionation between metal-silicate and the short half life of ^{182}Hf. Recent improvements of analytical techniques of W isotope analyses using TIMS and MC-ICP-MS equipped with a desolvating device allow to obtain highly precise $^{182}W/^{184}W$ ratios of terrestrial rocks. These led to findings of $m^{182}W$ anomalies (mostly positive) in old komatiites (2.4 –3.8 Ga) and young volcanic rocks with positive anomalies of 12 Ma Ontong Java Plateau and 6 Ma Baffin Bay (Rizo et al., 2016) and with negative anomalies of those such as the Loihi and Samoa basalts (Mundl et al., 2017). Recently, Kruijer and Kleine (2018) proposed that the ^{182}W excesses for an OJP sample by Rizo et al. (2016) may result from the nuclear field shift effect leading to defect of ^{183}W, as the NTIMS analyses utilized a double normalization involving the $^{183}W/^{184}W$ ratio.

In our study, high-precision W isotope ratio measurement with MC-ICP-MS (Thermo co. Ltd., NEPTUNE PLUS) equipped with desolvating nebulizer (ARIDAS II) following the chemical separation using both cation and anion exchange resin has been developed. We have measured the W standard solution (SRM 3163) and obtained the isotopic compositions with a precision of ±5ppm. However, the standard solution, which was processed by the cation or anion exchange chemistry in the same way as for rock samples, has systematic $^{182}W/^{184}W$ drift of -5ppm, which was also observed by Willbold et al. (2011) and Kruijer and Kleine (2018). This shift likely resulted from the nuclear field shift effect as mentioned by Kruijer and Kleine (2018). Therefore, we corrected the measured W isotope ratios of samples with the standard solution processed by the same method as that of the samples. This technique led to obtaining of the W isotopic compositions with reproducibility of several ppm. We have obtained negative $\mu^{182}W$ for the basalts with the high $^{3}He/^{4}He$ isotopic composition from the Loihi, Hawaii, through the developed analytical method. This result is consistent with that of Mundl et al., (2017). As the Earth’s core should have a negative $\mu^{182}W$ value of ca. -210, the Loihi sample we analyzed probably contains a component with a signature of core-mantle interaction. We have obtained the high-precision W isotope data for the fresh drilled basalts from Louisville. Louisville is known to have been originated from the primordial deep mantle source. We will discuss the obtained results and the early evolution of the deep mantle.

Acknowledgement –JSPS Grant-in-Aid has supported this project. We are grateful to M. Kawamura for experimental help and Y. Orihashi, T. Hanyu, M. Tejada for providing samples.

Hakubi Center/ Graduate School of Human and Environmental Studies, Kyoto University, 4. Research & Utilization Division, Japan Synchrotron Research Institute, 5. Graduate School of Science, Tohoku University, 6. Institute of Super Hard Materials, Jilin University

Technological developments in stable and homogeneous high temperature generation have been made using conventional $LaCrO_3$ or Re heater for Kawai-type multianvil apparatus (KMA) with tungusten carbide (WC) and sintered diamond (SD) anvils. For WC-KMA, stable temeperature generation to ~3000 K has been achieved under the pressures up to ~27 GPa mainly for quench experiments. Temperatures of ~2000-2300 K have been produced stably for 20-180 minutes at pressures to ~65 GPa for *in situ* X-ray measurements using SD-KMA, in addition to the *ex situ* experiments.

Some experimental studies for precise determination of subsolidus and melting phase relations have successfully been made for some simple mineral systems, such as $MgSiO_3$-Al_2O_3, $MgSiO_3$-$FeSiO_3$, $MgSiO_3$-$CaSiO_3$, $CaSiO_3$-SiO_2, Al_2O_3-SiO_2, $KAlSi_3O_8$-$NaAlSi_3O_8$, Al_2SiO_5, $Ca_3Al_2Si_3O_{12}$, etc. at temperatures near and above the typical geotherm at pressures corresponding to those of the mantle transition region to the middle part of the lower mantle. These studies have provided firm experimental databases for the mineralogy of the deep mantle, and also led to findings of some new high-pressure phases stable only under the very high-temperture conditions. Melting and associated partioning of some key trace elements in more complex chemical compositions have also been conducted under the pressures of the uppermost lower manlte to constrain the differentiation and evolution of the deep mantle.

Zr isotope constraints on early Earth differentiation

*Tsuyoshi Iizuka[1], Keita Itano[1], Shinji Yamamoto[2]

1. University of Tokyo, 2. Yokohama National University

The radionuclide 92Nb decays to 92Zr with a half-life of 37 Ma [1]. Because Nb and Zr can fractionate from each other during partial melting of the mantle and mineral crystallization as well as metal-silicate differentiation, Nb-Zr isotope systematics can potentially place chronological constraints on early planetary differentiation. Considering the initial abundance of 92Nb in the solar system (92Nb/93Nb = 1.7 ×10-5), yet, the possible Zr isotopic variation on the Earth would be highly restricted [2]. For instance, even a 4.53 Ga reservoir having a Nb/Zr ratio four times higher than that of CHUR is expected to display a 92Zr anomaly of only +10 ppm. Such reservoir with an elevated Nb/Zr ratio might be formed if Fe-Ti oxide and sulfide minerals presented as a liquidus phase during differentiation on the infant Earth.
Here we report our search for a Zr isotopic vestige of early Earth differentiation using ancient terrestrial zircons. Zirconium isotopic ratios in single zircon grains were measured using MC-ICP-MS with the desolvating nebulization technique, which allows us to achieve analytical precision of ±˜10 ppm. So far, the high-precision Zr isotopic analysis has been applied to detrital zircons with ages up to 4.3 Ga from the Jack Hills in the Yilgarn Craton, Western Australia and igneous zircons from the 4.0–3.6 Ga orthogneisses in the Acasta Gneiss Complex, northwestern Canada. These Acasta rock samples were previously studied for zircon Lu–Hf isotope systematics and the results indicated that their magmatic sources contained Hadean crustal components [3]. Our Zr isotopic data for the Jack Hills and Acasta zircons display no 92Zr anomalies larger than 10 ppm. By combining the Hf isotopic data for these zircon grain, we indicate the development of a 4.5 Ga enriched reservoir on the Earth that had a Lu/Hf of 0.07 and a Nb/Zr less than 0.4. Such reservoir could form via fractional crystallization processes within the shallow or upper mantle.

[S-IT21] Interaction and Coevolution of the Core and Mantle in the Earth and Planets

convener:Kenji Kawai(Department of Earth and Planetary Science, School of Science, University of Tokyo), Tsuyoshi Iizuka(University of Tokyo), Kenji Ohta(Department of Earth and Planetary Sciences, Tokyo Institute of Technology), Taku Tsuchiya(Geodynamics Research Center, Ehime University)

Recent observational and experimental investigations have significantly advanced our understanding of the structure and constituent materials of the deep Earth. Yet, even fundamental properties intimately linked with formation and evolution of the planet, such as details of the chemical heterogeneity in the mantle and light elements dissolved in the core, remained unclear. Seismological evidence has suggested a vigorous convection in the lower mantle, whereas geochemistry has suggested the presence of stable regions there that hold ancient chemical signatures. The amounts of radioactive isotopes that act as heat sources and drive dynamic behaviors of the deep Earth are also still largely unknown. We provide an opportunity to exchange the achievements and ideas, and encourage persons who try to elucidate these unsolved issues of the core-mantle evolution using various methods, including high-pressure and high-temperature experiments, high-precision geochemical and paleomagnetic analyses, high-resolution geophysical observations, geo-neutrino observations, and large-scale numerical simulations. Papers stimulating an interdisciplinary collaboration relating to establishment of the Japan-SEDI community are also welcomed.

Sample-scale compositional variation of the Inada granite, Ibaraki, Japan -toward the reduction of geoneutrino flux estimation errors from the Japanese crust-

*Kenta Ueki[1], Minami Kazuki[2], Tsuyoshi Iizuka[3], Sanshiro Enomoto[4], Hiroyuki Tanaka[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Earthquake Research Institute, University of Tokyo, 3. Department of Earth and Planetary Science, University of Tokyo, 4. Center for Experimental Nuclear Physics and Astrophysics, University of Washington

Geoneutrio observed at anti-neutrino observatory "KamLAND" in Kamioka (Hida City, Gifu Prefecture), enables us to directly observe the abundance of radiogenic elements in the deep earth. As crustal rocks exhibit a high concentration of geoneutrino producing radiogenic elements (Uranium and Thorium) than mantle rocks, we have to subtract the contribution of geoneutrino from the Japanese crust from the observation value in Kamioka to estimate geoneutrino flux from core and mantle. For the purpose, we estimated the 3D distribution of uranium and thorium in the Japanese crust by the stochastic modeling using the seismic velocity structure, geological information and geochemical database for the Japanese crustal rock. Geoneutrino flux calculated using the compositional map exhibits a very large error (up to 80%) at present.
We found that information on the compositional heterogeneity (spatial correlation) of various length scale, such as of the single rock suite scale (km to m scale), and sample scale (cm to mm scale) are essential to reduce the estimation error of crustal geoneutrino flux as small as the observation error of the geoneutrino on KamLAND. Therefore, we conducted a grid sampling of the granite of Inada, Ibaraki prefecture, to obtain quantitative knowledge on the small scale compositional heterogeneity. Samples (about 500g) were divided into several centimeter scale split (about 25g). Based on the compositional variations between small splits from one sample, we discuss the small scale sample wise compositional variation. Whole rock chemical composition of each small split was analyzed using XRF. Also, we conducted surface analysis using an ED-XRF to evaluate the spatial distribution of elements in each split. As a result, even within a single sample (about 500g), a compositional variation of about several% at maximum was observed. This result indicates that when conducting the analysis based on the rock chemical composition considering the spatial context, it is necessary to properly evaluate the sample scale heterogeneity, in addition to the tectonic scale, the rock suite scale, and microscopic scale.Also, this result will contribute to the reduction of the estimation error of geoneutrino from the Japanese crust.

National Research Institute for Earth Science and Disaster Resilience

To improve our understanding of the thermal evolution and structure of the deep Earth, it is necessary to know the shallow part of them. Surface heat flow provides important constraint on it. However, the number of heat flow data is limited and spatially very inhomogeneous and even in regions with measurements the data quality varies. For this reason, we have been working on compiling a comprehensive database of heat flow, thermal conductivity, and geothermal gradient. In 2004, Geological Survey of Japan published a digital geoscience map entitled "Geothermal Gradient and Heat Flow Data in and around Japan", which contains heat flow data in the northwestern Pacific area (from 0 to 60°N and from 120 to 160°E) and geothermal gradient data in and around Japan. In 2019, we will be releasing database entitled "Thermal Data Collection in and around Japan", which contains continuously updated of geothermal gradient and heat flow data and adds thermal conductivity data in and around Japan. Thermal conductivity data were compiled from published data and site-specific reports, and measured using the archived cores. This database offers considerable improvements over the previous version released in 2004, and will be published and available at https://www.gsj.jp/en/database/db-portal/index.html. It presents an opportunity to revisit the thermal state of the lithosphere along with other geophysical/geochemical constraints on heat flow extrapolation.

The estimation of the neutrino flux from the crust of the Japanese islands using the geochemical database

*Satoru Haraguchi[1], Kenta Ueki[1], Hikaru Iwamori[1,2,3]

1. Japan Agency for Marine-Earth Science and Technology, 2. Earthquake Research Institute, the University of Tokyo, 3. Tokyo Institute of Technology

Geoneutrino observed at the anti-neutrino observatory "KamLAND" at Kamioka allows us to obtain information on the amount and distribution of radiogenic elements (uranium and thorium) in the deep mantle and crust.. It is necessary to divide the contribution from Japanese from the observed neutrino flux on closely to precisely estimate the quantity of U, Th of the earth deep earth because such radiogenic elements exhibit high concentration in the crust. Previous estimation of the crust origin geoneutrino was estimated based on the relatively simple chemical assumption on the compositional variation and spatial distribution. However, the radioactive elements of the Japanese crustal rock are distributed with very wide compositional range with complex spatial distribution. Therefore, it is necessary to estimate spatial distribution of radioactive element in the Japanese crust for the precisely measurement of geoneutrino from Japanese crust. In addition, petrogical and geochemical structure of the Japanese crust of are fundamental information for understanding seismic activity, volcanic activity and tectonism. The analysis of the spatial variation of the chemical composition of the Japanese Islands crust is important in discussing about the evolution history of the Japanese Islands and the chemical evolution in the subduction zone.

In this study, we utilize DODAI to improve the estimation error of geoneutrino from the Japanese crust (Takeuchi et al., 2019). We published the database “DODAI” which compiled geochemical data published by the Japanese domestic journals and bulletins in the journal of the Geological Society of Japan (Haraguchi et al., 2018). This database incorporates the precise sampling position of individual geochemical data using an electronic map. Resolution of the positional information were improved drastically.
The "DODAI" database covers whole area of Japanese Islands with highly precise positional information is useful for data analysis and modeling. The geochemistry database with highly precise positional information is useful for modeling of the geochemical structure of the solid earth. In this study, we present the potential of the DODAI database and geoneutrion in the analysis of the geochemical structures of Japanese crust, as well as the deep earth.

Viscosity of potassium titanosilicate melt at high pressure

*Akio Suzuki[1]

1. Department of Earth Science, Graduate School of Science, Tohoku University

Viscosity of silicate melt is a fundamental property, which controls volcanic processes, including rates of melt extraction, ascent, and magma mixing. Titanium oxide is contained less than 10 wt% in terrestrial magmatic liquids, however, some lunar magmas contains it over 10 wt%. The addition of titanium to silicate melt affects on the properties such as viscosity, density, and compressibility. Especially the pressure dependence of viscosity is of great interest, because magma is generated in the planetary interiors. The aim of this study is to measure the viscosity of K2TiSi4O11 melt at high pressures to estimate the influence of the pressure-induced structural change of melt.
We performed in situ falling sphere viscometry in the pressure range from 1.3 to 7.4 GPa, by using the MAX-III high pressure apparatus at BL14C2 and NE7A beamlines at Photon Factory in KEK, Tsukuba, Japan. A falling platinum sphere in the melt was monitored by using an X-ray CCD camera with a YAG:Ce fluorescence screen. We observed that the viscosity of KTS4 melt decreased up to 3.3 GPa. In contrast, the pressure dependence in viscosity was not observed above 3.3 GPa. Based on XANES spectra of K2TiSi4O11 glasses quenched under high pressure, Paris et al. (1994) showed that the coordination number of titanium increased with increasing pressure. The present study suggests that the melt becomes depolymerized by the coordination change of titanium under high pressure.

Lattice thermal conductivity of wadsleyite and ringwoodite at the mantle transition zone pressures

*seiji kimura[1], Kenji Ohta[6], Takaaki Kawazoe[2], Kei Hirose[3], Hiroyuki Kagi[4], Takashi Yagi[5]

1. Department of Earth and Planetary Sciences Tokyo Institute of Technology, 2. Department of Earth and Planetary Systems Science, Hiroshima University, 3. Earth-Life Science Institute, Tokyo Institute of Technology, 4. Geochemical Research Center, Graduate School of Science, University of Tokyo, 5. National Institute of Advanced Industrial Science and Technology, 6. Department of Earth and Planetary Sciences, Tokyo Institute of Technology

The lattice thermal conductivities of wadsleyite (Wd) and ringwoodite (Rw), which predominantly occupy the Earth's mantle transition zone, are important transport properties to understand the dynamics and thermal structure of the mantle. In particular, the temperature in the subducting slab is mainly controlled by the thermal conduction of Wd and Rw. Wd and Rw are both thought to preserve a large amount of hydrogen ions, thus should play an important role as the main water reservoir in the Earth. Furthermore, it has been reported that the hydration affects the physical properties of minerals including thermal conductivity, and it is necessary to measure the lattice thermal conductivity of Wd and Rw considering their water content. However, so far, the reported lattice thermal conductivities of Wd and Rw has not been considered their water content (Xu et al., 2004). Here we measured the room temperature lattice thermal conductivity of $(Mg_{0.89}Fe_{0.11})_2SiO_4$ Wd and $(Mg_{0.91}Fe_{0.09})_2SiO_4$ Rw up to 27 GPa, respectively, to clarify their hydration dependence using the pulsed light heating thermoreflectance technique in a diamond anvil cell.The obtained results show similar pressure dependence of the lattice thermal conductivity to the previous study (Xu et al., 2004). However, the absolute values of the thermal conductivity are different; the lattice conductivities of hydrous Wd and Rd are ~52% and ~40% lower than the results of Xu et al. (2004), respectively. Our results suggest strong water content dependence of lattice thermal conductivities of Wd and Rw, implying that the water content in the mantle minerals is key factor for calculating the thermal structure in a subducting slab, mantle dynamics.

In-situ X-ray observations of the olivine-spinel transformation under shear deformation: preliminary results on the reaction-induced weakening

*Tomoaki Kubo[1], Moriyama Kazuya[1], Yuichiro Mori[1], Masahiro Imamura[1], Sanae Koizumi[2], Yu Nishihara[3], Akio Suzuki[4], Yuji Higo[5]

1. Kyushu Univ., 2. ERI, 3. GRC Ehime Univ., 4. Tohoku Univ., 5. JASRI

It has been suggested that high-pressure transformations cause rheological weakening and large deformation of subducting slabs in mantle transition zone (MTZ) . However, there have been few direct experimental evidences so far largely because of the difficulties in quantitative deformation experiments under such conitions. Here we report preliminary results on the olivine-spinel transformation experiments under shear deformation upto MTZ pressures. D-111 (DT-cup) type high-pressure deformation apparatus was newly used for this purpose combined with high-energy synchrotron mono X-rays (50-60 keV) at Photon Factory (PFAR NE7 beamline), which enables in-situ observations of interactions between transformation and creep behaviors. Sintered Mg_2SiO_4 forsterite was first deformed at 15-25 GPa at 600˚C in shear, and subsequently heated to higher temperatures (~0.2˚C/s) to cause the olivine-spinel transformation under shear deformation. The transformation started at much lower temperatures under shear deformation (~900-1100˚C depending on the overpressure from the phase boundary) compared to that without deformation (~1400˚C), suggesting that the shear deformation enhances the olivine-spinel transition rate. The shear strain rate in the sample monitored by X-ray radiography was ~3-4 x 10^{-6} (s^{-1}) at 600˚C, and increased up to ~2-3 x 10^{-4} (s^{-1}) with ramping temperatures even keeping the anvil displacement rate constant (200 micron/h). We observed that the shear weakening does not occur at the same temperature, but reflects on the initiation of the olivine transition. Also, the weakening effects become significant at larger overpressures (and low T). This implies that the weakening of the shear zone induced by the grain-size reduction due to the olivine-spinel transition, however further evidences from microstructural observations are necessary. We plan to install 8-ch acoustic emission measurement system attached with D-111 apparatus to capture the transformation-induced shear instabitiy. Results of D-DIA shear deformation study on the olivine-spinel transition in Fe_2SiO_4 will also be presented and compared with those of the D-111 study in Mg_2SiO_4 .

Internally resistive heated diamond anvil cell experiments with metal encapsulated minerals

*YAMAMOTO TOMONARI[1], Kenji Ohta[1], Sho Suehiro[1], Hayato Inoue[1]

1. Tokyo Institute of Technology

Heating technique is crucial for *in-situ* high pressure-temperature (*P-T*) studies into the physical and chemical properties of minerals in the diamond anvil cell (DAC) under deep Earth's conditions. External resistive heating methods that use resistive heaters such as AlChrom-O wire and graphite surrounding the DAC or just the diamonds (Dubrovinskaia and Dubrovinsky, 2003; Du et al., 2013). This approach creates a homogeneous temperature field in the sample chamber but limits the maximum temperature of about 1200℃ due to graphitization of diamond anvils. Double-sided laser heating with a DAC generates the *P-T* conditions corresponding to the center of the Earth's (Tateno et al., 2010). However, tightly focused laser beams, instabilities in output laser power and misalignment of the focused beams on the sample surface result in significant temperature variation within the sample in the DAC. Internally resistive heated DAC is an effective heating method to overcome the temperature limitation of external heated DAC and the significant temperature gradients experienced in conventional laser-heated DAC (e.g., Zha and Bassett, 2003). However, the internally resistive heated DAC is mostly applied to metal sample to study the properties of the planetary metallic core despite this technique could be applicable to an insulating mineral.

In this study, we modified the internally resistive heated DAC technique for nonmetallic material. We developed a microfabrication technique for total metal encapsulation of the nonmetallic sample. The sample encapsulated by platinum was loaded in DAC with thermal insulator and connected with two electrical leads to make electrical circuit for resistive heating. We confirmed very stable and homogeneous heating for insulating sample at 30 GPa to 2450 K in the modified internally resistive heated DAC. The highest temperature which this method can generate depends on the metal heater encapsulating the sample. This method offers a larger heating volume with more stable and uniform temperature than laser heating and at temperatures much greater than those that can be generated by external resistive heating methods.

Shear deformation on post-spinel

*Daisuke Yamazaki[1], Noriyoshi Tsujino[1], Yu Nishihara[2]

1. Institute for Planetary Materials, Okayama University, 2. GRC, Ehime University

Earth’ s lower mantle is mainly composed of ferro-periclase and bridgmanite. The viscosity of ferro-periclase is considered to be 2-3 orders of magnitude lower than that of bridgmanite. Such large discrepancy in viscosity may cause the significant effect of microstructure of the aggregate of bridgmanite and ferro-periclase on bulk viscosity. For example, bulk viscosity is low when the interconnected weak layer structure is formed, whereas bulk viscosity is as high as the viscosity of bridgmanite when the load bearing framework structure is formed [1].

Microstructural evolution from the load bearing framework structure to the interconnected weak layer structure in post-spinel phase (mixture of bridgmanite and ferro-periclase) during deformation was previously reported based on the rotational Drickamer apparatus [2]. This results suggests the important viscosity reduction during deformation in the lower mantle. We therefore considered that more detailed and precise experiments are necessary to discuss the lower mantle rheology quantitatively.

Deformation experiments under the lower mantle conditions can be conducted by using D111-type deformation Kawai-type high pressure apparatus. This apparatus was previously installed at UCL followed by PF-AR and Misasa. In this study, we use these apparatus for the deformation on post-spinel phase.

Starting material for deformation experiment was well-sintered aggregate of bridgmanite and ferro-periclase synthesized at 24 GPa and 1873 K. For the simple shear deformation, we used 45 degree cut design. In in-situ X-ray experiments at PF-AR, we used tapered and coned anvils for X-ray paths. On the other hand, in “quench” experiments at Misasa, we used a simple cubic anvils (TEL=2.0 mm). All deformation experiments were performed with constant D-rams displacement rate.
We deformed sample up to shear strain of ~0.8 with the 0.4 mm displacements of D-rams. SEM observation on the recovered sample by SEM shows that there is no significant evolution in microstructure, indicating that viscosity reduction is not expected with shear deformation to gamma~1. Lattice thermal conductivity of $CaSiO_3$ perovskite at high pressures and high temperatures

*Kotaro Onga[1], Kenji Ohta[1], Akira Hasegawa[1,2], Takashi Yagi[2], Kei Hirose[3,4], Yasuo Ohishi[5]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology, 3. Earth-Life Science Institute, Tokyo Institute of Technology, 4. Department of Earth and Planetary Science, The University of Tokyo, 5. Japan Synchrotron Radiation Research Institute

Laboratory measurements of thermal conductivity of deep Earth materials provide important information on the dynamics and thermal evolution of the mantle and the core. $CaSiO_3$ perovskite (CaPv) is a constituent of pyrolitic lower mantle and of the subducting oceanic crust at depth greater than 560 km. In recent years, there are many reports of the laboratory-based lower mantle thermal conductivity profiles, but the thermal conductivity of CaPv has never been measured and included in the models [1,2,3,4,5] . CaPv is an unquenchable high-pressure phase at ambient conditions, and temperature-induced structure change from tetragonal to cubic occurs at around 500 K [6]. Therefore, *in-situ* high pressure and temperature X-ray diffraction (XRD) and thermal conductivity measurements are required to determine the thermal conductivity of CaPv in the Earth’ s deep interior.
In this study, we determined the thermal conductivity of CaPv at about 50 GPa and high temperature to 1950 K by a combination of synchrotron XRD measurements and the pulsed light heating thermoreflectance technique. Based on our experimental results, we consider the effect of the presence of CaPv on the thermal conductivity of the pyrolitic lower mantle and the subducting oceanic crust.

Polycrystalline diamond sintered from ultradispersed nanodiamonds

*Masayuki Nishi[1,2], Koichiro Yamamoto[1], Youmo Zhou[1], Tetsuo Irifune[2,1]

1. Geodynamics Research Center, Ehime University, 2. Earth-Life Science Institute, Tokyo Institute of Technology

NPD is a binder-less nanodiamond aggregate (~50 nm) synthesized by direct conversion of graphite under high pressure and temperature [1]. Although NPD has extremely high hardness exceeding that of single-crystalline diamond, it is difficult to obtain the large size of the NPD above 1 cm^3, because extreme high pressure conditions are required. Here we show nanodiamond polyclystalline sintered from ultradispersive nanodiamond under relatively moderate pressure and temperature conditions.

We used a multi-anvil apparatus to sinter the nanodiamonds at 8-15 GPa and 1600-2300˚C, where the diamond is thermodynamically stabilized. The starting materials were enclosed in metal capsules. The microstructures and chemical compositions of the recovered samples were examined using a field-emission scanning electron microscope with energy-dispersive X-ray spectroscopy. Well-sintered polycrystalline were subjected to the Knoop indentation test to evaluate its hardness.

We succeeded in recovering the well-sintered polycrystalline diamonds with grain size of ~10-30 nm in some runs (Figure 1). Full width at half maximum of XRD peaks decreased with increasing temperature due to the grain growth of diamond particles. The color, hardness, and grain size of the sintered polycrystalline changed depending on the capsule materials as well as the pressure and temperature conditions. These features might be affected by the porosity, the grain size, and the impurities. Further studies are required to synthesize the polycrystalline with high hardness comparable to NPD.

Thermal conductivity measurements on iron and MgO periclase at high pressure and high temperature similar to the Earth’s mid-lower mantle conditions

*Akira Hasegawa[1,2], Kenji Ohta[2], Takashi Yagi[1], Kei Hirose[3,4]

1. National Institute of Advanced Industrial Science and Technology, 2. Tokyo Institude of Technology, 3. Earth-Life Science Institute, Tokyo Institude of Technology, 4. The University of Tokyo

The thermal transport properties of the Earth’s constituents are important information to constrain the thermal evolution and the heat budget of the Earth. In particular, the thermal conductivity of the core, the largest heat source of the Earth, and the lower mantle, occupying more than half the volume of the whole Earth, are indispensable.

In recent years, thermal conductivity measurement on the sample inside the diamond anvil cell has been carried out utilizing the thermoreflectance phenomenon, the reflectance of metal changes slightly due to the temperature perturbation of several kelvin (e.g. Hsieh et al., 2009 Phys Rev B; Yagi et al., 2011 Meas Sci Technol). However, the reported temperature condition is far from that in Earth’s interior.

In this study, we combined the pulsed light heating thermoreflectance method with high power CW laser heating to obtain the thermal conductivity of material *in-situ* at high pressures and temperatures. As a result of test measurement for Pt, we obtained thermal conductivities of Pt up to 60 GPa and 2000 K, which is in good agreement with the measured values using flash heating method in a laser heated diamond anvil cell (McWilliams et al., 2015 Phys Earth Planet In).

The thermal conductivities of iron and MgO periclase were measured up to 60 GPa and 1700 K with this developed system. We found that the obtained thermal conductivities of iron and MgO have negative temperature dependence, and are consistent with the literatures (Fe: Konôpková et al., 2016 Nature; Ohta et al., 2016 Nature, MgO; Manthilake et al., 2011 Proc National Acad Sci; Dekura and Tsuchiya, 2017 Phys Rev B). The newly developed system here would be a powerful tool to examine the thermal conductivity of Earth’s deep interior.

Azimuthal anisotropy in the lowermost mantle beneath Philippine from ScS-S times

*Satoru Tanaka[1]

1. Department of Deep Earth Structure and Dynamics Research Japan Agency for Marine-Earth Science and Technology

Introduction: Seismic anisotropy in the lowermost mantle has been detected by splitting of diffracted S and ScS phases, the discrepancy of shear wave splitting of SKS and SKKS, to date. In many cases, the propagation direction of such seismic waves is restricted due to the combination of sources and receivers. Thus, the azimuthal anisotropy using ray paths passing in multi-directions has been rarely discussed. Now, seismic networks and large-scale seismic arrays have been increasing especially in the eastern Asia where there are also many earthquakes. It is a good opportunity to examine an azimuthal variation of travel times passing through the outside of the Pacific Large Low Shear Velocity Province, where the existence of anisotropy in the lowermost mantle is expected.

Data and Method: I used the seismograms of earthquakes occurred in Mariana, east China, Indonesia, and Vanuatu that are record with the seismic stations belonging to IRIS GSN and PASSCAL, Thai Metrological Department, F-net, JISNET, NECESSArray. This geometry gives a good condition that the mid-points of seismic ray paths are located near Philippine with various azimuths.I measured ScS–S differential travel times using a waveform cross-correlation method, which can effectively cancel the heterogeneity in the crust and upper mantle and the uncertainty of hypocenters. The differential travel times are compared with theoretical travel times by PREM with correction of physical dispersion due to anelasticity for the typical period of 10 s, that for ellipticity of the Earth, finally I obtained about 500 residuals. Even though I used the differential travel times, the ScS–S residuals show the large scattering and the correlation with the residuals of S travel times are much larger than that of ScS phases. This means that the raw ScS–S residuals are affected by heterogeneity in the upper part of the lower mantle where only S waves are propagated. Thus, we applied the further corrections using 3D mantle heterogeneity models.

Results and Discussion: We used S-wave 3D models of S16U6L8, S4BL16, S40RTS, SEMUCB-WM, and a P-wave 3D model of GAP-P4 with conversion rate dlnVs/dlnVp=1.7. I found that the scatter of the ScS–S residuals are much improved and that the correlation coefficient between the residuals of ScS–S and ScS are increased and that between ScS–S and S are much reduced when the GAP-P4 model are used for the correction, probably due to its high spatial resolution in the upper lower mantle. As a result, only the ScS–S residuals corrected with the modified GAP-P4 can be used to infer seismic anisotropy in the lowermost mantle.

Then I fitted cos 2qand cos 4qcurves with least square to obtain the characteristics of the azimuthal variation of the ScS–S residuals, clearly indicating that cos 2qcomponent is significant with the fastest direction (the minimum ScS–S) is along ESE-WNW (N110˚E). This can be explained if [100] axis of post-perovskite is oriented vertically and the direction of [001] axis is ESE-WNW for the incident angle of 45˚. The S-wave fastest direction is nearly parallel to the plate motion directions of the Philippine Sea plate and Sunda block. The amplitude of the azimuthal variation in the ScS–S residual is ±1.1 s, which corresponds to 1.7 % anisotropy if we assume the D” thickness of 300 km based on the previous studies on the D” discontinuity.

Detailed 3-D S-velocity structure within D" at the western Pacific LLSVP margin: smaller scale plumes and paleoslabs

*Yuki Suzuki[1], Kenji Kawai[1], Robert J. Geller[1], Satoru Tanaka[2], Weerachai Siripuvaraporn[3], Songkhun Boonchaisuku[3], Noisagool Sutthipong[3], Yasushi Ishihara[2], Taweoon Kim, Koji MIYAKAWA[4], Nozomu Takeuchi[4]

1. The University of Tokyo, 2. Japan Agency for Marine-Earth Science and Technology, 3. Mahidol University, 4. Earthquake Research Institute, The University of Tokyo

Global tomographic models of shear velocity have shown two large-scale low shear velocity provinces (LLSVPs) in D″ beneath the Pacific and Africa. It has been controversial whether these LLSVPs are due to thermal effects, chemical effects, or their combination. The nature and origin of the LLSVPs are of fundamental importance since each of the proposed geodynamical scenarios carries different implications for the thermal, chemical and dynamical evolution of the Earth. Previous seismological studies based on travel-time analysis or forward modeling inferred a sharp-sided velocity contrast of the Pacific LLSVP beneath the western Pacific and suggested that the LLSVP is chemically distinct, although the suggested structures of the western edge of the Pacific LLSVP different from each other. To better understand the origin of LLSVPs, it is essential to infer the detailed three-dimensional (3-D) velocity structure within LLSVP beneath the western Pacific. We recently deployed a seismic array stations in Thailand (Thai Seismic Array—TSAR). We assemble waveforms recorded by TSAR as well as other networks such as TM, AU, MM, and MY, allowing us to sample a wider region than previous studies. We conducted waveform inversion using ~5,300 transverse component records of this dataset for the detailed 3-D shear velocity structure in the lowermost 400 km of the mantle beneath the western Pacific. The inferred model shows a low-velocity anomaly immediately above the core-mantle boundary (CMB) and high-velocity anomalies extending vertically from 400 km to the CMB. Taken into account the previous geodynamical simulation studies, the size of the inferred low velocity anomaly suggests a thermal plume rather than a chemical anomaly. The location of the high velocity anomaly in D″ is consistent with the paleo-Izanagi plate subduction boundary about 200 Ma. This implies that a cold paleo-slab produces the strong lateral velocity contrast at the western edge of the western Pacific LLSVP. Hence, we conclude that the western margin of the Pacific LLSVP and its sharp velocity boundary can be explained mainly by thermal effects, and this implies that the lowermost mantle would be well-mixed and the Pacific LLSVP would not be geochemical reservoir.

Possible interaction between the core and mantle inferred from a core surface flow model

*Masaki Matsushima[1]

1. Department of Earth and Planetary Sciences, School of Science, Tokyo Institute of Technology

Fluid flow in the Earth's liquid outer core is responsible for the dynamo action by which the geomagnetic field is generated and maintained. The fluid flow can be estimated from geomagnetic field data, such as spatial distribution of geomagnetic field and its temporal change referred to as secular variations. This implies that spatial and temporal variations of fluid flow in the core provide information on any interaction between the core and mantle. To investigate possible core-mantle interaction, a core surface flow model is obtained from a geomagnetic field model, COV-OBS.x1 (Gillet et al., 2015) using the method of Matsushima (2015). That is, inside a viscous boundary layer at the core-mantle boundary (CMB), magnetic diffusion is assumed to significantly contribute to temporal change of geomagnetic field, and the radial dependence of core flow is expressed in terms of a spiral similar to the Ekman spiral. Below the boundary layer, magnetic diffusion is neglected as in the frozen-flux approximation, and the tangentially magnetostrophic constraint is imposed on the flow.

Any inhomogeneous structure, such as temperature or heat flux, at the CMB is likely to have a strong effect on the core flow. The inhomogeneity successively influences the flow pattern. Therefore, average of fluid flow is expected to show possible core-mantle interaction. Hence, fluid flows inside and below the boundary layer are averaged over the time from 1840 to 2015 covered by the COV-OBS.x1 model. However, mean amplitudes of upwelling and downwelling flows as well as mean horizontal flows are found to be smaller than those at respective times. This result suggests that possible thermal heterogeneity due to the lowermost mantle structure has little effect on the core surface flow; that is, compositional convection is dominant in the Earth's outer core. It should be noted, however, that there is a noticeable upwelling flow corresponding to a counterclockwise vortex beneath the south of Africa, and that the location is just outside the tangent cylinder, an imaginary cylinder parallel to the rotational axis and attached to the equator of the inner core. This may indicate that the vortex corresponds to an edge of columnar convective motion, although the other edge in the northern hemisphere is unclear.

Determination of the noble gas partition coefficients between metal-silicate melts under high-pressure and high-temperature conditions

*Tomotaka Tanaka[1], Hideharu Kuwahara[2], Satoshi Kishi[1], Ryuichi Nomura[3], Kenji Mibe[5], Hiroyuki Kagi[4], Shigehiko Tateno[6], Hirochika Sumino[1]

1. Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo , 2. Geodynamics Research Center, Ehime University, 3. Kyoto University, 4. Geochemical Research Center, Graduate School of Science, University of Tokyo, 5. Earthquake Research Institute, University of Tokyo, 6. Earth-Life Science Institute, Tokyo Institute of Technology

Analyses of ocean island basalts reveal a geochemical reservoir characterized by unradiogenic, “primordial” noble gas signatures (e.g., high $^{3}He/^{4}He$ and low $^{40}Ar/^{36}Ar$ ratios), likely residing in the deep mantle. There has been much debate about the area holding the “primordial” noble gases deep in the Earth (Porcelli & Ballentine, 2002), including that the “primordial” noble gasses have been retained in the deepest region of the mantle since 4.4 Ga (Mukhopadhyay, 2012), or in the core since the core-mantle separation (Trieloff & Kunz, 2005; Bouhifd et al., 2013). However, the validity of latter strongly depends on the quantity of noble gases the core incorporates during accretion and can hold in the present day.

In order to investigate noble gas partitioning behavior between the core and mantle, noble gases were dissolved into metal-silicate melts under high temperature and pressure conditions, and then the samples were quenched, recovered, and analyzed for noble gas concentrations. Sample synthesis was performed at the Geodynamics Research Center, Ehime University. Noble-gas doped silicate glass and iron were melted and equilibrated under high pressure and temperature (3-6 GPa, 1700 and 1800 ˚C) using a multianvil apparatus. The sample capsule was cut and the polished surface of the section was investigated with scanning electron microscope and Raman spectroscopy. The chemical compositions of silicate and metal phases were determined with electron microprobe. And then, the noble gases in the silicate phase were extracted by an ultraviolet laser ablation apparatus and analyzed using a noble gas mass spectrometer at the University of Tokyo.

From the Raman spectra, it was found that crystallization (clinopyroxene) had occurred in samples synthesized at pressures of 6 GPa or higher, indicating that the sample quenching was not enough rapid. There is a possibility that noble gas may not be contained much in the crystallized part because a previous study showed that noble gas content in pyroxene crystal is smaller than those in glass (melt) by about 10^{-4} (Heber *et al.*, 2007). The noble gas concentrations in silicate glass phase are fairly homogeneous, even where a crack is formed during quenching. In future we will measure the noble gases in the iron part and determine the partition coefficient of the noble gases.

Measurement of T-dependent electrical resistivity of solid and liquid Fe and Pt at fixed P

*Innocent Ezenwa[1], Takashi Yoshino[1]

1. Institute for Planetary Materials, Okayama University

Knowledge of the thermal and electrical conductivity of solid and liquid Fe and its relevant alloys at P and T conditions is essential for understanding the cooling history of planetary cores and modelling their dynamo. The general understanding of the electrical transport properties of the transition metals at lower P will perhaps give insight in understanding Fe behavior at the inaccessible planetary core conditions. Theoretical investigation has suggested that the electrical and thermal conductivity of solid and liquid Fe at Earth’ s core conditions are similar in value (Wagle and Steinle-Neumann, (2017). At ambient T, experimental investigation showed that hcp ε -phase of Fe becomes paramagnetic at ~18GPa while Pt is paramagnetic and crystalize fcc at ambient conditions. Since Fe and Pt have an unfilled *d*-band electronic structure and at high P both exhibits closed packed crystal structures, experimental determination of the transport properties of molten Pt at lower P conditions is important for understanding the behavior of molten Fe preceding ε -phase at ~80 GPa. We develop a technique and cell design for the investigation of the electrical resistivity of metals that keeps it free from contamination using multianvil press. And, we report measurements on Fe and Pt. The sample was kept pure by making the electrodes and the sample the same composition while the thermocouple (TC) is placed close to the sample and taking through the gasket. The major challenge of TC breakage during compression and/or heating was overcome by shielding the TC with a cylindrical hollow coiling ring made of the same composition as the TC leads. The use of current polarity reversal to eliminate biased voltage as deployed in previous studies was adopted. On Fe and Pt, resistivity increases and decreases with T and P respectively, was observed. On melting, Fe result at 3 GPa agrees with very recent data by Silber et al. (2018) which showed an increasing difference in the resistivity value of solid and liquid with increasing P. While, Pt resistivity at 3 GPa appears constant comparable to its 1 atm value.

Ancient, highly depleted mantle constrained by Re-Os isotope and highly-siderophile element compositions of French Polynesian xenoliths

*Norikatsu Akizawa[1], Akira Ishikawa[2], Katsuhiko Suzuki[3], Tetsu Kogiso[4]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 3. Research and Development Center for Submarine Resources, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 4. Graduate School of Human and Environmental Studies, Kyoto University

Mantle xenoliths, which are fragmented mantle material trapped by ascending magma, can provide lithological and geochemical information of the inaccessible mantle. In order to better understand the lithological and geochemical characteristics of the mantle, we conducted extensive sampling of mantle xenoliths throughout French Polynesia archipelago: Tahiti, Moorea, and Rurutu islands. We collected a total of 42 mantle xenoliths: 1 lherzolite, 14 harzburgites, 22 dunites, 3 wehrlites, and 2 orthopyroxenites. Here, we present whole-rock rhenium-osmium isotope and highly-siderophile element (Os, Ir, Ru, Pt, Pd, and Re) compositions in addition to whole-rock major-element compositions. Osmium isotope ratio ($^{187}Os/^{188}Os$) of the mantle xenoliths ranges from 0.1172 to 0.1464, where the harzburgites show a statistical bimodal distribution with unradiogenic ($^{187}Os/^{188}Os < 0.125$) and radiogenic ($^{187}Os/^{188}Os > 0.125$) compositions. The harzburgites with unradiogenic $^{187}Os/^{188}Os$ are depleted with regards to whole-rock major-element compositions (< 1.22 wt% Al_2O_3), and chondrite-normalized patterns of highly-siderophile elements. Considering the lithological variation of the mantle xenoliths used herein, the mantle is considerably heterogeneous beneath French Polynesia archipelago. In particular, the contrasting isotopic compositions of the harzburgites suggest different mantle reservoirs with unradiogenic and radiogenic $^{187}Os/^{188}Os$ compositions. We propose a possibility that the harzburgites with unradiogenic $^{187}Os/^{188}Os$ are impinged mantle material beneath normal oceanic lithosphere due probably to ascending plumes.

First-principles prediction of hydrogen partitioning between the core and mantle

*Atsuroh Ohba[1], Taku Tsuchiya[1]

1. Ehime University Geodynamics Research Center

Some recent studies have reported high-P,T hydrous minerals which are stable at the core mantle boundary (CMB) pressure (Sano et al., 2008; Ohhira et al., 2016; Nishi et al., 2017). In order to elucidate the water circulation in the Earth's interior, experiments on the reaction between iron and hydrous minerals or water were also conducted (Iizuka-Oku et al., 2016; Mao et al., 2018; Clesi et al., 2018). However, the partition of hydrogen reported is different in different studies. In this study, we try estimating hydrogen partitioning between molten silicate and liquid iron under the CMB conditions based on the first principles calculation method combined with thermodynamic integration similar to our previous study (Xiong et al., 2018). Here, we assume following the exchange reaction of water between liquid iron and molten silicate is expressed as follows
(16MgSiO3+H2O) + 50Fe ⇔16MgSiO3 + (50Fe+H2O)
as a first example with ensuring the charge neutrality. Here, reaction free energy is calculated by the thermodynamic integration molecular dynamics method (Taniuchi & Tsuchiya, 2018). In the moment, simulations suggest that water prefer liquid iron. Now, additional computations are ongoing for improving numerical accuracy. The mechanism dissolving water into liquid iron is also investigated.

Microvolume stable isotope measuremetns and its applicaiton for high-pressure high-temperature experimental run products

*Madhusoodhan Satish-Kumar[1], Shinnosuke Aoyama[1]

1. Department of Geology, Faculty of Science, Niigata University

Light elements are very important in deep earth processes. Its composition in the lower mantle and core is still not well constrained. Stable isotope composition can be effectively used as an independent proxy. Although isotope fractionation in the deep earth occur in a narrow range, the volume of light element content in the mantle and core are extremely high, which can effectively cause significant natural isotopic compositional variations. It is necessary to accurately measure the isotope composition accurately in micro to nanomole scales, because the high-pressure experimental run products are small in volume. Recent studies have predicted the presence of isotope fractionation even at lower mantle and core *P-T* conditions, especially in magma ocean environment and during the core segregation. Despite the necessity of the micro-volume stable isotope measurement, there is always a tradeoff between the accuracy and the sample size.

At Niigata University, a MAT-253 mass spectrometer (Thermo Fisher Scientific) was installed through the MEXT Grant-in-Aid for Scientific Research on Innovative Areas. Carbon and oxygen isotopic compositions are measured using $CO_2$and multiple sulfur isotopic composition are measured using SF_6gas. A new micro-volume inlet system was installed and fundamental parameters such as pressure effect and capillary flow effect were tested. Using the micro-volume inlet system the minimum volume required for analysis is 1 micro-mole sample gas, and the precession for carbon and oxygen isotopic composition are better than 0.1‰. The precession for sulfur isotopes is ±0.3‰ and ±0.01‰ (1s) for $\delta^{34}S$ and $D^{33}S$, respectively, based on the repeated analyses of standard Ag_2S (IAEA S-1).Multiple sulfur isotope measurement system consists of 1) curie point pyrolyzer for rapid conversion of small volume samples to SF_6gas, 2) vacuum line system for pumping out non-condensable gasses, 3) gas chromatograph for purifying the SF_6gas and 4) micro-volume inlet system for introduction of sample gas to ionization chamber.
Multiple sulfur isotope ratios experimental run products were measured using the new system. Metal phases were separated and sulfur was extracted using Cr(II) reduction method [6]. Preliminary results indicate that S isotope fractionations occur in the pressure range of 3–5 GPa, under high-temperature conditions corresponding to the magma ocean environment. The negative $\delta^{34}S$ of mantle, can hence be explained by sulfur isotope fractionation in a magma ocean environment. Sulfur isotope measurements were also carried out on granitoid samples from the Archean with sulfide sulfur showing positive $\delta^{34}S$ values. Mass independent isotope fractionation, expressed as $\Delta^{33}S$, was also observed, suggesting that sulfur in the mantle alone cannot explain these variations. The incorporation of surface sulfur from sedimentary rocks and seawater is proposed.

Electrical resistivity of hcp Fe-Si alloys at high pressure and temperature

*Hayato Inoue[1], Sho Suehiro[1], Kenji Ohta[1], Kei Hirose[2,3], Yasuo Ohishi[4]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. Earth-Life Science Institute, Tokyo Institute of Technology, 3. Department of Earth and Planetary Science, The University of Tokyo, 4. Japan Synchrotron Radiation Research Institute

Silicon (Si) has been repeatedly suggested to be the major light element in the Earth’ s core that mainly consists of iron [1]. Alloying the light element(s) affects a variety of physical properties of iron. Electrical and thermal conductivities strongly constrain the dynamics and thermal evolution of Earth’ s core and these parameters are linked by the Wiedemann-Franz law ($\kappa = \sigma LT$; κ : thermal conductivity, σ : electrical conductivity, L: Lorenz number, T: absolute temperature). However, measurements of electrical and thermal conductivities under static condition at extremely high pressures (P) and temperature (T) are limited for pure iron [2], [3]. The estimates of the core conductivity considering the effect of light element(s) have been done based on the resistivity saturation model, but the validity of the model at the core condition is unclear [4], [5].
In this study, we examined electrical resistivity (the reciprocal of electrical conductivity) of Fe-2, 4 and 6.5 wt.%Si at high P-T conditions in an internally-heated diamond anvil cell (IHDAC) up to 99 GPa and 2910 K. Our results of electrical resistivity of hcp Fe-Si alloys showed its nonlinear temperature dependence, indicating the occurrence of the resistivity saturation. The resistivity saturation in Fe-Si alloys observed in this study supports the notion of high core conductivity and resulting molten lowermost mantle and young inner core.

Electrical resistivity and thermal conductivity of fcc Fe: Implications for the Mercury's core

*Hitoshi Gomi[1], Takashi Yoshino[1]

1. Okayama University

The Mercury's magnetic field may be sustained by the geodynamo motion in the liquid Fe core. However, its strength is about 1% of that of Earth. This weak magnetic field may implies a partly stratified core. Gomi et al. (2013) pointed out that the geometry of the thermal stratification depends critically on the depth dependency of the thermal conductivity. In this study, we conducted first-principles calculations on the face-centered cubic (fcc) Fe to constrain the electrical resistivity and the thermal conductivity of the Mercury's core.

We calculated the electrical resistivity and the thermal conductivity of fcc Fe by means of the Korringa-Kohn-Rostoker method combined with the coherent potential approximation (KKR-CPA) (Akai, 1989). The CPA was adopted to treat the disorder effects due to the atomic vibrations and the magnetic fluctuations on the electronic band structure (Glasbrenner et al., 2014; Ebert et al., 2015; Kou and Akai, 2018). Within the alloy analogy model, the thermal atomic displacements were represented by a discrete set of N_v displacement vectors $\Delta R_v(T)$, where $|\Delta R_v(T)|=\sqrt{<u^2>}$ is the root mean square displacement of atoms, which is based on the Debye model without zero point vibration. The lattice parameter and the Debye temperature are obtained from the equation of state of fcc Fe (Tsujino et al., 2013). In addition to the non-magnetic state, the magnetic disorder was simulated by the local magnetic disorder (LMD) approach. The conductivity was calculated by the Kubo-Greenwood formula with the vertex correction.

The calculated electrical resistivities and thermal conductivities with LMD state are consistent with the literature data at 0 GPa (Ho et al., 1972; 1983), whereas the non-magnetic results show smaller resistivity and larger thermal conductivity. This suggests the importance of the magnetic scattering at low pressures. However, our calculation predicts that the magnetic contribution banishes at higher pressures than 20 GPa. Figure 1 compares the present results and previous experiments (gray broken line; Secco and Scholoessin, 1989, gray square; Deng et al., 2013, open diamond; Pommier, 2018, black circle; Silber et al., 2018) on the electrical resistivity at ~5 GPa. Note that, within the fcc stability field, previous measurements have a large variation. Our calculated resistivity values are between Secco and Scholoessin (1989) and Silber et al. (2018).

We further calculated the electrical resistivity and the thermal conductivity of fcc Fe up to 50 GPa and 3000 K. The thermal conductivity increases with increasing pressure and temperature. This means that, if the inner core is absent, the thermal stratification starts from the bottom, and, after the onset of the inner core, a thick thermal stratified layer may develop at the top of the fluid core (Gomi et al., 2013).

Lateral heterogeneity in the lowermost outer core (F layer) of the Earth revealed by seismic analyses

*Toshiki Ohtaki[1], Satoshi Kaneshima[2], Taku Tsuchiya[3]

1. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST), 2. Department of Earth and Planetary Sciences, Kyushu University, 3. Geodynamics Research Center, Ehime University

We have determined seismic velocity structures of the lowermost outer core (F layer) beneath Northeast Pacific and Australia (Ohtaki and Kaneshima, 2015; Ohtaki et al., 2018), and found that the F layer is seismologically heterogeneous. These structures were obtained using a combination of two observations. First one is differential traveltimes between waves that reflect at the inner core boundary (ICB) and that graze the boundary; the second is dispersion (frequency dependence of velocity) of the grazing wave.

Our results show a somewhat strange velocity profile in the F layer beneath Australia, which has a lower-velocity-gradient layer than that of the Preliminary Reference Earth Model (PREM; Dziewonski and Anderson, 1981) on the ICB, and a higher-gradient layer just above the layer. Recent advance in high pressure research enables seismologists to translate lateral seismic velocity variation to relative chemical abundance in the outer core condition. Based on the results of Ichikawa and Tsuchiya (e.g., 2018), we showed light-element enrichment there. This result suggests that lighter fluid exists beneath Australia in the lowermost part of the liquid core, although the outer core is low-viscosity fluid.

The solid inner core of the Earth has quasi-hemispherical structure (e.g., Tanaka and Hamaguchi, 1997). As the origin of this hemispherical structure, uneven growth of the inner core has been proposed (e.g., Aubert et al., 2008; Alboussière et al., 2010; Monnereau et al., 2010). When the liquid in the outer core solidifies at the inner core surface, excess light element is partitioned to residue because the solid inner core is poorer in light elements compared with the liquid outer core. Thus, the uneven growth of the inner core is tied with an uneven release of the light elements to the F layer, which may be related to our results of the heterogeneous F layer. Then, a question arises: this heterogeneity has hemispherical structure like the inner core or local one?

We have not answered it yet because the survey areas of the above studies are restricted. Furthermore, other studies focusing F-layer velocity are not so many. Souriau (2015) determined lateral variations of velocity in the lower outer core using traveltimes of waves that turn there, and suggested that heterogeneity in F has degree-one feature. We also determined the seismic structure of the F layer beneath Antarctica using amplitude ratios between waves that turn just above the inner core and that get into the inner core. Although the resolution and reliability of structure obtained using amplitude ratios is lower than those using the method of our recent papers, the structure beneath Antarctica has a much lower velocity gradient in the F layer compared with PREM. Such a lower gradient is close to the model beneath Australia.

In this paper, we will show the summary of the heterogeneous F-layer structures of velocity and chemical abundance at this stage.

Flows and light element distribution in the outer core associated with heterogeneous growth of the inner core of the Earth

*Shin-ichi Takehiro[1], Youhei SASAKI[2]

1. Research Institute for Mathematical Sciences, Kyoto University, 2. Department of Mathematics, Kyoto University

Recent seismological observations suggest longitudinal heterogeneity of seismological wave velocity of the inner core of the Earth, which stimulates a discussion that phase change at the inner core boundary (ICB) does not occur uniformly in the horizontal directions. It is simply supposed from this suggestion that temperature is lower and concentration of light element is higher just above the solidification hemisphere at ICB, and vice versa. The heterogeneous structure of the inner core and thermodynamic properties just above ICB in the outer core is expected to be correlated, however, more recent analysis shows that distribution of seismological wave velocity anomaly does not correspond to longitudinal heterogeneity of the inner core.

There are two kinds of mechanisms explaining heterogeneous growth of the inner core. One of the mechanisms is that the heterogeneous thermal condition at the core mantle boundary (CMB) drives horizontal thermal convection which induces non-uniform temperature distribution at ICB. However, since this study uses co-density, which combines density variations by temperature and light element concentration, it cannot find distribution of the light elements just above ICB. Another mechanism is that hydrodynamic instability of the inner core surrounded by the phase boundary causes translational motion inside the inner core. However, since the theory assumes homogeneous light element distribution in the outer core, it is not clear this mechanism can explain the light element distribution above ICB.

In this study, by using a rotating spherical shell model in which temperature and light element concentration are independent variables, we perform numerical experiments of thermal and compositional convection related to two kinds of mechanisms. Obtained distributions of light element concentration are compared with the distribution of seismological wave velocity anomaly, and plausible dynamical regimes of thermal and compositional convection in the outer core are discussed.

Sharpness of the hemispherical boundary in the inner core beneath the northern Pacific

*Ryohei Iritani[1], Hitoshi Kawakatsu[1], Nozomu Takeuchi[1]

1. Earthquake Research Institute, Univ. of Tokyo

The hemispherical heterogeneity in the topmost of the Earth’ s inner core, faster velocity and higher attenuation in the eastern hemisphere and slower velocity and weaker attenuation in the western hemisphere, has been revealed by seismological studies. However, how the transition structure between two hemispheres looks like has not been known because of the difficulty to analyze complex core-sensitive data and the limitation of earthquake and seismic array distribution. In this study, we apply the array-based waveform inversion (Iritani et al., 2014) to core phase data that propagate beneath the northern Pacific, and investigate the nature of the transition structure in this region.Dataset used in this study consists of two directional event-station pairs, seismograms observed by the permanent European stations for events at Fiji-Tonga region, and USArray for events near Indonesia. We analyze the broadband vertical component of core phase data containing PKIKP and PKP phases (i.e. the epicentral distance between 145 –155 degree). Resultant analyzed waveforms for EU stations and USArray are 2,108 and 1,172 traces respectively.
In the analysis, waveform inversion approach is employed for each event data to measure traveltime and attenuation in the inner core. As a result, traveltime anomalies observed by EU stations show obvious positive anomaly suggesting mainly propagating the eastern hemisphere, while traveltimes observed by USAray show relatively smaller (or no) anomalies suggesting effects from both of hemispheres. On the other hand, attenuation parameters for both arrays show similar trend that suggests high attenuation corresponding to the eastern hemisphere. To investigate a hemispherical transition boundary in the sampled region, we conduct a ray theory based forward modeling of traveltimes by changing a shape of boundary from meridian boundary to eyeball shaped boundary, and its position. We compute root-mean-square (RMS) of residual between observations and theoretical traveltimes computed with each boundary model. Then, an eyeball shaped boundary, that is located at longitude of 158°W on the equatorial line and latitude of 80°N at the northernmost point, obtained as the preferred boundary model. Finally, we investigate a sharpness of the boundary by varying a width of hemispherical transition. We assume linear variation from the eastern and western hemisphere in a given width and compute RMS. As a result, a width of 600 km at the surface of the inner core shows smaller RMS than sharp boundary. Geophysical significance of this finding will be further discussed.

Stable carbon isotope fractionation in Fe-C system from first principles

*Haruhiko Dekura[1], Taku Tsuchiya[1]

1. Geodynamics Research Center, Ehime University

Carbon is the fourth most abundant element in the solar system and likely one of the constituent light elements in the Earth’s core. Determination of its equilibrium isotope fractionation factor (α) under high pressure (P) and temperature (T) is a key for understanding chemical evolution such as the whole Earth carbon distributions and the amount in the Earth’s core (e.g., Kumar et al., 2011). Because experimental measurement of the isotope fractionation remains technically challenging at the deep mantle condition, attempts to evaluate the α among mantle minerals by first-principles calculations have been made in recent years (e.g., Huang et al., 2014). Recently, our group initiated the theoretical determination of the α in the Fe-C system in the Earth’s deep interior with a full ab initio approach based on the density-functional theory. We performed ab initio lattice dynamics calculations for diamond and iron-carbide (hexagonal Fe7C3) having the two stable carbon isotopes (12C and 13C). The α between the two phases were then determined by using the Gibbs free energies calculated at P ~300 GPa and T ~2000-6000 K. The obtained $10^3 \ln \alpha$ dia-Fe7C3 is found to vary with T from ~+8‰ (2000 K) to ~+5‰ (6000 K). This result indicates that the Fe7C3 is enriched in the heavier isotope (13C) compared with diamond. This trend is qualitatively consistent with low-pressure experimental observations (Kumar et al., 2011).

[S-IT21] Interaction and Coevolution of the Core and Mantle in the Earth and Planets

convener:Kenji Kawai(Department of Earth and Planetary Science, School of Science, University of Tokyo), Tsuyoshi Iizuka(University of Tokyo), Kenji Ohta(Department of Earth and Planetary Sciences, Tokyo Institute of Technology), Taku Tsuchiya(Geodynamics Research Center, Ehime University)

Recent observational and experimental investigations have significantly advanced our understanding of the structure and constituent materials of the deep Earth. Yet, even fundamental properties intimately linked with formation and evolution of the planet, such as details of the chemical heterogeneity in the mantle and light elements dissolved in the core, remained unclear. Seismological evidence has suggested a vigorous convection in the lower mantle, whereas geochemistry has suggested the presence of stable regions there that hold ancient chemical signatures. The amounts of radioactive isotopes that act as heat sources and drive dynamic behaviors of the deep Earth are also still largely unknown. We provide an opportunity to exchange the achievements and ideas, and encourage persons who try to elucidate these unsolved issues of the core-mantle evolution using various methods, including high-pressure and high-temperature experiments, high-precision geochemical and paleomagnetic analyses, high-resolution geophysical observations, geo-neutrino observations, and large-scale numerical simulations. Papers stimulating an interdisciplinary collaboration relating to establishment of the Japan-SEDI community are also welcomed.

Sample-scale compositional variation of the Inada granite, Ibaraki, Japan -toward the reduction of geoneutrino flux estimation errors from the Japanese crust-

*Kenta Ueki[1], Minami Kazuki[2], Tsuyoshi Iizuka[3], Sanshiro Enomoto[4], Hiroyuki Tanaka[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Earthquake Research Institute, University of Tokyo, 3. Department of Earth and Planetary Science, University of Tokyo, 4. Center for Experimental Nuclear Physics and Astrophysics, University of Washington

Geoneutrio observed at anti-neutrino observatory "KamLAND" in Kamioka (Hida City, Gifu Prefecture), enables us to directly observe the abundance of radiogenic elements in the deep earth. As crustal rocks exhibit a high concentration of geoneutrino producing radiogenic elements (Uranium and Thorium) than mantle rocks, we have to subtract the contribution of geoneutrino from the Japanese crust from the observation value in Kamioka to estimate geoneutrino flux from core and mantle. For the purpose, we estimated the 3D distribution of uranium and thorium in the Japanese crust by the stochastic modeling using the seismic velocity structure, geological information and geochemical database for the Japanese crustal rock. Geoneutrino flux calculated using the compositional map exhibits a very large error (up to 80%) at present.
We found that information on the compositional heterogeneity (spatial correlation) of various length scale, such as of the single rock suite scale (km to m scale), and sample scale (cm to mm scale) are essential to reduce the estimation error of crustal geoneutrino flux as small as the observation error of the geoneutrino on KamLAND. Therefore, we conducted a grid sampling of the granite of Inada, Ibaraki prefecture, to obtain quantitative knowledge on the small scale compositional heterogeneity. Samples (about 500g) were divided into several centimeter scale split (about 25g). Based on the compositional variations between small splits from one sample, we discuss the small scale sample wise compositional variation. Whole rock chemical composition of each small split was analyzed using XRF. Also, we conducted surface analysis using an ED-XRF to evaluate the spatial distribution of elements in each split. As a result, even within a single sample (about 500g), a compositional variation of about several% at maximum was observed. This result indicates that when conducting the analysis based on the rock chemical composition considering the spatial context, it is necessary to properly evaluate the sample scale heterogeneity, in addition to the tectonic scale, the rock suite scale, and microscopic scale.Also, this result will contribute to the reduction of the estimation error of geoneutrino from the Japanese crust.

Towards a better estimation of the temperature distribution beneath the Japanese Islands

*Akiko Tanaka[1], Makoto Yamano[2], Hideki Hamamoto[3], Shusaku Goto[4], Takumi Matsumoto[5]

1. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, 2. Earthquake Research Institute, The University of Tokyo, 3. Center for Environmental Science in Saitama, 4. Institute for Geo-Resources and Environment National Institute of Advanced Industrial Science and Technology, 5. National Research Institute for Earth Science and Disaster Resilience

To improve our understanding of the thermal evolution and structure of the deep Earth, it is necessary to know the shallow part of them. Surface heat flow provides important constraint on it. However, the number of heat flow data is limited and spatially very inhomogeneous and even in regions with measurements the data quality varies. For this reason, we have been working on compiling a comprehensive database of heat flow, thermal conductivity, and geothermal gradient. In 2004, Geological Survey of Japan published a digital geoscience map entitled "Geothermal Gradient and Heat Flow Data in and around Japan", which contains heat flow data in the northwestern Pacific area (from 0 to 60°N and from 120 to 160°E) and geothermal gradient data in and around Japan. In 2019, we will be releasing database entitled "Thermal Data Collection in and around Japan", which contains continuously updated of geothermal gradient and heat flow data and adds thermal conductivity data in and around Japan. Thermal conductivity data were compiled from published data and site-specific reports, and measured using the archived cores. This database offers considerable improvements over the previous version released in 2004, and will be published and available at https://www.gsj.jp/en/database/db-portal/index.html. It presents an opportunity to revisit the thermal state of the lithosphere along with other geophysical/geochemical constraints on heat flow extrapolation.

The estimation of the neutrino flux from the crust of the Japanese islands using the geochemical database

*Satoru Haraguchi[1], Kenta Ueki[1], Hikaru Iwamori[1,2,3]

1. Japan Agency for Marine-Earth Science and Technology, 2. Earthquake Research Institute, the University of Tokyo, 3. Tokyo Institute of Technology

Geoneutrino observed at the anti-neutrino observatory "KamLAND" at Kamioka allows us to obtain information on the amount and distribution of radiogenic elements (uranium and thorium) in the deep mantle and crust.. It is necessary to divide the contribution from Japanese from the observed neutrino flux on closely to precisely estimate the quantity of U, Th of the earth deep earth because such radiogenic elements exhibit high concentration in the crust. Previous estimation of the crust origin geoneutrino was estimated based on the relatively simple chemical assumption on the compositional variation and spatial distribution. However, the radioactive elements of the Japanese crustal rock are distributed with very wide compositional range with complex spatial distribution. Therefore, it is necessary to estimate spatial distribution of radioactive element in the Japanese crust for the precisely measurement of geoneutrino from Japanese crust. In addition, petrogical and geochemical structure of the Japanese crust of are fundamental information for understanding seismic activity, volcanic activity and tectonism. The analysis of the spatial variation of the chemical composition of the Japanese Islands crust is important in discussing about the evolution history of the Japanese Islands and the chemical evolution in the subduction zone.

In this study, we utilize DODAI to improve the estimation error of geoneutrino from the Japanese crust (Takeuchi et al., 2019). We published the database “DODAI” which compiled geochemical data published by the Japanese domestic journals and bulletins in the journal of the Geological Society of Japan (Haraguchi et al., 2018). This database incorporates the precise sampling position of individual geochemical data using an electronic map. Resolution of the positional information were improved drastically.
The "DODAI" database covers whole area of Japanese Islands with highly precise positional information is useful for data analysis and modeling. The geochemistry database with highly precise positional information is useful for modeling of the geochemical structure of the solid earth. In this study, we present the potential of the DODAI database and geoneutrion in the analysis of the geochemical structures of Japanese crust, as well as the deep earth.

Viscosity of potassium titanosilicate melt at high pressure

*Akio Suzuki[1]

1. Department of Earth Science, Graduate School of Science, Tohoku University

Viscosity of silicate melt is a fundamental property, which controls volcanic processes, including rates of melt extraction, ascent, and magma mixing. Titanium oxide is contained less than 10 wt% in terrestrial magmatic liquids, however, some lunar magmas contains it over 10 wt%. The addition of titanium to silicate melt affects on the properties such as viscosity, density, and compressibility. Especially the pressure dependence of viscosity is of great interest, because magma is generated in the planetary interiors. The aim of this study is to measure the viscosity of K2TiSi4O11 melt at high pressures to estimate the influence of the pressure-induced structural change of melt.
We performed in situ falling sphere viscometry in the pressure range from 1.3 to 7.4 GPa, by using the MAX-III high pressure apparatus at BL14C2 and NE7A beamlines at Photon Factory in KEK, Tsukuba, Japan. A falling platinum sphere in the melt was monitored by using an X-ray CCD camera with a YAG:Ce fluorescence screen. We observed that the viscosity of KTS4 melt decreased up to 3.3 GPa. In contrast, the pressure dependence in viscosity was not observed above 3.3 GPa. Based on XANES spectra of K2TiSi4O11 glasses quenched under high pressure, Paris et al. (1994) showed that the coordination number of titanium increased with increasing pressure. The present study suggests that the melt becomes depolymerized by the coordination change of titanium under high pressure.

Lattice thermal conductivity of wadsleyite and ringwoodite at the mantle transition zone pressures

*seiji kimura[1], Kenji Ohta[6], Takaaki Kawazoe[2], Kei Hirose[3], Hiroyuki Kagi[4], Takashi Yagi[5]

1. Department of Earth and Planetary Sciences Tokyo Institute of Technology, 2. Department of Earth and Planetary Systems Science, Hiroshima University, 3. Earth-Life Science Institute, Tokyo Institute of Technology, 4. Geochemical Research Center, Graduate School of Science, University of Tokyo, 5. National Institute of Advanced Industrial Science and Technology, 6. Department of Earth and Planetary Sciences, Tokyo Institute of Technology

The lattice thermal conductivities of wadsleyite (Wd) and ringwoodite (Rw), which predominantly occupy the Earth's mantle transition zone, are important transport properties to understand the dynamics and thermal structure of the mantle. In particular, the temperature in the subducting slab is mainly controlled by the thermal conduction of Wd and Rw. Wd and Rw are both thought to preserve a large amount of hydrogen ions, thus should play an important role as the main water reservoir in the Earth. Furthermore, it has been reported that the hydration affects the physical properties of minerals including thermal conductivity, and it is necessary to measure the lattice thermal conductivity of Wd and Rw considering their water content. However, so far, the reported lattice thermal conductivities of Wd and Rw has not been considered their water content (Xu et al., 2004). Here we measured the room temperature lattice thermal conductivity of $(Mg_{0.89}Fe_{0.11})_2SiO_4$ Wd and $(Mg_{0.91}Fe_{0.09})_2SiO_4$ Rw up to 27 GPa, respectively, to clarify their hydration dependence using the pulsed light heating thermoreflectance technique in a diamond anvil cell.The obtained results show similar pressure dependence of the lattice thermal conductivity to the previous study (Xu et al., 2004). However, the absolute values of the thermal conductivity are different; the lattice conductivities of hydrous Wd and Rd are ~52% and ~40% lower than the results of Xu et al. (2004), respectively. Our results suggest strong water content dependence of lattice thermal conductivities of Wd and Rw, implying that the water content in the mantle minerals is key factor for calculating the thermal structure in a subducting slab, mantle dynamics.

It has been suggested that high-pressure transformations cause rheological weakening and large deformation of subducting slabs in mantle transition zone (MTZ) . However, there have been few direct experimental evidences so far largely because of the difficulties in quantitative deformation experiments under such conitions. Here we report preliminary results on the olivine-spinel transformation experiments under shear deformation upto MTZ pressures. D-111 (DT-cup) type high-pressure deformation apparatus was newly used for this purpose combined with high-energy synchrotron mono X-rays (50-60 keV) at Photon Factory (PFAR NE7 beamline), which enables in-situ observations of interactions between transformation and creep behaviors. Sintered Mg_2SiO_4 forsterite was first deformed at 15-25 GPa at 600˚C in shear, and subsequently heated to higher temperatures (~0.2˚C/s) to cause the olivine-spinel transformation under shear deformation. The transformation started at much lower temperatures under shear deformation (~900-1100˚C depending on the overpressure from the phase boundary) compared to that without deformation (~1400˚C), suggesting that the shear deformation enhances the olivine-spinel transition rate. The shear strain rate in the sample monitored by X-ray radiography was ~3-4 x 10^{-6} (s^{-1}) at 600˚C, and increased up to ~2-3 x 10^{-4} (s^{-1}) with ramping temperatures even keeping the anvil displacement rate constant (200 micron/h). We observed that the shear weakening does not occur at the same temperature, but reflects on the initiation of the olivine transition. Also, the weakening effects become significant at larger overpressures (and low T). This implies that the weakening of the shear zone induced by the grain-size reduction due to the olivine-spinel transition, however further evidences from microstructural observations are necessary. We plan to install 8-ch acoustic emission measurement system attached with D-111 apparatus to capture the transformation-induced shear instabitiy. Results of D-DIA shear deformation study on the olivine-spinel transition in Fe_2SiO_4 will also be presented and compared with those of the D-111 study in Mg_2SiO_4 .

Internally resistive heated diamond anvil cell experiments with metal encapsulated minerals

*YAMAMOTO TOMONARI[1], Kenji Ohta[1], Sho Suehiro[1], Hayato Inoue[1]

1. Tokyo Institute of Technology

Heating technique is crucial for *in-situ* high pressure-temperature (*P-T*) studies into the physical and chemical properties of minerals in the diamond anvil cell (DAC) under deep Earth's conditions. External resistive heating methods that use resistive heaters such as AlChrom-O wire and graphite surrounding the DAC or just the diamonds (Dubrovinskaia and Dubrovinsky, 2003; Du et al., 2013). This approach creates a homogeneous temperature field in the sample chamber but limits the maximum temperature of about 1200℃ due to graphitization of diamond anvils. Double-sided laser heating with a DAC generates the *P-T* conditions corresponding to the center of the Earth's (Tateno et al., 2010). However, tightly focused laser beams, instabilities in output laser power and misalignment of the focused beams on the sample surface result in significant temperature variation within the sample in the DAC. Internally resistive heated DAC is an effective heating method to overcome the temperature limitation of external heated DAC and the significant temperature gradients experienced in conventional laser-heated DAC (e.g., Zha and Bassett, 2003). However, the internally resistive heated DAC is mostly applied to metal sample to study the properties of the planetary metallic core despite this technique could be applicable to an insulating mineral.

In this study, we modified the internally resistive heated DAC technique for nonmetallic material. We developed a microfabrication technique for total metal encapsulation of the nonmetallic sample. The sample encapsulated by platinum was loaded in DAC with thermal insulator and connected with two electrical leads to make electrical circuit for resistive heating. We confirmed very stable and homogeneous heating for insulating sample at 30 GPa to 2450 K in the modified internally resistive heated DAC. The highest temperature which this method can generate depends on the metal heater encapsulating the sample. This method offers a larger heating volume with more stable and uniform temperature than laser heating and at temperatures much greater than those that can be generated by external resistive heating methods.

Shear deformation on post-spinel

*Daisuke Yamazaki[1], Noriyoshi Tsujino[1], Yu Nishihara[2]

1. Institute for Planetary Materials, Okayama University, 2. GRC, Ehime University

Earth’ s lower mantle is mainly composed of ferro-periclase and bridgmanite. The viscosity of ferro-periclase is considered to be 2-3 orders of magnitude lower than that of bridgmanite. Such large discrepancy in viscosity may cause the significant effect of microstructure of the aggregate of bridgmanite and ferro-periclase on bulk viscosity. For example, bulk viscosity is low when the interconnected weak layer structure is formed, whereas bulk viscosity is as high as the viscosity of bridgmanite when the load bearing framework structure is formed [1].

Microstructural evolution from the load bearing framework structure to the interconnected weak layer structure in post-spinel phase (mixture of bridgmanite and ferro-periclase) during deformation was previously reported based on the rotational Drickamer apparatus [2]. This results suggests the important viscosity reduction during deformation in the lower mantle. We therefore considered that more detailed and precise experiments are necessary to discuss the lower mantle rheology quantitatively.

Deformation experiments under the lower mantle conditions can be conducted by using D111-type deformation Kawai-type high pressure apparatus. This apparatus was previously installed at UCL followed by PF-AR and Misasa. In this study, we use these apparatus for the deformation on post-spinel phase.

Starting material for deformation experiment was well-sintered aggregate of bridgmanite and ferro-periclase synthesized at 24 GPa and 1873 K. For the simple shear deformation, we used 45 degree cut design. In in-situ X-ray experiments at PF-AR, we used tapered and coned anvils for X-ray paths. On the other hand, in “quench” experiments at Misasa, we used a simple cubic anvils (TEL=2.0 mm). All deformation experiments were performed with constant D-rams displacement rate.
We deformed sample up to shear strain of ~0.8 with the 0.4 mm displacements of D-rams. SEM observation on the recovered sample by SEM shows that there is no significant evolution in microstructure, indicating that viscosity reduction is not expected with shear deformation to gamma~1. Lattice thermal conductivity of $CaSiO_3$ perovskite at high pressures and high temperatures

*Kotaro Onga[1], Kenji Ohta[1], Akira Hasegawa[1,2], Takashi Yagi[2], Kei Hirose[3,4], Yasuo Ohishi[5]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology, 3. Earth-Life Science Institute, Tokyo Institute of Technology, 4. Department of Earth and Planetary Science, The University of Tokyo, 5. Japan Synchrotron Radiation Research Institute

Laboratory measurements of thermal conductivity of deep Earth materials provide important information on the dynamics and thermal evolution of the mantle and the core. $CaSiO_3$ perovskite (CaPv) is a constituent of pyrolitic lower mantle and of the subducting oceanic crust at depth greater than 560 km. In recent years, there are many reports of the laboratory-based lower mantle thermal conductivity profiles, but the thermal conductivity of CaPv has never been measured and included in the models [1,2,3,4,5] . CaPv is an unquenchable high-pressure phase at ambient conditions, and temperature-induced structure change from tetragonal to cubic occurs at around 500 K [6]. Therefore, *in-situ* high pressure and temperature X-ray diffraction (XRD) and thermal conductivity measurements are required to determine the thermal conductivity of CaPv in the Earth’ s deep interior.
In this study, we determined the thermal conductivity of CaPv at about 50 GPa and high temperature to 1950 K by a combination of synchrotron XRD measurements and the pulsed light heating thermoreflectance technique. Based on our experimental results, we consider the effect of the presence of CaPv on the thermal conductivity of the pyrolitic lower mantle and the subducting oceanic crust.

Polycrystalline diamond sintered from ultradispersed nanodiamonds

*Masayuki Nishi[1,2], Koichiro Yamamoto[1], Youmo Zhou[1], Tetsuo Irifune[2,1]

1. Geodynamics Research Center, Ehime University, 2. Earth-Life Science Institute, Tokyo Institute of Technology

NPD is a binder-less nanodiamond aggregate (~50 nm) synthesized by direct conversion of graphite under high pressure and temperature [1]. Although NPD has extremely high hardness exceeding that of single-crystalline diamond, it is difficult to obtain the large size of the NPD above 1 cm^3, because extreme high pressure conditions are required. Here we show nanodiamond polyclystalline sintered from ultradispersive nanodiamond under relatively moderate pressure and temperature conditions.

We used a multi-anvil apparatus to sinter the nanodiamonds at 8-15 GPa and 1600-2300˚C, where the diamond is thermodynamically stabilized. The starting materials were enclosed in metal capsules. The microstructures and chemical compositions of the recovered samples were examined using a field-emission scanning electron microscope with energy-dispersive X-ray spectroscopy. Well-sintered polycrystalline were subjected to the Knoop indentation test to evaluate its hardness.

We succeeded in recovering the well-sintered polycrystalline diamonds with grain size of ~10-30 nm in some runs (Figure 1). Full width at half maximum of XRD peaks decreased with increasing temperature due to the grain growth of diamond particles. The color, hardness, and grain size of the sintered polycrystalline changed depending on the capsule materials as well as the pressure and temperature conditions. These features might be affected by the porosity, the grain size, and the impurities. Further studies are required to synthesize the polycrystalline with high hardness comparable to NPD.

Thermal conductivity measurements on iron and MgO periclase at high pressure and high temperature similar to the Earth’s mid-lower mantle conditions

*Akira Hasegawa[1,2], Kenji Ohta[2], Takashi Yagi[1], Kei Hirose[3,4]

1. National Institute of Advanced Industrial Science and Technology, 2. Tokyo Institude of Technology, 3. Earth-Life Science Institute, Tokyo Institude of Technology, 4. The University of Tokyo

The thermal transport properties of the Earth’s constituents are important information to constrain the thermal evolution and the heat budget of the Earth. In particular, the thermal conductivity of the core, the largest heat source of the Earth, and the lower mantle, occupying more than half the volume of the whole Earth, are indispensable.

In recent years, thermal conductivity measurement on the sample inside the diamond anvil cell has been carried out utilizing the thermoreflectance phenomenon, the reflectance of metal changes slightly due to the temperature perturbation of several kelvin (e.g. Hsieh et al., 2009 Phys Rev B; Yagi et al., 2011 Meas Sci Technol). However, the reported temperature condition is far from that in Earth’s interior.

In this study, we combined the pulsed light heating thermoreflectance method with high power CW laser heating to obtain the thermal conductivity of material *in-situ* at high pressures and temperatures. As a result of test measurement for Pt, we obtained thermal conductivities of Pt up to 60 GPa and 2000 K, which is in good agreement with the measured values using flash heating method in a laser heated diamond anvil cell (McWilliams et al., 2015 Phys Earth Planet In).

The thermal conductivities of iron and MgO periclase were measured up to 60 GPa and 1700 K with this developed system. We found that the obtained thermal conductivities of iron and MgO have negative temperature dependence, and are consistent with the literatures (Fe: Konôpková et al., 2016 Nature; Ohta et al., 2016 Nature, MgO; Manthilake et al., 2011 Proc National Acad Sci; Dekura and Tsuchiya, 2017 Phys Rev B). The newly developed system here would be a powerful tool to examine the thermal conductivity of Earth’s deep interior.

Azimuthal anisotropy in the lowermost mantle beneath Philippine from ScS-S times

*Satoru Tanaka[1]

1. Department of Deep Earth Structure and Dynamics Research Japan Agency for Marine-Earth Science and Technology

Introduction: Seismic anisotropy in the lowermost mantle has been detected by splitting of diffracted S and ScS phases, the discrepancy of shear wave splitting of SKS and SKKS, to date. In many cases, the propagation direction of such seismic waves is restricted due to the combination of sources and receivers. Thus, the azimuthal anisotropy using ray paths passing in multi-directions has been rarely discussed. Now, seismic networks and large-scale seismic arrays have been increasing especially in the eastern Asia where there are also many earthquakes. It is a good opportunity to examine an azimuthal variation of travel times passing through the outside of the Pacific Large Low Shear Velocity Province, where the existence of anisotropy in the lowermost mantle is expected.

Data and Method: I used the seismograms of earthquakes occurred in Mariana, east China, Indonesia, and Vanuatu that are record with the seismic stations belonging to IRIS GSN and PASSCAL, Thai Metrological Department, F-net, JISNET, NECESSArray. This geometry gives a good condition that the mid-points of seismic ray paths are located near Philippine with various azimuths.I measured ScS–S differential travel times using a waveform cross-correlation method, which can effectively cancel the heterogeneity in the crust and upper mantle and the uncertainty of hypocenters. The differential travel times are compared with theoretical travel times by PREM with correction of physical dispersion due to anelasticity for the typical period of 10 s, that for ellipticity of the Earth, finally I obtained about 500 residuals. Even though I used the differential travel times, the ScS–S residuals show the large scattering and the correlation with the residuals of S travel times are much larger than that of ScS phases. This means that the raw ScS–S residuals are affected by heterogeneity in the upper part of the lower mantle where only S waves are propagated. Thus, we applied the further corrections using 3D mantle heterogeneity models.

Results and Discussion: We used S-wave 3D models of S16U6L8, S4BL16, S40RTS, SEMUCB-WM, and a P-wave 3D model of GAP-P4 with conversion rate dlnVs/dlnVp=1.7. I found that the scatter of the ScS–S residuals are much improved and that the correlation coefficient between the residuals of ScS–S and ScS are increased and that between ScS–S and S are much reduced when the GAP-P4 model are used for the correction, probably due to its high spatial resolution in the upper lower mantle. As a result, only the ScS–S residuals corrected with the modified GAP-P4 can be used to infer seismic anisotropy in the lowermost mantle.

Then I fitted cos 2qand cos 4qcurves with least square to obtain the characteristics of the azimuthal variation of the ScS–S residuals, clearly indicating that cos 2qcomponent is significant with the fastest direction (the minimum ScS–S) is along ESE-WNW (N110˚E). This can be explained if [100] axis of post-perovskite is oriented vertically and the direction of [001] axis is ESE-WNW for the incident angle of 45˚. The S-wave fastest direction is nearly parallel to the plate motion directions of the Philippine Sea plate and Sunda block. The amplitude of the azimuthal variation in the ScS–S residual is ±1.1 s, which corresponds to 1.7 % anisotropy if we assume the D” thickness of 300 km based on the previous studies on the D” discontinuity.

Detailed 3-D S-velocity structure within D" at the western Pacific LLSVP margin: smaller scale plumes and paleoslabs

*Yuki Suzuki[1], Kenji Kawai[1], Robert J. Geller[1], Satoru Tanaka[2], Weerachai Siripuvaraporn[3], Songkhun Boonchaisuku[3], Noisagool Sutthipong[3], Yasushi Ishihara[2], Taweoon Kim, Koji MIYAKAWA[4], Nozomu Takeuchi[4]

1. The University of Tokyo, 2. Japan Agency for Marine-Earth Science and Technology, 3. Mahidol University, 4. Earthquake Research Institute, The University of Tokyo

Global tomographic models of shear velocity have shown two large-scale low shear velocity provinces (LLSVPs) in D″ beneath the Pacific and Africa. It has been controversial whether these LLSVPs are due to thermal effects, chemical effects, or their combination. The nature and origin of the LLSVPs are of fundamental importance since each of the proposed geodynamical scenarios carries different implications for the thermal, chemical and dynamical evolution of the Earth. Previous seismological studies based on travel-time analysis or forward modeling inferred a sharp-sided velocity contrast of the Pacific LLSVP beneath the western Pacific and suggested that the LLSVP is chemically distinct, although the suggested structures of the western edge of the Pacific LLSVP different from each other. To better understand the origin of LLSVPs, it is essential to infer the detailed three-dimensional (3-D) velocity structure within LLSVP beneath the western Pacific. We recently deployed a seismic array stations in Thailand (Thai Seismic Array—TSAR). We assemble waveforms recorded by TSAR as well as other networks such as TM, AU, MM, and MY, allowing us to sample a wider region than previous studies. We conducted waveform inversion using ~5,300 transverse component records of this dataset for the detailed 3-D shear velocity structure in the lowermost 400 km of the mantle beneath the western Pacific. The inferred model shows a low-velocity anomaly immediately above the core-mantle boundary (CMB) and high-velocity anomalies extending vertically from 400 km to the CMB. Taken into account the previous geodynamical simulation studies, the size of the inferred low velocity anomaly suggests a thermal plume rather than a chemical anomaly. The location of the high velocity anomaly in D″ is consistent with the paleo-Izanagi plate subduction boundary about 200 Ma. This implies that a cold paleo-slab produces the strong lateral velocity contrast at the western edge of the western Pacific LLSVP. Hence, we conclude that the western margin of the Pacific LLSVP and its sharp velocity boundary can be explained mainly by thermal effects, and this implies that the lowermost mantle would be well-mixed and the Pacific LLSVP would not be geochemical reservoir.

Possible interaction between the core and mantle inferred from a core surface flow model

*Masaki Matsushima[1]

1. Department of Earth and Planetary Sciences, School of Science, Tokyo Institute of Technology

Fluid flow in the Earth's liquid outer core is responsible for the dynamo action by which the geomagnetic field is generated and maintained. The fluid flow can be estimated from geomagnetic field data, such as spatial distribution of geomagnetic field and its temporal change referred to as secular variations. This implies that spatial and temporal variations of fluid flow in the core provide information on any interaction between the core and mantle. To investigate possible core-mantle interaction, a core surface flow model is obtained from a geomagnetic field model, COV-OBS.x1 (Gillet et al., 2015) using the method of Matsushima (2015). That is, inside a viscous boundary layer at the core-mantle boundary (CMB), magnetic diffusion is assumed to significantly contribute to temporal change of geomagnetic field, and the radial dependence of core flow is expressed in terms of a spiral similar to the Ekman spiral. Below the boundary layer, magnetic diffusion is neglected as in the frozen-flux approximation, and the tangentially magnetostrophic constraint is imposed on the flow.

Any inhomogeneous structure, such as temperature or heat flux, at the CMB is likely to have a strong effect on the core flow. The inhomogeneity successively influences the flow pattern. Therefore, average of fluid flow is expected to show possible core-mantle interaction. Hence, fluid flows inside and below the boundary layer are averaged over the time from 1840 to 2015 covered by the COV-OBS.x1 model. However, mean amplitudes of upwelling and downwelling flows as well as mean horizontal flows are found to be smaller than those at respective times. This result suggests that possible thermal heterogeneity due to the lowermost mantle structure has little effect on the core surface flow; that is, compositional convection is dominant in the Earth's outer core. It should be noted, however, that there is a noticeable upwelling flow corresponding to a counterclockwise vortex beneath the south of Africa, and that the location is just outside the tangent cylinder, an imaginary cylinder parallel to the rotational axis and attached to the equator of the inner core. This may indicate that the vortex corresponds to an edge of columnar convective motion, although the other edge in the northern hemisphere is unclear.

Determination of the noble gas partition coefficients between metal-silicate melts under high-pressure and high-temperature conditions

*Tomotaka Tanaka[1], Hideharu Kuwahara[2], Satoshi Kishi[1], Ryuichi Nomura[3], Kenji Mibe[5], Hiroyuki Kagi[4], Shigehiko Tateno[6], Hirochika Sumino[1]

1. Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo , 2. Geodynamics Research Center, Ehime University, 3. Kyoto University, 4. Geochemical Research Center, Graduate School of Science, University of Tokyo, 5. Earthquake Research Institute, University of Tokyo, 6. Earth-Life Science Institute, Tokyo Institute of Technology

Analyses of ocean island basalts reveal a geochemical reservoir characterized by unradiogenic, “primordial” noble gas signatures (e.g., high $^{3}He/^{4}He$ and low $^{40}Ar/^{36}Ar$ ratios), likely residing in the deep mantle. There has been much debate about the area holding the “primordial” noble gases deep in the Earth (Porcelli & Ballentine, 2002), including that the “primordial” noble gasses have been retained in the deepest region of the mantle since 4.4 Ga (Mukhopadhyay, 2012), or in the core since the core-mantle separation (Trieloff & Kunz, 2005; Bouhifd et al., 2013). However, the validity of latter strongly depends on the quantity of noble gases the core incorporates during accretion and can hold in the present day.

In order to investigate noble gas partitioning behavior between the core and mantle, noble gases were dissolved into metal-silicate melts under high temperature and pressure conditions, and then the samples were quenched, recovered, and analyzed for noble gas concentrations. Sample synthesis was performed at the Geodynamics Research Center, Ehime University. Noble-gas doped silicate glass and iron were melted and equilibrated under high pressure and temperature (3-6 GPa, 1700 and 1800 ˚C) using a multianvil apparatus. The sample capsule was cut and the polished surface of the section was investigated with scanning electron microscope and Raman spectroscopy. The chemical compositions of silicate and metal phases were determined with electron microprobe. And then, the noble gases in the silicate phase were extracted by an ultraviolet laser ablation apparatus and analyzed using a noble gas mass spectrometer at the University of Tokyo.

From the Raman spectra, it was found that crystallization (clinopyroxene) had occurred in samples synthesized at pressures of 6 GPa or higher, indicating that the sample quenching was not enough rapid. There is a possibility that noble gas may not be contained much in the crystallized part because a previous study showed that noble gas content in pyroxene crystal is smaller than those in glass (melt) by about 10^{-4} (Heber *et al.*, 2007). The noble gas concentrations in silicate glass phase are fairly homogeneous, even where a crack is formed during quenching. In future we will measure the noble gases in the iron part and determine the partition coefficient of the noble gases.

Measurement of T-dependent electrical resistivity of solid and liquid Fe and Pt at fixed P

*Innocent Ezenwa[1], Takashi Yoshino[1]

1. Institute for Planetary Materials, Okayama University

Knowledge of the thermal and electrical conductivity of solid and liquid Fe and its relevant alloys at P and T conditions is essential for understanding the cooling history of planetary cores and modelling their dynamo. The general understanding of the electrical transport properties of the transition metals at lower P will perhaps give insight in understanding Fe behavior at the inaccessible planetary core conditions. Theoretical investigation has suggested that the electrical and thermal conductivity of solid and liquid Fe at Earth’ s core conditions are similar in value (Wagle and Steinle-Neumann, (2017). At ambient T, experimental investigation showed that hcp ε -phase of Fe becomes paramagnetic at ~18GPa while Pt is paramagnetic and crystalize fcc at ambient conditions. Since Fe and Pt have an unfilled *d*-band electronic structure and at high P both exhibits closed packed crystal structures, experimental determination of the transport properties of molten Pt at lower P conditions is important for understanding the behavior of molten Fe preceding ε -phase at ~80 GPa. We develop a technique and cell design for the investigation of the electrical resistivity of metals that keeps it free from contamination using multianvil press. And, we report measurements on Fe and Pt. The sample was kept pure by making the electrodes and the sample the same composition while the thermocouple (TC) is placed close to the sample and taking through the gasket. The major challenge of TC breakage during compression and/or heating was overcome by shielding the TC with a cylindrical hollow coiling ring made of the same composition as the TC leads. The use of current polarity reversal to eliminate biased voltage as deployed in previous studies was adopted. On Fe and Pt, resistivity increases and decreases with T and P respectively, was observed. On melting, Fe result at 3 GPa agrees with very recent data by Silber et al. (2018) which showed an increasing difference in the resistivity value of solid and liquid with increasing P. While, Pt resistivity at 3 GPa appears constant comparable to its 1 atm value.

Ancient, highly depleted mantle constrained by Re-Os isotope and highly-siderophile element compositions of French Polynesian xenoliths

*Norikatsu Akizawa[1], Akira Ishikawa[2], Katsuhiko Suzuki[3], Tetsu Kogiso[4]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 3. Research and Development Center for Submarine Resources, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 4. Graduate School of Human and Environmental Studies, Kyoto University

Mantle xenoliths, which are fragmented mantle material trapped by ascending magma, can provide lithological and geochemical information of the inaccessible mantle. In order to better understand the lithological and geochemical characteristics of the mantle, we conducted extensive sampling of mantle xenoliths throughout French Polynesia archipelago: Tahiti, Moorea, and Rurutu islands. We collected a total of 42 mantle xenoliths: 1 lherzolite, 14 harzburgites, 22 dunites, 3 wehrlites, and 2 orthopyroxenites. Here, we present whole-rock rhenium-osmium isotope and highly-siderophile element (Os, Ir, Ru, Pt, Pd, and Re) compositions in addition to whole-rock major-element compositions. Osmium isotope ratio ($^{187}Os/^{188}Os$) of the mantle xenoliths ranges from 0.1172 to 0.1464, where the harzburgites show a statistical bimodal distribution with unradiogenic ($^{187}Os/^{188}Os < 0.125$) and radiogenic ($^{187}Os/^{188}Os > 0.125$) compositions. The harzburgites with unradiogenic $^{187}Os/^{188}Os$ are depleted with regards to whole-rock major-element compositions (< 1.22 wt% Al_2O_3), and chondrite-normalized patterns of highly-siderophile elements. Considering the lithological variation of the mantle xenoliths used herein, the mantle is considerably heterogeneous beneath French Polynesia archipelago. In particular, the contrasting isotopic compositions of the harzburgites suggest different mantle reservoirs with unradiogenic and radiogenic $^{187}Os/^{188}Os$ compositions. We propose a possibility that the harzburgites with unradiogenic $^{187}Os/^{188}Os$ are impinged mantle material beneath normal oceanic lithosphere due probably to ascending plumes.

First-principles prediction of hydrogen partitioning between the core and mantle

*Atsuroh Ohba[1], Taku Tsuchiya[1]

1. Ehime University Geodynamics Research Center

Some recent studies have reported high-P,T hydrous minerals which are stable at the core mantle boundary (CMB) pressure (Sano et al., 2008; Ohhira et al., 2016; Nishi et al., 2017). In order to elucidate the water circulation in the Earth's interior, experiments on the reaction between iron and hydrous minerals or water were also conducted (Iizuka-Oku et al., 2016; Mao et al., 2018; Clesi et al., 2018). However, the partition of hydrogen reported is different in different studies. In this study, we try estimating hydrogen partitioning between molten silicate and liquid iron under the CMB conditions based on the first principles calculation method combined with thermodynamic integration similar to our previous study (Xiong et al., 2018). Here, we assume following the exchange reaction of water between liquid iron and molten silicate is expressed as follows
(16MgSiO3+H2O) + 50Fe ⇔16MgSiO3 + (50Fe+H2O)
as a first example with ensuring the charge neutrality. Here, reaction free energy is calculated by the thermodynamic integration molecular dynamics method (Taniuchi & Tsuchiya, 2018). In the moment, simulations suggest that water prefer liquid iron. Now, additional computations are ongoing for improving numerical accuracy. The mechanism dissolving water into liquid iron is also investigated.

Microvolume stable isotope measuremetns and its applicaiton for high-pressure high-temperature experimental run products

*Madhusoodhan Satish-Kumar[1], Shinnosuke Aoyama[1]

1. Department of Geology, Faculty of Science, Niigata University

Light elements are very important in deep earth processes. Its composition in the lower mantle and core is still not well constrained. Stable isotope composition can be effectively used as an independent proxy. Although isotope fractionation in the deep earth occur in a narrow range, the volume of light element content in the mantle and core are extremely high, which can effectively cause significant natural isotopic compositional variations. It is necessary to accurately measure the isotope composition accurately in micro to nanomole scales, because the high-pressure experimental run products are small in volume. Recent studies have predicted the presence of isotope fractionation even at lower mantle and core *P-T* conditions, especially in magma ocean environment and during the core segregation. Despite the necessity of the micro-volume stable isotope measurement, there is always a tradeoff between the accuracy and the sample size.

At Niigata University, a MAT-253 mass spectrometer (Thermo Fisher Scientific) was installed through the MEXT Grant-in-Aid for Scientific Research on Innovative Areas. Carbon and oxygen isotopic compositions are measured using $CO_2$and multiple sulfur isotopic composition are measured using SF_6gas. A new micro-volume inlet system was installed and fundamental parameters such as pressure effect and capillary flow effect were tested. Using the micro-volume inlet system the minimum volume required for analysis is 1 micro-mole sample gas, and the precession for carbon and oxygen isotopic composition are better than 0.1‰. The precession for sulfur isotopes is ±0.3‰ and ±0.01‰ (1s) for $\delta^{34}S$ and $D^{33}S$, respectively, based on the repeated analyses of standard Ag_2S (IAEA S-1).Multiple sulfur isotope measurement system consists of 1) curie point pyrolyzer for rapid conversion of small volume samples to SF_6gas, 2) vacuum line system for pumping out non-condensable gasses, 3) gas chromatograph for purifying the SF_6gas and 4) micro-volume inlet system for introduction of sample gas to ionization chamber.
Multiple sulfur isotope ratios experimental run products were measured using the new system. Metal phases were separated and sulfur was extracted using Cr(II) reduction method [6]. Preliminary results indicate that S isotope fractionations occur in the pressure range of 3–5 GPa, under high-temperature conditions corresponding to the magma ocean environment. The negative $\delta^{34}S$ of mantle, can hence be explained by sulfur isotope fractionation in a magma ocean environment. Sulfur isotope measurements were also carried out on granitoid samples from the Archean with sulfide sulfur showing positive $\delta^{34}S$ values. Mass independent isotope fractionation, expressed as $\Delta^{33}S$, was also observed, suggesting that sulfur in the mantle alone cannot explain these variations. The incorporation of surface sulfur from sedimentary rocks and seawater is proposed.

Electrical resistivity of hcp Fe-Si alloys at high pressure and temperature

*Hayato Inoue[1], Sho Suehiro[1], Kenji Ohta[1], Kei Hirose[2,3], Yasuo Ohishi[4]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. Earth-Life Science Institute, Tokyo Institute of Technology, 3. Department of Earth and Planetary Science, The University of Tokyo, 4. Japan Synchrotron Radiation Research Institute

Silicon (Si) has been repeatedly suggested to be the major light element in the Earth’ s core that mainly consists of iron [1]. Alloying the light element(s) affects a variety of physical properties of iron. Electrical and thermal conductivities strongly constrain the dynamics and thermal evolution of Earth’ s core and these parameters are linked by the Wiedemann-Franz law ($\kappa = \sigma LT$; κ : thermal conductivity, σ : electrical conductivity, L: Lorenz number, T: absolute temperature). However, measurements of electrical and thermal conductivities under static condition at extremely high pressures (P) and temperature (T) are limited for pure iron [2], [3]. The estimates of the core conductivity considering the effect of light element(s) have been done based on the resistivity saturation model, but the validity of the model at the core condition is unclear [4], [5].
In this study, we examined electrical resistivity (the reciprocal of electrical conductivity) of Fe-2, 4 and 6.5 wt.%Si at high P-T conditions in an internally-heated diamond anvil cell (IHDAC) up to 99 GPa and 2910 K. Our results of electrical resistivity of hcp Fe-Si alloys showed its nonlinear temperature dependence, indicating the occurrence of the resistivity saturation. The resistivity saturation in Fe-Si alloys observed in this study supports the notion of high core conductivity and resulting molten lowermost mantle and young inner core.

Electrical resistivity and thermal conductivity of fcc Fe: Implications for the Mercury's core

*Hitoshi Gomi[1], Takashi Yoshino[1]

1. Okayama University

The Mercury's magnetic field may be sustained by the geodynamo motion in the liquid Fe core. However, its strength is about 1% of that of Earth. This weak magnetic field may implies a partly stratified core. Gomi et al. (2013) pointed out that the geometry of the thermal stratification depends critically on the depth dependency of the thermal conductivity. In this study, we conducted first-principles calculations on the face-centered cubic (fcc) Fe to constrain the electrical resistivity and the thermal conductivity of the Mercury's core.

We calculated the electrical resistivity and the thermal conductivity of fcc Fe by means of the Korringa-Kohn-Rostoker method combined with the coherent potential approximation (KKR-CPA) (Akai, 1989). The CPA was adopted to treat the disorder effects due to the atomic vibrations and the magnetic fluctuations on the electronic band structure (Glasbrenner et al., 2014; Ebert et al., 2015; Kou and Akai, 2018). Within the alloy analogy model, the thermal atomic displacements were represented by a discrete set of N_v displacement vectors $\Delta R_v(T)$, where $|\Delta R_v(T)|=\sqrt{<u^2>}$ is the root mean square displacement of atoms, which is based on the Debye model without zero point vibration. The lattice parameter and the Debye temperature are obtained from the equation of state of fcc Fe (Tsujino et al., 2013). In addition to the non-magnetic state, the magnetic disorder was simulated by the local magnetic disorder (LMD) approach. The conductivity was calculated by the Kubo-Greenwood formula with the vertex correction.

The calculated electrical resistivities and thermal conductivities with LMD state are consistent with the literature data at 0 GPa (Ho et al., 1972; 1983), whereas the non-magnetic results show smaller resistivity and larger thermal conductivity. This suggests the importance of the magnetic scattering at low pressures. However, our calculation predicts that the magnetic contribution banishes at higher pressures than 20 GPa. Figure 1 compares the present results and previous experiments (gray broken line; Secco and Scholoessin, 1989, gray square; Deng et al., 2013, open diamond; Pommier, 2018, black circle; Silber et al., 2018) on the electrical resistivity at ~5 GPa. Note that, within the fcc stability field, previous measurements have a large variation. Our calculated resistivity values are between Secco and Scholoessin (1989) and Silber et al. (2018).

We further calculated the electrical resistivity and the thermal conductivity of fcc Fe up to 50 GPa and 3000 K. The thermal conductivity increases with increasing pressure and temperature. This means that, if the inner core is absent, the thermal stratification starts from the bottom, and, after the onset of the inner core, a thick thermal stratified layer may develop at the top of the fluid core (Gomi et al., 2013).

Lateral heterogeneity in the lowermost outer core (F layer) of the Earth revealed by seismic analyses

*Toshiki Ohtaki[1], Satoshi Kaneshima[2], Taku Tsuchiya[3]

1. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST), 2. Department of Earth and Planetary Sciences, Kyushu University, 3. Geodynamics Research Center, Ehime University

We have determined seismic velocity structures of the lowermost outer core (F layer) beneath Northeast Pacific and Australia (Ohtaki and Kaneshima, 2015; Ohtaki et al., 2018), and found that the F layer is seismologically heterogeneous. These structures were obtained using a combination of two observations. First one is differential traveltimes between waves that reflect at the inner core boundary (ICB) and that graze the boundary; the second is dispersion (frequency dependence of velocity) of the grazing wave.

Our results show a somewhat strange velocity profile in the F layer beneath Australia, which has a lower-velocity-gradient layer than that of the Preliminary Reference Earth Model (PREM; Dziewonski and Anderson, 1981) on the ICB, and a higher-gradient layer just above the layer. Recent advance in high pressure research enables seismologists to translate lateral seismic velocity variation to relative chemical abundance in the outer core condition. Based on the results of Ichikawa and Tsuchiya (e.g., 2018), we showed light-element enrichment there. This result suggests that lighter fluid exists beneath Australia in the lowermost part of the liquid core, although the outer core is low-viscosity fluid.

The solid inner core of the Earth has quasi-hemispherical structure (e.g., Tanaka and Hamaguchi, 1997). As the origin of this hemispherical structure, uneven growth of the inner core has been proposed (e.g., Aubert et al., 2008; Alboussière et al., 2010; Monnereau et al., 2010). When the liquid in the outer core solidifies at the inner core surface, excess light element is partitioned to residue because the solid inner core is poorer in light elements compared with the liquid outer core. Thus, the uneven growth of the inner core is tied with an uneven release of the light elements to the F layer, which may be related to our results of the heterogeneous F layer. Then, a question arises: this heterogeneity has hemispherical structure like the inner core or local one?

We have not answered it yet because the survey areas of the above studies are restricted. Furthermore, other studies focusing F-layer velocity are not so many. Souriau (2015) determined lateral variations of velocity in the lower outer core using traveltimes of waves that turn there, and suggested that heterogeneity in F has degree-one feature. We also determined the seismic structure of the F layer beneath Antarctica using amplitude ratios between waves that turn just above the inner core and that get into the inner core. Although the resolution and reliability of structure obtained using amplitude ratios is lower than those using the method of our recent papers, the structure beneath Antarctica has a much lower velocity gradient in the F layer compared with PREM. Such a lower gradient is close to the model beneath Australia.

In this paper, we will show the summary of the heterogeneous F-layer structures of velocity and chemical abundance at this stage.

Flows and light element distribution in the outer core associated with heterogeneous growth of the inner core of the Earth

*Shin-ichi Takehiro[1], Youhei SASAKI[2]

1. Research Institute for Mathematical Sciences, Kyoto University, 2. Department of Mathematics, Kyoto University

Recent seismological observations suggest longitudinal heterogeneity of seismological wave velocity of the inner core of the Earth, which stimulates a discussion that phase change at the inner core boundary (ICB) does not occur uniformly in the horizontal directions. It is simply supposed from this suggestion that temperature is lower and concentration of light element is higher just above the solidification hemisphere at ICB, and vice versa. The heterogeneous structure of the inner core and thermodynamic properties just above ICB in the outer core is expected to be correlated, however, more recent analysis shows that distribution of seismological wave velocity anomaly does not correspond to longitudinal heterogeneity of the inner core.

There are two kinds of mechanisms explaining heterogeneous growth of the inner core. One of the mechanisms is that the heterogeneous thermal condition at the core mantle boundary (CMB) drives horizontal thermal convection which induces non-uniform temperature distribution at ICB. However, since this study uses co-density, which combines density variations by temperature and light element concentration, it cannot find distribution of the light elements just above ICB. Another mechanism is that hydrodynamic instability of the inner core surrounded by the phase boundary causes translational motion inside the inner core. However, since the theory assumes homogeneous light element distribution in the outer core, it is not clear this mechanism can explain the light element distribution above ICB.

In this study, by using a rotating spherical shell model in which temperature and light element concentration are independent variables, we perform numerical experiments of thermal and compositional convection related to two kinds of mechanisms. Obtained distributions of light element concentration are compared with the distribution of seismological wave velocity anomaly, and plausible dynamical regimes of thermal and compositional convection in the outer core are discussed.

Sharpness of the hemispherical boundary in the inner core beneath the northern Pacific

*Ryohei Iritani[1], Hitoshi Kawakatsu[1], Nozomu Takeuchi[1]

1. Earthquake Research Institute, Univ. of Tokyo

The hemispherical heterogeneity in the topmost of the Earth’ s inner core, faster velocity and higher attenuation in the eastern hemisphere and slower velocity and weaker attenuation in the western hemisphere, has been revealed by seismological studies. However, how the transition structure between two hemispheres looks like has not been known because of the difficulty to analyze complex core-sensitive data and the limitation of earthquake and seismic array distribution. In this study, we apply the array-based waveform inversion (Iritani et al., 2014) to core phase data that propagate beneath the northern Pacific, and investigate the nature of the transition structure in this region.Dataset used in this study consists of two directional event-station pairs, seismograms observed by the permanent European stations for events at Fiji-Tonga region, and USArray for events near Indonesia. We analyze the broadband vertical component of core phase data containing PKIKP and PKP phases (i.e. the epicentral distance between 145 –155 degree). Resultant analyzed waveforms for EU stations and USArray are 2,108 and 1,172 traces respectively.
In the analysis, waveform inversion approach is employed for each event data to measure traveltime and attenuation in the inner core. As a result, traveltime anomalies observed by EU stations show obvious positive anomaly suggesting mainly propagating the eastern hemisphere, while traveltimes observed by USAray show relatively smaller (or no) anomalies suggesting effects from both of hemispheres. On the other hand, attenuation parameters for both arrays show similar trend that suggests high attenuation corresponding to the eastern hemisphere. To investigate a hemispherical transition boundary in the sampled region, we conduct a ray theory based forward modeling of traveltimes by changing a shape of boundary from meridian boundary to eyeball shaped boundary, and its position. We compute root-mean-square (RMS) of residual between observations and theoretical traveltimes computed with each boundary model. Then, an eyeball shaped boundary, that is located at longitude of 158°W on the equatorial line and latitude of 80°N at the northernmost point, obtained as the preferred boundary model. Finally, we investigate a sharpness of the boundary by varying a width of hemispherical transition. We assume linear variation from the eastern and western hemisphere in a given width and compute RMS. As a result, a width of 600 km at the surface of the inner core shows smaller RMS than sharp boundary. Geophysical significance of this finding will be further discussed.

Stable carbon isotope fractionation in Fe-C system from first principles

*Haruhiko Dekura[1], Taku Tsuchiya[1]

1. Geodynamics Research Center, Ehime University

Carbon is the fourth most abundant element in the solar system and likely one of the constituent light elements in the Earth’s core. Determination of its equilibrium isotope fractionation factor (α) under high pressure (P) and temperature (T) is a key for understanding chemical evolution such as the whole Earth carbon distributions and the amount in the Earth’s core (e.g., Kumar et al., 2011). Because experimental measurement of the isotope fractionation remains technically challenging at the deep mantle condition, attempts to evaluate the α among mantle minerals by first-principles calculations have been made in recent years (e.g., Huang et al., 2014). Recently, our group initiated the theoretical determination of the α in the Fe-C system in the Earth’s deep interior with a full ab initio approach based on the density-functional theory. We performed ab initio lattice dynamics calculations for diamond and iron-carbide (hexagonal Fe7C3) having the two stable carbon isotopes (12C and 13C). The α between the two phases were then determined by using the Gibbs free energies calculated at P ~300 GPa and T ~2000-6000 K. The obtained $10^3 \ln \alpha$ dia-Fe7C3 is found to vary with T from ~+8‰ (2000 K) to ~+5‰ (6000 K). This result indicates that the Fe7C3 is enriched in the heavier isotope (13C) compared with diamond. This trend is qualitatively consistent with low-pressure experimental observations (Kumar et al., 2011).

Lithology and zircon U-Pb geochronology of Paleoproterozoic and Paleozoic granitic complex in Maizuru Terrane from Tsuwano area, Shimane Prefecture, SW Japan

*Kosuke Kimura[1], Yasutaka Hayasaka[1], Tomoyuki Shibata[1], Kenta Kawaguchi[1], Hiroshi Fujiwara[1]

1. Hiroshima University

Maizuru Terrane is geographically distributed from Oshima Peninsula of Fukui Prefecture to western Shimane Prefecture, Southwest Japan. Maizuru Terrane is divided into three subzones, the Northern zone, Central zone, and Southern zone. Northern zone is mainly composed of granitic rocks and metamorphic rocks that derived from continental crust, and Siluro-Devonian granitoids have been reported from Maizuru-Oe area which is the type locality of the Maizuru Terrane (Fujii et al., 2008; Tsutsumi et al., 2014). Recently, Kimura et al. (2018) reported granitic complex from Tsuwano area, Shimane Prefecture. This complex contains not only Paleozoic granitoid that show same age of the Maizuru granite but also the late Paleoproterozoic granitoid and orthogneiss those are unreported so far from the basement rock distributed in Honshu island.

The granitic complex occurs in Tsuwano area is distributed discontinuously along with the northern margin of Maizuru Terrane, and about 2 km long. This complex occurs as lenticular blocks in a narrow zone of several hundred meters in width. This complex is mainly composed of granitic rocks and mafic rocks that intruded into granitic rocks, and suffered cataclasis in the major part. From the viewpoint of their age and lithology, this granitic complex could be divided into three groups, which are as follows:

1) early Paleoproterozoic metaquartzite: Quartz completely recrystallized and doesn’t show the dust rim. Grain boundary shows sutured texture. Detrital zircon grains show reddish brown color and rounded shape. Zircon U-Pb concordant ages are only older than 2.4 Ga, and the probability density curve shows two large peaks around 2.5 Ga and 2.7 Ga.

2) late Paleoproterozoic granitoids and orthogneiss: These rocks are most common in the granitic complex. These rocks show various lithology. Orthogneiss show banded structure and granoblastic texture. Zircon grains show reddish brown color and core-rim structure, and zircon U-Pb ages range 1.85-1.83 Ga. Furthermore, 2.8-2.05 Ga inherited ages are also yielded.

3) early Paleozoic rocks: These Paleozoic rocks are less in amount than Paleoproterozoic rocks in Tsuwano area. Paleozoic rocks are subdivided into plutonic rocks and volcaniclastic rocks. Plutonic rocks are leucocratic granodiorite and metagabbro. Their zircon U-Pb ages range from 423-411 Ma. On the other hand, volcaniclastic rock is felsic tuff that shows light brown to light greenish gray color, and this lithology varies from glassy to crystalline. Zircon U-Pb ages range from 424-413 Ma.

Metaquartzite have only older than 2.4 Ga concordant ages in spite of 1.85 Ga rocks are most common in this granitic complex. Therefore, the sedimentation age of metaquartzite is considered to be between 2.4

©2019. Japan Geoscience Union. All Right Reserved.

to 1.85 Ga. On the other hand, detrital monazite and zircon ages reported from orthoquartzite pebble that occur in the conglomerate layer of Tetori and Muro groups show 1.8 Ga peak (Yokoyama et al., 2002; Hisada et al., 2010). Therefore, metaquartzite occur in Tsuwano area have a different origin that of these orthoquartzite pebbles.

Ages of 2.7, 2.5 and 1.8 Ga that measured from metaquartzite and late Paleoproterozoic rocks are consistent with similar rocks reported from North China Craton.

Zircon U-Pb ages of early Paleozoic rocks range from ca. 424-411 Ma. These ages and occurrence of this granitic complex are consistent with that of Northern zone from Maizuru-Oe area. Therefore, the granitic complex of Tsuwano area can be compared with Northern zone of Maizuru Terrane.

Tectonic significance of new Zircon U-Pb ages of sedimentary complexes in the northern Hidaka Belt, central Hokkaido, northern Japan

*Futoshi Nanayama[1,5], Toru Yamasaki[1], Jun Tajika[2], Hideki Iwano[3], Tohru Danhara[3], Takafumi Hirata[4]

1. Geological Survey of Japan, AIST, 2. Docon Co. Ltd, 3. Kyoto Fission-Track Co.Ltd, 4. Tokyo Univ., 5. CWMD, Kumamoto Univ.

The Hidaka belt in the central axis zone of Hokkaido has been one of the areas where geological research is most delayed in Japan, and their depositional ages and tectonic settings were not clear untill now. It has been considered as late Cretaceous accretionary complex like the Shimato belt in southwestern Japan. In this study, zircon particles are extracted from turbidite sandston beds of eastern Rurochi Formation, central Kamiokoppe Formation and western Iwaonai Flysch and zircon U-Pb ages were measured by LA-ICP-MS method. As a result, age values of 52.4 ±0.5 Ma from Rurochi Formation, 54.9 ±0.3 Ma from Kamiokoppe Formation and 47.3 ±0.5 Ma from Iwaonai Flysch were obtained respectively. Looking down the entire Hidaka belt including the age data of the southern part of the Hidaka belt reported by Nanayama et al. (2018), the following four points have been clarified.
(1) Clastic rocks (Hidaka Supergroup) distributed in the Hidaka belt are within the age of Paleocene ~ early Eocene.
(2) The Hidaka belt is distributed widely across the east-west width of more than 100 km. However, its internal structure and age differences are not clear, and it can not be explained by the accretionary growth model which becomes younger in the eastward.
(3) There is no significant age difference in the eruption age of the three bands of in situ basalts (N-MORB) recognized in the Hidaka belt (Miyashita et al., 1997), and if this is explained by the ridge subduction model, It can be explained only one event.
(4) The Hidaka Supergroup was a sedimentary body mainly composed of turbidite facies filled in the sea area between the Paleo-Japan arc and the Paleo-Kuril arc in Paleocene ~ early Eocene age. After 47 Ma, according to the joining of two arc-trench systems, significant deformation was occurred it. So, it is considered to be "collision complex".

New age constraints and tectonic significance of Late Oligocene marine biosiliceous deposits in the Hidaka Belt, northeastern Hokkaido, northern Japan

*Futoshi Nanayama[1,6], Hiroshi Kurita[2], Toru Yamasaki[1], Jun Tajika[3], Hideki Iwano[4], Tohru Danhara[4], Takafumi Hirata[5]

1. Geological Survey of Japan, AIST, 2. Niigata Univ., 3. Docon Co. Ltd, 4. Kyoto Fission-Track Co. Ltd, 5. Tokyo Univ., 6. CWMD, Kumamoto Univ.

The Tatsuushi Formation distributed in the Kitami-Monbetsu area consisted of siliceous mudstone, and has been incorporated into the Hidaka Supergroup along associated with the surrounding the Uenkotan and Rurochi Formations (Tajika and Iwata, 1994). In this study, the depositional age of the Tatsuushi Formation was examined by three methods. Detrital zircon grains are separated from turbidite sandstone and a U-Pb age of 27.2 ±0.1 Ma is obtained by the LA-ICP-MS method. Dinoflagellate cysts indicate late Oligocene and early Miocene, respectively. Therefore, the U-Pb age is shown as the depositional age of this formation. The depositional age of the Hidaka Supergroup has been reported Paleocene to Early Eocene so far. Therefore, it is difficult to include this formation in Hidaka Supergroup. The Tatsuushi Formation can be compared to the Erimo Formation in the soutjern Hidaka Belt (Kurita and Kusunoki, 1997) and the lower part of the Tsubetsu and Kawakami Groups based on their depositional ages and affinity of the lithology (Kurita et al., 1998) distributed along the Abashiri tectonic line as the right-lateral strike-slip fault since late Oligocene. These siliceous mudstones may have been formed by the upwelling flow caused by the bottom deepwater brought from the Sea of Okhotsk by the opening of the Kuril basin.

This work was supported by JSPS KAKENHI Grant Number 16K05585.

Late Cretaceous sea-level changes and tectonic history recorded in the forearc sedimentary successions of the Northeast Japan

*Jun Arimoto[1], Reishi Takashima[2], Hiroshi Nishi[2], Yuji Orihashi[3], Toshiro Yamanaka[4]

1. Department of Earth Science, Graduate School of Science, Tohoku University, 2. The Center for Academic Resources and Archives, Tohoku University, 3. Department of Earth and Environmental Sciences, Graduate School of Hirosaki University, 4. Tokyo University of Marine Science and Technology

Elucidating tectonic history of the Cretaceous East Asian continental margin provides us essential information to understand the origin of modern Japanese islands and paleo-biogeography of terrestrial fauna and flora, with implications for connection with the Eurasia continent. One of the keys to reconstruct the geologic history of the NE Japan is the Upper Cretaceous to Paleogene siliciclastic sedimentary successions that filled a N-S trending large fore-arc basin (the Yezo forearc basin) along the Pacific margin. The Futaba, Kuji, and Yezo groups are known as representative strata among these successions, and have been well studied. Especially the Kuji and Futaba groups were accumulated in shallow-marine and non-marine environments, and their facies changes were reflected by relative sea-level changes attributed to global eustacy and regional tectonic uplift/subsidence. The previous studies for these two groups, however, have not fully made it clear that the observed depositional changes were derived from local tectonic effects or global eustatic sea-level changes due to lack of precise age controls. To address this issue, here we provide the latest age model of the Kuji Group and partly revised regional sequence stratigraphic correlation. Comparing our age-calibrated depositional sequences of the Kuji Group with an available global sea-level reconstruction would separates the influence of eustacy from that of regional tectonics which formed the Yezo forearc basin sedimentary successions.

The Kuji Group is distributed along the northeastern coastal area of the Iwate prefecture. The group mainly comprises sandy siltstone, coaly mudstone, sandstone and conglomerate, with intercalated coal and felsic tuff beds. The total thickness is over 700 m. It unconformably overlies the pre-Cretaceous accretionary complex and lower Cretaceous granitoids, and is unconformably overlain by the Paleogene siliciclastic succession. The Kuji Group is divided into three lithostratigraphic units: the Tamagawa (marine and non-marine), Kunitan (marine), and Sawayama (non-marine) formations, in ascending order. The overall succession consists of at least four largely upward-fining sequences. Previous studies on sedimentary facies analysis divided them into five depositional sequences derived from the third-order sea level change (DS1 to DS5) (Ref. 1).

The newly established age model, based on carbon isotope stratigraphy and U–Pb ages, indicates that the depositional sequences in the Kuji Group is correlated with the middle Turonian to middle Campanian stages. The DS2 to DS4 in the Kuji group are likely coeval with the depositional sequences of the adjacent Futaba Group (the Coniacian to Santonian stages) (Ref. 2). Relative sea-level changes recognized in the DS1 to DS4 are mostly consistent with the second- and third-order global eustatcy (Ref. 3). In contrast, the DS5, equivalent to the Sawayama Formation of the Kuji Group, represents lowstand systems tract (non-marine fluvial facies) with maximum thickness of 200 m. Similarly, development of shallower facies is implied in the Hakobuchi Formation (the Campanian stage; Ref. 4) of the Yezo Group, accumulated in the northern sub-basin. These coeval relative sea-level falls are apparently inconsistent with contemporaneous global transgressive trend, and thus are interpreted to reflect basin-wide uplift of the forearc region in the early Campanian. Here we provide a new constraint for the age of the major tectonic event occurred in the Late Cretaceous East Asian continental margin, possibly related to the change in

©2019. Japan Geoscience Union. All Right Reserved.

subducting oceanic plate motion (e.g. Ref. 5).

Paleo-stress analysis in coherent zone, an exhumed Cretacesou accretionary complex, Shimanto Belt, in Konan city and Geisei villege, Kochi prefecture, SW Japan

*Makoto Hashiguchi[1], Yoshitaka Hashimoto[1]

1. Kochi University

Stress state in a subduction zone can be exchanged between reverse-fault and normal-fault regimes with an earthquake cycle. A similar change in paleostresses has been also obtained in some exhumed accretionary complexes (e.g., Hashimoto et al., 2014). However, most of previous studies in exhumed accretionary complexes cover only mélange zones exposed to the coastline. Therefore, in this study, we examine the paleostress change in a coherent zone. In order to investigate a spatial relationship, we analyzed the paleostress in the coherent zone adjacent to a mélange zone.

The study area is in Konan City, Yasu Town and Geisei Village in Kochi Prefecture, Southwest Japan where the Cretaceous northern Shimanto Belt is cropped out. The geology of the study area is composed of the coherent and mélange zones in the northern and the southern sides, respectively. The coherent zone consists mainly of alternating layers of sandstone and mudstone. The strike and dip of bedding are about N 37 ˚E and 75 ˚S, respectively. The age of the coherent zone has been reported as Cenomanian–Campanian (100 Ma–72 Ma) from microfossils (Taira et al., 1988). As a result of the micro-fault analysis, six stress state (stress 1, 2, 3, 4, 5, and 6) were obtained. Four stresses (stress 1, 3, 5, and 6) could be reasonbale because many unique faults, which are micro-faults with misfit angle of less than 30 degree only in individual stress state, are found. Stress 2 and stress 4 are not treated as reasonable stress solutions because the number of the unique fault is small. Stress 1 and stress 3 are the reverse-fault stress regimes. Stress 5 is obscured for fault types. Stress 6 is a normal-fault stress regime.

In order to constrain stress magnitude, stress polygon was employed. Furthermore, a liner function between SHmax and Shmin can be obtained from the estimated paleo-stress, which can be drawn in the stress polygon. Sv is calculated from density and paleo-maximum depth (5.5 km from vitrinite reflectance). Stress magnitude would be constrained from the overlapping area between the stress polygon and the liner function. According to the results, the stress for the reverse fault regimes is larger than that for the normal fault stress regime. In addition, assuming that the reverse fault changed to a normal fault, the validity of the difference of shear stress (stress drop) was examined. The stress drop is estimated from the difference in the radius of Mohr circles ((SHmax - Shmin) / 2) between the normal fault and the reverse fault stress regimes. The stress drops between stress 1 (reverse fault) and stress 6 (normal fault) ranges, and stress 3 (reverse fault) and stress 6 (normal fault) range 1.8-14.0 MPa and 43 - 63 MPa, respectively. Susan L. et al. (2018) showd the distribution of stress drops from geophysical observations in trench type earthquakes rangeing approximately 0.01–100 MPa. The stress drops obtained from our results are consistent with the range of 0.01-100 MPa. Therefore, it is possible for our results to be related to earthquake cycles.

In conclusion, we would like to emphasize that the exchange of stress accompanying earthquake cycles occurs even in the coherent zone as the same as that observed in mélange zones based on the differences in stress magnitude between the reverse and normal fault stress regimes and the reasonable range of stress drop. The interpretation that the exchange of stress observed in the mélange zone and

©2019. Japan Geoscience Union. All Right Reserved.

also in the coherent zone implies that the exchange in stress state could be recorded after the mélange zone were located adjacent to coherent zonet. In other words, it is suggested that the micro-faults we examined in this study were activated within an accretionary wedge at the critical stress states.

Relationship between accretion of limestone blocks and subduction tectonics in Japan

*Koji Wakita[1]

1. Yamaguchi University

Detailed mechanism for accretion of limestone and basalt is not elucidated yet. Seamount collapse occurs in the tectonic erosion convergent margin such as the Japan trench, but the seamount accretion does not happen in accretionary convergent margin such as the Nankai trough. How are the limestone and basalt blocks preserved in accretionary complexes? The key to understand the reason of accretion of limestone and basalt is the tectono-stratigraphic position of limestone and basalt blocks. In the most of the Japanese accretionary complexes, limestone and basalt blocks occur in the youngest unit of each complex. The cessation of the development of the accretionary complex must be associated with the special tectonic setting, which caused less supply of detrital materials from the provenance area. Flat slab subduction is one of the candidates to cause the less igneous activities in the provenance area. The flat subduction may be caused by the subduction and accretion of buoyant body such as ocean plateau. This subduction and accretion of oceanic plateau caused the cessation of accretionary process, and may have allowed to preserve limestone and basalt block in the accretionary complexes in Japan.

Discussion

Discovery of faulted basin margin from the middle Miocene Tottori Grope, Tottori Prefecture, Southwest Japan and its significance

*Yuta Maruyma[1]

1. Shimane Umiversity

Some Miocene sedimentary basins in the San’in region extend N-S or NE-SW and, have been called the indentation of sedimentary basins. Several studies speculated that these basins were aulacogenes formed in association with the Japan Sea opening event, or extensional basins opened parallel to the rifting axis before the rotation of Southwest Japan. The little sedimentary geological and chronological studies for this type of sedimentary basins remain their evolution to have been still unknown. The precise reconstruction of evolution of these sedimentary basins leads to understanding of the deformation of Southwest Japan crust associated with the Japan Sea opening event and thus to know the concrete Japan Sea opening process. The geological information in the marginal part of such type of basin fills is indispensable in order to elucidate their evolution.

A sedimentary basin, extending almost N-S and called the Tottori Indentation, is spread in the eastern part of Tottori Prefecture, Southwest Japan. Because the sediments of this basin have not been suffered from extensive intrusion of the volcanic rocks in its southeastern part, unlike the other basin fills in the Shimane Prefecture, this is an ideal sediment succession as the target of the sedimentary basin analysis in order to know the evolution of this type of sedimentary basins. The present study conducted geological survey of the Tottori Group using a conventional sedimentary geological method (facies analysis) for reconstruction of the sedimentary environment of the southeastern part of the Tottori Group (Iwami Formation).
The Iwami Formation of the Tottori Group is made up from the Entsuji Conglomerate and Sandstone Member (EM) and Fuganji Mudstone Member (FM). The FM contains both freshwater and marine mudstones. New faults with large displacement on and near the boundary with the underlying rocks are discovered. One represents the boundary between the granitic rock and the EM sandstone with thin vertical veneer of the deformed Kawabara Volcanic Rock Member of the underlying Yazu Formation along the fault. The other is running within the EM sandstone. The presence of gravels of debris fall origin in the FM mudstone near the fault and the talus deposits together with the presence of the deformed Yazu Formation along the fault imply that the fault started to be activated after the Kawabara Member phase and may have been active during the Fuganji period to have formed the slope along the fault. As the result, the block to the west of the fault subsided to have formed a lacustrine basin. Another faults are also expected along the boundary between the basement rock or the Yazu Formation and the Iwami Formation based on the presence of small slump structures indicating a slope that dipped away from the boundary in the southeastern part of the group. Additional study is necessary in order to elucidate the basin type (e.g. strike slip basin or half graben) and to determine the specific timing of basin generation. The present study is financially supported by the Grant-in-aid for scientific research from the San’in Kaigan UNESCO Global Geopark Promotion Council.

Fault activity during Quaternary Period off the Shimane Peninsula based on the profiles acquired by the high-resolution seismic survey

*Masaaki Tanaka[1], Norihiro Matsuda[1], Masaru Nakamura[1], Yuichi Shimizu[1], Masanori Shimazaki[2], Kazuhito Hatakeyama[2]

1. The Chugoku Electric Power Co., Inc., 2. Sogo Geophysical Exploration Co., Ltd.

A number of faults are shown off the Shimane Peninsula by Tamaki *et al.* (1982), Japan Coast Guard (1991, 1992), Tokuyama *et al.* (2001) and others. The Chugoku Electric Power Co., Inc. (Energia) carried out seismic reflection survey by using mainly Sparker in 1981 in the area including some faults described by the above-mentioned authors. The investigated area was about 60 kilometers long along the shoreline and about 30 kilometers long perpendicular to the shoreline. Seismic survey lines were deployed at the interval of about 1 to 4 kilometers in it. Since then, Energia has continually been investigating to grasp more detailed locations and characteristics of the faults in the area by using the latest technology such as multi-channel seismic system and so on. Furthermore, Energia has referred to the concepts of sequence stratigraphy in its interpretation to improve the reliability of the evaluation for fault activity. Government organization MLIT, Cabinet Office and MEXT referred to the Energia's fault evaluation in their document published in 2014.

Structures found off the Shimane Peninsula mostly extend ENE-WSW, forming reverse faults and flexures. Ito and Arato (1999) and others indicate that the stress field off the San-in district was north-south compression during Late Miocene epoch and has been east-west compression since Pliocene epoch, and many folds and reverse faults extending ENE-WSW in this region were developed during Miocene epoch. Therefore, most faults off the Shimane Peninsula are considered to develop around Late Miocene epoch under the north-south compression stress field and end their activity by Latest Miocene epoch. However, Middle to Upper Pliocene (Unit-B) off the Shimane Peninsula is distributed in a narrow area, and it is also extremely thin. These factors have made the evaluation for fault activity during Quaternary period difficult.

On the basis of the above information, we conducted seismic survey in 2014 by using various sound sources off the Shimane Peninsula to grasp the detailed geological structure from shallow to deep. We also conducted bottom sampling for dating on the seismic line at about 7 kilometers off the coast of Kashima town in Matsue city. The samples collected in Unit-A were analyzed by tephrochronology and radiocarbon dating. As a result, we found the Sanbe-Unnan (SUn : about 50ka. Machida and Arai, 2011) tephra and a few samples dated as Late Pleistocene. This shows that most Unit-A is possibly Upper Pleistocene except its surface portion. We confirm that the conventional sparker profiles cannot distinguish Unit-A in more detail, but the high-resolution profiles acquired by multi-channel boomer system can distinguish it into more units : Middle to Upper Pleistocene and Holocene.
From the above, we confirm that faults existing within the area where Middle to Upper Pleistocene, have been inactive at least since Late Pleistocene epoch. Pleistocene possibly exist much more widely compared to the previous interpretation off the Shimane Peninsula. Additional multi-channel high-resolution boomer seismic survey may contribute to reveal the detailed fault activity under the east-west compressive stress field in Quaternary period.

Paleomagnetic directions of early Miocene sediments in central Japan and tectonic implications

*Hiroyuki Hoshi[1], Takuro Matsuo[2]

1. Department of Earth Sciences, Aichi University of Education, 2. Aichi Prefectural Kariya High School

We present new paleomagnetic data obtained from early Miocene (~18-17 Ma) sediments in three areas (Iwamura, Tengudana and Niinotoge) in central Japan. Oriented cores consisting mainly of mudstones and intercalated fine felsic tuffs were collected at more than 50 sites. Stepwise thermal demagnetization of both natural and isothermal remanent magnetizations suggests magnetite as a main magnetic carrier, with possible presence of greigite in rock samples from some sites. Site-mean directions of characteristic remanent magnetization components are all reverse polarity, suggesting deposition within the same reverse polarity chron, probably Chron C5Dr. Declinations of the site-mean directions are mostly southwesterly and deflected clockwise from the expected direction, indicating clockwise rotation after deposition. These declinations are similar to those from early Miocene and older rocks of the main part of the SW Japan arc, while they are significantly different from the undeflected paleomagnetic direction from Tomikusa, located 10-20 km northeast of Niinotoge. Thus, the Iwamura, Tengudana and Niinotoge areas are located on the main part of the SW Japan arc. It is suggested that the main part of the SW Japan arc has its eastern "rotational" boundary with a differentially rotated piece of crust between Niinotoge and Tomikusa.

Revised Cenozoic chronostratigraphy and tectonics in the Yatsuo Area, Toyama Prefecture, central Japan

*Takeshi Nakajima[1], Hideki Iwano[2], Tohru Danhara[2], Tohru Yamashita[2], Yukio Yanagisawa[1], Yoshihiro Tanimura[3], Mahito Watanabe[1], Takayuki Sawaki[1], Satoshi Nakanishi[4], Hiroyuki Mitsuishi[4], Okiyuki Yamashina[4], Seiichi Imahori[5]

1. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, 2. Kyoto Fission-Track Co., Ltd., 3. National Museum of Nature and Science, 4. JX Nippon Oil & Gas Exploration Corporation, 5. JX Nippon Oil & Gas Exploration Technical Services Corporation

Cenozoic chronostratigraphy of the Yatsuo Area in Toyama Prefecture is revised based on U-Pb and fission-track (FT) dating on the same zircon grains from tuff beds using LA-ICP-MS, mineralogical analysis of tuff beds and diatom biostratigraphy. The results reveal followings. Syn-rift volcanism (the Iwaine Formation) started at around 17.5 Ma. The Ikahama unconformity between the syn-rift Higashibessho Formation and the post-rift Tenguyama Formation was a relatively short duration (c. 0.5 m.y.) tectonic event around 15 Ma. The Otogawa Formation unconformably overlying the Tenguyama Formation is divided into Middle Miocene (Serravallian) lower portion and Late Miocene upper portion with a possible unconformity between them. The age of the Mita Formation ranges from 4 to 2 Ma and unconformably overlies the Otogawa Formation. Local correlation of a key tuff bed MT2 in the Mita Formation in previous reports was misleading and needs to be reassessed.

Facies and sequence stratigraphic analysis of the lowermost Nirehara Formation clarifies that the Nirehara Formation comprises many depositional cycles formed by sea level or lake level fluctuation in a coastal or lacustrine fan delta environment. The results also suggest that the Nirehara Formation was formed in an early rift basin, which is overlain by the syn-rift Yatsuo Group with an unconformity. Detrital zircon U-Pb and FT dating of sandstone in the Nirehara Formation suggests that possible source of sandstone was the Nohi Rhyolite.

Regional correlation of onshore and offshore Cenozoic chronostratigraphy in the Hokuriku district shows multistage rifting during Oligocene-Middle Miocene opening of the Sea of Japan. The regional correlation also suggests that post-rifting compressive tectonics was also incremental associated with fluctuation of strength and direction of compressive stress fields.

Petrogenesis of Oligocene to Miocene volcanic rocks in the Tonami area, central Japan: temporal evolution of continental- to island-arc volcanism during the Japan Sea opening

*Raiki Yamada[1], Toshiro Takahashi[2], Hayato Ueda[2]

1. Graduate school of science and technology, Niigata University, 2. Faculty of Science, Niigata University

The Japan islands was torn from the continent to form island-arc by spreading of the Japan Sea in Late Oligocene to Early Miocene. Basaltic to rhyolitic active volcanism occurred in the Japan arc during the Japan Sea opening. Since many researchers have targeted mainly mafic volcanic rocks for petrological study, petrological and geochemical studies on Oligocene to Miocene rhyolites are not still enough. Therefore, we examined Oligocene to Miocene volcanic rocks, including Chattian to Aquitanian and Burdigalian to Langhian rhyolites, on the basis of petrology and geochemistry.

Oligocene to Miocene strata consist of the Tori Conglomerate, Usunaka Moonstone Rhyolite, and the Iwaine and Iozen formations, in stratigraphically ascending order (Sudo, 1979; Ganzawa, 1983), the study area, Nanto City, Toyama Prefecture. The Tori Conglomerate is composed of conglomerate and sandstone, whereas the others are composed of volcanic and pyroclastic rocks; the Usunaka Moonstone Rhyolite, and the Iwaine and Iozen formations consist of rhyolitic welded tuff, andesites (lava and pyroclastic rocks), and rhyolites (lava and pyroclastic rocks), respectively. In this study, weighted averages of ^{238}U–^{206}Pb ages of 22.4 ±0.7 and 16.3 ±0.6 Ma are obtained from zircons in the Usunaka Moonstone Rhyolite (welded tuff) and the Iozen Formation (aphyric lava; the same outcrop as FU06 of Ganzawa (1983)). These ages indicate formation ages of the rhyolites, because they are consistent with K–Ar (Yamasaki and Miyajima, 1970; Ueda and Aoki, 1970) or fission track ages (Ganzawa, 1983), whose blocking temperatures are much lower than zircon U–Pb age.

Following petrogenesis of Oligocene to Miocene volcanic rocks is considered by whole-rock chemical compositions (major and trace elements, and Sr–Nd isotopes) and comparison with other studies. The Usunaka Moonstone Rhyolite (25–22 Ma) is alkalic rhyolite showing intermediate compositions between continental rifts and continental-arcs, and its magma was S-type and relatively dry. Therefore, it is continental-arc rift-type rhyolite, and mafic magma in subduction zone would have melted crustal materials derived from sedimentary rocks. Andesitic volcanism of the Iwaine Formation can be divided into two stages (e.g., Yamada and Yamada, 2018); amphibole-bearing andesite (high Sr andesite; 19–18 Ma?) and two pyroxene andesites (18–16.5 Ma?). Amphibole-bearing andesite is low-SiO_2 adakite (Martin et al., 2005) generated by partial melting of mantle wedge matasomatised by adakitic melt formed by slab melting. Two pyroxene andesites, who and equivalent beds have the large distribution in the Hokuriku region, are continental-arc type tholeiites, and their compositions suggest AFC (assimilation and fractional crystallization). The Iozen Formation (16.5–15.0 Ma) has intermediate chemical compositions between continental- and island-arcs, and its magma was I-type and had high water content. The Iozen Formation got primitively dacitic to rhyolitic composition, and almost only fractional crystallization occurred in magma chamber. High-temperature state, which had continued since the Iwaine Formation, in mantle wedge would had caused crustal melting.

Above genesis of Oligocene to Miocene volcanic rock in the study suggests that high temperature was kept in mantle wedge and continental crust during the back-arc spreading and that tectonic settings changed as time went on; continental-arc rift, continental-arc, and continental- to island-arc. This reflect that the Japan arc developed from continental- to island-arc through the Japan Sea opening, a back-arc formation.

Geology and post mid-Miocene tectonics of the Ogawa basin and the Atogura Nappe

*Akira Ono

The Sanbagawa Belt in the Kanto Mountains consists of the Sanbagawa Unit, Mikabu Unit and Atogura Nappe which are piling up in this order. The Atogura Nappe is widely distributed in the Yorii-Ogawa area. The main part of the Atogura Nappe is surrounded by autochthonous pre-Cretaceous geological units with high angle faults. The Atogura Nappe is unconformably overlaid by the early Miocene deposits in the Ogawa basin (Figure 1). The early Miocene Ogawa basin was a low mountainous area. The sea invaded, and conglomerates and sandstones of the Kozono Formation deposited. As the sea level rise further, mudstones of the Arakawa Formation deposited. Then the Miocene deposits and the Atogura Nappe were subjected to upheaval tectonics. Small rock masses of the Mikabu Unit in the Atogura Nappe are evidence for the post-early Miocene uplifts.

Gently dipping Miocene strata are distributed in the western part of the Ogawa basin which is divided into three areas, i.e., Notake, Iida and Central areas. Basement rocks of these areas are Yorii Formation, Atogura Formation and Kinshozan quartzdiorite, resepectively. In the Notake area, sandstones and conglomerates are widely distributed, and are overlaid by mudstones of the Arakawa Formation. The sandstone below the mudstone is about 3 m in thickness. The depth of the basement rock is unknown in the Notake area. However, judging from shallow Miocene valleys in the Ogawa basin, the thickness of the Kozono Formation may be about 50 - 100m. Miocene conglomerates are mainly composed of many large rounded granite clasts (open red circle in Figure 1). The provenance of the granite clasts appears to be the Ryoke Nappe located between the ridge lines rB and rC (Figure 1). Small Miocene deposits are exposed at three locations in the northeastern part of the Notake area. Miocene coarse sandstones unconformably overlie the Paleogene mudstones of the Yorii Formation at the northernmost exposure. The sandstones of about 10m in thickness are conformably overlaid by the Miocene mudstones. The boundary between the Kozono and Arakawa Formations is located at the altitude of about 140m in the Notake area.

In the Central area, Kinshozan quartz diorite is exposed widely, and is unconformably overlaid by sandstones of the Kozono Formation. In the Iida area, conglomerates are distributed near basement rocks (Figure 1, black circles), which mainly consist of clasts of chert, sandstone and mudstone. On the other hand, mudstones are widely exposed in hills and plains with low altitudes.

Figures 1A, 1B and 1C are schematic geological sections across the N-S direction of the western part of the Ogawa basin. Figure 1A is based on the assumption of slight post-Miocene uplift. On the other hand significant post-Miocene uplifts and tilting movements are assumed for Figure 1B. Judging from many exposures of the unconformity, early Miocene and present-day earth surfaces are close to each other in many localities (Figure 1C). Moreover, thin gently dipping Miocene deposits widely overlie the various rocks of the Atogura Nappe. These geological facts suggest that the Atogura Nappe and Miocene deposits were subjected to no remarkable tectonics after early Miocene. However, the quartz diorite in the Central area was subjected to upheaval tectonics. It is in contact with Miocene strata by high angle faults. However, early Miocene sandstones overlying the quartz diorite are distributed rather widely. Moreover, the Mikabu Unit is not exposed anywhere. Hence, no remarkable uplift occurred in the Central area. Contrary to the Central area small three blocks of Mikabu greenstones in the FujiYama area suggest a significant uplift of the Mikabu Unit. However, small exposures of Miocene sandstones are evidence for weak uplifts of the Atogura Nappe in the FujiYama area.

Paleostress transition estimated from small-scale deformation structures of the Sanbagawa metamorphic rocks in the Nagatoro area, Saitama Prefecture, central Japan

*Minami Nakamura[1], Aiko Takada[1,2], Hideo Takagi[1]

1. Waseda University , 2. Japan Petroleum Exploration Co., Ltd.

Low-grade metamorphic rocks of the Sanbagawa belt are well exposed in the Nagatoro area, Saitama Prefecture, where deformation structures such as folds, kink bands, faults, and mineral veins are well developed. Uemura and Kanesaki (1989) described deformed small structures in detail in the Nagatoro area, and reported that deformation stages (D1~D5) can be divided by cutting relationship. In low-ductility phase, contractional kink bands (D4 stage) were formed prior to extensional kink bands, small faults, and mineral veins (D5 stage). However, few studies have focused on the paleostress fields of D4 and D5 stages forming these structures. This study aims to determine the paleostress fields and to study its detailed deformation history of the Sanbagawa metamorphic rocks of in the Nagatoro area using paleostress analytical methods after Yamaji et al. (2006), and Yamaji and Sato (2011). We measured the attitudes (and slip directions) of 27 kink bands, 17 small faults, and 202 white mineral (quartz and/or calcite) veins to determine the paleostress fields. By using the Hough transform method (Yamaji et al., 2006), contractional kink bands (D4 stage) are indicated to have been subjected to Stress D4 (σ_1: 216˚/18˚, σ_3: 54˚/71˚), while the extensional kink bands and small faults (D5 stage) to the two different stresses; Stress D5-1 (σ_1: 180˚/79˚, σ_3: 47˚/8˚), and Stress D5-2 (σ_1: 33˚/32˚, σ_3: 211˚/58˚). These results are also consistent with those of paleostress analysis using the quartz veins (D5 stage). Furthermore, the stress analysis using calcite twins in the veins indicates that deformation structures in D5 stage were subjected to Stress D5-1 prior to Stress D5-2. These results imply that the Sanbagawa metamorphic rocks in the Nagatoro area have experienced the transition of three paleostress fields from D4 through D5-1 to D5-2 stages. Considering the mean ductility of each small structure and the deformation temperature (around 200 ˚C: Burkhard, 1993) estimated from the geometrical characteristics of calcite deformation twin, these small structures are sequentially formed at the time of exhumation of the Sanbagawa metamorphic rocks.

Estimation of the paleostress directions using “new dyke method” from the microcracks in the Tanzawa Tonalite

*Misaki Tomioka[1], Hideo Takagi[1]

1. Waseda University

The Tanzawa Tonalite intruded around 5-4 Ma (Tani et al. 2010) is located in the South Fossa Magna region that records the collision of Izu-Bonin Arc against the Honshu Arc. The paleostress direction has been estimated from the analysis of microcracks in quartz grains in the Tonalite (Sato and Takagi, 2010). Healed microcracks (HC) forming the plane of fluid inclusions are considered that they had formed just after the intrusion using fluid inclusion thermometry, and sealed microcracks (SC) had formed after HC formation by crosscutting relationship. The orientations of both HC and SC indicate that σ_{Hmax} keeps around N-S~NNE-SSW direction. Recently, Yamaji et al. (2010), and Yamaji and Sato (2011) developed new method of grouping the orientations of dikes or veins (cracks) recording different stress field, and then to determine σ_1, σ_2, σ_3 axes of each group and stress ratios by fitting mixed Bingham distribution (Bingham, 1974) (hereinafter called “new dyke method”). In this study, we estimated the paleostress using “new dyke method” for oriented samples used by Sato and Takagi (2010) to make it clear whether the σ_{Hmax} is σ_1 or σ_2.
We measured strikes and dips of intracrystalline HC and SC using U-stage, and then analysed the distribution using “new dyke method” and the correction developed by Kanai et al. (2014) to determine σ_1, σ_2 and σ_3.
As a result, the dominant stress directions for 16 points (HC) and for 22 points (SC) indicate that σ_1 for HC and SC concentrates in vertical and NE-SW direction, respectively. With correcting 10° clockwise rotation by paleomagnetic research (Kanamaru and Takahashi, 2005), the paleostress orientation results should be vertical around 4Ma, and in NNE-SSW direction after 4Ma. Accordingly, the σ_{Hmax} evaluated by HCs after Sato and Takagi (2010) is actually σ_2, and this vertical stress seems to reflect the stress caused by the lifting in vertical direction along with subduction of Philippine Sea Plate placing the volcanic islands on it. On the other hand, the NNE-SSW direction of σ_1 estimated by SCs can be explained by the collision of relatively large blocks that might be the Izu Peninsula collided around 1 Ma.

Ring faults topographically discovered in the Tono-Kurihashi granitic plutonic masses by using a cnstant vertical exaggeration stereoscopic map of slope, Kitakami massif

*Nobuo Doi[1], Michio Shirasawa[2], Ryuzo Yokoyama[2]

1. Research Center for Regional Disaster Management, Iwate University, 2. Yokoyama Geo-Spatial Information Laboratory Co., Ltd.

The Tono-Kurihashi granitic plutonic masses, the largest pluton in the Kitakami massif, were surveyed topographically by using a constant vertical exaggeration stereoscopic map of slope(CVES map)in scale 1/100,000 which was published by Yokoyama *et al*. (2012). Three ring fault systems about 11-13km in diameter were found out from Tono and Kurihashi plutonic masses. A granite porphyry intruded along the RF in the northern Tono plutonic mass. The ring fault system shows the deep structure of cauldron.
The northern Tono plutonic mass was composed of two granitic plutonic masses with different age (Nishimura *et al*., 1999). They have the different topographic features of plateau and hill, respectively, with steep slope and knick points between them. The old plutonic mass became hard because of recrystallization by the intrusion of new pluton, and remained as a plateau.
Many parallel faults, which were no extension into the Paleozoic wall rocks and the new plutonic mass, were also found out in the Tono-Kurihashi plutonic masses. Therefore, it was estimated that there was a long time between the old and new plutonic intrusions.

The Maizuru tectonic zone (MTZ), its formation and rearrangement as revealed by new zircon chronology data

*Yasutaka Hayasaka[1], Kosuke Kimura[1]

1. Graduate School of Science, Hiroshima University

In the Pre-Cretaceous terranes of Inner Zone of SW Japan showing low-angle piled nappe structure, only Maizuru zone shows a continuous narrow zonal arrangement. Therefore, the Pre-Cretaceous basement of the adjacent area is separated north and south by this zone. The Maizuru zone characterized by melange-like disrupted terrane with exotic blocks of plutonic complex called "Yakuno rocks" and has often been called Maizuru tectonic zone (MTZ) for that reason. MTZ is divided into three subzones, Northern, Central and Southern zones by their lithologies in its typical Maizuru area. The Southern Maizuru zone consists mainly of Yakuno ophiolite originated from the Permian intra-oceanic island arc and back-arc basin crust that occurred in the early Carboniferous oceanic crust, and the Central Maizuru zone consists of clastic rocks deposited in the back-arc basin.[1] In significant contrast with those two subzones, the Northern Maizuru zone is composed mainly of deformed granitic rocks with subordinate amount of pelitic gneiss, metagabbro and metadolerite indicating an affinity of a matured continental crust. [2] Zircon U-Pb ages of 441.9 ±2.8 Ma, 424-405 Ma, 291.6 ±4.3 Ma, and 249-243 Ma have been reported from granitic rocks of the Northern Maizuru zone of Type area so far. [3] [4] After that, granite mylonites of 488.7 ±0.9 Ma, 449.3 ±3.6 Ma, 323-301 Ma were also found in the Kume area of Okayama Prefecture 120 km west of the Type area. According to the age of intrusion, inherited ages, mode of occurrence and their similar geological setting, the Siluro–Devonian granites of the Northern zone can be correlated with the Khanka massif, southern Primorye, Russia.

Recently, we found granitic rocks showing zircon U-Pb ages of the Paleoproterozoic Era from the western end of MTZ in the Tsuwano area of Shimane Prefecture. [5] These granitic rocks exist as lenticular blocks in a narrow zone of 150 to 300 m in width. Zircon U-Pb ages are 1836 ±17 Ma for orthogneiss and 1853 ±14 Ma for tonalite, while that of granodiorite is 415.2 ±2.5 Ma. Paleoproterozoic zircon grains often contain inherited 2800-2100 Ma core. Furthermore, these rocks are accompanied by meta-quartzite blocks containing detrital zircon with two age clusters at around 2500 Ma and 2700 Ma. These Paleoproterozoic rocks are considered to be the exotic blocks originated from the North China Craton on the basis of their age affinity. In Tsuwano area, this narrow zone is embedded in the Permian strata and Jurassic accretionary complex and its metamorphic equivalents. Such a structure is anomalous to the piled nappe structure of the Pre-Cretaceous Terranes of SW Japan. As in response to the east-west change of dominant age of the Northern Maizuru zone, the age spectra of the detrital zircon of the adjacent Permo-Triassic strata in the MTZ also dominates the ages of 500-400 Ma in the eastern part, and the ages at around 1800 Ma dominates in the west. We consider that these blocks in the Northern Maizuru zone were displaced by the lateral fault movement along the northern boundary of MTZ.

Erosional features of Soma Slope Channel, off Miyagi, Japan

*Jih-Hsin Chang[1], Takahiko Inoue[1], Ayanori Misawa[1], Kohsaku Arai[1]

1. Geological Survey of Japan, National Institute of Advanced Industrial and Science Technology.

Located at the boundary between Pacific Plate and North America Plate, Tohoku (NE Japan) is the forearc slope of the active subduction zone, featuring as a tectonically active margin. In the central part off Tohoku, the bathymetric data off Miyagi show that there is a channel (Soma Slope Channel) connecting shallow marine (< 500 m) and slope terrace (>1000 m). The reflection seismic data across the Soma Slope Channel show more than 10 U-shaped and V-shaped reflectors, suggesting that channelized features and filling of the channels. Besides, the channel-shaped reflectors became shallower toward north, suggesting a series of northward migration of the Soma Slope Channel. The reflection seismic data along the axis of the Soma Slope Channel show a several regional erosional surfaces and could be regarded as stratigraphic sequences boundaries. The ages of these stratigraphic sequences boundaries derived from exploration well (MITI Soma-oki) indicates that this slope channel system is likely to develop during Pliocene-Pleistocene. It seems that the Pliocene-Pleistocene sequence are thick and the Miocene-age strata are generally deep south of the Soma Slope Channel, while Pliocene-Pleistocene sequence are thinner and the Miocene-age strata are shallower north of the Soma Slope Channel. Whether the Soma Slope Channel is structural-dominated or sedimentary-dominated as well as the mechanism of channel migration will be discussed in this study.

Preliminary Analysis Result for the Integrated Lineament Map in South Korea

*Hong-Jin Lee[1], Kyoungtae Ko[2], You Hong Kihm[2]

1. Geoscience Platfrom Division, Korea Institute of Geoscience and Mineral Resources, 2. Geology Division, Korea Institute of Geoscience and Mineral Resources

The geological lineament reflects the characteristics of various geological parameters and scale etc. In order to obtain more reliable analysis results, it is necessary to integrate the results from several experts' opinions. In this study, we used previous lineament data in the Korean Peninsula from the Korea Institute of Geoscience and Mineral Resources (KIGAM) and obtained new lineament data from the field geologists such as structural geologist, paleoseismologist, and geomophologist. To ensure the reliability of the newly lineament analysis data, we used high-resolution satellite images and hill-shade relief maps which were constructed by a digital elevation model from the National Geographic Information Institute of Korea (NGII). In the prevailing direction analysis from the acquired lineament data, the NNE-SSW direction was the most dominant, but the ENE-WSE and NNW-SSE directions also showed highly frequency depending on the experts. Different lineament analysis results based on the same data are interpreted as a result of subjective experience and analytical criteria from each expert. Therefore, it is necessary to establish integrated criteria and consider various geographical data for the publication of reliable nation-wide lineament map.

Seismicity along the Moradabad Basement Fault in the Central Ganga Plain: A Geological and Geophysical approach

*ANKIT GUPTA[1], Pitambar Pati[1], Chinmay Dash[1]

1. Indian Institute of Technology Roorkee

The basement of Indo-Gangetic plain is characterized by various fault bounded ridges and troughs. These Basement faults have great influence on the Ganga Plain tectonics. In response to the stress generated along the Himalaya these basement faults propagate surface ward and affect the sediment cover. This results in the form of Earthquakes along these basement faults. The present study shows several field evidences of surface deformation caused by the Moradabad basement fault. Soft sediment deformation structures (seismites) and surface faults are found at four different locations on the trace of the Moradabad basement fault in the upper Ganga Plain. Ground Penetrating Radar (GPR) survey across the fault also provides evidence of shallow subsurface deformations. The epicenters of historical earthquakes are concentrated along the Moradabad basement fault. The deformations can be attributed to possible pre-historic earthquake events associated with Moradabad basement fault as other impulsive stresses like slope instability, flood surges and rapid sediment deposition are absent. Close association of these secondary faults and deformation structures with the Moradabad basement fault indicate their origin is due to the stress release along this fault generated by Himalayan tectonics.

Petrological and geochronological studies of the volcanic rocks in the Muslim Bagh area, Pakistan

*Masanari Arao[1,2], Takeshi Imayama[1], Koshi Yagi[3], Chiaki Ikawa[3], Yoshihiro Sawada[4], Rehanul Haq Siddiqui[5], Said Rahim Khan[5]

1. Research Institute of Natural Sciences, Okayama University of Science, 2. Faculty of Biosphere - Geosphere Science, Okayama University of Science, 3. Hiruzen Institute for Geology and Chronology, 4. Emeritus Professor of Shimane University, 5. Geoscience Laboratory, Geological Survey of Pakistan

Several type volcanic rocks occurred in the Muslim Bagh (MB) area, which were developed mainly in the Cretaceous period at a continental active margin of the northwestern India subcontinent: Bibai-basalt intruded into the sediment from the Indian subcontinent, Bagh Complex(BC) consisting of melange and basalt-chert unit, and metamorphosed basalts in the Muslim Bagh Ophiolite (MBO) sequence. However, the division among these volcanic rocks is insufficient in terms of whole rock composition, mineral composition, and mineral assemblage. Radiolarians age of the chart layer in the BC implies that tholeiitic basalt in the BC formed during late Jurassic (Sawada et al., 1995), but there are no direct geochronological data for tholeiitic basalt. In addition, hornblende K-Ar age 82-67 Ma reported from meta-dolerite and gabbro in the MBO (Sawada et al., 1995) is unclear whether formation or metamorphic ages. In this study, whole-rock composition, mineral composition, and K-Ar age were investigated to understand the origin and ages of volcanic rocks in the MB area. According to SiO_2-(Na_2O+K_2O) discrimination diagram, the Bibai-basalt and a part of BC-basalt belong to alkali rock series (Alk.), whereas the MBO basalt and the other BC-basalt belong to non-alkali rock series. The latter series were classified into tholeiitic rock series (Tho.) based on FeO*/MgO-SiO_2 diagram. The Harker diagram indicate that the Bibai and BC(Alk.) basalts were rich in Ti and Nb, whereas the BC(Tho.)-basalt was rich in Cr. Alkali series rocks include abundant alkali feldspar, in contrast to plagioclase in non-alkali series rocks. The more metamorphic grade in the MBO-basalt increases, the more anorthite content in plagioclase and Mg/(Mg+Fe^{2+})ratio in hornblende increase. The Bibai-basalt contains Ti-clinopyroxene and Ti-amphibole, and the BC-basalt includes Ca-clinopyroxene. Based on these occurrences, the volcanic rocks in this study area are divided into four types. The BC (Tho.)-basalt yielded the K-Ar feldspar ages of ca. 78 Ma and ca. 51 Ma, which is significantly younger than the late Jurassic previously considered. The former age represents the formation age, whereas the latter age from altered sample may represent the timing of accretion or an apparent age affected by argon loss. The MBO-basalt mainly yielded the K-Ar amphibole ages from 78 Ma to 71 Ma with one exceptional age of ca. 99 Ma. The ca. 78-71 Ma ages are interpreted as the formation age, because there are no clear differences between low-grade and high-grade metamorphosed samples. These ages are also similar with the U-Pb zircon age of ca. 80 Ma obtained from plagiogranite in the MBO (Kakar et al., 2012). The ca. 99 Ma age older than other samples may attribute to the influence by excess argon. The similarities in whole-rock composition and formation ages between the MBO-basalt and BC (Tho.)-basalt implies that the BC(Tho.)-basalt was originally formed with the MBO-basalt. Then, the MBO-basalt experienced the metamorphism during obduction of ophiolite, whereas the BC(Tho.)-basalt was accreted to Indian continent without the metamorphism.

Petrogenesis of Oligocene to Miocene volcanic rocks in the Tonami area, central Japan: temporal evolution of continental- to island-arc volcanism during the Japan Sea opening

*Raiki Yamada[1], Toshiro Takahashi[2], Hayato Ueda[2]

1. Graduate school of science and technology, Niigata University, 2. Faculty of Science, Niigata University

The Japan islands was torn from the continent to form island-arc by spreading of the Japan Sea in Late Oligocene to Early Miocene. Basaltic to rhyolitic active volcanism occurred in the Japan arc during the Japan Sea opening. Since many researchers have targeted mainly mafic volcanic rocks for petrological study, petrological and geochemical studies on Oligocene to Miocene rhyolites are not still enough. Therefore, we examined Oligocene to Miocene volcanic rocks, including Chattian to Aquitanian and Burdigalian to Langhian rhyolites, on the basis of petrology and geochemistry.

Oligocene to Miocene strata consist of the Tori Conglomerate, Usunaka Moonstone Rhyolite, and the Iwaine and Iozen formations, in stratigraphically ascending order (Sudo, 1979; Ganzawa, 1983), the study area, Nanto City, Toyama Prefecture. The Tori Conglomerate is composed of conglomerate and sandstone, whereas the others are composed of volcanic and pyroclastic rocks; the Usunaka Moonstone Rhyolite, and the Iwaine and Iozen formations consist of rhyolitic welded tuff, andesites (lava and pyroclastic rocks), and rhyolites (lava and pyroclastic rocks), respectively. In this study, weighted averages of ^{238}U–^{206}Pb ages of 22.4 ±0.7 and 16.3 ±0.6 Ma are obtained from zircons in the Usunaka Moonstone Rhyolite (welded tuff) and the Iozen Formation (aphyric lava; the same outcrop as FU06 of Ganzawa (1983)). These ages indicate formation ages of the rhyolites, because they are consistent with K–Ar (Yamasaki and Miyajima, 1970; Ueda and Aoki, 1970) or fission track ages (Ganzawa, 1983), whose blocking temperatures are much lower than zircon U–Pb age.

Following petrogenesis of Oligocene to Miocene volcanic rocks is considered by whole-rock chemical compositions (major and trace elements, and Sr–Nd isotopes) and comparison with other studies. The Usunaka Moonstone Rhyolite (25–22 Ma) is alkalic rhyolite showing intermediate compositions between continental rifts and continental-arcs, and its magma was S-type and relatively dry. Therefore, it is continental-arc rift-type rhyolite, and mafic magma in subduction zone would have melted crustal materials derived from sedimentary rocks. Andesitic volcanism of the Iwaine Formation can be divided into two stages (e.g., Yamada and Yamada, 2018); amphibole-bearing andesite (high Sr andesite; 19–18 Ma?) and two pyroxene andesites (18–16.5 Ma?). Amphibole-bearing andesite is low-SiO_2 adakite (Martin et al., 2005) generated by partial melting of mantle wedge matasomatised by adakitic melt formed by slab melting. Two pyroxene andesites, who and equivalent beds have the large distribution in the Hokuriku region, are continental-arc type tholeiites, and their compositions suggest AFC (assimilation and fractional crystallization). The Iozen Formation (16.5–15.0 Ma) has intermediate chemical compositions between continental- and island-arcs, and its magma was I-type and had high water content. The Iozen Formation got primitively dacitic to rhyolitic composition, and almost only fractional crystallization occurred in magma chamber. High-temperature state, which had continued since the Iwaine Formation, in mantle wedge would had caused crustal melting.

Above genesis of Oligocene to Miocene volcanic rock in the study suggests that high temperature was kept in mantle wedge and continental crust during the back-arc spreading and that tectonic settings changed as time went on; continental-arc rift, continental-arc, and continental- to island-arc. This reflect that the Japan arc developed from continental- to island-arc through the Japan Sea opening, a back-arc formation.

Geology and post mid-Miocene tectonics of the Ogawa basin and the Atogura Nappe

*Akira Ono

The Sanbagawa Belt in the Kanto Mountains consists of the Sanbagawa Unit, Mikabu Unit and Atogura Nappe which are piling up in this order. The Atogura Nappe is widely distributed in the Yorii-Ogawa area. The main part of the Atogura Nappe is surrounded by autochthonous pre-Cretaceous geological units with high angle faults. The Atogura Nappe is unconformably overlaid by the early Miocene deposits in the Ogawa basin (Figure 1). The early Miocene Ogawa basin was a low mountainous area. The sea invaded, and conglomerates and sandstones of the Kozono Formation deposited. As the sea level rise further, mudstones of the Arakawa Formation deposited. Then the Miocene deposits and the Atogura Nappe were subjected to upheaval tectonics. Small rock masses of the Mikabu Unit in the Atogura Nappe are evidence for the post-early Miocene uplifts.

Gently dipping Miocene strata are distributed in the western part of the Ogawa basin which is divided into three areas, i.e., Notake, Iida and Central areas. Basement rocks of these areas are Yorii Formation, Atogura Formation and Kinshozan quartzdiorite, resepectively. In the Notake area, sandstones and conglomerates are widely distributed, and are overlaid by mudstones of the Arakawa Formation. The sandstone below the mudstone is about 3 m in thickness. The depth of the basement rock is unknown in the Notake area. However, judging from shallow Miocene valleys in the Ogawa basin, the thickness of the Kozono Formation may be about 50 - 100m. Miocene conglomerates are mainly composed of many large rounded granite clasts (open red circle in Figure 1). The provenance of the granite clasts appears to be the Ryoke Nappe located between the ridge lines rB and rC (Figure 1). Small Miocene deposits are exposed at three locations in the northeastern part of the Notake area. Miocene coarse sandstones unconformably overlie the Paleogene mudstones of the Yorii Formation at the northernmost exposure. The sandstones of about 10m in thickness are conformably overlaid by the Miocene mudstones. The boundary between the Kozono and Arakawa Formations is located at the altitude of about 140m in the Notake area.

In the Central area, Kinshozan quartz diorite is exposed widely, and is unconformably overlaid by sandstones of the Kozono Formation. In the Iida area, conglomerates are distributed near basement rocks (Figure 1, black circles), which mainly consist of clasts of chert, sandstone and mudstone. On the other hand, mudstones are widely exposed in hills and plains with low altitudes.

Figures 1A, 1B and 1C are schematic geological sections across the N-S direction of the western part of the Ogawa basin. Figure 1A is based on the assumption of slight post-Miocene uplift. On the other hand significant post-Miocene uplifts and tilting movements are assumed for Figure 1B. Judging from many exposures of the unconformity, early Miocene and present-day earth surfaces are close to each other in many localities (Figure 1C). Moreover, thin gently dipping Miocene deposits widely overlie the various rocks of the Atogura Nappe. These geological facts suggest that the Atogura Nappe and Miocene deposits were subjected to no remarkable tectonics after early Miocene. However, the quartz diorite in the Central area was subjected to upheaval tectonics. It is in contact with Miocene strata by high angle faults. However, early Miocene sandstones overlying the quartz diorite are distributed rather widely. Moreover, the Mikabu Unit is not exposed anywhere. Hence, no remarkable uplift occurred in the Central area. Contrary to the Central area small three blocks of Mikabu greenstones in the FujiYama area suggest a significant uplift of the Mikabu Unit. However, small exposures of Miocene sandstones are evidence for weak uplifts of the Atogura Nappe in the FujiYama area.

Paleostress transition estimated from small-scale deformation structures of the Sanbagawa metamorphic rocks in the Nagatoro area, Saitama Prefecture, central Japan

*Minami Nakamura[1], Aiko Takada[1,2], Hideo Takagi[1]

1. Waseda University , 2. Japan Petroleum Exploration Co., Ltd.

Low-grade metamorphic rocks of the Sanbagawa belt are well exposed in the Nagatoro area, Saitama Prefecture, where deformation structures such as folds, kink bands, faults, and mineral veins are well developed. Uemura and Kanesaki (1989) described deformed small structures in detail in the Nagatoro area, and reported that deformation stages (D1~D5) can be divided by cutting relationship. In low-ductility phase, contractional kink bands (D4 stage) were formed prior to extensional kink bands, small faults, and mineral veins (D5 stage). However, few studies have focused on the paleostress fields of D4 and D5 stages forming these structures. This study aims to determine the paleostress fields and to study its detailed deformation history of the Sanbagawa metamorphic rocks of in the Nagatoro area using paleostress analytical methods after Yamaji et al. (2006), and Yamaji and Sato (2011). We measured the attitudes (and slip directions) of 27 kink bands, 17 small faults, and 202 white mineral (quartz and/or calcite) veins to determine the paleostress fields. By using the Hough transform method (Yamaji et al., 2006), contractional kink bands (D4 stage) are indicated to have been subjected to Stress D4 (σ_1: 216˚/18˚, σ_3: 54˚/71˚), while the extensional kink bands and small faults (D5 stage) to the two different stresses; Stress D5-1 (σ_1: 180˚/79˚, σ_3: 47˚/8˚), and Stress D5-2 (σ_1: 33˚/32˚, σ_3: 211˚/58˚). These results are also consistent with those of paleostress analysis using the quartz veins (D5 stage). Furthermore, the stress analysis using calcite twins in the veins indicates that deformation structures in D5 stage were subjected to Stress D5-1 prior to Stress D5-2. These results imply that the Sanbagawa metamorphic rocks in the Nagatoro area have experienced the transition of three paleostress fields from D4 through D5-1 to D5-2 stages. Considering the mean ductility of each small structure and the deformation temperature (around 200 ˚C: Burkhard, 1993) estimated from the geometrical characteristics of calcite deformation twin, these small structures are sequentially formed at the time of exhumation of the Sanbagawa metamorphic rocks.

Estimation of the paleostress directions using “new dyke method” from the microcracks in the Tanzawa Tonalite

*Misaki Tomioka[1], Hideo Takagi[1]

1. Waseda University

The Tanzawa Tonalite intruded around 5-4 Ma (Tani et al. 2010) is located in the South Fossa Magna region that records the collision of Izu-Bonin Arc against the Honshu Arc. The paleostress direction has been estimated from the analysis of microcracks in quartz grains in the Tonalite (Sato and Takagi, 2010). Healed microcracks (HC) forming the plane of fluid inclusions are considered that they had formed just after the intrusion using fluid inclusion thermometry, and sealed microcracks (SC) had formed after HC formation by crosscutting relationship. The orientations of both HC and SC indicate that σ_{Hmax} keeps around N-S~NNE-SSW direction. Recently, Yamaji et al. (2010), and Yamaji and Sato (2011) developed new method of grouping the orientations of dikes or veins (cracks) recording different stress field, and then to determine σ_1, σ_2, σ_3 axes of each group and stress ratios by fitting mixed Bingham distribution (Bingham, 1974) (hereinafter called “new dyke method”). In this study, we estimated the paleostress using “new dyke method” for oriented samples used by Sato and Takagi (2010) to make it clear whether the σ_{Hmax} is σ_1 or σ_2.
We measured strikes and dips of intracrystalline HC and SC using U-stage, and then analysed the distribution using “new dyke method” and the correction developed by Kanai et al. (2014) to determine σ_1, σ_2 and σ_3.
As a result, the dominant stress directions for 16 points (HC) and for 22 points (SC) indicate that σ_1 for HC and SC concentrates in vertical and NE-SW direction, respectively. With correcting 10° clockwise rotation by paleomagnetic research (Kanamaru and Takahashi, 2005), the paleostress orientation results should be vertical around 4Ma, and in NNE-SSW direction after 4Ma. Accordingly, the σ_{Hmax} evaluated by HCs after Sato and Takagi (2010) is actually σ_2, and this vertical stress seems to reflect the stress caused by the lifting in vertical direction along with subduction of Philippine Sea Plate placing the volcanic islands on it. On the other hand, the NNE-SSW direction of σ_1 estimated by SCs can be explained by the collision of relatively large blocks that might be the Izu Peninsula collided around 1 Ma.

Ring faults topographically discovered in the Tono-Kurihashi granitic plutonic masses by using a cnstant vertical exaggeration stereoscopic map of slope, Kitakami massif

*Nobuo Doi[1], Michio Shirasawa[2], Ryuzo Yokoyama[2]

1. Research Center for Regional Disaster Management, Iwate University, 2. Yokoyama Geo-Spatial Information Laboratory Co., Ltd.

The Tono-Kurihashi granitic plutonic masses, the largest pluton in the Kitakami massif, were surveyed topographically by using a constant vertical exaggeration stereoscopic map of slope(CVES map)in scale 1/100,000 which was published by Yokoyama *et al*. (2012). Three ring fault systems about 11-13km in diameter were found out from Tono and Kurihashi plutonic masses. A granite porphyry intruded along the RF in the northern Tono plutonic mass. The ring fault system shows the deep structure of cauldron.
The northern Tono plutonic mass was composed of two granitic plutonic masses with different age (Nishimura *et al*., 1999). They have the different topographic features of plateau and hill, respectively, with steep slope and knick points between them. The old plutonic mass became hard because of recrystallization by the intrusion of new pluton, and remained as a plateau.
Many parallel faults, which were no extension into the Paleozoic wall rocks and the new plutonic mass, were also found out in the Tono-Kurihashi plutonic masses. Therefore, it was estimated that there was a long time between the old and new plutonic intrusions.

The Maizuru tectonic zone (MTZ), its formation and rearrangement as revealed by new zircon chronology data

*Yasutaka Hayasaka[1], Kosuke Kimura[1]

1. Graduate School of Science, Hiroshima University

In the Pre-Cretaceous terranes of Inner Zone of SW Japan showing low-angle piled nappe structure, only Maizuru zone shows a continuous narrow zonal arrangement. Therefore, the Pre-Cretaceous basement of the adjacent area is separated north and south by this zone. The Maizuru zone characterized by melange-like disrupted terrane with exotic blocks of plutonic complex called "Yakuno rocks" and has often been called Maizuru tectonic zone (MTZ) for that reason. MTZ is divided into three subzones, Northern, Central and Southern zones by their lithologies in its typical Maizuru area. The Southern Maizuru zone consists mainly of Yakuno ophiolite originated from the Permian intra-oceanic island arc and back-arc basin crust that occurred in the early Carboniferous oceanic crust, and the Central Maizuru zone consists of clastic rocks deposited in the back-arc basin.[1] In significant contrast with those two subzones, the Northern Maizuru zone is composed mainly of deformed granitic rocks with subordinate amount of pelitic gneiss, metagabbro and metadolerite indicating an affinity of a matured continental crust. [2] Zircon U-Pb ages of 441.9 ±2.8 Ma, 424-405 Ma, 291.6 ±4.3 Ma, and 249-243 Ma have been reported from granitic rocks of the Northern Maizuru zone of Type area so far. [3] [4] After that, granite mylonites of 488.7 ±0.9 Ma, 449.3 ±3.6 Ma, 323-301 Ma were also found in the Kume area of Okayama Prefecture 120 km west of the Type area. According to the age of intrusion, inherited ages, mode of occurrence and their similar geological setting, the Siluro–Devonian granites of the Northern zone can be correlated with the Khanka massif, southern Primorye, Russia.

Recently, we found granitic rocks showing zircon U-Pb ages of the Paleoproterozoic Era from the western end of MTZ in the Tsuwano area of Shimane Prefecture. [5] These granitic rocks exist as lenticular blocks in a narrow zone of 150 to 300 m in width. Zircon U-Pb ages are 1836 ±17 Ma for orthogneiss and 1853 ±14 Ma for tonalite, while that of granodiorite is 415.2 ±2.5 Ma. Paleoproterozoic zircon grains often contain inherited 2800-2100 Ma core. Furthermore, these rocks are accompanied by meta-quartzite blocks containing detrital zircon with two age clusters at around 2500 Ma and 2700 Ma. These Paleoproterozoic rocks are considered to be the exotic blocks originated from the North China Craton on the basis of their age affinity. In Tsuwano area, this narrow zone is embedded in the Permian strata and Jurassic accretionary complex and its metamorphic equivalents. Such a structure is anomalous to the piled nappe structure of the Pre-Cretaceous Terranes of SW Japan. As in response to the east-west change of dominant age of the Northern Maizuru zone, the age spectra of the detrital zircon of the adjacent Permo-Triassic strata in the MTZ also dominates the ages of 500-400 Ma in the eastern part, and the ages at around 1800 Ma dominates in the west. We consider that these blocks in the Northern Maizuru zone were displaced by the lateral fault movement along the northern boundary of MTZ.

Erosional features of Soma Slope Channel, off Miyagi, Japan

*Jih-Hsin Chang[1], Takahiko Inoue[1], Ayanori Misawa[1], Kohsaku Arai[1]

1. Geological Survey of Japan, National Institute of Advanced Industrial and Science Technology.

Located at the boundary between Pacific Plate and North America Plate, Tohoku (NE Japan) is the forearc slope of the active subduction zone, featuring as a tectonically active margin. In the central part off Tohoku, the bathymetric data off Miyagi show that there is a channel (Soma Slope Channel) connecting shallow marine (< 500 m) and slope terrace (>1000 m). The reflection seismic data across the Soma Slope Channel show more than 10 U-shaped and V-shaped reflectors, suggesting that channelized features and filling of the channels. Besides, the channel-shaped reflectors became shallower toward north, suggesting a series of northward migration of the Soma Slope Channel. The reflection seismic data along the axis of the Soma Slope Channel show a several regional erosional surfaces and could be regarded as stratigraphic sequences boundaries. The ages of these stratigraphic sequences boundaries derived from exploration well (MITI Soma-oki) indicates that this slope channel system is likely to develop during Pliocene-Pleistocene. It seems that the Pliocene-Pleistocene sequence are thick and the Miocene-age strata are generally deep south of the Soma Slope Channel, while Pliocene-Pleistocene sequence are thinner and the Miocene-age strata are shallower north of the Soma Slope Channel. Whether the Soma Slope Channel is structural-dominated or sedimentary-dominated as well as the mechanism of channel migration will be discussed in this study.

Preliminary Analysis Result for the Integrated Lineament Map in South Korea

*Hong-Jin Lee[1], Kyoungtae Ko[2], You Hong Kihm[2]

1. Geoscience Platfrom Division, Korea Institute of Geoscience and Mineral Resources, 2. Geology Division, Korea Institute of Geoscience and Mineral Resources

The geological lineament reflects the characteristics of various geological parameters and scale etc. In order to obtain more reliable analysis results, it is necessary to integrate the results from several experts' opinions. In this study, we used previous lineament data in the Korean Peninsula from the Korea Institute of Geoscience and Mineral Resources (KIGAM) and obtained new lineament data from the field geologists such as structural geologist, paleoseismologist, and geomophologist. To ensure the reliability of the newly lineament analysis data, we used high-resolution satellite images and hill-shade relief maps which were constructed by a digital elevation model from the National Geographic Information Institute of Korea (NGII). In the prevailing direction analysis from the acquired lineament data, the NNE-SSW direction was the most dominant, but the ENE-WSE and NNW-SSE directions also showed highly frequency depending on the experts. Different lineament analysis results based on the same data are interpreted as a result of subjective experience and analytical criteria from each expert. Therefore, it is necessary to establish integrated criteria and consider various geographical data for the publication of reliable nation-wide lineament map.

Seismicity along the Moradabad Basement Fault in the Central Ganga Plain: A Geological and Geophysical approach

*ANKIT GUPTA[1], Pitambar Pati[1], Chinmay Dash[1]

1. Indian Institute of Technology Roorkee

The basement of Indo-Gangetic plain is characterized by various fault bounded ridges and troughs. These Basement faults have great influence on the Ganga Plain tectonics. In response to the stress generated along the Himalaya these basement faults propagate surface ward and affect the sediment cover. This results in the form of Earthquakes along these basement faults. The present study shows several field evidences of surface deformation caused by the Moradabad basement fault. Soft sediment deformation structures (seismites) and surface faults are found at four different locations on the trace of the Moradabad basement fault in the upper Ganga Plain. Ground Penetrating Radar (GPR) survey across the fault also provides evidence of shallow subsurface deformations. The epicenters of historical earthquakes are concentrated along the Moradabad basement fault. The deformations can be attributed to possible pre-historic earthquake events associated with Moradabad basement fault as other impulsive stresses like slope instability, flood surges and rapid sediment deposition are absent. Close association of these secondary faults and deformation structures with the Moradabad basement fault indicate their origin is due to the stress release along this fault generated by Himalayan tectonics.

Petrological and geochronological studies of the volcanic rocks in the Muslim Bagh area, Pakistan

*Masanari Arao[1,2], Takeshi Imayama[1], Koshi Yagi[3], Chiaki Ikawa[3], Yoshihiro Sawada[4], Rehanul Haq Siddiqui[5], Said Rahim Khan[5]

1. Research Institute of Natural Sciences, Okayama University of Science, 2. Faculty of Biosphere - Geosphere Science, Okayama University of Science, 3. Hiruzen Institute for Geology and Chronology, 4. Emeritus Professor of Shimane University, 5. Geoscience Laboratory, Geological Survey of Pakistan

Several type volcanic rocks occurred in the Muslim Bagh (MB) area, which were developed mainly in the Cretaceous period at a continental active margin of the northwestern India subcontinent: Bibai-basalt intruded into the sediment from the Indian subcontinent, Bagh Complex(BC) consisting of melange and basalt-chert unit, and metamorphosed basalts in the Muslim Bagh Ophiolite (MBO) sequence. However, the division among these volcanic rocks is insufficient in terms of whole rock composition, mineral composition, and mineral assemblage. Radiolarians age of the chart layer in the BC implies that tholeiitic basalt in the BC formed during late Jurassic (Sawada et al., 1995), but there are no direct geochronological data for tholeiitic basalt. In addition, hornblende K-Ar age 82-67 Ma reported from meta-dolerite and gabbro in the MBO (Sawada et al., 1995) is unclear whether formation or metamorphic ages. In this study, whole-rock composition, mineral composition, and K-Ar age were investigated to understand the origin and ages of volcanic rocks in the MB area. According to SiO_2-(Na_2O+K_2O) discrimination diagram, the Bibai-basalt and a part of BC-basalt belong to alkali rock series (Alk.), whereas the MBO basalt and the other BC-basalt belong to non-alkali rock series. The latter series were classified into tholeiitic rock series (Tho.) based on FeO*/MgO-SiO_2 diagram. The Harker diagram indicate that the Bibai and BC(Alk.) basalts were rich in Ti and Nb, whereas the BC(Tho.)-basalt was rich in Cr. Alkali series rocks include abundant alkali feldspar, in contrast to plagioclase in non-alkali series rocks. The more metamorphic grade in the MBO-basalt increases, the more anorthite content in plagioclase and Mg/(Mg+Fe^{2+})ratio in hornblende increase. The Bibai-basalt contains Ti-clinopyroxene and Ti-amphibole, and the BC-basalt includes Ca-clinopyroxene. Based on these occurrences, the volcanic rocks in this study area are divided into four types. The BC (Tho.)-basalt yielded the K-Ar feldspar ages of ca. 78 Ma and ca. 51 Ma, which is significantly younger than the late Jurassic previously considered. The former age represents the formation age, whereas the latter age from altered sample may represent the timing of accretion or an apparent age affected by argon loss. The MBO-basalt mainly yielded the K-Ar amphibole ages from 78 Ma to 71 Ma with one exceptional age of ca. 99 Ma. The ca. 78-71 Ma ages are interpreted as the formation age, because there are no clear differences between low-grade and high-grade metamorphosed samples. These ages are also similar with the U-Pb zircon age of ca. 80 Ma obtained from plagiogranite in the MBO (Kakar et al., 2012). The ca. 99 Ma age older than other samples may attribute to the influence by excess argon. The similarities in whole-rock composition and formation ages between the MBO-basalt and BC (Tho.)-basalt implies that the BC(Tho.)-basalt was originally formed with the MBO-basalt. Then, the MBO-basalt experienced the metamorphism during obduction of ophiolite, whereas the BC(Tho.)-basalt was accreted to Indian continent without the metamorphism.

[S-VC35] Mitigation of volcanic disasters - basic and applied researches

convener:Shinji Takarada(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology), Mitsuhiro Yoshimoto(Mount Fuji Research Institute, Yamanashi Prefectural Government), Yasuhiro Ishimine(Research and Education Center for Natural Hazards, Kagoshima University), Tomohiro Kubo(National Research Institute for Earth Science and Disaster Prevention)

Volcanic disasters are caused by wide range of volcanic phenomena including ash fall, pyroclastic flow, debris avalanche, lahar, and lava flow. To mitigate volcanic disasters, wide range of technologies including simulation, data processing on GIS, and communication techniques are required. Researches on volcanic hazards mapping, eruption scenarios, and probabilistic eruption assessments are getting important. This session invites presentations and broad reviews related to these topics. Contributions on database technology, case studies of social and school educations, and specific examples of eruption crisis events are also encouraged.

Oil paintings describing the 1914 Sakurajima eruption

*Satoko Murotani[1]

1. National Museum of Nature and Science

The National Museum of Nature and Science (NMNS) possesses three oil paintings describing the 1914 Sakurajima eruption. These oil paintings were drawn by “Nanto Omure” and “Kanehide Yamashita”. They were disciples of “Seiki Kuroda” who was an oil painter representing Japan. One of these was drawn at the request of Prof. Fusakichi Omori. The status immediately after eruption painted with oil paints is eloquent the violence of volcanic smokes and thunders.

These pictures originally were hung in the Seismological Institute of the Imperial University. Now, these pictures do not have the frame, and were incurred dirty or moldy due to deterioration over time. So we restored and framed these oil paintings. For people who aren’t unfamiliar with science, we would be happy if these oil paintings become interested in historical volcanic eruption as a work of art, rather than as an educational tool for science.

Keywords: The 1914 Sakurajima eruption, oil printing, Fusakichi Omori, Seiki Kuroda, Nanto Omure, Kanehide Yamashita

Constructing and utilizing digitized volcanic hazardmap database

*Yuhki Kohno[1], Tomohiro Kubo[1], Yosuke Miyagi[1], Toshikazu Tanada[1]

1. National Research Institute for Earth Science and Disaster Resilience

National Research Institute for Earth Science and Disaster Resilience (NIED) has published “Volcanic Hazard Maps of Japan –Second Edition” recording whole volcanic hazard maps or hazard mitigation plans of 40 active volcanoes issued from 1983 to 2013. After that, volcanic hazardmaps are required under law to be prepared in each volcanic area in Japan since the 2014 eruption of Ontake volcano. NIED has been compiling and digitizing volcanic hazard information published by each Volcano Disaster Management Council established for 50 continuously monitored volcanoes in Japan. In this presentation, we report the progress of the project and examples of utilization for the digitized data.
Each digitized volcanic hazard information, with shapefile format, are converted into image data such as tile data in order to be useful on WebGIS as a layer. We are preparing online map to show easier the hazard information to residents or tourists in the volcanic area. The map will be expected as a promotion tool to the residents regarding volcanic disaster since calm period as well as a hazard map available online in emergencies, and it should be available to anytime, anyone and anywhere. Additionally we try to make tool analysing how many disasters have been possible to occur at each area where is divided into a several mesh over a target volcanic area on the map, applying Kubo et al.(2003). It may help users can recognize volcanic risks having possibility to occur at the place they are (or will be) by the information of each mesh.
We will welcome for discussion about how the way of effective expression of volcanic hazard information toward the target people or utilization of the information materials.

Pyroclastic fall simulation using Tephra2 and JRA-55

*Hisashi Sasaki[1], Shunsuke Miura[1], Shino Naruke[1]

1. Asia Air Survey Co., Ltd.

We present an example using Tephra2 and Japan Meteorological Agency's 55-year long-term reanalysis data (hereinafter abbreviated as JRA-55) for the pyroclastic fall simulation. The characteristics of JRA - 55 are that there is uniform data throughout Japan and there is no missing data. It is easy to reproduce the eruption that occurred after 1958 using Tephra2 and JRA-55. It is also effective for creating volcanic hazard maps and probability maps.

Research on observation method of volcanic ash-fall accumulation using spaceborne SAR

*Taku Ozawa[1], Eisuke Fujita[1]

1. National Research Institute for Earth Science and Disaster Resilience

Volcanic ash often causes heavy disaster due to debris flow. To mitigate such disaster, rapid observation of the volcanic ash distribution and forecast of debris flow from such observation are important. However, rapid observation of the volcanic ash distribution has been carried out mainly by on-site survey, and it is difficult to observe it rapidly. Then development of more rapid observation method are required. As one of solutions resolving such problem, utilization of satellite remote sensing technique is expected. Then, we began research on observation method of volcanic ash distribution using spaceborne SAR in “Cross-ministerial Strategis Innovation Promotion Program (SIP)-2nd season” as one of development items. In this presentation, we show results related to this development and explain the overview of this project.

In this development, we use InSAR coherence analysis. In InSAR results, clear fringes are seen if the coherence is high. On the other hand, noise is dominant if the coherence is low, and fringe becomes unclear. Generally, loss of coherence (decorrelation) is caused by difference of radar scatter at the pixel for InSAR pair. In a result from an interferometric pair including the eruption occurrence, decorrelation due to radar scatter change caused by volcanic ash accumulation is generally seen around the crater. For example, we analyzed PALSAR-2 InSAR pairs acquired before and after the Kuchinoerabujima eruption on January 17, 2019 and revealed that decorrelation area due to volcanic ash accumulation was seen within the range of about 1 km from the Shin-dake crater. Furthermore, decorrelation area extended to a range of about 1.5 km along the southwest and northwest valleys, which is consistent with the direction of pyroclastic flow.

Additionally, we analyzed InSAR pairs for December 18, 2018 and January 29, 2019 eruptions, and revealed the similar decorrelation around the crater. However, they were obviously small relative to that for January 17, 2019 eruption. Especially, that for January 17, 2019 eruption was limited to the vicinity of the crater. Thus, we could clearly see the difference in the volcanic ash accumulation area from InSAR coherence analysis.

If the relation between decorrelation and the amount of volcanic ash accumulation becomes clear quantitatively, the amount of volcanic ash accumulation will be obtained from InSAR coherence analysis. Then, in this development, we estimate decorrelation only due to volcanic ash accumulation, using a temporal coherence change model without volcanic ash effect constructed from InSAR coherence time-series analysis. Furthermore, we estimate coefficient converting coherence to the amount of volcanic ash accumulation from case studies. However, coherence basically saturates easily and thin accumulation of volcanic ash is difficult to detect, and therefore, it is difficult to detect the spatial distribution of volcanic ash accumulation. So, we attempt to estimate spatial distribution of volcanic ash accumulation by combining InSAR coherence analysis and ash-fall simulation in this development.

Method for estimation of debris flow runout in the volcanic area

*Yusuke Yamazaki[1], Naoki Fujimura[1], Sakiko Tetsuka[1], Masaki Mizuno[1], Yasuo Ishii[1], Toshihiro Kikui[2], Shinya Yoshida[2], Yuki Igarashi[2], Takao Yamakoshi[2]

1. Public Works Research Institute, 2. STC

Debris flows often occur even with a small amount of rainfall after a volcanic eruption. For disaster prevention and mitigation of debris flows in the volcanic mountainous areas, hazard maps and warning - evacuation systems are necessary. As basic information for such disaster prevention and mitigation, it is important to predict timings and areas of flood and sediment provided by debris flows in the volcanic areas after the eruptions.
Regarding debris flows associated with rainfalls after the volcanic eruptions, the authors assume that volcanic ash decreases the hydraulic conductivity of the topsoil layer of the basin slopes. Then surface flow occurs and volcanic ash deposited on the river channel easily becomes saturated by water. The saturated volcanic deposits result in flowing as debris flows because the deposits lose their stability by saturation. In order to analyze these, we observe rainfall events, soil moisture, surface flow, and ground surface conditions on a slope of two square meters in Arimura River basin in Sakurajima Island. Also, at the Arimura River No. 3 dam, the depth, surface velocity and load of the debris flow are continuously measured. In this presentation, we analyze these observation results and report the occurrence mechanism of surface flow and the flow mechanism of debris flows.
As a result of verifying the momentum conservation law of debris flows based on the measurements of the water depth, surface flow velocity and load data in Arimura River No. 3 dam, it seems appropriate. Although conditions for simulation such as spatial distribution of the depth of volcanic deposit, grain size distribution, runout path were determined by trial and errors, the results of simulation of the flow processes of the debris flows showed that simulated temporal changes in depth and velocity were closed to measured ones. As a future task, it is still necessary to obtain the information for spatial distribution of the depth of volcanic deposit, grain size distribution, runout path of the debris flows.

On the H_2S concentration continuous observation at Kurikoma volcano

*Hideyuki Itoh[1], Yasumichi Yamamoto[2], Kenji OOba[2], Morio Tsuji[1], Takeshi Ohba[3]

1. Faculty of policy studies, Iwate prefectural University, 2. JMS INc, 3. Tokai University

urikoma volcano is active volcano located on junction of miyagi, akita, iwate prefectures. Phreatic explosion occurred in 1944 and 1744, it generated acid water descended on the iwai river triggered by phreatic explosion.

Active fumaroles can have been observed along the ohjigoku-dani valley and showa crater, especially, trails are maintained along ohjigoku-dani valley, and many climbers are exposed to volcanic gas.

We installed the environmental h_2s sensors which called “odalog” (http://www.jmsystem.co.jp/kazan/odalog.html) in order to ascertain concentration of h_2s along the trail and beside the showa crater during june, 6 to october, 3, 2018.

The result of our observation, high concentration h_2s gas can been observed, especially, instantaneous maximum concentration can have been observed 334ppm at showa crater, and 38ppm at ohjigoku-dani valley. It is necessary to take immediate measures against volcanic gas for climbers.

A working hypothesis for source craters and sequence of the 1707 Hoei eruption of Fuji Volcano, Japan

*Masato Koyama[1]

1. Shizuoka Univ.

The 1707 Hoei eruption, one of the most voluminous and violent eruptions of Fuji Volcano, has been considered to have occurred from the NW-SE trending three craters (Hoei craters) on the southeastern flank of the volcano and to have made the bulge (Hoei mound) at the edge of the craters. The Akaiwa rock, located near the summit of the Hoei mound, has been thought to be an outcrop of older strata, which have unconformable relationship with overlying deposits.
On the basis of careful geomorphological and geological survey including SfM(Structure from Motion) technology with UAV photos, the strata exposed on the Akaiwa rock are revealed to be part of the proximal deposits of the Hoei eruption. Moreover, another NW-SE eruptive fissure is estimated to have opened between the Hoei mound and the Gotenniwa Higashi pyroclastic cone in the initial stage of the Hoei eruption and to have been buried by the subsequent eruptive deposits from the Hoei craters. The hypothesis of this fissure can resolve the problem thatlocation of a source crater of the basal pumice layer of the distal Hoei pyroclastic deposits is still unclear.

It is important to review the sequence of each eruption in the past in order to mitigate volcanic hazard in the future. Especially the Hoei eruption is regarded to be important because it represents large scale explosive eruption that is rare in the eruptive history of Fuji volcano, but may cause extensive disaster in the metropolitan area. Mt.Hoei has been considered to be protuberance formed during the Hoei eruption and to be composed of Old Fuji formation (Tsuya, 1955). The protuberance has been considered as a kind of bulge accompanied by lateral intrusion of degassed magma (Miyaji et al., 2011). Koyama (2018) suggested the bulge by intrusion of magma could cause sector collapse and the evacuation plan for such sector collapse should be made. In this presentation, we will discuss the genesis and the formation process of Mt.Hoei based on new data obtained from geological survey, geochemical analysis and palaeomagnetic measurements of the constituents of Mt. Hoei and the ultraproximal deposits of Hoei eruption.

Mt.Hoei located at the northeast of Hoei craters, consists of pyroclastic rocks including mainly dense blackish-grey scoriaceous lapilli, spatters, volcanic bombs capturing gabbro and gabbroic fragments. From these observations, microscopy, whole rock chemical composition analysis, palaeomagnetic measurements and XRD analysis results, Mt.Hoei (Akaiwa) is presumed that ultraproximal fall and surge deposits by phreatomagmatic eruptions, compared with Ho-Ⅲ(Stage 2) of Miyaji et al.,(2011) from petrography and chemical composition. In addition, 2nd and 3rd crater ridge, the wall of the erosion valley of Gotenniwa consists of fallout deposits of Hoei eruption, corresponding to Ho- Ⅰ to Ⅲ(Stage 1) of Miyaji et al.,(2011). Although the white and banded pumice layer cannot be confirmed at the base of the erosion valley of Gotenniwa at the present moment, the deposits show a gradual compositional change from andesite to the basalt (SiO_2 = 62.8 to 52.2 wt%) upward. The paleomagnetic directions obtained from the spatter cone in the 1st crater of Hoei, the deposit around the summit of Mt.Hoei and the fallout deposit at erosion valley of Gotenniwa coincides with 1707 A.D.of the paleomagnetic secular variation curve (JRFM 2K.1).

We estimated the formation process of Mt.Hoei based on these new findings, isopach maps of Hoei eruption(Miyaji et al., 2011), the model of magmatic development of Hoei eruption (Fujii, 2007 ; Yasuda et al.,2015), and historical records and drawings (Koyama, 2009). Mt.Hoei is not a bulge caused by the magmatic intrusion, but a pyroclastic cone of Hoei eruption formed in only 9 days.

1. The basaltic magmas contacted and mixed with the dacitic magma, white-banded pumice squirted from the vicinity of the 1st crater and was swept in the east direction by the westerlies (December 16th around 10 to 17 o'clock, Unit A, B of Miyaji et al.,(2011)).
2. As the crater expanded, the side of the mountain of the first crater was also scraped off, and abundant accessory materials were ejected in the east-south direction together with the essentials, and deposited near crater to form Mt.Hoei (December 17th before daylight, Unit C ~ F of Miyaji et al, (2011)).
3. The vent transitioned to the 2nd crater due to the landslide at the 1st crater edge or expansion of the vent. (December 17 to 19 th, Unit G ~ I of Miyaji et al, (2011))
4. The vent transitioned to the 1st crater due to the accessory materials of landslide were gradually ejected, Mt.Hoei (Akaiwa) was formed by intermittent phreatomagmatic eruptions (December 19-25 th, Unit J ~ M of Miyaji et al, (2011)).

©2019. Japan Geoscience Union. All Right Reserved.

5. As crater is restricted to the 1st crater, inflow of accessory materials stopped and Plinian eruption of basaltic magma continued for 6 days and ended (December 25 - 30 th, Unit N ~ Q of Miyaji et al, (2011)).

Airborne LiDAR Bathymetry reveals underwater topography of Lake Motosu
- The level of water raised by lava inflow -

*Tatsuro Chiba[1], Sin-ichi kaneta[1], Makoto Ohashi[1]

1. Asia Air Survey Co., Ltd.

1. Introduction

Lake Motosu is a dammed lake located northwest of Mt. Fuji, the elevation of the lake is about 900m. Aokigahara lava flow, which is occurred by the eruption of 864 AD, flood into the lake, and the northeast lake shoreline is seen like cut off by the truncated arc. Though regarding the characteristics of this lava flow, there is a study by Obata and Unno (1999), no survey of the shallow part of the lake had been conducted. Generally, the level of lake water is the possibility of rising up by the entry of a large amount of debris or lava flows. Of course, it is not a kind of transient phenomenon like Tsunami, but the possibility to rise permanently because of the bottom of the lake getting shallow. Airborne LiDAR Bathymetry measurement was carried out in order to investigate whether the level of water of Motosu Lake changes during Aokigahara lave flow entry, and the results are as bellows.

2. Airborne LiDAR Bathymetry

Airborne LiDAR Bathymetry, as follows ALB, is a measurement method aiming to measure depth and topography of shallow water along river and coast. The equipment used in this research consists of two pair of laser ranging systems for ground measurement using NIR laser and underwater measurement using visible range (532nm). The measurable depth depends upon the transparency of the object greatly. It was expected to be measurable up to 15m depth since Lake Motosu has high transparency throughout the year and is visible around 14-16m depth. The measurement carried out on 9th September 2017. Since the area terrain is heavily rough, Helicopter, which is easy to control flight height, is used and flew 11 courses.

3. Bathymetry

For ALB measurement, the position of the aircraft is determined by kinematic GNSS survey based upon GNSS-based Control Station, objective terrain of the ground and the seafloor are measured by both the data of the initial navigation device and the two channels of laser ranging device. The density of point-clouds was 10 to 100 points/m^2 on land and 1 to 5 points/m^2 on water. The maximum water depth was measured to be 11-15m. Based on pon point-clouds data, the topography of the lake bottom is totally different between the northern and southern measurement range. On the northern side, unique irregularities of Aokigahara lava can be seen from land to underwater. There is no change between the border of the surface of the lake and reach to around 15m continuously. On the other side, the topography of the southern side of the lacustrine terrace, there can be seen slightly higher hill than the seafloor closer to the lakeshore. Not less than two stages of rectangular flat surface can be seen on the northern slope of the hill.

4. Conclusion

On the northern side of the measurement range, there found lava topography divergent like branch coral and split on the center part, and there found red oxidized portion, so it is clear that the lava landscape was deposited on land (Obata and Unno, 1999). Continuously tracking terrain similar to this topography

©2019. Japan Geoscience Union. All Right Reserved.

to 15m water depth suggests that the level of water at the time of lava flow was at least 15m lower than the current one. Underwater archeology surveys are also conducted around the southern lacustrine terrace (Kamikuissiki Village Board of Education, 1999). Relics including turtle type earthenware have been ensured so far, most of relics were identified as the age of the beginning of the early stage of Kofun Period. Many of them are completed and it seems to have been submerged since there is no inconsistency that the time is the invasion time of Aokigahara lava flow in the Heian era. It is to be wished that the detailed investigation confirms the red oxidized portion of the underwater lava topography and the research of the possibility of flat surface to be the construction of the submerged village in the future.

Volcano monitoring using satellite thermal infrared imagery of CIRC (Compact Infrared Camera)

*Yuki Takakura[1], Koji Nakau[1], Junichiro Ishizawa[1]

1. Japan Aerospace Exploration Agency

Although volcanic activities are monitored by various approaches, it is difficult to observe some volcanoes in Japan using ground equipment (e.g. remote islands or submarine volcanos). In such case, satellite imagery is one of the powerful tools to monitor them. Satellite can observe extensive area simultaneously, including many volcanos. Thus, we can capture geothermal activities; lava flow, pyroclastic flow or heat of crater even at night.

To prevent or to mitigate volcanic disaster, the disaster management agencies needs ready-to-use dataset; information extracted from satellite imagery. Therefore, we developed “Volcano Monitoring System” (released in Sep 2018; https://kazan.jaxa.jp/); which system provides such information and visualized satellite infrared imagery of CIRC and other satellites. CIRC is uncooled microbolometer thermal infrared sensor for the earth observation and it is on board ALOS-2 satellite (Advanced Land Observing Satellite 2). On the Volcano Monitoring System, we can browse satellite RGB or infrared imagery as a map and get the variation of volcanic activity’s indices automatically extracted from satellite imagery. To produce concrete indices for volcano monitoring, we are studying several approaches of satellite infrared data processing in cooperation with the disaster management agencies. In such study, we are focusing on 12 volcanoes which are defined among us. In this presentation, we introduce “Volcano Monitoring System” and some volcanic events captured by CIRC.

Impact absorption properties of wooden buildings roof subjected to ballistic block collision

*Kohei Tateyama[1], Hiroyuki Yamada[2], Mitsuhiro Yoshimoto[3], Ryo Honda[3], Toshitsugu Fujii[3]

1. Ritsumeikan University, 2. National defense academy, 3. Mount Fuji Research Institute, Yamanashi Prefectural Government

Volcanic disasters include various factors such as eruption, lava flow, pyroclastic flow, debris avalanche, debris flow and so on. Especially, at the phreatic eruption of Mt. Ontake in September 27, 2014, most of the damages were caused by clashes of ballistic block. In order to prevent these damages, it is suggested that evacuation to a mountain hut is effective. Thus, evaluation of impact absorption properties for wooden buildings (e.g. mountain hut) against ballistic block collision is necessary. Previously, we reported the protective abilities of as-built wooden buildings, which were reinforced with high performance fabric using aramid fiber. In addition, the penetration boundary energy for a 15 mm thick wooden building roof was reported. However, the impact absorption properties of various type wooden buildings has not been clarified enough. Therefore, in this study, impact absorption properties of wooden buildings roof subjected to ballistic block collision was experimentally investigated.

A collision test was carried out at the velocity of 10 to 90 m/s using a large scale launching system. In this system, a projectile was accelerated by compressed air and then collided with the target. The projectile velocity was measured using two lasers and light receiving parts. In many cases, size of the ballistic block is almost the fist size (ϕ100 mm) under phreatic eruption. Therefore, Vitrified whetstone similar to the common ballistic block (density: 2400 kg/m^3) was used as the projectile, and the diameter was determined ϕ90 mm (mass: 2.66 kg). For the target, typical wooden roof structure (e.g. cedar boards, waterproof sheet, galvalume steel plate and cedar rafter) was used. Two types of thickness of cedar board (15 mm and 18 mm) were prepared. The thickness of the waterproof sheet and galvalume steel plate were 1.0 mm and 0.4 mm, respectively. The dimensions of the specimen were 600 mm ×600 mm. The components were fixed with nails and its spacing was approximately 150 mm. In addition, specimens in which two cedar plates were superimposed was also prepared. There are two kinds of superimposing methods: a ” staggered structure “ that is alternately superimposed on one another, and a "cross structure" in which plates are orthogonalized.

Collision test results revealed penetration boundary energies of 15 mm and 18 mm specimens, respectively. In previous study, it was shown the maximum collision energy of volcanic ballistic block (ϕ 2-64 mm) was 1700 J (in the case of ϕ64mm, 100 m/s), and average collision energy was less than approximately 1200J in many cases. From the result, it was revealed that the roof of cedar board having a thickness of 15 mm and 18 mm could prevent penetration of volcanic ballistic block. In addition, it was found that by superimposing the cedar boards, impact absorption properties can be improved simply. At the time of superimposition, the impact absorption properties was hardly improved in the ” staggered structure”. However, in the "cross structure", it was confirmed that the impact absorption properties were greatly improved. From this it was found that the "cross structure" is better when reinforcing by simple superimposition.

Earthquake Research Institute, University of Tokyo

Moto-Shirane volcano, which is part of Kusatsu-Shirane volcano, erupted on 23 January 2018 after 1500 years dormancy. One parson died and 11 other people were injured by the ballistic ejecta of this phreatic eruption. We report the results of a survey on the distribution of ballistic rocks around the crater and climbing trails and ski courses on May 10 - 12, 2018 and October 23 - 25, 2018.The maximum size of the ballistic rocks was measured at a total of 191 sites and the number density of the rocks (>64mm) was measured at a total of 64 sites. Ballistic rocks of the eruption are distributed within 500 meters around the main crater and is mainly distributed from north to northeast. The maximum size of ballistic rock was 4.8 m which fell to the western crater rim, and near the main crater was 3.4 m. The flight-distance of ballistic rocks with a major axis of about 20 cm, 50 cm, 100 cm, 200 cm are 400 to 650 m, 400 m, 350 m, 150 m, respectively. It suggests that the initial velocity of ballistic rocks of each size is different.

[S-VC35] Mitigation of volcanic disasters - basic and applied researches

convener:Shinji Takarada(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology), Mitsuhiro Yoshimoto(Mount Fuji Research Institute, Yamanashi Prefectural Government), Yasuhiro Ishimine(Research and Education Center for Natural Hazards, Kagoshima University), Tomohiro Kubo(National Research Institute for Earth Science and Disaster Prevention), Chairperson:Mitsuhiro Yoshimoto(山梨県富士山科学研究所), Yasuhiro Ishimine(鹿児島大学地域防災教育研究センター)

Volcanic disasters are caused by wide range of volcanic phenomena including ash fall, pyroclastic flow, debris avalanche, lahar, and lava flow. To mitigate volcanic disasters, wide range of technologies including simulation, data processing on GIS, and communication techniques are required. Researches on volcanic hazards mapping, eruption scenarios, and probabilistic eruption assessments are getting important. This session invites presentations and broad reviews related to these topics. Contributions on database technology, case studies of social and school educations, and specific examples of eruption crisis events are also encouraged.

Developing Ash-fall impact forecasting content.

*Tomohiro Kubo[1], Yosuke Miyagi[1], Setsuya Nakada[1], Eisuke Fujita[1], Masamitsu Miyamura[1]

1. National Research Institute for Earth Science and Disaster Prevention

The falling ash is expected to cause extensive damage over a wide area, because the ash widely spread out. For example, the highway road was closed to traffic due to falling ash, because the falling ash causes a car slip accident. In Mt.Aso 2016 Eruption, the Aso-shi lost power, because the ash fall an electric power substation. On the other hand, the wooden houses may be collapsed by over volcanic ash load. In addition, the buildings that are constructed by Reinforced Concrete or Steel such as a hospital, an office or a city hall are not collapsed, but the building equipment on the roof supposes to be damaged by the falling ash. Thus, we research the impact of the building equipment function due to falling ash by experimental study.

We report the experimental result of a cooling tower by falling ash. In addition, we report the prototype ash-fall impact forecasting content for the infrastructure and the building equipment, based on the Central Disaster Management Council report and the experimental result.

Keywords: ash-fall, damage estimation, volcano disaster countermeasure, experiment, building equipment

New Websites and a Pamphlet of IVHHN

*Yasuhiro Ishimine[1]

1. Research and Education Center for Natural Hazards, Kagoshima University

I will present an outline of new websites and a pamphlet of International Volcanic Health Hazard Network (= IVHHN), both of which have been translated into Japanese by the author. IVHHN is an IAVCEI commission which has been launched in 2003 and focuses on research and dissemination of information on volcanic health hazards. Dr. Claire Horwell and some other leading members of IVHHN have conducted a research project entitled “A New Evidence Base for Respiratory Health Interventions in Volcanic Eruption Crises”, which is called HIVE project for short, with a grant from Enhancing Learning and Research for Humanitarian Assistance (ELRHA), a global charity organization in 2015-2018. IVHHN has revised its websites and published in August 2018 to include new outcomes obtained from HIVE project. It is notable that the new websites include the guideline on recommended facemasks for respiratory protection during ashfall on the basis of the field research in Indonesia, Mexico and Japan carried out as a part of HIVE project. The guideline advises residents to stay indoors to reduce exposure to volcanic ash if possible and wear a well-fitting industry-certified facemask such as a N95 mask, or a DS2 mask, which is Japanese standard equivalent to N95, when they are cleaning up volcanic ash or stay outdoors for a long time. The guideline also mentions that industry-certified facemasks are not usually designed to fit children’s face, and thus, they are not effective for children. The new IVHHN websites add the guideline and some other scientific protocols for assessing volcanic health hazard. They also adopt a responsive layout to works well on smartphones. The websites also contain three new videos which describe the experience of coping with volcanic ash, how to protect yourself from breathing ash and how to properly fit a facemask. Subtitles are available in English by clicking on the CC button or you can switch to Spanish or Bahasa in the Settings button. They are also available on YouTube and Vimeo. As the author has been a member of IVHHN since 2005 and managed Japanese IVHHN website. he translated the revised English websites into Japanese and published in January 2019. The new Japanese pages is published newly obtained internet domain at http://www.ivhhn.jp/, while the Japanese website has been published at http://www.geocities.jp/ychojp/ivhhn/ for twelve years. The author printed 2,000 copies of the Japanese version IVHHN guideline on the protection from breathing volcanic ash as a pamphlet. A half of the copies were distributed at the general disaster drill on large-scale eruptions of Sakurajima held on 12 January 2019.IVHHN now prepare for another guideline on the health effects of volcanic gases, which has already been reviewed by the author and some other members of an IVHHN expert panel. The author also provides IVHHN with some photos of fumaroles taken at volcanic areas in Japan.

State of river water pollution derived from the recent volcanic activity of Mt Iwo-Yama, Kirishima volcanoes

*Yoshikazu Kikawada[1], Haruka Yamamoto[2], Wei Deng, Megumi Fukai

1. Faculty of Science and Technology, Sophia University, 2. Graduate School of Science and Technology, Sophia University

Mt Iwo-Yama belonging to the Kirishima Volcanoes erupted in 2018 for the first time in 250 years. The recent activity of the volcano has a profound effect on the regional economy, especially in the fields of agriculture and tourism. With the phreatic eruption in April 2018, muddy thermal water spouted out from the newly opened vents resulting pollution in the downstream river. As a result, about 1,400 farmers in the downstream area abandoned rice cultivation in 2018.
The muddy water from the newly opened vents is strongly acidic and high in the concentrations of chloride and sulfate with a remarkable amount of arsenic and some kinds of heavy metals. The mud from the vents is mainly composed of grayish argillaceous particles and elemental sulfur suggesting that it is originated from highly-altered zone related to the geothermal reservoir beneath the volcano.
The vents are still busy gushing the muddy thermal water and vapor/steam as of mid-February 2019, ten months after the eruptive events. Based on our continuous investigation, the overflowing water from the vents is constantly strongly acidic (pH <1) and contains a relatively high concentration of arsenic, although the overflow rate is not constant and changes on occasion. The results of our latest chemical analysis show the water contains around 5 mg/L arsenic. Besides, the spring water in the west flank area of the volcano, which is one of the headwaters of the local river, has become strongly acidic with a rise of volcanic activity. That spring water is also one of the reasons for water pollution in the downstream. As a result, even recently the river water pollution in the foot of the volcano is sometimes reported. The river water pollution thus remains as a problem to be solved both environmentally and economically.

Development of information tools for evacuation and rescue in the event of volcanic disaster

*Yosuke Miyagi[1], Setsuya Nakada[1], Tomohiro Kubo[1], Mitsuhiro Yoshimoto[2], Ryo Honda[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Mount Fuji Research Institute, Yamanashi Prefectural Government

Integrated Program for Next Generation Volcano Research (IPNGVR) conducted by Ministry of Education, Culture, Sports, Science and Technology, Japan started in 2016. This project takes notice to not only observation and prediction researches but also research for countermeasure technology of volcano disasters. National Research Institute for Earth Science and Disaster Resilience (NIED) has been in charge of one of the main theme which is named “Development of countermeasure technology for volcano disasters”. In this theme, we develop an information tool for volcano disasters, in which we consider disaster management personnel in local governments as users, and we try to provide appropriate information for them in both the event of disaster and normal times.

In the tragic disaster of Ontake Volcano in 2014, it was difficult for local governments to grasp whereabouts of climbers and to conduct rescue and search for victims. Even recently, climbers can approach to an active vent in many volcanoes in Japan, for example Mt. Fuji, it is quite important to grasp whereabouts of climbers in the event of disaster for proper decision of rescue and search. Experiments to acquire data of climbers in Mt. Fuji have conducted since 2015, named “Mt. Fuji Challenge”. Mt. Fuji is active volcano and gets more than 200,000 of visitors including climbers from all over the world each year. In experiments, we distribute beacons to climbers and receivers which are set in mountain trails detect signals from the beacons, then we can grasp the number and location of climbers who have the beacons. Numbers of beacon which we distributed were 2,300 in 2017 and 14,000 in 2018.

The tool developed in our research use the data from the above experiments as input data, and visualize on GIS software. As a result, it is possible to grasp whereabouts of climbers on map information, including trails, shelters and hazard information from hazard map. Even in normal times, information from the tool can be used for evacuation plans, including establishment of shelters or evacuation routes, instituted by local governments. And, by combining with hazard simulations, we can infer casualties in the event of disaster.
In this presentation, we introduce a summary of the experiments in Mt. Fuji in 2018, and report a progress of the development of the tool.

Ignimbrite, tephra-fall, caldera and fatalities of major volcanoes in the East and Southeast Asia

*Shinji Takarada[1], Joel Calupas Bandibas[1]

1. Geological Survey of Japan, AIST

Large-scale caldera-forming eruption can cause major destruction within 10 to several 100-km radius from the erupting volcano. The information about the area affected by ignimbrite and tephra falls and size of caldera are useful for future volcanic hazard assessment. Hence, the compilation of data about the distribution of ignimbrite and tephra fall, shape and size of caldera and fatalities caused by volcanic eruptions in East and Southeast Asia is very important.

The G-EVER Promotion Team of the Geological Survey of Japan, AIST is implementing the Asia-Pacific region earthquake and volcanic hazards mapping project, which compiles earthquake source regions, active faults, tephra falls, caldera, ignimbrite, and fatalities caused by earthquake and volcanic events, in collaborations with geohazard research institutes in the Asia-Pacific region. The G-EVER Promotion Team published the 1:10M Eastern Asia Earthquake and Volcanic Hazards Information Map in 2016 (Takarada et al., 2016). The contents of the map can also be viewed or downloaded using the Asia-Pacific Region Earthquake and Volcanic Hazard Information System at http://ccop-geoinfo.org/G-EVER/. The distribution of ignimbrite and tephra fall, shape of caldera and fatality data are updated and available on the site in 2019.

Ignimbrite: The distribution of large-scale ignimbrites (VEI>6) in East and Southeast Asia are compiled. Ignimbrites data are obtained from 19 volcanic caldera-forming eruptions in the region such as Toba 74 ka, Changbaishan 946AD, Tambora 1815AD, Rinjani-Samalas 1257AD, Aso-4, Aso-3, Aira-Ito, Kikai-Koya, Kikai-Nagase, Ata, Toya, Shikotsu 4.6 ka, Kutcharo I, Kutcharo IV, Krakatau 1883AD, Rabaul 7c, Pinatubo 1991AD, Hakone-Tokyo, and Towada-Hachinohe.

Tephra falls: The distribution of large-scale tephra falls (VEI>6) in East and Southeast Asia are compiled. Tephra falls data are obtained from 24 volcanic caldera-forming eruptions in the region such as Toba 74 ka, B-Tm 946AD, Tambora 1815AD, Rinjani-Samalas, Krakatau 1883AD, Rabaul 7c, Pinatubo 1991AD, Long Island 1660AD, Witori-Kimbe2, Ulleung-Oki and Ulleung-Yamato.

Caldera: The shape of major calderas (VEI>6) in East and Southeast Asia are compiled. There are 23 caldera data obtained from volcanoes such as Toba, Tambora, Aso, Aira, Kikai, Ata, Toya, Shikotu, Akan, Kutcharo, Taal, Krakatau, Rinjani-Samalas, Pinatubo, Rabaul, Long Island, Dakataua, Wiroti, Billy Michel, Towada, Mashu, and Moekeshi.

Fatalities: The number of volcanic eruption fatalities and their causes (i.e. pyroclastic flow, debris avalanche, tephra fall, lahar, tsunami, volcanic gas and other reasons) since 1400AD in East and Southeast Asia are complied. The 13 events at 9 volcanoes in Papua New Guinea, 3 events at 2 volcanoes in Solomon Islands, 6 events at 3 volcanoes in Vanuatu, 74 events at 27 volcanoes in Indonesia, 20 events at 6 volcanoes in the Philippines and 36 events at 21 volcanoes in Japan (152 events at 67 volcanoes in total) were compiled.

The data in ESRI shapefile and other formats are available for download at the Asia-Pacific Region

On the climber’ s attitudes to the Volcanic mitigation for active volcanoes.

*Hideyuki Itoh[1], Chizuru Totani[2], Mizuho Arai[2]

1. Faculty of policy studies, Iwate prefectural University, 2. Asia air Survey, Co.Ltd.

Following the Ontake disaster on September 27,2014, the act on active volcano special measures law was revised in 2015, local governments well informed of hazardous area, items for smooth alert evacuation by distributing volcanic hazard map. On the other hand, it is hard to say that the method of transmitting volcanic disaster information to climber is sufficiently under the present circumstances, it is urgent to provide information smoothly in emergency and evacuation method.

We carried out questionnaire survey on the climber in order to know the attitudes to the volcanic mitigation for active volcanoes. 74 respondents were collected at Kurikoma volcano, and 84 respondents were collected at Akita-Komagadake volcano.

At the result, climber in Akita –Komagadake, more than 62 percent of respondents visited from both Iwate and Akita prefecture, whereas in Kurikoma volcano, 56 percent of respondents visited from Kanto area by the large –scale bus with a sightseeing tour.

More than 67 percent of climbers have not issued climbing notifications in both volcanoes.
It is clear that the 40 percent of respondents in Kurikoma volcano, 25 percent of respondents in Akita –Komagadake climber are not recognized where they are climbing as active volcano, and eruption alert level is not also well understood.

[J] Poster | S (Solid Earth Sciences)：S-VC Volcanology

Mon. May 27, 2019 10:45 AM - 12:15 PM JST | Mon. May 27, 2019 1:45 AM - 3:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_3

[S-VC38] Active Volcanism

convener:Yuta Maeda(Nagoya University), Takahiro Miwa(National research institute for earth science and disaster prevention), Takeshi Nishimura(Department of Geophysics, Graduate School of Science, Tohoku University)

This session discusses various aspects of active volcanisms including, but not limited to, recent and historical eruptions, various phenomena associated with the volcanic activities, underground structures of the volcanoes, and developments of new instruments based on geophysical, geochemical, geological, and multidiscipline approaches. We also welcome studies on understanding and predicting the transitions of the eruptive activities from observational, theoretical, and experimental approaches.

[SVC38-P01] The structure of Showa-Shinzan Yaneyama Usu by seismic reflection surveys

The structure of Showa-Shinzan Yaneyama Usu by seismic reflection surveys

*Ryuichi Takei[1], Tomoki Tsutsui[1,2], Yuya Tada[2], Tomoya Moriwaki[2], Yosuke Aoki[3], Hiroshi Aoyama[4], Go Maruyama[5]

1. Graduate School of International Resource Sciences, The University of Akita, 2. Faculty of International Resource Sciences, The University of Akita, 3. Earthquake Research Institute, The University of Tokyo, 4. Graduate school of Science, The University of Hokkaido, 5. Marutec Co., Ltd.

Reflection seismic surveys at Usu-Showashinzan-Yaneyama was conducted in order to, estimate the shallow structure of the lava-dome base. Usu-Showashinzan is a young volcano formed in 1943-1945. It is characterized by consisting of a lava dome structure with top elevation of about 406.9m and a bun-shaped plateau called Yaneyama. Various geophysical explorations and geological surveys have been carried out in Showa-Shinzan until now, and the formation process and the supply route of magma have been discussed. However, the details of structure beneath Yaneyama are still unknown.
Total of 4 lines were conducted in 2017 and 2018 with 2 lines each, and seismic data were acquired. Two observation lines (Y17 and Y18) were set in the east-west direction on the east foot of the lava dome and two (G17 and G18) in the Guren-valley on the southwest foot of the lava dome. Both survey lines (Y17, G17) were conducted in 2017 with 24 receivers with using a hammer of 6.3kg as the seismic source. Other survey lines (Y18, G18) conducted in 2018 with 48 receivers with using a tamping rammer (MT-55L by Mikasa Industries) as the seismic source. Split-spread method was applied in all seismic lines. The receiver interval was 4m for Y lines and 3m for G lines. SU (Seismic Un*x) software was used for the seismic reflection analysis of the acquired seismograms. For 2018 lines with using tamping rammer, preprocessing is necessary before analysis of seismic reflection. That is based on the principle “SOSIE” (Yokokawa et.al. 1983).
As the result, the time sections on all the survey lines were obtained. Especially, in the G18 line, reflection profile down to 100m depth, which shows gentle valley structure in the middle of the line down to 80m depth and there is almost horizontal boundary at 100m depth.
The refraction tomography analysis and considering previous researches are going to be conducted.

Ground deformation associated with the 2014-2015 and the 2018-2019 volcanic activities at Azumayama

*Jun Okada[1], Shigeo Matsuura[2], Katsuya Ohmi[2], Takuya Yamamura[2], Yu Nihara[3], Susumu Seki[3]

1. Volcanology Research Department (Sendai Office), Meteorological Research Institute, JMA, 2. Seismology and Volcanology Division, Sendai Regional Headquarters, JMA, 3. Regional Volcanic Observation and Warning Center, Sendai Regional Headquarters, JMA

Azumayama is a basaltic to andesitic active volcano located in the volcanic front on the Tohoku (NE Japan) Arc. Historical eruptions occurred mainly in and around O-ana crater in the south flank of Issaikyosan. No eruption occurred for more than 40 years after the last one on December 1977. However, various volcanic phenomena have been observed in recent years. Repeated GPS surveys revealed local inflation-deflation around O-ana crater which plays in a cycle of 2-3-year and corresponds to the increase-decrease of seismicity during 2003-2009. Yoshida *et al.* (2012) estimated the pressure source 200 to 600 meters beneath the O-ana crater. This shows a good agreement with the thermal demagnetization source studied by Yamazaki *et al.* (2010). Monochromatic earthquakes were observed when fumarolic activity of O-ana crater was high during 2008-2011 (e.g. Ueki *et al.*, 2010). By analyzing the frequencies of these earthquakes Torimoto (2016) is beginning to understand the characteristics of shallow hydrothermal systems, a potential hotbed for phreatic eruptions. In more recent years, there are two volcanic unrests such as the 2014-2015 and the 2018-2019 activities. JMA released “Near-crater Warning” and raised Volcanic Alert Level from 1 to 2 on December 2014 and September 2018, respectively.

The start of the 2014-2015 activity can be marked by the slight tilt change at Jododaira station, 750m ESE from O-ana Crater. It showed East-downward ground deformation since late July 2014. Continuous GNSS measurements also captured local inflation around Issaikyosan since September 2014. Seismic activity started on middle October and culminated from December 2014 to middle January 2015. Similarly, the 2018-2019 activity can be recognized by the tilt data of Jododaira. A slow East-downward ground deformation started since May 2018. The tilting rate was significantly increased after the occurrence of the volcanic tremor on 22 July 2018 and remained almost constant (at least at the time of writing). Continuous GNSS data suggested also an inflation of the volcanic edifice since May 2018. The shallow seismicity started since middle August 2018 and remained active (at least at the time of writing).

Strong similarity exists in deformation characteristics between the 2014-2015 and the 2018-2019 activities, that is the dilatational ground deformation, both preceded to the activation of shallow seismicity. Except for the beginning of the activities tilting is maintained with almost the same rate and direction for more than several months. However, several discrepancies should be remarked: (1) Volcanic tremors are more frequent in the 2018-2019 than the 2014-2015. (2) The 2018-2019 activity may be triggered by a remarkable coincidental tilt change (about 1 micro radian at Jododaira station) and the associated volcanic tremor on 22 July 2018. (3) Slight tilt changes which may suggest a deep deflation of Azumayama were clearly observed at distant stations on the foot of Adatarayama, a neighboring volcano in the 2018-2019. These observational evidences may indicate the different volcanic processes in both activities. Regarding (3), other field observation results such as both the increase of SO_2/H_2S since late July 2018 and the enlargement of geothermal areas around O-ana crater can be triggered by the intermittent injection of volcanic fluids (e.g. hot volcanic gasses) from the depth of Azumayama. Results of both tilt and continuous GNSS observations will be presented in the session.

Seismology and Volcanology Division, Sendai Regional Headquarters, Japan Meteorological Agency, 4. Regional Volcanic Observation and Warning Center, Sendai Regional Headquarters, Japan Meteorological Agency

At Azumayama located on the prefectural boundary between Yamagata and Fukushima prefectures, volcanic tremors occurred on 22 July 2018. Changes in tiltmeter data from Joudodaira Station (around 1 km ESE of the Oana crater) indicated ground deformation with a remarkable rising trend in the direction toward the crater. Volcanic seismicity has mostly remained at high levels since August 2018, and volcanic activity has remained at high levels. Japan Meteorological Agency (JMA) issued a Near-crater Warning on 13 September and raised the Volcanic Alert Level from 1 (Potential for increased activity) to 2 (Do not approach the crater).

There are mainly three types of volcanic earthquakes in the vicinity of the Oana crater: the BH-type in which the dominant frequency is high, the BL-type in which the dominant frequency is low, and the BP-type / BT-type with the harmonic waveform. These volcanic earthquakes occur roughly at depths of less than 1 km.

From July to October 2018, BH-type earthquakes mainly occurred, and the proportion of BL-type earthquakes and BP-type / BT-type earthquakes slightly increased in November. After that, the proportion of the BL-type earthquakes decreased, but the proportion of the BP-type / BT-type earthquakes further increased. The proportion of the BP-type / BT-type earthquakes to the whole volcanic earthquakes is 25% in November and 50% since December, and it continues high levels. The BP-type / BT-type earthquakes that occurred after July 2018 have various types of characteristics, such as damped harmonic oscillators with a single frequency peak seen in the BP-type / BT-type earthquakes occurred from 2010 to 2011, damped harmonic oscillators with multiple frequency peaks and those with high-frequency earthquake near the beginning of the earthquake, and no systematic change of the dominant frequency can be observed. In this presentation, we introduce what we found as the results of focusing on waveform shape and amplitude ratio for the BP-type / BT-type earthquakes that occurred after July 2018.

In this research, under the agreement on collaboration and cooperation in the field of seismic / volcanic disaster prevention research between Earthquake Research Institute (ERI), the University of Tokyo and Seismology and Volcanology Department, JMA, I used facilities of ERI and discussed with the people of ERI. I express my gratitude to everyone involved.

The occurrence and petrology of the fine-grained pyroclastic materials of the Futatsudake-Shibukawa eruption in Haruna volcano.

*Teruyoshi Maruyama[1], Yuki Suzuki[2]

1. Department of Earth Sciences, School of Education , Waseda University, 2. Department of Earth Sciences, Faculty of Education and Integrated Arts of Sciences, Waseda University

Haruna volcano is an active volcano of Quaternary which is located in the southern end of the NE Japan arc. Haruna volcano has 500000 years active time. Geshi and Takeuchi (2012) showed the activity is classified into older period (500-240ka), and newer period (45ka-) following activity halt of about 200,000 years. The newest activity in Haruna volcano is Shibukawa eruption (late 5th to early 6th century) and Ikaho eruption (late 6th to early 7th century), both of which occurred at the location of present Futatsudake (ages by Geshi and Oishi (2011)). Occurrences of ejecta from two eruption, as described in Soda (1989), indicate the different manner of pyroclastic flow generation; explosive destruction of the lava dome in the Shibukawa eruption, while column collapse in the Ikaho eruption. Suzuki and Nakada (2007) carried out detailed petrological study for the Ikaho eruption. They proposed mush-like felsic magma was remobilized by the injection of mafic magma. The important point in the eruption triggering was that mixed magma and heated magma with considerably lower viscosity than the original mush-like magma opened the vent, resulting in the decompression of whole felsic magma reservoir. However, no study has revealed the magma plumbing system and the eruption triggering process of the Shibukawa eruption. For the purpose of understanding these points, we have conducted the petrological study of the Shibukawa eruption. In particular, in this research, in order to clarify the progress of eruption and the temporal change of the erupted magma, fine-grained pyroclastic materials were studied rather than pumice blocks in the block and ash flow (BAF).

We sampled fine-grained pyroclastic deposits at four sites locating at the northeastern to eastern foot of Haruna volcano. All sites locate at the periphery of BAF mapped in Soda (1989). Therefore, our investigated sites correspond to the region where pyroclastic surge deposit emplaces (example of Unzen 1991-1995 eruption; Fujii and Nakada, 1999). We could observe the basal part of fine-grained pyroclastic material in three sites. In all sites, the strata were divided into multiple units according to their facies. The juvenile pumice clasts, the coarse part of the deposit, had variation in color (white, gray, light gray). We measured whole rock compositions of the pumice samples and found they are felsic andesite (SiO_2 =60.7-61.9wt.%; N=22). Thin sections were prepared for ten representative pumices and one volcanic ash sample. It is necessary to study the volcanic ash sample, because it is not possible to discuss the change in magma composition from lower to the upper layer, only with the pumice clasts for which whole-rock chemical analyses were performed. The phenocryst phases (Pl+Opx+Am+Fe-Ti Ox) in all samples form aggregates, so when they crystallized, they were in equilibrium. We observed free crystals (Pl+Opx+Am), pumice particles, and lava particles in the thin sections of volcanic ash. All thin sections of pumice and ash include the dusty zone of Pl, so these products resulted from either through magma mixing (between felsic and mafic magmas) or the heating of felsic magma by the mafic magma. In four out of five samples of gray pumice, breakdown reaction rims of amphibole and groundmass crystals were confirmed, so magma that formed gray pumice likely underwent a different ascending process in conduit, in comparison with the magma that formed white pumice.

Suzuki and Fukushima (2019, this conference) studied pumice blocks in the BAF from the Futatsudake-Shibukawa eruption. This result is similar to our result. Therefore, we infer magmas formed these two products was homogeneous in magma chamber. The original pyroclastic flow was separated into rock mass flow and pyroclastic surge as they descended river valleys, resulting in simultaneous

The occurrence and petrology of the block and ash flow deposit from the Futatsudake-Shibukawa eruption, Haruna volcano

*Yuki Suzuki[1], Ryouto Fukushima[2]

1. Department of Earth Sciences, Faculty of Education and Integrated Arts of Sciences, Waseda University, 2. Department of Earth Sciences, School of Education, Waseda University

Haruna volcano is located in the southern end of the NE Japan arc. The latest two eruptions occurred at Futatsudake; Shibukawa eruption in late 5th to early 6th century (0.4 DRE km^3), and Ikaho eruption in late 6th to early 7th century (0.99 DRE km^3)(ages from Geshi and Oishi, 2011; volumes from Yamamoto, 2013). Suzuki and Nakada (2007) conducted petrological study of Ikaho eruption to reveal eruption triggering process. First, injection of mafic magma into the mush-like felsic magma generated mixed magma and heated felsic magma. Then, these low viscosity magmas opened the conduit and vent, resulting in the decompression of whole reservoir. It is indispensable to study two eruptions from a continuous view point, because two eruptions occurred from the same place at an interval of only several decades.

The outcrops of the Shibukawa eruption are categorized into those consisting of block-and-ash-flow (BAF) deposit (this presentation) and those consisting of fine pyroclasts derived from pyroclastic surge and phreatic explosion (Maruyama and Suzuki, 2019; this conference). Outcrops of BAF deposit locate in the vicinity of river valleys, while outcrops of fine pyroclasts locate away from the valleys. The BAF deposit includes relatively large (up to 30cm) juvenile pumiceous blocks, allowing more precise determination of bulk composition of erupted magma than the fine pyroclastic deposit. We investigated four outcrops, two of which locate along Owagawa and Noborisawagawa in the NE flank of the volcano, and two of which locate along Haruna-Shirakawa in the SE flank. Geshi and Oishi (2011) recently clarified the BAF deposit in the SE flank is the product of the Shibukawa eruption by the carbon dating. At some outcrops, BAF deposit could be divided into subunits by the existence of intercalated ash deposit. In any outcrop/subunit, juvenile blocks were classified into white, gray and dark gray. In some blocks, parts with different colors are in stripes or irregularly mixed.

The pumice blocks are homogeneous felsic andesite with 60.6-61.7 wt.% SiO_2(N=21). There is no systematic difference in the composition between the NE and SE flanks. In Unzen 1991-1995 eruption, the composition of the erupted magma changed with time, and there was a temporal change in the flow direction of the pyroclastic flow (Nakada and Motomura, 1999). The present data of Shibukawa eruption show no tendency like that. In the representative six samples covering the pumice color variation, Hb, Opx, Pl, Qtz and Fe-Ti oxides present as phenocryst phase. But, Qtz is quite rare, as we observed only one crystal in 8 thin sections. Phenocryst phases other than Qtz form aggregate, indicating they crystallized in equilibrium. Dusty zone was observed in the plagioclase rim, showing that the melt became undifferentiated just prior to the eruption, due to 1) mixing with hotter magma, or 2) heating by hotter magma. There is no change in whole rock composition and phenocryst assemblage with pumice block color. The different color is likely to be caused by different amount of groundmass crystal (Gardner*et al.*, 1998). The breakdown of Hb was observed only in dark gray blocks.

The felsic endmember magma of the Ikaho eruption erupted as white pumice (60 to 62 wt.% SiO_2). The white pumices contain phenocrysts of Hb, Opx, Pl and Fe-Ti oxides. Therefore, it is highly probable that the felsic magma similar to that in Ikaho eruption was active in the Shibukawa eruption. In the Ikaho eruption, ejecta with obvious characteristics of magma mixing (gray pumice and lava, down to 57.5 wt.% SiO_2) have been confirmed. It means that the mixing ratio of the high-temperature magma in the Shibukawa eruption (even if it happened) was very small. In the future, as well as exploring the eruption

triggering process of the Shibukawa eruption in detail, we need to investigate phenocrysts derived from the felsic magma for the Ikaho eruption. They might record the effects of heating and mixing by high-temperature magma, which occurred several decades before the eruption.

Report of Volcanic Activity at Kusatsu-Shiranesan in 2018

*Tsukasa Kobayashi[1], Koji Kato[1], Koichi Suemine[1], Kazuhiro Kimura[1], Yusuke Yoshigai[1], Yasuo Ogawa[2], Kenji Nogami[2], Wataru Kanda[2], Akihiko Terada[2]

1. Volcanological Division, Japan Meteorological Agency, 2. Volcanic Fluid Research Center, Tokyo Institute of Technology

Kusatsu-Shiranesan is the active volcano located in north-eastern Gunma-pref. Japan Meteorological Agency (JMA) monitors Kusatsu-Shiranesan volcanic activity. A group of pyroclastic cones, including Shiranesan, Ainomine, and Motoshiranesan, which stretch from the north to the south, are located in its highest western area. Latest magmatic eruption occurred about 3,000 years ago. All recent eruptions were occurred in the area around Yugama and Motoshiranesan area, and these eruptions were phreatic explosions.

In January 2018, phreatic explosion occurred at Motoshiranesan area. In April, volcanic seismicity in shallow areas beneath the Yugama crater increased. We report volcanic activity at Kusatsu-Shiranesan in 2018.

A phreatic explosion occurred at 10:02 on 23 January 2018 at the northern and western area of Kagamiike-kita cone in Motoshiranesan. Before the eruption, volcanic tremor occurred from 09:59, and significant tilt changes which indicate the upward of Motoshiranesan direction was obserbed by tiltmeter installed around Yugama crater by the Tokyo Institute of Technology. At around 10:02, low frequency earthquake was observed, and these tilt signals turned to the downward to the Motoshiranesan direction. After the eruption, a very small volcanic earthquake (BH-type earthquake) occurred frequently in a shallow place near Kagamiike-kita cone, but it gradually declined.
In late April 2018, earthquakes around shallow part of Yugama crater rapidly increased, and crustal deformation indicating the expansion of the shallow part around Yugama began to be observed with the tiltmeter installed around Yugama crater.By the geomagnetic observation, the variation of geomagnetic total intensity indicating thermal demagnetization was observed from April.
In early September, the volcanic earthquake activity decreased somewhat and the tiltmeter variation also became smaller. But on September 28, again the earthquake around the Yugama increased rapidly. And crustal deformation similar to April was observed by the tiltmeter installed around Yugama. After that, earthquake activity decreased gradually, but continued in January 2019.

Analysis result of GNSS continuous observation date from 2014 to 2015, in which period seismicity around Yugama crater was high, indicates the expansion of the deep part of northwest area of Kusatsu-Shiranesan. Similar changes was observed at several observation points in 2018.

We would like to thank Kakioka Magnetic Observatory, JMA for the use of his observation and analysis data.

Noble gas isotope composition of fumaroles and hydrothermal gases around Kusatsu-Shirane volcano

*Kotaro Toyama[1], Hirochika Sumino[1], Kaori Kawana[1], Yoshihide Akiyama[1], Takeshi Ohba[2], Muga Yaguchi[3], Akihiko Terada[4]

1. Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo, 2. Department of chemistry, School of Science, Tokia University, 3. Meteorological Research Institute, 4. Volcanic Fluid Research Center, Tokyo Institute of Technology

Mount Kusatsu-Shirane, an active stratovolcano consisting of three pyroclastic cones (from north to south, Mt. Shirane, Mt. Ainomine, and Mt. Motoshirane) erupted on 23 January 2018 at Mt. Motoshirane. This eruption was a phreatic eruption, which often occur without magma movement. Therefore, there is no or very small precursor geophysical signals. In contrast, the chemical and isotopic compositions of volcanic gases can change reflecting pressure rise of a gas reservoir which caused the phreatic eruption. Especially, helium isotope ratio ($^3He/^4He$) is regarded as a useful tracer for the volcanic activity, because it exhibits unique values corresponding to the origin (e.g., 7-8 Ra in the mantle and < 0.1 Ra in the curst, where 1 Ra denotes atmospheric $^3He/^4He$ ratio of 1.4×10^{-6} [1]). Some studies have reported pre-eruptive $^3He/^4He$ anomalies, suggesting the increase of supply of the magmatic helium into the hydrothermal system preceding eruption [2,3].

We report the noble gas (He, Ne, Ar) isotopes of fumaroles and hot-spring gases collected from 9 sites around Kusatsu-Shirane volcano during 2014 and 2018. The measured $^3He/^4He$ ratios were corrected for atmospheric contamination based on $^4He/^{20}Ne$ ratios. The air-corrected $^3He/^4He$ ratio of Sesshogawara fumarole, located on 2 km east of the 2018 phreatic vent, had been constant at 7.0-7.5 Ra during 2014 and 24 January 2018, and dropped to 6.5 Ra on 13 February 2018. The $^3He/^4He$ ratio increased to 7.6 Ra on 21 May 2018 and has been constant at about 7.5 Ra. The $^3He/^4$ He ratios of bubbling gases of Kusatsu-Yubatake hot spring, which located on 5 km east of the 2018 phreatic vent, had been constant at 6.5-6.9 Ra during 2014 and 12 February 2018, decreased to 6.0 Ra on 3 June 2018, and then increased to 7.5 Ra on 6 August 2018. The $^3He/^4$ He ratios of Hoshimata fumarole, which located on 3 km west of the 2018 phreatic vent, increased from 6.2 Ra to 7.3 Ra during 2 March 2018 and 19 June 2018. The trends observed in these sites seem to be associated with the 2018 eruption with different time lags, which may reflect the migration distance from the 2018 phreatic vent to the sites.

In Kusatsu-Shirane area, two hydrothermal reservoirs, one of which is located beneath Yugama crater of Mt. Shirane and the other is located beneath Mt. Motoshirane (between Ainomine and Mt. Motoshirane), have been proposed [4]. The $^3He/^4He$ ratios (7.2-8.1 Ra) of Kitagawa fumaroles on the northern flank of Mt. Shirane near the Yugama crater, may reflect the values of the gases derived from the hydrothermal reservoir beneath Mt. Shirane. On the other hand, the lower $^3He/^4He$ ratios observed in Sesshogawara, Kusatsu-Yubatake and Hoshimata after the eruption may result from another contribution from a reservoir having lower $^3He/^4He$ ratios (less than 6.5 Ra), which could be attributed to the hydrothermal reservoir beneath Mt. Motoshirane. The reservoir beneath Mt. Motoshirane may be enriched in radiogenic ^4He derived from the crust, because Mt. Motoshirane has not erupted for last 1500 years [5].

It has been proposed that the 2018 eruption was caused by sealing of gas pathway from magma to the hydrothermal reservoir beneath Mt. Shirane [4]. This would result in decrease of supply of magmatic gas with high $^3He/^4He$ ratio to Sesshogawara, Kusatsu-Yubatake, and Hoshimata. Therefore, the low $^3He/^4He$

©2019. Japan Geoscience Union. All Right Reserved.

ratios observed in these sites after the 2018 eruption may reflect relative increase of the contribution of gas supplied from the Mt. Motoshirane hydrothermal reservoir. In contrast, the high and relatively constant $^{3}He/^{4}He$ ratios at all of the sites since August 2018 suggest that the gas from the reservoir beneath Mt. Shirane is dominant. Ohba et al. [4] proposed that supply of magmatic gas to the Mt. Motoshirane reservoir increased before the eruption as a result of the sealing of gas pathway from magma to the Mt. Shirane reservoir, and that it caused high fluid pressure of the reservoir and subsequent phreatic eruption at Mt. Motoshirane. This implies that $^{3}He/^{4}He$ ratio of the Mt. Motoshirane reservoir also increased from a lower value to a higher value less than 6.5 Ra before the eruption. Although further study is necessary to constrain $^{3}He/^{4}He$ ratios of the reservoirs, the remarkable temporal $^{3}He/^{4}He$ variation after the eruption can be accounted for by the change in mixing ratio of the gases from the two reservoirs.

Self-potential and geomagnetic total intensity observations at Motoshirane volcano after the 2018 eruption

*Akira Yamazaki[1], Hideki Iino[1], Tatsurou Tanaka[1]

1. Kakioka Magnetic Observatory

A phreatic eruption occurred at Kusatsu-Shirane volcano (Motoshirane volcano) on January 23, 2018, and some impact craters were formed on the Kagami-ike crater floor and the Kagami-ike northern crater. After the eruption, the temporarily activated seismic activity near the crater has declined, and the fumarolic activity has ceased after late February 2018. In order to estimate geothermal status after the eruption, we carried out self-potential (SP) and geomagnetic total intensity observations at Motoshirane volcano. Measurements of the SP were conducted at about 130 points around the summit of Motoshirane volcano from June 30 to July 2, 2018. Copper-Copper sulfate electrodes were used, the measurement interval was about 50 m, and the measurement was carried out by the so-called full potential method. We applied -1.3mV/m as correlation coefficient for correction of the topographic effect to all the SP measurement stations. The coefficient was obtained from a clear negative correlation (-1.3 mV/m) between the elevation and the potential in the survey line on the eastern slope of the Kagami-ike. As a result of the SP, we detected a positive anomaly, 200~500mV in magnitude, developing around the summit of Motoshirane volcano. By comparison of the result of the 4th Joint Observation of Kusatsu-Shirane Volcano in 2003, we found temporal variations of the SP near Kagami-ike northern crater which may have been caused by the eruption. As for the geomagnetic total intensity observation, we selected ten repetitive observation stations around the summit of Motoshirane volcano, and carried out first observation in June 2018 (June 28-30). Following the first observation, we carried out repeated observation in August (August 28-29) and October (October 7). As a result, no significant changes in the geomagnetic total intensity in the period from June to October, 2018. It suggests that rapid thermal demagnetization or magnetization by cooling does not occur at underground of Motoshirane volcano.

Eruption processes of the 3rd and 4th stage of Niigata-Yakeyama Volcano, Japan, inferred from microlite texture and chemical composition

*Takumi Yoshida[1], Takeshi Saito[1]

1. Shinshu University

Niigata-Yakeyama volcano, which belongs to the Myoko volcano group, is one of the most active and youngest volcanoes in Japan. In the 3rd stage of Yakeyama activity, Maeyama lava flows and Hayakawa pyroclastic flows were generated to the northern slope of the volcano. In the 4th stage activity, Yakeyama lava flows, which forms present lava dome at the summit, and Otani pyroclastic flows were effused. Otani pyroclastic flow deposit contains well-vesiculated lavas, while lavas from Hayakawa pyroclastic flow are poorly-vesiculated. In this study, groundmass textural analysis of the eruptive products at the 4th stage was carried out. Chemical composition of plagioclase phenocrysts and microlites of the eruptive products at the 3rd and 4th stage were analyzed in order to examine the eruption process of the 3rd and 4th stage of Yakeyama volcano.

Microlite number density (MND) and crystallinity of plagioclase in Otani pyroclastic flow deposits were obtained from groundmass textural analysis. Our results indicated that Otani pyroclastic flows showed lower MND and intermediate crystallinity compared with Hayakawa pyroclastic flow deposits. As a result of chemical composition analysis, phenocryst in the samples of the 3rd stage activity shows An#(Ca/Ca+Na) =0.65~0.84. Microlite of andesite of Maeyama lava flow has an average An# of 0.61, which is lower than that of dacite lava of Maeyama Lava flow (average An# =0.54). Phenocryst of the 4th stage activity has An# =0.45~0.89. Microlite of Yakeyama lava flow and Otani pyroclastic flow have average An# of 0.63 and 0.62, respectively. The An# of plagioclase microlite becomes lower with decreasing crystal size.

Plagioclase microlite becomes lower An# with higher degree of H2O exsolution due to decompression (e.g. Nakamura, 2011). Our results suggest that microlite in dacite lava of Maeyama lava flow has undergone high decompression compared with andesite lava of Maeyama lava flow. However, there were little difference between plagioclase microlite of lava flow and that of pyroclastic flow samples. Eruptive products of the 4th eruption have relatively homogeneous SiO2 composition. Plagioclase microlite of Otani pyroclastic flow deposit, showing lower MND and higher An# than Hayakawa pyroclastic flow, may be crystallized under a condition of lower undercooling. Another possibility is that rapid vesiculation and H2O exsolution may proceed before microlite crystallization and prevent from decreasing An#.

Estimation of subsurface structure of Shinyu crater lake, Tateyama Caldera, based on the water level and seismic observation data

*Ryohei Kawaguchi[1], Naoko Saito[2], Shin'ya Onizawa[1]

1. Meteorological Research Institute, 2. Toyama local Meteorological office, Japan Meteorological Agency

Shinyu, located in the Tateyama caldera is a crater lake with the diameter of about 40 m and the depth of about 5.6 m. The water level of Shinyu is maintained by the influx of hot water from vents at the bottom of Shinyu. Shinyu had continued the full water level for decades, but periodic geyser activity was reported from 2014 which has the period of 0-20 days (Fukui et al 2018). In order to investigate the activity of the water level change in Shinyu, we installed water level meter and seismometer around Shinyu from June to October in 2017 and 2018. In this study, we estimate the underground structure of Shinyu based on the temporal changes of water level and seismic data.

The water level change was observed by a bubble type water level meter which has a sampling period of 10 minutes. In addition, a seismometer was installed at about 20 m from the Shinyu. The seismic data was recorded with a sampling frequency of 100 Hz.

During the observation period, we were able to obtain the water level change data of 7 cycles in 2017 and 8 cycles in 2018, respectively. For the preliminary analysis, we examined the periods of water level changes, dividing the water level change cycle into four categories, dry-up, rising in the water level, full water level, and descent in the water level. As a result, the period of the dry-up is about 3 days, the rise in water level is about 4.5 days, the full water is 0 to 20 days and the descent in water level is about 0.5 days. The period of raising and decent of the water levels were almost constant for each cycle. During the rising and full of the water level, rising of hot water with gas bubbles were observed by the image of Shinyu surface taken by time-lapse camera. The amplitudes level of seismometer data was clearly different between the period of rising and full of water level and the period of dry-up and decent of water level. These indicate that geyser activity of Shinyu is occurred by boiling of hot water in the water reservoir located below the Shinyu.
When the shape of Shinyu is conical and the flux of the hot water drop under the Shinyu is constant, the flux of dropping hot water is estimated about 0.06 m^3/s by the size of Shinyu and the period of the descent of water level. According the data of water level meter, the rate of water level descent were 1.2-2.5 $\times 10^{-3}$ m/s. From these data, the radius of cylindrical pipe assuming below the Shinyu was estimated to be 2.8-4.0 m. We also report on the result of comparing the time scale of water level changes using the observed data and simulation result based on the previous geyser model.

Real time monitoring of underground temperature in Jigokudani, Midagahara volcano using LPWA devices

*Tohru Watanabe[1], Toyama branch NTT West[2]

1. Gradudate School of Science and Engineering, University of Toyama, 2. Nippon Telegraph and Telephone West Corporation

Jigokudani is an active geothermal area in Midagahara volcano, Toyama prefecture, central Japan. It was formed as a result of repeated phreatic eruptions over 40,000 years. Increased volcanic activity in this area has been observed since 2011. In order to detect a precursory signal of a phreatic eruption, seismicity, observations should be conducted on seismicity, ground deformation, geothermal activity, volcanic gas, etc. A real time monitoring system of underground temperature using LPWA (Low Power, Wide Area) devices has been tested since 30 August 2018. An LPWA device (NHR, SS05-ST) is composed of thermometer and transmitter (LoRaWAN). 10 devices were deployed in Jigokudani. Temperature sensors (thermocouples) were placed at the depth of 50 cm. Transmitters send temperature data every 30 minutes to a gateway to the internet situated in Hotel Tateyama. The distances from the gateway to LPWA devices are within 1 km. Underground temperatures can be monitored on internet devices. Since Jigokudani has a heavy snowfall in winter, 7 devices were removed and 3 devices were left to test in winter. Though temperature data could be received until December 2018, no data could be received since then. Transmitters of around 50 cm high above the ground must be covered with snow. During summer and fall, LPWA devices are useful for real time monitoring.

Keywords: underground temperature, LPWA, real time monitoring

Varying chemical and isotopic compositions of fumarolic gases from the summit and from the 1962-63 eruptive vents at Yakedake Volcano, Japan

*Takeshi Saito[1], Shun Sawamura[2], Kazuhiro Amita[3], Taketoshi Mishima[4], Shinji Ohsawa[4]

1. Institute of Science, Academic Assembly School of Science and Technology, Shinshu University, 2. Graduate School of Science and Technology, Shinshu University, 3. Graduate School of Engineering Science, Akita University, 4. Beppu Geothermal Research Laboratory, Institute for Geothermal Sciences, Graduate School of Science, Kyoto University

Since the latest phreatic eruption in 1962-1963, Yakedake volcano has remained dormant, but fumarolic activity around the summit area has continued steadily during the past hundred years. Recently, temperature, chemical, and isotopic compositions of fumarolic gases discharged from the summit fumaroles were ascertained for 2013-2017 (Saito et al., 2019). This time, fumarolic gases discharged from the 1962-63 eruptive vents, which locate about 300m north of the summit, were collected and chemical and isotopic compositions were analyzed. We compared our results from the 1962-63 eruptive vents with those from the summit fumaroles in order to evaluate the formation of volcanic hydrothermal system beneath the volcano.

Discharge temperatures of the fumaroles around the 1962-63 vents were 95-100˚C: slightly lower temperatures than those from the summit fumaroles but higher than the boiling temperature at the elevation. Chemical analysis revealed that fumarolic gases from the 1962-63 vents contain lower amounts of SO_2 than the summit fumaroles. Higher CO_2/total S ratio and lower apparent equilibrium temperatures of the 1962-63 fumaroles coincide with lower discharge temperatures. On the other hand, the 1962-63 fumaroles show higher He/Ar ratio than the summit fumaroles, suggesting higher contribution of magmatic fluid.

The isotopic compositions of water (D, ^{18}O) show that the fumarolic fluids from the summit fumaroles were probably formed by mixing of the magmatic fluids and local meteoric water. The isotopic compositions of the 1962-63 fumaroles show much lower values not only than the summit fumaroles but than local meteoric water, suggesting that the fluids suffered isotopic fractionation due to evaporation of the fumarolic gases.

Our results possibly indicate that volcanic hydrothermal system beneath the summit region differ from that under the 1962-63 vents.

Eruption age determination of the latest two lava flows and characteristics of volcaniclastic materials from the recent activity of Yokodake Volcano, Japan

*Hiroya Nitta[1], Takeshi Saito[1], Yorinao Shitaoka[2]

1. Shinshu University of Science and Technology, 2. Department of Environment System, Faculty of Geo-environmental Science, Rissho University

Yokodake volcano, which effused nine lava flows (Y1~Y9), is the only active volcano belonging to Yatsugatake volcano groups in central Japan. Eruption ages of Y1-Y8 lava were not determined distinctively. To evaluate the latest activity of Yokodake volcano, we carried out paleomagnetic studies and tried to estimate the eruption ages of the Y8 and Y9 lava flows. However, several candidates for paleomagnetic ages were remained (Nitta and Saito, 2018, JPGU; Nitta and Saito, 2018, fall meeting of the volcanological society of Japan). In this study, we applied thermoluminescence (TL) dating for Y8 and Y9 lava and viscous remanent magnetization (VRM) dating for Y9 lava. In addition, the volcaniclastic layers were found just above the Y9 lava and around the surface of the summit region. We will report characteristics of the volcaniclastic layers, discussing the recent activities of this volcano.

TL dating was performed by using poly-minerals (ca 10~50 μm) sample extracted from Y8 and Y9 lava. TL age of Y8 sample was 3.3 ±1.2 ka. Y9 lava sample didn't emit TL intensity. As for Y9 lava, we tried to estimate the age using VRM. However, the estimated ages were widely scattered. We conclude eruption age of the Y8 lava is ca. 3.3 ka, which is consistent with our previous paleomagnetic age of 3.35~3.85ka. On the other hand, five eruption ages of Y9 lava (0.60 ka, 1.80 ka, 1.90~1.95 ka, 2.20~2.25 ka, 2.4~2.45 ka) are still remained.

We recognized light gray volcanic ash deposit just above Y9 lava which composed of sand to silt size and contained carbonaceous material. It may be comparable to NYk-1 tephra (Okuno, 1995). Four volcaniclastic layers were found at summit region and the lower layer is a possibility of being correlated with NYk-2 tephra (2.35~2.15 cal ka BP; Okuno and Kobayashi, 2010). Two volcaniclastic layers above NYk-2 tephra seem to be derived from Yokodake volcano, suggesting at least two volcanic eruptions were occurred after NYk-2 tephra eruption.

Estimating the date of the 2007 eruption of Mount Ontake Volcano using waveform correlation

*Shuhei Nishijima[1], Toshiko Terakawa[1], Shinichiro Horikawa[1]

1. Graduate School of Environmental Studies, Nagoya University

Mt. Ontake volcano erupted on late March, 2007. However, we do not know the exact time of the eruption with a Volcanic Explosivity Index 0 because of little visual evidence. I tried to estimate the date of the 2007 eruption, using a waveform correlation method. A previous study reports that focal mechanisms of volcanic earthquakes associated with the latest eruption in 2014 changed from normal/strike-slip faulting with east-west tension to reverse faulting with east-west compression. Based on this fact, I selected 10 and 8 volcanic events for the pre- and the post-periods of the 2014 eruption as template events. I applied the technique to continuous seismic waveforms from 22 December 2006 to 31 March 2007. I detected 2375 (pre-eruption type) and 1659 (post-eruption type) events corresponding to the pre- and the post-eruption events, respectively. I found that events with east-west tension (pre-eruption type) became active at the early stage until a very long period (VLP) event occurred on 25 January, and during the period from 5 to 19 February. On the other hand, the activity of events with east-west compression (post-eruption type) became dominant for 11 days after the VLP event occurred, and during the period from 20 February to 24 March. Subsequently, neither type of events became dominant. The activity of pre-eruption type events synchronized with the period when the length of the baseline in the east-west direction across Mt. Ontake increased. This suggests that events of pre-eruption type are related to the magma intrusion process beneath the volcano. The activation of events of post-eruption type following to the VLP event, which is well modeled by a tensile crack with a strike of N20W, may be related to contraction processes after the event released water vapor from the volcano. Based on the changes in types of detected events as well as the seismicity, I concluded that Mt. Ontake would have erupted on 20 February or between 11 and 12 March, 2007.

Seismic activity beneath Mt. Ontake volcano before and after the 2007 and 2014 eruptions

*Yoshiko Yamanaka[1], Shinichiro Horikawa[1], Yuta Maeda[1]

1. Graduate School of Encironmental Studies, University of NAGOYA

We developed a portable seismic telemetry system. This system is compact size, and the consumption electricity is small (Horikawa et al., 2017VSJ). From October 2017 performance test of this system has been carried out in the summit region of Mt. Ontake volcano. 10 seismic observations were installed. We determined seismic activity around Mount Ontake volcano by using those 10 summit observations and the seismic networks of Nagoya University and Japan Meteorological Agency, and obtained station corrections. Most of earthquakes were located beneath the craters of the 2014 eruption, and those depths were close in sea level or were shallower. The seismic activity is almost distributed on a straight line at -1.5km from 0km in depth and spreads through the northeast-southwest direction at around -1.5km (Yamanaka et al., 2018JpGU).

We try to determine seismicity linked to the 2007 and 2014 eruption of the Mount Ontake by using obtained station corrections. Before the 2014 eruption, earthquakes occurred from 1.0 km to -0.6 km linearly. This seismic activity is on an extension line of the 2017-2018 linear activity. After the 2014 eruption, earthquakes spread in the north and south direction from around -0.6 km in depth. The seismic activity gradually become shallow and extended to the current seismic activity. The events before the 2007 eruption also occurred from 3.0 km to 0 km on an extension line of the 2017-2018 linear activity. It is considered that some kind of fluid has risen through almost the same passage at the 2007 and 2014 eruptions.

Effect of rain and snowmelt correction of tiltmeter data - Application example for Ontakesan Volcano -

*Kazuhiro Kimura[1,5], Katsuhisa Kawashima[2], Takane Matsumoto[2], Akihiko SASAKI[4], Tsutomu Iyobe[3], Junichi Miyamura[1], Masaki Nakahashi[1]

1. Japan Meteorological Agency, 2. Research Institute for Natural Hazards and Disaster Recovery, Niigata University, 3. Faculty of Engineering, Kyoto University, 4. Department of Geography and Environmental Studies, Kokushikan University, 5. Graduate School Science and Technology, Niigata University

Japan Meteorological Agency(JMA) installed a tiltmeter about 3km southeast of Mt. Ontake in 2010. A clear tilt change was observed northwest upward from several minutes before the 2014 phreatic eruption and northwest downward after the eruption. Kimura and Nakahashi (2015) applied the rain correction method using the tank model and precipitation data to the tiltmeter data of east-west component of the summer (From June to October), and they detected the small tilt change of west rising from September 10, 2014 when the earthquake activity became active. However, the similar tilt change of west rising has been confirmed several times and it has not been able to remove the influence of snowmelt in the spring (From March to May).

Miyamura et al. (2017) developed the rain and snowmelt correction method that adds the snow-tank to the tank model by Kimura et al. (2015) that uses snowmelt amount data as input values in addition to the precipitation data. They applied this method to the tiltmeter data of east-west component, and they confirmed that the influence of snowmelt in the spring was removed from the tiltmeter data. We used a method using a TR model that uses temparature and solar radiation as indices with reference to Matsumoto et al. (2010). Because there is not the continuous meteorological observation data for a long time near the tiltmeter (altitude 2195 m), they used the meteorological observation data at Kaidakogen (altitude 1130 m) closest to the tiltmeter (about 11.5km). In order to consider the difference between the two meteorological observation data, they compared with the meteorological observation data at Kaidakogen and the meteorological data near the tiltmeter observed by Kawashima et al. (2016).

There is a large seasonal changes from spring to summer every year for the tiltmeter data of north-south component. We applied the method of Miyamura et al (2017) to the tiltmeter data of north-south component, and it is able to remove this seasonal changes. Focusing on the 2014 phreatic eruption of Mt. Ontake, we detected the tilt change of north rising from the mid August 2014. In other words, the tilt change began north rising from the mid August 2014, and turned to northwest rising from around September 10. Similar tilt change could not be confirmed during the reserch period (April 2011 - September 2017).

We considered this tilt change while related to two previous studies. First, with reference to hypocenters before and after the eruption by Kato et al (2015), assuming an open crack model with NNW-SSE strike and moving its upper end from the 2 km to 1 km depth. As a result, we were able to confirm the tilt change pattern from north rising to northwest rising. Next, Miyaoka and Takagi (2016) applied the stacking method to the GNSS baseline length data, they detected that the change of the long baseline began from the middle of August and the change of the short baseline began from the beginning of September. They inferred that the pressure source migrated to a shallower region from a deeper region. The results of these previous studies are consistent with the tilt change applied the rain and snowmelt correction method to the tiltmeter data, and are considered to indicate the effectiveness of this method.

Spatial Variation of b-value around Mt. Fuji influenced by the Eastern Shizuoka Earthquake of 15 March 2011

*Takumi Murakoshi[1], Tomonari Miyashita[2]

1. National Defense Academy, 2. JASDF

The Eastern Shizuoka earthquake occurred on March 15, 2011 (Mj6.4). The hypocenter of the earthquake was approximately 6 km southwest of Mt. Fuji’ s peak at a subsurface depth of about 15 km. Estimating spatial variation of the b-value of the Gutenberg–Richter relation is important in the examination of time and spatial changes in volcanic and seismic activity after large earthquakes. This study aims to evaluate changes in seismic activity after the 2011 Eastern Shizuoka earthquake using the spatial variation of the b-value. Hypocentral data from July 2001 to December 2017 was obtained from the JMA catalog. As a result, the b-value for earthquakes around Mt. Fuji was significantly smaller during the period after the 2011 Eastern Shizuoka earthquake than during the period from July 2001 through February 2011, and it continued to gradually recover after the Eastern Shizuoka earthquake.

Keywords: b-value, Mt. Fuji, 2011 Eastern Shizuoka Earthquake

Present condition of submarged volcano, Teishi Knoll, off Ito, Eastern Izu Peninsula

*Toshiro Yamanaka[1], Yoshifumi Kawada[2], Takuro Noguchi[3], Mayumi Hatta[3], Kei Okamura[3]

1. Tokyo Univ. Marine Science and Technology, 2. Tohoku University, 3. Kochi University

Teishi Knoll is a submerged volcano belonging to Eastern Izu volcanic zone and located c. 4 km east off the coastline of Ito City, Eastern Izu Peninsula. The volcano erupted in July, 1989, then the cone shaped knoll with a crater on the summit was formed. The Japan Meteorological Agency has reported that the Eastern Izu volcanic zone is composed of some small volcanoes including scoria cones, tuff rings, maars, and lava domes, erupted on land and many submerged volcanoes distributed densely on the seafloor off the coast. Detail of the submerged volcanoes has been unknown yet. The volcanoes have been considered to distribute on several lines of northwest-southeast direction reflecting the stress field of this area. Previous activities of the volcanic zone have been reported; Ohmuroyama Volcano was formed by eruption about 4 ka, Kawago-daira Volcano was formed about 3.2 ka, and Iwanoyama-Iwoyama volcanic chain was formed by a fissure eruption about 2.7 ka. The last eruption of the volcano belonging to the zone is considered the Teishi eruption in 1989.

In Japan there are confirmed 110 active volcanoes, 12 volcanoes of them are located below sea surface. Such submerged volcanoes have not been observed continuously due to its difficulty by visual observation, therefore, those volcanoes have not ranked according their activity by Japan Meteorological Agency. Therefore, we started observation of Teishi volcano in December, 2017, for evaluation whether active magma supply is still continuing or the intrusive magma causing of 1989 eruption is just cooling. Geochemical (water chemistry) and geophysical (heat-flow) observation has been done using training vessels of TUMSAT every half year.

We have not accumulated enough data yet, measurements of geothermal gradient were performed every time. For calculation of the heat-flow it is required the temperature record of the bottom water, so we started long-term temperature observation on the seafloor from the last December. On the other hand, chemistry of the bottom water in the crater showed slight positive anomaly of dissolved inorganic carbon and significant positive anomaly of manganese relative to the bottom water obtained from outside of the crater. Those chemical anomalies suggest that any thermal activity is still alive in the volcano.

Descriptions and age of volcanic products before the caldera formation in the northern part of Izu-Oshima, off Tokyo, Pacific Ocean

*Satoshi Terayama[1], Takehiko Suzuki[1], Makoto Kobayashi[2]

1. Tokyo Metropolitan University, 2. Research Center for Volcanic Hazards and Their Mitigation, Tokyo Metropolitan University

Introduction

Izu-Oshima Volcano erupted in 1986 is an active volcano that will erupt in near future. The volcano has been studied for a long time, and many studies has been conducted (Nakamura, 1964; Koyama and Hayakawa, 1996; Kawanabe, 2012 and so on). However, most previous studies focused on ″Syn-and post-caldera volcano″ (Kawanabe, 1998) after the caldera formation of Izu-Oshima Volcano. There are few studies discussed ″Younger Edifice of Pre-caldera volcano″. In this study, the purpose is to investigate the volcanic products of Younger Edifice of Pre-caldera volcano and older period with little investigation and to clarify the eruption history. The description of the volcanic products should be important in considering prediction of volcanic eruption and volcanic disaster prevention.

The study site is a coast called Goishihama located between the Chigasaki and Kazehayasaki capes in the northernmost part of Izu-Oshima. At the site volcanic products are exposed on the coasted cliff with a width of about 1 km and a height of about 30-40 m. Volcanic products that can be observed along Goishihama are described by Isshiki (1984), who reported mainly volcanic product of ″Okata volcano″ and ″Older Edifice of Pre-caldera volcano″. However, its description is limited, and description and discussion of fall-out tephra have not been done. In this study, we investigated volcanic products that are exposed on the sea cliff of Goishihama. As a result, some new views on the observable layer were obtained.

Results

The fall-out tephra group composed of 31 eruptive products is named ″Goishihama fall-out tephra group″. We sampled black humus buried soil from three horizon in ″Goishihama fall-out tephra group″ and determined the radiocarbon age. Ages are 11076-10713, 12027-11747, 18117-17803 cal BP in descending order. Therefore, it was revealed that ″Goishihama fall-out tephra group″ is the volcanic products of ″Younger Edifice of Pre-caldera volcano″ after 20 ka. Isshiki(1984) showed no description of the volcanic products of ″Younger Edifice of Pre-caldera volcano″ at Goishihama. As a future issue, it is necessary to correlate Goishihama with 95 fall-out of O1 to O95 distributed mainly in southwest part of the island by Tazawa (1980).

In addition, a fine white pumice with a diameter of about 1 mm was found slightly in the ″Goishihama fall-out tephra group″. After sampling the layer, we washed and observed it with a microscope, colorless and transparent pumice type volcanic glass shards were discovered. The chemical composition of the volcanic glass was measured, that is, SiO_2=78.07 wt.%, CaO=0.61 wt.%, FeO=0.75 wt.%, Al_2O_3=12.74 wt.%, K_2O=3.29 wt.%, showing a rhyolitic tephra. Therefore, it is not a tephra from the Izu-Oshima volcano formed by basaltic magma. The source of this rhyolitic tephra seems to be Kozushima Volcano or Niijima Volcano. These results suggest that ″Goishihama fall-out tephra group″ is the products of ″Younger Edifice of Pre-caldera volcano″ and that this rhyolitic tephra can be compared with O55 (Niijima Miyatsukayama tephra) (Saito et al., 2007). Thus, in this study, a new radio carbon age was obtained from Goishihama, and a rhyolitic tephra was newly discovered. The future issue is to correlate tephra in the outcrop of this study site with those in other outcrops, and it is needed to confirm the correlating of rhyolitic tephra.

Time change of p-value by Schuster method using earthquakes around Izu-Ohsima summit

*Hiroyuki Takayama[1]

1. Volcanological Division 1st labolatory, Meteorological Research Institute

Morita et al.(2016) and Morita et al.(2017) consider relation between volcanic earthquakes in Izu-Ohsima island and earth tide. Takayama et al.(2018) divide Izu-Oshima into 5 area and calculate p-value and consider relation between earthquakes and earth tide.

We use Schuster method (Schuster (1897)) whether occurrence of earthquake relate earth tide or not. This method is check null hypothesis of no correlation between earthquake occurrence and earth tide. Specifically, we set tide phase angle of earthquake occurrence as Di,

$$R=(\sum \cos Di)^2+(\sum \sin Di)^2$$

$$p=\exp(-R/N)$$

we test relation between earthquake occurrence and earth tide by this p-value. P-value falls in 0 to 1. If p-value is nearly 0, we reject null hypothesis. We calculate tide phase angle to each tidal component. In this research, we use principal lunar semi-diurnal tide (after this, we abbreviate M2).

In principal, if earthquake catalogue contain swarm, we can’ t calculate precise p-value. So, we avoid this problem to decluster catalogue.

In this study, we investigate time change of p-value in summit earthquakes. Detection capability of JMA catalogue in summit area is magnitude 0.0. After we decluster this catalogue, p-value is 0.011. So, we divide summit earthquake by time and calculate p-value of M2 in each group.

Specifically, we use JMA catalogue from April 2002 to January 2017. We pick up earthquakes of Izu-Ohsima summit. The number of earthquakes larger than magnitude 0.0 is 1084. After declusterd, the number of earthquakes is 901. We pick up 100 earthquakes from declusterd catalogue. We calculate p-value by M2 in 801 earthquake lists.
As a result, p-value increase and decrease periodically in time. Maximum is 0.98, minimum is 0.0030. If we select standard of rejection of null hypothesis as 0.05, periods of p-value less than this standard are around 2006, around 2010 and around 2014. Morita et al.(2017) suggest that release of volatile component from magma increase when earthquakes correlate earth tide. In the above three periods, release of volatile component increase possible. Also, Morita et al.(2017) suggest that release of volatile component from magma increase from 2013. This coincide with 2014 period.

Standard stratigraphy and characteristic properties of late Quaternary tephras on the Niijima-island: Report of geochemistry and refractive indices of volcanic glass shards, orthopyroxene, hornblende, and cummingtonite

*Kaori Aoki[1], Makoto Kobayashi[1], Fumikatsu NISHIZAWA[1,2], Masanori Murata[1], Daisuke Ishimura[1], Takehiko Suzuki[1]

1. Research Center for Volcanic Hazards and Their Mitigation, Tokyo Metropolitan University, 2. Mount Fuji Research Institute, Yamanashi Prefectural Government

Tokyo Metropolis has the twenty-three wards, the Tama district, and the islands area. The population of the islands area is 25,353 (1st January 2019). The islands area, namely, the Izu-Ogasawara Islands consist of 21 volcanoes (islands and submarine volcanoes), excluding some islands. For residents in this area, volcanic disasters are always the threat. Accordingly, to integrate the fundamental information for preventing volcanic disasters, we investigate the history of volcanic activities, the pattern of each eruption, and the mass volume of erupted tephras and try to establish the high-resolution tephrochronology (Kobayashi *et al.*, 2019a,b). This project focuses on establishing the database of tephras collected form each island of the Izu Islands and their petrographic description and geochemical data. Also, it is likely that such tephra across the sea would deposit in the hemipelagic sediment around volcanic islands. Our tephra database of the Izu Islands has been a powerful tool to identify the source of marine tephra bearing in drilled core CK09-03,C9010E collected at the site of 100 km east from the Izu Island, off the Boso Peninsula (Aoki et al., 2019). Today, we present the petrographic and geochemical characters of many tephras provided through volcanic activities of the Niijima island during late Quaternary.

At the Daisan-yama, Fujimi Touge, and Miyatsukayama on Niijima island, and also Jinaijima off 1.6km west of Niijima island, we have recognized 21 eruptive events at least, including some tephras derived from off-island (Kobayashi *et al.*, 2019a). Kobayashi et al. (2019a) recognized as Niijima Origin tephra felsic magma events and mafic magma events on Nijjima islnad. On the island, as widespread marker tephra, AT and K-Ah tephra were detected. After tephra samples were washed by the ultrasonic cleaner, we collected the description of petrographic characters, major-element chemistry determined by EDS and refractive indices (RI) of volcanic glass shards, orthopyroxene, hornblende, and cummingtonite in each tephra. Generally, felsic tephra derived from vents on the Niijima island include often a small amount scoria grain. Most felsic tephras consist of felsic volcanic glass shards, and including plagioclase, quartz (including β-quartz), orthopyroxene, hornblende, cummingtonite, and occasionally biotite. The characteristic fact of Niijima Origin tephra is that RIs of heavy minerals (orthopyroxene and hornblende) has broad variations. Especially, RIs of orthopyroxene in Akasakimine tephra series, Miyatsukayama tephra series, and Miyatsukayama Nannbu tephra series show the bimodal or trimodal histograms within the limit of 1.700-1.730, including high RIs over 1.730 slightly, considered as close to ferrosilite. Also, there is the tendency that RIs of hornblende in Akasakimine tephra series and Miyatsukayama tephra series show the bimodal histograms or broad variations within the limit of 1.663-1.688. On the other hand, RIs of cummingtonite in Niijima Origin tephra during 60 ka show the unimodal histograms within the limit of 1.658-1.669. RIs of felsic volcanic glass shards in Niijima Origin tephra show within the limit of 1.492-1.501. By comparison that common range of RIs on Quaternary tephra in Japan is 1.501-1.505 (Machida and Arai, 1992), RIs of Niijima Origin tephra would be classified to lower RI groups in Japanese Quaternary tephras.

©2019. Japan Geoscience Union. All Right Reserved.

The content of SiO_2 in volcanic glass shards is 77.7-78.2 wt%, Na_2O+K_2O is 7.2-7.7 wt% generally, excluding some tephra which range is within the limit of 7.0-8.3 wt%. The content of FeO* is 0.7-1.0 wt% and high-SiO_2 is harmonious to the lower RIs of volcanic glass shards (Furuta *et al.*,1986; Kikkawa, 1990).

Tephrostratigraphy and its eruption history of the Latest Activity in the Kozushima Volcano, the Izu Islands

*Makoto Kobayashi[1], Masanori Murata[1], Fumikatsu NISHIZAWA[2], Takehiko Suzuki[1,3]

1. Research Center for Volcanic Hazards and their mitigations, Tokyo Metropolitan Univ., 2. Fuji Research Institute, Yamanashi Prefectural Government, 3. Department of Geography, Tokyo Metropolitan Univ.

In this study, we defined the younger eruptive activity since the eruptive event of Chichibuyama A tephra (ca. 22–26 ka; Suga et al., 1992, 2003) composed of pyroclastic deposits from the southern part of Kozushima covering the whole island as "the Latest Activity". In order to establish the tephrostratigraphy during this period, we are aiming to construct more detailed eruption history of Kozushima Volcano.
As a result of the topographical interpretation using DEM, we recognized Tenjo-san edifice (pyroclastic cone and lava domes), Kobeyama-Hanadateyama volcanic chain (lava domes) and Kushigamine (pyroclastic cone) as younger volcanic landforms presumably formed by the Latest Activity.

In addition, according to the geological survey, we recognized deposits associated with eight eruptions events in minimum. At Loc. 16 in the north part of Nachi-san, northern Kozushima, we recognized pyroclastic surge deposit composed of alternate layers such as pumice, volcanic lapilli and coarse ash so on (no. 16-1; Tenjo-san Tephra (AD 838)), fall-out deposit including altered volcanic blocks and lapillus (no. 16-2), medium to fine fall-out ash deposit (ca. 10 cm in thickness) containing pumice clasts (no. 16-3), densely scattered zone composed of scoria clasts with diameter of several mm (no. 16-4) and densely scatter zone composed of coarse volcanic ash (no. 16-5) in descending order. On the other hand, at the Akabane-tunnel (Loc. 4) in southern Kozushima, Tenjo-san tephra (no. 4-1), densely scattered zone composed of coarse ash (no. 4-2), medium to fine volcanic ash deposit (ca. 3 cm in thickness) containing pumices (no. 4-3), densely scattered zone composed of scoria clasts with diameter of several mm (no. 4-4), fine volcanic ash deposit with a thickness of ca. 9 cm (no. 4-5) and pyroclastic surge deposit composed of alternated layers such as volcanic lapilli and coarse ash (no. 4-6) in descending order. Widespread tephra of K-Ah was detected between no. 4-2 and no. 4-3. Among these eruption deposits, it is suggested that the eruption of no. 16-2 occurred around central to northern part of Kozushima because these deposits distributed only these areas. In contrast, medium to fine air fall ash deposits (no. 16-3 and no. 4-3) containing pumices and fall-out fine ash deposit (no. 4-5) are very prominent layers, then, we are deeming these deposits as widespread tephras originated by relatively larger eruptions. ^{14}C datings for charcoal scattered in tephric loess or humus soil just below tephra layer were applied. ^{14}C ages are 1300±20 yr BP under the fall-out ash deposit correlated with the no.16-2 (Loc. 15; 262 m lava dome), 5790±30 yr BP at top of the no. 4-2, 8850±30 yr BP and 9390±30 yr BP above and below the no. 4-3, respectively, and 12030±30 yr BP just under the no. 4-6. Considering the calendar years and tephrostratigraphic relation, the ages of tephras during Latest Activity comprises five eruptions of ca. 1.1-1.2 ka (no. 16-2), ca. 7.5 ka (no.16-3 and no. 4-3), ca. 10 ka (no. 4-4) and ca.13.5 ka (no. 4-6).

Currently, we are further collecting data on mineral compositions, the refractive indexes and the major element compositions of volcanic glass shards for each tephra, and we are studying from the viewpoint of correlation with eruption deposits from Kobeyama-Hanadateyama volcanic chain, and Niijima Volcano origin tephra (Miyatsukayama, Shikinejima and Miyatsuikayama South: Kobayashi et al., 2018). In the presentation on the day, we will report the eruption history of the Latest Activity of Kozushima Volcano based on the results of these studies.

Characteristics of hypocenter distribution connected with velocity structures in and around Miyakejima, Kozushima and Hachijojima volcanoes

*Hiroko Hagiwara[1], Hidefumi Watanabe[1]

1. Tokyo Metroplitan Government

The aim of this study was to examine the characteristics of seismic activities in association with the seismic velocity structures in and around the Izu islands. We focused on three seismic activities, the swarm off the west coast of Miyakejima on April 2013, the swarm off the northeast coast of Kozushima on April 2018 and the low frequency earthquakes beneath Hachijojima from 2003 to 2018. To construct the 3-D velocity structure models for Miyakejima and Kozushima we used the data of the swarm accompanied with the 2000 Miyakejima eruption, while for Hachijojima we used the data from 2003 to 2018 based on the Izu islands volcanic observation system. These travel times were adopted to the tomographic inversion method (Zhang and Thurber, 2003). The relocated precise hypocenters on the velocity imaging maps revealed an interesting relationship between seismicity and structure. In the target region, both Miyakejima and Kozushima swarms occur at 5-10 km and 2-6 km depth, in the border of high-velocity zones adjacent to or underlain by the low-velocity zones in figure 1 and figure 2. Their swarm regions were located nearby the two end sides of the 2000 swarm, where the huge seismic activity occurred repeatedly. That suggests the upward moving of magmatic fluids. In contrast, the Hachijojima earthquakes occur at 10-14 km depth in the middle-velocity area around a high-velocity zone in figure 3. This high-velocity zone is supposed to be somewhat cold body beneath Nishiyama volcano in Hachijojima. We interpret that the former low-velocity zones consist of hot magmatic materials and the latter high-velocity zone consists of the solidified volcanic body. On the basis of three case studies, it is suggested that volcanic fluids derived from hot magma or solidified magma caused the upper or surrounding seismic activities through complex crack systems.

Deformation of Miyakejima volcano measured by GNSS campaign observation (2013-2015)

*Haruna Watanabe[1], Takeshi Matsushima[2], Miyo Fukui, Atsushi Watanabe[3], Jun Oikawa[3], Takashi OKUDA[4], Taku Ozawa[5], Yosuke Miyagi[5]

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University, 2. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, 3. Earthquake Research Institute, University of Tokyo, 4. Earthquake and Volcanology Research Center, 5. National Research Institute for Earth Science and Disaster Resilience

Miyakejima is an active volcano located about 180 km south of Tokyo, and since the 20th century it erupted at intervals of about 20 years (1940, 1962, 1983, and 2000). Fukui et al. (2015) conducted GNSS campaign observations and estimated the pressure source of Miyakejima from 2011 to 2013. Therefore, in this research, we estimated the crustal deformation of Miyakejima from 2013 to 2015, the position of the pressure source and the volume change, and estimate the temporal change of the pressure source of Miyakejima.

We conducted GNSS campaign observations at 15 reference points arranged so as to be distributed almost evenly throughout Miyakejima from 2 September to 6 September 2013 and from 31 August to 4 September 2015. We used the data obtained from this GNSS campaign observation and the data for the same period of continuous observation points established by the Geospatial Information Authority of Japan etc. In order to analyze the obtained data, the coordinate value of the observation point for each year was obtained using RTKLIBver.2.4.2 software (Takasu et al., 2007).

The pressure source was estimated based on horizontal displacement from 2013 to 2015. The optimum value of the variation was obtained by using MaGCAP-V software (Meteorological Research Institute, 2008) for analyzing crustal activity for volcano. Although the positions of the pressure sources have not changed significantly from 2011 to 2013, it is presumed that the pressure source at the depth of about 0.3~8 km continues to contract and the pressure source at the depth of about 13 km continues to expand.

This work is partly supported by MEXT under Earthquake and Volcano Hazards Observation and Research Program, and also supported by Earthquake Research Institute, The University of Tokyo under Joint Usage Program.

Characteristic properties of distal and proximal tephras in the Mikurajima Island, Izu Islands.

*Tomohiro Tano[1], Takehiko Suzuki[1,2], Makoto Kobayashi[2], Masanori Murata[2]

1. Faculty of Urban Environmental Sciences, Tokyo Metropolitan University, 2. Research Center for Volcanic Hazards and Their Mitigation, Tokyo Metropolitan University

Mikurajima of the Izu Islands is the stratovolcano island and located at 200 km south of Tokyo. The latest volcanic activity is about 6,300 years ago, there is no eruption activities in history. Mikurajima volcano is characterized by high occurrence frequency of andesite in volcanic front on the Izu arc(Isshiki,1980). Study on tephras distributed in the Mikurajima volcano has been reported by Sugihara & Shimada(1999),and Sekiguchi et al.(2001).They reported 6 tephra in Mikurajima island.(From the top Kozushima Tenzyosan:A.D.838,Iz-Kt,latest eruption of Mikurajima volcano:Mk-3,Kikai-Akahoya:7.3ka(Machida & Arai,2003),red scoria originated Mikurajima:Mk-2,rhyolithic tephra with unknown source:Mk-G, and fall pumice Mikurajima volcano tephra:Mk-1).The latest tephra of Mikurajima volcano:Mk-3,erupted from the lava dome in the southeastern in part of the islands(Sugihara & Shimada,1999).However, comparison/identification is insufficient of tephra compared to Iz-Kt. So it is necessary to compare and examine the Niijima Mukaiyama tephra(A.D.886,Iz-Mk).
They are rhyolithic tephra and indicated SiO2=77-79 wt.%. They erupted same age and constituent minerals and the refractive index of volcanic glasses are similar. So difficult to identify in distal place. Recently both can be distinguished by content of K2O in volcanic glasses. Iz-Kt indicated high K2O content compared with Iz-Mk. Both tephras are important indicator tephra widely distributed in the Izu islands. So it is important to clarify Iz-Kt distribution on Mikurajima.
In this research, we report on the tephras confirmed in Mikurajima. We found 18 tephras on Mikurajima island, and 4 tephras are confirmed(Iz-Kt,Mk-1,2,3).
1)The tephra confirmed Iz-Kt in previous study, we performed refractive index measurement by RIMS2000 and principal component analysis by SEM-EDS for volcanic grasses. This tephra present cryptotephra in topsoil. This glasses is pumice type and reflective index indicated n=1.496-497.Principal component:SiO2=77.0-78.5 wt.%,Al2O3=12.5-13.0 wt.%,FeO=0.5-1.3 wt.%,CaO=0.2-1.7 wt.%,K2O=2.7-3.9 wt.% and Na2O=3.6-4.6 wt.%.Iz-Kt and Iz-Mk confirmed on the Izu islands,they shows 3.8 wt% and 3.5 wt.% K2O content, respectively. So this tephra confirmed Iz-Kt.
2)For the latest tephra on Mikurajima volcano Mk-3,it is bad foaming yellow pumice between black volcanic sand.Maximum particle size of pumice is 10cm and maximum layer thickness is over 200cm.The lithophasies of MK-3 shows Prinian eruption.However,the detail of Mk-3 are unknown and under consideration.We performed principal component analysis as well.As a result,SiO2=62.3-70.7 wt.%,Al2O3=14.8-21.0 wt.%,FeO=2.2-3.8 wt.%,CaO=4.1-7.5 wt.%,K2O=0.3-0.9 wt.%,Na2O=3.8-4.4 wt.%.The values indicate andesite-dacite.
As a future work,to find and confirmed indicator tephra originated another volcano (like Iz-Kt and Mk-G).By comparing and identifying indicator tephra, I believe that we provide new distribute axis and age axis for history of eruption history in Mikurajima and tephra in the Izu Islands.And it is important to grasp detail of Mk-3 which is the latest eruption of Mikurajima volcano in order to grasp the volcanic activity of Mikurajima.

Pseudo thermal anomalies in the shortwave infrared bands of the Himawari-8 AHI and their correction for volcano thermal observation

*Takayuki Kaneko[1], ATSUSHI YASUDA[1], Yoshizaki Yoshito[2], Takasaki Kenji[3], Yoshiaki HONDA[4]

1. Earthquake Research Institute, University of Tokyo, 2. Meteorological Satellite Center, Japan Meteorological Agency, 3. Japan Fisheries Research and Education Agency, 4. Center for Environmental Remote Sensing, Chiba University

Volcanic eruptions bring high-temperature gas or magma to the surface. Therefore, thermal observations of volcanic eruptions can be used to investigate the timeline of eruptive sequences. Eruptive activity includes processes that can change over short periods of time, which is sometimes related to the eruptive mode or the timing of its transitions. If we could observe short-term eruptive processes by detecting thermal changes, this would be beneficial for analyzing the eruptive sequence of volcanoes. Himawari-8 is a meteorological geostationary satellite operating above the equator at a longitude of 140.7 deg E and carrying a newly developed sensor, the Advanced Himawari Imager (AHI). With its improved performance, the Himawari-8 AHI enables the collection of high-frequency thermal observations that had never been obtained before. However, while observing volcanoes with the AHI, we noticed a frequent thermal anomaly in the nighttime 1.6-um and 2.3-um images. Because this anomaly occurred regardless of volcanic activity, it was considered to be a pseudo thermal anomaly. In-depth examination of the AHI observation data for several inactive volcanoes showed that the pseudo thermal anomaly was often seen around the vernal and autumn eclipse periods, and its in?uence persisted for about 6 months of each year. Further, daily variation of the anomaly peaked when it was midnight in the areas around 140 deg E. At this time and position, the AHI was facing the sun, suggesting that the anomaly was caused by stray light. We devised a correction method by assuming that the observed thermal radiance in a pixel consists of components from the radiating volcanic ground surface and stray light contamination. The latter can be estimated using values from nearby inactive pixels. Thus, the component from the radiating volcanic ground surface can be obtained by subtracting the estimated stray light from the observed thermal radiance. We evaluated the validity of this method using data from the 2017 Nishinoshima eruption and found that it satisfactorily removed the stray light component. An adoption of this correction allowed us to use all nighttime 1.6-um and 2.3-um images obtained by the AHI, half of which were formerly unusable due to the degradation caused by stray light.

Shallow earthquakes in Unzen Volcano inferred from dense seismic observation and resistivity structure

*Hashimoto Tasuku[1], Koki Aizawa[2], Takeshi Matsushima[2], Hiroshi Shimizu[2], Yuto Hayashida[1], Yuhei Yuasa[1], Kaori Tsukamoto[1], Yuto Yamamoto[3], Kanta Miyano[3], Megumi Kamizono[1], Satoshi Matsumoto[2]

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University, 2. Institute of Seismology and Volcanology, Faculty of Science, Kyushu University, 3. Department of Earth and Planetary Sciences, School of Science, Kyushu University

Unzen volcano is a stratovolcano located in central part of the Shimabara peninsula of Kyushu Island, Japan. During the eruption periods 1991-1995, the seismicity was vigorous at shallow level beneath the Heisein-Shinzan lava dome (Umakoshi et al., 2001), then the number of shallow earthquakes decreased significantly after the eruptions. However, since 2010, the number of shallow earthquakes have been increasing steadily beneath Mt. Fugen and Heiseishinzan lava dome (Japan Metrological Agency (JMA)). The most of the hypocenters were estimated 1 to 2 km below sea level, while importantly, several earthquakes were located above sea level since February 2017. The P-wave arrivals of the earthquakes above sea level show the downward motion at all stations of JMA, MLIT, and Kyushu university. The coda, which shows relatively longer period oscillation, continues approximately 20 to 30 seconds. According to JMA, this type of shallowest earthquakes has occurred 5 times in 2018. Mildon et al. (2016) reported the similar non-DC earthquakes at Krafla volcano, Iceland, and suggested closing clacks model to explain the observation.

In order to explore the shallow earthquake activity beneath Unzen volcano, we established (1) 12 seismic stations around Mt. Fugen and Heisei-Shinzan lava dome in August, 2018. In addition, (2) broad-band magnetotelluric (MT) observation was conducted in October and November, 2018 to estimate subsurface resistivity structure. We recorded telluric fields at 12 sites around Mt. Fugen and Heisei-Shinzen lava dome, and recorded MT fields at two sites at the mid flank of the Unzen volcano. The main purpose of this study is to investigate the relationship between the shallow earthquakes and volcanic fluids beneath Unzen volcano. In particular, the locations and initial motions of the shallowest earthquakes are investigated. We will present the preliminary analysis of the shallow earthquakes obtained from the dense seismic records, and the preliminary resistivity structure.

Characteristics of shallow volcanic earthquakes beneath the summit of Unzen Volcano

*Kanta Miyano[1], Hiroshi Shimizu[2], Takeshi Matsushima[2], Satoshi Matsumoto[2], Koki Aizawa[2], Hashimoto Tasuku[3], Yuto Hayashida[3], Yuhei Yuasa[3]

1. Department of Earth and Planetary Sciences, School of Science, Kyushu University, 2. Institute of Seismology and Volcanology, Faculty of Science, Kyushu University, 3. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University

Unzen Volcano is located in the central part of the Shimabara peninsula, western Kyushu, Japan. The last eruption took place in 1990-1995, and a lava dome complex was formed during the eruption. High level seismicity was observed before and during the eruption. In particular, isolated tremor occurred in the volcanic edifice above sea level preceding the lava dome emergence (Shimizu et al., 1992). Predominant frequencies of the isolated tremor’ s waveforms were comparatively low (2 - 4 Hz) and the duration was long (30 - 180 s). Moreover, extremely-shallow earthquakes occurred beneath the growing lava dome. Unzen Volcano has been in dormancy since the end of the 1990-1995 eruption. However, shallow volcanic earthquakes have been observed below the summit since 2010, and the hypocenters are determined by Japan Meteorological Agency (JMA) and Institute of Seismology and Volcanology, Kyushu University (SEVO). In order to reveal the generation mechanism of these earthquakes, we investigated the characteristics of the hypocenters and wave forms.

First, we relocated the hypocenters of these earthquakes from Jan. 1 to Sep. 7 2018. The relocated hypocenters are distributed beneath the lava dome and Mt. Fugen, and they are classified into 3 groups. Focal depths of Group 2 and 3 are located 1km and 2km below sea level under Mt. Fugen, while Group 1 (three earthquakes in this period) locates above sea level beneath the lava dome. The first motions of P-waves for Group 1 are all “down” in this study, and the duration times are longer than those of Group 2 and 3.

Next, we calculated particle motions of these earthquakes using relocated hypocenters. The result indicates that the earthquakes of Group 2 and 3 have clear P and S phases, which are similar to tectonic earthquakes. On the other hand, no obvious S phase is recognized in the seismograms of Group 1.

Spectral analysis shows that the seismograms of Group 1 are lacking in high frequency components and the low frequency (2 - 5 Hz) is dominant compared with Group 2 and 3.

We will discuss candidates for the source mechanism of these earthquakes based on the results of wave form analyses.

Pyroclastic deposits and the stratigraphy on the outcrop to north east from Mt.Unzen

*Daisuke Nagai[1]

1. Mt.Unzen disaster memorial hall

Pyroclastic flows occurred at many times during formation of lava dome on the Heisei eruption of Mt.Unzen. There were some studies of pyroclastic flows on Mt. Unzen (Kobayashi and Kato, 1985). After the Heisei erupyion many studies reported about it (Kobayashi and Nakada, 1991, Watanabe and Hoshizumi, 1995). It is important about understanding the characteristics of the volcano from the past activities. In this study, the pyroclastic deposits and the stratigraphy 150ka on Mt.Unzen be reported.

Relative gravity changes in Aso Volcano (Kumamoto Prefecture) observed from 2015 to 2018

*Yusuke Miyauchi[1], Takahito Kazama[1], Yoichi Fukuda[1], Shin Yoshikawa[2], Takahiro Ohkura[2], Jun Nishijima[3], Yasuhiro Fujimitsu[3]

1. Graduate School of Science, Kyoto University, 2. Aso Volcanological Laboratory, Kyoto University, 3. Graduate School of Engineering, Kyushu University

Gravity measurement is one of the most effective methods to understand mass variations due to volcanism. In Aso Volcano, Kumamoto Prefecture, spatiotemporal gravity variations have been monitored by repeated relative gravity measurements every several years since 1964 (Yoshikawa et al., 2009). Gravity data was frequently collected 3-4 times every year during the active period of Aso Volcano from 2011 to 2016 and revealed spatiotemporal variations in hydrothermal mass under the volcano (Sofyan et al., 2016). However, any gravity data has not been collected after March 2016 due to Kumamoto Earthquake which occurred in April 2016. Since the volcanism became quieter after a phreatic explosion was observed in October 2016, a series of volcanic activities including the quiet period should be discussed in terms of mass variations to predict future volcanic activities. In order to monitor gravity changes in Aso Volcano after the volcanically active period, we repeated relative gravity measurements in May, August and November 2017, and in March, May, August and November 2018. We measured relative gravity values at gravity points around Aso Volcano using CG5 relative gravimeters owned by Kyushu University and Aso Volcanological Laboratory (CG5-KYU and CG5-AVL, respectively) and a LaCoste relative gravimeter G680 owned by Graduate School of Science, Kyoto University (LC-G680). We also collected continuous gravity data using CG5-AVL at the AVL station even when it was not used for the campaign gravity measurements, in order to understand the long-term instrumental drift. A gravity value relative to AVL was obtained for each point and survey, by correcting the effects of instrumental height, tide, instrumental drift, and scaling factor. The spatiotemporal absolute gravity data was then calculated, using the absolute gravity values measured at reference stations. We finally estimated the spatial distributions of the absolute gravity change around Aso Volcano before and after Kumamoto Earthquake. We found that the absolute gravity increased at the gravity points around the Aso crater. Since this absolute gravity change includes the effect of crustal deformation due to Kumamoto Earthquake, we subtracted the effect from the absolute gravity values using the quasi-vertical deformation data derived from the InSAR analyses (Geospatial Information Authority of Japan) and the typical gravity gradient value of -0.2 mGal/m. We found that the residual of the absolute gravity change still increases by up to 0.1 mGal at the areas of Kusa-senri and the Naka-dake crater, which implies mass accumulation under these areas. In the future, we will model time variations of the volcanic mass distributions in the volcano and compare them with the spherical pressure source proposed by the leveling data (Sudo et al., 2016). In addition, the gravity data should be repeatedly obtained and reprocessed more accurately, by considering the spatial variation of the gravity gradient value and correcting the effect of ground deformation using the continuous GNSS data.

In Aso volcano, leveling survey has been conducted since 1937 by Kyoto University. As a result of these surveys, subsidence in Kusasenri about 3km west-southwest of Naka-dake crater has been observed. And this subsidence was considered to be caused by a contraction source located at about 3km west of Naka-dake crater with a depth of 4 to 6 km (Sudo et al. 2006). A seismic tomography study showed a low velocity zone of a 2 to 3 km diameter located at a depth of 6km in Kusasenri (Sudo and Kong, 2001), almost in accordance with the position of contraction source. Therefore, this low velocity zone is considered to correspond to a magma chamber.
We conducted a first-order leveling survey at Aso volcano during the period from Sep.30 to Oct.6 2018, for the first time since 2012 and after the 2016 Kumamoto Earthquake. As a result, mean square errors of the conducted survey were ranging from ±0.18 to ±0.21 mm/km.
From the obtained survey data, we calculated the relative height of each bench mark referred to a bench mark (960701A) which corresponds to GEONET 960701 GNSS station, located at the south-western foot of central cones of Aso volcano. We also calculated the height difference of 960701A between September 2012 and September 2018, using F3 solutions of GEONET, resulting in the vertical displacements of the benchmarks during the period from September 2012 to September 2018.
It was found that the obtained displacements show ground accordance with 2.5-D surface deformation of the 2016 Kumamoto earthquake detected by SAR interferometry. Therefore, we can conclude that the vertical displacements in Aso volcano detected by leveling survey are attributed to the surface deformation during the 2018 Kumamoto Earthquake.

Title

Magma evolution during the Aso-3 caldera-forming eruption cycle deduced from the chemistry of plagioclase phenocrysts

Author

Yuki Matsukida, Tsuyoshi Iizuka, Takayuki Ushikubo, Kenji Shimizu, Nobuo Geshi,

Isoji Miyagi, Morihisa Hamada

Introduction

Caldera-forming eruptions are the most destructive type of volcanic activity and exert a great influence on the Earth’ s surface. Therefore, the underlying magmatic mechanism leading to caldera-forming eruptions is of fundamental importance in volcanology. The Aso volcano is the largest (18×25 km in diameter) caldera in the southwestern Japan Island Arc and formed through four large eruption cycles. In this study, we have investigated the evolution of magmas that erupted during the second youngest cycle among the four cycles, the Aso-3 cycle at 123 ka. It ejected >150 km^3 of pyroclasts that are divided into the following four units in stratigraphic ascending order: 3W, a plinian pumice fall deposit; 3A, a pumice flow deposit containing dominantly aphyric pumice and glassy ash; 3B, a scoria flow deposit characterized by abundant aphyric scoria; and 3C, a scoria flow deposit consisting mainly of porphyritic scoria and glassy ash matrix.

On the basis of major and trace element compositions and Sr-Nd-Pb isotope ratios of whole rocks as well as phenocrysts, Kaneko et al. (2015) argued that the pre-eruptive magma chamber was chemically stratified from a mafic lower part to a felsic upper part. The previous study further estimated water contents in the melts using the hygrometer based on plagioclase-melt partitioning of anorthite-albite components (Lange et al., 2009), but the estimates have large uncertainty. Here we determined hydrogen contents of plagioclase phenocrysts. By combining the hydrogen contents with major and trace element compositions of the plagioclase phenocrysts, this study aims to better understand pre-eruptive magma evolution and water behavior of the Aso-3 cycle.

Methods

Plagioclase as well as pyroxene and oxide mineral phenocrysts were separated from pumices of 3W, an obsidian clast of 3A, a welded clast of 3B, and a pumice clast of 3C. Major and trace elements in phenocrysts were quantified by electron probe microanalyzer (EPMA) and laser ablation-inductively

©2019. Japan Geoscience Union. All Right Reserved.

coupled plasma-mass spectrometry (LA-ICP-MS), respectively. In LA-ICP-MS analysis, Ca contents measured by EPMA were used for internal standard normalization. OH contents in plagioclase phenocrysts were determined by secondary ion mass spectrometry (SIMS).

Results

Anorthite contents (#An) of plagioclase phenocrysts are variable even in individual units, but show the systematic increase in ascending order, consistent with the results of Kaneko et al. (2015). REE patterns of plagioclase and pyroxene show positive and negative Eu anomalies, respectively. Plagioclase Ce content degreases as #An increases (Figure 1). On the other hand, OH contents in plagioclase phenocrysts are significantly higher in 3W (~250 ppm) as compared to the others (<50 ppm) (Figure 2).

Discussion

OH contents in a plagioclase phenocryst of 3W are significantly higher than those of 3A-C, nevertheless Ce contents of plagioclase are not significantly different between 3W and 3A. Considering that the partition coefficients of Ce between anhydrous major minerals and melt are similar to those of OH, this finding suggests that H_2O was lost from the melt through gas exsolution or fractional crystallization of hydrous minerals. Alternatively, given the fast diffusion of hydrogen relative to Ce in plagioclase, it may be attributed to secondary loss of hydrogen from plagioclase phenocrysts of 3A-C during welding processes. From the observation of thin sections of 3W and 3A, however, microlite was rarely observed, suggesting that the secondary thermal effects would be restricted for both 3W and 3A. Furthermore, little hydrous phenocrysts have been observed from ejecta of the Aso-3 cycle. Therefore, the results of this study suggest that gas exsolution and degassing occurred between the eruptions of 3W and 3A.

Relationship between duration of eruption tremor and eruption volume

*Azusa Mori[1], Hiroyuki Kumagai[1]

1. Nagoya University Environmental Studies

We studied the high-frequency seismic signals of eruption tremors during recent eruptions at various volcanoes and quantified their seismic source amplitudes (A_s) and cumulative source amplitudes (I_s) in the 5–10 Hz based on the assumption of isotropic *S*-wave radiation. A_s and I_s correspond to the maximum and the cumulative value of amplitudes at the source during eruption tremor. We previously found that the power law relations between A_s and I_s holds for eruption tremors. We also found the proportional relation between eruption rate and A_s for eruption tremors by comparing seismic and geodetic data during sub-Plinian eruptions at Kirishima. In this study, we further investigated time variations of eruption tremors and found the scaling relation between duration of eruption tremor and eruption volume.

We calculated the envelope width (p) using the estimated values of A_s and I_s and investigated the relation between p and I_s. p is defined as I_s/A_s and can be used as a parameter of duration (T) of a seismic envelope waveform (Kumagai et al., JGR, 2018). We found that p is proportional to 0.4 power of I_s. We also found that envelope waveforms of eruption tremors in 5–10 Hz have the following features; the amplitudes of envelope waveforms gradually increase, remain roughly constant during a certain period, and gradually decrease to the noise level. Moreover, p tends to increase with A_s. These envelope waveforms can be approximated as trapezoids, where A_s and T correspond to their height and lower base, respectively. We found that the ratios of upper to lower bases for these envelope waveforms are roughly constant. In this case, the proportionality between p and T holds. Based on the relation between eruption rate and A_s, eruption volume (V) is proportional to I_s. Therefore, the relation between p and I_s as shown above indicates that T is proportional to 0.4 power of V. We found that this proportional relation is consistent with the estimates of T and V for various Plinian eruptions compiled by Mastin et al. (JVGR, 2009). This indicates that the scaling relation between duration of eruption tremor and eruption volume in Plinian eruptions holds over a wide range of eruption size.

Crustal deformation accompanied with the eruption of Shinmoe-dake in early March 2018

*Tsuyoshi Watanabe[1], Takashi Yokota[1], Susumu Kurahashi[1], Kenta Enomoto[1]

1. Aichi Institute of Technology

Shinmoe-dake is a part of Kirishima volcano group composed of 20 Quaternary volcanoes located in southern Kyushu, Japan, erupted on 19 January 2011. This eruption began with a phreatomagmatic event including atmospheric vibration and eventually developed to subplinian eruptions within a week. From GNSS data, position and volume change of the magma chamber were estimated to be about 5 km to the northwest of the top of Shinmoe-dake at a depth of 8-9 km and 1.3×10^7 m^3. Shinmoe-dake erupted on 11 October 2017 after an interval of six years, however, this eruption ended in a week. While the extension of baseline length between the sites across Mt. Kirishima has been detected by GNSS observation since July 2017, indicating the possibility of magma accumulation. Eventually, the extension of baseline length led to eruption on 1 March 2018. In this study, in order to clarify the mechanism of the volcanic eruption, we investigated the crustal deformation accompanied with a series of volcanic activities occurred in early March 2018 at Shinmoe-dake by using GNSS data, then estimated the position of the magma chamber.

For the study, GEONET F3 solutions obtained by GNSS observation sites located mainly in the Kyushu district from 1 January 2013 to 25 March 2018 were used. Firstly, common mode bias was removed from time series of GEONET F3 solutions according to the method of Wdowinski et al. (1997). Secondly, visco-elastic deformation due to the 2016 Kumamoto earthquake was corrected by using a code of Fukahata and Matsu’ura (2005, 2006). In this time, we used the co-seismic fault model of Geospatial Information Authority of Japan (GSI, 2016) and calculated the visco-elastic deformation, where the calculation was conducted on the condition that an elastic material with thickness of 25 km lies on a Maxwell visco-elastic half-space with viscosity of 2×10^{18} Pas. Thirdly, to estimate elastic deformation due to subduction of the Philippine Sea plate (PH), we reproduced the upper surface of the PH by 170 rectangular faults based on the result of Hirose et al. (2008) and estimated coupling ratio. The Green’s functions of rectangular faults were calculated by the formula of Okada (1985). Using horizontal and vertical velocities of GEONET 150 sites between 1 January 2013 and 31 March 2016, we conducted a back-slip inversion analysis with smoothing constraint of coupling ratio among the adjacent faults. Assuming the interplate coupling obtained by the analysis continues after July 2017, we corrected the effect of the plate subduction from original data. After completing three processes above mentioned, finally, the positions of the magma chambers were estimated in two periods: inflation phase (1 July 2017–28 February 2018) and deflation phase (14 February 2018–25 March 2018) by using the Mogi’s model. We selected 7 GEONET sites located around Shinmoe-dake and estimated the positions of Mogi sources (longitude, latitude, and depth) corresponding to the two phases by performing a grid search in the ranges of 130.6-131.1˚every 0.001˚for longitude, 31.7-32.1˚every 0.001˚for latitude, and 4-15 km every 0.1 km for depth. The volume change of the Mogi sources were assumed to be 1.6×10^7 m^3 in the inflation phase and -0.7×10^7 m^3 in the deflation phase, according to the results of Japan Meteorological Agency (JMA). The result showed that the positions of the magma sources were estimated not to be just under the top of Shinmoe-dake but to be about 6-7 km to the northwest of it at a depth of 7-12 km. Although our result is generally consistent with that of JMA, the depth of the magma sources in the inflation phase was estimated to be approximately 4 km deep part. For the next step, we investigate the effects of topography and heterogeneous structure on crustal deformation.

At Iwo-yama that active volcano located in Ebino kogen volcanic area of Kirishima Volcanoes, fumarolic activity has risen again from December 2015 after dozen year's silence and suddenly increasing of seismicity (50 times and more a day) and volcanic tremors was observed several times. And phreatic eruption occurred in April 2018. Morita (2018) inferred inflation spherical pressure source as Mogi source from leveling survey between June 2015 and December 2015. The source's depth is about 700m beneath Iwo-yama and the source was considered that correspond with bottom of conductive layer inferred clay layer from MT survey (Tsukamoto et al., 2018). But, leveling can detect vertical displacement only and the inferred source is not considered horizontal displacement. So, we will improve pressure source inferred from leveling adding detect horizontal displacement from GNSS observation in this study.

As result of the observation, radial crustal deformation was detected several months before the occurrence of the phreastic eruption and after the eruption occurred. Estimating those displacement using an elevation-modified Mogi model, volume increse of the pressure source located at 700m depth below Iwo-yama was estimated. The depth of this pressure source coincided with the depth of the clay layer and it was found that the pressure source had expanded under the clay layer before the eruption occurred. But, for the GNSS observation point of the edifice before eruption, displacement which can’t be explained by the pressure source under the clay layer has been detected. This displacement is thought to be due to the rise of hot water to the shallow part as the pressure source under the clay layer expands.

We conducted GNSS continuous observation point around Iwo-yama established by Japan Meteorological Agency to verify the pressure source under the clay layer. As a result, displacements which can’t be explained by this model detected at these observation points. Using the GNSS continuous observation points throughout Kirishima, we estimated the pressure source of this displacement. Then, we could estimate the spherical pressure source located 7 km deep in the vicinity of Ebino-dake. This model is consistent with the source of crustal deformation before and after the eruption of Shinmoe-dake volcano in 2011 estimated by Nakao et al. (2018). Therefore, those displacement is thought to be due to volume change of magma chamber of Shinmoe-dake. In conclusion, the crustal deformation around Iwo-yama is due to these three sources, spherical pressure source under clay layer, displacement due to hot water rising to shallow part of Iwo-yama, magma chamber of Shinmoe-dake.

Regional vertical deformation around Aira caldera from GNSS data

*Kazuho Nakai[1], Masato Iguchi[2], Takahiro Ohkura[3]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, 2. Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University, 3. Aso Volcanological Laboratory, Institute for Geothermal Sciences, Graduate School of Science, Kyoto University

We investigated regional ground deformation around Aira caldera by analyzing vertical displacement observed by GNSS.

We used daily coordinate data from F3 solutions of GEONET stations in Kyusyu for periods from 1998 to 1999 and 2015 to 2016 when the ground uplift rate was larger than 18 mm/yr at 960719 station (North of Sakurajima). In order to increase number of stations, we analyzed RINEX data around Aira caldera and Sakurajima observed by Kyoto University and obtained daily coordinate data calculated based on the coordinates of the F3 solution of the GEONET stations closest to each observation point by using RTKLIB Ver. 2.4.2. The vertical displacement rate was estimated by removing the coseismic or antenna change steps and the annual and semiannual components. The ground deformation close to Kirishima volcano was affected by the pressure source located about 9 km beneath the Karakuni-dake (Nakao et al. 2013). We removed these effects causing inflation of the pressure source.

The ground within a radius of 20 km from the center of Aira caldera was uplifted in the both periods. The amount of uplift near the center of Aira caldera is larger than that in distant region and the largest uplift of station (25 mm/yr in 1998-1999 and 20 mm/yr in 2015-2016) was obtained at northern part of Sakurajima. In contrast, the ground subsidence was detected at distances from 20 to 30 km away from the center of the caldera during the period in 1998-1999 and from 30 to 40 km during the period in 2015-2016. The amounts of subsidence were about 3 mm/yr in the both periods.

We applied a model of dual source of Mogi-type (Mogi, 1958) to the ground deformation. In the period of 1998-1999, an inflation source was obtained at a depth of 10 km and a deflation source at a depth of 14 km beneath the Aira caldera. The amounts of volume change were estimated at about $+1.8\times10^7$ m^3 and -1.5×10^7 m^3, respectively. Similarly, in the period of 2015-2016, an inflation source was obtained at a depth of 10 km and a deflation source at a depth of 30 km. The amounts of volume change were estimated at about $+1.5\times10^7$ m^3 and -3.3×10^7 m^3, respectively. The order of volume change of the inflation source is almost same as the deflation source in the both periods.

The spatial distribution of the vertical displacement rate can be explained by the shallow inflation source and the deep deflation source. The shallow inflation source coincide with A-source beneath the Aira caldera (Hotta et al. 2016) corresponding to magma reservoir. Considering similarity of the volume changes, magma seems to move from to the shallow magma reservoir around 10 km deep from a deeper part.

Vertical ground deformation in Sakurajima volcano measured by precise leveling survey (during Nov. 2017 - Nov. 2018)

*Keigo Yamamoto[1], Takeshi Matsushima[2], Shin Yoshikawa[3], Hiroyuki Inoue[3], Tadaomi Sonoda[1], Kosei Takishita[1], Kazuho Nakai[1], Masaki Uchida[3], Ryo Oyanagi[3], Yoshinosuke Kamiya[2], Takahiro Ohkura[3]

We conducted the precise leveling survey in Sakurajima volcano, southwest Japan in November 2018, in order to evaluate the vertical ground deformation associated with the recent eruptive activity of the volcano. The leveling routes measured in this survey are about 21 km long in total, including Sakurajima western flank route and Sakurajima northern flank route. These leveling routes were measured during the period from November 12 to 29. As a result of the preparatory calibrations and careful measurements, mean square errors of the conducted survey were achieved with a good accuracy ranging from ±0.18 to ± 0.25 mm/km.
From the measured data, we calculated the relative height of each benchmark referring to the reference benchmark BM.S.17 which is located at the western coast of Sakurajima. The calculated relative heights of the benchmarks were then compared with those of the previous survey conducted in November 2017 (Yamamoto et al., 2018), resulting in the relative vertical displacements of the benchmarks during the period from November 2017 to November 2018.
The resultant displacements indicate the ground subsidence (-6.2 mm at maximum) at benchmarks around the central part of Sakurajima. The ground subsidence is also detected at benchmarks along Sakurajima northern flank route, suggesting that the inflation of the magma reservoir beneath Aira caldera was not remarkable during the period between November 2017 and November 2018. From the preliminary analysis based on a spherical source model (Mogi, 1958), the deflation source is located beneath Minamidake crater. The results indicate that the pressure decrease is suggested at the magma reservoir beneath Minamidake caused by the eruptive magma ejection.

Spatiotemporal gravity variations from the 1990s in Sakurajima Volcano, revealed by repeated relative gravity measurements

*Ryo Oyanagi[1], Takahito Kazama[1], Keigo Yamamoto[2], Hiromitsu Oshima[3], Kazumi Okada[3], Tadaomi Sonoda[2], Masato Iguchi[2]

1. Graduate School of Science, Kyoto University, 2. DPRI, Kyoto University, 3. ISV, Hokkaido University

Gravity observation is one of the most effective methods to detect spatiotemporal mass variations in volcanoes. In and around Sakurajima Volcano, relative gravity measurements were first started in 1975 and have been repeated 20 times until 2018. The long-term gravity variations from 1975 to 1992 was modeled by Kazama et al. (2018), to understand volcanic mass variations associated with active eruptions at the Minami-dake summit during the same period. They showed that the relative gravity increase in Sakurajima cannot be fully explained by two spherical deflation sources, which were expected from the leveling data. Instead, they found that the gravity increase can be modeled by an additional point mass of 6.0 E+10 kg/yr at 5 km depth under the Kita-dake summit. However, Kazama et al. (2018) modeled the volcanic mass distributions only from 1975 to 1992, and mass distributions during the subsequent period from the late 1990s to the 2010s should be modeled as well to understand present mass accumulating processes and forecast future volcanic activities of Sakurajima Volcano.

We therefore analyzed the GPS and relative gravity data obtained from the late 1990s to the 2010s, to model the long-term pressure and mass sources under Sakurajima Volcano as follows. We first subtracted the effect of tectonic crustal deformation in the southern Kyushu Island from the horizontal displacement data of the GEONET F3 solution, using the method of Takayama and Yoshida (2007). We also reproduced the residual horizontal displacement data by a spherical pressure source of Mogi (1958), assuming the inflation of a magma reservoir located under Aira Caldera; in this calculation, several parameters about the location and volume change of the pressure source were determined by the grid search method so as to most reproduce the horizontal displacement data. The inflation source was calculated to be located at 9 km depth under the center of Aira caldera with the inflation rate of 5.5 E+6 m3/yr. However, this inflation source never agrees with the gravity increase observed in Sakurajima volcano after the late 1990s, because the source inflation and consequent ground uplift leads to the gravity decrease (Hagiwara, 1977).

After correcting the effect of the inflating pressure source, the observed gravity values were found to increase at rates of +7.49 and +1.61 microGal/yr at S110 (located at the summit of Sakurajima) and S16 (located at the western foot of Sakurajima), respectively. We thus calculated theoretical gravity variations in Sakurajima Volcano by assuming a point mass under the center of the volcano, so as to explain the observed gravity increase; in this calculation, the parameters about the depth and mass increase were determined with the trial-and-error method. The point mass was estimated to be located at 3.3 km depth below sea level with a mass increasing rate of 2.3 E+10 kg/yr. This result implies that the mass accumulation continues under Sakurajima Volcano even now, although the present accumulating rate reduced by less than half compared with that from the 1970s to the former 1990s. We will sophisticate the pressure/mass source models in the future, to reveal the mass redistribution processes associated with volcanic activities of Sakurajima Volcano.

Investigation into the crater of Sakurajima volcano during eruption using UAV

*Shunsuke Miura[1], Takumi Mochiduki[1], Kouji Fujita[1], Toshihiro Urayama[1], Hisashi Sasaki[1], Tatsuro Chiba[1]

1. Asia Air Survey Co.,Ltd

1. Intoroduction
Measuring the active crater topography can obtain important information on volcanologically and disaster prevention, but the flight over the crater is risky involved in the eruption and is dangerous. The Minamidake crater of Sakurajima has repeated vigorous eruptions over a long period of time, and the topography change is intense. The Minamidake crater has A crater and B crater, and on the east slope there is Showa crater. Ministry of Land, Infrastructure, Transport and Tourism has regularly conducted airborne laser surveying to clarify the geometry shape. However, airborne laser surveying has become difficult due to the activation of eruption activity. Especially it was difficult to measure the topography of Minamidake crater, west of the Showa crater. Therefore, in this study, in order to grasp detailed crater circumstances of Minamidake crater and Showa crater on Sakurajima, we tried near-field photographing by UAV and terrain measurement utilizing SfM / MVS.

2. Investigation of Showa crater and Minamidake crater of Sakurajima by UAV
The UAV used is Matrice 210 (manufactured by DJI), and the installed camera is ZENMUSE X4S (visible light) and ZENMUSE XT2 (thermal infrared). DJI's UAV has an altitude limit of 500 m above ground level from the takeoff and landing point as a safety measure. For this reason, the takeoff and landing site was the upper stream of the Amida River (around 600 m altitude) outside the entry restriction. The photographing by UAV was performed three times in total, about 15 minutes using the moving picture photographing method.In UAV photographing of visible light, we were able to confirm the state inside the Showa crater, which is unknown by the surveillance camera at the foot. On the other hand, inside the Minamidake crater, due to the influence of the plume, it was impossible to photograph clearly. In the thermal infrared photography, resolution as much as visible light could not be obtained, but we could confirm the movement of the plume inside the Minamidake crater. Moreover, in the thermal infrared, it was possible to capture a high resolution movie rather than photographing with a helicopter, and at Showa crater the stratification of the crater wall could also be confirmed.

3. Create 3D model and orthoimage
An image was cut out from the movie of the visible light that was shot, and an orthoimage of 0.5 m resolution of the Showa crater and a 3D model were made by SfM / MVS. Actually the Showa crater was almost stopped, except for some fumaroles, it was possible to clearly shoot the crater bottom. On the other hand, the Minamidake crater was greatly affected by the plume, a lot of clouds appeared above the crater, and the crater bottom was unknown. We are going to try SfM / MVS analysis using measurement results of thermal infrared with less influence of plume compared with visible light.

4. Conclusion
In order to eliminate the influence of the plume and to obtain a clearer image, it is thought that low-altitude flight to the crater's sky or inside the crater is necessary. Currently, since images are recorded on the SD card, collection after returning is a major premise, but in the future it is desirable to create models from images obtained by wireless communication.

[1] Primary Objective

Southern Kyushu is a typical island arc region: subduction of Philippine Sea plate under Kyushu off Hyuganada with high seismic activity, the Aira caldera with active volcanic activity, the extending Okinawa trough, and the East China Sea. Our project is aimed at clarifying the detailed velocity structure of the crust beneath southern Kyushu and recognizing interactions with crustal activities in these regions.
It is also concerned about the occurrence of large-scale eruptions at the Aira caldera larger than the 1914 Taisho eruption in Sakurajima volcano. Accordingly, we also intend to reveal the caldera structure of the Aira caldera in order to deepen the understanding of the present magma supply system beneath the Aira caldera.
This reports an outline of the second seismic exploration carried out in November 2018.

[2] Report of Seismic Exploration in 2018

For our purpose mentioned above, we carried out the first seismic exploration in November 2017, which consists of 9 shot points with charges of about 200 kg dynamite in the land area and 906 temporary seismic stations including 42 OBSs along about 165 km long profile running transversely across the Osumi Peninsula, the central part of the Aira caldera, the Satsuma Peninsula, the Koshiki Strait and the Koshiki Islands.
The second seismic exploration was carried out in November 2018. In this 2018 exploration, 872 temporary seismic stations were deployed along the 2017 seismic main profile. The equipment at each station is same as that in 2017. In addition, we widely deployed 49 seismic temporary stations with a 4.5 Hz three components seismometerand a portable data logger ”GSX” in Sakurajima volcano in order to estimate the 3-D velocity structure beneath the volcano.
In the 2018 exploration, artificial explosions by the seismic air-gun blasting system(6000 cubic inches) were applied at 50m or 100m intervals along the sea profiles (Profile-B, Profile-D, Profile-F, Profile-H). We successfully observed the seismic refraction and reflection signals generated from the air-gun in a distance range of more than 20 km. We also introduced 4 big vibrator vehicles in the land area, which vibrates continuously during about 4 hours at the fixed locations. In addition, we carried out the seismic reflection profiling with 5 km long profile in the northeastern area in Sakurajima volcano.

Flow and emplacement mechanism of Koya Ignimbrite

*Keiko Suzuki-Kamata[1], Reina NAKAOKA[1], Tomomi Yamane[2]

1. Kobe Ocean-Bottom Exploration Center , 2. Department of Planetology, Graduate School of Science, Kobe University

Koya ignimbrite sourced from Kikai caldera 7.3 ka and traveled across the sea to reach the adjacent islands and the mainland of south Kyushu 40-90 km distant. Proximal facies of Koya ignimbrite, called Takeshima pyroclastic-flow deposit, comprise two or more flow units with a maximum thickness of 30 m, but the distal deposits collectively called Koya ignimbrite are consist of one flow unit and are exclusively very thin. Lag Breccia of Koya ignimbrite is recognized as layer 2b of 5 m thick on Takeshima and layer 1 of 2 m thick on Satsuma-Iwo Jima.

Koya ignimbrite contains essential pumices and volcanic glasses, both exhibiting a bimodal compositional distribution, e.g., ~60 and ~70 wt.% SiO_2 (Fujihara and Suzuki-Kamata, 2013). In addition to the silicic component, reflecting contribution the mafic component increases upwards from the basal to middle level of the deposit, and this vertical variation likely indicates progressive aggradation of pyroclasts. Koya ignimbrite overlies the ground layer consisting of crystal and fine pumice 1~5cm thick, and segregation pipe is commonly recognized in the ignimbrite in distributed area. The pyroclastic-surge deposit showing cross lamination overlies the ignimbrite on south of Osumi Peninsula. The surge deposit is rich in the mafic component, and suggests that the surge is formed at the late stage of ignimbrite eruption.

Koya ignimbrite distributes from the shoreline to the highland 1900m above sea level in Yakushima. Koya ignimbrite shows different lithofacies depending on altitude, which is thick and massive deposit more than severeal meters thick at lower area, and thin less than 50cm and composed of layer 1 at the base at higher altitude of 1600m above sea level. Mafic component is contained from the base of Koya ignimbrite in the north-west area on Yakushima both the lower area and the higher area, but mafic component increases upwards from the basal to middle level of the deposit in south-west area of Yakusima as same as Kyushu, Kuchinoerabujima and Tanegashima. This suggests that the earlier Koya ignimbrite climbing up the mountain area flows back due to the gravity in the north-west area and deposited thick at the lower area.

While silicic component can be recognized throughout the ignimbrite, mafic component exist only at the upper level of it at Tanegashima. The early phase products of Koya ignimbrite eruption reached to Tanegashima because this vertical variation is equal to that of the ignimbrites on proximal area, Satsuma Peninsula and Osumi Peninsula (Fujihara and Suzuki-Kamata, 2013). Lower contents of mafic component from upper most level compared with that of Osumi Peninsula suggest that the flows which contain abundant in mafic component occured at the later phase of the ignimbrite eruption cannot reach to Tanegashima. This is conformable the fact that the ignimbrites on Osumi Peninsula are thicker than that of Tanegashima. Based on above, it is estimated that Koya ignimbrite lost a great many amount of pyroclasts in the sea during traveling across the sea and the Koya ignimbrite widely lies on the sea floor around Kikai caldera. Koya ignimbrite became the low aspect ratio ignimbrite after passing the sea area, and low density pyroclastic surge was formed in the mountain area reflecting the topography.

The existence of a landslide-like bathymetric feature is reported (Japan Coast Guard, 2007) to the south of Mt.Kaimon volcano that started eruption at the shallow sea area about 4400 years ago. We conducted the multichannel seismic reflection and bathymetric surveys in March and October 2018 using T/S 'Fukae-maru' to investigate how the landslide-like bathymetric feature was formed and where the source was if it was formed by a landslide. The bathymetric data (Figure) are used to make hill-shade map, slope map and terrain ruggedness index map, which characterize bathymetric features. We acquired seismic reflection data sets along eleven survey lines across the landslide-like bathymetric feature (green lines in Figure), which allows us to provide eleven seismic reflection profiles. The seismic reflection profiles indicate that there is a clear reflection boundary, which divide into two areas: The lower layers below the reflection boundary observed at large area and were not affected by stress. Many reverse faults and folds in the upper layers above the reflection boundary with its thickness of about 70m, which were formed by horizontally compressional stress. The analysis of the reflection profiles and the bathymetric lead to, divide the landslide-like bathymetric feature area into four areas. We name each area North-Eastern, South-Eastern, Central and Western part, which shows characteristic features as bellows:

・North-Eastern part; this area is large rugged sea bottom and slope. In the reflection profile, the boundary of upper and lower layers is not so clear. Deeper layers are not observed.

・South-Eastern part; this part is little rugged sea bottom and slope. In the reflection profile, there are some reverse faults and the fault strikes are East-West direction. Stratified structures are also found in spots.

・Central part; this part is the least rugged sea bottom and slope of four area. In the reflection profile, there are a lot of reverse faults. The fault strikes are always North-northwest-South-southeast direction. Stratified structures are found at eastern and western edge.

・Western part; this part is not as large as North-Eastern part, but large rugged sea bottom and slope. In the reflection profile, there are many (but less than Central part) reverse faults, and the fault strikes are North-South.

These characteristic features duggest that an event sweeping the ocean bottom was occurred at northern North-Eastern part, and directions the sweeping landslide are moving in south and west-southwest. It is because deeper layers are effected by collapse at North-eastern part, compressional stress is estimated by faults and folds (direction at the eastern part is North-South and at the central-western part is East-West) and bathymetric feature is more rugged at the eastern part.

Occurrence and distribution of pyroclastic fall deposits of Kuchinoerabujima volcano 2018-2019 eruption

*Masashi NAGAI[1], Shojiro Nakagawa[2], Yu Iriyama[1], Takahiro Miwa[1], Toshikazu Tanada[1], Hideki Ueda[1], Setsuya Nakada[1]

1. Volcano Research Department, National Research Institute for Earth Science and Disaster Resilience, 2. Yakushima Chigaku Club

At Kuchierabujima volcano, eruption began intermittently from October 21, 2018. Relatively large eruptions such as Yakushima and Tanegashima Islands adjacent to the east side of Kuchinoerabujima Island are observed on December 18 and 28, 2018, January 17 and 29, 2019. The ash fall distribution survey was conducted on three eruptions excluding the December 28 eruption where the ash fall axis was in the southeast direction and ash fall on the land was small. In Kuchinoerabujima Island, we conducted an investigation in early February, 2019. We also used information provided by Japan Meteorological Agency Kuchinoerabujima Volcano Disaster Prevention Liaison Office and interviews with local residents.

The Ash fall deposits on Yakushima and Tanegashima Islands are all light gray to reddish light gray colored sandy to silty volcanic ash layers, the component are mainly composed of lithic fragments and hydrothermal altered fragments and small amount of fresh vitreous rock fragments. At the eruption of January 17, 2019 where the largest one during a series of eruptions, on the ash fall axis extending to the east, 400 g/m^2 of ash deposited in the northwestern part of Yakushima Island, 100 g/m^2 in the northeast part, and 20 g/m^2 in the southern tip part of Tanegashima Island. Part of the deposit had the characteristics that ash particles fell as mud rain. In the northern part of Yakushima Island, fine lapilli was also included, and the maximum particle diameter tended to be larger on the north side than the ash fall axis. The deviation between the axis of ash fall axis and the axis of maximum particle diameter distribution can be explained by the difference in wind direction and wind speed at altitude. In Kuchinoerabujima Island, there was an ash fall axis from the summit crater to the southeast direction as total air fall deposit of the series of eruptions, and a deposit amount of about 12 kg/m^2 was confirmed at a distance of about 1.5 km. The layer corresponding to the eruption on January 17 is coarse deposit contains lapilli with long diameter of about 5 cm or more.

The amounts of air fall deposits were obtained by the method of Fierstein and Nathenson (1992) using average deposition density of 1000 kg/m^3. Based on the distribution data of distant deposits such as Yakushima Island, they are estimated to be ca.29,000 tons on the December 18, 2018 eruption, ca.62,000 tons for the January 17, 2019 eruption, and ca.14,000 tons for the January 29, 2019 eruption. These are smaller than the amount of air fall deposit of May 29, 2015 eruption estimated in the same method, ca.120,000 tons. When adding the depositional mass data of Kuchinoerabujima which is the proximal area to these distal data, the total of air fall deposits from December 2018 to January 2019 is estimated to be about 130,000 tons.

Ground Deformation around Domestic Active Volcanoes detected by InSAR of ALOS-2/PALSAR-2

*Takafumi Taniguchi[1], Isao Kageyama[1], Okuyama Satoshi[2], Shinobu Ando[2]

1. Japan Meteorological Agency, 2. Meteorological Research Institute

Monitoring of volcanic activity by observing ground deformation is one of useful means to understand signs of eruption such as accumulation and migration of magma. Japan Meteorological Agency (JMA) monitors volcanic activity by tiltmeter, light wave distance measuring equipment and GNSS around volcanoes. However, there are some problems only using these ground-based observation methods. Observable ground deformation is restricted to point information such as the tilt at the observation point and relative position between observation points. Also, it is difficult to install and maintain observation device at an isolated island such as Nishinoshima volcano. It is important to grasp surface ground deformation around volcanoes using not only ground-based observation but also satellite data like SAR (Synthetic Aperture Rader). In this presentation, we mainly report on the analysis results of the long-term pair (2015 to 2018) around the domestic active volcanoes.

Some of PALSAR-2 data were prepared by the Japan Aerospace Exploration Agency (JAXA) via Coordinating Committee for the Prediction of Volcanic Eruption (CCPVE) as part of the project ‘ALOS-2 Domestic Demonstration on Disaster Management Application’ of the Volcano Working Group. Also, we used some of PALSAR-2 data that are shared within PALSAR Interferometry Consortium to Study our Evolving Land surface (PIXEL). PALSAR-2 data belongs to JAXA. We would like to thank Dr.Ozawa (NIED) for the use of his RINC software. In the process of the InSAR, we used Digital Ellipsoidal Height Model (DEHM) based on ‘the digital elevation map 10m-mesh’ provided by GSI, and Generic Mapping Tools (P.Wessel and W.H.F.Smith, 1999) to prepare illustrations.

Volcano-hydrothermal inflation revealed by the spatial variation of stress field at the Tatun Volcano Group, northern Taiwan

*Hsin-Chieh Pu[1], Cheng-Horng Lin[2,3,4,5], Ya-Ju Hsu[2], Li-Chin Chang[3]

1. Central Weather Bureau, Taiwan, ROC., 2. Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan, ROC., 3. Taiwan Volcano Observatory at Tatun, Taipei, Taiwan, ROC., 4. Department of Geosciences, National Taiwan University, Taipei 10617, Taiwan, ROC., 5. National Center for Research on Earthquake Engineering, National Applied Research Laboratories, Taipei, Taiwan, ROC.

To investigate the volcanic behaviors, the Taiwan Volcano Observatory at Tatun has deployed a dense seismic network in the Tatun Volcano Group (TVG), where the government and business metropolis-Taipei city is bounded and various phenomenon related to volcano-hydrothermal activity were found. This network is composed of 40 seismic stations for covering an area of ~10 km by ~10 km. Based on the seismic data recorded by this network, we have solved an extremely huge number of 1,016 earthquake focal mechanisms with depths less 5 km from 2012 to 2017. Then the detailed spatial variations of the local stress field near the surface are firstly inverted from these focal mechanisms. Overall, local earthquakes were dominated by both the sub-horizontal extensional stress striking ESE-WNW and sub-vertical compressional stress. In detail, the orientations of extensional stress formed the abnormal pattern of a couple of semi curves around the Dayoukeng area. In this particular area of Dayoukeng, the magnitude of compressional stress at the sub-vertical component was stronger than the others principle stresses based on the significantly lower ∅values in local than the surrounding area. We ascribe these local variations to an inflating phenomenon buried in the Dayoukeng area. This inflating mechanism should be induced by the volcano-hydrothermal fluid. The current volcano-hydrothermal activity represented by inflation is principally concentrated at the Dayoukeng area and disturbs the faulting behaviors of local earthquakes in the TVG.

Topographic change and crustal deformation associated with December 2018 eruption of Krakatau volcano in Indonesia

*Hiroshi Yarai[1], Tomokazu Kobayashi[1], Shinya Yamada[1]

1. GSI of Japan

Krakatau volcano is located in the Sunda Strait between Java Island of Indonesia and Sumatra Island. A high tsunami occurred on this Sunda Strait on December 22, 2018, causing major damage. It is estimated that this tsunami was caused by the collapse of Krakatau volcano. Therefore, in order to grasp the topography change of Krakatau volcano, we analyzed SAR intensity image observed by the Japanese earth observation satellite "Daichi 2" (ALOS-2) before and after the eruption. As a result of the analysis, a clear topographic change was observed in the southwestern part of the island on December 24 after eruption. It is thought that the southwestern part of the island collapsed by this 24th.

Furthermore, for capturing crustal deformation before and after the eruption, SAR interferometry was carried out using Daichi-2 SAR data. As a result, the displacement of the LOS's distance increased in the islands surrounding the Anaku Krakatau Island. Although the characteristic of the change suggests contraction centered around the Anak and Krakatau Island, it is not isotropic but it extends somewhat north and south. Therefore, the source may not be a simple mogi source.

[J] Poster | S (Solid Earth Sciences)：S-VC Volcanology

Mon. May 27, 2019 5:15 PM - 6:30 PM JST | Mon. May 27, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_25

[S-VC38] Active Volcanism

convener:Yuta Maeda(Nagoya University), Takahiro Miwa(National research institute for earth science and disaster prevention), Takeshi Nishimura(Department of Geophysics, Graduate School of Science, Tohoku University)

This session discusses various aspects of active volcanisms including, but not limited to, recent and historical eruptions, various phenomena associated with the volcanic activities, underground structures of the volcanoes, and developments of new instruments based on geophysical, geochemical, geological, and multidiscipline approaches. We also welcome studies on understanding and predicting the transitions of the eruptive activities from observational, theoretical, and experimental approaches.

The structure of Showa-Shinzan Yaneyama Usu by seismic reflection surveys

*Ryuichi Takei[1], Tomoki Tsutsui[1,2], Yuya Tada[2], Tomoya Moriwaki[2], Yosuke Aoki[3], Hiroshi Aoyama[4], Go Maruyama[5]

1. Graduate School of International Resource Sciences, The University of Akita, 2. Faculty of International Resource Sciences, The University of Akita, 3. Earthquake Research Institute, The University of Tokyo, 4. Graduate school of Science, The University of Hokkaido, 5. Marutec Co., Ltd.

Reflection seismic surveys at Usu-Showashinzan-Yaneyama was conducted in order to, estimate the shallow structure of the lava-dome base. Usu-Showashinzan is a young volcano formed in 1943-1945. It is characterized by consisting of a lava dome structure with top elevation of about 406.9m and a bun-shaped plateau called Yaneyama. Various geophysical explorations and geological surveys have been carried out in Showa-Shinzan until now, and the formation process and the supply route of magma have been discussed. However, the details of structure beneath Yaneyama are still unknown.
Total of 4 lines were conducted in 2017 and 2018 with 2 lines each, and seismic data were acquired. Two observation lines (Y17 and Y18) were set in the east-west direction on the east foot of the lava dome and two (G17 and G18) in the Guren-valley on the southwest foot of the lava dome. Both survey lines (Y17, G17) were conducted in 2017 with 24 receivers with using a hammer of 6.3kg as the seismic source. Other survey lines (Y18, G18) conducted in 2018 with 48 receivers with using a tamping rammer (MT-55L by Mikasa Industries) as the seismic source. Split-spread method was applied in all seismic lines. The receiver interval was 4m for Y lines and 3m for G lines. SU (Seismic Un*x) software was used for the seismic reflection analysis of the acquired seismograms. For 2018 lines with using tamping rammer, preprocessing is necessary before analysis of seismic reflection. That is based on the principle “SOSIE” (Yokokawa et.al. 1983).
As the result, the time sections on all the survey lines were obtained. Especially, in the G18 line, reflection profile down to 100m depth, which shows gentle valley structure in the middle of the line down to 80m depth and there is almost horizontal boundary at 100m depth.
The refraction tomography analysis and considering previous researches are going to be conducted.

Ground deformation associated with the 2014-2015 and the 2018-2019 volcanic activities at Azumayama

*Jun Okada[1], Shigeo Matsuura[2], Katsuya Ohmi[2], Takuya Yamamura[2], Yu Nihara[3], Susumu Seki[3]

1. Volcanology Research Department (Sendai Office), Meteorological Research Institute, JMA, 2. Seismology and Volcanology Division, Sendai Regional Headquarters, JMA, 3. Regional Volcanic Observation and Warning Center, Sendai Regional Headquarters, JMA

Azumayama is a basaltic to andesitic active volcano located in the volcanic front on the Tohoku (NE Japan) Arc. Historical eruptions occurred mainly in and around O-ana crater in the south flank of Issaikyosan. No eruption occurred for more than 40 years after the last one on December 1977. However, various volcanic phenomena have been observed in recent years. Repeated GPS surveys revealed local inflation-deflation around O-ana crater which plays in a cycle of 2-3-year and corresponds to the increase-decrease of seismicity during 2003-2009. Yoshida *et al.* (2012) estimated the pressure source 200 to 600 meters beneath the O-ana crater. This shows a good agreement with the thermal demagnetization source studied by Yamazaki *et al.* (2010). Monochromatic earthquakes were observed when fumarolic activity of O-ana crater was high during 2008-2011 (e.g. Ueki *et al.*, 2010). By analyzing the frequencies of these earthquakes Torimoto (2016) is beginning to understand the characteristics of shallow hydrothermal systems, a potential hotbed for phreatic eruptions. In more recent years, there are two volcanic unrests such as the 2014-2015 and the 2018-2019 activities. JMA released “Near-crater Warning” and raised Volcanic Alert Level from 1 to 2 on December 2014 and September 2018, respectively.

The start of the 2014-2015 activity can be marked by the slight tilt change at Jododaira station, 750m ESE from O-ana Crater. It showed East-downward ground deformation since late July 2014. Continuous GNSS measurements also captured local inflation around Issaikyosan since September 2014. Seismic activity started on middle October and culminated from December 2014 to middle January 2015. Similarly, the 2018-2019 activity can be recognized by the tilt data of Jododaira. A slow East-downward ground deformation started since May 2018. The tilting rate was significantly increased after the occurrence of the volcanic tremor on 22 July 2018 and remained almost constant (at least at the time of writing). Continuous GNSS data suggested also an inflation of the volcanic edifice since May 2018. The shallow seismicity started since middle August 2018 and remained active (at least at the time of writing).

Strong similarity exists in deformation characteristics between the 2014-2015 and the 2018-2019 activities, that is the dilatational ground deformation, both preceded to the activation of shallow seismicity. Except for the beginning of the activities tilting is maintained with almost the same rate and direction for more than several months. However, several discrepancies should be remarked: (1) Volcanic tremors are more frequent in the 2018-2019 than the 2014-2015. (2) The 2018-2019 activity may be triggered by a remarkable coincidental tilt change (about 1 micro radian at Jododaira station) and the associated volcanic tremor on 22 July 2018. (3) Slight tilt changes which may suggest a deep deflation of Azumayama were clearly observed at distant stations on the foot of Adatarayama, a neighboring volcano in the 2018-2019. These observational evidences may indicate the different volcanic processes in both activities. Regarding (3), other field observation results such as both the increase of SO_2/H_2S since late July 2018 and the enlargement of geothermal areas around O-ana crater can be triggered by the intermittent injection of volcanic fluids (e.g. hot volcanic gasses) from the depth of Azumayama. Results of both tilt and continuous GNSS observations will be presented in the session.

BP-type and BT-type volcanic earthquakes in Azumayama

*Yusuke Yoshigai[1], Yuichi Morita[2], Katsuya Ohmi[3], Yu Nihara[4], Tsukasa Kobayashi[1]

1. Volcanological Division, Japan Meteorological Agency, 2. Earthquake Research Institute, University of Tokyo, 3. Seismology and Volcanology Division, Sendai Regional Headquarters, Japan Meteorological Agency, 4. Regional Volcanic Observation and Warning Center, Sendai Regional Headquarters, Japan Meteorological Agency

At Azumayama located on the prefectural boundary between Yamagata and Fukushima prefectures, volcanic tremors occurred on 22 July 2018. Changes in tiltmeter data from Joudodaira Station (around 1 km ESE of the Oana crater) indicated ground deformation with a remarkable rising trend in the direction toward the crater. Volcanic seismicity has mostly remained at high levels since August 2018, and volcanic activity has remained at high levels. Japan Meteorological Agency (JMA) issued a Near-crater Warning on 13 September and raised the Volcanic Alert Level from 1 (Potential for increased activity) to 2 (Do not approach the crater).

There are mainly three types of volcanic earthquakes in the vicinity of the Oana crater: the BH-type in which the dominant frequency is high, the BL-type in which the dominant frequency is low, and the BP-type / BT-type with the harmonic waveform. These volcanic earthquakes occur roughly at depths of less than 1 km.

From July to October 2018, BH-type earthquakes mainly occurred, and the proportion of BL-type earthquakes and BP-type / BT-type earthquakes slightly increased in November. After that, the proportion of the BL-type earthquakes decreased, but the proportion of the BP-type / BT-type earthquakes further increased. The proportion of the BP-type / BT-type earthquakes to the whole volcanic earthquakes is 25% in November and 50% since December, and it continues high levels. The BP-type / BT-type earthquakes that occurred after July 2018 have various types of characteristics, such as damped harmonic oscillators with a single frequency peak seen in the BP-type / BT-type earthquakes occurred from 2010 to 2011, damped harmonic oscillators with multiple frequency peaks and those with high-frequency earthquake near the beginning of the earthquake, and no systematic change of the dominant frequency can be observed. In this presentation, we introduce what we found as the results of focusing on waveform shape and amplitude ratio for the BP-type / BT-type earthquakes that occurred after July 2018.

In this research, under the agreement on collaboration and cooperation in the field of seismic / volcanic disaster prevention research between Earthquake Research Institute (ERI), the University of Tokyo and Seismology and Volcanology Department, JMA, I used facilities of ERI and discussed with the people of ERI. I express my gratitude to everyone involved.

The occurrence and petrology of the fine-grained pyroclastic materials of the Futatsudake-Shibukawa eruption in Haruna volcano.

*Teruyoshi Maruyama[1], Yuki Suzuki[2]

1. Department of Earth Sciences, School of Education , Waseda University, 2. Department of Earth Sciences, Faculty of Education and Integrated Arts of Sciences, Waseda University

Haruna volcano is an active volcano of Quaternary which is located in the southern end of the NE Japan arc. Haruna volcano has 500000 years active time. Geshi and Takeuchi (2012) showed the activity is classified into older period (500-240ka), and newer period (45ka-) following activity halt of about 200,000 years. The newest activity in Haruna volcano is Shibukawa eruption (late 5th to early 6th century) and Ikaho eruption (late 6th to early 7th century), both of which occurred at the location of present Futatsudake (ages by Geshi and Oishi (2011)). Occurrences of ejecta from two eruption, as described in Soda (1989), indicate the different manner of pyroclastic flow generation; explosive destruction of the lava dome in the Shibukawa eruption, while column collapse in the Ikaho eruption. Suzuki and Nakada (2007) carried out detailed petrological study for the Ikaho eruption. They proposed mush-like felsic magma was remobilized by the injection of mafic magma. The important point in the eruption triggering was that mixed magma and heated magma with considerably lower viscosity than the original mush-like magma opened the vent, resulting in the decompression of whole felsic magma reservoir. However, no study has revealed the magma plumbing system and the eruption triggering process of the Shibukawa eruption. For the purpose of understanding these points, we have conducted the petrological study of the Shibukawa eruption. In particular, in this research, in order to clarify the progress of eruption and the temporal change of the erupted magma, fine-grained pyroclastic materials were studied rather than pumice blocks in the block and ash flow (BAF).

We sampled fine-grained pyroclastic deposits at four sites locating at the northeastern to eastern foot of Haruna volcano. All sites locate at the periphery of BAF mapped in Soda (1989). Therefore, our investigated sites correspond to the region where pyroclastic surge deposit emplaces (example of Unzen 1991-1995 eruption; Fujii and Nakada, 1999). We could observe the basal part of fine-grained pyroclastic material in three sites. In all sites, the strata were divided into multiple units according to their facies. The juvenile pumice clasts, the coarse part of the deposit, had variation in color (white, gray, light gray). We measured whole rock compositions of the pumice samples and found they are felsic andesite (SiO_2 =60.7-61.9wt.%; N=22). Thin sections were prepared for ten representative pumices and one volcanic ash sample. It is necessary to study the volcanic ash sample, because it is not possible to discuss the change in magma composition from lower to the upper layer, only with the pumice clasts for which whole-rock chemical analyses were performed. The phenocryst phases (Pl+Opx+Am+Fe-Ti Ox) in all samples form aggregates, so when they crystallized, they were in equilibrium. We observed free crystals (Pl+Opx+Am), pumice particles, and lava particles in the thin sections of volcanic ash. All thin sections of pumice and ash include the dusty zone of Pl, so these products resulted from either through magma mixing (between felsic and mafic magmas) or the heating of felsic magma by the mafic magma. In four out of five samples of gray pumice, breakdown reaction rims of amphibole and groundmass crystals were confirmed, so magma that formed gray pumice likely underwent a different ascending process in conduit, in comparison with the magma that formed white pumice.

Suzuki and Fukushima (2019, this conference) studied pumice blocks in the BAF from the Futatsudake-Shibukawa eruption. This result is similar to our result. Therefore, we infer magmas formed these two products was homogeneous in magma chamber. The original pyroclastic flow was separated into rock mass flow and pyroclastic surge as they descended river valleys, resulting in simultaneous

emplacement of the BAF and fine-grained pyroclastic materials at different distances from the river valleys.

The occurrence and petrology of the block and ash flow deposit from the Futatsudake-Shibukawa eruption, Haruna volcano

*Yuki Suzuki[1], Ryouto Fukushima[2]

1. Department of Earth Sciences, Faculty of Education and Integrated Arts of Sciences, Waseda University, 2. Department of Earth Sciences, School of Education, Waseda University

Haruna volcano is located in the southern end of the NE Japan arc. The latest two eruptions occurred at Futatsudake; Shibukawa eruption in late 5th to early 6th century (0.4 DRE km^3), and Ikaho eruption in late 6th to early 7th century (0.99 DRE km^3)(ages from Geshi and Oishi, 2011; volumes from Yamamoto, 2013). Suzuki and Nakada (2007) conducted petrological study of Ikaho eruption to reveal eruption triggering process. First, injection of mafic magma into the mush-like felsic magma generated mixed magma and heated felsic magma. Then, these low viscosity magmas opened the conduit and vent, resulting in the decompression of whole reservoir. It is indispensable to study two eruptions from a continuous view point, because two eruptions occurred from the same place at an interval of only several decades.

The outcrops of the Shibukawa eruption are categorized into those consisting of block-and-ash-flow (BAF) deposit (this presentation) and those consisting of fine pyroclasts derived from pyroclastic surge and phreatic explosion (Maruyama and Suzuki, 2019; this conference). Outcrops of BAF deposit locate in the vicinity of river valleys, while outcrops of fine pyroclasts locate away from the valleys. The BAF deposit includes relatively large (up to 30cm) juvenile pumiceous blocks, allowing more precise determination of bulk composition of erupted magma than the fine pyroclastic deposit. We investigated four outcrops, two of which locate along Owagawa and Noborisawagawa in the NE flank of the volcano, and two of which locate along Haruna-Shirakawa in the SE flank. Geshi and Oishi (2011) recently clarified the BAF deposit in the SE flank is the product of the Shibukawa eruption by the carbon dating. At some outcrops, BAF deposit could be divided into subunits by the existence of intercalated ash deposit. In any outcrop/subunit, juvenile blocks were classified into white, gray and dark gray. In some blocks, parts with different colors are in stripes or irregularly mixed.

The pumice blocks are homogeneous felsic andesite with 60.6-61.7 wt.% SiO_2(N=21). There is no systematic difference in the composition between the NE and SE flanks. In Unzen 1991-1995 eruption, the composition of the erupted magma changed with time, and there was a temporal change in the flow direction of the pyroclastic flow (Nakada and Motomura, 1999). The present data of Shibukawa eruption show no tendency like that. In the representative six samples covering the pumice color variation, Hb, Opx, Pl, Qtz and Fe-Ti oxides present as phenocryst phase. But, Qtz is quite rare, as we observed only one crystal in 8 thin sections. Phenocryst phases other than Qtz form aggregate, indicating they crystallized in equilibrium. Dusty zone was observed in the plagioclase rim, showing that the melt became undifferentiated just prior to the eruption, due to 1) mixing with hotter magma, or 2) heating by hotter magma. There is no change in whole rock composition and phenocryst assemblage with pumice block color. The different color is likely to be caused by different amount of groundmass crystal (Gardner*et al.*, 1998). The breakdown of Hb was observed only in dark gray blocks.

The felsic endmember magma of the Ikaho eruption erupted as white pumice (60 to 62 wt.% SiO_2). The white pumices contain phenocrysts of Hb, Opx, Pl and Fe-Ti oxides. Therefore, it is highly probable that the felsic magma similar to that in Ikaho eruption was active in the Shibukawa eruption. In the Ikaho eruption, ejecta with obvious characteristics of magma mixing (gray pumice and lava, down to 57.5 wt.% SiO_2) have been confirmed. It means that the mixing ratio of the high-temperature magma in the Shibukawa eruption (even if it happened) was very small. In the future, as well as exploring the eruption

©2019. Japan Geoscience Union. All Right Reserved.

triggering process of the Shibukawa eruption in detail, we need to investigate phenocrysts derived from the felsic magma for the Ikaho eruption. They might record the effects of heating and mixing by high-temperature magma, which occurred several decades before the eruption.

Report of Volcanic Activity at Kusatsu-Shiranesan in 2018

*Tsukasa Kobayashi[1], Koji Kato[1], Koichi Suemine[1], Kazuhiro Kimura[1], Yusuke Yoshigai[1], Yasuo Ogawa[2], Kenji Nogami[2], Wataru Kanda[2], Akihiko Terada[2]

1. Volcanological Division, Japan Meteorological Agency, 2. Volcanic Fluid Research Center, Tokyo Institute of Technology

Kusatsu-Shiranesan is the active volcano located in north-eastern Gunma-pref. Japan Meteorological Agency (JMA) monitors Kusatsu-Shiranesan volcanic activity. A group of pyroclastic cones, including Shiranesan, Ainomine, and Motoshiranesan, which stretch from the north to the south, are located in its highest western area. Latest magmatic eruption occurred about 3,000 years ago. All recent eruptions were occurred in the area around Yugama and Motoshiranesan area, and these eruptions were phreatic explosions.

In January 2018, phreatic explosion occurred at Motoshiranesan area. In April, volcanic seismicity in shallow areas beneath the Yugama crater increased. We report volcanic activity at Kusatsu-Shiranesan in 2018.

A phreatic explosion occurred at 10:02 on 23 January 2018 at the northern and western area of Kagamiike-kita cone in Motoshiranesan. Before the eruption, volcanic tremor occurred from 09:59, and significant tilt changes which indicate the upward of Motoshiranesan direction was obserbed by tiltmeter installed around Yugama crater by the Tokyo Institute of Technology. At around 10:02, low frequency earthquake was observed, and these tilt signals turned to the downward to the Motoshiranesan direction. After the eruption, a very small volcanic earthquake (BH-type earthquake) occurred frequently in a shallow place near Kagamiike-kita cone, but it gradually declined.
In late April 2018, earthquakes around shallow part of Yugama crater rapidly increased, and crustal deformation indicating the expansion of the shallow part around Yugama began to be observed with the tiltmeter installed around Yugama crater.By the geomagnetic observation, the variation of geomagnetic total intensity indicating thermal demagnetization was observed from April.
In early September, the volcanic earthquake activity decreased somewhat and the tiltmeter variation also became smaller. But on September 28, again the earthquake around the Yugama increased rapidly. And crustal deformation similar to April was observed by the tiltmeter installed around Yugama. After that, earthquake activity decreased gradually, but continued in January 2019.

Analysis result of GNSS continuous observation date from 2014 to 2015, in which period seismicity around Yugama crater was high, indicates the expansion of the deep part of northwest area of Kusatsu-Shiranesan. Similar changes was observed at several observation points in 2018.

We would like to thank Kakioka Magnetic Observatory, JMA for the use of his observation and analysis data.

Noble gas isotope composition of fumaroles and hydrothermal gases around Kusatsu-Shirane volcano

*Kotaro Toyama[1], Hirochika Sumino[1], Kaori Kawana[1], Yoshihide Akiyama[1], Takeshi Ohba[2], Muga Yaguchi[3], Akihiko Terada[4]

1. Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo, 2. Department of chemistry, School of Science, Tokia University, 3. Meteorological Research Institute, 4. Volcanic Fluid Research Center, Tokyo Institute of Technology

Mount Kusatsu-Shirane, an active stratovolcano consisting of three pyroclastic cones (from north to south, Mt. Shirane, Mt. Ainomine, and Mt. Motoshirane) erupted on 23 January 2018 at Mt. Motoshirane. This eruption was a phreatic eruption, which often occur without magma movement. Therefore, there is no or very small precursor geophysical signals. In contrast, the chemical and isotopic compositions of volcanic gases can change reflecting pressure rise of a gas reservoir which caused the phreatic eruption. Especially, helium isotope ratio ($^3He/^4He$) is regarded as a useful tracer for the volcanic activity, because it exhibits unique values corresponding to the origin (e.g., 7-8 Ra in the mantle and < 0.1 Ra in the curst, where 1 Ra denotes atmospheric $^3He/^4He$ ratio of 1.4×10^{-6} [1]). Some studies have reported pre-eruptive $^3He/^4He$ anomalies, suggesting the increase of supply of the magmatic helium into the hydrothermal system preceding eruption [2,3].

We report the noble gas (He, Ne, Ar) isotopes of fumaroles and hot-spring gases collected from 9 sites around Kusatsu-Shirane volcano during 2014 and 2018. The measured $^3He/^4He$ ratios were corrected for atmospheric contamination based on $^4He/^{20}Ne$ ratios. The air-corrected $^3He/^4He$ ratio of Sesshogawara fumarole, located on 2 km east of the 2018 phreatic vent, had been constant at 7.0-7.5 Ra during 2014 and 24 January 2018, and dropped to 6.5 Ra on 13 February 2018. The $^3He/^4He$ ratio increased to 7.6 Ra on 21 May 2018 and has been constant at about 7.5 Ra. The $^3He/^4$ He ratios of bubbling gases of Kusatsu-Yubatake hot spring, which located on 5 km east of the 2018 phreatic vent, had been constant at 6.5-6.9 Ra during 2014 and 12 February 2018, decreased to 6.0 Ra on 3 June 2018, and then increased to 7.5 Ra on 6 August 2018. The $^3He/^4$ He ratios of Hoshimata fumarole, which located on 3 km west of the 2018 phreatic vent, increased from 6.2 Ra to 7.3 Ra during 2 March 2018 and 19 June 2018. The trends observed in these sites seem to be associated with the 2018 eruption with different time lags, which may reflect the migration distance from the 2018 phreatic vent to the sites.

In Kusatsu-Shirane area, two hydrothermal reservoirs, one of which is located beneath Yugama crater of Mt. Shirane and the other is located beneath Mt. Motoshirane (between Ainomine and Mt. Motoshirane), have been proposed [4]. The $^3He/^4He$ ratios (7.2-8.1 Ra) of Kitagawa fumaroles on the northern flank of Mt. Shirane near the Yugama crater, may reflect the values of the gases derived from the hydrothermal reservoir beneath Mt. Shirane. On the other hand, the lower $^3He/^4He$ ratios observed in Sesshogawara, Kusatsu-Yubatake and Hoshimata after the eruption may result from another contribution from a reservoir having lower $^3He/^4He$ ratios (less than 6.5 Ra), which could be attributed to the hydrothermal reservoir beneath Mt. Motoshirane. The reservoir beneath Mt. Motoshirane may be enriched in radiogenic ^4He derived from the crust, because Mt. Motoshirane has not erupted for last 1500 years [5].

It has been proposed that the 2018 eruption was caused by sealing of gas pathway from magma to the hydrothermal reservoir beneath Mt. Shirane [4]. This would result in decrease of supply of magmatic gas with high $^3He/^4He$ ratio to Sesshogawara, Kusatsu-Yubatake, and Hoshimata. Therefore, the low $^3He/^4He$

©2019. Japan Geoscience Union. All Right Reserved.

ratios observed in these sites after the 2018 eruption may reflect relative increase of the contribution of gas supplied from the Mt. Motoshirane hydrothermal reservoir. In contrast, the high and relatively constant $^{3}He/^{4}He$ ratios at all of the sites since August 2018 suggest that the gas from the reservoir beneath Mt. Shirane is dominant. Ohba et al. [4] proposed that supply of magmatic gas to the Mt. Motoshirane reservoir increased before the eruption as a result of the sealing of gas pathway from magma to the Mt. Shirane reservoir, and that it caused high fluid pressure of the reservoir and subsequent phreatic eruption at Mt. Motoshirane. This implies that $^{3}He/^{4}He$ ratio of the Mt. Motoshirane reservoir also increased from a lower value to a higher value less than 6.5 Ra before the eruption. Although further study is necessary to constrain $^{3}He/^{4}He$ ratios of the reservoirs, the remarkable temporal $^{3}He/^{4}He$ variation after the eruption can be accounted for by the change in mixing ratio of the gases from the two reservoirs.

Self-potential and geomagnetic total intensity observations at Motoshirane volcano after the 2018 eruption

*Akira Yamazaki[1], Hideki Iino[1], Tatsurou Tanaka[1]

1. Kakioka Magnetic Observatory

A phreatic eruption occurred at Kusatsu-Shirane volcano (Motoshirane volcano) on January 23, 2018, and some impact craters were formed on the Kagami-ike crater floor and the Kagami-ike northern crater. After the eruption, the temporarily activated seismic activity near the crater has declined, and the fumarolic activity has ceased after late February 2018. In order to estimate geothermal status after the eruption, we carried out self-potential (SP) and geomagnetic total intensity observations at Motoshirane volcano. Measurements of the SP were conducted at about 130 points around the summit of Motoshirane volcano from June 30 to July 2, 2018. Copper-Copper sulfate electrodes were used, the measurement interval was about 50 m, and the measurement was carried out by the so-called full potential method. We applied -1.3mV/m as correlation coefficient for correction of the topographic effect to all the SP measurement stations. The coefficient was obtained from a clear negative correlation (-1.3 mV/m) between the elevation and the potential in the survey line on the eastern slope of the Kagami-ike. As a result of the SP, we detected a positive anomaly, 200~500mV in magnitude, developing around the summit of Motoshirane volcano. By comparison of the result of the 4th Joint Observation of Kusatsu-Shirane Volcano in 2003, we found temporal variations of the SP near Kagami-ike northern crater which may have been caused by the eruption. As for the geomagnetic total intensity observation, we selected ten repetitive observation stations around the summit of Motoshirane volcano, and carried out first observation in June 2018 (June 28-30). Following the first observation, we carried out repeated observation in August (August 28-29) and October (October 7). As a result, no significant changes in the geomagnetic total intensity in the period from June to October, 2018. It suggests that rapid thermal demagnetization or magnetization by cooling does not occur at underground of Motoshirane volcano.

Eruption processes of the 3rd and 4th stage of Niigata-Yakeyama Volcano, Japan, inferred from microlite texture and chemical composition

*Takumi Yoshida[1], Takeshi Saito[1]

1. Shinshu University

Niigata-Yakeyama volcano, which belongs to the Myoko volcano group, is one of the most active and youngest volcanoes in Japan. In the 3rd stage of Yakeyama activity, Maeyama lava flows and Hayakawa pyroclastic flows were generated to the northern slope of the volcano. In the 4th stage activity, Yakeyama lava flows, which forms present lava dome at the summit, and Otani pyroclastic flows were effused. Otani pyroclastic flow deposit contains well-vesiculated lavas, while lavas from Hayakawa pyroclastic flow are poorly-vesiculated. In this study, groundmass textural analysis of the eruptive products at the 4th stage was carried out. Chemical composition of plagioclase phenocrysts and microlites of the eruptive products at the 3rd and 4th stage were analyzed in order to examine the eruption process of the 3rd and 4th stage of Yakeyama volcano.

Microlite number density (MND) and crystallinity of plagioclase in Otani pyroclastic flow deposits were obtained from groundmass textural analysis. Our results indicated that Otani pyroclastic flows showed lower MND and intermediate crystallinity compared with Hayakawa pyroclastic flow deposits. As a result of chemical composition analysis, phenocryst in the samples of the 3rd stage activity shows An#(Ca/Ca+Na) =0.65~0.84. Microlite of andesite of Maeyama lava flow has an average An# of 0.61, which is lower than that of dacite lava of Maeyama Lava flow (average An# =0.54). Phenocryst of the 4th stage activity has An# =0.45~0.89. Microlite of Yakeyama lava flow and Otani pyroclastic flow have average An# of 0.63 and 0.62, respectively. The An# of plagioclase microlite becomes lower with decreasing crystal size.

Plagioclase microlite becomes lower An# with higher degree of H2O exsolution due to decompression (e.g. Nakamura, 2011). Our results suggest that microlite in dacite lava of Maeyama lava flow has undergone high decompression compared with andesite lava of Maeyama lava flow. However, there were little difference between plagioclase microlite of lava flow and that of pyroclastic flow samples. Eruptive products of the 4th eruption have relatively homogeneous SiO2 composition. Plagioclase microlite of Otani pyroclastic flow deposit, showing lower MND and higher An# than Hayakawa pyroclastic flow, may be crystallized under a condition of lower undercooling. Another possibility is that rapid vesiculation and H2O exsolution may proceed before microlite crystallization and prevent from decreasing An#.

Estimation of subsurface structure of Shinyu crater lake, Tateyama Caldera, based on the water level and seismic observation data

*Ryohei Kawaguchi[1], Naoko Saito[2], Shin'ya Onizawa[1]

1. Meteorological Research Institute, 2. Toyama local Meteorological office, Japan Meteorological Agency

Shinyu, located in the Tateyama caldera is a crater lake with the diameter of about 40 m and the depth of about 5.6 m. The water level of Shinyu is maintained by the influx of hot water from vents at the bottom of Shinyu. Shinyu had continued the full water level for decades, but periodic geyser activity was reported from 2014 which has the period of 0-20 days (Fukui et al 2018). In order to investigate the activity of the water level change in Shinyu, we installed water level meter and seismometer around Shinyu from June to October in 2017 and 2018. In this study, we estimate the underground structure of Shinyu based on the temporal changes of water level and seismic data.

The water level change was observed by a bubble type water level meter which has a sampling period of 10 minutes. In addition, a seismometer was installed at about 20 m from the Shinyu. The seismic data was recorded with a sampling frequency of 100 Hz.

During the observation period, we were able to obtain the water level change data of 7 cycles in 2017 and 8 cycles in 2018, respectively. For the preliminary analysis, we examined the periods of water level changes, dividing the water level change cycle into four categories, dry-up, rising in the water level, full water level, and descent in the water level. As a result, the period of the dry-up is about 3 days, the rise in water level is about 4.5 days, the full water is 0 to 20 days and the descent in water level is about 0.5 days. The period of raising and decent of the water levels were almost constant for each cycle. During the rising and full of the water level, rising of hot water with gas bubbles were observed by the image of Shinyu surface taken by time-lapse camera. The amplitudes level of seismometer data was clearly different between the period of rising and full of water level and the period of dry-up and decent of water level. These indicate that geyser activity of Shinyu is occurred by boiling of hot water in the water reservoir located below the Shinyu.
When the shape of Shinyu is conical and the flux of the hot water drop under the Shinyu is constant, the flux of dropping hot water is estimated about 0.06 m^3/s by the size of Shinyu and the period of the descent of water level. According the data of water level meter, the rate of water level descent were 1.2-2.5 $\times 10^{-3}$ m/s. From these data, the radius of cylindrical pipe assuming below the Shinyu was estimated to be 2.8-4.0 m. We also report on the result of comparing the time scale of water level changes using the observed data and simulation result based on the previous geyser model.

Real time monitoring of underground temperature in Jigokudani, Midagahara volcano using LPWA devices

*Tohru Watanabe[1], Toyama branch NTT West[2]

1. Gradudate School of Science and Engineering, University of Toyama, 2. Nippon Telegraph and Telephone West Corporation

Jigokudani is an active geothermal area in Midagahara volcano, Toyama prefecture, central Japan. It was formed as a result of repeated phreatic eruptions over 40,000 years. Increased volcanic activity in this area has been observed since 2011. In order to detect a precursory signal of a phreatic eruption, seismicity, observations should be conducted on seismicity, ground deformation, geothermal activity, volcanic gas, etc. A real time monitoring system of underground temperature using LPWA (Low Power, Wide Area) devices has been tested since 30 August 2018. An LPWA device (NHR, SS05-ST) is composed of thermometer and transmitter (LoRaWAN). 10 devices were deployed in Jigokudani. Temperature sensors (thermocouples) were placed at the depth of 50 cm. Transmitters send temperature data every 30 minutes to a gateway to the internet situated in Hotel Tateyama. The distances from the gateway to LPWA devices are within 1 km. Underground temperatures can be monitored on internet devices. Since Jigokudani has a heavy snowfall in winter, 7 devices were removed and 3 devices were left to test in winter. Though temperature data could be received until December 2018, no data could be received since then. Transmitters of around 50 cm high above the ground must be covered with snow. During summer and fall, LPWA devices are useful for real time monitoring.

Varying chemical and isotopic compositions of fumarolic gases from the summit and from the 1962-63 eruptive vents at Yakedake Volcano, Japan

*Takeshi Saito[1], Shun Sawamura[2], Kazuhiro Amita[3], Taketoshi Mishima[4], Shinji Ohsawa[4]

1. Institute of Science, Academic Assembly School of Science and Technology, Shinshu University, 2. Graduate School of Science and Technology, Shinshu University, 3. Graduate School of Engineering Science, Akita University, 4. Beppu Geothermal Research Laboratory, Institute for Geothermal Sciences, Graduate School of Science, Kyoto University

Since the latest phreatic eruption in 1962-1963, Yakedake volcano has remained dormant, but fumarolic activity around the summit area has continued steadily during the past hundred years. Recently, temperature, chemical, and isotopic compositions of fumarolic gases discharged from the summit fumaroles were ascertained for 2013-2017 (Saito et al., 2019). This time, fumarolic gases discharged from the 1962-63 eruptive vents, which locate about 300m north of the summit, were collected and chemical and isotopic compositions were analyzed. We compared our results from the 1962-63 eruptive vents with those from the summit fumaroles in order to evaluate the formation of volcanic hydrothermal system beneath the volcano.

Discharge temperatures of the fumaroles around the 1962-63 vents were 95-100˚C: slightly lower temperatures than those from the summit fumaroles but higher than the boiling temperature at the elevation. Chemical analysis revealed that fumarolic gases from the 1962-63 vents contain lower amounts of SO_2 than the summit fumaroles. Higher CO_2/total S ratio and lower apparent equilibrium temperatures of the 1962-63 fumaroles coincide with lower discharge temperatures. On the other hand, the 1962-63 fumaroles show higher He/Ar ratio than the summit fumaroles, suggesting higher contribution of magmatic fluid.

The isotopic compositions of water (D, ^{18}O) show that the fumarolic fluids from the summit fumaroles were probably formed by mixing of the magmatic fluids and local meteoric water. The isotopic compositions of the 1962-63 fumaroles show much lower values not only than the summit fumaroles but than local meteoric water, suggesting that the fluids suffered isotopic fractionation due to evaporation of the fumarolic gases.

Our results possibly indicate that volcanic hydrothermal system beneath the summit region differ from that under the 1962-63 vents.

Eruption age determination of the latest two lava flows and characteristics of volcaniclastic materials from the recent activity of Yokodake Volcano, Japan

*Hiroya Nitta[1], Takeshi Saito[1], Yorinao Shitaoka[2]

1. Shinshu University of Science and Technology, 2. Department of Environment System, Faculty of Geo-environmental Science, Rissho University

Yokodake volcano, which effused nine lava flows (Y1~Y9), is the only active volcano belonging to Yatsugatake volcano groups in central Japan. Eruption ages of Y1-Y8 lava were not determined distinctively. To evaluate the latest activity of Yokodake volcano, we carried out paleomagnetic studies and tried to estimate the eruption ages of the Y8 and Y9 lava flows. However, several candidates for paleomagnetic ages were remained (Nitta and Saito, 2018, JPGU; Nitta and Saito, 2018, fall meeting of the volcanological society of Japan). In this study, we applied thermoluminescence (TL) dating for Y8 and Y9 lava and viscous remanent magnetization (VRM) dating for Y9 lava. In addition, the volcaniclastic layers were found just above the Y9 lava and around the surface of the summit region. We will report characteristics of the volcaniclastic layers, discussing the recent activities of this volcano.

TL dating was performed by using poly-minerals (ca 10~50 μm) sample extracted from Y8 and Y9 lava. TL age of Y8 sample was 3.3 ±1.2 ka. Y9 lava sample didn't emit TL intensity. As for Y9 lava, we tried to estimate the age using VRM. However, the estimated ages were widely scattered. We conclude eruption age of the Y8 lava is ca. 3.3 ka, which is consistent with our previous paleomagnetic age of 3.35~3.85ka. On the other hand, five eruption ages of Y9 lava (0.60 ka, 1.80 ka, 1.90~1.95 ka, 2.20~2.25 ka, 2.4~2.45 ka) are still remained.

We recognized light gray volcanic ash deposit just above Y9 lava which composed of sand to silt size and contained carbonaceous material. It may be comparable to NYk-1 tephra (Okuno, 1995). Four volcaniclastic layers were found at summit region and the lower layer is a possibility of being correlated with NYk-2 tephra (2.35~2.15 cal ka BP; Okuno and Kobayashi, 2010). Two volcaniclastic layers above NYk-2 tephra seem to be derived from Yokodake volcano, suggesting at least two volcanic eruptions were occurred after NYk-2 tephra eruption.

Estimating the date of the 2007 eruption of Mount Ontake Volcano using waveform correlation

*Shuhei Nishijima[1], Toshiko Terakawa[1], Shinichiro Horikawa[1]

1. Graduate School of Environmental Studies, Nagoya University

Mt. Ontake volcano erupted on late March, 2007. However, we do not know the exact time of the eruption with a Volcanic Explosivity Index 0 because of little visual evidence. I tried to estimate the date of the 2007 eruption, using a waveform correlation method. A previous study reports that focal mechanisms of volcanic earthquakes associated with the latest eruption in 2014 changed from normal/strike-slip faulting with east-west tension to reverse faulting with east-west compression. Based on this fact, I selected 10 and 8 volcanic events for the pre- and the post-periods of the 2014 eruption as template events. I applied the technique to continuous seismic waveforms from 22 December 2006 to 31 March 2007. I detected 2375 (pre-eruption type) and 1659 (post-eruption type) events corresponding to the pre- and the post-eruption events, respectively. I found that events with east-west tension (pre-eruption type) became active at the early stage until a very long period (VLP) event occurred on 25 January, and during the period from 5 to 19 February. On the other hand, the activity of events with east-west compression (post-eruption type) became dominant for 11 days after the VLP event occurred, and during the period from 20 February to 24 March. Subsequently, neither type of events became dominant. The activity of pre-eruption type events synchronized with the period when the length of the baseline in the east-west direction across Mt. Ontake increased. This suggests that events of pre-eruption type are related to the magma intrusion process beneath the volcano. The activation of events of post-eruption type following to the VLP event, which is well modeled by a tensile crack with a strike of N20W, may be related to contraction processes after the event released water vapor from the volcano. Based on the changes in types of detected events as well as the seismicity, I concluded that Mt. Ontake would have erupted on 20 February or between 11 and 12 March, 2007.

Seismic activity beneath Mt. Ontake volcano before and after the 2007 and 2014 eruptions

*Yoshiko Yamanaka[1], Shinichiro Horikawa[1], Yuta Maeda[1]

1. Graduate School of Encironmental Studies, University of NAGOYA

We developed a portable seismic telemetry system. This system is compact size, and the consumption electricity is small (Horikawa et al., 2017VSJ). From October 2017 performance test of this system has been carried out in the summit region of Mt. Ontake volcano. 10 seismic observations were installed. We determined seismic activity around Mount Ontake volcano by using those 10 summit observations and the seismic networks of Nagoya University and Japan Meteorological Agency, and obtained station corrections. Most of earthquakes were located beneath the craters of the 2014 eruption, and those depths were close in sea level or were shallower. The seismic activity is almost distributed on a straight line at -1.5km from 0km in depth and spreads through the northeast-southwest direction at around -1.5km (Yamanaka et al., 2018JpGU).

We try to determine seismicity linked to the 2007 and 2014 eruption of the Mount Ontake by using obtained station corrections. Before the 2014 eruption, earthquakes occurred from 1.0 km to -0.6 km linearly. This seismic activity is on an extension line of the 2017-2018 linear activity. After the 2014 eruption, earthquakes spread in the north and south direction from around -0.6 km in depth. The seismic activity gradually become shallow and extended to the current seismic activity. The events before the 2007 eruption also occurred from 3.0 km to 0 km on an extension line of the 2017-2018 linear activity. It is considered that some kind of fluid has risen through almost the same passage at the 2007 and 2014 eruptions.

Effect of rain and snowmelt correction of tiltmeter data - Application example for Ontakesan Volcano -

*Kazuhiro Kimura[1,5], Katsuhisa Kawashima[2], Takane Matsumoto[2], Akihiko SASAKI[4], Tsutomu Iyobe[3], Junichi Miyamura[1], Masaki Nakahashi[1]

1. Japan Meteorological Agency, 2. Research Institute for Natural Hazards and Disaster Recovery, Niigata University, 3. Faculty of Engineering, Kyoto University, 4. Department of Geography and Environmental Studies, Kokushikan University, 5. Graduate School Science and Technology, Niigata University

Japan Meteorological Agency(JMA) installed a tiltmeter about 3km southeast of Mt. Ontake in 2010. A clear tilt change was observed northwest upward from several minutes before the 2014 phreatic eruption and northwest downward after the eruption. Kimura and Nakahashi (2015) applied the rain correction method using the tank model and precipitation data to the tiltmeter data of east-west component of the summer (From June to October), and they detected the small tilt change of west rising from September 10, 2014 when the earthquake activity became active. However, the similar tilt change of west rising has been confirmed several times and it has not been able to remove the influence of snowmelt in the spring (From March to May).

Miyamura et al. (2017) developed the rain and snowmelt correction method that adds the snow-tank to the tank model by Kimura et al. (2015) that uses snowmelt amount data as input values in addition to the precipitation data. They applied this method to the tiltmeter data of east-west component, and they confirmed that the influence of snowmelt in the spring was removed from the tiltmeter data. We used a method using a TR model that uses temparature and solar radiation as indices with reference to Matsumoto et al. (2010). Because there is not the continuous meteorological observation data for a long time near the tiltmeter (altitude 2195 m), they used the meteorological observation data at Kaidakogen (altitude 1130 m) closest to the tiltmeter (about 11.5km). In order to consider the difference between the two meteorological observation data, they compared with the meteorological observation data at Kaidakogen and the meteorological data near the tiltmeter observed by Kawashima et al. (2016).

There is a large seasonal changes from spring to summer every year for the tiltmeter data of north-south component. We applied the method of Miyamura et al (2017) to the tiltmeter data of north-south component, and it is able to remove this seasonal changes. Focusing on the 2014 phreatic eruption of Mt. Ontake, we detected the tilt change of north rising from the mid August 2014. In other words, the tilt change began north rising from the mid August 2014, and turned to northwest rising from around September 10. Similar tilt change could not be confirmed during the reserch period (April 2011 - September 2017).

We considered this tilt change while related to two previous studies. First, with reference to hypocenters before and after the eruption by Kato et al (2015), assuming an open crack model with NNW-SSE strike and moving its upper end from the 2 km to 1 km depth. As a result, we were able to confirm the tilt change pattern from north rising to northwest rising. Next, Miyaoka and Takagi (2016) applied the stacking method to the GNSS baseline length data, they detected that the change of the long baseline began from the middle of August and the change of the short baseline began from the beginning of September. They inferred that the pressure source migrated to a shallower region from a deeper region. The results of these previous studies are consistent with the tilt change applied the rain and snowmelt correction method to the tiltmeter data, and are considered to indicate the effectiveness of this method.

Spatial Variation of b-value around Mt. Fuji influenced by the Eastern Shizuoka Earthquake of 15 March 2011

*Takumi Murakoshi[1], Tomonari Miyashita[2]

1. National Defense Academy, 2. JASDF

The Eastern Shizuoka earthquake occurred on March 15, 2011 (Mj6.4). The hypocenter of the earthquake was approximately 6 km southwest of Mt. Fuji’ s peak at a subsurface depth of about 15 km. Estimating spatial variation of the b-value of the Gutenberg–Richter relation is important in the examination of time and spatial changes in volcanic and seismic activity after large earthquakes. This study aims to evaluate changes in seismic activity after the 2011 Eastern Shizuoka earthquake using the spatial variation of the b-value. Hypocentral data from July 2001 to December 2017 was obtained from the JMA catalog. As a result, the b-value for earthquakes around Mt. Fuji was significantly smaller during the period after the 2011 Eastern Shizuoka earthquake than during the period from July 2001 through February 2011, and it continued to gradually recover after the Eastern Shizuoka earthquake.

Keywords: b-value, Mt. Fuji, 2011 Eastern Shizuoka Earthquake

Present condition of submarged volcano, Teishi Knoll, off Ito, Eastern Izu Peninsula

*Toshiro Yamanaka[1], Yoshifumi Kawada[2], Takuro Noguchi[3], Mayumi Hatta[3], Kei Okamura[3]

1. Tokyo Univ. Marine Science and Technology, 2. Tohoku University, 3. Kochi University

Teishi Knoll is a submerged volcano belonging to Eastern Izu volcanic zone and located c. 4 km east off the coastline of Ito City, Eastern Izu Peninsula. The volcano erupted in July, 1989, then the cone shaped knoll with a crater on the summit was formed. The Japan Meteorological Agency has reported that the Eastern Izu volcanic zone is composed of some small volcanoes including scoria cones, tuff rings, maars, and lava domes, erupted on land and many submerged volcanoes distributed densely on the seafloor off the coast. Detail of the submerged volcanoes has been unknown yet. The volcanoes have been considered to distribute on several lines of northwest-southeast direction reflecting the stress field of this area. Previous activities of the volcanic zone have been reported; Ohmuroyama Volcano was formed by eruption about 4 ka, Kawago-daira Volcano was formed about 3.2 ka, and Iwanoyama-Iwoyama volcanic chain was formed by a fissure eruption about 2.7 ka. The last eruption of the volcano belonging to the zone is considered the Teishi eruption in 1989.

In Japan there are confirmed 110 active volcanoes, 12 volcanoes of them are located below sea surface. Such submerged volcanoes have not been observed continuously due to its difficulty by visual observation, therefore, those volcanoes have not ranked according their activity by Japan Meteorological Agency. Therefore, we started observation of Teishi volcano in December, 2017, for evaluation whether active magma supply is still continuing or the intrusive magma causing of 1989 eruption is just cooling. Geochemical (water chemistry) and geophysical (heat-flow) observation has been done using training vessels of TUMSAT every half year.

We have not accumulated enough data yet, measurements of geothermal gradient were performed every time. For calculation of the heat-flow it is required the temperature record of the bottom water, so we started long-term temperature observation on the seafloor from the last December. On the other hand, chemistry of the bottom water in the crater showed slight positive anomaly of dissolved inorganic carbon and significant positive anomaly of manganese relative to the bottom water obtained from outside of the crater. Those chemical anomalies suggest that any thermal activity is still alive in the volcano.

Descriptions and age of volcanic products before the caldera formation in the northern part of Izu-Oshima, off Tokyo, Pacific Ocean

*Satoshi Terayama[1], Takehiko Suzuki[1], Makoto Kobayashi[2]

1. Tokyo Metropolitan University, 2. Research Center for Volcanic Hazards and Their Mitigation, Tokyo Metropolitan University

Introduction

Izu-Oshima Volcano erupted in 1986 is an active volcano that will erupt in near future. The volcano has been studied for a long time, and many studies has been conducted (Nakamura, 1964; Koyama and Hayakawa, 1996; Kawanabe, 2012 and so on). However, most previous studies focused on ″Syn-and post-caldera volcano″ (Kawanabe, 1998) after the caldera formation of Izu-Oshima Volcano. There are few studies discussed ″Younger Edifice of Pre-caldera volcano″. In this study, the purpose is to investigate the volcanic products of Younger Edifice of Pre-caldera volcano and older period with little investigation and to clarify the eruption history. The description of the volcanic products should be important in considering prediction of volcanic eruption and volcanic disaster prevention.

The study site is a coast called Goishihama located between the Chigasaki and Kazehayasaki capes in the northernmost part of Izu-Oshima. At the site volcanic products are exposed on the coasted cliff with a width of about 1 km and a height of about 30-40 m. Volcanic products that can be observed along Goishihama are described by Isshiki (1984), who reported mainly volcanic product of ″Okata volcano″ and ″Older Edifice of Pre-caldera volcano″. However, its description is limited, and description and discussion of fall-out tephra have not been done. In this study, we investigated volcanic products that are exposed on the sea cliff of Goishihama. As a result, some new views on the observable layer were obtained.

Results

The fall-out tephra group composed of 31 eruptive products is named ″Goishihama fall-out tephra group″. We sampled black humus buried soil from three horizon in ″Goishihama fall-out tephra group″ and determined the radiocarbon age. Ages are 11076-10713, 12027-11747, 18117-17803 cal BP in descending order. Therefore, it was revealed that ″Goishihama fall-out tephra group″ is the volcanic products of ″Younger Edifice of Pre-caldera volcano″ after 20 ka. Isshiki(1984) showed no description of the volcanic products of ″Younger Edifice of Pre-caldera volcano″ at Goishihama. As a future issue, it is necessary to correlate Goishihama with 95 fall-out of O1 to O95 distributed mainly in southwest part of the island by Tazawa (1980).

In addition, a fine white pumice with a diameter of about 1 mm was found slightly in the ″Goishihama fall-out tephra group″. After sampling the layer, we washed and observed it with a microscope, colorless and transparent pumice type volcanic glass shards were discovered. The chemical composition of the volcanic glass was measured, that is, SiO_2=78.07 wt.%, CaO=0.61 wt.%, FeO=0.75 wt.%, Al_2O_3=12.74 wt.%, K_2O=3.29 wt.%, showing a rhyolitic tephra. Therefore, it is not a tephra from the Izu-Oshima volcano formed by basaltic magma. The source of this rhyolitic tephra seems to be Kozushima Volcano or Niijima Volcano. These results suggest that ″Goishihama fall-out tephra group″ is the products of ″Younger Edifice of Pre-caldera volcano″ and that this rhyolitic tephra can be compared with O55 (Niijima Miyatsukayama tephra) (Saito et al., 2007). Thus, in this study, a new radio carbon age was obtained from Goishihama, and a rhyolitic tephra was newly discovered. The future issue is to correlate tephra in the outcrop of this study site with those in other outcrops, and it is needed to confirm the correlating of rhyolitic tephra.

Time change of p-value by Schuster method using earthquakes around Izu-Ohsima summit

*Hiroyuki Takayama[1]

1. Volcanological Division 1st labolatory, Meteorological Research Institute

Morita et al.(2016) and Morita et al.(2017) consider relation between volcanic earthquakes in Izu-Ohsima island and earth tide. Takayama et al.(2018) divide Izu-Oshima into 5 area and calculate p-value and consider relation between earthquakes and earth tide.

We use Schuster method (Schuster (1897)) whether occurrence of earthquake relate earth tide or not. This method is check null hypothesis of no correlation between earthquake occurrence and earth tide. Specifically, we set tide phase angle of earthquake occurrence as Di,

$$R=(\sum \cos Di)^2+(\sum \sin Di)^2$$

$$p=\exp(-R/N)$$

we test relation between earthquake occurrence and earth tide by this p-value. P-value falls in 0 to 1. If p-value is nearly 0, we reject null hypothesis. We calculate tide phase angle to each tidal component. In this research, we use principal lunar semi-diurnal tide (after this, we abbreviate M2).

In principal, if earthquake catalogue contain swarm, we can’ t calculate precise p-value. So, we avoid this problem to decluster catalogue.

In this study, we investigate time change of p-value in summit earthquakes. Detection capability of JMA catalogue in summit area is magnitude 0.0. After we decluster this catalogue, p-value is 0.011. So, we divide summit earthquake by time and calculate p-value of M2 in each group.

Specifically, we use JMA catalogue from April 2002 to January 2017. We pick up earthquakes of Izu-Ohsima summit. The number of earthquakes larger than magnitude 0.0 is 1084. After declusterd, the number of earthquakes is 901. We pick up 100 earthquakes from declusterd catalogue. We calculate p-value by M2 in 801 earthquake lists.
As a result, p-value increase and decrease periodically in time. Maximum is 0.98, minimum is 0.0030. If we select standard of rejection of null hypothesis as 0.05, periods of p-value less than this standard are around 2006, around 2010 and around 2014. Morita et al.(2017) suggest that release of volatile component from magma increase when earthquakes correlate earth tide. In the above three periods, release of volatile component increase possible. Also, Morita et al.(2017) suggest that release of volatile component from magma increase from 2013. This coincide with 2014 period.

Standard stratigraphy and characteristic properties of late Quaternary tephras on the Niijima-island: Report of geochemistry and refractive indices of volcanic glass shards, orthopyroxene, hornblende, and cummingtonite

*Kaori Aoki[1], Makoto Kobayashi[1], Fumikatsu NISHIZAWA[1,2], Masanori Murata[1], Daisuke Ishimura[1], Takehiko Suzuki[1]

1. Research Center for Volcanic Hazards and Their Mitigation, Tokyo Metropolitan University, 2. Mount Fuji Research Institute, Yamanashi Prefectural Government

Tokyo Metropolis has the twenty-three wards, the Tama district, and the islands area. The population of the islands area is 25,353 (1st January 2019). The islands area, namely, the Izu-Ogasawara Islands consist of 21 volcanoes (islands and submarine volcanoes), excluding some islands. For residents in this area, volcanic disasters are always the threat. Accordingly, to integrate the fundamental information for preventing volcanic disasters, we investigate the history of volcanic activities, the pattern of each eruption, and the mass volume of erupted tephras and try to establish the high-resolution tephrochronology (Kobayashi *et al.*, 2019a,b). This project focuses on establishing the database of tephras collected form each island of the Izu Islands and their petrographic description and geochemical data. Also, it is likely that such tephra across the sea would deposit in the hemipelagic sediment around volcanic islands. Our tephra database of the Izu Islands has been a powerful tool to identify the source of marine tephra bearing in drilled core CK09-03,C9010E collected at the site of 100 km east from the Izu Island, off the Boso Peninsula (Aoki et al., 2019). Today, we present the petrographic and geochemical characters of many tephras provided through volcanic activities of the Niijima island during late Quaternary.

At the Daisan-yama, Fujimi Touge, and Miyatsukayama on Niijima island, and also Jinaijima off 1.6km west of Niijima island, we have recognized 21 eruptive events at least, including some tephras derived from off-island (Kobayashi *et al.*, 2019a). Kobayashi et al. (2019a) recognized as Niijima Origin tephra felsic magma events and mafic magma events on Nijjima islnad. On the island, as widespread marker tephra, AT and K-Ah tephra were detected. After tephra samples were washed by the ultrasonic cleaner, we collected the description of petrographic characters, major-element chemistry determined by EDS and refractive indices (RI) of volcanic glass shards, orthopyroxene, hornblende, and cummingtonite in each tephra. Generally, felsic tephra derived from vents on the Niijima island include often a small amount scoria grain. Most felsic tephras consist of felsic volcanic glass shards, and including plagioclase, quartz (including β-quartz), orthopyroxene, hornblende, cummingtonite, and occasionally biotite. The characteristic fact of Niijima Origin tephra is that RIs of heavy minerals (orthopyroxene and hornblende) has broad variations. Especially, RIs of orthopyroxene in Akasakimine tephra series, Miyatsukayama tephra series, and Miyatsukayama Nannbu tephra series show the bimodal or trimodal histograms within the limit of 1.700-1.730, including high RIs over 1.730 slightly, considered as close to ferrosilite. Also, there is the tendency that RIs of hornblende in Akasakimine tephra series and Miyatsukayama tephra series show the bimodal histograms or broad variations within the limit of 1.663-1.688. On the other hand, RIs of cummingtonite in Niijima Origin tephra during 60 ka show the unimodal histograms within the limit of 1.658-1.669. RIs of felsic volcanic glass shards in Niijima Origin tephra show within the limit of 1.492-1.501. By comparison that common range of RIs on Quaternary tephra in Japan is 1.501-1.505 (Machida and Arai, 1992), RIs of Niijima Origin tephra would be classified to lower RI groups in Japanese Quaternary tephras.

©2019. Japan Geoscience Union. All Right Reserved.

The content of SiO_2 in volcanic glass shards is 77.7-78.2 wt%, Na_2O+K_2O is 7.2-7.7 wt% generally, excluding some tephra which range is within the limit of 7.0-8.3 wt%. The content of FeO* is 0.7-1.0 wt% and high-SiO_2 is harmonious to the lower RIs of volcanic glass shards (Furuta *et al.*,1986; Kikkawa, 1990).

Tephrostratigraphy and its eruption history of the Latest Activity in the Kozushima Volcano, the Izu Islands

*Makoto Kobayashi[1], Masanori Murata[1], Fumikatsu NISHIZAWA[2], Takehiko Suzuki[1,3]

1. Research Center for Volcanic Hazards and their mitigations, Tokyo Metropolitan Univ., 2. Fuji Research Institute, Yamanashi Prefectural Government, 3. Department of Geography, Tokyo Metropolitan Univ.

In this study, we defined the younger eruptive activity since the eruptive event of Chichibuyama A tephra (ca. 22–26 ka; Suga et al., 1992, 2003) composed of pyroclastic deposits from the southern part of Kozushima covering the whole island as "the Latest Activity". In order to establish the tephrostratigraphy during this period, we are aiming to construct more detailed eruption history of Kozushima Volcano.
As a result of the topographical interpretation using DEM, we recognized Tenjo-san edifice (pyroclastic cone and lava domes), Kobeyama-Hanadateyama volcanic chain (lava domes) and Kushigamine (pyroclastic cone) as younger volcanic landforms presumably formed by the Latest Activity.

In addition, according to the geological survey, we recognized deposits associated with eight eruptions events in minimum. At Loc. 16 in the north part of Nachi-san, northern Kozushima, we recognized pyroclastic surge deposit composed of alternate layers such as pumice, volcanic lapilli and coarse ash so on (no. 16-1; Tenjo-san Tephra (AD 838)), fall-out deposit including altered volcanic blocks and lapillus (no. 16-2), medium to fine fall-out ash deposit (ca. 10 cm in thickness) containing pumice clasts (no. 16-3), densely scattered zone composed of scoria clasts with diameter of several mm (no. 16-4) and densely scatter zone composed of coarse volcanic ash (no. 16-5) in descending order. On the other hand, at the Akabane-tunnel (Loc. 4) in southern Kozushima, Tenjo-san tephra (no. 4-1), densely scattered zone composed of coarse ash (no. 4-2), medium to fine volcanic ash deposit (ca. 3 cm in thickness) containing pumices (no. 4-3), densely scattered zone composed of scoria clasts with diameter of several mm (no. 4-4), fine volcanic ash deposit with a thickness of ca. 9 cm (no. 4-5) and pyroclastic surge deposit composed of alternated layers such as volcanic lapilli and coarse ash (no. 4-6) in descending order. Widespread tephra of K-Ah was detected between no. 4-2 and no. 4-3. Among these eruption deposits, it is suggested that the eruption of no. 16-2 occurred around central to northern part of Kozushima because these deposits distributed only these areas. In contrast, medium to fine air fall ash deposits (no. 16-3 and no. 4-3) containing pumices and fall-out fine ash deposit (no. 4-5) are very prominent layers, then, we are deeming these deposits as widespread tephras originated by relatively larger eruptions. ^{14}C datings for charcoal scattered in tephric loess or humus soil just below tephra layer were applied. ^{14}C ages are 1300±20 yr BP under the fall-out ash deposit correlated with the no.16-2 (Loc. 15; 262 m lava dome), 5790±30 yr BP at top of the no. 4-2, 8850±30 yr BP and 9390±30 yr BP above and below the no. 4-3, respectively, and 12030±30 yr BP just under the no. 4-6. Considering the calendar years and tephrostratigraphic relation, the ages of tephras during Latest Activity comprises five eruptions of ca. 1.1-1.2 ka (no. 16-2), ca. 7.5 ka (no.16-3 and no. 4-3), ca. 10 ka (no. 4-4) and ca.13.5 ka (no. 4-6).

Currently, we are further collecting data on mineral compositions, the refractive indexes and the major element compositions of volcanic glass shards for each tephra, and we are studying from the viewpoint of correlation with eruption deposits from Kobeyama-Hanadateyama volcanic chain, and Niijima Volcano origin tephra (Miyatsukayama, Shikinejima and Miyatsuikayama South: Kobayashi et al., 2018). In the presentation on the day, we will report the eruption history of the Latest Activity of Kozushima Volcano based on the results of these studies.

Characteristics of hypocenter distribution connected with velocity structures in and around Miyakejima, Kozushima and Hachijojima volcanoes

*Hiroko Hagiwara[1], Hidefumi Watanabe[1]

1. Tokyo Metroplitan Government

The aim of this study was to examine the characteristics of seismic activities in association with the seismic velocity structures in and around the Izu islands. We focused on three seismic activities, the swarm off the west coast of Miyakejima on April 2013, the swarm off the northeast coast of Kozushima on April 2018 and the low frequency earthquakes beneath Hachijojima from 2003 to 2018. To construct the 3-D velocity structure models for Miyakejima and Kozushima we used the data of the swarm accompanied with the 2000 Miyakejima eruption, while for Hachijojima we used the data from 2003 to 2018 based on the Izu islands volcanic observation system. These travel times were adopted to the tomographic inversion method (Zhang and Thurber, 2003). The relocated precise hypocenters on the velocity imaging maps revealed an interesting relationship between seismicity and structure. In the target region, both Miyakejima and Kozushima swarms occur at 5-10 km and 2-6 km depth, in the border of high-velocity zones adjacent to or underlain by the low-velocity zones in figure 1 and figure 2. Their swarm regions were located nearby the two end sides of the 2000 swarm, where the huge seismic activity occurred repeatedly. That suggests the upward moving of magmatic fluids. In contrast, the Hachijojima earthquakes occur at 10-14 km depth in the middle-velocity area around a high-velocity zone in figure 3. This high-velocity zone is supposed to be somewhat cold body beneath Nishiyama volcano in Hachijojima. We interpret that the former low-velocity zones consist of hot magmatic materials and the latter high-velocity zone consists of the solidified volcanic body. On the basis of three case studies, it is suggested that volcanic fluids derived from hot magma or solidified magma caused the upper or surrounding seismic activities through complex crack systems.

Deformation of Miyakejima volcano measured by GNSS campaign observation (2013-2015)

*Haruna Watanabe[1], Takeshi Matsushima[2], Miyo Fukui, Atsushi Watanabe[3], Jun Oikawa[3], Takashi OKUDA[4], Taku Ozawa[5], Yosuke Miyagi[5]

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University, 2. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, 3. Earthquake Research Institute, University of Tokyo, 4. Earthquake and Volcanology Research Center, 5. National Research Institute for Earth Science and Disaster Resilience

Miyakejima is an active volcano located about 180 km south of Tokyo, and since the 20th century it erupted at intervals of about 20 years (1940, 1962, 1983, and 2000). Fukui et al. (2015) conducted GNSS campaign observations and estimated the pressure source of Miyakejima from 2011 to 2013. Therefore, in this research, we estimated the crustal deformation of Miyakejima from 2013 to 2015, the position of the pressure source and the volume change, and estimate the temporal change of the pressure source of Miyakejima.

We conducted GNSS campaign observations at 15 reference points arranged so as to be distributed almost evenly throughout Miyakejima from 2 September to 6 September 2013 and from 31 August to 4 September 2015. We used the data obtained from this GNSS campaign observation and the data for the same period of continuous observation points established by the Geospatial Information Authority of Japan etc. In order to analyze the obtained data, the coordinate value of the observation point for each year was obtained using RTKLIBver.2.4.2 software (Takasu et al., 2007).

The pressure source was estimated based on horizontal displacement from 2013 to 2015. The optimum value of the variation was obtained by using MaGCAP-V software (Meteorological Research Institute, 2008) for analyzing crustal activity for volcano. Although the positions of the pressure sources have not changed significantly from 2011 to 2013, it is presumed that the pressure source at the depth of about 0.3~8 km continues to contract and the pressure source at the depth of about 13 km continues to expand.

This work is partly supported by MEXT under Earthquake and Volcano Hazards Observation and Research Program, and also supported by Earthquake Research Institute, The University of Tokyo under Joint Usage Program.

Characteristic properties of distal and proximal tephras in the Mikurajima Island, Izu Islands.

*Tomohiro Tano[1], Takehiko Suzuki[1,2], Makoto Kobayashi[2], Masanori Murata[2]

1. Faculty of Urban Environmental Sciences, Tokyo Metropolitan University, 2. Research Center for Volcanic Hazards and Their Mitigation, Tokyo Metropolitan University

Mikurajima of the Izu Islands is the stratovolcano island and located at 200 km south of Tokyo. The latest volcanic activity is about 6,300 years ago, there is no eruption activities in history. Mikurajima volcano is characterized by high occurrence frequency of andesite in volcanic front on the Izu arc(Isshiki,1980). Study on tephras distributed in the Mikurajima volcano has been reported by Sugihara & Shimada(1999),and Sekiguchi et al.(2001).They reported 6 tephra in Mikurajima island.(From the top Kozushima Tenzyosan:A.D.838,Iz-Kt,latest eruption of Mikurajima volcano:Mk-3,Kikai-Akahoya:7.3ka(Machida & Arai,2003),red scoria originated Mikurajima:Mk-2,rhyolithic tephra with unknown source:Mk-G, and fall pumice Mikurajima volcano tephra:Mk-1).The latest tephra of Mikurajima volcano:Mk-3,erupted from the lava dome in the southeastern in part of the islands(Sugihara & Shimada,1999).However, comparison/identification is insufficient of tephra compared to Iz-Kt. So it is necessary to compare and examine the Niijima Mukaiyama tephra(A.D.886,Iz-Mk).
They are rhyolithic tephra and indicated SiO2=77-79 wt.%. They erupted same age and constituent minerals and the refractive index of volcanic glasses are similar. So difficult to identify in distal place. Recently both can be distinguished by content of K2O in volcanic glasses. Iz-Kt indicated high K2O content compared with Iz-Mk. Both tephras are important indicator tephra widely distributed in the Izu islands. So it is important to clarify Iz-Kt distribution on Mikurajima.
In this research, we report on the tephras confirmed in Mikurajima. We found 18 tephras on Mikurajima island, and 4 tephras are confirmed(Iz-Kt,Mk-1,2,3).
1)The tephra confirmed Iz-Kt in previous study, we performed refractive index measurement by RIMS2000 and principal component analysis by SEM-EDS for volcanic grasses. This tephra present cryptotephra in topsoil. This glasses is pumice type and reflective index indicated n=1.496-497.Principal component:SiO2=77.0-78.5 wt.%,Al2O3=12.5-13.0 wt.%,FeO=0.5-1.3 wt.%,CaO=0.2-1.7 wt.%,K2O=2.7-3.9 wt.% and Na2O=3.6-4.6 wt.%.Iz-Kt and Iz-Mk confirmed on the Izu islands,they shows 3.8 wt% and 3.5 wt.% K2O content, respectively. So this tephra confirmed Iz-Kt.
2)For the latest tephra on Mikurajima volcano Mk-3,it is bad foaming yellow pumice between black volcanic sand.Maximum particle size of pumice is 10cm and maximum layer thickness is over 200cm.The lithophasies of MK-3 shows Prinian eruption.However,the detail of Mk-3 are unknown and under consideration.We performed principal component analysis as well.As a result,SiO2=62.3-70.7 wt.%,Al2O3=14.8-21.0 wt.%,FeO=2.2-3.8 wt.%,CaO=4.1-7.5 wt.%,K2O=0.3-0.9 wt.%,Na2O=3.8-4.4 wt.%.The values indicate andesite-dacite.
As a future work,to find and confirmed indicator tephra originated another volcano (like Iz-Kt and Mk-G).By comparing and identifying indicator tephra, I believe that we provide new distribute axis and age axis for history of eruption history in Mikurajima and tephra in the Izu Islands.And it is important to grasp detail of Mk-3 which is the latest eruption of Mikurajima volcano in order to grasp the volcanic activity of Mikurajima.

Pseudo thermal anomalies in the shortwave infrared bands of the Himawari-8 AHI and their correction for volcano thermal observation

*Takayuki Kaneko[1], ATSUSHI YASUDA[1], Yoshizaki Yoshito[2], Takasaki Kenji[3], Yoshiaki HONDA[4]

1. Earthquake Research Institute, University of Tokyo, 2. Meteorological Satellite Center, Japan Meteorological Agency, 3. Japan Fisheries Research and Education Agency, 4. Center for Environmental Remote Sensing, Chiba University

Volcanic eruptions bring high-temperature gas or magma to the surface. Therefore, thermal observations of volcanic eruptions can be used to investigate the timeline of eruptive sequences. Eruptive activity includes processes that can change over short periods of time, which is sometimes related to the eruptive mode or the timing of its transitions. If we could observe short-term eruptive processes by detecting thermal changes, this would be beneficial for analyzing the eruptive sequence of volcanoes. Himawari-8 is a meteorological geostationary satellite operating above the equator at a longitude of 140.7 deg E and carrying a newly developed sensor, the Advanced Himawari Imager (AHI). With its improved performance, the Himawari-8 AHI enables the collection of high-frequency thermal observations that had never been obtained before. However, while observing volcanoes with the AHI, we noticed a frequent thermal anomaly in the nighttime 1.6-um and 2.3-um images. Because this anomaly occurred regardless of volcanic activity, it was considered to be a pseudo thermal anomaly. In-depth examination of the AHI observation data for several inactive volcanoes showed that the pseudo thermal anomaly was often seen around the vernal and autumn eclipse periods, and its in?uence persisted for about 6 months of each year. Further, daily variation of the anomaly peaked when it was midnight in the areas around 140 deg E. At this time and position, the AHI was facing the sun, suggesting that the anomaly was caused by stray light. We devised a correction method by assuming that the observed thermal radiance in a pixel consists of components from the radiating volcanic ground surface and stray light contamination. The latter can be estimated using values from nearby inactive pixels. Thus, the component from the radiating volcanic ground surface can be obtained by subtracting the estimated stray light from the observed thermal radiance. We evaluated the validity of this method using data from the 2017 Nishinoshima eruption and found that it satisfactorily removed the stray light component. An adoption of this correction allowed us to use all nighttime 1.6-um and 2.3-um images obtained by the AHI, half of which were formerly unusable due to the degradation caused by stray light.

Shallow earthquakes in Unzen Volcano inferred from dense seismic observation and resistivity structure

*Hashimoto Tasuku[1], Koki Aizawa[2], Takeshi Matsushima[2], Hiroshi Shimizu[2], Yuto Hayashida[1], Yuhei Yuasa[1], Kaori Tsukamoto[1], Yuto Yamamoto[3], Kanta Miyano[3], Megumi Kamizono[1], Satoshi Matsumoto[2]

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University, 2. Institute of Seismology and Volcanology, Faculty of Science, Kyushu University, 3. Department of Earth and Planetary Sciences, School of Science, Kyushu University

Unzen volcano is a stratovolcano located in central part of the Shimabara peninsula of Kyushu Island, Japan. During the eruption periods 1991-1995, the seismicity was vigorous at shallow level beneath the Heisein-Shinzan lava dome (Umakoshi et al., 2001), then the number of shallow earthquakes decreased significantly after the eruptions. However, since 2010, the number of shallow earthquakes have been increasing steadily beneath Mt. Fugen and Heiseishinzan lava dome (Japan Metrological Agency (JMA)). The most of the hypocenters were estimated 1 to 2 km below sea level, while importantly, several earthquakes were located above sea level since February 2017. The P-wave arrivals of the earthquakes above sea level show the downward motion at all stations of JMA, MLIT, and Kyushu university. The coda, which shows relatively longer period oscillation, continues approximately 20 to 30 seconds. According to JMA, this type of shallowest earthquakes has occurred 5 times in 2018. Mildon et al. (2016) reported the similar non-DC earthquakes at Krafla volcano, Iceland, and suggested closing clacks model to explain the observation.

In order to explore the shallow earthquake activity beneath Unzen volcano, we established (1) 12 seismic stations around Mt. Fugen and Heisei-Shinzan lava dome in August, 2018. In addition, (2) broad-band magnetotelluric (MT) observation was conducted in October and November, 2018 to estimate subsurface resistivity structure. We recorded telluric fields at 12 sites around Mt. Fugen and Heisei-Shinzen lava dome, and recorded MT fields at two sites at the mid flank of the Unzen volcano. The main purpose of this study is to investigate the relationship between the shallow earthquakes and volcanic fluids beneath Unzen volcano. In particular, the locations and initial motions of the shallowest earthquakes are investigated. We will present the preliminary analysis of the shallow earthquakes obtained from the dense seismic records, and the preliminary resistivity structure.

Characteristics of shallow volcanic earthquakes beneath the summit of Unzen Volcano

*Kanta Miyano[1], Hiroshi Shimizu[2], Takeshi Matsushima[2], Satoshi Matsumoto[2], Koki Aizawa[2], Hashimoto Tasuku[3], Yuto Hayashida[3], Yuhei Yuasa[3]

1. Department of Earth and Planetary Sciences, School of Science, Kyushu University, 2. Institute of Seismology and Volcanology, Faculty of Science, Kyushu University, 3. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University

Unzen Volcano is located in the central part of the Shimabara peninsula, western Kyushu, Japan. The last eruption took place in 1990-1995, and a lava dome complex was formed during the eruption. High level seismicity was observed before and during the eruption. In particular, isolated tremor occurred in the volcanic edifice above sea level preceding the lava dome emergence (Shimizu et al., 1992). Predominant frequencies of the isolated tremor’ s waveforms were comparatively low (2 - 4 Hz) and the duration was long (30 - 180 s). Moreover, extremely-shallow earthquakes occurred beneath the growing lava dome. Unzen Volcano has been in dormancy since the end of the 1990-1995 eruption. However, shallow volcanic earthquakes have been observed below the summit since 2010, and the hypocenters are determined by Japan Meteorological Agency (JMA) and Institute of Seismology and Volcanology, Kyushu University (SEVO). In order to reveal the generation mechanism of these earthquakes, we investigated the characteristics of the hypocenters and wave forms.

First, we relocated the hypocenters of these earthquakes from Jan. 1 to Sep. 7 2018. The relocated hypocenters are distributed beneath the lava dome and Mt. Fugen, and they are classified into 3 groups. Focal depths of Group 2 and 3 are located 1km and 2km below sea level under Mt. Fugen, while Group 1 (three earthquakes in this period) locates above sea level beneath the lava dome. The first motions of P-waves for Group 1 are all “down” in this study, and the duration times are longer than those of Group 2 and 3.

Next, we calculated particle motions of these earthquakes using relocated hypocenters. The result indicates that the earthquakes of Group 2 and 3 have clear P and S phases, which are similar to tectonic earthquakes. On the other hand, no obvious S phase is recognized in the seismograms of Group 1.

Spectral analysis shows that the seismograms of Group 1 are lacking in high frequency components and the low frequency (2 - 5 Hz) is dominant compared with Group 2 and 3.

We will discuss candidates for the source mechanism of these earthquakes based on the results of wave form analyses.

Pyroclastic deposits and the stratigraphy on the outcrop to north east from Mt.Unzen

*Daisuke Nagai[1]

1. Mt.Unzen disaster memorial hall

Pyroclastic flows occurred at many times during formation of lava dome on the Heisei eruption of Mt.Unzen. There were some studies of pyroclastic flows on Mt. Unzen (Kobayashi and Kato, 1985). After the Heisei erupyion many studies reported about it (Kobayashi and Nakada, 1991, Watanabe and Hoshizumi, 1995). It is important about understanding the characteristics of the volcano from the past activities. In this study, the pyroclastic deposits and the stratigraphy 150ka on Mt.Unzen be reported.

Relative gravity changes in Aso Volcano (Kumamoto Prefecture) observed from 2015 to 2018

*Yusuke Miyauchi[1], Takahito Kazama[1], Yoichi Fukuda[1], Shin Yoshikawa[2], Takahiro Ohkura[2], Jun Nishijima[3], Yasuhiro Fujimitsu[3]

1. Graduate School of Science, Kyoto University, 2. Aso Volcanological Laboratory, Kyoto University, 3. Graduate School of Engineering, Kyushu University

Gravity measurement is one of the most effective methods to understand mass variations due to volcanism. In Aso Volcano, Kumamoto Prefecture, spatiotemporal gravity variations have been monitored by repeated relative gravity measurements every several years since 1964 (Yoshikawa et al., 2009). Gravity data was frequently collected 3-4 times every year during the active period of Aso Volcano from 2011 to 2016 and revealed spatiotemporal variations in hydrothermal mass under the volcano (Sofyan et al., 2016). However, any gravity data has not been collected after March 2016 due to Kumamoto Earthquake which occurred in April 2016. Since the volcanism became quieter after a phreatic explosion was observed in October 2016, a series of volcanic activities including the quiet period should be discussed in terms of mass variations to predict future volcanic activities. In order to monitor gravity changes in Aso Volcano after the volcanically active period, we repeated relative gravity measurements in May, August and November 2017, and in March, May, August and November 2018. We measured relative gravity values at gravity points around Aso Volcano using CG5 relative gravimeters owned by Kyushu University and Aso Volcanological Laboratory (CG5-KYU and CG5-AVL, respectively) and a LaCoste relative gravimeter G680 owned by Graduate School of Science, Kyoto University (LC-G680). We also collected continuous gravity data using CG5-AVL at the AVL station even when it was not used for the campaign gravity measurements, in order to understand the long-term instrumental drift. A gravity value relative to AVL was obtained for each point and survey, by correcting the effects of instrumental height, tide, instrumental drift, and scaling factor. The spatiotemporal absolute gravity data was then calculated, using the absolute gravity values measured at reference stations. We finally estimated the spatial distributions of the absolute gravity change around Aso Volcano before and after Kumamoto Earthquake. We found that the absolute gravity increased at the gravity points around the Aso crater. Since this absolute gravity change includes the effect of crustal deformation due to Kumamoto Earthquake, we subtracted the effect from the absolute gravity values using the quasi-vertical deformation data derived from the InSAR analyses (Geospatial Information Authority of Japan) and the typical gravity gradient value of -0.2 mGal/m. We found that the residual of the absolute gravity change still increases by up to 0.1 mGal at the areas of Kusa-senri and the Naka-dake crater, which implies mass accumulation under these areas. In the future, we will model time variations of the volcanic mass distributions in the volcano and compare them with the spherical pressure source proposed by the leveling data (Sudo et al., 2016). In addition, the gravity data should be repeatedly obtained and reprocessed more accurately, by considering the spatial variation of the gravity gradient value and correcting the effect of ground deformation using the continuous GNSS data.

In Aso volcano, leveling survey has been conducted since 1937 by Kyoto University. As a result of these surveys, subsidence in Kusasenri about 3km west-southwest of Naka-dake crater has been observed. And this subsidence was considered to be caused by a contraction source located at about 3km west of Naka-dake crater with a depth of 4 to 6 km (Sudo et al. 2006). A seismic tomography study showed a low velocity zone of a 2 to 3 km diameter located at a depth of 6km in Kusasenri (Sudo and Kong, 2001), almost in accordance with the position of contraction source. Therefore, this low velocity zone is considered to correspond to a magma chamber.
We conducted a first-order leveling survey at Aso volcano during the period from Sep.30 to Oct.6 2018, for the first time since 2012 and after the 2016 Kumamoto Earthquake. As a result, mean square errors of the conducted survey were ranging from ±0.18 to ±0.21 mm/km.
From the obtained survey data, we calculated the relative height of each bench mark referred to a bench mark (960701A) which corresponds to GEONET 960701 GNSS station, located at the south-western foot of central cones of Aso volcano. We also calculated the height difference of 960701A between September 2012 and September 2018, using F3 solutions of GEONET, resulting in the vertical displacements of the benchmarks during the period from September 2012 to September 2018.
It was found that the obtained displacements show ground accordance with 2.5-D surface deformation of the 2016 Kumamoto earthquake detected by SAR interferometry. Therefore, we can conclude that the vertical displacements in Aso volcano detected by leveling survey are attributed to the surface deformation during the 2018 Kumamoto Earthquake.

Introduction

Caldera-forming eruptions are the most destructive type of volcanic activity and exert a great influence on the Earth’ s surface. Therefore, the underlying magmatic mechanism leading to caldera-forming eruptions is of fundamental importance in volcanology. The Aso volcano is the largest (18×25 km in diameter) caldera in the southwestern Japan Island Arc and formed through four large eruption cycles. In this study, we have investigated the evolution of magmas that erupted during the second youngest cycle among the four cycles, the Aso-3 cycle at 123 ka. It ejected >150 km^3 of pyroclasts that are divided into the following four units in stratigraphic ascending order: 3W, a plinian pumice fall deposit; 3A, a pumice flow deposit containing dominantly aphyric pumice and glassy ash; 3B, a scoria flow deposit characterized by abundant aphyric scoria; and 3C, a scoria flow deposit consisting mainly of porphyritic scoria and glassy ash matrix.

On the basis of major and trace element compositions and Sr-Nd-Pb isotope ratios of whole rocks as well as phenocrysts, Kaneko et al. (2015) argued that the pre-eruptive magma chamber was chemically stratified from a mafic lower part to a felsic upper part. The previous study further estimated water contents in the melts using the hygrometer based on plagioclase-melt partitioning of anorthite-albite components (Lange et al., 2009), but the estimates have large uncertainty. Here we determined hydrogen contents of plagioclase phenocrysts. By combining the hydrogen contents with major and trace element compositions of the plagioclase phenocrysts, this study aims to better understand pre-eruptive magma evolution and water behavior of the Aso-3 cycle.

Methods

Plagioclase as well as pyroxene and oxide mineral phenocrysts were separated from pumices of 3W, an obsidian clast of 3A, a welded clast of 3B, and a pumice clast of 3C. Major and trace elements in phenocrysts were quantified by electron probe microanalyzer (EPMA) and laser ablation-inductively

©2019. Japan Geoscience Union. All Right Reserved.

coupled plasma-mass spectrometry (LA-ICP-MS), respectively. In LA-ICP-MS analysis, Ca contents measured by EPMA were used for internal standard normalization. OH contents in plagioclase phenocrysts were determined by secondary ion mass spectrometry (SIMS).

Results

Anorthite contents (#An) of plagioclase phenocrysts are variable even in individual units, but show the systematic increase in ascending order, consistent with the results of Kaneko et al. (2015). REE patterns of plagioclase and pyroxene show positive and negative Eu anomalies, respectively. Plagioclase Ce content degreases as #An increases (Figure 1). On the other hand, OH contents in plagioclase phenocrysts are significantly higher in 3W (~250 ppm) as compared to the others (<50 ppm) (Figure 2).

Discussion

OH contents in a plagioclase phenocryst of 3W are significantly higher than those of 3A-C, nevertheless Ce contents of plagioclase are not significantly different between 3W and 3A. Considering that the partition coefficients of Ce between anhydrous major minerals and melt are similar to those of OH, this finding suggests that H_2O was lost from the melt through gas exsolution or fractional crystallization of hydrous minerals. Alternatively, given the fast diffusion of hydrogen relative to Ce in plagioclase, it may be attributed to secondary loss of hydrogen from plagioclase phenocrysts of 3A-C during welding processes. From the observation of thin sections of 3W and 3A, however, microlite was rarely observed, suggesting that the secondary thermal effects would be restricted for both 3W and 3A. Furthermore, little hydrous phenocrysts have been observed from ejecta of the Aso-3 cycle. Therefore, the results of this study suggest that gas exsolution and degassing occurred between the eruptions of 3W and 3A.

Relationship between duration of eruption tremor and eruption volume

*Azusa Mori[1], Hiroyuki Kumagai[1]

1. Nagoya University Environmental Studies

We studied the high-frequency seismic signals of eruption tremors during recent eruptions at various volcanoes and quantified their seismic source amplitudes (A_s) and cumulative source amplitudes (I_s) in the 5–10 Hz based on the assumption of isotropic *S*-wave radiation. A_s and I_s correspond to the maximum and the cumulative value of amplitudes at the source during eruption tremor. We previously found that the power law relations between A_s and I_s holds for eruption tremors. We also found the proportional relation between eruption rate and A_s for eruption tremors by comparing seismic and geodetic data during sub-Plinian eruptions at Kirishima. In this study, we further investigated time variations of eruption tremors and found the scaling relation between duration of eruption tremor and eruption volume.

We calculated the envelope width (p) using the estimated values of A_s and I_s and investigated the relation between p and I_s. p is defined as I_s/A_s and can be used as a parameter of duration (T) of a seismic envelope waveform (Kumagai et al., JGR, 2018). We found that p is proportional to 0.4 power of I_s. We also found that envelope waveforms of eruption tremors in 5–10 Hz have the following features; the amplitudes of envelope waveforms gradually increase, remain roughly constant during a certain period, and gradually decrease to the noise level. Moreover, p tends to increase with A_s. These envelope waveforms can be approximated as trapezoids, where A_s and T correspond to their height and lower base, respectively. We found that the ratios of upper to lower bases for these envelope waveforms are roughly constant. In this case, the proportionality between p and T holds. Based on the relation between eruption rate and A_s, eruption volume (V) is proportional to I_s. Therefore, the relation between p and I_s as shown above indicates that T is proportional to 0.4 power of V. We found that this proportional relation is consistent with the estimates of T and V for various Plinian eruptions compiled by Mastin et al. (JVGR, 2009). This indicates that the scaling relation between duration of eruption tremor and eruption volume in Plinian eruptions holds over a wide range of eruption size.

Crustal deformation accompanied with the eruption of Shinmoe-dake in early March 2018

*Tsuyoshi Watanabe[1], Takashi Yokota[1], Susumu Kurahashi[1], Kenta Enomoto[1]

1. Aichi Institute of Technology

Shinmoe-dake is a part of Kirishima volcano group composed of 20 Quaternary volcanoes located in southern Kyushu, Japan, erupted on 19 January 2011. This eruption began with a phreatomagmatic event including atmospheric vibration and eventually developed to subplinian eruptions within a week. From GNSS data, position and volume change of the magma chamber were estimated to be about 5 km to the northwest of the top of Shinmoe-dake at a depth of 8-9 km and 1.3×10^7 m^3. Shinmoe-dake erupted on 11 October 2017 after an interval of six years, however, this eruption ended in a week. While the extension of baseline length between the sites across Mt. Kirishima has been detected by GNSS observation since July 2017, indicating the possibility of magma accumulation. Eventually, the extension of baseline length led to eruption on 1 March 2018. In this study, in order to clarify the mechanism of the volcanic eruption, we investigated the crustal deformation accompanied with a series of volcanic activities occurred in early March 2018 at Shinmoe-dake by using GNSS data, then estimated the position of the magma chamber.

For the study, GEONET F3 solutions obtained by GNSS observation sites located mainly in the Kyushu district from 1 January 2013 to 25 March 2018 were used. Firstly, common mode bias was removed from time series of GEONET F3 solutions according to the method of Wdowinski et al. (1997). Secondly, visco-elastic deformation due to the 2016 Kumamoto earthquake was corrected by using a code of Fukahata and Matsu’ura (2005, 2006). In this time, we used the co-seismic fault model of Geospatial Information Authority of Japan (GSI, 2016) and calculated the visco-elastic deformation, where the calculation was conducted on the condition that an elastic material with thickness of 25 km lies on a Maxwell visco-elastic half-space with viscosity of 2×10^{18} Pas. Thirdly, to estimate elastic deformation due to subduction of the Philippine Sea plate (PH), we reproduced the upper surface of the PH by 170 rectangular faults based on the result of Hirose et al. (2008) and estimated coupling ratio. The Green’s functions of rectangular faults were calculated by the formula of Okada (1985). Using horizontal and vertical velocities of GEONET 150 sites between 1 January 2013 and 31 March 2016, we conducted a back-slip inversion analysis with smoothing constraint of coupling ratio among the adjacent faults. Assuming the interplate coupling obtained by the analysis continues after July 2017, we corrected the effect of the plate subduction from original data. After completing three processes above mentioned, finally, the positions of the magma chambers were estimated in two periods: inflation phase (1 July 2017–28 February 2018) and deflation phase (14 February 2018–25 March 2018) by using the Mogi’s model. We selected 7 GEONET sites located around Shinmoe-dake and estimated the positions of Mogi sources (longitude, latitude, and depth) corresponding to the two phases by performing a grid search in the ranges of 130.6-131.1˚every 0.001˚for longitude, 31.7-32.1˚every 0.001˚for latitude, and 4-15 km every 0.1 km for depth. The volume change of the Mogi sources were assumed to be 1.6×10^7 m^3 in the inflation phase and -0.7×10^7 m^3 in the deflation phase, according to the results of Japan Meteorological Agency (JMA). The result showed that the positions of the magma sources were estimated not to be just under the top of Shinmoe-dake but to be about 6-7 km to the northwest of it at a depth of 7-12 km. Although our result is generally consistent with that of JMA, the depth of the magma sources in the inflation phase was estimated to be approximately 4 km deep part. For the next step, we investigate the effects of topography and heterogeneous structure on crustal deformation.

Sources under Iwo-yama, Kirishima Volcanoes derived from GNSS observation and Precise leveling survey.

*Yuki Koga[1], Takeshi Matsushima[2], Kazunari Uchida[2], Dan Muramatsu[1], Yuichi Iwasa[1]

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu university , 2. Institute of Seismology and Volcanology, Faculty of Science, Kyushu University

At Iwo-yama that active volcano located in Ebino kogen volcanic area of Kirishima Volcanoes, fumarolic activity has risen again from December 2015 after dozen year's silence and suddenly increasing of seismicity (50 times and more a day) and volcanic tremors was observed several times. And phreatic eruption occurred in April 2018. Morita (2018) inferred inflation spherical pressure source as Mogi source from leveling survey between June 2015 and December 2015. The source's depth is about 700m beneath Iwo-yama and the source was considered that correspond with bottom of conductive layer inferred clay layer from MT survey (Tsukamoto et al., 2018). But, leveling can detect vertical displacement only and the inferred source is not considered horizontal displacement. So, we will improve pressure source inferred from leveling adding detect horizontal displacement from GNSS observation in this study.

As result of the observation, radial crustal deformation was detected several months before the occurrence of the phreastic eruption and after the eruption occurred. Estimating those displacement using an elevation-modified Mogi model, volume increse of the pressure source located at 700m depth below Iwo-yama was estimated. The depth of this pressure source coincided with the depth of the clay layer and it was found that the pressure source had expanded under the clay layer before the eruption occurred. But, for the GNSS observation point of the edifice before eruption, displacement which can’t be explained by the pressure source under the clay layer has been detected. This displacement is thought to be due to the rise of hot water to the shallow part as the pressure source under the clay layer expands.

We conducted GNSS continuous observation point around Iwo-yama established by Japan Meteorological Agency to verify the pressure source under the clay layer. As a result, displacements which can’t be explained by this model detected at these observation points. Using the GNSS continuous observation points throughout Kirishima, we estimated the pressure source of this displacement. Then, we could estimate the spherical pressure source located 7 km deep in the vicinity of Ebino-dake. This model is consistent with the source of crustal deformation before and after the eruption of Shinmoe-dake volcano in 2011 estimated by Nakao et al. (2018). Therefore, those displacement is thought to be due to volume change of magma chamber of Shinmoe-dake. In conclusion, the crustal deformation around Iwo-yama is due to these three sources, spherical pressure source under clay layer, displacement due to hot water rising to shallow part of Iwo-yama, magma chamber of Shinmoe-dake.

Regional vertical deformation around Aira caldera from GNSS data

*Kazuho Nakai[1], Masato Iguchi[2], Takahiro Ohkura[3]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, 2. Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University, 3. Aso Volcanological Laboratory, Institute for Geothermal Sciences, Graduate School of Science, Kyoto University

We investigated regional ground deformation around Aira caldera by analyzing vertical displacement observed by GNSS.

We used daily coordinate data from F3 solutions of GEONET stations in Kyusyu for periods from 1998 to 1999 and 2015 to 2016 when the ground uplift rate was larger than 18 mm/yr at 960719 station (North of Sakurajima). In order to increase number of stations, we analyzed RINEX data around Aira caldera and Sakurajima observed by Kyoto University and obtained daily coordinate data calculated based on the coordinates of the F3 solution of the GEONET stations closest to each observation point by using RTKLIB Ver. 2.4.2. The vertical displacement rate was estimated by removing the coseismic or antenna change steps and the annual and semiannual components. The ground deformation close to Kirishima volcano was affected by the pressure source located about 9 km beneath the Karakuni-dake (Nakao et al. 2013). We removed these effects causing inflation of the pressure source.

The ground within a radius of 20 km from the center of Aira caldera was uplifted in the both periods. The amount of uplift near the center of Aira caldera is larger than that in distant region and the largest uplift of station (25 mm/yr in 1998-1999 and 20 mm/yr in 2015-2016) was obtained at northern part of Sakurajima. In contrast, the ground subsidence was detected at distances from 20 to 30 km away from the center of the caldera during the period in 1998-1999 and from 30 to 40 km during the period in 2015-2016. The amounts of subsidence were about 3 mm/yr in the both periods.

We applied a model of dual source of Mogi-type (Mogi, 1958) to the ground deformation. In the period of 1998-1999, an inflation source was obtained at a depth of 10 km and a deflation source at a depth of 14 km beneath the Aira caldera. The amounts of volume change were estimated at about $+1.8\times10^7$ m^3 and -1.5×10^7 m^3, respectively. Similarly, in the period of 2015-2016, an inflation source was obtained at a depth of 10 km and a deflation source at a depth of 30 km. The amounts of volume change were estimated at about $+1.5\times10^7$ m^3 and -3.3×10^7 m^3, respectively. The order of volume change of the inflation source is almost same as the deflation source in the both periods.

The spatial distribution of the vertical displacement rate can be explained by the shallow inflation source and the deep deflation source. The shallow inflation source coincide with A-source beneath the Aira caldera (Hotta et al. 2016) corresponding to magma reservoir. Considering similarity of the volume changes, magma seems to move from to the shallow magma reservoir around 10 km deep from a deeper part.

Vertical ground deformation in Sakurajima volcano measured by precise leveling survey (during Nov. 2017 - Nov. 2018)

*Keigo Yamamoto[1], Takeshi Matsushima[2], Shin Yoshikawa[3], Hiroyuki Inoue[3], Tadaomi Sonoda[1], Kosei Takishita[1], Kazuho Nakai[1], Masaki Uchida[3], Ryo Oyanagi[3], Yoshinosuke Kamiya[2], Takahiro Ohkura[3]

1. Disaster Prevention Research Institute, Kyoto University, 2. Fuculty of Sciences, Kyushu University, 3. Gruduate School of Science, Kyoto University

We conducted the precise leveling survey in Sakurajima volcano, southwest Japan in November 2018, in order to evaluate the vertical ground deformation associated with the recent eruptive activity of the volcano. The leveling routes measured in this survey are about 21 km long in total, including Sakurajima western flank route and Sakurajima northern flank route. These leveling routes were measured during the period from November 12 to 29. As a result of the preparatory calibrations and careful measurements, mean square errors of the conducted survey were achieved with a good accuracy ranging from ±0.18 to ± 0.25 mm/km.
From the measured data, we calculated the relative height of each benchmark referring to the reference benchmark BM.S.17 which is located at the western coast of Sakurajima. The calculated relative heights of the benchmarks were then compared with those of the previous survey conducted in November 2017 (Yamamoto et al., 2018), resulting in the relative vertical displacements of the benchmarks during the period from November 2017 to November 2018.
The resultant displacements indicate the ground subsidence (-6.2 mm at maximum) at benchmarks around the central part of Sakurajima. The ground subsidence is also detected at benchmarks along Sakurajima northern flank route, suggesting that the inflation of the magma reservoir beneath Aira caldera was not remarkable during the period between November 2017 and November 2018. From the preliminary analysis based on a spherical source model (Mogi, 1958), the deflation source is located beneath Minamidake crater. The results indicate that the pressure decrease is suggested at the magma reservoir beneath Minamidake caused by the eruptive magma ejection.

Spatiotemporal gravity variations from the 1990s in Sakurajima Volcano, revealed by repeated relative gravity measurements

*Ryo Oyanagi[1], Takahito Kazama[1], Keigo Yamamoto[2], Hiromitsu Oshima[3], Kazumi Okada[3], Tadaomi Sonoda[2], Masato Iguchi[2]

1. Graduate School of Science, Kyoto University, 2. DPRI, Kyoto University, 3. ISV, Hokkaido University

Gravity observation is one of the most effective methods to detect spatiotemporal mass variations in volcanoes. In and around Sakurajima Volcano, relative gravity measurements were first started in 1975 and have been repeated 20 times until 2018. The long-term gravity variations from 1975 to 1992 was modeled by Kazama et al. (2018), to understand volcanic mass variations associated with active eruptions at the Minami-dake summit during the same period. They showed that the relative gravity increase in Sakurajima cannot be fully explained by two spherical deflation sources, which were expected from the leveling data. Instead, they found that the gravity increase can be modeled by an additional point mass of 6.0 E+10 kg/yr at 5 km depth under the Kita-dake summit. However, Kazama et al. (2018) modeled the volcanic mass distributions only from 1975 to 1992, and mass distributions during the subsequent period from the late 1990s to the 2010s should be modeled as well to understand present mass accumulating processes and forecast future volcanic activities of Sakurajima Volcano.

We therefore analyzed the GPS and relative gravity data obtained from the late 1990s to the 2010s, to model the long-term pressure and mass sources under Sakurajima Volcano as follows. We first subtracted the effect of tectonic crustal deformation in the southern Kyushu Island from the horizontal displacement data of the GEONET F3 solution, using the method of Takayama and Yoshida (2007). We also reproduced the residual horizontal displacement data by a spherical pressure source of Mogi (1958), assuming the inflation of a magma reservoir located under Aira Caldera; in this calculation, several parameters about the location and volume change of the pressure source were determined by the grid search method so as to most reproduce the horizontal displacement data. The inflation source was calculated to be located at 9 km depth under the center of Aira caldera with the inflation rate of 5.5 E+6 m3/yr. However, this inflation source never agrees with the gravity increase observed in Sakurajima volcano after the late 1990s, because the source inflation and consequent ground uplift leads to the gravity decrease (Hagiwara, 1977).

After correcting the effect of the inflating pressure source, the observed gravity values were found to increase at rates of +7.49 and +1.61 microGal/yr at S110 (located at the summit of Sakurajima) and S16 (located at the western foot of Sakurajima), respectively. We thus calculated theoretical gravity variations in Sakurajima Volcano by assuming a point mass under the center of the volcano, so as to explain the observed gravity increase; in this calculation, the parameters about the depth and mass increase were determined with the trial-and-error method. The point mass was estimated to be located at 3.3 km depth below sea level with a mass increasing rate of 2.3 E+10 kg/yr. This result implies that the mass accumulation continues under Sakurajima Volcano even now, although the present accumulating rate reduced by less than half compared with that from the 1970s to the former 1990s. We will sophisticate the pressure/mass source models in the future, to reveal the mass redistribution processes associated with volcanic activities of Sakurajima Volcano.

Investigation into the crater of Sakurajima volcano during eruption using UAV

*Shunsuke Miura[1], Takumi Mochiduki[1], Kouji Fujita[1], Toshihiro Urayama[1], Hisashi Sasaki[1], Tatsuro Chiba[1]

1. Asia Air Survey Co.,Ltd

1. Intoroduction
Measuring the active crater topography can obtain important information on volcanologically and disaster prevention, but the flight over the crater is risky involved in the eruption and is dangerous. The Minamidake crater of Sakurajima has repeated vigorous eruptions over a long period of time, and the topography change is intense. The Minamidake crater has A crater and B crater, and on the east slope there is Showa crater. Ministry of Land, Infrastructure, Transport and Tourism has regularly conducted airborne laser surveying to clarify the geometry shape. However, airborne laser surveying has become difficult due to the activation of eruption activity. Especially it was difficult to measure the topography of Minamidake crater, west of the Showa crater. Therefore, in this study, in order to grasp detailed crater circumstances of Minamidake crater and Showa crater on Sakurajima, we tried near-field photographing by UAV and terrain measurement utilizing SfM / MVS.

2. Investigation of Showa crater and Minamidake crater of Sakurajima by UAV
The UAV used is Matrice 210 (manufactured by DJI), and the installed camera is ZENMUSE X4S (visible light) and ZENMUSE XT2 (thermal infrared). DJI's UAV has an altitude limit of 500 m above ground level from the takeoff and landing point as a safety measure. For this reason, the takeoff and landing site was the upper stream of the Amida River (around 600 m altitude) outside the entry restriction. The photographing by UAV was performed three times in total, about 15 minutes using the moving picture photographing method.In UAV photographing of visible light, we were able to confirm the state inside the Showa crater, which is unknown by the surveillance camera at the foot. On the other hand, inside the Minamidake crater, due to the influence of the plume, it was impossible to photograph clearly. In the thermal infrared photography, resolution as much as visible light could not be obtained, but we could confirm the movement of the plume inside the Minamidake crater. Moreover, in the thermal infrared, it was possible to capture a high resolution movie rather than photographing with a helicopter, and at Showa crater the stratification of the crater wall could also be confirmed.

3. Create 3D model and orthoimage
An image was cut out from the movie of the visible light that was shot, and an orthoimage of 0.5 m resolution of the Showa crater and a 3D model were made by SfM / MVS. Actually the Showa crater was almost stopped, except for some fumaroles, it was possible to clearly shoot the crater bottom. On the other hand, the Minamidake crater was greatly affected by the plume, a lot of clouds appeared above the crater, and the crater bottom was unknown. We are going to try SfM / MVS analysis using measurement results of thermal infrared with less influence of plume compared with visible light.

4. Conclusion
In order to eliminate the influence of the plume and to obtain a clearer image, it is thought that low-altitude flight to the crater's sky or inside the crater is necessary. Currently, since images are recorded on the SD card, collection after returning is a major premise, but in the future it is desirable to create models from images obtained by wireless communication.

[1] Primary Objective

Southern Kyushu is a typical island arc region: subduction of Philippine Sea plate under Kyushu off Hyuganada with high seismic activity, the Aira caldera with active volcanic activity, the extending Okinawa trough, and the East China Sea. Our project is aimed at clarifying the detailed velocity structure of the crust beneath southern Kyushu and recognizing interactions with crustal activities in these regions.
It is also concerned about the occurrence of large-scale eruptions at the Aira caldera larger than the 1914 Taisho eruption in Sakurajima volcano. Accordingly, we also intend to reveal the caldera structure of the Aira caldera in order to deepen the understanding of the present magma supply system beneath the Aira caldera.
This reports an outline of the second seismic exploration carried out in November 2018.

[2] Report of Seismic Exploration in 2018

For our purpose mentioned above, we carried out the first seismic exploration in November 2017, which consists of 9 shot points with charges of about 200 kg dynamite in the land area and 906 temporary seismic stations including 42 OBSs along about 165 km long profile running transversely across the Osumi Peninsula, the central part of the Aira caldera, the Satsuma Peninsula, the Koshiki Strait and the Koshiki Islands.
The second seismic exploration was carried out in November 2018. In this 2018 exploration, 872 temporary seismic stations were deployed along the 2017 seismic main profile. The equipment at each station is same as that in 2017. In addition, we widely deployed 49 seismic temporary stations with a 4.5 Hz three components seismometerand a portable data logger ”GSX” in Sakurajima volcano in order to estimate the 3-D velocity structure beneath the volcano.
In the 2018 exploration, artificial explosions by the seismic air-gun blasting system(6000 cubic inches) were applied at 50m or 100m intervals along the sea profiles (Profile-B, Profile-D, Profile-F, Profile-H). We successfully observed the seismic refraction and reflection signals generated from the air-gun in a distance range of more than 20 km. We also introduced 4 big vibrator vehicles in the land area, which vibrates continuously during about 4 hours at the fixed locations. In addition, we carried out the seismic reflection profiling with 5 km long profile in the northeastern area in Sakurajima volcano.

Flow and emplacement mechanism of Koya Ignimbrite

*Keiko Suzuki-Kamata[1], Reina NAKAOKA[1], Tomomi Yamane[2]

1. Kobe Ocean-Bottom Exploration Center , 2. Department of Planetology, Graduate School of Science, Kobe University

Koya ignimbrite sourced from Kikai caldera 7.3 ka and traveled across the sea to reach the adjacent islands and the mainland of south Kyushu 40-90 km distant. Proximal facies of Koya ignimbrite, called Takeshima pyroclastic-flow deposit, comprise two or more flow units with a maximum thickness of 30 m, but the distal deposits collectively called Koya ignimbrite are consist of one flow unit and are exclusively very thin. Lag Breccia of Koya ignimbrite is recognized as layer 2b of 5 m thick on Takeshima and layer 1 of 2 m thick on Satsuma-Iwo Jima.

Koya ignimbrite contains essential pumices and volcanic glasses, both exhibiting a bimodal compositional distribution, e.g., ~60 and ~70 wt.% SiO_2 (Fujihara and Suzuki-Kamata, 2013). In addition to the silicic component, reflecting contribution the mafic component increases upwards from the basal to middle level of the deposit, and this vertical variation likely indicates progressive aggradation of pyroclasts. Koya ignimbrite overlies the ground layer consisting of crystal and fine pumice 1~5cm thick, and segregation pipe is commonly recognized in the ignimbrite in distributed area. The pyroclastic-surge deposit showing cross lamination overlies the ignimbrite on south of Osumi Peninsula. The surge deposit is rich in the mafic component, and suggests that the surge is formed at the late stage of ignimbrite eruption.

Koya ignimbrite distributes from the shoreline to the highland 1900m above sea level in Yakushima. Koya ignimbrite shows different lithofacies depending on altitude, which is thick and massive deposit more than severeal meters thick at lower area, and thin less than 50cm and composed of layer 1 at the base at higher altitude of 1600m above sea level. Mafic component is contained from the base of Koya ignimbrite in the north-west area on Yakushima both the lower area and the higher area, but mafic component increases upwards from the basal to middle level of the deposit in south-west area of Yakusima as same as Kyushu, Kuchinoerabujima and Tanegashima. This suggests that the earlier Koya ignimbrite climbing up the mountain area flows back due to the gravity in the north-west area and deposited thick at the lower area.

While silicic component can be recognized throughout the ignimbrite, mafic component exist only at the upper level of it at Tanegashima. The early phase products of Koya ignimbrite eruption reached to Tanegashima because this vertical variation is equal to that of the ignimbrites on proximal area, Satsuma Peninsula and Osumi Peninsula (Fujihara and Suzuki-Kamata, 2013). Lower contents of mafic component from upper most level compared with that of Osumi Peninsula suggest that the flows which contain abundant in mafic component occured at the later phase of the ignimbrite eruption cannot reach to Tanegashima. This is conformable the fact that the ignimbrites on Osumi Peninsula are thicker than that of Tanegashima. Based on above, it is estimated that Koya ignimbrite lost a great many amount of pyroclasts in the sea during traveling across the sea and the Koya ignimbrite widely lies on the sea floor around Kikai caldera. Koya ignimbrite became the low aspect ratio ignimbrite after passing the sea area, and low density pyroclastic surge was formed in the mountain area reflecting the topography.

Investigating Origin of landslide-like bathymetric feature at southern Mt.Kaimon using bathymetric and multichannel seismic reflection surveys

*hiroto yamaguchi[1], Satoshi Shimizu[2], Hikaru Iwamaru[2], Mamoru Sano[2], Nobukazu Seama[3,2], Misaki Horiuchi[3], Tetsuo Matsuno[2,3], Yoshiyuki Tatsumi[2,3]

1. Department of Planetology, Faculty of Science, Kobe university, 2. Kobe ocean-bottom exploration center, 3. Department of Planetology, Graduate School of Science, Kobe university

The existence of a landslide-like bathymetric feature is reported (Japan Coast Guard, 2007) to the south of Mt.Kaimon volcano that started eruption at the shallow sea area about 4400 years ago. We conducted the multichannel seismic reflection and bathymetric surveys in March and October 2018 using T/S 'Fukae-maru' to investigate how the landslide-like bathymetric feature was formed and where the source was if it was formed by a landslide. The bathymetric data (Figure) are used to make hill-shade map, slope map and terrain ruggedness index map, which characterize bathymetric features. We acquired seismic reflection data sets along eleven survey lines across the landslide-like bathymetric feature (green lines in Figure), which allows us to provide eleven seismic reflection profiles. The seismic reflection profiles indicate that there is a clear reflection boundary, which divide into two areas: The lower layers below the reflection boundary observed at large area and were not affected by stress. Many reverse faults and folds in the upper layers above the reflection boundary with its thickness of about 70m, which were formed by horizontally compressional stress. The analysis of the reflection profiles and the bathymetric lead to, divide the landslide-like bathymetric feature area into four areas. We name each area North-Eastern, South-Eastern, Central and Western part, which shows characteristic features as bellows:

・North-Eastern part; this area is large rugged sea bottom and slope. In the reflection profile, the boundary of upper and lower layers is not so clear. Deeper layers are not observed.

・South-Eastern part; this part is little rugged sea bottom and slope. In the reflection profile, there are some reverse faults and the fault strikes are East-West direction. Stratified structures are also found in spots.

・Central part; this part is the least rugged sea bottom and slope of four area. In the reflection profile, there are a lot of reverse faults. The fault strikes are always North-northwest-South-southeast direction. Stratified structures are found at eastern and western edge.

・Western part; this part is not as large as North-Eastern part, but large rugged sea bottom and slope. In the reflection profile, there are many (but less than Central part) reverse faults, and the fault strikes are North-South.

These characteristic features duggest that an event sweeping the ocean bottom was occurred at northern North-Eastern part, and directions the sweeping landslide are moving in south and west-southwest. It is because deeper layers are effected by collapse at North-eastern part, compressional stress is estimated by faults and folds (direction at the eastern part is North-South and at the central-western part is East-West) and bathymetric feature is more rugged at the eastern part.

Occurrence and distribution of pyroclastic fall deposits of Kuchinoerabujima volcano 2018-2019 eruption

*Masashi NAGAI[1], Shojiro Nakagawa[2], Yu Iriyama[1], Takahiro Miwa[1], Toshikazu Tanada[1], Hideki Ueda[1], Setsuya Nakada[1]

1. Volcano Research Department, National Research Institute for Earth Science and Disaster Resilience, 2. Yakushima Chigaku Club

At Kuchierabujima volcano, eruption began intermittently from October 21, 2018. Relatively large eruptions such as Yakushima and Tanegashima Islands adjacent to the east side of Kuchinoerabujima Island are observed on December 18 and 28, 2018, January 17 and 29, 2019. The ash fall distribution survey was conducted on three eruptions excluding the December 28 eruption where the ash fall axis was in the southeast direction and ash fall on the land was small. In Kuchinoerabujima Island, we conducted an investigation in early February, 2019. We also used information provided by Japan Meteorological Agency Kuchinoerabujima Volcano Disaster Prevention Liaison Office and interviews with local residents.

The Ash fall deposits on Yakushima and Tanegashima Islands are all light gray to reddish light gray colored sandy to silty volcanic ash layers, the component are mainly composed of lithic fragments and hydrothermal altered fragments and small amount of fresh vitreous rock fragments. At the eruption of January 17, 2019 where the largest one during a series of eruptions, on the ash fall axis extending to the east, 400 g/m^2 of ash deposited in the northwestern part of Yakushima Island, 100 g/m^2 in the northeast part, and 20 g/m^2 in the southern tip part of Tanegashima Island. Part of the deposit had the characteristics that ash particles fell as mud rain. In the northern part of Yakushima Island, fine lapilli was also included, and the maximum particle diameter tended to be larger on the north side than the ash fall axis. The deviation between the axis of ash fall axis and the axis of maximum particle diameter distribution can be explained by the difference in wind direction and wind speed at altitude. In Kuchinoerabujima Island, there was an ash fall axis from the summit crater to the southeast direction as total air fall deposit of the series of eruptions, and a deposit amount of about 12 kg/m^2 was confirmed at a distance of about 1.5 km. The layer corresponding to the eruption on January 17 is coarse deposit contains lapilli with long diameter of about 5 cm or more.

The amounts of air fall deposits were obtained by the method of Fierstein and Nathenson (1992) using average deposition density of 1000 kg/m^3. Based on the distribution data of distant deposits such as Yakushima Island, they are estimated to be ca.29,000 tons on the December 18, 2018 eruption, ca.62,000 tons for the January 17, 2019 eruption, and ca.14,000 tons for the January 29, 2019 eruption. These are smaller than the amount of air fall deposit of May 29, 2015 eruption estimated in the same method, ca.120,000 tons. When adding the depositional mass data of Kuchinoerabujima which is the proximal area to these distal data, the total of air fall deposits from December 2018 to January 2019 is estimated to be about 130,000 tons.

Ground Deformation around Domestic Active Volcanoes detected by InSAR of ALOS-2/PALSAR-2

*Takafumi Taniguchi[1], Isao Kageyama[1], Okuyama Satoshi[2], Shinobu Ando[2]

1. Japan Meteorological Agency, 2. Meteorological Research Institute

Monitoring of volcanic activity by observing ground deformation is one of useful means to understand signs of eruption such as accumulation and migration of magma. Japan Meteorological Agency (JMA) monitors volcanic activity by tiltmeter, light wave distance measuring equipment and GNSS around volcanoes. However, there are some problems only using these ground-based observation methods. Observable ground deformation is restricted to point information such as the tilt at the observation point and relative position between observation points. Also, it is difficult to install and maintain observation device at an isolated island such as Nishinoshima volcano. It is important to grasp surface ground deformation around volcanoes using not only ground-based observation but also satellite data like SAR (Synthetic Aperture Rader). In this presentation, we mainly report on the analysis results of the long-term pair (2015 to 2018) around the domestic active volcanoes.

Some of PALSAR-2 data were prepared by the Japan Aerospace Exploration Agency (JAXA) via Coordinating Committee for the Prediction of Volcanic Eruption (CCPVE) as part of the project ‘ALOS-2 Domestic Demonstration on Disaster Management Application’ of the Volcano Working Group. Also, we used some of PALSAR-2 data that are shared within PALSAR Interferometry Consortium to Study our Evolving Land surface (PIXEL). PALSAR-2 data belongs to JAXA. We would like to thank Dr.Ozawa (NIED) for the use of his RINC software. In the process of the InSAR, we used Digital Ellipsoidal Height Model (DEHM) based on ‘the digital elevation map 10m-mesh’ provided by GSI, and Generic Mapping Tools (P.Wessel and W.H.F.Smith, 1999) to prepare illustrations.

Volcano-hydrothermal inflation revealed by the spatial variation of stress field at the Tatun Volcano Group, northern Taiwan

*Hsin-Chieh Pu[1], Cheng-Horng Lin[2,3,4,5], Ya-Ju Hsu[2], Li-Chin Chang[3]

1. Central Weather Bureau, Taiwan, ROC., 2. Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan, ROC., 3. Taiwan Volcano Observatory at Tatun, Taipei, Taiwan, ROC., 4. Department of Geosciences, National Taiwan University, Taipei 10617, Taiwan, ROC., 5. National Center for Research on Earthquake Engineering, National Applied Research Laboratories, Taipei, Taiwan, ROC.

To investigate the volcanic behaviors, the Taiwan Volcano Observatory at Tatun has deployed a dense seismic network in the Tatun Volcano Group (TVG), where the government and business metropolis-Taipei city is bounded and various phenomenon related to volcano-hydrothermal activity were found. This network is composed of 40 seismic stations for covering an area of ~10 km by ~10 km. Based on the seismic data recorded by this network, we have solved an extremely huge number of 1,016 earthquake focal mechanisms with depths less 5 km from 2012 to 2017. Then the detailed spatial variations of the local stress field near the surface are firstly inverted from these focal mechanisms. Overall, local earthquakes were dominated by both the sub-horizontal extensional stress striking ESE-WNW and sub-vertical compressional stress. In detail, the orientations of extensional stress formed the abnormal pattern of a couple of semi curves around the Dayoukeng area. In this particular area of Dayoukeng, the magnitude of compressional stress at the sub-vertical component was stronger than the others principle stresses based on the significantly lower ∅values in local than the surrounding area. We ascribe these local variations to an inflating phenomenon buried in the Dayoukeng area. This inflating mechanism should be induced by the volcano-hydrothermal fluid. The current volcano-hydrothermal activity represented by inflation is principally concentrated at the Dayoukeng area and disturbs the faulting behaviors of local earthquakes in the TVG.

Keywords: focal mechanism, stress field, Tatun volcano group, inflation

Topographic change and crustal deformation associated with December 2018 eruption of Krakatau volcano in Indonesia

*Hiroshi Yarai[1], Tomokazu Kobayashi[1], Shinya Yamada[1]

1. GSI of Japan

Krakatau volcano is located in the Sunda Strait between Java Island of Indonesia and Sumatra Island. A high tsunami occurred on this Sunda Strait on December 22, 2018, causing major damage. It is estimated that this tsunami was caused by the collapse of Krakatau volcano. Therefore, in order to grasp the topography change of Krakatau volcano, we analyzed SAR intensity image observed by the Japanese earth observation satellite "Daichi 2" (ALOS-2) before and after the eruption. As a result of the analysis, a clear topographic change was observed in the southwestern part of the island on December 24 after eruption. It is thought that the southwestern part of the island collapsed by this 24th.

Furthermore, for capturing crustal deformation before and after the eruption, SAR interferometry was carried out using Daichi-2 SAR data. As a result, the displacement of the LOS's distance increased in the islands surrounding the Anaku Krakatau Island. Although the characteristic of the change suggests contraction centered around the Anak and Krakatau Island, it is not isotropic but it extends somewhat north and south. Therefore, the source may not be a simple mogi source.

[S-VC38] Active Volcanism

convener:Yuta Maeda(Nagoya University), Takahiro Miwa(National research institute for earth science and disaster prevention), Takeshi Nishimura(Department of Geophysics, Graduate School of Science, Tohoku University), Chairperson:Takehiko Suzuki, Maya Yasui

This session discusses various aspects of active volcanisms including, but not limited to, recent and historical eruptions, various phenomena associated with the volcanic activities, underground structures of the volcanoes, and developments of new instruments based on geophysical, geochemical, geological, and multidiscipline approaches. We also welcome studies on understanding and predicting the transitions of the eruptive activities from observational, theoretical, and experimental approaches.

Discussion

Tephrochoronology in the southwest part of basaltic Izu-oshima volcanic island during last 20,000 years, off Tokyo, Pacific Ocean

*Takehiko Suzuki[1], Satoshi Terayama[1], Jun Matsukaze[1], Yuichi Kato[1]

1. Faculty of Urban Environmental Sciences, Tokyo Metropolitan University

The Izu-oshima volcano (110 km SSW of Tokyo) in northern Izu-Bonin Arc, is one of the most active Quaternary volcanoes in Japan. This volcano originating from basaltic magma has frequently erupted; that is, 12 times of major eruptions occurred after 2 ka. Studies of its eruption history have been carried out by Nakamura (1964), Kawanabe (2012) and so on. However, precise ages of eruption preceding the caldera formation occurred at 1.8 ka have not been determined. Here, we re-examine the chronological framework of eruption history of the Younger Edifice of pre-caldera.

Fall-out tephras are typically exposed along so-called Great Cut of Beds in SW part of the island. Previous studies by Tazawa (1990) and Uesugi et al. (1994) have described this outcrop, numbering each tephra layer using serial numbers (O1–95 and Osb96–127). All tephras except O55 and O58 are proximal fall-out tephras composed of scoriaceous lapilli and/or scoriaceous ash. Due to the large number of tephras and lithological similarity, it is difficult to confirm each tephra defined by previous studies except several characteristic ones such as O95, O58, and O55. O55 and O58 are rhyolitic tephras from Nijima island and Omuro-dashi submarine depression, respectively (Saito et al., 2007).

Uesugi et al. (1994) estimated the age of the lowest tephra to be 25 ka or older by using 15 radiocarbon ages. However, this estimation is not reliable because it was determined using two oldest conventional radiocarbon ages (non-calibration) of 14–13 ka for the same horizon (just above O64) and under the assumption that the frequency of the tephra occurrence (154 years interval) is constant.
In this study, radiocarbon dating was performed for organic tephric loess collected from 9 horizons above O55 and 16 under O55. The oldest radiocarbon age is 18,598–18,287 cal BP, determined at the horizon 4 m below O95. The age of O95, the most prominent scoria fall deposit, is most likely to be 16–17 ka judging from several radiocarbon ages. It is 2400–3700 years younger than the estimated age (19.4–19.7 ka) by Uesugi et al. (1994). We also recognized widespread K-Ah tephra using volcanic glass geochemistry. Two radiocarbon ages determined at 45 cm above and 55 cm below K-Ah are 6,882–6,747 cal BP and 8167–8021 cal BP, respectively. These ages are concordant with revised age of K-Ah (7,307–7,196 cal yrs BP; McLean et al., 2018), indicating the age of horizon detected K-Ah is older than estimated age of 6,330±85 yBP by Uesugi et al. (1994). These results indicate that the interval between O95 and K-Ah is shorter (67–75%) than previous estimation, suggesting higher frequent occurrence of the eruptions in this period.

Tephrostratigraphy at Daisan-yama and Jinai-jima, and correlation with eruption deposits from Mamashitaura Volcanoes in Niijima Volcano, Izu-islands

*Makoto Kobayashi[1], Masanori Murata[1], Kaori Aoki[1], Daisuke Ishimura[1,2], Takehiko Suzuki[1,2]

1. Research Center for Volcanic Hazards and Their Mitigations, Tokyo Metropolitan Univ., 2. Department of Geography, Tokyo Metropolitan Univ.

In this study, we established tephrostratigraphy at both sites of Daisen-yama and Jinai-jima, and correlated with eruption deposits from Mamashitaura volcanoes based on the characteristics of the mineral compositions, the refractive indexes and major chemical element compositions of the volcanic glass shards. We are aiming to clear long-term eruption history of Niijima volcano.
We recognized deposits associated with at least 20 eruption deposit events at Daisan-yama and Jinai-jima. Based on the stratification of widespread tephra AT, it is considered that the history of the explosive eruption of Niijima volcano and the surrounding volcanoes during late Quaternary (past about 50,000 years) are preserved at these sites. At the both sites, as the ca. 20ka tephra layers, there are coarse fall-out ash deposits containing accretionary lapilli (N), fine fall-out ash deposits (P; Kozushima-Chichibuyama A (Suga et al., 1992)), AT, fine fall-out ash deposits containing pumices (S; Kozushima-Chichibuyama B (Suga et al., 1992)), pyroclastic surge deposits that squeezes phalanx of pumices with diameter several cm (T), fall-out ash deposits containing volcanic lapilli and pumices (V) and pyroclastic surge deposits (X) in descending orders. At Jinai-jima, as lower tephra layers, there are pyroclastic deposit containing many altered volcanic lapilli and blocks (Y) and pyroclastic surge deposit (Z) covering Jinai-jima lava.
Ito and Isobe (2007) suggested that eruption deposits from Mamashitaura Volcanoes were divided into upper Mamashitaura Volcano (cummingtonite rhyolite; ca. 20 ka) and lower Mamashitaura Volcano (biotite rhyolite; >ca. 35 ka) based on the difference of mineral compositions, paleo-soil layers and ^{14}C ages of charcoals contained therein. We recognized that upper Mamashitaura Volcano deposits composed of pyroclastic surge and pyroclastic cone deposits including rhyolite blocks and lapilli, that the lower layer contained more altered brown volcanic breccia (basalt?). On the other hand, lower Mamashitaura Volcanoes deposits composed of pyroclastic flow and pyroclastic surge deposits with a thickness of 20 m or more, and the debris flow containing many volcanic blocks covering them.
We collected data mineral compositions, refractive indexes and major chemical element compositions of glass shards for Daisan-yama and Jinai-jima tephras (T, V, X etc.) and Mamashitaura Volcano deposits. Tephra-T contains many minerals of hornblende and cummingtonite, and is characterized by refractive indexes (1.497-1.500), K_2O contents (3.0-3.3 wt.%) and CaO contents (0.7-1.0 wt %). These characteristics closely resemble features of some of upper Mamashitaura Volcano deposits. On the other hand, the lower tephras V and X are similar to lower Mamashitaura Volcano deposits in point of contain biotite in addition to hornblende and cummingtonite, but the refractive indexes and CaO contents of the volcanic glass shards are significantly different. This suggests that it is difficult to correlation them.
As a result of currently in progress, it is highly likely that T-tephra is eruption deposits from upper Mamashitaura Volcano, and it is appropriate to think that the age is 30,000 to several thousand years ago. On the other hand, we can’ t recognize eruption deposits from the lower Mamashitaura Volcano at Daisan-yama and Jinai-jima.

1. Earthquake Research Institute,The University of Tokyo

1.Introduction

Magma mixing is thought to be the major eruption triggers of arc volcanoes. This process can control whether magmas will erupt or stall in the crust. However, magma mixing processes have not been revealed well. Therefore, it is important to reveal mixing process at magma reservoir.
For this purpose, we focus on Unzen 1991-95 eruption. This eruption is characterized by continuous growth of dacitic lava domes and pyroclastic flows caused by collapse of the lava domes. During the eruption, two vulcanian eruptions were recognized. Previous studies proposed that magma mixing between nearly aphyric, mafic and crystal-rich, silicic end-members occurred in the magma chamber (e.g., Sato et al., 1999). Because there are lots of geophysical and geological studies, this eruption is suitable for getting more detailed information about pre-eruptive processes.
Recent studies demonstrated that igneous amphiboles are powerful tools to constrain pre-eruptive magmatic conditions (e.g., Ridolfi and Renzulli, 2012; Putirka, 2016). For example, empirical equations relating temperature and SiO_2 content of co-existing melt with amphibole composition were proposed by Putirka (2016). By using these equations, we can constrain physicochemical conditions of melts in which individual phenocryst crystallized.
Our previous results suggest that the 1991-95 magma was formed by three-component mixing, in which contribution of the newly-recognized 3rd endmember magma (MT magma) (Iwahashi et al., JpGU2018).
Products of 1991-95 eruption often contain crystal clots. They consist of amphibole, plagioclase and Fe-Ti oxides. Because magma reservoir of Unzen volcano is thought to be mushy (e.g., Nakamnura et al., 1995), crystal clots are possible to be part of mushy magma reservoir. Therefore, in this study, we expect to get more detailed information about pre-eruptive process of 1991-95 eruption using crystal clots in addition to amphibole phenocrysts.

2.Methods

We used 11 dacitic samples erupted at different times during the 1991-95 eruption. All of these samples contain crystal clots. They are composed of amphiboles, plagioclases, Fe-Ti oxides and interstitial glass. The major element compositions of amphibole phenocrysts and constituent minerals and glasses in crystal clots were measured by using EPMA at ERI, University of Tokyo.

3.Results

Amphiboles in crystal clots are classified into four types; Type A, Type B, Type C, Type D. Amphibooles of Type A has zonal structure, Type B has reaction rim, Type C has both zonal structure and reaction rim and Type D is almost homogenous. These amphiboles are classified magnesiohornblende and tchermakite based on their compositions. There is an apparent compositional gap between these two clusters. Crystallization temperatures are estimated to be ~750-800ºC and ~850-950ºC for magnesiohornblendes and tchermakites, respectively. Amphiboles in crystal clots reveal temperatures of ~750-800ºC. Estimated SiO_2 contents of melts coexisted with amphiboles (SiO_2^{melt}) are ~66-73wt.% and ~60-67wt.% for magnesiohornblendes and tchermakites, respectively. On the other hand, SiO_2 contents of interstitial melts are ~68-72wt.%. Almost all plagioclases in crystal clots have oscillatory zoned texture. An content (=100*Ca/Ca+Na) of these rim are 60-75.

©2019. Japan Geoscience Union. All Right Reserved.

4.Discussion

H_2O saturation depth estimated for the interstitial melt compositions are consistent with that of main magma chamber in which the silicic endmember magma was thought to be stored.
On the other hand, zonal texture of amphibole often cut by other crystals and this implies that MT magma reservoir may present before 1991-95 eruption. In addition, comparison of temperatures estimated by amphiboles with phase diagram by Noguchi et al.(2008) indicate that there may be almost no plagioclases in MT magma reservoir.
In addition to these results below, we plan to present some new picture of pre-eruptive process at 1991-95 eruption and MT magma reservoir.

Petrological study of Pinatubo 1991 eruption ~ Discussions of magma plumbing model~

*Tomohisa Tamura[1,2], Mitsuhiro Nakagawa[2]

1. West Japan Engineering Consultants, Inc., 2. Earth and Planetary System Science, Hokkaido University

Introduction

Pinatubo volcano which locates at Northern Luzon island, Philippines caused cataclysmic eruption on June 15, 1991. This eruption includes the four main eruptive products, dome lava andesite on June 7 (J7-LD), basaltic mafic enclave in J7-LD (J7-ME), andesitic scoria from first Plinian eruption on June 12 (J12-P) and dacite pumice from climactic Plinian eruption on June 15 (J15-C). J15-C is separated into two types which constitute gray, precise and phenocryst-poor pumice (J15-CP) and white, bubbly and phenocryst-rich pumice (J15-CR). There are many petrological studies of Pinatubo volcano 1991 eruption, and magma plumbing model of this eruption is established by Pallister*et al.* (1996). Their model indicates magma mixing that andesitic magma is generated by mixing between felsic magma and mafic magma in magma reservoir. However, we carry out whole rock and mineral compositions of 1991 products in detail, and obtain the new findings of magma plumbing model of 1991 eruption.

Analytical methods

We made many thin sections and observed them under polarizing microscope, and counted the modal compositions of phenocrysts.Whole rock and mineral compositions were determined by X-ray fluorescence (XRF) and Scanning electron microscope / Wavelength dispersive X-ray spectroscopy (SEM-WDS) at Hokkaido University, respectively.

Results and Discussions

1991 products mainly include plagioclase and amphibole phenocrysts, and there is a few olivine, clinopyroxene, biotite, quartz and opaque minerals. For Harker diagram of major elements, all products stand in a straight line and it means magma mixing trend. J15-C composition, however, has compositional variation and another trend which crosses the mixing trend. J7-LD and J12-P also have slightly crossed compositional variation. This crossed trend and compositional variation are clearly confirmed in K_2O and Rb contents. The contents of amphibole and biotite which include many potassium do not relate the compositional variation. Therefore, felsic magma of Pinatubo volcano has had the compositional heterogeneous before mafic magma injected into felsic magma reservoir.

Plagioclase and amphibole cores have wide compositional range. According to calculating the equilibrium melt compositions from plagioclase and amphibole cores, we estimate the two felsic endmember that are less-evolved melt, D1 and more-evolved melt, D2. Their melt compositions correspond with glass compositions hosted in melt inclusions of plagioclase and amphibole crystals. Above discussion indicates that felsic magma has the heterogenous, and we estimate that the heterogeneous felsic magma was generated by mixing between D1 and D2.

For minerals of 1991 products, normal and reversal zonings coexist and are repeated from line profile analyses. The melt composition and temperature of magma were heterogeneous and convection occurred in magma reservoir because the composition of plagioclase depends on the melt composition and temperature of magma.

Conclusions

The compositional variation of dacitic magma is consistent with one of minerals, plagioclase and amphibole, for example. The felsic magma has compositional heterogeneous before mafic magma injection, and two different compositional endmember magma coexist (D1 and D2). The continuous compositions of felsic magma were generated between D1 and D2 because of the convection in magma

reservoir. Before 1991 eruption, mafic magma injected into the heterogeneous felsic magma and mixed together, so that andesitic magma which has slightly compositional variation was generated.

Rediscovery of the Higuruma Debris Avalanche Deposit in Asama-Kurofu Volcano

*Maya Yasui[1], Masaki Takahashi[1], Tatsuo Kanamaru[1]

1. College of Humanities and Sciences, Nihon University

Asama-Kurofu volcano experienced a large-scale sector collapse in its later stage indicated by a horse-shoe shaped caldera and debris avalanche deposit in the distal flank. The area immediately east of the collapsed caldera is occupied by younger volcanic edifices of Hotokeiwa and Maekake. The medial area that is a flank slope of the former Kurofu is thickly covered with the younger deposits from Hotokeiwa and Maekake. Therefore, few information was available for the distribution and thickness of the debris avalanche deposit. Hummocky topography develops on the eastern area of Maekake and Hotokeiwa volcanoes. Geological survey especially in the valley bottom in the hummocky area in the Gunma Prefecture Asama Dairy Farm, the Nagakurayama National Forest, and its vicinity was carried out in this study. Outcrops of the deposits those occurrences were typical of debris avalanche were occasionally found in the valley bottom. In addition, 50-meter deep borehole core sample was taken on the ENE flank slope of Maekake volcano. This is a part of the “integrated program for next generation volcano research and human resource development” supported by ministry of education, culture, sports, science and technology, Japan. Thick debris avalanche deposit of 27 meters was recognized in the lower half of the borehole core sample. That is, weakly stratified and partly solidified tuff breccia that is characterized by heterogeneous matrix and occasional mega-blocks is observed. Whole-rock chemical analyses of the blocks from these deposits show that they are the same as those of the Asama-Kurofu and Asama-Sennin volcanoes. The distribution of “Higuruma debris avalanche” was shown on Yagi (1936) ‘s geologic map but few descriptions were made about it. The deposit confirmed in this study corresponds to the Higuruma debris avalanche and the description including thickness will be a clue for understanding the scale of the sector collapse.

[S-VC39] Hydrothermal systems of volcanoes

convener:Yasuhiro Fujimitsu(Department of Earth Resources Engineering, Faculty of Engineering, Kyushu University), Wataru Kanda(Volcanic Fluid Research Center, School of Science, Tokyo Institute of Technology), Takeshi Ohba(Department of chemistry, School of Science, Tokia University), Chairperson:Yasuhiro Fujimitsu(Faculty of Engineering, Kyushu University), Takeshi Ohba, Wataru Kanda

There is a diversity of hydrothermal systems between magmas and the ground surface in various geoscientific environments. Understanding of the hydrothermal systems contributes to understanding of the earth systems, and is essential for utilization of geothermal energy and prediction of volcanic eruption. In this session, we will discuss the topics on subsurface structures and heat and fluid flows of "hydrothermal systems of volcanoes" from the perspectives of geophysics, geochemistry, geology and geothermal reservoir engineering. Any research approaches, theoretical, observational and experimental, are welcome.

Hydrothermal system of Tokachidake volcano, Japan: Examination from multi-disciplinary surveys

*Ryo Takahashi[1], Noritoshi Okazaki[1], Makoto Tamura[1]

1. Geological Survey of Hokkaido, Hokkaido Research Organization

Tokachidake volcano, located in central Hokkaido, Japan, has had intermittent magmatic eruptions during the 20th century. Recently, increases in seismic activity, ground inflation around the active craters and chemical changes of thermal waters are observed, and hence, a magmatic eruption in the near future is of concern. The 1926 eruption induced a large-scale lahar (Taisho lahar). Uesawa (2014) proposed that large amounts of thermal water were released as a hydrothermal surge from the interior of the volcanic edifice, expanding the scale of the Taisho lahar. In addition, chemical and thermal changes related to volcanic activity were observed in thermal waters around the volcano (Takahashi et al., 2015). These phenomena are deeply related to hydrothermal systems. Therefore, to detect precursor activities precisely at Tokachidake volcano, we should understand the subvolcanic hydrothermal systems. In this study, we performed multi-disciplinary surveys, such as magnetotelluric (MT) survey, geological investigations and thermal water and fumarolic gas observations, to examine the subvolcanic hydrothermal systems.

We performed MT survey at 13 stations along an NW-SE survey line across the volcano, and detected several conductive zones in the edifice. A conductive zone was detected at more than 3–4 km depth beneath the summit crater area (deep conductive zone). Volcanic earthquakes did not occur in this conductive zone, but their hypocenters were distributed surrounding the zone. This would indicate that the outer margin of the conductive zone is coincident with the brittle-ductile transition zone. Another conductive zone is distributed at 300–1,500 m depth beneath the summit crater area (shallow conductive zone).

In order to discuss the shallow hydrothermal system, we investigated phreatic ejecta, the 1926 debris avalanche deposits and accessory ejecta, all of which record subsurface hydrothermal environments. As a result, we revealed that an alteration zone with a pyrophyllite+quartz assemblage occurs at depths of >500 m beneath the crater area (Takahashi & Yahata, 2018). This zone reflects a high-temperature environment (200–300 ˚C). Also, fumarolic gas observations suggest that high-temperature (200–300 ˚C) hydrothermal systems exist the shallow subsurface. We can consider that the shallow hydrothermal system inferred from these investigations is coincident with the shallow conductive zone detected by MT survey.

We have observed the thermal waters around Tokachidake volcano over a period of more than three decades. At Fukiage spa area, thermal waters caused chemical and thermal changes by the supply of the magmatic NaCl-type thermal water associated with the increase in volcanic activity (Takahashi et al., 2015). A distribution area of the NaCl-type thermal water around magma would be detected as a conductive zone because thermal waters with high temperature and high NaCl concentration show high conductivity. Thus, we can consider that the deep conductive zone is interpreted as a distribution area of the NaCl-type thermal water.
In consequence of multi-disciplinary surveys at Tokachidake volcano, we revealed the subvolcanic hydrothermal systems. We should continue careful observations and revise the model to understand more precisely the volcanic activity of the volcano.

Fumarole and hot spring activities after the 2015 eruption of Hakone Volcano and their relationships with the seismicity and crustal deformation

*Kazutaka Mannen[1], Masatake Harada[1], Yohei Yukutake[1], George Kikugawa[1]

1. Hot Springs Research Institute of Kanagawa Prefecture

A very small phreatic eruption occurred at Hakone volcano in 2015. Before the eruption, in Owakudani, where the eruption center formed, there has been no significant fumarole activity; however, more than 20 craters and fumaroles formed associated with the eruption and they still remain active. We have routinely measured the steam temperatures emitted from the fumaroles and analyzed chemical composition of hot spring and surface waters every two weeks since we were permitted to enter the eruption center. In this presentation, we show the temporal changes and its relationship with the seismic activity and crustal deformation.

1. Steam temperature of fumaroles
Among the more than 20 fumaroles, we have measured 10 fumaroles that are significant and accessible (Mannen et al., 2019). We have only two stable fumaroles named 15-12 (since May 1, 2017) and 16-1 (since January 11, 2018) for routine measurement.

The temperature of 15-12 was higher than 150 ºC before August 2017. However, the temperature lowered gradually up to 120 ºC until the late 2018. The temperature of 16-1 was approximately 140 ºC when we started measurement. However, the steam temperature also lowered gradually and marked 130 ºC in the late 2018.

On the other hand, fumaroles named 15-1 and 15-14B continuously emit high temperature steams and higher than 150 ºC even in the late 2018 without significant decline although steam vents of these fumaroles are unstable and migrate frequently. We suppose that the steam temperature and emission are on decline since detection of high temperature steam is getting difficult and extinction of fumarolic activity is common recently. The highest temperature ever recorded was 162.0 ºC from 15-1 observed on August 23, 2017.

2. Chemical composition of hot springs and surface waters
In Owakudani area, we routinely correct and analyze waters from 13 sources including natural springs, stream water and artificial hot springs, which is made by mixing of steam emitted from steam well and water (Kikugawa et al., 2019). The stream water, watershed of which includes the eruption center, shows high Cl content associated with the 2015 volcanic unrest ($Cl/SO_4 > 1.0$; Mannen et al. 2018). The Cl concentration lowered to the background level ($Cl/SO_4 \sim 0.2$) until early 2017; however, increased slightly from November 2017 to January 2018 ($Cl/SO_4 \sim 0.3$). The artificial hot springs from No. 52 steam well also showed significant rise of electric conductivity and Cl content and decline of pH.

Our measurement of volcanic gas from underfloor of a building in Owakudani shows continuous decline of CO_2/H_2S ratio after the eruption. The decline rate seemed to lower in 2017; however, it was not clear. On the other hand, Daita et al. (2018) reported that CO_2/H_2S ratio of volcanic gas from Kamiyu, north of Owakudani showed rise from around June 2017.

©2019. Japan Geoscience Union. All Right Reserved.

3. Seismicity and crustal deformation in 2017
In Hakone volcano, earthquake swarm, deep low frequency earthquakes and increase of baseline length across the volcano have observed before increase of geothermal activity (Harada et al. 2018; Mannen et al. 2018). After the 2015 eruption, there has been no earthquake swarm; however, there were slight increase of seismicity from the late April to the early May in 2017 beneath Mt. Kintoki (Yukutake et al. 2018). Before the earthquake swarm, in the mid-April, deep low frequency earthquakes (DLF) was found active by matched filter method (Yukutake, 2017). The baseline length across Hakone volcano started to increase from the early May in 2017 and ended in the late November of the year with total stretch of 12 mm (the total stretch during the 2015 eruption and unrest was 21 mm). In the period, there is no significant change in steam temperature. Increase of hydrothermal activity was implied by the changes in chemical compositions of artificial hot spring water and surface water in the late April and in November respectively.

The observed trend of the weak change in 2017 are similar to that of the volcanic unrests in 2013 and 2015. We thus suppose that there was a small increase of volcanic activity in 2017. Comparing to the changes in 2013 and 2015, seismicity and stretch rate of the baseline in 2017 are notably lower. Daita et al (2018) also pointed out that the increase in CO2/H2S ratio in 2017 was significantly lower than that observed in 2013 and 2015. Such differences observed in 2017 may imply that the magma-hydrothermal system of Hakone volcano has altered by the 2015 eruption (Daita et al, 2018).

A possible geothermal source at around 4 km depth estimated by the seismic observation in Ibusuki geothermal area

*Junzo Kasahara[1,3], Yoko Hasada[2,1], Hiroyasu Kuzume[1]

1. ENAA, 2. Daiwa Exploration and Consulting Co., 3. Shizuoka Univ.

Introduction: The Medipolis is located in Ibusuki geothermal area, Japan. There are three geothermal boreholes in the field. The geothermal characteristics of the boreholes were studied by NEDO (2008-2010). The IK-1 borehole is commercially used for the electric power generation. The IK-4 is used for observation. The depths of three boreholes are around 1,500 m. The temperature of the boreholes was approximately 250˚C around the 900 m-depth and the production depth for the steam is around 1,200 m. The temperature model by NEDO (2008-2010) proposes a hot reservoir around the NE direction of IK-1 and IK-4 boreholes although it is not confirmed by real drillings.

To know the precise geothermal characteristics of this field, we conducted a seismic observation by a fiber-optic distributed acoustic sensor (DAS) and ground surface seismometers in November 2018.

Field observation: We installed 20 sets of 3C seismometers along the 2 km-long EW line and deployed a fiber-optic cable for the DAS and distributed temperature (DTS) measurements down to 977 m depth. We measured the temperature and seismic signals using the same fiber-optic cable for DAS and DTS. The total DAS observation period is 4.5 days. The interval of ground surface seismometers is approximately 100 m. We observed seven natural earthquakes by DAS and surface seismometers. The largest observed earthquake is M5.2 which occurred west of Tanegashima with 123 km focal depth. The temperature of the IK-4 was measured as 264˚C by DTS at the 914 m depth.

Observed waveforms: The first arrivals of the M5.2 earthquake measured by DAS are traveling from the 977 m depth to the wellhead with the velocity of 4 km/s~3 km/s. There are no evident reflections from the deeper zone than 1,000 m. In addition, any evident attenuation of seismic waves is not identified in the high temperature zone around the 914 m-depth.

Surface seismometers show unusual waveform characteristics. Although the amplitudes of the P-wave first arrivals of M5.2 earthquake on vertical seismometers are small, the EW and the NS seismometers show small P first arrivals and succeeding large amplitude phase with a second delay. Because this phase is recognized only on EW and NS components, this phase is possibly P-to-S converted phase. The aftershocks of the M5.2 Tanegashima also showed similar waveforms as those of the M5.2 event. Other earthquakes also showed similar characteristics on the horizontal components.

Interpretation of P-to-S converted phase: We examined the cause of estimated P-to-S conversion. The delay time from the P first arrival to the P-to-S converted phase is estimated as ~0.8 s. We assumed a low Vp/Vs zone at the 4 km-depth with 500 m thick and calculated synthetic waveforms generated by deep seismic sources corresponding to natural earthquakes. The seismic velocity profile estimated by the DAS observation is used in the calculation. The models can explain the observed characteristics such as small P amplitude and large P-to-S converted phase on horizontal components, when incident seismic wave is slightly oblique to the low Vp/Vs zone. We also estimated borehole waveforms and ground surface waveforms.

©2019. Japan Geoscience Union. All Right Reserved.

Discussion and conclusions: According to the simulation, there is a chance to prove the presence of the low Vs zone at the 4 km-depth. Because the temperature around ~900 m is 264˚C, the low Vs zone might be useful for a future geothermal energy source. For either case, more detailed study of the proposed low Vs zone is required.

Time variation in the chemical and isotopic composition of fumarolic gases at Kusatsu-Shirane volcano Japan

*Takeshi Ohba[1], Muga Yaguchi[2], Nozomi Numanami[1], Kotaro Toyama[3], Hirochika Sumino[3], Urumu Tsunogai[4], Masanori Ito[4], Ryo Shingubara[4]

1. Department of chemistry, School of Science, Tokia University, 2. Meteorological Research Institute, JMA, 3. The University of Tokyo Graduate School of Arts and Sciences Department of Basic Science, 4. Nagoya University Graduate School of Environmental Studies

At Kusatsu-Shirane volcano Japan, the intense seismic activity took place in 2014 and 2018. To investigate the relationship between the activity and the chemistry of fumarolic gas, the gas samples have been repeatedly analyzed. A monotonic decrease in CO2/H2O, He/H2O and N2/H2O ratios since July 2014 to November 2017 suggests the decline of magmatic component. On contrary CH4/H2O ratio significantly increased during the seismically quiet period, suggesting the reduced condition in hydrothermal system favoring to the formation of CH4. The high N2/He ratio in the quiet period suggests the addition of component originating in crustal rock hosting hydrothermal system. The N2/He ratio in 2018 was definitely lower than the ratio in 2014, indicating the evolution of magma brought by the degassing. The δD(H2O), δ18O(H2O) and CO2/H2O ratio of fumarolic gas were modeled with the following processes; the generation of vapor phase after the mixing between magmatic gas and a cold groundwater with meteoric origin, the addition of vapor phase with meteoric origin, and the partial condensation of water vapor near surface. Only a single magmatic gas is necessary for the above modeling.

Behavior of Arsenic and Mercury related to hydrothermal activities in Kirishima, Satsuma Iwojima, and Yamagawa, Kyushu Japan

*Motoya Habuchi[1], Harue Masuda[1], Tsuyoshi Shintani[1], Shuzo Furuya[1], Keigo Mori[1], Jun-ichiro Ishibashi[2], Takeshi Matsushima[2], Akinori Takeuchi[3], Syogo Oshima[4], Reo Ikawa[5]

1. Osaka City University, 2. Kyushu University, 3. National Institute for Environmental Studies, 4. West Japan Engineering Consultants, Inc., 5. National Institute of Advanced Industrial Science and Technology

Arsenic and mercury behave in similar manners during migration from the deep to the surface of the Earth with magmatic and associating hydrothermal activities. In this study, we sampled total 57 hydrothermal and local meteoric waters from Kirishima, Satsuma-Iwojima and Yamagawa in November 2017 to December 2018 to trace the migration processes of arsenic and mercury related to the volcanic and its associating hydrothermal activities. We analyzed concentrations of major components, arsenic and mercury and hydrogen and oxygen isotope ratios.
The highest temperature of hydrothermal water, which was taken from the craters phreatically exploded in the April 2018, was 94.5 ˚C and the pH was 0.8-1.7. The maximum concentrations of chloride ion and sulfate ion were 300 mM and 190 mM, and the positively linear relationship between these two components indicated the simple mixing of acidic hydrothermal fluid and local meteoric water. In many high temperature hydrothermal waters, $\delta^{2}H$ and $\delta^{18}O$ were in the range of magmatic water, -25 to -5‰ and +4 to +9 ‰. Total arsenic concentration in the hydrothermal waters was 1210-4640 μg/l, which had a positively linear relationship with sulfate ion concentration. Dissolved and suspended total mercury concentrations in hydrothermal waters were 0.5-85 ng/l and 0.5-826 ng/l, respectively. Since highly mercury concentrated hydrothermal water also contained high arsenic, these were derived from the same magmatic fluid. Chloride and sulfate ion concentrations of hot spring waters derived from fumarole in Kirishima and Kurinodake were < 0.2 mM and 26 mM at the maximum. Total arsenic concentration was 0.58-24 μg/l, and total suspended mercury concentration was 1980 ng/l at the maximum. Hot spring waters in Satsuma Iwojima and Yamakawa,contained high total arsenic concentration when the seawater directly infiltrated and the highest concentration was 2500 μg/l for the one of hot spring water in Satsuma Iwojima. In these areas, the highest total dissolved mercury concentration was 177 ng/l for a hot spring water with pH of 1.4 in Satuma Iwojima. Both arsenic and mercury are rising up from the deep with magmatic fluid. However, the two elements may behave differently along the migration path; mercury moves preferentially with vapor and removed from the water during flowing path on the surface, while arsenic preferentially behaves with hydrothermal water and remains as a dissolved phase in the surface water.

The chemical composition of thermal waters from spring and hot pool at Mt. Iwoyama of Kirishima volcano

*Muga Yaguchi[1], Takeshi Ohba[2], Kotaro Toyama[3], Fukuoka Regional Headquarters JMA[4], Kagoshima Meteorological Office JMA[4]

1. Meteorological Research Institute, 2. Tokai University, 3. Graduate School of the University of Tokyo, 4. Japan Meteorological Agency

Mt. Iwoyama of Kirishima volcanic complex is an active volcano where fumarolic activity restarted in December 2015 at summit crater. After the restart of the fumaroles, volcanic activities at the surface, such as the expansion of fumarolic area, the appearance of thermal springs and water quality changes in springs around Mt Iwoyama have been observed. In April 2018, small phreatic eruptions occurred at the south of the summit and west flank of Mt. Iwoyama, and boiling hot pools have appeared in some of the newly created craters after the eruptions. In this study, the chemical composition of water samples collected from a natural spring site on the west flank of Mt. Iwoyama and hot pools in the newly created craters have been analyzed to obtain information for evaluation of volcanic activity at this mountain.

Between August 2016 to March 2018 (about a month before the eruption), the Cl/SO_4 of the spring water increased from 0.07 to 0.9. About a month after the eruption, the ratio increased to 1.6 as of May 2018, and remain between 1.2 and 1.6 since then to January 2019.

Cl/SO_4 molar ratio of hot water pool in one of the southern craters was 1.3 in May 2018 and 1.8-2.3 in January 2019. The ratio of hot water pool in the western crater was 1.3 in July 2018, 1.9 in October 2018 and 2.2 in January 2019. The increase of Cl/SO_4 molar ratio may be caused by several reasons, for example, the ascent of volatile-rich magma or chemical composition change of volatiles along with the progress of degassing.

Re-examination of origin of the variety in magmatic-hydrothermal fluids

*Hiroshi Shinohara[1]

1. Geological Survey of Japan, AIST

A variety of magmatic-hydrothermal fluids, including volcanic gases, hot spring waters and geothermal waters, is created from a magma and we will re-evaluate those origins with particular interest on variation of Cl/S ratios. Giggenbach (1996) classified fluids in a magmatic-hydrothermal system as 1) Acid Cl-SO_4 water, 2) Neutral NaCl water, 3) Bicarbonate water and 4) Steam heated acid SO_4 waters. The acid Cl-SO_4 waters are formed by condensation of magmatic gases discharged from a magma. The neutral NaCl waters are formed from the acid water through neutralization and S-mineral deposition due to water-rock interaction at lowering temperature. The bicarbonate waters and acid SO_4 waters are formed by mixing of CO_2 or H_2S derived from vapor separation of a deep hydrothermal system with meteoric water or the neutral NaCl waters. The principal differentiation process is the neutralization and S-mineral deposition of the acid Cl-SO_4 water under a temperature gradient to create the neutral NaCl water. However, we also need to consider other factors than the temperature dependence.

Water-rock reactions also have pressure dependent. HCl content in hydrothermal fluids has a negative pressure dependence; a hydrothermal solution has a larger HCl content at a lower pressure than at a higher pressure (Shinohara and Fujimoto, 1996; Botcharnikov et al., 2015). The pressure dependence implies that hydrothermal fluids discharged from a magma at a high pressure tend to have less acid than volcanic gases discharge at the surface. The average Cl/S ratio of the Japanese volcanic gases is about 0.2 (Shinohara 2013), whereas the ratio is about 0.5 in melt inclusion of basaltic magmas and is about 10 in those of silicic magmas. Therefore, a hydrothermal fluid formed by a complete solidification of the magma will have Cl/S ratio much larger than those of volcanic gases or the acid Cl-SO_4 waters. These evidences suggest that the acid Cl-SO_4 waters and the neutral NaCl waters have distinct origins with different condition of a magma degassing. Compilation of chemical compositions of hot spring waters and hydrothermal waters in Japan show a clear two frequency peaks of acid and near neutral pH with a gap at pH 4-5 (Muraoka et al., 2007). This pH distribution also suggests that the distinct origin of the two types of the hydrothermal fluids.

Measuring the electrical resistivity of rocks is a powerful and reliable method used to investigate volcanic edifices at depth. The electrical resistivity has two main contributions: (i) the conduction in the bulk pore fluid, associated to saturation, the ionic strength, and temperature of pore water, and (ii) the surface conductivity, related to the formation of secondary minerals. In volcanic environments, these two contributions are controlled by numerous interactions between hydrology, geology, tectonic settings and magmatic forcing. As a consequence, the evaluation of electrical resistivity images is strongly non-unique, and its interpretation remains complex.

Here, we propose a new approach to address this issue. First, we performed a 3-D electrical resistivity imagery of the Miyake-jima volcano using Magnetotellurics. Next, we combined the resistivity model obtained with hypocenters distribution. We revealed the sharp boundary between the saturated and unsaturated region, and a large conductive hydrothermal system connected to the main fumarolic area through a fractured region. Finally, we created a multiphase flow model of the volcano that constrains the resistivity model in term of temperature, fluid content and alteration.

MT survey and 3-D resistivity structure in the Niseko area, southwestern Hokkaido

*Makoto Tamura[1], Toru Mogi[2], Junna Kanahiro[2], Daisuke Oka[1], Junya Maruyama[1], Takahiro Suzuki[1], Noritoshi Okazaki[1]

1. Geological Survey of Hokkaido, Hokkaido Research Organization, 2. Division of Sustainable Resource Engineering, Fucluty of Engineering, Hokkaido University

In the Niseko area, southwestern Hokkaido, there are many volcanoes distributed along East-West direction that is so called “Niseko volcanic group”. And many hot springs are distributed around Iwaonupuri and Niseko-Annupuri volcano. Recently, geothermal explorations for energy development have been performed in this area.
During such situation, we are carrying out the priority research “Modelling of geothermal structure and assessment of geothermal resource potentials in the Niseko area” for sustainable application of geothermal resources. In this presentation, we show the MT survey and the 3-D resistivity structure analysis result as a part of this research.
We performed wideband MT survey at 18 stations in 2017 and 24 stations in 2018 around the Niseko area. Five components of electromagnetic fields were measured by ADU-07e and ADU-08e (manufactured by Metronix Geophisics). We obtained 32Hz data that was recorded for more than 5 days, 1024Hz data that was recorded more than 5 nights (1:00-5:00 : LT) and 32kHz data that was recorded one hour. Horizontal components of magnetic field data recorded at Ookura Vil., Yamagata Pref. were used for the remote reference processing of 32Hz and 1024Hz data. For 32kHz sampled data, we measured data at the same time in multiple stations for the remote reference processing. Also, we performed noise elimination processing for 50Hz electrical power lines.
MT responses at the frequency band of 12288-0.000488Hz were estimated using the robust time series processing code BIRRP (Chave and Thomson, 2004). Furthermore, we tried to obtain a 3-D resistivity structure with the aid of the ModEM inversion scheme (Egbert and Kelbert, 2012). Topographic effects might strongly affect the MT impedances because the survey area is located from the top to the foot of the volcano. In order to consider the topography into the 3D inversion, we used inland DEM data of 10m spacing provided by Geospatial Information Authority of Japan, and the seabed data of 500m spacing provided by Japan Coast Guard. Three-dimensional inversion was performed using four components of the tensor impedance from the field records.
In the results, we detected several conductive zones. A conductive zone was detected from the surface to several kilometers depth beneath the Iwaonupuri volcano. This would indicate volcanic hydrothermal system or hydrothermal rock alteration area. Also, we detected conductive zones around Ooyunuma Pond that is a hot spring bog, and southern foot of the Niseko-Annupuri volcano area where many hot springs are distributed. These conductive zones would indicate thermal water aquifers or related altered area.

Acknowledgement
The MT equipments (ADU-07) were used by Joint Usage Program in Earthquake Research Institute, University of Tokyo. Also, we used Magnetic field data of Geothermal Energy Research & Development CO., Ltd., for remote reference processing. We would like to thank these institutions.

Hydrothermal fluid activity of the Tatun Volcano Group, Taiwan, revealed by self-potentials and seismicity

*Hong-Jia Chen[1], Zhi-Xian Yang[1], Chien-Chih Chen[1,2], Cheng-Horng Lin[3,4]

1. Department of Earth Sciences, National Central University, Taiwan., 2. Earthquake-Disaster & Risk Evaluation and Management, National Central University, Taoyuan, Taiwan., 3. Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan., 4. Taiwan Volcano Observatory at Tatun, Taipei, Taiwan.

The objective of our research was to unravel the evolutions of the hydrothermal activities in the Tatun Volcano Group, Taiwan. We observed the significant variations of monthly earthquake counts, daily cumulative earthquake counts, and self-potential power spectral densities (PSDs) after April 21, 2016, providing strong evidence to identify hydrothermal fluid activities. This was further confirmed by the simulated electrical impedances using the resistivity forward modeling. Thus, an upward hydrothermal fluid movement is required to generate weaker PSDs of self-potentials at different frequencies. Herein, we concluded that geoelectric monitoring, along with seismic monitoring, help to understand the evolution of a hydrothermal system beneath a volcanic region.

Utilizing the electrical conductivity distribution to unravel the hydrothermal system beneath Mt.Hasan composite volcano and its vicinity, southwest Cappodocia, Turkey

*Sabri Bulent Tank[1], Mustafa Karas[1]

1. Bogazici University

The electrical conductivity structure in the vicinity of Mt.Hasan composite volcano at Central Anatolia, Turkey was imaged by means of wide-band magnetotellurics data collected at 38 sounding locations and three-dimensional numerical modeling. The primary aim in this study was to decipher the major elements that drive a hydrothermal system beneath study area in detail. Therefore, following the dimensionality analyses performed by plotting induction arrows and phase tensor ellipses, the electromagnetic impedance data were numerically modeled in the data-space for imaging (i) the shallow and (ii) the deep electric structure with different frequency tables. While the former approach, provided information on the the thickness of a surficial (surface-to-2 km) and widespread welded ignimbrite layer, the latter approach, revealed the geometry of the deeper two layers beneath the ignimbrites that make up the clay cap. These layers that are found on the top of one another are interpreted as smectite (<10 Ohmm) and smectite-illite mixed (<10-15 Ohmm) layers. And finally beneath the smectite and smectite-illite layers, there is a cone-shaped anomaly (10 –60 Ohmm) that may have been serving as a reservoir for different vents in the area.

Three-dimensional Magnetotelluric Inversion to map geothermal structures in Eburru Geothermal field, Kenya.

*JUSTUS MAITHYA[1], Yasuhiro FUJIMITSU[2]

1. Graduate School of Engineering, Department of Earth Resources Engineering, Kyushu University, 2. Faculty of Engineering, Department of Earth Resources Engineering, Kyushu University

To explore the geothermal system in Eburru geothermal field in an attempt to delineate possible heat sources and fluid flow pathways governing the system, 107 Magnetotelluric (MT) soundings were deployed in the field. The MT data was analyzed using phase tensor to determine the dimensionality of the subsurface resistivity structure. These data were inverted to a fully three-dimensional resistivity model. Overall, the inverted resistivity model fits the MT data very well as evidenced by the data misfit curves. Consequently, 2-D inversion were carried out and a joint interpretation was made on the basis of the two models. The preferred 3-D model images a resistive top layer overlying a very conductive layer (~ 10 ohm.m) interpreted as the hydrothermally altered clay cap of the system and a moderate resistivity layer (about 30 ohm.m). These layers are underlain by a higher resistivity zone (~ 100 ohm.m). To characterize the resistivity structure in the field, resistivity profiles were extracted from the 3-D model in order to cut across the known geological structures. The profiles analysed show a deep reaching conductive channel connecting two conductors located at ~ 1 km from the surface and at a depth of ~ 4 km. This channel can be interpreted as potential path way used by geothermal fluid to migrate to the surface and manifests as fumaroles and hot spring. The occurrence of fumaroles along faults suggests leakage of steam where the cap is likely to have been cut by the faults. The resultant 3-D resistivity models are generally similar to the two-dimensional (2-D) inversion models, however, the deeper portion of the 3-D model seems to be more realistic than that of the 2-D model.

Changes in the chemistry of spring water related to the recent volcanic activity of Mt Iwo-Yama, Kirishima volcanic area

*Haruka Yamamoto[1], Yoshikazu Kikawada[2], Megumi Fukai, Wei Deng

1. Graduated school of Fuculty of Sience and Technology Sophia University, 2. Fuculty of Sience and Technology Sophia University

Mt Iwo-Yama is an active volcano in the Kirishima volcanic area. The west flank of the volcano is known as the Ebino Highland. The volcano erupted in April 2018 for the first time in 250 years. The vents have opened with the phreatic eruptions and then formed boiling muddy pools. In this study, we discuss the current status of the volcanic activity of Mt Iwo-Yama based on the water chemistry of muddy crater lakes and the springs in the Ebino Highland.

We collected the sample water repeatedly from the muddy crater lakes at the summit area (V1) and the west flank (V2). The former one is the vent opened on April 19th, 2018 and the latter one is that opened on April 26th, 2018. In addition, we also collected repeatedly the specific spring water located along the small stream in the Ebino Highland. We labeled the spring water as S1 to S4 in the order of distance from the summit area. The collected water samples were chemically analyzed in our laboratory.

The V1 and V2 water contain extremely high concentrations of chloride and sulfate ions. Those two are very acidic, and the pH of them sometimes show the value lower than unity. These are considered that thermal water is supplied from the geothermal reservoir directly. At this writing, although the estimated temperatures for both reservoirs of V1 and V2 by the quartz geothermometer are over 200 deg-C, the temperature for V2 is a little higher than that of V1.

The fluctuations of Cl/SO4 ratio at S1, S2 and S3 are similar to that of V2. Also, the fluctuation of the ratio at S4, which is most far from the summit among the four, seems to be similar to these with 1- month time lag. From this, it is suggested that these springs in the Ebino Highland are affected by the geothermal activity related to V2. The concentration of dissolved chemical components and water temperature at S1 changed from an increasing trend to decreasing trend in August 2018. Conversely, these at S4 are on an increasing trend since September 2018.

The volcanic activity of Mt Iwo-Yama is remained to be active. Based on the water chemistry, the temperature of the geothermal system seems to be higher in the west flank area, that is the Ebino Highland area, than the summit area. The changes in the water chemistry of the hot springs suggesting the rise of thermal activity in the Ebino Highland have been observed. Further, the new fumaroles were opened in the west flank area since autumn 2018. In conclusion, it is considered that the geothermal activity of Mt Iwo-Yama is expanding from the summit area to the west flank area. This means that the thermal activity in the Ebino Highland area will become more active, and the fumarolic area will expand to the western part of the Ebino highland.

Hydrothermal circulation process related to phreatic eruption of Iwo-Yama at Kirishima volcanoes

*Keigo Mori[1], Harue Masuda[1], Tsuyoshi Shintani[1], Motoya Habuchi[1], Syuzou Furuya[1], Jun-ichiro Ishibashi[2], Takeshi Matsushima[2], Syogo Oshima[3], Reo Ikawa[4]

1. Osaka City University, 2. Kyushu University, 3. West Japan Engineering Consultants, Inc., 4. AIST

A phreatic eruption occurred on a south crater of Iwo-yama, Kirishima active volcano, on April 19, 2018, and active hydrothermal activities including fumarole and high temperature water outflow have continued until now. We analyzed major chemical compositions of waters sampled on the 12th and 13th October 2018 in order to clarify the hydrothermal systems beneath the Iwo-yama related to the phreatic eruption. Water temperature, pH, ORP, and EC were measured *in situ* using electrodes. Na^+ and K^+ were quantified using an atomic absorption spectrophotometer, and Si, As, Al^{3+}, Mn^{2+}, and Fe^{2+} were analyzed by ICP-MS. Ca^{2+} and Mg^{2+} were quantified by EDTA titration, while those of some samples by ICP-MS. Alkalinity was analyzed by neutralization titration. F^-, Cl^-, Br^-, NO_3^-, PO_4^{3-} and SO_4^{2-} were analyzed by ion chromatography. Hydrogen and oxygen isotope ratios of waters were analyzed by cavity ring down spectrophotometry.
The temperature and pH of erupting hot waters in the south and west craters were 70~ 97 ℃ and 1.3 ~ 2.1, respectively. The temperature and pH of low temperature springs in the northeastern wetland out of the craters were about 20 ℃ and 2.2 ~ 5.2. Cl^- and SO_4^{2-} concentrations ranged within 1000 ~ 8000 ppm and 2,000 to 10,000 ppm for hot waters and 3 ~ 300 ppm and 10 to 1100 ppm for low temperature spring waters. Positively linear relationship indicated the same origin of between concentrations of Cl^- and SO_4^{2-}. The d^2H and $d^{18}O$ of the highest Cl^- and SO_4^{2-} concentrated water were -18 ‰and -4.0 ‰, indicating high contribution of magmatic water. Strongly acidic water was formed by oxidation of magmatic components due to mixing of meteoric water in the groundwater aquifer. The all analyzed waters can be explained simple mixing of the above high temperature water with local meteoric water. It is notable that up to about 3000 ppb As was confirmed in the hot water.
The silica geothermometer indicated the highest temperature of 262 ˚C for the hot water containing the highest Cl^- concentration, suggesting the aquifer temperature is higher than that. The formation of high temperature water in the groundwater aquifer must be related to the phreatic eruption.

Determination on the stable isotopic compositions of H_2O in a volcanic plume

*Masanori Ito[1], Urumu Tsunogai[1], Koji U Takahashi[2], Fumiko Nakagawa[1]

1. Nagoya University, Graduate School of Environmental Studies, 2. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

The fumarolic H_2O occupied more than 80% of volatiles ejected from volcanic fumaroles (volcanic gases). The origin of fumarolic H_2O is either magma (magmatic water) or groundwater (meteoric water). Because of the significant differences in the isotopic ratios (δ D and δ^{18}O) of H_2O between magmatic water and meteoric water, we can differentiate the origins of fumarolic H_2O (magmatic water or meteoric water), if we can determine the isotopic ratios of fumarolic H_2O from those in volcanic plumes during a volcanic eruption. This is extremely useful for us to differentiate the mechanism of each volcanic eruption, magmatic eruption or phreatic eruption.
In this study, we determined the isotopic ratios of H_2O in a volcanic plume that had been ejected from accessible fumaroles to confirm whether the isotopic ratios (δ D and δ^{18}O) estimated from plume H_2O is consistent with those of fumarolic H_2O or not.
The samples were taken in Hakone volcano from 2014 to 2018. We collected around 20 volcanic plume samples into pre-evacuated glass bottle (ca. 1000 ml) during each sampling, while changing the distances from the fumarole. Besides, we also collected the fumarolic H_2O through condensation using a cold trap. The isotopic ratios (δ D and δ^{18}O) of plume H_2O showed strong linear correlation (R^2 = 0.9 or more) with the reciprocal of H_2O concentration. The isotopic ratios (δ D and δ^{18}O) estimated as the intercept of the linear correlation found in the plume H_2O was consistent with fumarolic H_2O. We concluded that we can estimate the stable isotopic ratios of fumarolic H_2O remotely using those in plume H_2O.
This study was supported by MEXT Scientific Research Program grants “Integrated Program for Next Generation Volcano Research and Human Resource Development”.

Radon measurements at Aso volcano: an experimental automatic radon station operative within the proximal zone of Nakadake

*Corrado CIGOLINI[1], Shin Yoshikawa[2], Tomo Shibata[3], Marco Laiolo[1], Diego Coppola[1]

1. Department of Earth Sciences, University of Torino, Italy, 2. Aso Volcanological Laboratory, Kyoto University, Japan, 3. Institute for Geothermal Sciences, Graduate school of Science, Kyoto University, Japan

Radon measurements at Aso Volcano first started on May 2015 and persisted until January 2016. They were resumed on August 2017 and they are currently on-going. Radon data have been collected by means of an in-soil automatic station located at about 1.06 km from the active crater (crater 1) together with soil temperatures (measured at the sampling site and 1 m below) and local atmospheric parameters (JMA).
During earlier measurements Aso volcano was affected by a sporadic explosive activity, which marked the ceasing of a Strombolian phase, and was followed by moderate phreatomagmatic events. Radon measurements been compared with ground-based and satellite thermal data, the latter collected by the MIROVA system. Radon concentrations were fluctuating from 300 to about 1100 Bq/m^3 during May-July 2015, and they reached a minimum two weeks before the strong degassing that occurred at the beginning of August. On August 8, 2015 the Volcanic Radiative Power (VRP) detected by MIROVA was slightly below 1 MW. Since then there has been an increasing trend in Radon emissions (up to about 900 Bq/m^3) that preceded the strong phreatic explosion of September 14. By the end of September, a new increasing trend reached a relative maximum (up to 1900 Bq/m^3) one week before the explosion of the 23 of October 2015. Then, radon data persistently fluctuated well above 900 Bq/m^3. This time span was accompanied by a general decrease of the detected thermal anomalies which were nearly coeval with the replenishment of the crater lake.
During 2017 radon emissions reached their relative maxima (up to 1380 Bq/m3) during fall-winter, whereas in 2018 the higher peak reaches 1450 Bq/m3 during the early fall (October 3). Several peaks seems to be correlated with the thermal gradient at the measurement site. However, some other peaks appear somehow coeval with some thermal anomalies in the crater area detected by the MIROVA system. Among these the one that occurred on May 15 that touched 1250 Bq/m3 and preceded the drastic increase in temperature of the South wall (up to 715 ˚C, according to JMA data). Two other minor anomalous peaks were recorded on June 13 and July 29, both were well above 800 Bq/m3. A systematic analysis of all radon data shows that radon emissions, in absence of anomalous spikes, are inversely correlated with soil temperatures and that the contribution of atmospheric pressure marginally affect radon emissions. The spectrum of the radon signal shows the existence of both diurnal and semidiurnal peaks, typically observed during continuous radon measurements. Future work should be concentrated in the attempt to better correlate radon emissions with the changes in volcanic activity, including the effects of environmental parameters on the radon signal.

Evolution of the hydrothermal system of Aso volcano during the 2014-2016 eruption period, as inferred by the ACTIVE observations

*Takuto Minami[1], Mitsuru Utsugi[2], Hisashi Utada[1], Tsuneomi Kagiyama[3]

1. Ocean Hemisphere Research Institute, Earthquake Research Institute,The University of Tokyo, 2. Aso Volcanological Laboratory, Institute for Geothremal Sciences, Graduate School of Science, Kyoto University, 3. Aso Geopark Promotion Council

Electrical resistivity structures provide important information about hydrothermal systems of volcanos. Previous studies using the magnetotelluric method have revealed shallow resistivity structures associated with conductive cap rocks underlain by hydrothermal reservoirs (e.g. Nurhasan et al. 2006). However, evolution of such a hydrothermal system over volcanic eruptions has never been understood in detail.

We have intermittently conducted observations of an electromagnetic volcano monitoring system, ACTIVE (Utada et al. 2007), in Aso volcano for about half a decade. ACTIVE system consists of transmitter dipoles for controlled-source electric currents and an array of induction-coil receivers for measuring the vertical component of the induced magnetic field dependent on the subsurface resistivity structure. ACTIVE system in Aso volcano recently succeeded in detecting temporal variation in the resistivity structure over the magmatic eruptions that started in November 2014 and ceased in May 2015 (hereafter referred to as the magmatic eruption period (MEP)). In our previous study, three-dimensional inversions for the two sets of ACTIVE responses obtained in August 2014 and August 2015 revealed (1) a broad increase in resistivity ~400 m below the bottom of the first Nakadake crater and (2) a decrease in resistivity ~100 m beneath the western rim of the crater (Minami et al. 2018). Both changes in resistivity presumably originated before MEP because the corresponding variation in the ACTIVE response happened mainly between the two observation campaigns in August 2014 and just after the starting of MEP, say, on November 26, 2015. The decrease of resistivity at shallow level implies presence of a temporal fluid reservoir which appeared prior to MEP and possibly contributed to the phreatomagmatic eruptions in September 2015 and October 2016. We are now analyzing the ACTIVE responses after MEP to resolve evolution of the hydrothermal system of Aso volcano over the active period spanning from November 2014 to October 2016.

In the presentation, we comprehensively discuss evolution of the hydrothermal system of Aso volcano from August 2014 to August 2017, including MEP from August 2014 to May 2015 and the two phreatomagmatic eruption events in September 2015 and in October 2016, by using ACTIVE data sets.

3-D Inversion of Magnetotelluric data from the Aluto-Langano Geothermal Field, Ethiopia

*Dejene Bekele[1], Yasuhiro FUJIMITSU[2]

1. Graduate School of Engineering, Department of Cooperative Resources Engineering, Kyushu University, 2. Faculty of Engineering, Department of Earth Resources Engineering, Kyushu University

The Main Ethiopian rift valley hosts a number of geothermal prospected area, which is known to be actively deforming with reoccurring periods of uplift and setting. One of the regions where the prospected area is confirmed by drilling is the Aluto-Langano geothermal area. Aluto area is situated in the Main Ethiopian rift valley system bounded by latitude 7.60˚-7.96˚ N and longitude 38.68˚-38.92˚ E. This field has been studied by the Geological Survey of Ethiopia (GSE) since1980s, and these studies subsequently led to the drilling of 10 exploration wells. This field is currently developed with a Binary power plant of a 7.2 MWe installed capacity. From the results of various regional geoscientific studies in this part of the Ethiopian rift, the area of Aluto-Langano geothermal field was observed to have relatively higher exploitable geothermal potential in Ethiopia. However, more studies are required in order to obtain more information about the subsurface structure and heat source below the Aluto volcanic complex (AVC) and to delineate the parameters of the geothermal reservoir in the area. To address this, Electro Consultant (ELC) and GSE carried out magnetotelluric surveys in the Aluto-Langano geothermal field in 2009 and 2015 respectively. This study combines the two surveys done covering the whole Aluto volcanic complex with a total of 166 MT stations. The MT data was processed and used in the construction of a 3-D MT inversion model, which was then interpreted alongside the available geological information. The dimensionality analysis of MT data was carried out based on the strike and dimensions of the resistivity distribution around the MT sites, by plotting the Phase tensor for each MT site for the frequency range of 10^{4} -10^{-3} Hz. Most of the maps of phase tensor exhibit 3-D structures, hence need for 3-D inversion. In order to get 3-D conductivity models of the subsurface, the MT data were inverted in the period range of 10^{-3}–10^{4}s at uniform distributed discrete periods using the ModEM code. The resultant 3-D resistivity model shows a highly conductive zone with a diameter of around 10 km in the center of the Aluto volcanic complex at depths between 800–2500 m. The identified resistivity distribution corresponds very well to the conceptual reservoir model of a high-enthalpy geothermal system with its mushroom shaped zoning comprising a resistive up-flow zone overlain by a conductive clay cap. From well data analysis it is known that the conductive cap at Aluto is related to rock units and therefore, eliciting the origin of the heat source and delineating the subsurface structure in the study area. The 3-D resistivity model images the resistivity structure in the study area hence showing the origin of Aluto heat sources and delineating the location of faults and fracture system. In particular, the cap rock zones of the geothermal reservoir system by studying low resistivity zones at relatively shallow depths are important in selecting future drilling targets.

Interpretation of Gravity Data to Delineate the Geothermal Reservoir Extent and Assess the Geothermal Resource in the Municipality of Isa, Southern Kyushu, Japan

*CARLOS OSMIN POCASANGRE[1], Yasuhiro Fujimitsu[1], Jun Nishijima[1]

1. Department of Earth Resources Engineering, Kyushu University

The municipality of Isa is located in the southern part of Kyushu Island, and it is considered one of the wealthiest places in Japan because one of the most important gold mines is found in this area, Hishikari mine. Additionally, there are many hydrothermal manifestations, e.g., Hishikari, Yunoo, Kawanami, and Kintaro hot springs, which can be exploited by the community as an electric power source. Until now, the geothermal resource has not been used for power generation purpose although Geological Survey of Japan had carried out some preliminary geothermal assessments, which show that the power potential density is between 10 and 20 kW/km^2. To calibrate the previous value, first, this study attempts to analyze and interpret the gravity data for delineating the geothermal reservoir boundary and the assessment of geothermal resource. Accordingly, the corresponding researchers conducted 2-D and 3-D gravity modeling in the current research. This modeling is an essential stage of the complete gravity analysis in the region, because the filtering gravity methods, i.e., Horizontal-Derivative and Tilt-Derivative, can quickly detect steep gradients and indicate the location of faults or geological boundaries, however, they cannot estimate geological structure depth and shape. For this purpose, an area of 10 x 10 km was selected and analyzed considering a Bouguer Density of 2.45 g/cm^3. The Bouguer Anomaly result shows a high value at the center, which extends 5.61 km^2 wide and could represent the probable geothermal resource. According to the Kagoshima geological map, volcanic and sedimentary rocks are the dominant type of rocks in this area. Cretaceous Shimanto group controls the fundamental structure of the deepest element. This arrangement is typically composed of sandstone, shale, acidic tuff with subordinate conglomerates, and their alterations, also Pliocene volcanic rocks and alluvial deposits. Similarly, Kakuto and Okuchi Basin, which are located at east and west respectively, control the region. The 2-D gravity modeling was carried out requiring a density contrast between the two assumed layers, i.e., the basement and the low-density deposit, and thus a value of 0.4 g/cm^3 was assigned. Likewise, the horizontal size of the cells was set at 100 m. The profile trending NW- SE shows a significant depression 400 m to 700 m deep located next to Hishikari hot spring. In this way, the hydrothermal fluids might be flowing up to the surface forming altered rocks and hot springs by using a possible geological fault. For a better understanding of the region, the authors also carried out 3-D gravity modeling. The result shows an area which has density values below 2.4 g/cm^3 and the zone NE-SW direction that starts at the Uonogoe area and ends at the Yamada area. Besides, a large anomaly located in the central area that has density values above 2.5 g/cm^3 is evident. This anomaly represents the hydrothermal alteration zone that hosts the propylitic altered rocks having precious minerals such as gold and silver. Between these evidenced zones, we could infer the location of the geothermal reserve which has an area of 4.06 km^2. Integrating past research reports carried out by NEDO, using the Volumetric method with the calculated geothermal reserve area, and a Monte Carlo simulation, we estimated a geothermal power potential of 90 kW (22.5 kW/km^2) for 20 years. Nevertheless, this result needs to be corrected by further geoscientific investigations including inversion modelings.

Conductive and convective heat fluxes inferred from temperature profile of a borehole in Izu-Oshima volcano

*Shin'ya Onizawa[1]

1. Volcanology Research Department, Meteorological Research Institute, JMA

A 1,000 m-deep borehole was drilled at the western rim of the caldera of Izu-Oshima volcano by Earthquake Research Institute, University of Tokyo in 1998. Temperature profiles of deep borehole provide information of subsurface heat and groundwater flows, which are clues to understand structure of geothermal fluid systems in volcanic and geothermal areas. Here, conducive and convective heat fluxes of Izu-Oshima volcano are estimated by using the temperature profile data.

A wellhead altitude of the borehole is 547 m, so as that the bottom depth is 453 m bsl. The borehole penetrates main strata in this area. Above the sea level, the edifice is mainly composed of the alternation of scoria, lava and volcanic ash (“Post-caldera” and “Pre-caldera younger edifice”). Tuff breccias become dominant approximately below the sea level (“Pre-caldera older edifice”). “The basement”, which comprises altered volcanic and volcaniclastic sedimentary rocks, appears from 250 m bsl. to the well bottom (Nakada *et al.* 1999).

Groundwater level is 36 m asl. Thus, about 500 m of a thick unsaturated zone develops above the level. Characteristics of the ground temperature profile are divided at the groundwater level. In the unsaturated zone, 16-17 degC of a constant temperature continues at depths of ca. 50-350 m (ca. 500-200 m asl.). From 200 m asl. to the groundwater level, the temperature gradient gradually increases. This downward convex pattern of the temperature profile implies a strong downward flow of meteoric water infiltrating into the unsaturated volcanic edifice. At the groundwater level, the temperature is about 37 degC. Below the level, ca. 0.28 degC/m of a steep temperature gradient is observed, reaching 173.3 degC at the well bottom. The gradient is not constant but seems to be two upward convex patterns implying upward flows of groundwater.

The temperature profile in the saturated zone below the groundwater level was analyzed. The temperature gradients seem to depend on the lithology. Therefore, correction of lithology should be conducted to quantitatively extract information on the convective heat fluxes. Since a bulk density has been inferred by borehole gravimeter measurements in intervals of about 10 m, the porosity for each depth can be calculated by assuming densities of the rock without pore and water filling the pore. The bulk thermal conductivity for each depth was calculated by a relationship proposed for porous basaltic rocks by Robertson (1988).

The temperature profile data were analyzed by assuming a one-dimensional steady vertical groundwater flow. The model was applied to two depth ranges; 1) upper part of the Pre-caldera older edifice, and 2)

©2019. Japan Geoscience Union. All Right Reserved.

the basement. In the upper part of the Pre-caldera older edifice, *Pe* = 0.91 of the Péclet number was obtained, suggesting the convective heat flux is comparable to the conductive heat flux. The estimated conductive and convective heat fluxes and the Darcy velocity are 0.45 –0.56 W/m^2, 0.41 –0.51 W/m^2 and (1.42-1.78)*10^{-6} m/s, respectively. In the basement layer, as compared to the upper part of the older edifice of pre-caldera, *Pe=0.31-0.41* of smaller Péclet numbers were obtained, suggesting that the conductive heat flux is dominant. The conductive and convective heat fluxes and the Darcy velocity are 0.32 –0.39 W/m^2, 0.12 –0.13 W/m^2 and (4.71-4.98)*10^{-7} m/s, respectively.

Honda *et al.* (1979) inferred 0.2 W/m^2 of the conductive heat flux at the depth of 500-700 m (within the basement layer) at the northwestern coastal area. The estimated flux is about three times of the averaged terrestrial heat flux. The conductive heat flux within the basement layer in the caldera region inferred by this study is one and a half times to twice of the flux at the coastal area. The convective flux is added to this. When these heat fluxes are applied to 100 km^2 of the area (approximately whole the island scale), the total heat flow is estimated as to be 20-51 MW.

Numerical model of the hydrothermal system at the Akakura Caldera in Kurikoma Area

*Yasuhiro Fujimitsu[1], Daichi Yoshioka[2]

1. Department of Earth Resources Engineering, Faculty of Engineering, Kyushu University, 2. Department of Earth Resources Engineering, Graduate School of Engineering, Kyushu University

The Akakura Caldera is located at the southern part of Kurikoma Area, and is one of the old calderas in Tohoku District. It was formed by the huge pyroclastic flow about 3 million years ago. This study conducts numerical simulations of the hydrothermal system development that is modeled after the Akakura Caldera. In the numerical modeling, the structures such as a magma chamber that was associated with the formation of the caldera structure (Magma 1), high permeable fracture zone associated with a reverse fault and a circular fracture, impermeable layers filled with quartz and fracture clouds were considered and emplacement of a magma chamber that generated the post-caldera volcanic activity of 0.8 to 1.4 Ma (Magma 2) was also included. The calculation period was 3 million years from the emplacement of Magma 1 to the present and Magma 2 was emplaced 2.2 million years after the emplacement of Magma 1. The initial temperature of Magmas 1 and 2 was set as 1000 deg C. For the size of Magma 2, two kinds of diameter (2.5 km and 3.5 km) were adopted for the modeling. As a result, it was indicated that a supercritical geothermal fluid region still remains at the depth of 5 km until about 100 thousands years after the emplacement of Magma 2. It is inferred that a high enthalpy hydrothermal system can exist at a piston-cylinder type caldera with a post-caldera volcanic activity like the Akakura Caldera until about 10 thousands years after the commencement of the post-caldera volcanic activity.

[J] Poster | S (Solid Earth Sciences)：S-VC Volcanology

Mon. May 27, 2019 5:15 PM - 6:30 PM JST | Mon. May 27, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_26

[S-VC39] Hydrothermal systems of volcanoes

convener:Yasuhiro Fujimitsu(Department of Earth Resources Engineering, Faculty of Engineering, Kyushu University), Wataru Kanda(Volcanic Fluid Research Center, School of Science, Tokyo Institute of Technology), Takeshi Ohba(Department of chemistry, School of Science, Tokia University)

There is a diversity of hydrothermal systems between magmas and the ground surface in various geoscientific environments. Understanding of the hydrothermal systems contributes to understanding of the earth systems, and is essential for utilization of geothermal energy and prediction of volcanic eruption. In this session, we will discuss the topics on subsurface structures and heat and fluid flows of "hydrothermal systems of volcanoes" from the perspectives of geophysics, geochemistry, geology and geothermal reservoir engineering. Any research approaches, theoretical, observational and experimental, are welcome.

Changes in the chemistry of spring water related to the recent volcanic activity of Mt Iwo-Yama, Kirishima volcanic area

*Haruka Yamamoto[1], Yoshikazu Kikawada[2], Megumi Fukai, Wei Deng

1. Graduated school of Fuculty of Sience and Technology Sophia University, 2. Fuculty of Sience and Technology Sophia University

Mt Iwo-Yama is an active volcano in the Kirishima volcanic area. The west flank of the volcano is known as the Ebino Highland. The volcano erupted in April 2018 for the first time in 250 years. The vents have opened with the phreatic eruptions and then formed boiling muddy pools. In this study, we discuss the current status of the volcanic activity of Mt Iwo-Yama based on the water chemistry of muddy crater lakes and the springs in the Ebino Highland.

We collected the sample water repeatedly from the muddy crater lakes at the summit area (V1) and the west flank (V2). The former one is the vent opened on April 19th, 2018 and the latter one is that opened on April 26th, 2018. In addition, we also collected repeatedly the specific spring water located along the small stream in the Ebino Highland. We labeled the spring water as S1 to S4 in the order of distance from the summit area. The collected water samples were chemically analyzed in our laboratory.

The V1 and V2 water contain extremely high concentrations of chloride and sulfate ions. Those two are very acidic, and the pH of them sometimes show the value lower than unity. These are considered that thermal water is supplied from the geothermal reservoir directly. At this writing, although the estimated temperatures for both reservoirs of V1 and V2 by the quartz geothermometer are over 200 deg-C, the temperature for V2 is a little higher than that of V1.

The fluctuations of Cl/SO4 ratio at S1, S2 and S3 are similar to that of V2. Also, the fluctuation of the ratio at S4, which is most far from the summit among the four, seems to be similar to these with 1- month time lag. From this, it is suggested that these springs in the Ebino Highland are affected by the geothermal activity related to V2. The concentration of dissolved chemical components and water temperature at S1 changed from an increasing trend to decreasing trend in August 2018. Conversely, these at S4 are on an increasing trend since September 2018.

The volcanic activity of Mt Iwo-Yama is remained to be active. Based on the water chemistry, the temperature of the geothermal system seems to be higher in the west flank area, that is the Ebino Highland area, than the summit area. The changes in the water chemistry of the hot springs suggesting the rise of thermal activity in the Ebino Highland have been observed. Further, the new fumaroles were opened in the west flank area since autumn 2018. In conclusion, it is considered that the geothermal activity of Mt Iwo-Yama is expanding from the summit area to the west flank area. This means that the thermal activity in the Ebino Highland area will become more active, and the fumarolic area will expand to the western part of the Ebino highland.

Hydrothermal circulation process related to phreatic eruption of Iwo-Yama at Kirishima volcanoes

*Keigo Mori[1], Harue Masuda[1], Tsuyoshi Shintani[1], Motoya Habuchi[1], Syuzou Furuya[1], Jun-ichiro Ishibashi[2], Takeshi Matsushima[2], Syogo Oshima[3], Reo Ikawa[4]

1. Osaka City University, 2. Kyushu University, 3. West Japan Engineering Consultants, Inc., 4. AIST

A phreatic eruption occurred on a south crater of Iwo-yama, Kirishima active volcano, on April 19, 2018, and active hydrothermal activities including fumarole and high temperature water outflow have continued until now. We analyzed major chemical compositions of waters sampled on the 12th and 13th October 2018 in order to clarify the hydrothermal systems beneath the Iwo-yama related to the phreatic eruption. Water temperature, pH, ORP, and EC were measured *in situ* using electrodes. Na^+ and K^+ were quantified using an atomic absorption spectrophotometer, and Si, As, Al^{3+}, Mn^{2+}, and Fe^{2+} were analyzed by ICP-MS. Ca^{2+} and Mg^{2+} were quantified by EDTA titration, while those of some samples by ICP-MS. Alkalinity was analyzed by neutralization titration. F^-, Cl^-, Br^-, NO_3^-, PO_4^{3-} and SO_4^{2-} were analyzed by ion chromatography. Hydrogen and oxygen isotope ratios of waters were analyzed by cavity ring down spectrophotometry.
The temperature and pH of erupting hot waters in the south and west craters were 70~ 97 ℃ and 1.3 ~ 2.1, respectively. The temperature and pH of low temperature springs in the northeastern wetland out of the craters were about 20 ℃ and 2.2 ~ 5.2. Cl^- and SO_4^{2-} concentrations ranged within 1000 ~ 8000 ppm and 2,000 to 10,000 ppm for hot waters and 3 ~ 300 ppm and 10 to 1100 ppm for low temperature spring waters. Positively linear relationship indicated the same origin of between concentrations of Cl^- and SO_4^{2-}. The d^2H and $d^{18}O$ of the highest Cl^- and SO_4^{2-} concentrated water were -18 ‰and -4.0 ‰, indicating high contribution of magmatic water. Strongly acidic water was formed by oxidation of magmatic components due to mixing of meteoric water in the groundwater aquifer. The all analyzed waters can be explained simple mixing of the above high temperature water with local meteoric water. It is notable that up to about 3000 ppb As was confirmed in the hot water.
The silica geothermometer indicated the highest temperature of 262 ˚C for the hot water containing the highest Cl^- concentration, suggesting the aquifer temperature is higher than that. The formation of high temperature water in the groundwater aquifer must be related to the phreatic eruption.

Determination on the stable isotopic compositions of H_2O in a volcanic plume

*Masanori Ito[1], Urumu Tsunogai[1], Koji U Takahashi[2], Fumiko Nakagawa[1]

1. Nagoya University, Graduate School of Environmental Studies, 2. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

The fumarolic H_2O occupied more than 80% of volatiles ejected from volcanic fumaroles (volcanic gases). The origin of fumarolic H_2O is either magma (magmatic water) or groundwater (meteoric water). Because of the significant differences in the isotopic ratios (δ D and δ^{18}O) of H_2O between magmatic water and meteoric water, we can differentiate the origins of fumarolic H_2O (magmatic water or meteoric water), if we can determine the isotopic ratios of fumarolic H_2O from those in volcanic plumes during a volcanic eruption. This is extremely useful for us to differentiate the mechanism of each volcanic eruption, magmatic eruption or phreatic eruption.
In this study, we determined the isotopic ratios of H_2O in a volcanic plume that had been ejected from accessible fumaroles to confirm whether the isotopic ratios (δ D and δ^{18}O) estimated from plume H_2O is consistent with those of fumarolic H_2O or not.
The samples were taken in Hakone volcano from 2014 to 2018. We collected around 20 volcanic plume samples into pre-evacuated glass bottle (ca. 1000 ml) during each sampling, while changing the distances from the fumarole. Besides, we also collected the fumarolic H_2O through condensation using a cold trap. The isotopic ratios (δ D and δ^{18}O) of plume H_2O showed strong linear correlation (R^2 = 0.9 or more) with the reciprocal of H_2O concentration. The isotopic ratios (δ D and δ^{18}O) estimated as the intercept of the linear correlation found in the plume H_2O was consistent with fumarolic H_2O. We concluded that we can estimate the stable isotopic ratios of fumarolic H_2O remotely using those in plume H_2O.
This study was supported by MEXT Scientific Research Program grants “Integrated Program for Next Generation Volcano Research and Human Resource Development”.

Radon measurements at Aso volcano: an experimental automatic radon station operative within the proximal zone of Nakadake

*Corrado CIGOLINI[1], Shin Yoshikawa[2], Tomo Shibata[3], Marco Laiolo[1], Diego Coppola[1]

1. Department of Earth Sciences, University of Torino, Italy, 2. Aso Volcanological Laboratory, Kyoto University, Japan, 3. Institute for Geothermal Sciences, Graduate school of Science, Kyoto University, Japan

Radon measurements at Aso Volcano first started on May 2015 and persisted until January 2016. They were resumed on August 2017 and they are currently on-going. Radon data have been collected by means of an in-soil automatic station located at about 1.06 km from the active crater (crater 1) together with soil temperatures (measured at the sampling site and 1 m below) and local atmospheric parameters (JMA).
During earlier measurements Aso volcano was affected by a sporadic explosive activity, which marked the ceasing of a Strombolian phase, and was followed by moderate phreatomagmatic events. Radon measurements been compared with ground-based and satellite thermal data, the latter collected by the MIROVA system. Radon concentrations were fluctuating from 300 to about 1100 Bq/m^3 during May-July 2015, and they reached a minimum two weeks before the strong degassing that occurred at the beginning of August. On August 8, 2015 the Volcanic Radiative Power (VRP) detected by MIROVA was slightly below 1 MW. Since then there has been an increasing trend in Radon emissions (up to about 900 Bq/m^3) that preceded the strong phreatic explosion of September 14. By the end of September, a new increasing trend reached a relative maximum (up to 1900 Bq/m^3) one week before the explosion of the 23 of October 2015. Then, radon data persistently fluctuated well above 900 Bq/m^3. This time span was accompanied by a general decrease of the detected thermal anomalies which were nearly coeval with the replenishment of the crater lake.
During 2017 radon emissions reached their relative maxima (up to 1380 Bq/m3) during fall-winter, whereas in 2018 the higher peak reaches 1450 Bq/m3 during the early fall (October 3). Several peaks seems to be correlated with the thermal gradient at the measurement site. However, some other peaks appear somehow coeval with some thermal anomalies in the crater area detected by the MIROVA system. Among these the one that occurred on May 15 that touched 1250 Bq/m3 and preceded the drastic increase in temperature of the South wall (up to 715 ˚C, according to JMA data). Two other minor anomalous peaks were recorded on June 13 and July 29, both were well above 800 Bq/m3. A systematic analysis of all radon data shows that radon emissions, in absence of anomalous spikes, are inversely correlated with soil temperatures and that the contribution of atmospheric pressure marginally affect radon emissions. The spectrum of the radon signal shows the existence of both diurnal and semidiurnal peaks, typically observed during continuous radon measurements. Future work should be concentrated in the attempt to better correlate radon emissions with the changes in volcanic activity, including the effects of environmental parameters on the radon signal.

Evolution of the hydrothermal system of Aso volcano during the 2014-2016 eruption period, as inferred by the ACTIVE observations

*Takuto Minami[1], Mitsuru Utsugi[2], Hisashi Utada[1], Tsuneomi Kagiyama[3]

1. Ocean Hemisphere Research Institute, Earthquake Research Institute,The University of Tokyo, 2. Aso Volcanological Laboratory, Institute for Geothremal Sciences, Graduate School of Science, Kyoto University, 3. Aso Geopark Promotion Council

Electrical resistivity structures provide important information about hydrothermal systems of volcanos. Previous studies using the magnetotelluric method have revealed shallow resistivity structures associated with conductive cap rocks underlain by hydrothermal reservoirs (e.g. Nurhasan et al. 2006). However, evolution of such a hydrothermal system over volcanic eruptions has never been understood in detail.

We have intermittently conducted observations of an electromagnetic volcano monitoring system, ACTIVE (Utada et al. 2007), in Aso volcano for about half a decade. ACTIVE system consists of transmitter dipoles for controlled-source electric currents and an array of induction-coil receivers for measuring the vertical component of the induced magnetic field dependent on the subsurface resistivity structure. ACTIVE system in Aso volcano recently succeeded in detecting temporal variation in the resistivity structure over the magmatic eruptions that started in November 2014 and ceased in May 2015 (hereafter referred to as the magmatic eruption period (MEP)). In our previous study, three-dimensional inversions for the two sets of ACTIVE responses obtained in August 2014 and August 2015 revealed (1) a broad increase in resistivity ~400 m below the bottom of the first Nakadake crater and (2) a decrease in resistivity ~100 m beneath the western rim of the crater (Minami et al. 2018). Both changes in resistivity presumably originated before MEP because the corresponding variation in the ACTIVE response happened mainly between the two observation campaigns in August 2014 and just after the starting of MEP, say, on November 26, 2015. The decrease of resistivity at shallow level implies presence of a temporal fluid reservoir which appeared prior to MEP and possibly contributed to the phreatomagmatic eruptions in September 2015 and October 2016. We are now analyzing the ACTIVE responses after MEP to resolve evolution of the hydrothermal system of Aso volcano over the active period spanning from November 2014 to October 2016.

In the presentation, we comprehensively discuss evolution of the hydrothermal system of Aso volcano from August 2014 to August 2017, including MEP from August 2014 to May 2015 and the two phreatomagmatic eruption events in September 2015 and in October 2016, by using ACTIVE data sets.

3-D Inversion of Magnetotelluric data from the Aluto-Langano Geothermal Field, Ethiopia

*Dejene Bekele[1], Yasuhiro FUJIMITSU[2]

1. Graduate School of Engineering, Department of Cooperative Resources Engineering, Kyushu University, 2. Faculty of Engineering, Department of Earth Resources Engineering, Kyushu University

The Main Ethiopian rift valley hosts a number of geothermal prospected area, which is known to be actively deforming with reoccurring periods of uplift and setting. One of the regions where the prospected area is confirmed by drilling is the Aluto-Langano geothermal area. Aluto area is situated in the Main Ethiopian rift valley system bounded by latitude 7.60˚-7.96˚ N and longitude 38.68˚-38.92˚ E. This field has been studied by the Geological Survey of Ethiopia (GSE) since1980s, and these studies subsequently led to the drilling of 10 exploration wells. This field is currently developed with a Binary power plant of a 7.2 MWe installed capacity. From the results of various regional geoscientific studies in this part of the Ethiopian rift, the area of Aluto-Langano geothermal field was observed to have relatively higher exploitable geothermal potential in Ethiopia. However, more studies are required in order to obtain more information about the subsurface structure and heat source below the Aluto volcanic complex (AVC) and to delineate the parameters of the geothermal reservoir in the area. To address this, Electro Consultant (ELC) and GSE carried out magnetotelluric surveys in the Aluto-Langano geothermal field in 2009 and 2015 respectively. This study combines the two surveys done covering the whole Aluto volcanic complex with a total of 166 MT stations. The MT data was processed and used in the construction of a 3-D MT inversion model, which was then interpreted alongside the available geological information. The dimensionality analysis of MT data was carried out based on the strike and dimensions of the resistivity distribution around the MT sites, by plotting the Phase tensor for each MT site for the frequency range of 10^{4} -10^{-3} Hz. Most of the maps of phase tensor exhibit 3-D structures, hence need for 3-D inversion. In order to get 3-D conductivity models of the subsurface, the MT data were inverted in the period range of 10^{-3}–10^{4}s at uniform distributed discrete periods using the ModEM code. The resultant 3-D resistivity model shows a highly conductive zone with a diameter of around 10 km in the center of the Aluto volcanic complex at depths between 800–2500 m. The identified resistivity distribution corresponds very well to the conceptual reservoir model of a high-enthalpy geothermal system with its mushroom shaped zoning comprising a resistive up-flow zone overlain by a conductive clay cap. From well data analysis it is known that the conductive cap at Aluto is related to rock units and therefore, eliciting the origin of the heat source and delineating the subsurface structure in the study area. The 3-D resistivity model images the resistivity structure in the study area hence showing the origin of Aluto heat sources and delineating the location of faults and fracture system. In particular, the cap rock zones of the geothermal reservoir system by studying low resistivity zones at relatively shallow depths are important in selecting future drilling targets.

Interpretation of Gravity Data to Delineate the Geothermal Reservoir Extent and Assess the Geothermal Resource in the Municipality of Isa, Southern Kyushu, Japan

*CARLOS OSMIN POCASANGRE[1], Yasuhiro Fujimitsu[1], Jun Nishijima[1]

1. Department of Earth Resources Engineering, Kyushu University

The municipality of Isa is located in the southern part of Kyushu Island, and it is considered one of the wealthiest places in Japan because one of the most important gold mines is found in this area, Hishikari mine. Additionally, there are many hydrothermal manifestations, e.g., Hishikari, Yunoo, Kawanami, and Kintaro hot springs, which can be exploited by the community as an electric power source. Until now, the geothermal resource has not been used for power generation purpose although Geological Survey of Japan had carried out some preliminary geothermal assessments, which show that the power potential density is between 10 and 20 kW/km^2. To calibrate the previous value, first, this study attempts to analyze and interpret the gravity data for delineating the geothermal reservoir boundary and the assessment of geothermal resource. Accordingly, the corresponding researchers conducted 2-D and 3-D gravity modeling in the current research. This modeling is an essential stage of the complete gravity analysis in the region, because the filtering gravity methods, i.e., Horizontal-Derivative and Tilt-Derivative, can quickly detect steep gradients and indicate the location of faults or geological boundaries, however, they cannot estimate geological structure depth and shape. For this purpose, an area of 10 x 10 km was selected and analyzed considering a Bouguer Density of 2.45 g/cm^3. The Bouguer Anomaly result shows a high value at the center, which extends 5.61 km^2 wide and could represent the probable geothermal resource. According to the Kagoshima geological map, volcanic and sedimentary rocks are the dominant type of rocks in this area. Cretaceous Shimanto group controls the fundamental structure of the deepest element. This arrangement is typically composed of sandstone, shale, acidic tuff with subordinate conglomerates, and their alterations, also Pliocene volcanic rocks and alluvial deposits. Similarly, Kakuto and Okuchi Basin, which are located at east and west respectively, control the region. The 2-D gravity modeling was carried out requiring a density contrast between the two assumed layers, i.e., the basement and the low-density deposit, and thus a value of 0.4 g/cm^3 was assigned. Likewise, the horizontal size of the cells was set at 100 m. The profile trending NW- SE shows a significant depression 400 m to 700 m deep located next to Hishikari hot spring. In this way, the hydrothermal fluids might be flowing up to the surface forming altered rocks and hot springs by using a possible geological fault. For a better understanding of the region, the authors also carried out 3-D gravity modeling. The result shows an area which has density values below 2.4 g/cm^3 and the zone NE-SW direction that starts at the Uonogoe area and ends at the Yamada area. Besides, a large anomaly located in the central area that has density values above 2.5 g/cm^3 is evident. This anomaly represents the hydrothermal alteration zone that hosts the propylitic altered rocks having precious minerals such as gold and silver. Between these evidenced zones, we could infer the location of the geothermal reserve which has an area of 4.06 km^2. Integrating past research reports carried out by NEDO, using the Volumetric method with the calculated geothermal reserve area, and a Monte Carlo simulation, we estimated a geothermal power potential of 90 kW (22.5 kW/km^2) for 20 years. Nevertheless, this result needs to be corrected by further geoscientific investigations including inversion modelings.

Conductive and convective heat fluxes inferred from temperature profile of a borehole in Izu-Oshima volcano

*Shin'ya Onizawa[1]

1. Volcanology Research Department, Meteorological Research Institute, JMA

A 1,000 m-deep borehole was drilled at the western rim of the caldera of Izu-Oshima volcano by Earthquake Research Institute, University of Tokyo in 1998. Temperature profiles of deep borehole provide information of subsurface heat and groundwater flows, which are clues to understand structure of geothermal fluid systems in volcanic and geothermal areas. Here, conducive and convective heat fluxes of Izu-Oshima volcano are estimated by using the temperature profile data.

A wellhead altitude of the borehole is 547 m, so as that the bottom depth is 453 m bsl. The borehole penetrates main strata in this area. Above the sea level, the edifice is mainly composed of the alternation of scoria, lava and volcanic ash (“Post-caldera” and “Pre-caldera younger edifice”). Tuff breccias become dominant approximately below the sea level (“Pre-caldera older edifice”). “The basement”, which comprises altered volcanic and volcaniclastic sedimentary rocks, appears from 250 m bsl. to the well bottom (Nakada *et al.* 1999).

Groundwater level is 36 m asl. Thus, about 500 m of a thick unsaturated zone develops above the level. Characteristics of the ground temperature profile are divided at the groundwater level. In the unsaturated zone, 16-17 degC of a constant temperature continues at depths of ca. 50-350 m (ca. 500-200 m asl.). From 200 m asl. to the groundwater level, the temperature gradient gradually increases. This downward convex pattern of the temperature profile implies a strong downward flow of meteoric water infiltrating into the unsaturated volcanic edifice. At the groundwater level, the temperature is about 37 degC. Below the level, ca. 0.28 degC/m of a steep temperature gradient is observed, reaching 173.3 degC at the well bottom. The gradient is not constant but seems to be two upward convex patterns implying upward flows of groundwater.

The temperature profile in the saturated zone below the groundwater level was analyzed. The temperature gradients seem to depend on the lithology. Therefore, correction of lithology should be conducted to quantitatively extract information on the convective heat fluxes. Since a bulk density has been inferred by borehole gravimeter measurements in intervals of about 10 m, the porosity for each depth can be calculated by assuming densities of the rock without pore and water filling the pore. The bulk thermal conductivity for each depth was calculated by a relationship proposed for porous basaltic rocks by Robertson (1988).

The temperature profile data were analyzed by assuming a one-dimensional steady vertical groundwater flow. The model was applied to two depth ranges; 1) upper part of the Pre-caldera older edifice, and 2)

©2019. Japan Geoscience Union. All Right Reserved.

the basement. In the upper part of the Pre-caldera older edifice, *Pe* = 0.91 of the Péclet number was obtained, suggesting the convective heat flux is comparable to the conductive heat flux. The estimated conductive and convective heat fluxes and the Darcy velocity are 0.45 –0.56 W/m^2, 0.41 –0.51 W/m^2 and (1.42-1.78)*10^{-6} m/s, respectively. In the basement layer, as compared to the upper part of the older edifice of pre-caldera, *Pe=0.31-0.41* of smaller Péclet numbers were obtained, suggesting that the conductive heat flux is dominant. The conductive and convective heat fluxes and the Darcy velocity are 0.32 –0.39 W/m^2, 0.12 –0.13 W/m^2 and (4.71-4.98)*10^{-7} m/s, respectively.

Honda *et al.* (1979) inferred 0.2 W/m^2 of the conductive heat flux at the depth of 500-700 m (within the basement layer) at the northwestern coastal area. The estimated flux is about three times of the averaged terrestrial heat flux. The conductive heat flux within the basement layer in the caldera region inferred by this study is one and a half times to twice of the flux at the coastal area. The convective flux is added to this. When these heat fluxes are applied to 100 km^2 of the area (approximately whole the island scale), the total heat flow is estimated as to be 20-51 MW.

Numerical model of the hydrothermal system at the Akakura Caldera in Kurikoma Area

*Yasuhiro Fujimitsu[1], Daichi Yoshioka[2]

1. Department of Earth Resources Engineering, Faculty of Engineering, Kyushu University, 2. Department of Earth Resources Engineering, Graduate School of Engineering, Kyushu University

The Akakura Caldera is located at the southern part of Kurikoma Area, and is one of the old calderas in Tohoku District. It was formed by the huge pyroclastic flow about 3 million years ago. This study conducts numerical simulations of the hydrothermal system development that is modeled after the Akakura Caldera. In the numerical modeling, the structures such as a magma chamber that was associated with the formation of the caldera structure (Magma 1), high permeable fracture zone associated with a reverse fault and a circular fracture, impermeable layers filled with quartz and fracture clouds were considered and emplacement of a magma chamber that generated the post-caldera volcanic activity of 0.8 to 1.4 Ma (Magma 2) was also included. The calculation period was 3 million years from the emplacement of Magma 1 to the present and Magma 2 was emplaced 2.2 million years after the emplacement of Magma 1. The initial temperature of Magmas 1 and 2 was set as 1000 deg C. For the size of Magma 2, two kinds of diameter (2.5 km and 3.5 km) were adopted for the modeling. As a result, it was indicated that a supercritical geothermal fluid region still remains at the depth of 5 km until about 100 thousands years after the emplacement of Magma 2. It is inferred that a high enthalpy hydrothermal system can exist at a piston-cylinder type caldera with a post-caldera volcanic activity like the Akakura Caldera until about 10 thousands years after the commencement of the post-caldera volcanic activity.

ALOS-2 and Sentinel-1A and 1B, which have highly enhanced capacity compared to previous SAR satellites, were launched in 2014, and their utilization has been widely expanding as the data has accumulated for approximately four years. Other long-operating SAR satellites like TerraSAR-X and Cosmo-SkyMed also contribute to expanding the SAR utilization. Now we are facing a new and abundant era of the satellite SAR, along with a worldwide trend to an open and free data policy of satellite data, with next-generation advanced SAR satellite plans by several countries, and with several plans to construct SAR constellations by private sectors. In addition, SAR technologies with other platforms, such as ground-based SAR with high temporal resolution and UAV (Unmanned Aerial Vehicle) SAR with flexible operability, have also been developed and used for various targets. These facts indicate that the SAR utilization has become widespread in both basic researches (e.g., earth science) and diverse applications (e.g., disaster prevention and forest monitoring). In this session, we would like to widely invite research and application results with regard to SAR, sharing our knowledge and having a discussion for the advancement of the SAR utilization.

1. TokyoDenki University

Synthetic Aperture Radar, SAR, is a sensor that irradiates radio waves (microwaves) and receives radio waves reflected and returned from the ground surface.

It is characterized that SAR can observe the target regardless of weather and day and night. Even when the plume is blowing hard, SAR signal can penetrate through the clouds and smokes and can observe the crater.

The Kilauea volcano to be investigated is one of the five shield volcanoes that made up the Island of Hawaii on Hawaii Island. It is an active volcano that is presumed to have formed about 600,000 years ago, and is presumed that it appeared on the sea surface about 100 thousand years ago and the eruption is still continuing, but the eruption of 2018 stopped the flow of the lava did. The Kilauea is known for its calm eruption, but since 1983 it continues to erupt almost continuously, depending on the direction of the lava flow, lava may swallow the settlement and destroy the settlement.

This research will detect the deformation of the volcanic mountain by using the interferometric SAR technique. INSAR uses two types of data with different times and finds variates from the differential distance between from the satellite to the target (phase difference).

Using this method, we measure the crustal deformation with accuracy of several mm to several cm by capturing the variation near the crater of Kilauea volcano which can not be investigated locally. We will quantitatively evaluate the crustal deformation around the crater using image data of two periods including the eruption occurrence period from October 9, 2014 to July 31, 2018.

As a result, the crater was subsided by 6.5 cm from November 25, 2014 to March 27, 2018 in the ascending orbit, and it was subsided by 9 cm during the period from October 9, 2014 to December 14, 2017 in descending orbit.

As a future task, since we observed fluctuations in the north direction other than vertical component fluctuations in the crater, we plan to conduct research including the relation with the ground characteristics of Hawaii Island.

ALOS-2 observation of the 2017 Sefidsang earthquake, northeastern Iran: a blind shallow-dipping thrust event near the Eastern Kopeh Dagh

*Nematollah Ghayournajarkar[1], Yo Fukushima[2]

1. Graduate School of Science, Tohoku University, 2. International Research Institute of Disaster Science, Tohoku University

The Iranian plateau is deformed between the converging Arabian and Eurasian plates. Their convergence is principally taken up by the active Makran subduction zone to the South, in addition to shortening and strike-slip faulting accommodated by crustal structures, which are non-uniformly distributed in several continental deformation domains such as the Zagros, Alborz and Kopeh Dagh mountain ranges. During the last decade, several studies carried out in the Zagros, Alborz and central Iran have produced a better understanding of active deformation in these zones. Conversely, such detailed studies are less common in northeast Iran.
Indeed, despite all the efforts made by previous workers to shed light on active tectonics in northeast Iran, this region still suffers from a lack of detailed structural and kinematics data and should be considered as a concealed segment in the geodynamic puzzle of the Arabia-Eurasia collision. This matter is made worse by the facts that northeast Iran is the second populated region and one of the most seismically active deformation domains in the country that has experienced at least nine large earthquakes (M >= 7) during the last six centuries (Tchalenko, 1975; Ambraseys and Melville, 1982; Berberian and Yeats, 1999, 2001).
On 5 April 2017, an Mw 6.1 earthquake occurred in the northeastern region of Iran, about 90 km southeast of the city of Mashhad, the second most populous city in Iran with a population of over 3 million people. The epicenter (35.776 N, 60.436 E, USGS) was at a remote mountainous area, about 30 km northeast of the Sefidsang district where approximately 5000 people live, and the depth was about 13 km. This earthquake raised an opportunity to study the deformation pattern in the SE of the Kopeh Dagh Mountains.
Space geodetic observations of ground deformation provide important data to investigate the seismogenic fault and the subsurface deformation mechanics. Here we used ALOS-2 synthetic aperture radar data to produce SAR interferograms using the GMTSAR software (Sandwell et al., 2010) to investigate coseismic and postseismic deformation associated with the 2017 Sefidsang earthquake. The ascending and descending interferograms were produced and both indicate thrust-dominated slip that is consistent with seismic data sets, with the maximum line-of-sight coseismic displacement of 9.9 and 13 cm, respectively. The obtained coseismic deformation maps have good consistency with Sentinel-1 interferograms that showed maximum line-of-sight displacement of 10.5 and 13.7 cm for ascending and descending interferograms, respectively (Xu et al., 2018).
We also used ascending SAR data acquired on 2017/06/24 to 2018/12/22 for evaluating the postseismic deformation caused by this earthquake. The produced interferogram does not show any displacement more than the noise level (~1 cm).

InSAR ground displacements and slip distribution associated with secondary fault slips of the 2016 Kumamoto earthquake

*Yo Fukushima[1], Daisuke Ishimura[2]

1. International Research Institute of Disaster Science, Tohoku University, 2. Department of Geology, Tokyo Metropolitan University

By using interferometric synthetic aperture radar (InSAR) and field reconnaissance surveys, activation of numerous secondary faults associated with the occurrence of the 2016 Kumamoto earthquake has been identified (e.g., Fujiwara et al., 2016, EPS). In this study, we investigated the characteristics of the displacements of secondary faults around the Miyaji district, Aso, within the Aso caldera, and further inverted for the slip distribution of the secondary faults.

In this study, we used RINC software (Ozawa et al., 2016, EPS) to produce three interferograms with different line-of-sight directions, and unwrapped with SNAPHU (Chen and Zebker, 2000). The unwrapped interferograms are “un-referenced”, and each of them contains an unknown offset. The offset values were estimated using the daily coordinates data (F3 solution) of the GEONET network provided by the Geospatial Information Authority of Japan, and are subtracted from the interferograms. Finally, displacements along three line-of-sight directions are decomposed into EW, NS, and UD components, and EW and NS components were further used to derive the horizontal displacements in N50E direction, parallel to the secondary faults in Miyaji. The main characteristics of the ground displacements are as follows. (1) Two strands of parallel displacement discontinuity traces, corresponding to the surface fault, are observed, with a separation of around 0.8 km. (2) The length of the northern and southern strands of traces are around 1.3 km and 2.3 km. (3) Each of the two strands of traces are composed of multiple en-echelon traces. (4) The fault displacements of the northern strand were up to 5 cm for both vertical (northern side downward) and right-lateral directions. (5) The fault displacements of the southern strand were up to 8cm for vertical (northern side downward) and 10cm for right-lateral directions.

Next, we simultaneously estimated the slip distribution and geometry of the two faults (Fukushima et al., 2013, 2018), after removing long wavelength displacements by polynomial fitting. As for the fault geometry, we assumed that the top of the faults reach the averaged location of the fault strands and we set the dip angles as model parameters. We conducted non-negative least squares inversion for the fault slip, prohibiting reverse and left-lateral faulting based on the observed ground displacements. Two types of inversions were made on the assumption of the rake angle; one is assuming a uniform rake angle for all the fault elements, and the other is solving for the vertical and left-lateral slips. The two types of inversions both succeeded in explaining the ground displacement data, so we adopted the result of the simpler model with uniform rake angle as our preferred model.

In our preferred model, two faults dip northward with the southern one having a lower angle (48 degrees) than the northern one (67 degrees), making two faults merge at a depth of approximately 1.3 km. The lower limit of the slip area on the southern fault coincided the merging depth of 1.3 km, and the maximum slip of 25 cm was obtained at a depth of approximately 0.7 km. The slip on the northern fault was limited to shallower than 0.4 km with smaller slips of up to 12 cm.

Surface displacements at the Kumamoto plain using persistent scatterer interferometry and comparison with groundwater levels

*Kazuya Ishitsuka[1], Takeshi Tsuji[2]

1. Kyoto Univ., 2. Kyushu Univ.

After the 2016 Kumamoto earthquake, change in groundwater levels has been observed at the Kumamoto plain, which is likely associated with the alteration of the aquifer system by the earthquake. Surface displacement can occur due to groundwater level changes at a confined aquifer because pore pressure changes lead to the deformation of its granular skeleton. Persistent scatterer interferometry (PSI) using a satellite imaging is a powerful method to estimate spatial and temporal pattern of surface displacements. In this study, we estimated surface displacement at the Kumamoto plain from May 2016 to June 2017 using PSI analysis of ALOS-2/PALSAR-2 images. Moreover, we compared the displacement pattern in the period after the earthquake with the displacement from Jan. 2007 to Jan. 2011 using ALOS/PALSAR images.

As a result of analysis, we estimated surface displacement with the magnitude of about 2-3 cm along the Futagawa and Hinagu fault systems. We interpreted that the displacements along the fault traces were due to the afterslip. On the other hand, we also found surface displacements apart from the fault traces. For example, surface uplift up to 4 cm/year was observed during about 1 year after the earthquake around the west flank of Aso volcano. The displacement began several months after the earthquake, and generally correlated with the areas of groundwater level increased. Since the displacement pattern was not observed in ALOS/PALSAR results, we speculated that the displacement was induced by the groundwater level changes by the earthquake. In addition, we estimated the skeletal storage coefficients from surface displacements and groundwater levels, and found that the coefficients differed by the earthquake at several locations, indicating the temporal alteration of permeability or compressibility of the aquifer. Our results demonstrate the effectiveness of the surface displacement monitoring combined with groundwater level data at the aquifer system.

Acknowledgements: The ALOS-2/PALSAR-2 level 1.1 data used in this study were provided by the PIXEL (PALSAR Interferometry Consortium to Study our Evolving Land Surface) group in cooperative research with the Earthquake Research Institute, University of Tokyo. The ALOS-2/PALSAR-2 data belongs to the Japan Aerospace Exploration Agency. The groundwater level data used in this study were measured by several public institutes, and the data were corrected by the working group in Japan Association of Groundwater Hydrology.

Forest fire detection in the low biomass dry forest with JICA-JAXA Forest Early Warning System in the Tropics (JJ-FAST).

*Manabu Watanabe[1], Christian Naohide koyama[1], Masato Hayashi[2], Izumi Nagatani[2], Takeo Tadono[2], Masanobu Shimada[1,2]

1. School of Science and Engineering, Tokyo denki university, 2. JAXA/EORC

JICA-JAXA Forest Early Warning System in the Tropics (JJ-FAST, [1]) is first and only one SAR-based deforestation detection system monitoring tropical forest globally. The JJ-FAST started from November 2016, and has a merit to operate not only in dry season, but also in rainy season. The current system uses change of gamma_0 for deforestation detection. Watanabe et al. [2] pointed out the JJ-FAST detected not only the deforestation sites, but also detected severely damaged forest fire sites occurred in a dense forest. In this paper, detectability of forest fire in the low biomass dry forest with JJ-FAST system were examined.

JJ-FAST detected 168 deforestation sites between Nov. 11 and Dec. 23, 2018 in South Africa. MODIS burned area product [3] obtained between Oct. 10 and Dec. 31, 2018 were overlapped and confirmed that the almost all the polygons detected by the JJ-FAST deforestation detection algorithm were overlapped with the burned area detected by MODIS. The forest fire area were also identified by Sentinel-2 data. BBC news [4] reported severe wildfire occurred in George, South Africa on Oct. 30, and the area was also coincident with the one detected by the JJ-FAST algorithm. The JJ-FAST algorithm also detected 82 deforestation sites in Mozambique between Aug. 13 and Nov. 5, 2018. These sites were also overlapped with the MODIS burned area. From these facts, we concluded that the current JJ-FAST deforestation detection algorithm could detected severely damaged forest fire area in the low biomass dry forest. It is known that forest fire in dense forest is detected by increase of radar backscattering in HH polarization [2]. This is explained that forest fire makes forest canopy dry and induces more double bounce scattering, implying the increase of backscattering in HH polarization. In the case of low biomass dry forest, forest fire makes forest canopy dry and induces lower volume scattering in a tree canopy layer, implying the decrease of backscattering in HV. The decrease of volume scattering also occurred in the dense forest. But higher density of burned trees left on the ground still induces brighter radar reflection in HV and make it difficult to detects the forest fire sites in HV polarization.

Nominal operation results of Japanese ALOS-2

*Shinichi Sobue[1]

1. Japan Aerospace Exploration Agency

The Advanced Land Observing Satellite-2 (ALOS-2) was successfully launched on 24th May 2014. The mission sensor of ALOS-2 is the Phased Array type L-band Synthetic Aperture Radar-2 called PALSAR-2 which is the state of the art L-band SAR system. Until now after the successful completion of initial checkout after launching, ALOS-2 has been contributed to a lot of emergency observations for natural disasters, not only in Japan but also in the world. Furthermore, based on the Basic Observation Scenario (BOS) of ALOS-2, 10m global map data and other mode data are routinely collected and archived. This paper describes the results of ALOS-2 operation in nominal operation phase.

[S-TT45] Synthetic Aperture Radar

convener:Youhei Kinoshita(University of Tsukuba), Yu Morishita(Geospatial Information Authority of Japan), Shoko Kobayashi(Tamagawa University), Takahiro Abe(Earth Observation Research Center, Japan Aerospace Exploration Agency), Chairperson:Yohei Kinoshita(RESTEC), Takahiro Abe(JAXA)

ALOS-2 and Sentinel-1A and 1B, which have highly enhanced capacity compared to previous SAR satellites, were launched in 2014, and their utilization has been widely expanding as the data has accumulated for approximately four years. Other long-operating SAR satellites like TerraSAR-X and Cosmo-SkyMed also contribute to expanding the SAR utilization. Now we are facing a new and abundant era of the satellite SAR, along with a worldwide trend to an open and free data policy of satellite data, with next-generation advanced SAR satellite plans by several countries, and with several plans to construct SAR constellations by private sectors. In addition, SAR technologies with other platforms, such as ground-based SAR with high temporal resolution and UAV (Unmanned Aerial Vehicle) SAR with flexible operability, have also been developed and used for various targets. These facts indicate that the SAR utilization has become widespread in both basic researches (e.g., earth science) and diverse applications (e.g., disaster prevention and forest monitoring). In this session, we would like to widely invite research and application results with regard to SAR, sharing our knowledge and having a discussion for the advancement of the SAR utilization.

Estimation of velocity distribution of Shirase Glacier derived from SAR data obtained by ERS-1/2 tandem mission

*Koichiro Doi[1,2], Yuichi Aoyama[1,2], Kazuki Nakamura[3], Tsutomu Yamanokuchi[4], Kazuo Shibuya[1]

Shirase Glacier is one of the fastest flowing ice stream in Antarctica flowing into the southernmost of Lutzow-Holm Bay in Dronning Maud Land, East Antarctica. It is important to clarify the spatial flow rate distribution with a high resolution to investigate causes of the fast flow and the temporal flow rate changes. In order to make a high resolution flow velocity map, we apply a usual interferometric Synthetic Aperture Radar (InSAR) technique to the obtained data. However, since flowing velocity of the ice stream is greater than 2 km/year (Nakamura et al., 2007, Aoyama et al., 2016), it is difficult to estimate the flow velocity by applying an InSAR technique to the ordinal repeat cycle SAR mission data.

Tandem mission by European Satellite of Remote sensing (ERS)-1/2 was conducted in 1996 and 1999. In this tandem mission, ERS-2 had flown after ERS-1 in the same orbit with an interval of one day, and many InSAR pairs with one day temporal baseline were obtained through the mission.

We successfully obtained two SAR interferograms over Shirase Glacier using this tandem mission InSAR pairs acquired at 1996/06/02-1996/06/03 and 1999/11/14-1999/11/15. We estimated surface displacements along range direction (direction of radar illumination) by applying differential InSAR (DInSAR) with a TanDEM-X 90m DEM (Rizzoli et al., 2017) to remove topographic phase. We also estimated displacements along azimuth direction (direction perpendicular to range direction) by applying a split beam interferometry (SBI) (Bechor and Zebker, 2006) technique to the two InSAR pairs. By combining the range and azimuth displacements, spatial flow velocity distributions can be derived with a high resolution.

In the presentation, we will show two dimensional flow velocity maps with a resolution of approximately 20 m at the two periods and discuss spatial and temporal velocity changes. We will also compare the obtained flow velocity with those by in-situ GNSS measurements in the glacier.

Heavy rainfall-induced displacement of more than 2.5m in the Kushiro Marsh in 2016, detected by ALOS-2 SAR

*Satoshi Fujiwara[1], Yu Morishita[1], Takayuki Nakano[1], Yuji Miura[1], Yasuaki Kakiage[1], MURAMATSU Hiroki[1], Hiroshi Une[1]

1. GSI of Japan

The Kushiro Marsh in eastern Hokkaido is the largest wetland in Japan. Monitoring changes in environmental conditions is important to support preservation of the wetland. In the summer of 2016, Hokkaido was affected by several typhoons and suffered record-breaking heavy rainfall. We constructed ~50 ALOS-2 SAR interferograms, covering the Kushiro Marsh for the period 2014 to 2018, including the summer of 2016. A time series of vertical displacement of the wetland detected by the interferograms corresponded with water level changes in the rivers in the wetland. This implied that the SAR data had successfully detected the height change of the water surface in the wetland. Between August 6, 2016 and September 5, 2016, an area of the wetland (~1 km) to the southeast of Akanuma shifted ~2.7 m horizontally in the downstream direction, which coincided with a large and rapid increase in the water level caused by the heavy rains. This large displacement remained after the water level decreased. Prior to this large horizontal shift, an uplift of ~10 cm was identified in almost the same region. This uplift might have been caused by the leaking of groundwater from the basement of the Akanuma pond, and implied that the peat layer, which had a thickness of several meters floated slightly, like a floating islands, possibly causing the large horizontal shift.

Surface deformation of Asama Volcano, Japan, detected by time-series InSAR combining persistent and distributed scatterers, 2014-2018

*Yosuke Aoki[1], Xiaowen Wang[1]

1. Earthquake Research Institute, University of Tokyo

Asama volcano, located in Central Japan, is one of the most active volcanoes in Japan. Surface deformation at Asama volcano has rarely been documented because of its high topography and snow cover at the summit. In this study, we present first Interferometric Synthetic Aperture Radar (InSAR) observation of ground deformation of Asama volcano with 120 Sentinel-1 SAR images from both ascending and descending tracks and 20 ALOS-2 images from a descending track acquired between 2014 and 2018. We exploited both persistent and distributed scatterers to overcome SAR signal decorrelation and applied the three-dimensional unwrapping method to retrieval displacement time series efficiently. Our observations reveal asymmetric deformation at Asama volcano with two main deformation regions at the northeast and southeast flanks of the volcano, respectively. The northeast flank (NEF) exhibits line-of-sight (LOS) extensions in all the three SAR datasets with maximum velocities of 14, 10, and 12 mm/year for the descending ALOS-2, ascending and descending Sentinel-1 measurements, respectively. The southeast flank (SEF) shows LOS extension in the ascending observations and LOS shortening in the descending observations with velocities between -12 and 9 mm/year, respectively. Decomposition of the LOS displacements reveals nearly pure vertical subsidence at the NEF, while the SEF also shows an evident eastward component other than vertical subsidence. Comparisons of the vertical subsidence at two continuous GPS stations near the summit crater with our InSAR observations indicate small discrepancies smaller than 3 mm/year. We interpret that the subsidence at the NEF is primarily due to the cooling contraction of pyroclastic deposits emplaced in the 1783 eruption, and the SEF is susceptible to flank instability. The asymmetric deformation of the volcano may also be related to the hydrothermal activity that is controlled by the underground structure of the volcano. This study highlights that much more efforts should be taken to monitor the slope instability of Asama volcano in the future.

Improvement of Airborne L-band-SAR (Pi-SAR-L2) Coherence by Pixel by Pixel Resampling

*Makoto Murakami[1], Masato Furuya[1], Taku Ozawa[4], Youichiro Takada[1], Yosuke Aoki[3], Masanobu Shimada[2], Shohei Narita[1]

1. Hokkaido University, 2. Tokyo Denki University, School of Science and engineerring, 3. Earthquake Research Institute, The University of Tokyo, 4. National Research Institute for Earth Science and Disaster Resilience

1. Introduction

Although Airborne SAR is advantageous in terms of flexibility of flight path direction and observation scheduling, the deviation from the flight path linearity due to the perturbation by wind irregularity makes interferometry difficult. We have been working on a development of L band airplane SAR interferometric technique with an aim to use it for volcanic deformation monitoring. The most effective way to improve the coherence between 2 airborne observations is precise coregistration of the slave image against the master image. We here present a new method of precise coregistraion for airborne SAR interferometry using pixel by pixel resampling capability of RINC software package developed by Taku Ozawa at NIED. We demonstrate the usefulness of this technique utilizing airborne repeat path SAR data acquired by JAXA’ s airborne L-band SAR system (pi-sar-l2) over southern Kyushu volcanoes (Sakurajima volcano, Kirishima volcano and Unzen volcano) .

2. The classic coregistration method

Because the flight path of satellite is relatively smooth, the coregistration between master and slave images based on two dimensional quadratic function fitting is sufficient. Our interferometric process for airborne SAR started with the same technique. However, our preliminary tests suggested the insufficiency of this classic method for airborne SAR failing to faithfully follow high frequency component of pixel offset caused by irregularity of the airplane flight path due to the wind fluctuations especially in along-track direction.

3. Precise coregistration method using pixel by pixel matching technique

©2019. Japan Geoscience Union. All Right Reserved.

To improve the effectiveness of coresistration, we employ an additional step to fit the two dimensional pixel offset field after the primary fitting using a quadratic function. In the process of the additional fitting for the the primary fitting residuals, we use an empirical smooth function fitting capability of Matlab software package. Thus we calculate the offset values between master and slave for every pixel of master image and then we carry out coregistration using pixel by pixel resampling capability of RINC software package. This additional procedure significantly improves the coherence as we see below.

3. Demonstration of Usefulness of New method using data over Kirishima volcano

We tested the usefulness of the new method for the repeat path SAR data acquired on 2014 and 2016 over the Kirishima volcano complex. The figure shows the comparison of the coherence between the results of classic and new methods. The area of good coherence increases significantly in the image derived by the new method in the right hand, where brighter colorization corresponds to better coherence. The improvement of the lower half of the image is obvious. Although there still remain stripes of worse coherence which run in the direction perpendicular to the azimuthal axis, the width of those stripes is reduced. This bad coherency seems to be caused by abrupt change of flight speed of the airplane. In this particular observation, our target is Iwoyama dome which is a nest of recent phreatic activity, and the coherence there is actually greatly improved by the new method resulting in better understanding of the ongoing inflation mechanism which will be reported elsewise. In the presentation, we will show the test results using other data sets and discuss the usefulness of the new methods.

Ionospheric delay estimation in SAR interferometry: Significance of the method using the split-spectrum double-difference interferogram

*Taku Ozawa[1]

1. National Research Institute for Earth Science and Disaster Resilience

Split-spectrum method is used as a useful method in reducing the ionospheric delay which is one of the major error factors in SAR interferometry (e.g., Brcic et al., 2010; Rosen et al., 2010; Gomba et al., 2016). This method divides chirp signal of SAR into high and low bands, and generates interferograms for each bands. The ionospheric delay and crustal deformation components are extracted from them. Generally, the ionospheric delay component phai,iono can be estimated from

$\Phi_{iono}=f_L f_H(\Phi_L f_H - \Phi_H f_L)/(f_0(f_H^2-f_L^2))$ -(1)

where f0, fl, fh are center frequencies of full, lower, and higher bands. phai,l phai,h are phase differences of interferograms for lower and higher bands. Empirically, for interferometric pairs with high coherence, the ionospheric delay component can be accurately estimated from this equation. However, that with low coherence, the accuracy degrades mainly due to the difficulty of unwrapping. Then Wegmüller et al. (2018) proposed the method using following equation,

$\Phi_{iono}=A\Phi_0 + B(\Phi_H-\Phi_L)$ -(2)

where phai,0 is phase difference of full-band interferogram, and A, B are coefficient derived from center frequencies. In general, the better coherence is obtained for interferometric pair with wider bandwidth, and therefore the first term is relatively easier to unwrap than that with divided frequencies. Since the second term falls within the value of $-\pi$ to $+\pi$ in most cases, it is possible to easily obtain the phase difference. Furthermore, since A is approximately 0.5, equation (2) can be approximated to

$2\Phi_{iono}=\Phi_0 + 2B(\Phi_H-\Phi_L)$ -(3)

As mentioned before, the second term can easily estimate the phase difference, and then it is possible to obtain an interferogram showing only the ionospheric delay component without unwrapping.

Now, we are developing ionospheric delay estimation tools based on the above three equations. In this presentation, we describe the results of test analysis on several pairs using tools under development. In this analysis, SAR images divided the band in half are used. For high and low frequency pairs, interferograms are generated. After removing orbital and topographic fringes, the spectrum filter (Goldstein and Werner, 1998) is applied to them. From these interferograms, ionospheric delay is estimated using each equation. An outlier removing filter and a Gaussian filter are applied to ionospheric delay image.

First, as a pair with relatively high coherence, the interferometric pair of ALOS-2/PALSAR-2 images which observed Azuma-yama on September 9, 2014 and August 11, 2015 was analyzed. About this pair, almost the same results were obtained from analysis using each equation. However, as a result from interferometric pair which observed on March 7, 2016 and April 18, 2016, included large crustal deformation associated with the 2016 Kumamoto earthquake, differences were obtained in results from analysis using each equation. In particular, in the analysis using Eq. (1), the unwrapping error in the vicinity of the fault seems to have a big influence. In manual analysis, if the error is correctly masked, it is considered that roughly the same result as equation (2) is obtained. In a result from equation (3), the ionospheric delay component was obtained even in the vicinity of the fault. However, in other interfering pairs with particularly poor coherence, the ionospheric delay could not be properly estimated by the analysis using Equation (3) in some cases.

Although there are few analysis cases at the present time and more case analysis is required, it is generally felt that the method based on equation (2) can estimate the ionosphere delay with relatively high

©2019. Japan Geoscience Union. All Right Reserved.

accuracy. However, in cases where large crustal deformation are included such that unwrapping is difficult, the method based on equation (3) may be better. It may be necessary to select a method which is appropriate for a case.

Detecting surface displacement accosiated with the 2018 slow slip event around Boso peninsla by use of Sentinel-1 InSAR with atmospheric correction

*Youhei Kinoshita[1], Tadahiro Nimura[1], Ryoichi Furuta[1]

1. RESTEC, Remote Sensing Technology Center of Japan

The slow slip, also denoted as the slow eathquake, is known to release accumulated strain energy with no or slight seismic wave radiation. The slow slip is usually detected by highly accurate geophysical measurements such as the Global Navigation Satellite System (GNSS) and seismometers because of very small surface deformation on the order of millimeters to centimeters, and small ground oscillation (named as a tremor). Until now, several papers reported slow slip events, for example, at Tokai area (e.g. Yamamoto et al. 2005, EPS; Ozawa et al. 2016, EPS), Cascadia (e.g. Dragert et al. 2004, EPS; Hawthorne and Bartlow 2018, JGR), and Nankai Trough (e.g. Kobayashi 2017, EPS; Ozawa 2017, EPS). The area around Boso Peninsla is also a location where slow slip events have occuered with intervals of several years (Fukuda 2018, JGR). However, most of the reffered papers here used GNSS observations that have a limitation of low spatial resolution (Usually a few tens of kilometers between ground stations). In this study we conducted the InSAR analysis to detect the surface displacement accosiated with the 2018 slow slip event near the Boso peninsla by use of Sentinel-1 observations and numerically-derived atmospheric models.

In the InSAR andalysis we used Sentinel-1 TOPS IW data with three satellite paths (path 39, 141, and 46). Paths 39 and 141 are ascending direction and path 46 is descending direction. The interferometric analysis was conducted by GAMMA software with the 1-arcsecond SRTM DEM for the topographic fringe simulation. All of the InSAR pairs have absolute perpendicular baselines below 200m, indicating most InSAR pairs showed good coherence. Because the expected surface displacement has an amplitude of 2cm or below (by GNSS observations), we performed the stacking analysis for each paths to enhance the detectability of line-of-sight (LOS) displacements. In addition, we applied the MSM-based atmospheric delay correction to each interferograms to further increase the detectability of the surface displacement signal.

The stacking result showed that the surface displacement signal with an amplitude of approximately 1 cm in the LOS direction was clearly detected in path 141. The displacement signal extended spatially to approximately 20 km in both north-south and east-west direction. The spatial distribution and amplitude of InSAR-detected displacement was consistent with the GNSS observation. On the other hand, There were no clear displacement signal in the stacked interferogram in paths 39 and 46. This would be due to the significant atmospheric delay effect in several interferograms of these paths. Therefore we only used the stacking interferogram in path 141 for the fault modeling.

We also performed the assessment of the atmospheric delay correction effectiveness. Phase standard deviations (SDs) calculated on the area outside of the expected displacement signal clearly showed the effectiveness of the atmospheric delay correction. Before the correction, SDs of the stacked interferograms were 5.9 cm, 7.5 cm, and 4.2 cm for paths 39, 46, and 141, respectively, which decreased to 2.7 cm, 4.6 cm, and 1.6 cm after the correction. Although the spatial and temporal resolutions of MSM were 10 km and 3 hours that were not significant for the InSAR atmospheric delay modeling, it showed good performance for the InSAR stacking.

Based on the derived displacement signal in path 141, we performed a forward modeling to estimate preliminary fault parameters using the simple Okada fault model. The estimated fault model suggested

©2019. Japan Geoscience Union. All Right Reserved.

that the upper-left corner of the fault was located at 140.8 degrees in longitude and 34.98 degrees in latitude with the depth of 15 km, which was consistent with the boundary of the Phillipine plate. The fault length and width were set to 50 km and 30 km with the dip angle of 18 degrees. The estimated slip amount was 13 cm with the rake of 105 degrees, which was equivalent to the moment magnitude of 6.6.

ALOS-2 and Sentinel-1A and 1B, which have highly enhanced capacity compared to previous SAR satellites, were launched in 2014, and their utilization has been widely expanding as the data has accumulated for approximately four years. Other long-operating SAR satellites like TerraSAR-X and Cosmo-SkyMed also contribute to expanding the SAR utilization. Now we are facing a new and abundant era of the satellite SAR, along with a worldwide trend to an open and free data policy of satellite data, with next-generation advanced SAR satellite plans by several countries, and with several plans to construct SAR constellations by private sectors. In addition, SAR technologies with other platforms, such as ground-based SAR with high temporal resolution and UAV (Unmanned Aerial Vehicle) SAR with flexible operability, have also been developed and used for various targets. These facts indicate that the SAR utilization has become widespread in both basic researches (e.g., earth science) and diverse applications (e.g., disaster prevention and forest monitoring). In this session, we would like to widely invite research and application results with regard to SAR, sharing our knowledge and having a discussion for the advancement of the SAR utilization.

Development of InSAR tropospheric phase delay correction system at MRI (2nd report)

*Okuyama Satoshi[1], Shinobu Ando[1], Toshiki Shimbori[1]

1. Meteorological Research Institute

Introduction

SAR Interferometry is a technique which utilize the phase information of the SAR images to detect surface displacement which took place between two observations. However, its result contains the effect of medium between the antenna and the target such as tropospheric delay. Conventional method to correct tropospheric delay is proposed by Fujiwara et al. (1999), which assumes that the delay is a function of topographic height. On the other hand, correction using numerical weather model, which is independent data from SAR interferogram, is also proposed (Hobiger et al., 2008; Ozawa and Shimizu, 2010). We started the development of tropospheric delay correction system in MRI and reported our preliminary result (Okuyama et al., 2018). In our preliminary analysis, we calculated zenith delay and projected it on line-of-sight of the SAR observation. As an improvement, we replaced this by the integration of refractivity along line-of-sight of the SAR observation.

System composition

Our correction system consists of three units: 1) read grid point values (NuSDaS format) and interpolate in time to generate gridded data at the observation time, 2) calculate refractivity at each gridpoint, and 3) integrate refractivity to calculate the delay at each pixel in the interferogram. This composition allows us to replace each unit separately. For example, when new weather model is released, we replace unit 1) only, leaving the rest of the units unchanged.

Difference from preliminary result

We corrected interferogram of PALSAR-2 (path125/frame660, 2015/1/4 - 2015/8/16) using JMA-MA (Meso Analysis) data by both (A) projecting zenith delay on line-of-sight and (B) integrating the refractivity along line-of-sight. As stated above, tropospheric delay tends to have strong correlation between topography. Thus, we use correlation coefficient between phase and topographic height as a measure of correction quality. We obtained correlation coefficient of -0.431 for original interferogram, -0.097 for correction (A), and -0.047 for correction (B).
The difference between (A) and (B) shows correlation between delay and topography, however its factor shows horizontal variation. This is caused by the horizontal variation of the refractivity. The maximum difference between (A) and (B) is -2.1 radians.

Future direction

We will develop the support for other model types such as JMA-LA (Local Analysis) or JMA-GA (Global Analysis) as next step and validate the algorithm of interpolation/refractivity.

Mitigation of atmospheric delay in InSAR for fair estimate of crustal deformation at Azumayama volcano

*Kana Abe[1], Yoshiko Ogawa[1], Yasuhiro Hisada[1], Hirohide Demura[1], Taku Ozawa[2], Satoshi Miura[3], Akira Kusakabe[1], Takehiro Arai[1]

1. The University of Aizu, 2. National Research Institute for Earth Science and Disaster Resilience, 3. Graduate School of Science, Tohoku University

Azumayama volcano is one of the five active volcanoes in Fukushima prefecture which is now issued volcanic alert level 2. Since 2014 winter, the volcano had/has been issued the level 1 and 2 repeatedly according to the situation. It is the most active volcano in the Fukushima pref. We have been working to clarify time-series of crustal deformation at Azumayama volcano.

Abe et al. [2017, JpGU] conducted InSAR (Interferometric Synthetic Aperture Radar) analysis using ALOS2 (Advanced Land Observing Satellite 2)/PALSAR2 (Phased Array L-band Synthetic Aperture Radar-2) data and estimated crustal deformation around Azumayama volcano . However, some of the results showed subsidence at the west of Azumayama which would be due to atmospheric delay and ionospheric delay.

In this study, we attempted to correct atmospheric delay and ionospheric delay in InSAR analysis using three numerical weather models: MSM (MesoScale Model), LFM (Local Forecast model) and WRF (Weather Research and Forecasting). WRF is created by using MSM data to improve resolution of time. Then we tried to estimate the amount of crustal deformation more precisely from 2014 fall to 2017 fall after applying atmospheric correction. Eight of the ALOS2/PALSAR2 data were used for the InSAR analysis. We evaluated the InSAR results after performing each atmospheric correction based on each numerical model and compare them quantitatively and select suitable weather model among the three.

Artifacts and false fringe in InSAR results seem to be reduced. Comparing InSAR analysis results with the value of GNSS (Global Navigation Satellite System) analysis at ground stations, correction by LFM and WRF showed similar trend better than that by MSM. Numerical weather models with higher resolutions seem effective in correcting atmospheric delay in InSAR. Uplift and subsidence at the Oana crater and subsidence in the western part of Azumayama were detected during 2014 fall - 2015 summer and 2015 summer - 2015 fall, respectively, which reflect actual deformation.

Unusual displacement observed in InSAR analysis results of fumarolic area of active volcanos: An example of the Kamiyu district in Hakone Volcano

*Ryosuke Doke[1], Kazuhiro Itadera[1]

1. Hot Springs Research Institute of Kanagawa Prefecture

In this presentation, we report on the characteristics and causes of displacements observed in the InSAR analysis results of ALOS-2/PALSAR-2 data for the fumarolic area in the Kamiyu area of the Hakone volcano.

The Kamiyu fumarolic area is in the northern slope of the central cone of the Hakone volcano and located about 500m north of the Owakudani fumarolic area that had phreatic eruptions in 2015. The Kamiyu fumarolic area was formed around 2003 after the 2001 swarm earthquake occurred at the Hakone Volcano (Tsujiuchi et al., 2003). The most active fumarole in the Kamiyu area is the area called E region, which was activated after the earthquake swarm induced by the 2011 Tohoku Earthquake (Yukutake et al., 2011; Harada et al., 2012). The scale of the E region is about 200m north to south and about 150m east to west. Moreover, the heat flux from the E region is estimated to be 7 to 8 MW (Mannen et al., 2018).

The observation by ALOS-2/PALSAR-2 for the Hakone volcano has been carried out repeatedly, mainly in four orbits, and each orbit is performed almost once every several months. From October 2014 to the end of 2018, data from descending orbit with right looking angles were obtained 22, and 15 scenes in Path 18 and 19, respectively, and data from ascending orbit with right looking angles were obtained 11 scenes in Paths 125 and 126, respectively. In this study, we performed DInSAR analysis with the latest interference pairs for all these data and clarified the displacement of the ground surface in the Kamiyu E region.

In the observation from the east side (Paths 18, 19), the Kamiyu E region displaced about 3 to 5 cm toward the satellite with respect to a reference point outside the fumarolic area during about four years. Moreover, in the observation from the west side (Paths 125, 126) displaced about 10 to 13 cm away from the satellite during the same period. These results suggest that the E region steadily displaces in the northeast direction in the long term, which also coincides with the inclination direction of the E region so that it is considered that the landslide displacement is occurring.

On the other hand, the analysis results of Paths 18 and 19 observed from the east side show the seasonal displacement that the area moved toward the satellite in the summer seasons and away from the satellite in winter seasons. In Paths 125 and 126 observed from the west side, such seasonal displacement is not observed, but these Paths have few observations in the summer and cannot judge the actual seasonal displacement. One of the possible causes of this seasonal displacement is a seasonal change in contrast between the vapor amount inside of the fumarolic area and that of the outside. The amount of water vapor near the ground changes seasonally outside of the fumarolic area whereas it is almost saturated throughout the year in the fumarolic area. Such contrast between the summer and winter is possibly affecting the DInSAR results. Another possible cause is an effect of the difference of soil moisture between summer and winter season because the fumarolic area is almost bare land and surface scattering is more dominant than forest area. Other factors are also conceivable, but we are considering the possibilities to evaluate the fumarolic activities from this seasonal displacement, in addition to accurately evaluate the

landslide movement in the fumarolic area.

Detection of Deformation Signals at Mud Volcanoes in Semau Island, Indonesia

*Naufal Setiawan[1], Masato Furuya[1]

1. Hokkaido University

Mud volcanoes are associated with fluid and solid material vertical extrusion from its source layer (mud reservoir). The size and shape of the mud volcanoes throughout the world are diverse. Furthermore, the reason behind this event is difference in each region but predominantly occurred at convergent plate margins. To date, the most mud extrusion known is in the Mediterranian Sea and Tethyan belt (including Azerbaijan, south Greece, Iran, and Turkmenistan).

Semau Island, located in Timor area of Indonesia, is one of the islands where the northern margin of Australian continental plate meets Banda sea plate. Previous geologic map identified Semau island hosted six mud volcanoes with no description in its size [Barber, et al. 1986], and some of them erupt only mud, whereas others produce mud with an admixture of liquid hydrocarbons [Kholodov. 2002].

In order to detect any possible deformation signals in the mud volcanoes in this region, we applied InSAR method. Twenty four (24) ascending images and ten (10) descending images of ALOS/PALSAR data spanning from 2006 to 2011 were acquired. Because our research area is not covered by single observation image, we concatenate the consecutive frame number. To enhance the processing step in GAMMA software, the oceanic areas and some part of other islands that not our interest were cropped to focus on Semau Island. Interferograms of ALOS/PALSAR dataset were consist of eleven (11) ascending pairs and four (4) descending pairs. Then, using AW3D30 DEM data we tried to remove topographic fringe. During the processing, images were multi-looked in range and azimuth by 2 and 6 respectively. While the oversampling in the azimuth direction can be avoided due to the effect of azimuth slope is limited, range oversampling by a factor of two is needed for good quality of interferogram. This procedure is to avoid uncorrelated contributions that arise in the spectral cross-correlation from interferogram generation. Finally, we applied low order polynomial to mitigate the effects of long wavelength phase trends in our interferograms.

The deformation signal is hardly detected in the majority of the data pairs, due to the unwrapping errors in some pairs and also probably due to the small size of mud volcanoes. Despite low coherence in the possible mud extrusion source, in two image pairs, we detected the possible signal from the mud volcano area that is identical to the location described from the previous geologic map. However, since the geologic map from the previous study was derived from aerial photograph interpretation and the signal detection is in slope area, further research is needed to confirm if it is related to active mud volcanism or simply a landslide signal.

Extraction of supraglacial lakes on debris-covered glacier using ALOS-2/PALSAR-2

Chikako Kinefuchi[2], *Chiyuki Narama[1], Tsutomu Yamanokuchi[3], Takeo Tadono[4]

1. Niigata University, Program of Field Research in the Environmental Sciences, 2. Graduate School of Science and Technology, Niigata University, 3. RESTEC, 4. JAXA

In the eastern part of the Himalaya (eastern Nepal and Bhutan), large drainages occur from supraglacial lakes on debris-covered glaciers when large lake connects to englacial network (Komori et al., 2012; Rounce et al., 2016; Miles et al., 2018). In the Himalaya, it is difficult to monitor the variations of supraglacial lakes during summer, because most optical satellite images are covered by cloud due to Indian monsoon. It is possible to investigate supraglacial lake under cloud using ALOS-2/PALSAR-2 of microwave sensor. However, backscatter of supraglacial lake differs in relief conditions on debris-covered glacier, and ice cliff and depression also have lower backscatter. In this study, we try to extract supraglacial lakes correctly using ALOS-2/PALSAR-2 data analysis.

Observation of the water level fluctuation at Ozegahara by ALOS-2/PALSAR-2

*Wataru Iwatate[1], Masanobu Shimada[1]

1. Tokyo Denki University

The SAR can measure the phase and the amplitude of the reflected wave from the surface object. This phase contains information on the round trip distance from the antenna to the surface of the earth in general, and more precisely the fraction of the above distance off the wave length. By differenciating two individual measurements, it can detect a slight distance difference. By using this InSAR technique, we can see the change of the Earth's surface due to earthquakes and volcanic eruptions in a visible form. On the water surface such as river, sea, lake, it is always moving by waves, so it is difficult to measure in places where the reflecting surface is not constant. However, in wetlands where grass and reeds are growing on top, the radar signal emitted to the water surface may reflect back from the grass and reeds, and return to the satellite.

Therefore, our research themes were defined to verify the possibility of observation on the water level change during two different observations. The target area was selected from the Honjou's largest Ozasegahara in wetlands. This Ozegahara is located in the Oze National Park, around the border areas of Fukushima, Tochigi Prefecture, Gunma, and Niigata Prefectures, and it is composed of 2,000 m class mountains. The observation was carried out using the period from September 2014 to May 2018 of PALSAR - 2 installed in JAXA 's Daichi 2 (ALOS 2). Since it is told that the water level of Ozegahara decreases, if the numerical value obtained by using the interference SAR technique shows a decrease, we can verify the possibility of observation on the water surface. In fact, we got an average of about -6.6 cm as a annual decreases. Comparing rainfall, etc., we can see that the water level goes down, and it was possible to show that the water level observation in the wetland zone is possible.

As future developments, it is conceivable to conduct verification in terms of accuracy from the possibility. One way to do this is to observe it using GPS or water gauge.

The steady crustal deformation around the Omaezaki, Sionomisaki, Muroto and Ashizuri, using InSAR time-series analysis 2

*Shinobu Ando[1], Akio Kobayashi[1]

1. Seismology and Tsunami Research Department, Meteorological Research Institute

At the Meteorological Research Institute, we are working on detection of crustal deformation using satellite SAR data as a method to detect changes in locked part such as slow slips and pre-slips at the plate boundary.

Especially focusing on the large-scale earthquake of the Nankai-Trough which is concerned about the occurrence in the near future, near the cape from Tokai to Shikoku which is close to the subduction zone of the plate and is thought to be susceptible to the change of the fixation state Analysis was conducted as an object.

We carried out InSAR time series for ALOS/PALSAR data to detect the steady crustal deformation around the cape from Tokai to Shikoku. As a result, we confirmed that the result of InSAR time series analysis correspond to GNSS data (Ando et al., 2018).

In this report, we tried to analysis for these data using InSAR time series analysis because of the archive data of ALOS-2/PALSAR-2 (operation period: 2014 -) has been adequately accumulated. In this analysis, interferograms were generated using RINC software (Ozawa et al., 2016), and then we carried out InSAR time series analysis about these data by SBAS method using GIAnT software (Agram et al., 2011). The data of each area used for the analysis is as follows.

Omaezaki: path 19 (18 scenes) and path 126 (11 scenes),

Shionomisaki: path 20 (16 scenes) and path 128 (11 scenes),

Muroto: path 21 (14 scenes) and path 128 (10 scenes),

Ashizuri: path 22 (14 scenes) and path 129 (10 scenes).

In principle, we used all data in which the archive exists for analysis in any path, but recalculated after excluding data which is clearly an error by checking the analysis result. The cumulative displacement result of Omaezaki (path 19) is shown in Fig.1.

As a result, we detected the elongation of displacement around the cape and shortening of displacement in the inland. The trends of these displacement distributions are similar to those of ALOS/PALSAR. In this presentation, we also report on the comparison with the GNSS observation results in the analysis area.

Some of PALSAR-2 data we used were provided by the Japan Aerospace Exploration Agency (JAXA) via the 6th ALOS-2 research announcement (RA-6). PALSAR-2 data belongs to JAXA. In the process of the InSAR, we used Digital Ellipsoidal Height Model (DEHM) based on the digital elevation map 10m-mesh provided by Geospatial Information Authority of Japan (GSI), and Generic Mapping Tools (P.Wessel and W.H.F.Smith, 1999) to prepare illustrations.

Evaluation of InSAR analysis result using pipe strain gauge data in Otari village, Nagano prefecture, Japan

*Tomoya Kiyosawa[1], Hiroshi, P. Sato[2]

1. Department of Geography, Graduate School of Science and Technology, Nihon University , 2. College of Humanities and Science, Nihon University

In order to detect landslide surface deformation, InSAR (Synthetic Aperture Radar interferometry) images were produced and interpreted in the study area of Ahara area in Otari Villege, Nagano Prefecure in Japan. The images were produced from time-series ALOS-2/PALSAR-2 data, taken from September 2014 to March 2018. More than 50 InSAR images were produced; however, at most four images gave good coherence available to interpret and detect the deformation. The one was taken on and the three were after Kamishiro Fault earthquake (M 6.7) on 22 Nov 2014. As a result of images interpretation, westwards deformation was detected up to ca. 2.5 cm and 4.5 cm along LoS (line of sight) on and after the earthquake, respectively.

To take measures against landslide disaster, Nagano Prefecture installed pipe type strain gauge in Ahara area, and the measured strain data were used to evaluate the image-detected deformation. As a result, at the slip layer of 8-m depth from the ground, the strain gauge measured 13 μST on the earthquake and it also indicated westward deformation. Empirically, strain over ca. 20,000 μST cuts electric measurement cables, and this strain is known to be equal to 2-3 cm deformation under the ground. Therefore, 13 μST is thought to be correspondent to 0.0013 cm deformation. Thus, the image-detected deformation itself was proved by the gauge-measured strain data and westward deformation direction was harmonized with the gauge-measured strain data. However, it was found that the image-detected deformation amount is 2,000 times larger than the strain gauge-calculated deformation amount.

Focusing on the deformation after the earthquake, as the observation periods of the images were not overlapped with measurement period of the strain gauge, assuming that the deformation proceeds at uniform speed in landslide body, then, both data were compared in daily mean deformation speed. The image-detected speed was calculated as 0.025-0.064 cm/day, and strain gauge-detected speed 0.000083 cm/day was calculated from 58 μST. It was found that the image-detected deformation speed is 300-780 times larger than the strain gauge-calculated speed. We think that this difference is attributed to the fact that InSAR measured the deformation not on the ground but along LoS distance and strain gauge measured the deformation not on the ground but under the ground. Furthermore, we think that the reason of more difference of the deformation amount on the earthquake than after the earthquake is that the image on the earthquake includes the deformation not only by landslide surface deformation but also crustal deformation by the earthquake.

DEM creation using ALOS / PALSAR interferometric SAR and its accuracy evaluation.

*takahashi koya[1], Masanobu Shimada[1]

1. tokyo denki university

Digital Elevation Model (DEM) is a digital representation of the terrain on the ground surface, with the ground surface divided into equally spaced squares and the elevation of the center point of the square is given. In general, it expresses the surface of the earth that does not include vegetation, buildings, bridges, etc. DEM is often used in geographic information systems and is used as basic data in creating a three-dimensional map on a computer. There are several methods of making DEM, such as parallax measurement that combines optical pictures observed from multiple directions, interference processing of synthetic aperture radar, airborne laser surveying to find height using a laser mounted on an aircraft, etc. In this study We will prepare DEM by Synthetic Aperture Radar (SAR) and study related errors. DEM is created using synthetic aperture radar installed in ALOS and compared with DEM of Geographical Survey Institute. We measured the error, calculated the difference from the theoretical value, and evaluated its effectiveness. As a result, DEM creation by SAR was conducted for Hatoyama cho Higashi-gun (forest, residential area, Tabata), and the difference from the theoretical value occurred several centimeters to several tens of meters, but the average error was 9.94 m Therefore, through this study, we believe that practicality of DEM creation by SAR is sufficient.

Approach to monitoring ground deformation using InSAR time series analysis all over Japan

*Kyonosuke Hayahsi[1], Tatsuya Yamashita[1], Masaki Kuwahara[1], Masaki Honda[1], Kazuki Sakai[1], Hiroshi Munekane[1], Tomokazu Kobayashi[1]

1. GSI of Japan

GSI (Geospatial Information Authority Japan) has been monitoring ground deformation all over Japan with ALOS-2 data by applying two-pass Differential Synthetic Aperture Radar Interferometry (D-InSAR) method. The two-pass D-InSAR method is a procedure to extract deformation that occurred between two observations from two radar images obtained from two observations. The two-pass D-InSAR method is susceptible to errors due to tropospheric disturbances, ionospheric disturbances, and change of the ground surface such as vegetation, which can be obstacles in detecting small ground deformations. Tropospheric disturbances and ionospheric disturbances may be reduced by Ray-tracing algorithm using numerical weather prediction model data (Kobayashi et al., 2014) and Split-Spectrum method (Gomba et al., 2016), respectively. However, it is still a challenging task to detect the ground deformation less than several centimeters with two-pass D-InSAR method.
Recently, InSAR time series analysis has been developed where a number of images are processed and statistically analyzed to extract deformations with enhanced accuracies. Persistent Scatter Interferometry method (PSI method) and Small Baseline Subset algorithm method (SBAS method) are typical examples of InSAR time series analysis. GSI has been developed the InSAR time series analysis system (GSITSA) which includes PSI method and SBAS method (Kobayashi et al., 2018). Kobayashi et al., (2018) compared the result of InSAR time series analysis with levering data of same period in subsidence area and showed that with InSAR time series analysis one could detect ground deformation with a velocity of 1 cm / year or less. Thus ground deformation detection capability of InSAR time series analysis is better than that of the two-pass D-InSAR method, and the analysis should be useful for monitoring ground deformation all over Japan more accurately. Furthermore, with Advanced Land Observing Stellite-4 (ALOS-4) that is planned for launch in the 2020 fiscal year, the observation frequency will be increased by five-fold compared to that of ALOS-2, and the InSAR time series analysis should be more applicable.
With this background, we investigated the characteristics of PSI method and SBAS method using GSITSA for consideration of introducing InSAR time series analysis into our future strategy for ground deformation monitoring. In this study, we conducted InSAR time series analysis with ALOS-2 data for Niigata Plain and Tsugaru Plain as examples of land subsidence area, and Mt. Kirishima (Mt. Iwoyama) and Mt. Usu as examples of active volcano area, respectively. In InSAR time series analysis, we were able to detect similar ground deformation in the areas where ground deformation were detected by the two-pass D-InSAR method. In addition, we were able to detect some ground deformation of about 1 cm per year that could not be detected with the two-pass D-InSAR method.
In this presentation, we will show the results of comparison between PSI method and SBAS method, and discuss the optimal analysis strategy focusing on spatial scale and vegetation.
"Acknowledgment"

Development of InSAR tropospheric phase delay correction system at MRI (2nd report)

*Okuyama Satoshi[1], Shinobu Ando[1], Toshiki Shimbori[1]

1. Meteorological Research Institute

Introduction

SAR Interferometry is a technique which utilize the phase information of the SAR images to detect surface displacement which took place between two observations. However, its result contains the effect of medium between the antenna and the target such as tropospheric delay. Conventional method to correct tropospheric delay is proposed by Fujiwara et al. (1999), which assumes that the delay is a function of topographic height. On the other hand, correction using numerical weather model, which is independent data from SAR interferogram, is also proposed (Hobiger et al., 2008; Ozawa and Shimizu, 2010). We started the development of tropospheric delay correction system in MRI and reported our preliminary result (Okuyama et al., 2018). In our preliminary analysis, we calculated zenith delay and projected it on line-of-sight of the SAR observation. As an improvement, we replaced this by the integration of refractivity along line-of-sight of the SAR observation.

System composition

Our correction system consists of three units: 1) read grid point values (NuSDaS format) and interpolate in time to generate gridded data at the observation time, 2) calculate refractivity at each gridpoint, and 3) integrate refractivity to calculate the delay at each pixel in the interferogram. This composition allows us to replace each unit separately. For example, when new weather model is released, we replace unit 1) only, leaving the rest of the units unchanged.

Difference from preliminary result

We corrected interferogram of PALSAR-2 (path125/frame660, 2015/1/4 - 2015/8/16) using JMA-MA (Meso Analysis) data by both (A) projecting zenith delay on line-of-sight and (B) integrating the refractivity along line-of-sight. As stated above, tropospheric delay tends to have strong correlation between topography. Thus, we use correlation coefficient between phase and topographic height as a measure of correction quality. We obtained correlation coefficient of -0.431 for original interferogram, -0.097 for correction (A), and -0.047 for correction (B).
The difference between (A) and (B) shows correlation between delay and topography, however its factor shows horizontal variation. This is caused by the horizontal variation of the refractivity. The maximum difference between (A) and (B) is -2.1 radians.

Future direction

We will develop the support for other model types such as JMA-LA (Local Analysis) or JMA-GA (Global Analysis) as next step and validate the algorithm of interpolation/refractivity.

Mitigation of atmospheric delay in InSAR for fair estimate of crustal deformation at Azumayama volcano

*Kana Abe[1], Yoshiko Ogawa[1], Yasuhiro Hisada[1], Hirohide Demura[1], Taku Ozawa[2], Satoshi Miura[3], Akira Kusakabe[1], Takehiro Arai[1]

1. The University of Aizu, 2. National Research Institute for Earth Science and Disaster Resilience, 3. Graduate School of Science, Tohoku University

Azumayama volcano is one of the five active volcanoes in Fukushima prefecture which is now issued volcanic alert level 2. Since 2014 winter, the volcano had/has been issued the level 1 and 2 repeatedly according to the situation. It is the most active volcano in the Fukushima pref. We have been working to clarify time-series of crustal deformation at Azumayama volcano.

Abe et al. [2017, JpGU] conducted InSAR (Interferometric Synthetic Aperture Radar) analysis using ALOS2 (Advanced Land Observing Satellite 2)/PALSAR2 (Phased Array L-band Synthetic Aperture Radar-2) data and estimated crustal deformation around Azumayama volcano . However, some of the results showed subsidence at the west of Azumayama which would be due to atmospheric delay and ionospheric delay.

In this study, we attempted to correct atmospheric delay and ionospheric delay in InSAR analysis using three numerical weather models: MSM (MesoScale Model), LFM (Local Forecast model) and WRF (Weather Research and Forecasting). WRF is created by using MSM data to improve resolution of time. Then we tried to estimate the amount of crustal deformation more precisely from 2014 fall to 2017 fall after applying atmospheric correction. Eight of the ALOS2/PALSAR2 data were used for the InSAR analysis. We evaluated the InSAR results after performing each atmospheric correction based on each numerical model and compare them quantitatively and select suitable weather model among the three.

Artifacts and false fringe in InSAR results seem to be reduced. Comparing InSAR analysis results with the value of GNSS (Global Navigation Satellite System) analysis at ground stations, correction by LFM and WRF showed similar trend better than that by MSM. Numerical weather models with higher resolutions seem effective in correcting atmospheric delay in InSAR. Uplift and subsidence at the Oana crater and subsidence in the western part of Azumayama were detected during 2014 fall - 2015 summer and 2015 summer - 2015 fall, respectively, which reflect actual deformation.

Unusual displacement observed in InSAR analysis results of fumarolic area of active volcanos: An example of the Kamiyu district in Hakone Volcano

*Ryosuke Doke[1], Kazuhiro Itadera[1]

1. Hot Springs Research Institute of Kanagawa Prefecture

In this presentation, we report on the characteristics and causes of displacements observed in the InSAR analysis results of ALOS-2/PALSAR-2 data for the fumarolic area in the Kamiyu area of the Hakone volcano.

The Kamiyu fumarolic area is in the northern slope of the central cone of the Hakone volcano and located about 500m north of the Owakudani fumarolic area that had phreatic eruptions in 2015. The Kamiyu fumarolic area was formed around 2003 after the 2001 swarm earthquake occurred at the Hakone Volcano (Tsujiuchi et al., 2003). The most active fumarole in the Kamiyu area is the area called E region, which was activated after the earthquake swarm induced by the 2011 Tohoku Earthquake (Yukutake et al., 2011; Harada et al., 2012). The scale of the E region is about 200m north to south and about 150m east to west. Moreover, the heat flux from the E region is estimated to be 7 to 8 MW (Mannen et al., 2018).

The observation by ALOS-2/PALSAR-2 for the Hakone volcano has been carried out repeatedly, mainly in four orbits, and each orbit is performed almost once every several months. From October 2014 to the end of 2018, data from descending orbit with right looking angles were obtained 22, and 15 scenes in Path 18 and 19, respectively, and data from ascending orbit with right looking angles were obtained 11 scenes in Paths 125 and 126, respectively. In this study, we performed DInSAR analysis with the latest interference pairs for all these data and clarified the displacement of the ground surface in the Kamiyu E region.

In the observation from the east side (Paths 18, 19), the Kamiyu E region displaced about 3 to 5 cm toward the satellite with respect to a reference point outside the fumarolic area during about four years. Moreover, in the observation from the west side (Paths 125, 126) displaced about 10 to 13 cm away from the satellite during the same period. These results suggest that the E region steadily displaces in the northeast direction in the long term, which also coincides with the inclination direction of the E region so that it is considered that the landslide displacement is occurring.

On the other hand, the analysis results of Paths 18 and 19 observed from the east side show the seasonal displacement that the area moved toward the satellite in the summer seasons and away from the satellite in winter seasons. In Paths 125 and 126 observed from the west side, such seasonal displacement is not observed, but these Paths have few observations in the summer and cannot judge the actual seasonal displacement. One of the possible causes of this seasonal displacement is a seasonal change in contrast between the vapor amount inside of the fumarolic area and that of the outside. The amount of water vapor near the ground changes seasonally outside of the fumarolic area whereas it is almost saturated throughout the year in the fumarolic area. Such contrast between the summer and winter is possibly affecting the DInSAR results. Another possible cause is an effect of the difference of soil moisture between summer and winter season because the fumarolic area is almost bare land and surface scattering is more dominant than forest area. Other factors are also conceivable, but we are considering the possibilities to evaluate the fumarolic activities from this seasonal displacement, in addition to accurately evaluate the

landslide movement in the fumarolic area.

Detection of Deformation Signals at Mud Volcanoes in Semau Island, Indonesia

*Naufal Setiawan[1], Masato Furuya[1]

1. Hokkaido University

Mud volcanoes are associated with fluid and solid material vertical extrusion from its source layer (mud reservoir). The size and shape of the mud volcanoes throughout the world are diverse. Furthermore, the reason behind this event is difference in each region but predominantly occurred at convergent plate margins. To date, the most mud extrusion known is in the Mediterranian Sea and Tethyan belt (including Azerbaijan, south Greece, Iran, and Turkmenistan).

Semau Island, located in Timor area of Indonesia, is one of the islands where the northern margin of Australian continental plate meets Banda sea plate. Previous geologic map identified Semau island hosted six mud volcanoes with no description in its size [Barber, et al. 1986], and some of them erupt only mud, whereas others produce mud with an admixture of liquid hydrocarbons [Kholodov. 2002].

In order to detect any possible deformation signals in the mud volcanoes in this region, we applied InSAR method. Twenty four (24) ascending images and ten (10) descending images of ALOS/PALSAR data spanning from 2006 to 2011 were acquired. Because our research area is not covered by single observation image, we concatenate the consecutive frame number. To enhance the processing step in GAMMA software, the oceanic areas and some part of other islands that not our interest were cropped to focus on Semau Island. Interferograms of ALOS/PALSAR dataset were consist of eleven (11) ascending pairs and four (4) descending pairs. Then, using AW3D30 DEM data we tried to remove topographic fringe. During the processing, images were multi-looked in range and azimuth by 2 and 6 respectively. While the oversampling in the azimuth direction can be avoided due to the effect of azimuth slope is limited, range oversampling by a factor of two is needed for good quality of interferogram. This procedure is to avoid uncorrelated contributions that arise in the spectral cross-correlation from interferogram generation. Finally, we applied low order polynomial to mitigate the effects of long wavelength phase trends in our interferograms.

The deformation signal is hardly detected in the majority of the data pairs, due to the unwrapping errors in some pairs and also probably due to the small size of mud volcanoes. Despite low coherence in the possible mud extrusion source, in two image pairs, we detected the possible signal from the mud volcano area that is identical to the location described from the previous geologic map. However, since the geologic map from the previous study was derived from aerial photograph interpretation and the signal detection is in slope area, further research is needed to confirm if it is related to active mud volcanism or simply a landslide signal.

Extraction of supraglacial lakes on debris-covered glacier using ALOS-2/PALSAR-2

Chikako Kinefuchi[2], *Chiyuki Narama[1], Tsutomu Yamanokuchi[3], Takeo Tadono[4]

1. Niigata University, Program of Field Research in the Environmental Sciences, 2. Graduate School of Science and Technology, Niigata University, 3. RESTEC, 4. JAXA

In the eastern part of the Himalaya (eastern Nepal and Bhutan), large drainages occur from supraglacial lakes on debris-covered glaciers when large lake connects to englacial network (Komori et al., 2012; Rounce et al., 2016; Miles et al., 2018). In the Himalaya, it is difficult to monitor the variations of supraglacial lakes during summer, because most optical satellite images are covered by cloud due to Indian monsoon. It is possible to investigate supraglacial lake under cloud using ALOS-2/PALSAR-2 of microwave sensor. However, backscatter of supraglacial lake differs in relief conditions on debris-covered glacier, and ice cliff and depression also have lower backscatter. In this study, we try to extract supraglacial lakes correctly using ALOS-2/PALSAR-2 data analysis.

Observation of the water level fluctuation at Ozegahara by ALOS-2/PALSAR-2

*Wataru Iwatate[1], Masanobu Shimada[1]

1. Tokyo Denki University

The SAR can measure the phase and the amplitude of the reflected wave from the surface object. This phase contains information on the round trip distance from the antenna to the surface of the earth in general, and more precisely the fraction of the above distance off the wave length. By differenciating two individual measurements, it can detect a slight distance difference. By using this InSAR technique, we can see the change of the Earth's surface due to earthquakes and volcanic eruptions in a visible form. On the water surface such as river, sea, lake, it is always moving by waves, so it is difficult to measure in places where the reflecting surface is not constant. However, in wetlands where grass and reeds are growing on top, the radar signal emitted to the water surface may reflect back from the grass and reeds, and return to the satellite.

Therefore, our research themes were defined to verify the possibility of observation on the water level change during two different observations. The target area was selected from the Honjou's largest Ozasegahara in wetlands. This Ozegahara is located in the Oze National Park, around the border areas of Fukushima, Tochigi Prefecture, Gunma, and Niigata Prefectures, and it is composed of 2,000 m class mountains. The observation was carried out using the period from September 2014 to May 2018 of PALSAR - 2 installed in JAXA 's Daichi 2 (ALOS 2). Since it is told that the water level of Ozegahara decreases, if the numerical value obtained by using the interference SAR technique shows a decrease, we can verify the possibility of observation on the water surface. In fact, we got an average of about -6.6 cm as a annual decreases. Comparing rainfall, etc., we can see that the water level goes down, and it was possible to show that the water level observation in the wetland zone is possible.

As future developments, it is conceivable to conduct verification in terms of accuracy from the possibility. One way to do this is to observe it using GPS or water gauge.

The steady crustal deformation around the Omaezaki, Sionomisaki, Muroto and Ashizuri, using InSAR time-series analysis 2

*Shinobu Ando[1], Akio Kobayashi[1]

1. Seismology and Tsunami Research Department, Meteorological Research Institute

At the Meteorological Research Institute, we are working on detection of crustal deformation using satellite SAR data as a method to detect changes in locked part such as slow slips and pre-slips at the plate boundary.

Especially focusing on the large-scale earthquake of the Nankai-Trough which is concerned about the occurrence in the near future, near the cape from Tokai to Shikoku which is close to the subduction zone of the plate and is thought to be susceptible to the change of the fixation state Analysis was conducted as an object.

We carried out InSAR time series for ALOS/PALSAR data to detect the steady crustal deformation around the cape from Tokai to Shikoku. As a result, we confirmed that the result of InSAR time series analysis correspond to GNSS data (Ando et al., 2018).

In this report, we tried to analysis for these data using InSAR time series analysis because of the archive data of ALOS-2/PALSAR-2 (operation period: 2014 -) has been adequately accumulated. In this analysis, interferograms were generated using RINC software (Ozawa et al., 2016), and then we carried out InSAR time series analysis about these data by SBAS method using GIAnT software (Agram et al., 2011). The data of each area used for the analysis is as follows.

Omaezaki: path 19 (18 scenes) and path 126 (11 scenes),

Shionomisaki: path 20 (16 scenes) and path 128 (11 scenes),

Muroto: path 21 (14 scenes) and path 128 (10 scenes),

Ashizuri: path 22 (14 scenes) and path 129 (10 scenes).

In principle, we used all data in which the archive exists for analysis in any path, but recalculated after excluding data which is clearly an error by checking the analysis result. The cumulative displacement result of Omaezaki (path 19) is shown in Fig.1.

As a result, we detected the elongation of displacement around the cape and shortening of displacement in the inland. The trends of these displacement distributions are similar to those of ALOS/PALSAR. In this presentation, we also report on the comparison with the GNSS observation results in the analysis area.

Some of PALSAR-2 data we used were provided by the Japan Aerospace Exploration Agency (JAXA) via the 6th ALOS-2 research announcement (RA-6). PALSAR-2 data belongs to JAXA. In the process of the InSAR, we used Digital Ellipsoidal Height Model (DEHM) based on the digital elevation map 10m-mesh provided by Geospatial Information Authority of Japan (GSI), and Generic Mapping Tools (P.Wessel and W.H.F.Smith, 1999) to prepare illustrations.

Evaluation of InSAR analysis result using pipe strain gauge data in Otari village, Nagano prefecture, Japan

*Tomoya Kiyosawa[1], Hiroshi, P. Sato[2]

1. Department of Geography, Graduate School of Science and Technology, Nihon University , 2. College of Humanities and Science, Nihon University

In order to detect landslide surface deformation, InSAR (Synthetic Aperture Radar interferometry) images were produced and interpreted in the study area of Ahara area in Otari Villege, Nagano Prefecure in Japan. The images were produced from time-series ALOS-2/PALSAR-2 data, taken from September 2014 to March 2018. More than 50 InSAR images were produced; however, at most four images gave good coherence available to interpret and detect the deformation. The one was taken on and the three were after Kamishiro Fault earthquake (M 6.7) on 22 Nov 2014. As a result of images interpretation, westwards deformation was detected up to ca. 2.5 cm and 4.5 cm along LoS (line of sight) on and after the earthquake, respectively.

To take measures against landslide disaster, Nagano Prefecture installed pipe type strain gauge in Ahara area, and the measured strain data were used to evaluate the image-detected deformation. As a result, at the slip layer of 8-m depth from the ground, the strain gauge measured 13 μST on the earthquake and it also indicated westward deformation. Empirically, strain over ca. 20,000 μST cuts electric measurement cables, and this strain is known to be equal to 2-3 cm deformation under the ground. Therefore, 13 μST is thought to be correspondent to 0.0013 cm deformation. Thus, the image-detected deformation itself was proved by the gauge-measured strain data and westward deformation direction was harmonized with the gauge-measured strain data. However, it was found that the image-detected deformation amount is 2,000 times larger than the strain gauge-calculated deformation amount.

Focusing on the deformation after the earthquake, as the observation periods of the images were not overlapped with measurement period of the strain gauge, assuming that the deformation proceeds at uniform speed in landslide body, then, both data were compared in daily mean deformation speed. The image-detected speed was calculated as 0.025-0.064 cm/day, and strain gauge-detected speed 0.000083 cm/day was calculated from 58 μST. It was found that the image-detected deformation speed is 300-780 times larger than the strain gauge-calculated speed. We think that this difference is attributed to the fact that InSAR measured the deformation not on the ground but along LoS distance and strain gauge measured the deformation not on the ground but under the ground. Furthermore, we think that the reason of more difference of the deformation amount on the earthquake than after the earthquake is that the image on the earthquake includes the deformation not only by landslide surface deformation but also crustal deformation by the earthquake.

DEM creation using ALOS / PALSAR interferometric SAR and its accuracy evaluation.

*takahashi koya[1], Masanobu Shimada[1]

1. tokyo denki university

Digital Elevation Model (DEM) is a digital representation of the terrain on the ground surface, with the ground surface divided into equally spaced squares and the elevation of the center point of the square is given. In general, it expresses the surface of the earth that does not include vegetation, buildings, bridges, etc. DEM is often used in geographic information systems and is used as basic data in creating a three-dimensional map on a computer. There are several methods of making DEM, such as parallax measurement that combines optical pictures observed from multiple directions, interference processing of synthetic aperture radar, airborne laser surveying to find height using a laser mounted on an aircraft, etc. In this study We will prepare DEM by Synthetic Aperture Radar (SAR) and study related errors. DEM is created using synthetic aperture radar installed in ALOS and compared with DEM of Geographical Survey Institute. We measured the error, calculated the difference from the theoretical value, and evaluated its effectiveness. As a result, DEM creation by SAR was conducted for Hatoyama cho Higashi-gun (forest, residential area, Tabata), and the difference from the theoretical value occurred several centimeters to several tens of meters, but the average error was 9.94 m Therefore, through this study, we believe that practicality of DEM creation by SAR is sufficient.

Approach to monitoring ground deformation using InSAR time series analysis all over Japan

*Kyonosuke Hayahsi[1], Tatsuya Yamashita[1], Masaki Kuwahara[1], Masaki Honda[1], Kazuki Sakai[1], Hiroshi Munekane[1], Tomokazu Kobayashi[1]

1. GSI of Japan

GSI (Geospatial Information Authority Japan) has been monitoring ground deformation all over Japan with ALOS-2 data by applying two-pass Differential Synthetic Aperture Radar Interferometry (D-InSAR) method. The two-pass D-InSAR method is a procedure to extract deformation that occurred between two observations from two radar images obtained from two observations. The two-pass D-InSAR method is susceptible to errors due to tropospheric disturbances, ionospheric disturbances, and change of the ground surface such as vegetation, which can be obstacles in detecting small ground deformations. Tropospheric disturbances and ionospheric disturbances may be reduced by Ray-tracing algorithm using numerical weather prediction model data (Kobayashi et al., 2014) and Split-Spectrum method (Gomba et al., 2016), respectively. However, it is still a challenging task to detect the ground deformation less than several centimeters with two-pass D-InSAR method.
Recently, InSAR time series analysis has been developed where a number of images are processed and statistically analyzed to extract deformations with enhanced accuracies. Persistent Scatter Interferometry method (PSI method) and Small Baseline Subset algorithm method (SBAS method) are typical examples of InSAR time series analysis. GSI has been developed the InSAR time series analysis system (GSITSA) which includes PSI method and SBAS method (Kobayashi et al., 2018). Kobayashi et al., (2018) compared the result of InSAR time series analysis with levering data of same period in subsidence area and showed that with InSAR time series analysis one could detect ground deformation with a velocity of 1 cm / year or less. Thus ground deformation detection capability of InSAR time series analysis is better than that of the two-pass D-InSAR method, and the analysis should be useful for monitoring ground deformation all over Japan more accurately. Furthermore, with Advanced Land Observing Stellite-4 (ALOS-4) that is planned for launch in the 2020 fiscal year, the observation frequency will be increased by five-fold compared to that of ALOS-2, and the InSAR time series analysis should be more applicable.
With this background, we investigated the characteristics of PSI method and SBAS method using GSITSA for consideration of introducing InSAR time series analysis into our future strategy for ground deformation monitoring. In this study, we conducted InSAR time series analysis with ALOS-2 data for Niigata Plain and Tsugaru Plain as examples of land subsidence area, and Mt. Kirishima (Mt. Iwoyama) and Mt. Usu as examples of active volcano area, respectively. In InSAR time series analysis, we were able to detect similar ground deformation in the areas where ground deformation were detected by the two-pass D-InSAR method. In addition, we were able to detect some ground deformation of about 1 cm per year that could not be detected with the two-pass D-InSAR method.
In this presentation, we will show the results of comparison between PSI method and SBAS method, and discuss the optimal analysis strategy focusing on spatial scale and vegetation.
"Acknowledgment"

Mon. May 27, 2019 1:45 PM - 3:15 PM JST | Mon. May 27, 2019 4:45 AM - 6:15 AM UTC | A08 TOKYO BAY MAKUHARI HALL

[S-TT46] Seismic Big Data Analysis Based on the State-of-the-Art of Bayesian Statistics

convener:Hiromichi Nagao(Earthquake Research Institute, The University of Tokyo), Aitaro Kato(Earthquake Research Institute, the University of Tokyo), Takuto Maeda(Graduate School of Science and Technology, Hirosaki University), Keisuke Yano(The university of Tokyo), Chairperson:Nana Yoshimitsu(Earthquake Research Institute, The University of Tokyo), Takeru Matsuda(Graduate School of Information Science and Technology, The University of Tokyo)

Recently, a big seismic database has been being constructed that collects data of vibrators implemented in such as buildings, lifelines and smartphones, in addition to seismic data of the conventional continuous/temporal dense seismic observation arrays. Development of methodologies and algorithms, which are inadequate at this moment, optimized to comprehensively analyze the seismic big data is essential in order to utilize the big database as much as possible for prevention/mitigation of earthquake disasters and clarification of earthquake phenomena. On the other hand, recent progress of Bayesian statistics is significant, which is the mathematical basis of various methodologies, such as machine learning, especially deep learning, to extract valuable information from big data. The state-of-the-art of Bayesian statistics is expected to substantially advance seismic big data analyses.
This session mainly accepts presentations that focus on analyses of seismic big data, especially related to analysis methods based on Bayesian statistics such as machine learning, sparse modeling and data assimilation, and their applications to real seismic data. Presentations related to mathematical or statistical theories beneficial to data analyses, feasibility studies of algorithms eventually applicable to real seismic data, and the current status of seismic observations and analysis results are also highly welcome.

Bayesian inference is a powerful tool in inversion analyses of geophysical problems. In Bayesian inference, we always encounter a problem in determining the relative weight between observed data and prior information. ABIC (Akaike's Bayesian Information Criterion) gives an objective solution to this problem by maximizing the marginal likelihood for the relative weight. In principle, ABIC gives us an inverse solution that mostly follows observed data when we have enough amounts of data with good accuracy, and gives us an inverse solution that mostly follows prior information when observed data are insufficient and/or inaccurate.

In inversion analyses using ABIC, we do not manually adjust the relative weight. Hence, geophysically unrealistic results are quite easily obtained. Because of that, someone may think that inversion analyses using ABIC is difficult in dealing with or even unreliable. However, this is an excellent point of ABIC. If we obtain a geophysically unrealistic result, this implies that some problems are hidden in this analysis.

In this talk, we show some examples of the invention of inversion methods inspired by ABIC, including the discovery of the importance of modeling errors. As shown by these examples, we can get closer to the true solution not by manually adjusting the relative weight to obtain a seemingly good-looking result, but by determining the relative weight statistically. It is a harder way to determine the relative weight statistically, but we should pursue this way to understand geophysical problems more appropriately.

A seismic wavefield estimation in a dense seismograph network: An optimization for the MeSO-net

*Takahiro Shiina[1], Takuto Maeda[2], Masayuki Kano[3], Aitaro Kato[1], Naoshi Hirata[1]

1. Earthquake Research Institute, The University of Tokyo, 2. Graduate School of Science and Technology, Hirosaki University, 3. Graduate school of science, Tohoku University

MeSO-net (Metropolitan Seismic Observation network) is a dense seismograph network deployed in and around Tokyo, Japan [Kasahara et al., 2009; Sakai and Hirata, 2009]. Station separation of the MeSO-net is about 5 km on average and ~2 km at the densest area. Recently, some reconstructing method of seismic wavefield in such dense seismograph networks have been developed [e.g., Langston, 2007; Kano et al., 2017]. Kano et al. [2017] proposed a wavefield imaging method based on the data assimilation: they demonstrated the reconstructions of wavefield up to ~1 Hz using the MeSO-net. Their method can simultaneously determine layered structures and location of the hypocenter. Seismic wave gradiometry (SWG) method is also well known as another method for estimating 2D seismic wavefield. The SWG method has low computational cost and can apply to observations without assumptions of hypocenter and structural heterogeneity. Therefore, the SWG method will be useful for monitoring wavefield and investigating ground motions without source data as prior information.
We adopt the SWG method developed by Maeda et al. [2016] to estimate seismic wavefield within the MeSO-net. In this method, amplitude and its spatial gradients of seismic wave at grid points are estimated from observed amplitude at surrounding stations. Interpolation coefficients used for the estimation are determined by the weighted least squares technique and are only depended on a grid-station distance.
In order to optimize the interpolation coefficient, we perform the analysis based on numerical modeling. The finite difference modeling, the OpenSWPC [Maeda et al., 2017], is used to simulate seismic waves at any grid points and sites of which locations correspond to the MeSO-net stations. For the simulated waveforms, we adopt bandpass filter of 0.1-0.2 Hz which is lower than the upper-limit frequency of our numerical modeling, ~0.25 Hz. Then, we synthesize waveform at a grid point from simulated ones at surrounding sites by the SWG method. As the weighting function imposing to the least square, we assume the 2D Gaussian form with respecting to the grid-station distance. The 2D Gaussian weight is characterized by the lengths in two orthogonal axes, long and short arms, and a rotation angle of the short axis in the clockwise direction from the north. The ” optimization” in this study is to find the three parameters which maximize the three-components cross-correlation coefficient between the SWG-synthesize and the simulated waveforms at the grid point. We investigate the parameters by the grid search technique.
We carry out the numerical simulations for hypocenters of 12 directions with 30 degree interval. The hypocenters are located at a depth of 10 km and a distance of 150 km from the center of the MeSO-net. In this case, the determined Gaussian weight realize the highest reproducibility of the seismic wavefield for wave incidence from an arbitrary direction. The obtained Gaussian weights mark small and isotropic shapes near the central area of the MeSO-net, whereas they mark large and elliptical shapes around edges of the network. These shapes of the optimum weight would represent the configuration of the MeSO-net stations and demonstrate that the high-reproducible area of seismic waveform is expanded. Moreover, we confirmed that the accuracy of the seismic wavefield estimation can improve when selecting the interpolation coefficients coinciding with the incoming direction of the seismic waves.

Uncertainty quantification based on 4DVar data assimilation for massive simulation models

*Shin-ichi Ito[1], Masayuki Kano[2], Hiromichi Nagao[1]

1. The University of Tokyo, 2. Tohoku University

Data assimilation (DA) is a fundamental computational technique that integrates numerical simulation models and observation data on the basis of Bayesian statistics. Originally developed for meteorology, especially weather forecasting, DA is now an accepted technique in various scientific fields. One key issue that remains controversial is the implementation of DA in massive simulation models under the constraints of limited computation time and resources. This work proposes a DA technique based on a four dimensional variational (4DVar) method for massive autonomous models that produces optimum estimates and their uncertainties within reasonable computation time and resource constraints. The uncertainties are given as several elements of an inverse Hessian matrix, which is the covariance matrix of a normal distribution that approximates the target posterior probability density function in the neighborhood of the optimum. The proposed method based on a second-order adjoint method allows us to directly evaluate the elements of the inverse Hessian matrix without computing all of its elements. Some numerical tests assuming a massive simulation model confirm that the proposed method works well and enables us to evaluate the uncertainties of the parameters involved in the assumed model faster than the conventional DA approaches. Such information regarding uncertainty is valuable, as it can be used to optimize the design of experiments.

Bayesian approach for statistical modeling and forecasting of aftershock activities

*Takahiro Omi[1]

1. Institue of Industrial Science, the University of Tokyo

A large earthquake triggers a considerable number of aftershocks, which potentially cause additional damage in the affected area. It is therefore important to forecast aftershock activities as early as possible after a main shock. A basic method for forecasting aftershocks was proposed in 1989. However, for practical application of aftershock forecasting, we have to additionally consider (i) the missing of early aftershocks (ii) the forecast uncertainty. We consider such features by taking Bayesian statistical approach. In this talk, we briefly explain our forecasting method and demonstrate its utility.

Bias Correction for the Distribution of Aftershocks Within Short-Term Period Immediately After Large Main Shock

*Kosuke Morikawa[1], Hiromichi Nagao[2], Shin-ichi Ito[2], Shin'ichi Sakai[2], Naoshi Hirata[2]

1. Osaka University, 2. Earthquake Research Institute, The University of Tokyo

The main shock of a large earthquake often makes it difficult to identify a number of subsequent aftershocks. Knowing the distribution of magnitudes and arrival times of the aftershocks is essential to figure out the characteristics of the sequence of earthquakes, which enables us to predict the frequency of earthquakes depending on space and time. Such the distribution of aftershocks should be estimated within a couple of days eventually since most of the large aftershocks occur within one day from the main shock. However, an exact count of all aftershocks right after a main shock is very hard due to large signal-to-noise ratio, so that an estimated distribution of the aftershocks is usually biased.

An adoption of a likelihood that incorporates models of the detection rate of aftershocks can be a solution to correct the bias, but the simultaneous dependency on both magnitudes and arrival times of the aftershocks makes this difficult. Thus using nonparametric models for the detection rate is unrealistic though misspecification of the model may lead to a severe biased estimator.

In this study, we propose two detection rate models that are individually conditional on the magnitudes and the arrival times. The Generalized Moments of Methods (GMM)-type estimator overcomes the difficulty in estimation due to the imcompletely defined joint distribution. With the use of prior information, the distribution of the aftershocks can be effectively estimated within short-time period.

Deep-learning-based Earthquake Detection for Continuous Seismic Network Records

*Keisuke Yano[1], Takahiro Shiina[2], Sumito Kurata[1], Aitaro Kato[2], Fumiyasu Komaki[1], Shin'ichi Sakai[2], Naoshi Hirata[2]

1. Graduate School of Information Science and Technology, The University of Tokyo, , 2. Earthquake Research Institute, The University of Tokyo

Over the last decade, continuous seismic data have been enormously acquired on seismic networks consisting of multiple sensors at distributed locations. Analyzing these data efficiently and thoroughly offers substantial benefits to seismology. The first important step in the analysis is earthquake detection, that is, detecting earthquakes in continuous massive datasets.

In this talk, we present a deep-learning-based scheme for earthquake detection from continuous records in a seismic network. We work with a convolutional neural network (CNN), which is one of the most powerful supervised learning techniques, to capture features discriminating between earthquakes and noises. Our scheme has an advantage of utilizing multiple stations in a seismic network to discriminate between earthquakes and noises.

We apply our scheme to continuous data on Metropolitan Seismic Observation network (MeSO-net) from September 4, 2011 to September 16, 2011. We show our scheme improves on CNNs based on few stations especially in preventing mis-detection. In addition, the trained network in the last fully connected layer has quasi-sparsity, by which we identify features important for CNN to recognize earthquakes.

[S-TT46] Seismic Big Data Analysis Based on the State-of-the-Art of Bayesian Statistics

convener:Hiromichi Nagao(Earthquake Research Institute, The University of Tokyo), Aitaro Kato(Earthquake Research Institute, the University of Tokyo), Takuto Maeda(Graduate School of Science and Technology, Hirosaki University), Keisuke Yano(The university of Tokyo)

Recently, a big seismic database has been being constructed that collects data of vibrators implemented in such as buildings, lifelines and smartphones, in addition to seismic data of the conventional continuous/temporal dense seismic observation arrays. Development of methodologies and algorithms, which are inadequate at this moment, optimized to comprehensively analyze the seismic big data is essential in order to utilize the big database as much as possible for prevention/mitigation of earthquake disasters and clarification of earthquake phenomena. On the other hand, recent progress of Bayesian statistics is significant, which is the mathematical basis of various methodologies, such as machine learning, especially deep learning, to extract valuable information from big data. The state-of-the-art of Bayesian statistics is expected to substantially advance seismic big data analyses.
This session mainly accepts presentations that focus on analyses of seismic big data, especially related to analysis methods based on Bayesian statistics such as machine learning, sparse modeling and data assimilation, and their applications to real seismic data. Presentations related to mathematical or statistical theories beneficial to data analyses, feasibility studies of algorithms eventually applicable to real seismic data, and the current status of seismic observations and analysis results are also highly welcome.

P-wave Polarity Determination of Waveform Data Observed in Western Japan, Using Deep Learning

*Shota Hara[1], Yukitoshi Fukahata[2], Yoshihisa Iio[2]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University

In order to determine focal mechanisms of earthquakes, it is necessary to determine first-motion polarities of P-wave. Researches on various automatic determination algorithms has been developed, but the performance of conventional algorithms has been significantly lower than that of human experts. Therefore, check by human experts is commonly needed, when we apply an automatic determination algorithm to observed waveform data. In this study, we develop a model of the convolutional neural network (CNN) that can determine P-wave first-motion polarities of seismic waveforms, in which P-wave arrival times determined by human experts are given beforehand. We use about 130 thousand 250 Hz and about 40 thousand 100 Hz waveform data observed in the San-in and the northern Kinki area, western Japan, to train and test the CNN. The P-wave polarities determined by the CNN have the accuracy of about 98 % for the 250 Hz data and about 95 % for the 100 Hz data. To examine the regional dependence, we divide seismic waveform data according to the observational area and trained the CNN using the data of one region, and applied the CNN to the data of the other region. As a result, the accuracy was different only by about 2 %. This means that there is almost no need to retrain the CNN by region.

Trans-dimensional Bayesian inversion for a radially anisotropic S-wave velocity model in the crust and upper mantle: Application to the Australian continent

*Toru Taira[1], Kazunori Yoshizawa[2]

1. Graduate School of Science, Hokkaido University, 2. Faculty of Science, Hokkaido University

The velocity structure and discontinuities in the upper mantle, such as Lithosphere-Asthenosphere Boundary (LAB) and Mid-Lithosphere Discontinuity (MLD), have been investigated through a number of seismological studies, in which both body and surface waves have been employed. Many studies using body waves have extracted information on the upper mantle from the later arrivals of teleseismic body waves by deconvolving the vertical component from the horizontal components, which produces "receiver functions". While they are good at constraining impedance contrasts across the discontinuities, they are not sensitive to the absolute velocity. In contrast, surface waves enable us to recover the absolute velocity, though sharp velocity jumps cannot be resolved due to their lower frequency content (< 0.05Hz). In view of such different sensitivities of receiver functions and surface waves, the joint inversions of body and surface waves will be the most effective approach to the accurate estimation of seismic velocity structures in the crust and upper mantle.

In this study, we develop a new method for non-linear joint inversion of Ps receiver functions and multi-mode Rayleigh and Love surface waves using trans-dimensional Bayesian formulation, following the earlier works by Bodin et al., (2012, JGR). This trans-dimensional approach allows us to constrain the complexity of earth model with little a priori information, in which the number of model parameters (e.g. number of layers) can also be treated as a part of unknowns. The reversible-jump Markov Chain Monte Carlo approach (Green, 1995, Biometrika) is used to sample models with variable dimension in proportion to the posterior distribution of the Earth models. Assuming that data errors follow the Gaussian distribution, we also estimate the variances of the data errors at the same time. Such an approach is called 'Hierarchical Bayes' (e.g. Malinverno and Briggs, 2004, Geophysics), in which the overfitting of the models can be prevented. Parallel Tempering method (e.g. Sambridge, 2014, GJI) is also incorporated in our inversions, which makes the model samplings more efficient enabling us to extend the parameter search ranges.

With this method, we jointly inverted the Ps receiver function, multi-mode Rayleigh and Love dispersion curves from Yoshizawa (2014, PEPI) for a radially anisotropic 1-D shear velocity model under Global Seismographic Network (GSN) stations in Australia. Our preliminary result for the WRAB station in the central Australia implies the existence of two MLDs with negative and positive velocity jumps at around 90 km and 150 km depths, respectively, and LAB at around 220km depth. The depths of MLDs are consistent with an earlier receiver function study by Ford et al. (2010, EPSL) and such multiple MLDs are also reported by another study in North America (Calo et al., 2016, EPSL). Our estimated LAB depth at 220 km is deeper than that from the earlier surface wave study (Yoshizawa & Kennett, 2015, GRL), in which the Lithosphere-Asthenosphere Boundary under cratons is supposed to be a smooth transition. Still, we can still see the common feature of strong radial anisotropy (SH>SV) in the asthenospheric depth below 220 km, indicating the effects of strong shear flow under the fast-moving Australian continent.

In recent years, dense seismic observation networks have been constructed. For example, the Metropolitan Seismic Observation network called MeSO-net has been observing ground motions since 2011 with the average intervals of ~5 km in the Tokyo metropolitan located on the Kanto sedimentary basin, Japan. Utilizing seismograms of MeSO-net, we have developed a wavefield reconstruction method by simultaneously estimating subsurface velocity structures and source locations using replica exchange Monte Carlo (REMC) method [Kano et al. 2017, GJI, JGR]. The reconstructed wavefield can be used as input ground motions to simulate seismic response of infrastructure for the purpose of rapid evaluation of seismic hazards. In this presentation, we will summarize the REMC-based wavefield estimation method and discuss future developments and applications of the method.

Bayesian oscillator decomposition for seismic data

*Takeru Matsuda[1]

1. The University of Tokyo

Many time series including seismic data are naturally considered as a superposition of several oscillators. Matsuda and Komaki (2017a,b) proposed a Bayesian statistical method for decomposing time series data into oscillators by using Gaussian linear state space models. For example, this method can be used to extract neural oscillators (such as alpha, beta, and gamma) from neuroimaging data. In this study, we apply this method to seismic data and investigate the extracted oscillators.

Uncertainty evaluation of source parameter estimates by MCMC in Oklahoma

*Nana Yoshimitsu[1], Takuto Maeda[2], William Ellsworth[3]

1. The University of Tokyo, Earthquake Research Institute, 2. Hirosaki University, 3. Stanford Univerisy

Stress drop is important parameter to understand earthquake source characteristics and to improve hazard assessment. Many studies use the spectral ratio method to measure the moment ratio and two corner frequencies by comparing theoretical and observed spectral ratio in the frequency domain and obtain the stress drop. Accurate stress drop estimates are difficult to make because it depends on the accuracy of the three parameters. The Markov Chain Monte Carlo (MCMC) method is effective to estimate high dimensional parameters. In this study, we evaluate the uncertainty of the estimation and trade-off among parameters from a statistical perspective.

We analyzed five clusters of events near Cushing, Oklahoma, each containing a M 4+ event. Empirical Green’ s function events used as the denominator all locate within 2 km of the target event. We analyzed 5.12 seconds of the time-aligned seismogram from twice the S wave arrival time. Spectral ratios between a large event ($M_L > 4$) and small events were formed by stacking all stations to remove path effects. Then, analyzed spectral ratios between event pairs using the Metropolis-Hastings algorithm to estimate moment ratio and two corner frequencies for the Brune model. We updated the value of moment ratio and two corner frequencies with 300,000 iterations which first 100,000 calculations was ignored as burn-in.

In most cases, the distribution of the sampling showed ellipsoidal shape in the 3D parameter space. We searched the axial direction of the sampling distribution by principal component analysis (PCA), and estimated loadings of the principal component and contribution rate. Some spectral ratio showed irregular shape from ideal shape because of small magnitude difference or contamination by noise. The percentage of the contribution rate indicates how well the sampling distribution is explained by each component. The contribution rate of the first principal component with irregular shape of the spectral ratio was lower than 80 % while it was higher than 80 % with normal shape of the spectral ratio. The loadings among three parameters and three principal components also showed different pattern in the case of normal shape and irregular shape of the spectral ratio. These different trend of the contribution rate and the loadings indicates different pattern of the sampling distribution of a spectral ratio that have irregular shape. Thus, the combination of MCMC and PCA analysis have a possibility that to automatically classify spectral ratios which have irregular shape and ideal shape.

Trans-dimensional Bayesian inversion for a radially anisotropic S-wave velocity model in the crust and upper mantle: Application to the Australian continent

*Toru Taira[1], Kazunori Yoshizawa[2]

1. Graduate School of Science, Hokkaido University, 2. Faculty of Science, Hokkaido University

The velocity structure and discontinuities in the upper mantle, such as Lithosphere-Asthenosphere Boundary (LAB) and Mid-Lithosphere Discontinuity (MLD), have been investigated through a number of seismological studies, in which both body and surface waves have been employed. Many studies using body waves have extracted information on the upper mantle from the later arrivals of teleseismic body waves by deconvolving the vertical component from the horizontal components, which produces "receiver functions". While they are good at constraining impedance contrasts across the discontinuities, they are not sensitive to the absolute velocity. In contrast, surface waves enable us to recover the absolute velocity, though sharp velocity jumps cannot be resolved due to their lower frequency content (< 0.05Hz). In view of such different sensitivities of receiver functions and surface waves, the joint inversions of body and surface waves will be the most effective approach to the accurate estimation of seismic velocity structures in the crust and upper mantle.

In this study, we develop a new method for non-linear joint inversion of Ps receiver functions and multi-mode Rayleigh and Love surface waves using trans-dimensional Bayesian formulation, following the earlier works by Bodin et al., (2012, JGR). This trans-dimensional approach allows us to constrain the complexity of earth model with little a priori information, in which the number of model parameters (e.g. number of layers) can also be treated as a part of unknowns. The reversible-jump Markov Chain Monte Carlo approach (Green, 1995, Biometrika) is used to sample models with variable dimension in proportion to the posterior distribution of the Earth models. Assuming that data errors follow the Gaussian distribution, we also estimate the variances of the data errors at the same time. Such an approach is called 'Hierarchical Bayes' (e.g. Malinverno and Briggs, 2004, Geophysics), in which the overfitting of the models can be prevented. Parallel Tempering method (e.g. Sambridge, 2014, GJI) is also incorporated in our inversions, which makes the model samplings more efficient enabling us to extend the parameter search ranges.

With this method, we jointly inverted the Ps receiver function, multi-mode Rayleigh and Love dispersion curves from Yoshizawa (2014, PEPI) for a radially anisotropic 1-D shear velocity model under Global Seismographic Network (GSN) stations in Australia. Our preliminary result for the WRAB station in the central Australia implies the existence of two MLDs with negative and positive velocity jumps at around 90 km and 150 km depths, respectively, and LAB at around 220km depth. The depths of MLDs are consistent with an earlier receiver function study by Ford et al. (2010, EPSL) and such multiple MLDs are also reported by another study in North America (Calo et al., 2016, EPSL). Our estimated LAB depth at 220 km is deeper than that from the earlier surface wave study (Yoshizawa & Kennett, 2015, GRL), in which the Lithosphere-Asthenosphere Boundary under cratons is supposed to be a smooth transition. Still, we can still see the common feature of strong radial anisotropy (SH>SV) in the asthenospheric depth below 220 km, indicating the effects of strong shear flow under the fast-moving Australian continent.

In recent years, dense seismic observation networks have been constructed. For example, the Metropolitan Seismic Observation network called MeSO-net has been observing ground motions since 2011 with the average intervals of ~5 km in the Tokyo metropolitan located on the Kanto sedimentary basin, Japan. Utilizing seismograms of MeSO-net, we have developed a wavefield reconstruction method by simultaneously estimating subsurface velocity structures and source locations using replica exchange Monte Carlo (REMC) method [Kano et al. 2017, GJI, JGR]. The reconstructed wavefield can be used as input ground motions to simulate seismic response of infrastructure for the purpose of rapid evaluation of seismic hazards. In this presentation, we will summarize the REMC-based wavefield estimation method and discuss future developments and applications of the method.

Bayesian oscillator decomposition for seismic data

*Takeru Matsuda[1]

1. The University of Tokyo

Many time series including seismic data are naturally considered as a superposition of several oscillators. Matsuda and Komaki (2017a,b) proposed a Bayesian statistical method for decomposing time series data into oscillators by using Gaussian linear state space models. For example, this method can be used to extract neural oscillators (such as alpha, beta, and gamma) from neuroimaging data. In this study, we apply this method to seismic data and investigate the extracted oscillators.

Uncertainty evaluation of source parameter estimates by MCMC in Oklahoma

*Nana Yoshimitsu[1], Takuto Maeda[2], William Ellsworth[3]

1. The University of Tokyo, Earthquake Research Institute, 2. Hirosaki University, 3. Stanford Univerisy

Stress drop is important parameter to understand earthquake source characteristics and to improve hazard assessment. Many studies use the spectral ratio method to measure the moment ratio and two corner frequencies by comparing theoretical and observed spectral ratio in the frequency domain and obtain the stress drop. Accurate stress drop estimates are difficult to make because it depends on the accuracy of the three parameters. The Markov Chain Monte Carlo (MCMC) method is effective to estimate high dimensional parameters. In this study, we evaluate the uncertainty of the estimation and trade-off among parameters from a statistical perspective.

We analyzed five clusters of events near Cushing, Oklahoma, each containing a M 4+ event. Empirical Green’ s function events used as the denominator all locate within 2 km of the target event. We analyzed 5.12 seconds of the time-aligned seismogram from twice the S wave arrival time. Spectral ratios between a large event ($M_L > 4$) and small events were formed by stacking all stations to remove path effects. Then, analyzed spectral ratios between event pairs using the Metropolis-Hastings algorithm to estimate moment ratio and two corner frequencies for the Brune model. We updated the value of moment ratio and two corner frequencies with 300,000 iterations which first 100,000 calculations was ignored as burn-in.

In most cases, the distribution of the sampling showed ellipsoidal shape in the 3D parameter space. We searched the axial direction of the sampling distribution by principal component analysis (PCA), and estimated loadings of the principal component and contribution rate. Some spectral ratio showed irregular shape from ideal shape because of small magnitude difference or contamination by noise. The percentage of the contribution rate indicates how well the sampling distribution is explained by each component. The contribution rate of the first principal component with irregular shape of the spectral ratio was lower than 80 % while it was higher than 80 % with normal shape of the spectral ratio. The loadings among three parameters and three principal components also showed different pattern in the case of normal shape and irregular shape of the spectral ratio. These different trend of the contribution rate and the loadings indicates different pattern of the sampling distribution of a spectral ratio that have irregular shape. Thus, the combination of MCMC and PCA analysis have a possibility that to automatically classify spectral ratios which have irregular shape and ideal shape.

[S-CG49] Hard-Rock Drilling Science: From Continental to Deep Sea Drilling, and Oman Project

convener:Katsuyoshi Michibayashi(Department of Earth and Planetary Sciences, Nagoya University), Eiichi TAKAZAWA(Department of Geology, Faculty of Science, Niigata University), Norikatsu Akizawa(Department of Ocean Floor Geoscience, Atmosphere and Ocean Research Institute, The University of Tokyo), Chairperson:Katsuyoshi Michibayashi

The Oman Drilling Project (OmDP) has completed to drill numerous hard-rock cores within ancient oceanic lithosphere and the underlying subduction zone of the Samail ophiolite in Oman, with support from ICDP, IODP, Japan Society for the Promotion of Science, the Sloan Foundation's Deep Carbon Observatory, US, and European research agencies. Moreover, a number of IODP expeditions have focused on hard-rock drilling over the last several years including Expedition 352 in 2014, which drilled the volcanic sequence associated with subduction initiation in the Bonin fore-arc, Expedition 357, which drilled the Lost City hydrothermal field, Expedition 360, which drilled the lithosphere associated with ultraslow-spreading at the Southwest Indian Ridge in 2016, and Expedition 366, which drilled the serpentinite seamounts in the Mariana fore-arc. In this session, we invite presentations on the scientific results of hard-rock drilling at these and other sites. We also invite related presentations on oceanic lithosphere, island arc formation, and any other significant issue that could be addressed by future hard-rock drilling. This includes marine studies of oceanic lithosphere and on-land geological investigations of ophiolites, accreted arcs, and subduction complexes. The session is intended to be interdisciplinary, including the fields of geophysics, geochemistry, petrology, engineering, and biology.

The East Taiwan Ophiolite (ETO) occurs as blocks and thrust sheets associated with the Lichi Mélange in the Coastal Range of eastern Taiwan. The blocks consist of serpentinized harzburgite, serpentinite breccia, gabbro, dikes of dolerite and plagiogranite, pillow basalts, and red clay within a mud- and serpentinite-rich mélange matrix. New U-Pb zircon dating of a pegmatite gabbro yields a weighted mean age of 16.65±0.20 Ma. This age is earlier than the North Luzon Arc, but overlaps with the late–stage spreading of the South China Sea. ETO glassy basalt has low K_2O, MgO and high CaO contents, similar to MORB. REE and trace element patterns show both N-MORB patterns with LREE depletion and E-MORB patterns with slight LREE enrichment. A few samples show slight depletion in Nb-Ta, and Ti and enrichment in Rb, Ba, U and Sr, indicating a hint of subduction influence. Most ETO basalt plots within the overlapping fields of N-MORB and BABB on Ti-V, Cr-Y, Nb/Yb- Th/Yb and Hf/3-Th-Ta discrimination diagrams. The geochemical compositions of the ETO basalt are emblematic of mid-ocean ridge or back-arc lava, and the Pb isotope values are similar to those of MORB of the South China Sea from IODP Expedition 349. We interpret ETO basalt as fragments of the subducted South China Sea basement that were scrapped off and accreted to the Luzon forearc during the process of subduction initiation along the nascent Manila Trench. Blocks of mantle material in the mélange may originate from the upper plate of the arc-continent collision and were mixed with lower plate crustal material in a subduction channel now represented by the Lichi Mélange.

Drilling a continuous section through the lower oceanic crust and into the uppermost mantle has been an unfulfilled scientific ambition for more than 60 years since before the development of plate tectonics. Although an imperfect analogue of in situ, intact ocean crust, the 96 Ma Samail ophiolite of Oman is the largest and best preserved on-land exposure of ancient ocean crust that formed in some type of fast spreading ocean ridge, in the Tethyan ocean shortly before its obduction on to the Arabian margin. Offset drilling by Oman Drilling Project has now sampled critical intervals of the mid to lower oceanic crust and the uppermost mantle preserved in the Samail ophiolite. In a series of 400 m-deep diamond-cored boreholes the Oman Drilling Project has made with near 100 % rates of recovery, continuous objective observations from the lower sheeted dikes and the dike-gabbro transition zone (Hole GT3A), the mid-crustal transition from foliated to layered cumulate gabbros (Hole GT2A), deep layered gabbros including mineralised fault zones (Hole GT1A), and across the crust-mantle transition from layered gabbros through dunites into residual harzburgites of the Samail upper mantle (Holes CM1A and CM2B). Observations of drillcore, complemented by instrumental (e.g., X-ray CT, Infrared scanning) and geophysical wireline logging, now provide the opportunity to objectively quantify the conditions and extent of seawater-rock exchange in the mid to lower oceanic crust and uppermost mantle. These new observations will lead to better understand the role and influence of deep hydrothermal circulation on the accretion of the lower oceanic crust and the improved quantification of geochemical and isotopic exchanges between the oceans and new crust formed at mid-ocean ridges.

Here we present some preliminary results constraining peridotite alteration in cores from several Oman Drilling Project (OmanDP) boreholes, from the Samail ophiolite in the Sultanate of Oman. Hole BT1B in Wadi Mansah east of Fanjah was drilled through 200 m of fully carbonated and/or serpentinized peridotites of the mantle wedge, through the basal thrust of the ophiolite, into the metamorphic sole. Holes BA1B, BA3A and BA4A were drilled into extensively serpentinized peridotite of the eastern Wadi Tayin massif.

Fully carbonated peridotites (listvenites) and serpentinites of Hole BT1B reflect carbonation and hydration by fluids rising from the Cretaceous subduction zone at the base of the ophiolite, at about 100° C (Falk & Kelemen GCA 2015). Though there is extensive, 0.01-10 m scale chemical variation, the average, volatile-free composition of the listvenites is almost identical to that of partially serpentinized harzburgites throughout the ophiolite mantle section. This observation and thermodynamic modeling indicate that, during addition of CO2, H2O, Ca and K from subduction zone fluids, Mg/Fe/Si ratios were nearly unchanged, suggesting very minor export of dissolved, major elements. In turn, this requires a large increase in solid volume. One possibility is that major volume expansion occurred at a serpentinization front, perhaps advancing via reaction-driven cracking, followed by smaller amounts of expansion at the carbonation front. Observed mineral parageneses and thermodynamic modeling require relatively CO2-rich aqueous fluids, and perhaps an exsolved, CO2-dominated fluid. CO2 contents were higher than for fluids in equilibrium with underlying metasediments at any likely depth for formation of the observed listvenite, and thus suggest that fluids derived from higher temperature and pressure devolatilization migrated up the subduction zone to this site.

Highly serpentinized peridotites from Holes BA1B, BA3A and BA4A record steep chemical gradients, with sharply decreasing f(O2) and f(CO2) downhole, beginning at the present-day erosional surface. Moreover, inferred conditions based on mineral parageneses are consistent with present-day borehole water compositions. Oxygen fugacity reaches the limit for H2 production from H2O at < 100 meters below the surface. These borehole observations are consistent with previous observations (14C in carbonates, reduced sulfides, oxides and metals, highly alkaline and reduced fluids, H2 gas) and thermodynamic modeling indicating that carbonation and serpentinization-related redox reactions are ongoing. Given experimental data suggesting that serpentinization of olivine is slow, evidence for low temperature “serpentinization” raises interesting questions about natural rates, and the nature of reactants and products, in the present-day weathering environment.

There are numerous gas and liquid, two-phase inclusions in dolomite crystals in a white-green-colored listvenite recovered through Oman Drilling Project Phase 1 (specimen name z68w). Most of the fluid inclusions are tiny, <6 micrometer across and seems to be too small to provide detectable Raman spectra of fluids. Fluid inclusions >6 micrometer across in dolomite provide Raman spectra of H_2O, but they become dark possibly due to destruction during the cooling processes and usually prohibit from observation of melting ices. So far, Raman microscopy indicated that they are filled with H_2O and do not detect any other gasses such as CH_4 or CO_2. Melting temperature of ice in the tiny fluid inclusions, on a Linkam THM600 heating stage with a Nikon 100X objective lens indicates that they are filled with saline fluids with 1.1 ±0.5 wt% NaCl equivalent (n=42, Figure 1), which is much lower than that of seawater (3.5 wt% NaCl). Homogenization temperature of vapor-liquid suggests that the fluid inclusions were formed at temperature >139 ±31˚C (n=8, Figure 2). The fluid inclusions are mainly in dolomite veins, which cut magnesite and quartz (Figure 3, Raman mapping of magnesite, quartz, and dolomite). The present data indicate that low-salinity aqueous fluids were available during the crystallization of dolomite veins after the formation of magnesite-quartz assemblage. If seawater carries carbon to form listvenite from peridotite or serpentinite, the present low-salinity data suggest that chlorine needs to be absorbed by some phases during the fluid migration or be diluted by mixing with meteoric water.

Hydration and development of fracture network within oceanic lower crust: an evidence from CM1A of Oman Drilling

*Atsushi Okamoto[1], Kazuki Yosida[1], Ryosuke Oyanagi[2], Oman Drilling Project Phase 2 Science Party[3]

1. Graduate School of Environmental Studies, 2. JAMSTEC, 3. Oman Drillng Project Phase 2 Science Party

The rate and extent of hydration of oceanic lithosphere are of special importance for understanding of the global water budget, the physical properties of crust-mantle boundary and potential limit of microbial activities in the crusts. It has been suggested that Moho transition zone and uppermost mantle has been highly serpentinized. If the fluid source for serpentinization is seawater, the fluid infiltration through the “less permeable” lower crust should occur. In this study, we report the nature of serpentinization in olivine within the lower crusts that was recovered from the CM1A site of the Oman Drilling Project, and discuss the relationship between hydration, fluid flow and fracturing based on the modeling of distinct element method (DEM).

The gabbroic rocks of the lower crust showed layer structures composed of light and dark colored layers with few to several tens millimeter thickness. The former is mainly composed of plagioclase and clinopyroxnene and the latter is enriched in olivine. The olivine grains were serpentinized with forming mesh-like textures, and the extent of serpentinization increases with increasing the modal abundance of olivine. The serpentine veins within the olivine grains do not always contain brucite, and show the zoning of Al, indicating an influx of silica and aluminum from plagioclase during serpentinization. The large amount of magnetite was formed in the serpentine mesh veins, indicating that olivine with high Fe content (Mg# = ~0.82) effectively produce hydrogen compared to the common mantle peridotite (Mg# = ~0.9). Radial cracks, which are filled with chlorite, are also developed around the serpentinized olivine grains. These features indicated that the reaction-induced fracturing occurred as the force of crystallization exceeds the tensile strength of the matrix minerals as suggested by the previous studies (Jamtveit et al., 2008; Kelemen and Hirth, 2012). It is also noted that fractures in olivine tends to developed in horizontal direction (parallel to the gabbroic layering) whereas those with in the plagioclase developed in vertical direction.

We conducted the DEM simulation on serpentinization in layered gabbro, which treats the reaction, advective fluid flow and fracturing, and the reaction rate is defined as a function of fluid pressure (Okamoto and Shimizu, 2015; Shimizu and Okamoto, 2016). The model reproduces a simultaneous development of contrasting fracture patterns inside and outside of the olivine grains, and shows the development of fracture network connecting the olivine grains, and shows the positive feedback of serpentinization, fracturing and permeability enhancement in vertical direction. These results indicate that the reaction-induced fracturing play essential roles on the fluid infiltration through the lower crusts and mantle hydration.

[S-CG56] Ocean Floor Geosciences

convener:Kyoko Okino(Atmosphere and Ocean Research Institute, The University of Tokyo), Chairperson:Arata Kioka, Atsushi Noda

Most of Earth's volcanism and much of its tectonic activity occur on and beneath the seafloor. Various phenomena on the seafloor are closely linked to plate tectonics, Earth and atmosphere. Seafloor rocks and sediments record Earth's evolution and heat and material fluxes on the Earth. Ocean Floor Geosciences session covers a broad range of research on LIPs, crustal movement and structure etc. Any fields of research and approach are welcomed. The session aims to encourage discussion among scientists from different study fields and to integrate our understanding of ocean floor. The session is co-chaired by K. Tadokoro (Nagoya Univ.), O. Ishizuka (AIST), T. Toki (Univ. Ryukyus), and N. Takahashi (JAMSTEC).

The South Sandwich arc-trench system, located in between South America and Antarctica, is one of the unexplored subduction zones of the world. It was originated in Mesozoic fragmentation of Gondwana, and Neogene westward subduction of South American plate causes formation of South Sandwich volcanic arc and back-arc opening of West and East Scotia Sea. The formation of Scotia Sea is closely related to the opening of Drake Passage Gateway, and thus it caused the development of the Antarctic Circumpolar Current and affected the earth’ s climate. However, detail back-arc opening process of Scotia Sea is poorly understood. Sediment accumulated in the South Sandwich Trench is expected to contain large amount of diatom and IRD (ice-rafted debris), but the nature of the sediment in the trench is unknown because of the lack of sediment cores.
On 2019 December-2020 January, R/V Hakuho Maru will visit the South Sandwich Arc and Weddell Sea as a part of around the world cruise for her 30th anniversary. During this cruise, we plan to take 1) dredge samples of forearc high of South Sandwich Arc possibly recording initiation process of oceanic island arc, as well as 2) sediment cores in South Sandwich Trench as an input to a subduction zone in polar region. By comparing the findings during this cruise to accumulated knowledge on backarc-arc-trench system around Japan, we try to understand the formation and evolution of the world southernmost arc-trench system.

Seismic imaging of the source zone of the 2011 Tohoku-oki earthquake

*Dapeng Zhao[1], Xin Liu[1]

1. Department of Geophysics, Tohoku University

The great 2011 Tohoku-oki earthquake (*Mw* 9.0) is the best-documented megathrust earthquake in the world, but its causal mechanism is still in controversy because of the poor state of knowledge on the nature of the megathrust zone. *Zhao et al*. (2011) used seismic tomography to study structural heterogeneity in the megathrust zone and suggested that lateral structural variations atop the subducting Pacific slab, such as the subducted seafloor topography, seamounts and sediments, affected nucleation of the 2011 Tohoku-oki earthquake. In contrast, *Bassett et al*. (2016) used residual topography and gravity data to constrain the Tohoku forearc structure and proposed that variations in the forearc lithology of the overriding Okhotsk plate were the main cause of along-strike variations of the Tohoku-oki slip behavior. In this work we constrain the structure of the Tohoku forearc using seismic tomography, residual topography and gravity data. We apply a tomographic method (*Zhao et al*., 2002) to invert 144,354 *P*-wave arrival-time data recorded at 382 permanent seismic stations in Tohoku from 4760 local shallow and intermediate depth earthquakes that occurred during January 2000 to June 2016.

Our results reveal a close relationship between structural heterogeneities in and around the megathrust zone and rupture processes of the 2011 Tohoku-oki earthquake (*Liu and Zhao*, 2018). Its mainshock nucleated in an off-Miyagi area with high seismic velocity, low seismic attenuation and strong seismic coupling, indicating a large asperity (or a cluster of asperities) in the Tohoku megathrust zone. Strong coseismic high-frequency radiations also occurred in high-velocity patches, whereas large afterslips took plate in low-velocity areas, which may reflect changes in fault friction and lithological variations. These results indicate that structural anomalies in and around the Tohoku megathrust originate from both the upper Okhotsk plate and the lower Pacific plate, which controlled the generation and rupture processes of the 2011 Tohoku-oki earthquake. This huge earthquake was caused by collision of harder rocks in both the upper and lower plates.

This work sheds new light on the causal mechanism of megathrust earthquakes. It also suggests that the location of a future great earthquake may be pinpointed by investigating the detailed structure of the megathrust zone.

In this presentation, we will also show our new results obtained by adding the data recorded by the S-net that has been installed in the eastern Japan forearc region under the Pacific Ocean.

Drastic export of organic carbon to hadal trench driven by megathrust earthquake

*A. Kioka[1], T. Schwestermann[1], J. Moernaut[1], K. Ikehara[2], T. Kanamatsu[3], C. M. McHugh[4], C. dos Santos Ferreira[5], G. Wiemer[5], N. Haghipour[6], A. J. Kopf[5], T. I. Eglinton[6], M. Strasser[1,5]

Despite a growing understanding of pivotal role of the carbon cycle in governing the Earth system, the nature and quantification of carbon supply to hadal environments remains poorly constrained. The giant 2011 Tohoku-oki earthquake has been inferred to remobilise fine-grained, young surface sediment enriched in organic matter from the slope into the >7 km deep Japan Trench. Yet, this hypothesis and assessment of its significance for the carbon cycle has been hindered by limited data density and resolution in the hadal zone. Here we combine new high-resolution bathymetry data with subbottom profiler images and sediment cores taken during 2012–2016, in order to map for the first time the spatial extent of the earthquake-triggered event deposit along the hadal Japan Trench. We quantify a sediment volume of ~0.2 km^3 deposited from spatially-widespread remobilisation of young surficial seafloor slope sediments triggered by the 2011 earthquake and its aftershock sequence. The mapped volume and organic carbon content in sediment cores encompassing the 2011 event reveals that this single tectonic event delivered >1 Tg of organic carbon to the hadal trench. This carbon is comparable to high carbon fluxes described for other Earth system processes, shedding new light on the impact of large earthquakes on long-term carbon cycling in the deep sea.

How do trench-fill sediments subduct under the accretionary wedge?

*Atsushi Noda[1], Hiroaki Koge[2], Yasuhiro Yamada[3], Ayumu Miyakawa[1], Juichiro Ashi[2]

1. National Institute of Advanced Industrial Science and Technology, 2. Atomosphere and Ocean Research Institute, The University of Tokyo, 3. Japan Agency for Marine-Earth Science and Technology

Ancient exhumed accretionary complexes sometimes have combinations of low-grade accretionary rocks from trench-fill turbidites, high-pressure/low-temperature metamorphic rocks including psammitic schists, and forearc basin deposits composed of sandy submarine fan deposits, whose provenance and depositional ages are similar to each other. For example of the southwestern Japan, sandstones in the Shimanto Accretionary Complex and psammitic schists in the Sanbagawa Metamorphic Complex are derived from terrigenous trench-fill deposits showing the similar geochemical and geochronological characteristics each other; the former is composed of accretionary rocks at the shallow part of the subduction zone and the latter comprises metamorphic rocks subducted to deeper than 10~km. Generally, at accretionary-type subduction zones, because weak layers within sediments deposited on the oceanic plate are used as a decollement, the lower pelagic and hemipelagic sediments can subduct beneath accretionary wedge through the subduction channel, but the upper terrigenous sediments are accreted at the toe of the wedge. Growth of accretionary wedge enabled to develop a forearc basin between the wedge and the backstop. At tectonically erosive subduction zones, most of the trench-fill sediments can subduct beneath the frontal prisms, but accretionary wedge cannot be grew at the same time. Therefore, it is difficult to explain coexistence of growth of accretionary wedge derived from coarse-grained trench-fill sediments and subduction of them deeper than seismogenic zone at the same time. In this study, we attempt to identify an importance of seafloor roughness for transportation of trench-fill sediments to deep during subduction. For this purpose, we conducted sandbox analogue experiments by using an unfixed rigid backstop on a subduction channel with the cases of smooth surface (Exp. A) and rough surface representing a seamount or ridge on subducting lower plate (Exp. B). The results of Exp. A showed progressive thickening of the accretionary wedge pushed the backstop down, meaning stepping down of the decollement and narrowing the subduction channel. On the other hand, Exp. B showed a subducting seamount lifted up the backstop, stepped up the d{\'e}collement, and then widened the subduction channel. Subduction of a rigid material like a chain of seamounts is a possible mechanism to open subduction channels for transportation of terrigenous sediments from the trench to high-pressure condition. Significant sediment supply to the trench and rough surface of subducting oceanic plate are required to enable subduction of protolith of HP-LT metamorphic rocks, accretion of trench-fill sediments at the shallow part, and formation of forearc basin simultaneously.

Formation process of a slope basin in the Nankai Accretionary prism reconstructed from high-resolution SBP integrated with core data of ODP Site 1175 and Site 1176

*Yuichi Okuma[1], Asuka Yamaguchi[1], Hiroaki Koge[1], Rina Fukuchi[1], Juichiro Ashi[1]

1. Atmosphere and Ocean Research Institute, the University of Tokyo

Upper plates of subduction zones record various phenomena associated with plate subduction. Geological records of slope basins overrapping accretionary prisms are useful to reconstruct tectonic activities of decollements and/or splay faults. In general, low-frequency sources are preferred for seismic reflection profiling to avoid attenuation in the water. However, low-frequency sources permit limited resolution of profiles due to trade-off relationship of frequency and resolution. For this reason, only limited studies focused on detail structures of the shallow portion of the deep-sea slope basins (e.g., Tsuji et al., 2014, *EPS*). In this study, we conducted interpretation of subsurface structures and reconstructed the formation process of the slope basin on the Nankai accretionary prism using high-resolution cross section images obtained by deep towed subbottom profiler on the R/V Hakuho-maru KH-16-5 cruise around the Nankai Trough off Muroto. This slope basin is located at 80 kilometers to southwest of the cape Muroto and a depth of 3000 m, and 8 kilometers long in northwest-southeast and 6.5 kilometers long in northeast-southwest forming an ellipse shape. An obvious strike-slip fault including normal-slip orientation at 1 kilometer seaward from the basin and a splay fault at 2 kilometers from the strike-slip fault are confirmed by Underwood et al. (2003, *JSR*), there is a high possibility that the basin records those activities. Moreover, Kodaira et al. (2000, *Science*) reported the existence of a subducted seamount at north of the slope basin, which means that subduction of this seamount had an impact on formation of the basin. Two cores from Site 1175 and Site 1176 were obtained by Ocean Drilling Program (ODP) Leg 190 around the basin, we also compared the result of interpretation to depositional structures and age. The high-resolution cross section shows a splay fault, strike-slip fault and hillock associated with minor faults including a strike-slip fault with reverse fault component at the center of the hillock. In the landward region from the strike-slip fault on the hillock, structures indicating relative subsidence of landward margin of the basin were confirmed. Additionally, basin strata show the evidence of landward migration of a depocenter in that region, which is coincident with the structures in the seismic profiles (Shipboard Scientific Party, 2001). The dip angle near the Site 1175 increase with depth, which suggest continuous tilting. Only normal faults exist in the landward region from the top of the hillock. Especially, four normal faults getting through to the seafloor are attributed to successive faulting because the displacement of those faults increase with depth. In addition, landslide deposit flowed from landward slopes is ascertained in the cross section. On the other hand, the reverse fault group being part of a splay fault is included in the trenchward region from the strike slip fault. The subbottom profile shows the evidence of obvious reverse and normal faulting around that region. Notably, reverse faulting is dominant in trenchward-half of the hillock, although no faults are getting through to the seafloor. The reflecting surfaces correspond with volcanic ash or sand layers by comparison both reflection surfaces and stratigraphic succession of cores on the Site 1175 and Site1175. Depositional age from analysis of ash suggest that the tilting in landward region from the strike-slip fault was getting low in activity and calmed within 28 ka. It is difficult to presume the moment of initiation of tilting due to depth limit of SBP, however, the basin already started tilting when the 105 ka surface deposited because that tilting of the surface confirmed around Site 1175. Additionally, the number of faults cutting surface younger than 28 ka is less than those cutting older than that surface, and no faults except the well-developed strike-slip fault at the center of the hillock reach the

©2019. Japan Geoscience Union. All Right Reserved.

seafloor. Therefore, those results indicate that a high likelihood of that the tilting at shallow portion of the basin caused by faulting of the splay fault, and suggest that the tilting had initiated before deposition of 105 ka surface and stopped by 28 ka at the latest. In this way, deep towed SBP integrated with core data has a great potential for reconstructing high time-resolution basin growth and fault activity.

About the turbidity current considered that it occurred in the northern Suruga Bay, Central Japan by the typhoon No.24. -The traces of the accidents and the phenomenon at the sea floor detected the OBSs Array-

*Nakao Nagisa[1], Hisatoshi Baba[2], Hiroshi Sato[3], Kayoko Tsuruga[4], Izumi Sakamoto[2], Takahito Nishimiya[5], Masanao Shinohara[3], Shintaro Abe[6]

1. Tokai University, 2. Department of Marine and Earth Science, Tokai University, 3. Earthquake Research Institute, University of Tokyo, 4. Tokyo University of Marine Science and Technology, 5. Meteorological Research Institute, Japan Meteorological Agency, 6. Association for the Development of Earthquake Prediction

In August 2018, Structural exploration based on "The integrated research project for the Fujikawa fault zone" began in the northern Suruga Bay. We installed 18 pop-up type Ocean Bottom Seismographs (OBSs) in this survey line (from Shimizu to Heda). In addition, we installed 4 OBSs in other survey lines for the observation of seismic activities around the Suruga Bay.

The typhoon No.24 passed off in the vicinity of the Suruga Bay from September 30th to October 1st 2018. After passing off that, various accidents of OBS occurred. Those accidents of OBS are as follows:

1. 4 OBSs drifted on the coast.

2. The movement of the installation position of the 2 OBSs was confirmed.

3. 1 OBS did not have a transponder response and it was missing.

4. The two OBSs have a transponder response, but they do not pop-up.

From this and the above, in this study, we considered OBS to have an accidentally due to a phenomenon occurred at the seafloor in the northern part of Suruga Bay by typhoon 24.

We analyzed using seismic wave, submarine topography and mud and considered them.

・According to the waveform record obtained by OBS, the accidenty spread from the central part of Suruga Bay of the extension of the Fujikawa estuary.

・It was a tilt that caused turbidity flow to occur by hanging from the Fujikawa estuary to the survey line.

・When the bottom sampling was done at the installation point and recovery point, the same particle size was present.

From the above,the cause of the accidenty in the OBS in the northern Suruga Bay is presumed to have flowed into the Suruga bay, where the sediments originating from the Fujikawa streamed OBSs.

©2019. Japan Geoscience Union. All Right Reserved.

From this, there is a high possibility that a turbid flow has occurred in northern Suruga Bay.

Mon. May 27, 2019 3:30 PM - 5:00 PM JST | Mon. May 27, 2019 6:30 AM - 8:00 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_17

[S-CG56] Ocean Floor Geosciences

convener:Kyoko Okino(Atmosphere and Ocean Research Institute, The University of Tokyo)

Most of Earth's volcanism and much of its tectonic activity occur on and beneath the seafloor. Various phenomena on the seafloor are closely linked to plate tectonics, Earth and atmosphere. Seafloor rocks and sediments record Earth's evolution and heat and material fluxes on the Earth. Ocean Floor Geosciences session covers a broad range of research on LIPs, crustal movement and structure etc. Any fields of research and approach are welcomed. The session aims to encourage discussion among scientists from different study fields and to integrate our understanding of ocean floor. The session is co-chaired by K. Tadokoro (Nagoya Univ.), O. Ishizuka (AIST), T. Toki (Univ. Ryukyus), and N. Takahashi (JAMSTEC).

Signature of plume-ridge interaction on bathymetry and geochemistry along mid-ocean ridges: Insights from the Réunion Plume and Central Indian Ridge

*Clement Vincent[1], Jung-Woo Park[1], Sang-Mook Lee[1], Jonguk Kim[2], Sang-Joon Pak[2]

1. Seoul National University, 2. Korea Institute of Ocean Science and Technology

Plume-ridge interaction is an important thermal and geological process, which results in various physical and chemical anomalies along a significant length of the global mid-ocean ridges system. Despite numerous studies, some remaining questions to be solved are origin and mechanisms of geochemical variations and their possible influence on the morphology of mid-ocean ridges. The Central Indian Ridge, with a slow to intermediate spreading rate, provides an ideal opportunity to explore distant plume-ridge interactions. Presently, the ridge is moving away from the hotspot. The hotspot which started at the Deccan Traps (65 Ma) is presently 1000 km away from the Central Indian Ridge, at the Réunion Island. Paleogeographic reconstruction suggests that the hotspot crossed the middle part of the Central Indian Ridge (MCIR) between 8˚S and 17˚S at ~34 Ma. Studies suggest that the plume material that flows into the Central Indian Ridge is more or less concentrated around 19˚S, to the south of Marie Celeste Fracture Zone (MCFZ). In addition, recent geochemical study show southward-increasing gradient in Réunion mantle component between 14˚S and 18˚S north of MCFZ. The detailed mechanism of the plume interaction on the MCIR is in debate. In this study, we revisited the MCIR with additional Nd, Sr and Pb isotope analyses and ship-board high-resolution bathymetry data to constrain the influence of the Ré union plume on geochemistry and bathymetry of the MCIR. The results show that the geochemical anomaly observed between 14˚S and 18˚S are found only in the northern part of segments and subsegments, and these enrichments correlate with the shallow axial bathymetry. The localized geochemical and bathymetric anomalies can be ascribed to a hotspot leading edge effect where the hotspot leading segments are offset in the direction of the plume and are more influenced by the plume materials. It appears that discontinuities such as transform faults and the non-transform discontinuities influence the flow of mantle plume material into the ridge, and that the proximity of the ridge to the hotspot plays an important role in the plume-ridge interaction.

Spreading rate and its stability of Chile Ridge near the Chile Triple Junction

*Takanori Ishihara[1], Takeshi Matsumoto[1]

1. Ryukyu university

Chile triple junction (CTJ) is located at 46°13'S, 75°13'W off the coast of Chile and is composed of Nazca plate, Antarctic plate and South America plate, forming a ridge-trench-trench type triple junction. Chile ridge that is an active spreading ridge is subducting under the South America plate at CTJ and is the only ridge system that is currently subducting under trench in the world. Therefore this area is an important target to study the behavior of the active ridge just before subduction. And also, the mechanism and a possible driving force of the active ridge subduction are also to be studied by subsurface structure, age, development history, and so on through marine geophysical survey. The authors analysed total geomagnetic data from the tracks along the segments and attempted to obtain seafloor spreading rate at each segment and seafloor age from magnetic anomaly, and spreading stability in this area by the magnetic N/R boundary strikes derived from the three component magnetic data. Both the total force and the three-component magnetic data for this study were obtained from MR16-09 cruise by R/V MIRAI, Leg1 and Leg2. Marine Trackline data that were achived in National Geophysical Data Center were also used supplementarily. Seafloor spreading rate decrease is shown along almost all the tracks close to the trench, and comparison of several track data along the Segment SCR1 shows the same characteristics that spreading rate along the southern track is slower than that along the northern track. Moreover, the result from the other segments show that SCR1’s spreading rate (about3.0cm/yr) is higher than SCR3’s one (about 2.0cm/yr). These results show spreading rate is decreasing as the ridge is close to the trench. This mightbe due to declining of igneous activity and reduction of magma supply rate near the trench as Matsumoto et al (2013) showed. The reason why the young seafloor subducts early is that increasing of slab pull force caused by thickening of the oceanic lithosphere by cooling with closing the trench. Magnetic N/R boundary strike shows almost uniform trends, except near Guamblin fracture zone, so spreading stability is attained on the whole.

Newly Mapped Seamounts on the Antarctic Plate off Southern Chile

*Toshiya Fujiwara[1], Natsue Abe[2], Naomi Harada[3], Mirai MR16-09 Leg 2 Shipboard Science Party

1. Research and Development Center for Earthquake and Tsunami, Japan Agency for Marine-Earth Science and Technology, 2. Research and Development Center for Ocean Drilling Science, 3. Research and Development Center for Global Change

We conducted bathymetry, gravity, and magnetic survey of seamounts on the Antarctic Plate off southern Chile in the R/V Mirai MR16-09 Leg 2 cruise (January 20 - February 5, 2017: Puerto Montt - Punta Arenas). The survey including transit was an unprecedented opportunity to collect data in the regions of the Pacific Ocean where it has been sparsely surveyed.

A SeaBeam 3012 multibeam echo sounder was used for the bathymetric survey. The Micro-G LaCoste and Romberg S-116 shipboard gravity meter, a Geometrics G-882 cesium towing magnetometer, and a Tierra Tecnica SFG1214 shipboard three-component magnetometer were used for the gravity and magnetic surveys, respectively. Unfortunately, dredge rock sampling and seismic reflection survey was not conducted.

The seamounts are located on the Antarctic Plate. The mid-ocean ridge (Chile Ridge) was considered to be already subducted beneath the South American Plate. Magnetic Anomaly 6a was identified by Cande et al. (1982) on the seafloor in the vicinity of the seamounts. The crustal age around the seamounts is 18 Ma according to Muller et al. (2008). We observed magnetic anomaly stripes with amplitudes of about 400 nT, therefore, we will examine the crustal age and the seafloor spreading rate.

Since the seafloor was covered with a sedimentary layer, abyssal hills and their strikes could not be identified. The largest seamount was located at 51˚00'S, 79˚25'W. The seamount has a major axis of about 17 km, a minor axis of 10 km, and the strike of the major axis is N45˚W. The water depth of the base of the seamount is about 3900 m and the shallowest depth is about 2900 m, thus the relative height is about 1000 m. The seamount was surrounded by a moat with the maximum deep of 100 m. The basal area is about 160 square kilometers and the volume above the seafloor is about 70 cubic kilometers. The seamounts have calderas, and the depth and the diameter of the largest seamount are 200 m and 2.5 km, respectively.

The existence of the largest seamount was estimated by satellite altimetry and gravity observations. The relative height was estimated to be 364 m (Kim and Wessel (2011) seamount catalogue, ID: KW-05846). However, the accurate estimation of such a small seamount is difficult. We observed free-air gravity anomaly of about +20 mGal at the base of the seamount, and of about +50 mGal over the top of the seamount, thus the peak-to-trough amplitude of the gravity anomaly was 30 mGal. The gravity anomaly due to the seamount with 20 mGal larger amplitude was observed compared with a satellite-based gravity anomaly (Sandwell et al., 2014).

Surface-ship gravimetry on board MR16-09 Cruise by R/V MIRAI - Characteristrics of gravity anomaly around the Chile Triple Junction

*Takeshi Matsumoto[1], Takanori Ishihara[1]

1. Faculty of Science, University of the Ryukyus

MR16-09 cruise by R/V MIRAI traversed the Southeast Pacific and the Western Pacific from December 2016 to March 2017, with the portcall at Fiji, Chile, New Zealand and Mutsu. Gravity measurement was also carried out during the whole cruise except for within the EEZ of other countries.
During Leg2 of this cruise, the Segment SCR1 of the Chile Ridge, an active spreading ridge producing the Nazca plate and the Antarctica plate, was also surveyed in order to detect the characteristics of the gravity anomaly due to the subduction of the active mid-oceanic ridge below the South American Plate at the Chile Trench at the Chile Triple Junction (CTJ) located off Taitao Peninsula on the west coast of Chile.
The shipboard gravimeter used for the survey was a relative measurement system. Micro-g LaCoste air-sea gravity meter S-116 is equipped on board MIRAI. Normally, ‘gravity tie’ is carried out during the portcall at the wharf and the gravity base stations nearby where absolute value of gravity is known in order to obtain the absolute gravity value during the cruise. However, it was difficult to obtain accurate values after correcting the drift of the gravimeter because gravity tie was carried out only at 3 stations at the beginning (Shimizu), at the end (Sekinehama) and during the cruise (Punta Arenas). Therefore, correction of the value at the gravity measurement points on the survey lines was carried out using the latest global gravity 1’ grid data (Sandwell et al., 2014, Sandwell et al., 2013, Sandwell et al., 2009) derived from satellite altimetry data etc.

Let the grid intervals in the x and y directions of the grid data be dx and dy, respectively. Let g11, g21, g12, g22 be the gravitational values at the four corner points of this area (approximated by a rectangle) enclosed by x1, x2 (x1 < x2) for x-coordinate and y1, y2 (y1 > y2) for y-coordinate. The linearly interpolated value at the point (x, y) within this the area is

g1 = g11 * (x2 - x) * (y1 - y)

g2 = g21 * (x - x1) * (y1 - y)

g3 = g12 * (x2 - x) * (y - y2)

g4 = g22 * (x - x1) * (y - y2)

Then,

g = (g1 + g2 + g3 + g4) / (dx * dy).

Based on the difference between the gravity values obtained by this interpolation and the measured values, the drift rate at each leg was determined as,

Leg 1: 0.216 mgal/day

Leg 2: 0.520 mgal/day

©2019. Japan Geoscience Union. All Right Reserved.

Leg 3: -0.599 mgal/day

Leg 4: 0.562 mgal/day.

The measured gravity was corrected using these drift rates to obtain the final free air anomalies during the cruise.

Bouguer anomaly along the 3 survey lines on the Segment SCR1 (including the CTJ) of the Chile Ridge off the Chilean west coast was obtained by the two-dimensional calculation (assuming that the same seafloor topography and sub-seafloor structure are continuous along the trench/ridge axis direction) by use of the profiles of free air anomaly and seafloor topography along these survey lines. Regardless of the topographic undulation on the western side of the ridge/trench, the Bouguer anomaly decreased relatively uniformly towards the trench/ridge axis. This pattern is similar to that of the normal trenches and mid-ocean ridges. The rate of decrease as approaching the trench is about 1.5~2 mgal/km in the Western Pacific trench, <0.1 mgal/km for the Mid-Atlantic Ridge. However, the result of the current gravity survey shows that the decrease rate is 0.4~0.8 mgal/km.

In addition, geophysical traverses across the Tonga-Kermadec arc-trench, the southern East Pacific Rise (Leg1), the Bellingshausen Sea, the Amundsen Sea, the Eltanin-Udintzev fracture zones (Leg3), the South Fiji Basin, the Solomon arc-trench, and the West Caroline Plateau were obtained during the cruise.

Faculty of Science, Yamagata University, 5. Priority Organization for Innovation and Excellence, Kumamoto University, 6. Faculty of Science, Kyoto University

The Afar area (Ethiopia) is well known as one of continental rifts transitioning to oceanic spreading centers. In order to delineate subsurface electric properties and document an initial stage of the formation process of magnetic stripes, we carried out wideband magnetotelluric (MT) measurements and ground magnetic survey along a common profile in 2016 and 2017. This profile, approximately 55km long, cuts across the Dabbahu rift in the Afar Depression. In magnetic survey on foot, we recorded total magnetic fields at 2.4 meters above the ground every 4 seconds by utilizing GSM-19 Overhauser magnetometer (GEM systems). In MT survey, we obtained electromagnetic and electric data at 14 sites using MTU-5A (Phoenix Geophysics) and ELOG1K-PHX (NT system design) systems. In this presentation, we will introduce the outline of our project and show results of magnetic and MT surveys.

Evolution of oceanic core complexes in the Shikoku Basin: when backarc basins cease to open

*Kyoko Okino[1], Yasuhiko Ohara[2,3], Masakazu Fujii[4], Tomoko Hanyu[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Japan Coast Guard, 3. Japan Agency for Marine-Earth Science and Technology, 4. National Institute of Polar Research

How and why backarc basins cease to open is one of the unsolved questions in plate tectonics. The Shikoku Basin is a typical backarc basin, that was formed behind the proto Izu-Bonin arc and stopped opening at ca.15 Ma. The post-spreading volcanism has formed a series of seamounts along the remnant spreading axis in the northern basin, whereas multiple oceanic core complexes have developed just before the spreading stop in the southern basin. Oceanic core complexes (OCC) are exposed lower crust and/or upper mantle materials along detachment faults, that are supposed to develop when melt supply rate M (=magmatic accommodation / plate separation) is around 0.5. The OCC is, therefore, a good indicator for temporal variation of melt supply when the backarc system died. During Yokosuka YK18-07 and Hakuho-maru KH-18-02 cruises in 2018 summer, we conducted the geophysical mapping (multibeam bathymetry, scalar and vector magnetics, and gravity) of an OCC at 23°50’ N, 138°50’ E in the southernmost Shikoku Basin and its adjusting areas. The OCC is tentatively named Mado Megamullion. We compiled these new datasets and previously collected data and analyzed detailed bathymetry and magnetic and gravity anomalies. In this presentation, we show the results and discuss the structure and evolutionary process of this OCC and its implications for demise of backarc opening system.

The Mado Megamulliion is about 20 km square domed high, located at the intersection of remnant ridge segment and transform fault. Its surface is characterized prominent corrugations parallel to flow lines. The mantle Bouguer anomaly is about 20mGal higher than the surroundings. This observation is consistent with the fact that high-density gabbro and peridotite samples were recovered both by Shinkai6500 dive in YK18-07 and dredge hauls in KH-18-02. A part of recovered rock samples show the deformation structure, suggesting that the surface of this OCC is a detachment fault surface. Magnetic anomaly distribution shows generally linear, positive and negative bands over the OCC as same as in the well-ordered abyssal hill area, suggesting continuous crust formation from ridge segments. The widths of lineations are, however, longer at the OCC, indicating clear asymmetric spreading during detachment faulting. The spreading asymmetry is often observed over world OCC areas. The equivalent magnetization value seems to be positively shifted, that may suggest the effect of induced magnetization of OCC massif. The result of vector magnetic field analysis shows clear, strong and ridge-parallel magnetic boundaries in well-ordered abyssal hill areas, that is consistent with normal seafloor spreading and block model. In contrast, the clear, systematic magnetic boundaries don’t exist. The estimated three dimensionality is not so strong. Within the rift valley south of the Mado Megamullion, a small domed high with high Bouguer anomaly exists. This is likely NTO (non-transform offset) massif, previously reported along mid-ocean ridges. Another corrugated surface is observed at neighboring segment, that shows typical detachment surface morphology but are not accompanied by gravity anomalies.
The structure and evolutionary process of the Mado Megamullion and the adjacent OCC-like massifs infer the temporal variation of melt supply on the final stage of backarc opening. Multiple core complexes including world largest Godzilla Megamullion are distributed along the Parece Vela Rift, south of the study area. The integrated analysis of these OCCs is a key to understand the demise of backarc systems.

Thermal evolution of the Lanzo orogenic peridotite massif in western Alps: implications on thermal structure near subcontinental lithosphere-asthenosphere boundary

*Tomo Aoki[1], Kazuhito Ozawa[1], Jean-Louis Bodinier[3], Françoise Boudier[2]

1. The University of Tokyo, 2. Montpellier 2 University, 3. Geosciences Montpellier

Lithosphere-asthenosphere boundary (LAB) is a zone where heat, momentum, and materials are exchanged between conductive mantle and underlying convective mantle, and plays an important role in plate tectonics (McKenzie & Priestley, 2005; Fischer et al., 2010; Kawakatsu & Utada, 2017). Its internal structure and dynamic behavior are, however, far from understood. This study addresses this issue on the basis of petrological study of an orogenic peridotite complex. Lanzo massif in the western Alps, Northern Italy. We attempt to clarify temporal change of internal thermal structure of the complex during exhumation, from which the original thermal structures before exhumation may be estimated.
Lanzo massif is one of the largest mantle exposure thought to be a subcontinental lithospheric mantle exhumed related to the opening of the Jurassic Piedmont Sea between European continent and Adriatic continent, following slow spreading of the Atlantic mid ocean ridge (Müntener & Piccardo, 2003). The massif consists dominantly of plagioclase-bearing lherzolite, stable at the pressure lower than 1GPa, with subordinate amount of mafic rocks occurring as layers or dikes (Bodinier, 1988; Bodinier et al., 1991). The Lanzo massif divided into three bodies on the basis of petrographic characteristics: north, central and south. Previous studies argued that the northern part represents subcontinental lithospheric mantle and that the southern part may be of asthenospher origin (Bodinier, 1988; Bodinier et al. 1991). Therefore, the complex may represent a zone of lithosphere-asthenosphere boundary and can provide information on processes operated there (Bodinier, 1988; Bodinier et al., 1991; Kaczmarek & Müntener, 2008).
We examined plagioclase-bearing lherzolite collected from 16 localities covering the entire massif. Systematic variations of microstructures and mineral chemical compositions were confirmed, which is principally consistent with previous studies (Bodinier, 1988; Bodinier et al., 1991). All constituent minerals show chemical heterogeneity on grain scales, which is regarded as record of various processes the rocks underwent. Grain-scale zonings of Al and Ca in pyroxene, fluorescence-corrected Ca in olivine adjacent to pyroxenes, Cr and Al in spinel adjacent to plagioclase, and Ca and Na in plagioclase suggest that monotonous cooling and decompression accompanied by deformation occurred during decompression of the Lanzo massif. We quantified the space-dependent thermal history of Lanzo by using Ca-in-orthopyroxene geothermometer after Lindsley (1983) and Ca-in-olivine geothermometers calibrated on the basis of experimental results of Köhler & Brey (1990). All the estimated temperatures decrease from the southern body towards the northern body. The calculated temperatures were critically examined if they represent closure temperatures or a condition at which Lanzo resided for a certain period of time. The grain-scale zoning patterns indicate that the temperatures from core of orthopyroxene recorded a long residence, whereas those from rim of pyroxenes and both core and rim of olivine represent closure temperatures (Tc) at various timings during monotonous cooling. The decrease in temperatures of pyroxene cores from the south to the north by ~60K may represent a geotherm near LAB zone. All the Tc decrease from the north to the south and the difference of temperatures between the core and rim of orthopyroxene increases from the southern body to the northern body. This suggests that the cooler and probably shallower northern body cooled at slower rate at a wide temperature range (Tc=700-1100˚C) than the hotter and probably deeper southern body. A thermal gradient recorded in the Lanzo massif is estimated to be ~6K/km, which is greater than those estimated for deep subcontinental

lithosphere at steady thermal state (Mckenzie et al., 2005). We speculate that the high geotherm might have caused by thermal perturbation from asthenosphere.

Keywords: lithosphere-asthenosphere boundary, mantle peridotite, thermal structure

Comparison of the back-arc basins of the South and the Central Ryukyus in the northwest Pacific

*Kohsaku Arai[1], Ayanori Misawa[1], Takahiko Inoue[1]

1. Institute of Geology and Geoinformation, National Institute of Advanced Industrial and Technology

The Ryukyu Arc, which extend for over 1200 km along the east coast of Asia from Kyushu to Taiwan, and the associated Ryukyu Trench, are products of the subduction of the Philippine Sea Plate (PSP) beneath the Eurasian Plate. The PSP is subducting northwestward beneath the Eurasian Plate at a convergence rate of 4–9 cm/yr (Seno et al., 1993). The major islands of the Ryukyu Arc are considered the forearc highs.
The Okinawa Trough is a back-arc basin located beside of the Ryukyu Arc that was formed in the late Miocene (Gungor et al., 2012) or the late Pliocene–early Pleistocene (Sibuet et al., 1998). Formation of the Okinawa Trough was a key geological event associated with complex tectonics and changes in the topographic configuration of the Ryukyu Arc. Geological Survey of Japan (GSJ), AIST has started the marine geological mapping project around Ryukyu Arc since the 2008 FY. Multi-channel (16 ch or 32 ch) high-resolution seismic profiles were acquired during these cruises by the GI-gun (355cu. inch) systems. In our investigation into the deformation of the Ryukyu Arc using the high-density seismic profiles, we found that the normal faults parallel to the trench axis are well developed on the back-arc side of the arc. Slope of northern off the Southern Ryukyu (Miyako-jima and Ishigaki-jima) is simply downthrown to the axis of Okinawa Trough and reach to 2000 m in depth. In the other hand, the Central Ryukyu, northwestern off the Okinawa-jima is characterized by the small basin structure which accompanies with active normal faults. The faults show ENE-WSW strike and dip to the north with clear half graben structure. We present the tectonics of these structure compare the back-arc basins of the South Ryukyu with the Central Ryukyu.

Geochemistry and zircon U-Pb ages of mafic rocks in the Mikabu and Sorachi-Yezo belts: Comparison with the Shatsky Rise

*Naoto Kimura[1], Yuji Ichiyama[1], Shohei Takahashi[1], Hisatoshi Ito[2], Akihiro Tamura[3], Tomoaki Morishita[3]

1. Chiba University, 2. Central Research Institute of Electric Power Industry, 3. Kanazawa University

Large igneous provinces (LIPs) are large volcanic edifices on the Earth, such as oceanic plateaus and continental traps. It is commonly believed that LIPs are formed by large-scale magmatism caused by the upwelling of unusually hot mantle plume from the deep mantle (e.g., Coffin and Eldholm, 1994). Therefore, the genesis and formation mechanisms of LIPs is crucial to understand the dynamics of the Earth’s interior and episodic global events. Recent studies have revealed that the fragments of accreted oceanic plateaus are preserved in orogenic belts as ophiolites and accretionary complexes (e.g., Kerr et al., 2000; Ichiyama et al., 2014). The investigation of accreted oceanic plateaus will help to enhance our understanding of LIPs.

The Mikabu belt in SW Japan and Sorachi-Yezo belt in central Hokkaido, North Japan contain large accreted fragments of a paleo-oceanic plateau (Kimura et al., 1994). Recently, Ichiyama et al. (2014) proposed that the Mikabu and Sorachi-Yezo picrites with highly magnesian olivine phenocrysts (up to Fo_{94}) were produced by an unusually hot mantle plume. They also suggested that these picrites are derived from the Late Jurassic oceanic plateau (hereafter named “Mikabu-Sorachi plateau”) formed on the Izanagi plate, which was possibly produced together with the Shatsky Rise at the Pacific-Izanagi-Farallon triple junction in the Pacific Ocean. However, the geochronological and geochemical comparison between the Mikabu-Sorachi and Shatsky Rise has been poorly constrained.

The Mikabu and Sorachi-Yezo mafic rocks are geochemically divided into depleted (D)-type and enriched (E)-type in the same manner as the picrites. The D-type is depleted in light rare earth elements (LREE), whereas the E-type is relatively enriched in LREE. These types were produced by higher degrees of partial melting (30-50%) than MORB. The U-Pb zircon analyses of gabbroic rocks in both belts yield the weighted mean $^{206}Pb/^{238}U$ zircon ages of 153.1-146.3 Ma for the Mikabu rocks and 146.2 and 137.6 Ma for the Sorachi-Yezo rocks.

A wide geochemical variety of basalts were recovered from the Shatsky Rise during the IODP Expedition 324 (Expedition 324 Scientists, 2010; Sano et al., 2012). The U1349-type and Normal-type basalts of the Shatsky Rise are closely similar in geochemical composition to the Mikabu-Sorachi D-type and E-type rocks, respectively. The radiometric ages of the Shastky Rise basalts show 144.6-133.9 Ma (Mahoney et al., 2005; Geldmacher et al., 2014). The magnetic anomaly lineations of the Shatsky Rise exhibit that the formation of the rise started at M21 (about 147 Ma). The zircon U-Pb ages of the Mikabu-Sorachi mafic rocks are almost coeval with the formation ages of the Shatsky Rise. However, the older radiometric ages than 147 Ma are shown in this study. Recently, Sawada et al. (2019) also report the zircon U-Pb age of 154.6 Ma for the Mikabu metabasite from the Toba area.

The magnetic anomaly lineation of M29 (about 157 Ma) drawn at the southwest of the Shatsky Rise implies that the triple junction was already present at 157 Ma. The Mikabu-Sorachi plateau was produced on the Izanagi plate before the Shatsky Rise at the triple junction. The igneous rocks in the Mikabu-Sorachi belt possibly record the information on initiation mechanisms of the triple junction and

Submersible magnetics reveals relationship between off-axis volcanism and hydrothermal systems of the Kairei and Yokoniwa fields at the Central Indian Ridge

*Masakazu Fujii[1], Kyoko Okino[2]

1. National Institute of Polar Research and SOKENDAI, 2. Atmosphere and Ocean Research Institute, The University of Tokyo

The Kairei (KHF) and Yokoniwa hydrothermal fields (YHF)are hosted in mafic as well as ultramafic rocks distributed at an off-axis volcanic knoll of the Central Indian Ridge. Despite intensive investigations, their geological and geophysical background is still debated. Here, we show the results of near-seafloor magnetic anomaly surveys conducted using a submersible. We investigated the bulk magnetization of the hydrothermally altered zone and the surrounding lava flows and evaluated their intensities compared with previously reported values at axial areas of seafloor spreading environments. The KHF is characterized by low coherence between observed and modeled anomalies and low values of magnetization. This result suggests that magnetic minerals within basaltic lava flows were likely altered by hydrothermal fluid circulation. The variation pattern in the observed magnetic anomalies above the lava flows is in phase with that of the modeled magnetic anomalies for the simple assumption that the magnetization direction is parallel to the geomagnetic field. This result suggests that these lava flows preserve normal magnetic polarity corresponding to the Brunhes Chron. The estimated magnetic-anomaly-derived absolute magnetizations (MADAM) show a reasonable correlation with the natural remanent magnetizations of rock samples collected from the seafloor of the same region; their relationship is consistent with previously reported datasets from the Mariana Trough and Mid-Atlantic Ridge. The estimated MADAM intensity reaches 20 A/m in the study area, which is clearly greater than those of previously reported off-axis areas, suggesting that recent volcanic eruption may have occurred in these off-axis areas. The high magnetization distributions are commonly observed at the bottoms of the western slope from the KHF and YHF. This finding provides new insight into the distribution of highly magnetized lava flows in the off-axis areas and indicates the distribution of recent off-axis volcanic activities, which is potentially linked to the sub-seafloor hydrothermal circulation.

Shipboard magnetic and gravity surveys around the Iheya North Knoll and the Iheya Minor Ridge in the Mid-Okinawa Trough: Preliminary results of KR18-14 Leg1/Leg2 cruises

*Kazuya Kitada[1], Takafumi Kasaya[1], Hisanori Iwamoto[1], Yoshifumi Nogi[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Institute of Polar Research

The Okinawa Trough, an active back-arc basin behind the Ryukyu trench, exhibits active rifting associated with extension of the continental margin. In the Mid-Okinawa Trough, more than 10 hydrothermal vent sites belonging to relatively large hydrothermal vent fields at the Iheya North Knoll, the Iheya Minor Ridge, the Izena Hole and etc., were discovered by previous studies (e.g., Halbach et al., 1989; Sakai et al., 1990; Momma et al., 1996; Kasaya et al., 2015; Nakamura et al., 2015). Although shipboard magnetic and gravity surveys are too low in resolution to investigate the hydrothermal sites, they are important for understanding the geological background of the hydrothermal systems across an entire region. As for the area off Kumejima Island in the Okinawa Trough, Kitada et al. (2018) revealed the characteristics of the submarine volcanic activity around a hydrothermal area by using dense magnetic and gravity data. In order to characterize sub-seafloor structures and the spatial distribution of the submarine volcanic activity around the Iheya North Knoll and the Iheya Minor Ridge, we conducted detailed magnetic and gravity surveys with a line spacing of 0.5 nmi aboard research vessel Kairei during the KR18-14 Leg1 and Leg2 cruises from October to November 2018. Additionally, we also compiled magnetic, gravity and bathymetric data which were collected during previous cruises by the Japan Agency for Marine-Earth Science and Technology (JAMSTEC) over the recent years. Magnetization intensities were estimated from observed magnetic anomalies, without applying annihilator. Bouguer gravity anomalies were calculated from free-air anomalies obtained. The distribution of magnetization intensity and variation in Bouguer gravity anomalies revealed the characteristics of submarine volcanic activity. Most of the knolls in the area show a relatively high magnetization (~1.0 to ~3.0 A/M) corresponding to the individual submarine knolls. Higher Bouguer gravity anomalies (~45 to ~55 mgal) implying the lower crustal thickness were observed in the Iheya graben. The knolls including the Iheya Minor Ridge, elongated in the ENE-WSW direction parallel to the graben, exhibit the ENE-WSW trending magnetization distribution with relatively high positive intensities, so volcanism appears to be constrained by normal faults forming the rift structure. On the other hand, the Iheya North Knoll have a relatively low magnetization of ~-1.0 to ~0.0 A/M with less variation of the magnetization. Although the data are sparse (the line spacing of ~1.5 to ~2 nmi), low magnetization (~1.5 A/M) with no prominent magnetic signature was also observed in the Izena Hole. Moreover, these knolls are located on the area where the Bouguer gravity anomaly is changed from ~30 to ~10 mgal and ~45 to ~30 mgal, respectively. The magmatism associated with submarine volcanic activity and back-arc rifting will be discussed based on the results obtained from these dense surveys.

A shallow seabed drilling was performed in February 2019 at Higashi Ensei Hydrothermal Field, Northern Okinawa Trough (Cruise ID: KM19-E01). Two localities were selected to investigate natures of sub-seafloor lithology with and without self-potential anomaly (SP anomaly) measured by near-bottom AUV survey. Here such a SP anomaly is to be resulted from a sub-seafloor orebody consisted of mainly sulfides. A seabed drilling apparatus, BMS (Boring machine system, Cellula Robotics Ltd.), was deployed twice from R/V Kaimei. At the first drilling in the cruise, the drilled hole reached to a formation 44m beneath the seafloor but stopped there due to significant venting through the drilled hole. Volcaniclastics with and without sulfide blocks or veins were sampled even poor recovery in the shallow part of the hole. Contrasting to it, the second drilled hole reached to 10 m beneath the seafloor where intact mafic-intermediate lava flow, i.e. volcanic basement, was sampled. In the second hole, little sulfide were retrieved except orange-colored one, probably realgar associating with orpiment and stibnite, in the first core, shallower than 1.5mbsf. On board IP measurement both as well as standard MSCL and visual core description were performed for the cores from the first hole. Further, an ROV dive observation was conducted within 16.5 hours after the drilling of the first hole. An exotic white sediment was recognized in the vicinity of the hole, similarly to the IODP exp.331 at Iheya-North Knoll, and successfully sampled. In this presentation, retrieved drilled samples as well as those sampled by ROV will be reported.

Hiruzen Institute for Geology and Chronology, 8. Faculty of Science, University of the Ryukyus, 9. Japan Agency for Marine-Earth Science and Technology

Intense hydrothermal activity associated with sulfide mineralization had been observed in the Gondou field, which is located at the seafloor around a water depth of 1330-1470 mbsl (meters below the sea level) at the western flank of the Daisan-Kume Knoll (Minami and Ohara, 2017; Ishikawaet al., 2016). Scientific drilling was performed by J-MARES during the SIP Integrated Ocean Resource Surveying System JM17-04 Cruise from October to November, 2017. Sediment cores were obtained from 5 sites in Southern area of the Gondou field by drilling using BMS (Benthic Multi-coring System) installed on *Shincho-maru*. Mineralogy and geochemistry of the obtained cores were studied based on VCD (Visual Core Description), microscopic observation, XRD (X-ray diffractometer) analysis, and electron probe microanalyzer (EPMA) analysis.
Most part of the obtained sediment, except for the surface hemipelagic sediment within a few mbsf (meters below the seafloor), was hydrothermally altered intensely. Abundant occurrence of illite (or illite/smectite mixed-layer mineral) was observed, which is common signature among hydrothermal alteration in hydrothermal fields in the Okinawa Trough. Whereas, occurrence of chlorite was limitedly recognized within a layer of 5-15 m thickness in each site. Kaolin minerals were identified in altered pumiceous volcaniclastic sediment in two sites. These specific occurrences may reflect subseafloor fluid migration of distinctive chemistry, based on the idea that chlorite formation would be related to interaction with heated seater-derived fluid while kaolin minerals formation would be related to interaction with acidic fluid. Occurrence of sulfate minerals such as anhydrite and barite is also limited, which may provide another information about subseafloor fluid migration.

Acknowledgements
This study was conducted under the framework of the Next-Generation Technology for Ocean Resources Exploration Project, Cross-ministerial Strategic Innovation Promotion Program (SIP) funded by the Japanese cabinet office. The sediment cores used in this study were provided from J-MARES (Research and Development Partnership for Next Generation Technology of Marine Resources Survey).

New type of self-potential anomaly observed near a hydrothermal site of Oomuro-dashi volcano, Izu-Ogasawara arc

*Yoshifumi Kawada[1,2], Takafumi Kasaya[2]

1. International Research Institute of Disaster Science, Tohoku University, 2. Japan Agency for Marine-Earth Science and Technology

Using a deep-towed electrode array, we identified a pair of positive and negative self-potential anomalies observed near an active hydrothermal field associated with a quarterly rhyolitic volcano, Oomuro-dashi, Izu-Ogasawara arc. Results with different rowed directions, the magnitude of both anomalies is of the order of millivolt. The negative anomaly is located immediately above the most active area; the positive self-potential anomaly is located a few hundreds of meters away from the most active hydrothermal area, where no apparent hydrothermal activity has been detected. The discovery of the positive self-potential anomaly in marine environments is probably the first time.

The origin of the negative self-potential anomalies may be explained by the geo-battery mechanism (Sato and Mooney, 1960), in which the presence of a conductive ore body crossing the redox gradient results in the upward electron transfer to give a negative self-potential anomaly above the body. Oxidized materials near the seafloor are reduced. In other words, an ore body near the seafloor behaves as a cathode. We have reported negative self-potential anomalies many times above hydrothermal areas of other sites (e.g., Sato et al., 2017; Kawada and Kasaya, 2017, 2018).

The origin of this newly founded positive self-potential anomaly is problematic. One possibility is that an anode of the geo-battery, where reduced materials are oxidized, is exhumed near to the seafloor. If this is true, shallow drilling or piston coring may confirm signals from oxidized chemical reactions around an anode. This is important for the understanding of the geo-battery because its anode is usually located far below the seafloor and cannot be accessed easily. Another possibility is the streaming potential, which is caused by a local charge imbalance due to the flow of electrolytes in the pore space. Although this mechanism is estimated to be minor in marine environments, a positive self-potential anomaly of the order of one millivolt may not be immediately rejected above an area of upward fluid flow. However, the area of this positive self-potential anomaly is away from the active hydrothermal site, where upward fluid discharge is expected.

Numerical simulation of submarine hydrothermal ore-deposits due to a coupled process of fluid migration and reactive geochemical transport

*Claudia Fujita[1], Hajime Yamamoto[1], Jun-ichiro Ishibashi[2], Takeshi Tsuji[3]

1. Taisei Corporation, 2. Department of Earth and Planetary Sciences, Faculty of Science, Kyushu University, 3. Department of Earth Resources Engineering, Faculty of Science, Kyushu University

Submarine hydrothermal ore-deposits are known to be rich in metal resources and are to be found abundant around the Japanese islands. In recent years, several studies (mostly field surveys) had been carried out and a lot of data on chemical, physical and biological properties of compounds have been gathered especially for hydrothermal fields in the Okinawa Trough. However, the mechanism of formation (hydrothermal fluid flow in combination with geochemical reaction) of these deposits is not yet clearly understood.

Hydrothermal ore-deposits are formed by precipitation of metal elements from hydrothermal fluid due to rapid cooling around the seafloor where the fluid discharges. Contrary to the hydrothermal systems in the mid-ocean ridges, hydrothermal systems in the Okinawa Trough has a fluid discharge region at the seafloor in sediment-rich environment. The sediment is often composed of two components; one is hemipelagic sediment possibly transported from the continental margin and the other is volcaniclastic sediment derived from felsic volcanism in the vicinity. Because these two components have quite different permeability, it is expected complicated fluid migration within the discharge region.

In this study, we investigated the above process using a numerical code TOUGHREACT V3.0 –OMP, which is for coupled non-isothermal multiphase fluid flow and geochemical reactive transport. A 2-dimensional radial model with the radius of 5 km and a depth of 1 km below the seafloor was chosen to represent a sufficient area of the discharge region around the hydrothermal vent. The center of the radial model represented a fluid conduit (10 cm diameter) where the venting hydrothermal fluid of 300 ˚C ascends from basal to the seafloor, with a flow rate of ~1000 t/day. Almost all model parameters are chosen based on available results of geophysical survey of the Iheya hydrothermal fields in the Okinawa Trough[1)]. The geological structures were set as having diverse permeability from 1×10^{-10} m^2 to 1×10^{-16} m^2, which reflects alternating pumiceous volcaniclastics layer and hemipelagic sediment layer. The initial thermal gradient was set to 4.8 ˚C/100 m. The top boundary (seafloor) was set to constant pressure condition (20 MPa) and a basal heat flux was also imposed at the bottom (5.6×10^{6} W/m^2), assuming a pumice thermal conductivity of 0.96 W-m/˚C.

The geochemical setting included initial concentrations of primary species, as, for instance, Na^{+}, SO_4^{-2}, H_4SiO_4, Ca^{+2}, S^{-2}, Zn^{+2}, HCO_3^{-} or NH_3 for seawater and hydrothermal fluid separately. Chemical reaction including precipitation of minerals) caused by mixing of the both fluids and cooling was considered in this setting. In order to simulate accumulation of mineral precipitations to form hydrothermal deposits over a long-time duration (an order of thousands of years), the numerical simulation was conducted for 10000 years.

As a result, the following features were clarified: First, high velocity venting hydrothermal fluid ascends to the seafloor through the fluid conduit at the center of the model, whereas nearby cold water percolates downward from the seafloor and convection occurs. Second, among the alternating layer structure, preferential horizontal flow is obvious for layers with high permeability, which resulted in primary sulfide precipitation with a lateral extend.

These results are likely to be consistent to recent field studies during scientific drilling into the submarine

Mineral composition and grain size distribution of REY-rich mud in the Minamitorishima EEZ: Implication for formation process of extremely REY-rich mud

*Sakai Takumi[1], Erika Tanaka[1], Kazutaka Yasukawa[1,2], Junichiro Ohta[2,1], Koichiro Fujinaga[2,1], Kentaro Nakamura[1], Yasuhiro Kato[3,1,2]

1. Department of Systems Innovation, School of Engineering, University of Tokyo, 2. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology, 3. Frontier Research Center for Energy and Resources, School of Engineering, The University of Tokyo

In 2011, it was reported that deep-sea sediments containing high concentrations of rare-earth elements and yttrium (REY) are widely distributed in the Pacific Ocean, and can constitute a new mineral resource for the industrially critical elements [1]. Moreover, the “extremely REY-rich mud” containing more than 5,000 ppm of total REY (ΣREY) was discovered within the Japanese exclusive economic zome (EEZ) around Minamitorishima Island [2], and various researches to reveal a detailed spatial distribution of the extremely REY-rich mud has been carried out [3]. However, the formation mechanism(s) of the extremely REY-rich mud have not been completely elucidated yet.

Recently, based on multi-elemental compositions of 49 piston core samples collected from the Minamitorishima EEZ, it was confirmed that the deep-sea sediments in the area could be classified into nine sedimentary units based on characteristic chemical compositions [4]. This chemostratigraphy indicated that there are at least three “ΣREY peaks” containing 2,000 ppm of ΣREY in the Minamitorishima EEZ [4]. A previous study targeting the extremely REY-rich mud corresponding to the 1st ΣREY peak (i.e, the shallowest ΣREY peak in the chemostratigraphy) demonstrated that grain sizes of biogenic Ca-phosphate (BCP) and authigenic phillipsite were largest in the horizon with the maximum ΣREY concentration, based on analyses of mineral composition and grain size distribution [5]. However, whether this feature is common in all of the ΣREY peak units remains uncertain. In addition, no systematic investigation of relationships between each chemostratigraphic unit and mineral composition and grain size distribution has been carried out.

Here, we aimed to characterize each chemostratigraphic unit from the perspectives of the mineral composition and grain size distribution, and also to provide a constraint on the formation process of the extremely REY-rich mud. We selected 80 sediment samples from the 17 piston cores collected within the Minamitorishima EEZ to cover all units of the chemostratigraphy. The mineral composition was estimated by microscopic observation following the standard protocols of the International Ocean Discovery Program. The grain size distribution was measured by using laser diffraction spectroscopy. As the result, we revealed systematic variations in mineral composition and grain size distribution of each chemostratigraphic unit, and confirmed that grain sizes of BCP and phillipsite in all the ΣREY peak units were coarser (i.e., more enriched in silt- to sand-sized fractions) than other units. The increased sizes of BCP grains as a common feature of the ΣREY peaks imply that a grain-size sorting by enhanced bottom currents concentrated coarse BCP grains on the seafloor and contributed to the formation of extremely REY-rich mud for multiple times throughout the sedimentary history of the area.

Geochemical and morphological features of manganese micronodules in REY-rich mud within the Minamitorishima EEZ, western North Pacific Ocean

*Satoshi Kino[1], Kazutaka Yasukawa[1,2], Keishiro Azami[1], Erika Tanaka[1], Koichiro Fujinaga[2,1], Kentaro Nakamura[1], Yasuhiro Kato[1,2]

1. Department of Systems Innovation, School of Engineering, University of Tokyo, 2. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology

Manganese micronodules are small grains (< 1 mm) composed of manganese oxides, and constitute one of the important components of pelagic sediments. The micronodules show high contents of various heavy metals, especially of some redox-sensitive transition metals [1]. In addition to chemical compositions, the abundance and texture of micronodules can be affected by sedimentation rates and/or redox conditions of the sediment column [1, 2]. Therefore, the micronodules have been regarded as a useful indicator of the sedimentary environment.

Recently, deep-sea sediment extremely enriched in rare-earth elements and yttrium (REY) was discovered within the Japanese exclusive economic zone (EEZ) around Minamitorishima Island [3]. Previous studies reported that the extremely REY-rich mud contains significant amounts of biogenic calcium phosphate, which is a main host of REY, and phillipsite grains [3, 4]. In addition to them, manganese micronodules were also recognized in the sediment column, which were especially abundant in the extremely REY-rich layer [3, 4]. However, detailed features of the micronodules in the REY-rich mud within the Minamitorishima EEZ have not been investigated yet. Manganese micronodules in the REY-rich mud are about μm –mm ferromanganese oxides. Because their abundance and chemical compositions are considered to reflect respectively the sedimentation rate and redox conditions when they were buried [4], the micronodules can provide important constraints on the depositional environment of the REY-rich mud.

In this study, therefore, to characterize the manganese micronodules in the REY-rich mud within the Minamitorishima EEZ, we implemented (1) microscopic observations of the shape, surface texture, and relative abundance of the micronodules, and (2) bulk chemical analysis of them by using ICP-MS. We compared the geochemical features of the micronodules with those of macronodules both on the seafloor of the Minamitorishima EEZ, and also with those of macro- and micronodules in other areas.

The Minamitorishima micronodules are generally characterized by diagenetic features, although showing a compositional shift towards hydrogenetic features in some samples. Based on the integration of the observational and analytical results, we will discuss the possible changes in the sedimentary environment (e.g., sedimentation rates and redox conditions) involving the formation of the extremely REY-rich mud.

Seafloor sediment thickness around the Japan and Kurile trenches obtained by traveltime analysis for PS converted wave recoded by ocean bottom seismograms

*Ryosuke Azuma[1], Genti Toyokuni[1], Ryota Takagi[1], Syuichi Suzuki[1], Makiko Sato[1], Takashi NAKAYAMA[1], Naoki Uchida[1], Ryota Hino[1]

1. Recearch Center for Prediction of Earthquake and Volcanic Eruption, Graduate School of Science, Tohoku University

seafloor observation network for earthquake and tsunamis has been working in the Japan and Kurile trench subduction zones since 2016 (S-net, installed by National Research Institute for Earth Science and Disaster Resilience). The seismograms recorded by such the ocean bottom observatories are very useful for a precise hypocenter estimation. On the other hand, to obtain precise location results, it is also necessary to take suitable correction for traveltime delay due to the presence of the thick low-velocity sediments below sites, because the thickness of sediments differs with sites.

This study aims to estimate thickness of the sedimentary layer below the sites of the S-net and pop-up-type ocean bottom seismometers (OBSs). We then focused on traveltime difference between direct P-waves and PS waves converted at the sedimentary basement.

In the analysis, we first estimated a sensor direction based on gravitational acceleration and particle motions of teleseismic surface waves on accelerograms and then transformed components of velocity waveforms from XYZ to UD, NS and EW (Takagi et al., this meeting). Next, we picked PS arrivals on horizontal components of velocity records, for thirty of intraslab earthquakes observed at twenty of the S-net sites located on the outer slope of the Kurile and Japan trenches and the landward slope of the Kurile trench (off Nemuro). As a result, we obtained PS-P traveltime difference of ~1.4 s at the most of sites, ~1.6 s near the Japan and Kurile trenches junction, and 1.8 and 2.7 s on the lower and upper portions of the landward slope of the Kurile trench. Considering the standard deviation of PS-P of ~0.15 s at each site, our result suggests that PS-P traveltimes at the junction and other trench-outer region differs significantly while that variation between neighbor sites seems to be small.

The obtained PS-P traveltime differences for the outer-trench sites is consistent with those by seismic surveys (1.0–1.5 s, Kodaira et al., 2014; Fujie et al., 2016) and OBS observations (0.9–1.2 s, Hino et al., 2009) at the outer rise of the Japan trench. Therefore, picked PS arrivals on the S-net records in this study coincide with those by the previous studies. Assuming a Vp/Vs ratio of 8.0 and an average Vp of 2.0 km/s in the sediments estimated by the wide-angle seismic surveys (Kodaira et al., 2014; Fujie et al., 2016) at the Japan and Kurile trench-outer rise regions, sediments thickness below the S-net sites would be 350~400 m, which is also consistent with results of the seismic reflection section (Kodaira et al., 2014; Fujie et al., 2016). By further analysis for PS converted wave at the inner-trench sites of OBSs and S-net besides off Nemuro, we will investigate the distribution of thickness of the sedimentary layer in the forearc region of the east Japan.

Examination of critical taper theory based on bathymetry data in subduction zones

*Hiroaki Koge[1], Juichiro Ashi[1], Jin-Oh Park[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

The fold-and-thrust belts and submarine accretionary wedges lie along compressive plate boundaries. The critical taper model has been recognized to be the most appropriate theory that describes the first-order mechanics of these structures. Applying the critical taper model in the subduction zones, we can estimate the frictional coefficient of the plate boundary fault with only simple topographical parameters from the cross-section. Thus, this model has been also used in discussions related to earthquakes.
However, in the critical taper model, the following two problems could be pointed out when acquiring the topographic parameters. 1) It is impossible to apply the critical taper model to the area without seismic cross-section. 2) In the depth conversion in the seismic cross-section, the depth of the plate boundary fault largely depends on the velocity model and affects the estimation of the décollement dip angle β. Thus, it is unreliable in terms of accurate comparison. Therefore, when comparing the result with various velocity models, the reliability is low in terms of accurate comparison.
Therefore, in this research, we developed a new method to obtain the topographical parameters only from bathymetry data instead of the seismic cross-section. We verified the validity of the method from the results, with comparing the result from the décollement dip angle β obtained from the seismic cross-sections and the result from the trench seaward slope angle β obtained from the bathymetry. We check the validity of the new method using the Nankai Trough as the target area. In the Nankai Trough, many seismic cross-sections have been acquired for the disaster mitigation of the large earthquake, and the observation based on various methods such as seismic waves or GPS has proceeded. Thus, it should be easy for acquiring the topographical parameters and interpreting the result of the critical taper model.
We found the theoretical blind spot of the critical taper model in the condition of the subduction zone under the sea. When a high pore pressure ratio is assumed for the whole wedge, the effect of β on the result is very small for the effective friction coefficient. Therefore, it is sufficiently possible to discuss the frictional distribution of the plate boundary fault with only the bathymetry data. It is although necessary to pay attention to relatively large error up to about 20%. Since the bathymetry data is spatially densely acquired data, it was possible to calculate the friction distribution of the shallow plate boundary fault along the trench axis in the high density.
As a preliminary interpretation of the results with the bathymetrical critical taper model , this metho is considered to be effective to contribute to earthquake/tsunami disaster mitigation in sea areas where seismic activity segments are not sufficiently studied.

Active structures of the Sagami Bay Fault by high-resolution sub-bottom profiling and pin-point core sampling

*Juichiro Ashi[1], Asuka Yamaguchi[2], Natsumi Okutsu[1], Ayanori Misawa[3]

1. Graduate School of Frontier Sciences, The University of Tokyo, 2. Atmosphere and Ocean Research Institute, The University of Tokyo, 3. National Institute of Advanced Industrial Science and Technology

Seafloor knolls called the Okinoyama Bank Chain are aligned in the eastern slope of the NW trending Sagami Trough. Existence of the Sagami Tectonic Line is estimated at the slope base and interpreted as a tectonic boundary of a subdution zone (Kimura, 1973, Kagaku). Ohkochi (1990, Chigaku Zasshi) reported active faults and an anticlinal fold based on seismic profiles. An eastward dipping reflector is recognized at the southeastern extension of the Kozu-Matsuda Fault by onshore-offshore integrated seismic imaging and interpreted as a splay fault of the plate boundary fault (Sato et al., 2010, Annual Meeting abstract of the Geological Society of Japan). However, Deformation of shallow sediment recording recent activity has not been clarified. The purpose of this study is to reveal recent fault activity by high resolution subbottom survey and sediment sampling. We carried out deep towed subbottom survey and pinpoint sediment sampling by remotely operqated vehicle NSS in the southwest slope of the Misaki Knoll during the Hakuho-maru cruises KH-10-3, KH-11-9 and KH-16-5. NSS can take piston cores at pinpoint accuracy by four propeller thrusters, video cameras and a payload fuck. Deep towed subbottom survey can obtain high resolution subsurface structure by pinging 1.1 to 1.6 kHz chirp frequency and receiving near the seafloor. Subbottom profiles across the southwest slope base of the Miura Knoll show a reflector suggesting a fault plane at the scarp base. The reflector dips 30 degree to northeast. Although the hanging wall shows structureless, the foot wall exhibits horizontal reflectors or chaotic suggesting talus deposit. We successfully obtained a 6-meter-long core after confirming a dipping reflector of a possible fault plane. The upper 1.2 meters of the core sample consists of alternation of dark green silty mud and pebbly mud with shell fragments of Calyptogena fossils. Thin silt layers are intercalated with dark green clay at about 15 cm intervals. A 5-mm thick zone, which suggesting a fault plane and consists of silty mud and granule size clasts, is recognized at 2.25 m from the core top. This zone, dipping 30 degree toward north to east after paleomagnetic restoration, is interpreted to correspond to the reflector of the fault plane on subbottom profiles. We also present shallow subsurface structures around the Miura Knoll.

Fault Distribution and Structural Characteristic in the Nankai Trough Area, Japan

*Rei Arai[1], Narumi Takahashi[1], Minako Katsuyama[1], Shigeyoshi Tanaka[1], Hiromi Kamata[1], Tomoyuki Sato[2], Takahiko Inoue[2], Yoshiyuki Kaneda[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Institute of Advanced Industrial Science and Technology, 3. Kagawa University

As part of “The Comprehensive Evaluation of Offshore Fault Information Project” by the Ministry of Education, Culture, Sports, Science and Technology, JAMSTEC has conducted collecting marine seismic reflection/refraction data, bathymetric data, well data acquired within the Japan EEZ and surrounding areas, and assembling a database to serve data for future scientific research.

Data includes 1) seismic reflection/refraction data acquired by JAMSTEC, AIST(Japan Geological Survey), and Japan Coastal Guard for purposes of geological investigation and research, and 2) seismic reflection data acquired for purposes of oil and gas exploration by Ministry of Economy, Trade and Industry and Japanese oil companies.

Since 2D multichannel seismic reflection were acquired and processed according to survey standards of the early era to the recent, the original data were re-processed by applying the state-of-the-art data processing methods to obtain unified high-quality seismic profile which capable of interpreting subsurface structures and fault morphology. Within the Nankai Trough and the Izu-Ogasawara area more than 180,000 km of 2D single/multichannel data and 4,800 km^2 of 3D multichannel data was collected to set for geological interpretation.

To identify a fault which caused earthquakes in geological history, a seismic profile must show not only geomorphological feature but also subsurface displacement or flexure in sedimentary layers and bed rocks. In order to determine the fault surface and morphology, the same structure must exist on other successive profiles, and bathymetric data also helps to trace lineament caused by fault activities.
The Nankai Trough is a part of plate boundaries where the Philippine Sea Plate subducts beneath the overlying the Eurasian Plate, and seismic reflection/refraction studied have been conducted to reveal the structure of the plate boundary and to understand the mechanics of seismic hazards. This project allows to use widely acquired data from scientific purposes to economic purposes in the Nankai Trough area, and as a result, the preliminary fault distribution on the area has been mapped. Offshore of Hamamatsu, Shizuoka Pref., seismic reflection profile shows compressive structures of the two known fault zones, the Enshu fault system and the Kodaiba fault system, which extends to offshore of Shima, Mie pref. Seismic reflection profiles which cross the trough shows that the beneath the forearc basin deposits and the old accretional prism a seismic reflector that dips landward iles just above the oceanic crust. This reflector is known as the spray fault (e.g. Park et al., 2002) and can be traced in other profile, with length of more than 50km.Off the Shikoku island to Hyuganada, seismic reflection data show very complex structures such as subsiding of a seamounts and ridges or mud domes which form along faults.

Seismicity in the central Ryukyu Trench by the Ocean Bottom Seismometers

*Ren Yakabu[1], Mamoru Nakamura[1], Yusuke Yamashita[2], Masanao Shinohara[3], Tomoaki Yamada[3], Hajime Shiobara[3], Kimihiro Mochizuki[3]

1. University of the Ryukyus, 2. DPRI, Kyoto University, 3. ERI, Tokyo University

We investigated the seismicity in the central Ryukyu Trench from the island of Amami to Okinawa between January 2015 and September 2016. Five ocean-bottom seismometers (OBSs) and 20 short-period seismometers of the Japan Meteorological Agency (JMA) were used. We analyzed the events with JMA magnitude over 3.0, which occurred near the trench running from Amami to Okinawa. The P and S arrivals were selected using the WIN system.

Subsequently, we determined the hypocenters. To achieve this, we first revised the 1-D velocity structure model in this region. For the velocity structure in the island arc area, we calculated the 1-D velocity structure with the Joint Hypocenter Determination method using the software VELEST (Kissling et al., 1994). We implemented the original model (JMA2001) first, then we adopted the revised model for the calculation of the travel time to the JMA stations. For the velocity structure beneath the OBSs, we built the velocity model based on a refraction survey performed near Okinawa (Kodaira et al., 1996; Nishizawa et al., 2017). Subsequently, we selected the PS-P time differences at each OBS station and computed the sediment layer correction. Using these values, we adopted the hypocenter determination modifying the software hypomh.

In addition, we investigated the seismicity for the earthquake swarm that occurred near the trench axis from May to June 2016. The swarm began with a M 5.7 earthquake at 12:44 (JST) on May 27th, 2016. We identified the P-S time difference of the earthquakes which were recorded at the NS02 of the OBS station from April 1st to May 27th, 2016.

The relocated hypocenters were shallower compared to those in the JMA catalog by 20-30 km, on average. The change in the depth is larger (approximately 60 km) near the trench axis. The relocated epicenters changed slightly with respect to the JMA epicenters in almost area near the trench. However, the relocated epicenters in the south of Okinawa moved trench-ward compared with the JMA epicenters.

In the P-S time diagram of the period preceding the 2016 earthquake swarm, we identified events with short-duration of P-S times approximately 12 h before the start of the swarm. Although this would constitute a foreshock activity of the swarm, it had not been recorded by the JMA seismic network. This suggests that the earthquake swarm had a precursor activity.

Seismic structure of subducted Philippine Sea plate beneath Kyushu inferred from Po/So waves

*Azusa Shito[1]

1. Institute of Seismology and Volcanology, Kyushu University

Po/So waves are oceanic Pn/Sn phases that are characterized by their high-frequency (f>2.5 Hz) content, long-duration, and great travel distances (up to 3000km) through the oceanic lithosphere [e.g., Linehan, 1940; Walker, 1977, 1982]. In our previous study [Shito et al., 2013], we demonstrated that Po/So waves develop from the multiple forward scatterings of P and S waves in oceanic lithosphere due to the laminated small-scale heterogeneities. Shito et al. [2015] analyzed Po/So waves in the Philippine Sea Plate, which consists of three regions with different lithospheric ages. They found that Po/So waves propagate more effectively in older regions and demonstrated that the increase in propagation efficiency of Po/So waves depending on the age of the oceanic lithosphere can be qualitatively explained by thickening of the oceanic lithosphere including small-scale heterogeneities and a reduction in the intrinsic attenuation. This study showed that Po/So waves are powerful tool to explore structural variations of the oceanic lithosphere.

Recently, such structural variations (e.g., thickness) of the incoming oceanic lithosphere are supposed to affect seismic and volcanic activity of the subduction zone [Yamamoto et al., 2013; Shibata et al., 2014]. However, it is poorly known that such structural variations of the oceanic lithosphere remain or dissipate after the subduction. In this study, we investigate the structural variations of the subducted Philippine Sea plate by using Po/So waves. We analyze Po/So waves from the earthquakes (mb>3.0, depth>50 km) that occurred in the subducted Philippine Sea slab beneath Kyushu. We compare Po/So waves propagating through different portion of the subducted Philippine Sea Plate and discuss the relation between observed features (velocity and energy) of the Po/So waves and the structural variations of the Philippine Sea plate. We verify that Po/So waves trace deeper extension of Kyushu-Palau Ridge (KPR) that is subducting beneath the Hyuga-nada region.

Acknowledgments
The data analyzed in this study were obtained from Hi-net (NIED) stations in Kyushu. The source parameters of the earthquakes were provided by JMA. This work was supported by JSPS KAKENHI Grant Number JP18K03807.

Slope failure features and their distribution in the forearc off northwestern Sumatra

*Kenji Hirata[1], Toshiya Fujiwara[2], Ayanori Misawa[3], Kohsaku Arai[3]

1. National Research Institue for Earth Science and Diaster resilience, 2. Japan Agency for Marine-Earth Science and Technology, 3. National Institute of Advanced Industrial Science and Technology

In Feb. 2005 and Oct. 2009, we conducted multi-narrow beam bathymetric (MNB) surveys during NT05-02 cruise with R/V Natsushima (NT05-02 scientific party, scientific party,http://www.jamstec.go.jp/jamstec-e/sumatra/ natsushima/bm/contents.html)and KY09-09 cruise with R/V KAIYO (Hirata et al.,2012, JAMSTEC report), respectively. Apporox. 1 degree angular intervals of multi narrow beams with both the R/Vs makes us possible to retrieve detailed bathymetry with high resolution of ~35 meters in azimuthal direction for seafloor of ~2000 meters in water depth beneath ship tracks. Hirata et al. integrated these multi-narrow beam bathymetric data to construct detailed bathymetric data (grid data of ~37 meters interval for the surveyed area with ~50 km x ~100 km, surrounded by latitudes 3˚50’ N and 5˚00’ N, and longitudes 93˚10’ E and 94˚10’ E). In this study, we identify slope failure features in the forearc region off the northwestern Sumatra, and discuss its spatial distribution in terms of the geological processes.

To identify bathymetric features clearly, we make four kinds of maps as follows; slope angle map, slope angle change map, slope (direction) azimuth map, as well as plain bathymetric map. Slope angle is defined by arctangent of dz/ds, where z is the water depth and s is unit distance vector projected the steepest descending direction on horizontal plain. Slope angle change is defined by arctangent of second derivative of a unit distance vector s. Slope (direction) azimuth is defined by arctangent of dx/dy, where x and y are due east and due north components, respectively, of unit distance vector projected the steepest descending direction on horizontal plain. As a sample, we show figures consisting of slope angle map ((b) in Fig), slope angle change map (c), slope (direction) azimuth map (d) as well as plain bathymetric map (a) for a small rectangular region in the forearc off northwest Sumatra. We finally interpret such kinds of maps to identify slope failure features, etc (e).

We can identify the upper portion of slope failure structures with an elevation difference of about 1 km which bounded the western edge of the outer arc high, although we cannot retrieve bathymetry of the Sumatra Trench at ~ 4500 meters water depth because the multi-narrow beam survey systems can sounding up to less than 3000 meters. The slope failure structures are created by several to more than ten of successive landslides in the region shown in Fig. The landslide features show uneroded and sharp crowns, implying that the landslide features nearby the Sumatra Trench are created “recently” in geological time scale. Slope failure features with weak to strong rounded crowns come to appear as our sample point migrates landward. This can be explained from the formation process of the outer arc high off northwestern Sumatra ; thick, upper sedimentary layers in the top of subducting Indo-Australia plate that are stripped off at the toe of the forearc obduct onto the outer arc high so that accretional process proceeds (Mosher et al.,2008, Mar.Geol.; Misawa et al., 2014, EPSL).This means that landward (eastward) of the outer arc high is accreted older than its seaward (westward).

©2019. Japan Geoscience Union. All Right Reserved.

On the one hand, there are exceptions to such a geological rule; we can find several slope failure features with uneroded, sharp crowns in a landward region where many slope failure features with weak and strong rounded crowns exist (e.g., two slope failure structures with a width of ~ 1 km around a location of4° 06’ N, 93°39’ E). These relatively fresh failure structures existing landward of the outer arc high possibly relate to recent activation of major thrusts proposed in the outer arc high off northwest Sumatra (Hirata et al., 2010, AGU).

Origin and migration of fluid in the Sumatra subduction input: application of a geochronological method using a long-lived radioisotope of dissolved iodine

*Satoko Owari[1], Hitoshi Tomaru[1]

1. Chiba university

Iodine has a strong biophilic character and is highly enriched in organic matter in the marine environment. Organic matter is decomposed by thermogenic and microbial processes during the sedimentation and releases iodine into the interstitial water. Iodine has one stable isotope (^{127}I) and one long-lived radio isotope (^{129}I) with the half-life of 15.7 Myr. Therefore, the ^{129}I/^{127}I ratio of marine interstitial water has been used for identifying the origin of fluid. We applied iodine geochronology to the interstitial waters extracted from the deep drilling cores recovered by IODP Exp. 362, where Sumatra subduction input sediments develop more than 1400 m without major fractures. The concentration and isotopic ratio (^{129}I/^{127}I) of iodine dissolved in the interstitial water were analyzed in order to characterize the source and potential age of iodine prior to the subduction and examine the basic geological factors controlling the fluid migration in the input sediment body.

Concentrations of iodine and methane increase and TOC decreases toward 200 meters below seafloor (mbsf) and 1250 mbsf, which indicate degradation of organic matter around that depth and subsequent release of iodine and methane into the interstitial water. Iodine gradient is controlled by the degradation of iodine-rich organic matter microbially in shallow sediment (at 200 mbsf) and geothermally in deep sediment (at 1250 mbsf), respectively. The ^{129}I/^{127}I ratios between 0 and 400 mbsf vary between 300 $\times 10^{-15}$ and 800 $\times 10^{-15}$, and the lowest ratio of 300×10^{-15} is found at 175 mbsf. There are some thick sand layers > 60 meters between 0 and 400 mbsf. These porous layers transport allochthonous dissolved iodine and interstitial water, which are relatively old. However ^{129}I/^{127}I of 1300×10^{-15} at 67 mbsf corresponding to the sediment age of 3 Ma at 200 mbsf which is the zone of degradation of organic matter. ^{129}I/^{127}I between 400 to 1480 mbsf decrease from 700 $\times 10^{-15}$ to 400×10^{-15}, resulting from mixing with deep (old) iodine and shallow (young) iodine. In the input sediment, iodine gradient is strongly controlled by degradation of organic matter and the migration is controlled by vertical diffusion which indicates poor fluid migration or slow migration rate. However, the horizontal advection/migration of interstitial water is significant within the thick-porous sandy layers.

Challenge to Future Deep-Water Mapping: Unmanned Bathymetric Survey Competition "Shell Ocean Discovery XPRIZE"

*MASANAO SUMIYOSHI[1]

1. Hydrographic and Oceanographic Department, Japan Coast Guard

Unmanned survey technology is utilized in the world of bathymetric survey in the present age, when unmanned technologies are developing in various fields. Especially Autonomous Underwater Vehicle (AUV) is actively used in order to acquire high resolution bathymetric data in the deep waters. The technological innovation is needed to further advance the unmanned and automated deep-water mapping, including AUV operations of launch and retrieval. In order to encourage such innovation, an international competition of unmanned deep-water mapping, "Shell Ocean Discovery XPRIZE" has been held for 3 years.
The University of New Hampshire actively develops many hydrographic and oceanographic survey technologies that will open a new era, and as a part of these efforts GEBCO-NF Alumni Team challenges the international unmanned deep-water competition. The author has been strongly pushing the research and development of technology of bathymetric survey for this challenge as a member of this team, who was studying abroad to this university until 2017 to learn the latest hydrographic survey technologies.
This team had passed through Round 1 (semi-final: ~ 2000 m) held in November 2017, and challenged Round 2 (final: ~ 4000 m) as one of the finalists in the last November. In this paper, we report our efforts and achievements of the GEBCO-NF Alumni team, including those in Round 2.

Prototype of deep-sea ocean bottom pressure recorder with self-calibration capability using “A-0-A” approach for detection of long-term crustal deformation

*Yusaku Ohta[1], Ryota Hino[1], Syuichi Suzuki[1], Makiko Sato[1], Yui Nishimagi[1], Hiroaki Kajikawa[2], Tokihiko Kobata[2]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University, 2. National Metrology Institute of Japan, National Institute of Advanced Industrial Science and Technology

Ocean bottom pressure gauge (OBP) can continuously observe the vertical crustal deformation in the seafloor. However, a nature of long-term drift of pressure sensors causes a serious problem in detection of the long-term crustal deformation. A possible approach to remove the sensor drift on the sea-floor is to use a dead-weight tester as the pressure standard to make in-situ calibration on the seafloor by periodically switching between the ambient pressure and the reference pressure (Sasagawa et al. 2016). Recently, an alternative approach, an “A-0-A” method, using the internal pressure of the instrument housing as the reference pressure was proposed (e.g. Wilcock et al., 2018). We investigated the long-term drift behavior and ability of “A-0-A” method by a laboratory experiment using dead-weight tester as a pressure standard (e.g. Nishimagi et al. AGU fall meeting, 2018). We regard the reading at high applied pressure as ambient pressure point (“A”) and that at atmospheric pressure as zero-point (“0”). Although the residual time series between the “A” and “0”, however, showed small discrepancy, we found drift characteristics of “A” and “0” are basically similar to each other.

Based on these laboratory experiment results, we have started to develop a proto-type of ocean bottom pressure recorder with self-calibration capability using “A-0-A” approach for deep-water (up to 7,000 m) deployment. We install all the equipments including a pressure sensor in a 17-in glass sphere. To measure both of the internal and external (water) pressure by a single sensor, we adopt 3-way a ball valve controlled by an electric actuator in front of the sensor, as in the previous self-calibrating system using a dead-weight tester. The actuator is operated by the microcomputer to switch by arbitrary interval. We also install alternative barometer to compare the internal pressure value recorded by the pressure sensor. The development is still under way, and we will show more detail characteristic of the prototype system and its potential abilites.

Noise reduction and surface wave array dispersion measurements applied to NOMan's broadband OBS data

*Yuki Kawano[1], Takehi Isse[1], Hitoshi Kawakatsu[1], Akiko Takeo[1], Hajime Shiobara[1]

1. Earthquake Research Institute, The University of Tokyo

To achieve better performance of broadband ocean bottom seismometer (BBOBS) survey, we applied noise reduction analysis and dispersion measurements to the vertical component seismograms of the Normal Oceanic Mantle (NOMan) project arrays, which are previously analyzed by Takeo et al. (2018). Our noise reduction targets on the tilt noise that is significant for low-frequency (<0.1 Hz) BBOBS vertical records. Tilt noise is generated by the seafloor current which flows pass the BBOBS. It originally only dominates horizontal records, but the misalignment between the seismic sensor's vertical axis and gravitational direction allows projection of noisy horizontal tilt noise onto vertical records. Hence, vertical tilt noise can be estimated from the transfer function between horizontal and vertical records (Crawford and Webb, 2000). We developed a noise reduction method which is suitable for Japanese BBOBS based on the approach of Crawford and Webb (2000) and Bell et al. (2015). By performing noise reduction analysis, we achieved about 20 dB noise reduction at the frequency lower than 50 mHz and extracted lots of buried seismic signals. To verify the effect of noise reduction analysis, we compared array dispersion measurement results which derived from tilt noise removed and non-removed data. Using the method of Takeo et al. (2018), we measured average phase velocity and azimuthal anisotropy of fundamental mode Rayleigh waves to estimate isotropic and azimuthally anisotropic Vsv (βv) profiles. The results show that tilt noise removed data can provide us with more precise low-frequency measurements and the better-constrained structure at a depth of 80 km or deeper. Our results indicate that noise reduction preprocessing is important for improving Japanese BBOBS analysis.

High-tech dredge system for abyssal bedrock research; dredge system with acoustic real time monitoring on deep sea floor.

*Teruaki Ishii[1], Yukihiro - Kida[2], Izumi - Sakamoto[3], Shiki -- Machida[4]

1. Center for Integrated Research and Education of Natural Hazards, Sizuoka University, 2. JAMSTEC, 3. Toukai University, 4. Chiba Institute of Technology

It is very important to recover geological samples including hard rocks and soft materials from ocean floor to investigate bedrocks itself as well as sea floor environment on the basis of the material scientific aspects. Dredge haul methods being a simple and easy way with low costs, have been widely used for recovering the bedrocks. One of author (TI) has been working on the dredge hauls during about 40 years on the several Japanese and American Research Vessels (R/Vs), that is, R/V Tansei Maru, R/V Hakuho Maru, R/V Yokosuka, and R/V Kairei as well as R/V Atlantis-II, R/V Melville (2 times), R/V Moana Wave, and R/V Thomas Thompson, respectively. He has been proposing the (1) ORI-TI type dredge system, which has been improved and still improving on the basis of the better ideas gathered from the above mentioned all cruises. The dredge systems in the US Research Vessels have been continuing the conventional and basic technical methods, that is, box type chin-bag dredge (within or without fishing net) and using tension-meter as well as pinger.

On the other hand, Japanese scientists have been recently improving the traditional dredge systems with active introduction of high technique, for example, (2) transponder system and/or (3) deep sea TV camera system during dredge hauls. (4) new underwater acoustic transmission system of real-time TV-image.

(1)ORI-TI (Ocean Research Institute T. Ishii) type dredge system is composed of box type chain-bag dredge with steel bucket which can recover any sea bottom material including hard rocks as well as sand, mud and organisms(Ishii, 2017).

(2)Acoustic transponder attached on the dredge wire can mention real-time position of the dredge system on monitor showing pre-surveyed bathymetric map in the navigation room, This system helps safe and reliable rock sampling (Machida et al, 2011).

(3) Box-cage type dredge with installed deep sea TV camera system can record occurrence of bed rocks during dredge hauls (Sakamoto et al, 2017).

(4) New underwater acoustic transmission system of real-time TV -image with every 2 second from Shinkai 6500 to R/V Yokosuka put to practical use (Sakurai, 2018) on the basis of the new underwater acoustic communication system (Kida et al, 2018). If we can get low price (about USD$10,000) above mentioned system in a near future, it will be applied to the dredge hauls with real-time monitor on the sea bottom. The author (T.I.) assumes that its application fields are very wide; piston core, mooring system, ocean bottom seismometer, net fishing etc.

Construction of Database System on Offshore Faults around Japan

*Hiromi Kamata[1], Narumi Takahashi[1,2], Shigeyoshi Tanaka[1], Rei Arai[1], Minako Katsuyama[1], Ayako Nakanishi[1], Hiroyuki Fujiwara[2], Tsuneo Ohsumi[2], Takahiko Inoue[3], Tomoyuki Sato[3], Yoshiyuki Kaneda[4]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Research Institute for Earth Science and Disaster Resilience, 3. National Institute of Advanced Industrial Science and Technology, 4. Kagawa University

JAMSTEC has performed the project for “Comprehensive Evaluation of Offshore Fault Information” sponsored by the Ministry of Education, Culture, Sports, Science and Technology (MEXT) since FY2013. The project consists of three themes named “Sub-theme 1” gathering various kinds of existing geological/geophysical information and constructing offshore fault database system (DB), “Sub-theme 2” re-processing seismic data and interpreting offshore faults based on unified evaluation standard, and “Sub-theme 3” building offshore fault models conducted by NIED.

In Sub-theme 1, JAMSTEC has obtained or borrowed huge volumes of multi-channel seismic (MCS)/single-channel seismic (SCS) reflection data and ocean bottom seismometer (OBS) refraction data surveyed around Japan from various organizations including national research institutes and private enterprises, and has collected seismic velocity information, bathymetry data etc. After the quality check of these data, they are made into a database and unitary management of them are carried out. The final output of Sub-theme 1 is an offshore fault DB comprising the data sets of collected/re-processed seismic data and overall offshore fault information provided by Sub-theme 2 and Sub-theme 3. In Sub-theme 2, the past old-fashioned MCS data have been re-processed applying the latest sophisticated technology with de-multiple filtering and noise suppression for obtaining the high resolution profile of these seismic sections. Using the MCS/SCS data, offshore faults around Japan have been identified based on unified evaluation standard. Some geological horizons and a plate boundary have been also interpreted to model subsurface geometry and 3D velocity structure. The final output of Sub-theme 2 is to delineate the spatial distribution and continuity of identified faults on the high resolution bathymetric map such as a red relief image map, and to organize their features/parameters such as type, length, dipping direction, extension etc. after the seismic time–depth conversion using 3D velocity structure model. The 3D velocity structure has been modeled using collected OBS refraction data, velocity analysis results in MCS re-processing and some available published data. In Sub-theme 3, NIED has built the offshore fault models based on a fault information catalog completed by Sub-theme 2. The model validation for historical earthquake source faults with the magnitude over seven has been also conducted through ground motion and tsunami simulations.

This poster presentation focuses on the offshore fault DB constructed by Sub-theme 1 of the project. JAMSTEC has finished the clarification of faults in the Sea of Japan, and around the sea area of the Nansei Islands and Izu-Ogasawara Islands by FY2017. We are currently working on the interpretation of subsurface structure and fault distribution in the Nankai Trough area, and continue to register MCS/SCS reflection time/depth sectional figures, 3D velocity models, NIED’s fault models and their parameters into the DB sequentially. The trial operation of the DB has been also done at the subcommittee of the Headquarters for Earthquake Research Promotion of MEXT. The DB is highly expected to become a useful tool that contribute to tsunami hazard evaluation and disaster management conducted by Japanese government and local authorities, and that improve the public awareness against disaster prevention.

An integration method for multiple sets of seafloor backscatter intensity data

*Shiki Machida[1,2], Taichi Sato[3], Kazutaka Yasukawa[2]

1. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology, 2. University of Tokyo, 3. AIST

Acoustic backscattering of the seafloor is thought to provide a useful signal representing the existence of hard materials, such as lava flows with ferromanganese crust along the slope of seamount or knoll [1, 2], and ferromanganese nodules on the seafloor [3]. Previous investigations using vessel-equipped multi-narrow beam echo sounder (MBES) [1–3] identified variations of distributions over an area of tens or hundreds of square kilometres. Therefore, vessel-equipped MBES can provide a more economical exploration for vast areas than that provided by underwater apparatuses such as a deep-towed side scan sonar. However, a disadvantage inhibiting its use is that the different physical and technical parameters, such as sounder characteristics, observation period, and processing, yield different absolute values of backscatter intensity for the same area. As a solution, we propose a generally applicable method for obtaining the widespread distribution of deep-sea solid materials using a combination of several datasets of vessel-equipped MBES.

The Japanese exclusively economic zone (EEZ) around Minamitorishima Island in the western North Pacific is the best candidate area in which to analyse vessel-equipped multibeam backscatter data. This is due to the fact that several research cruises, operated by the Japan Agency for Marine-Earth Science and Technology (JAMSTEC), have obtained multiple sets of backscatter data, combined with bathymetry mapping. These data were obtained with an identical MBES (SeaBeam 3012. multibeam system) for each of the four cruises of *R/V Mirai*(MR14-E02, MR15-E01 Legs 2 and 3, and MR15-02) in 2014 and 2015, and with the other MBES (SeaBeam 2112.004 multibeam system) during a cruise of *R/V Yokosuka* (YK10-05) in 2010.

We identified two important components for successfully integrating several sets of backscatter intensity data collected by vessel-equipped MBES, as follows. (1) The folding points in the trend of the second-order differential values of the histogram of backscatter data correspond to the boundaries between different types of geology, e.g. barren pelagic sediment and dense ferromanganese nodules. (2) These thresholds each indicate that the same geologic boundaries appear at similar intervals in the histogram, even if the absolute values of intensity are different for each dataset. In particular, this latter component ensures linear fitting of the thresholds used to adjust each dataset to the arbitrary standard data. We need the confirmation of the geographical distributions of the identified boundary intensities between the different datasets. In this presentation, we will show an example of data integration for nine datasets to map the backscatter intensity of a region of approximately 155,500 km^2in the Japanese EEZ around Minamitorishima Island.

A precise calculation of average depth for ETOPO1

*Yasushi Harada[1], Sae Horiuchi[1]

1. School of Marine Science and Technology, Tokai University

NOAA calculated global ocean average depth as -3688m (https://www.ngdc.noaa.gov/mgg/global/etopo1_ocean_volumes.html) , but in their method, there are deviations for distribution of sampling points, especially at high latitude area. Generally, perfect uniform sampling points are needed to calculate precise average depth using digital elevation data such as ETOPO1.

We tried a different method for creating uniform sampling points on spherical surface. Yamaji(2001) created this software called GSS generator(GSS). The GSS makes almost perfect uniform sampling points on sphere, but not on WGS84 ellipsoid. Therefore we compared the two methods, and performed a statistical analysis for both methods.

We found that the two methods produced similar average depth values and the errors, and that the average depth of ETOPO1 is 3685.9 ±0.5m and about 2m shallower than NOAA’s 3688m value.

[S-CG56] Ocean Floor Geosciences

convener:Kyoko Okino(Atmosphere and Ocean Research Institute, The University of Tokyo)

Most of Earth's volcanism and much of its tectonic activity occur on and beneath the seafloor. Various phenomena on the seafloor are closely linked to plate tectonics, Earth and atmosphere. Seafloor rocks and sediments record Earth's evolution and heat and material fluxes on the Earth. Ocean Floor Geosciences session covers a broad range of research on LIPs, crustal movement and structure etc. Any fields of research and approach are welcomed. The session aims to encourage discussion among scientists from different study fields and to integrate our understanding of ocean floor. The session is co-chaired by K. Tadokoro (Nagoya Univ.), O. Ishizuka (AIST), T. Toki (Univ. Ryukyus), and N. Takahashi (JAMSTEC).

Signature of plume-ridge interaction on bathymetry and geochemistry along mid-ocean ridges: Insights from the Réunion Plume and Central Indian Ridge

*Clement Vincent[1], Jung-Woo Park[1], Sang-Mook Lee[1], Jonguk Kim[2], Sang-Joon Pak[2]

1. Seoul National University, 2. Korea Institute of Ocean Science and Technology

Plume-ridge interaction is an important thermal and geological process, which results in various physical and chemical anomalies along a significant length of the global mid-ocean ridges system. Despite numerous studies, some remaining questions to be solved are origin and mechanisms of geochemical variations and their possible influence on the morphology of mid-ocean ridges. The Central Indian Ridge, with a slow to intermediate spreading rate, provides an ideal opportunity to explore distant plume-ridge interactions. Presently, the ridge is moving away from the hotspot. The hotspot which started at the Deccan Traps (65 Ma) is presently 1000 km away from the Central Indian Ridge, at the Réunion Island. Paleogeographic reconstruction suggests that the hotspot crossed the middle part of the Central Indian Ridge (MCIR) between 8˚S and 17˚S at ~34 Ma. Studies suggest that the plume material that flows into the Central Indian Ridge is more or less concentrated around 19˚S, to the south of Marie Celeste Fracture Zone (MCFZ). In addition, recent geochemical study show southward-increasing gradient in Réunion mantle component between 14˚S and 18˚S north of MCFZ. The detailed mechanism of the plume interaction on the MCIR is in debate. In this study, we revisited the MCIR with additional Nd, Sr and Pb isotope analyses and ship-board high-resolution bathymetry data to constrain the influence of the Ré union plume on geochemistry and bathymetry of the MCIR. The results show that the geochemical anomaly observed between 14˚S and 18˚S are found only in the northern part of segments and subsegments, and these enrichments correlate with the shallow axial bathymetry. The localized geochemical and bathymetric anomalies can be ascribed to a hotspot leading edge effect where the hotspot leading segments are offset in the direction of the plume and are more influenced by the plume materials. It appears that discontinuities such as transform faults and the non-transform discontinuities influence the flow of mantle plume material into the ridge, and that the proximity of the ridge to the hotspot plays an important role in the plume-ridge interaction.

Spreading rate and its stability of Chile Ridge near the Chile Triple Junction

*Takanori Ishihara[1], Takeshi Matsumoto[1]

1. Ryukyu university

Chile triple junction (CTJ) is located at 46°13'S, 75°13'W off the coast of Chile and is composed of Nazca plate, Antarctic plate and South America plate, forming a ridge-trench-trench type triple junction. Chile ridge that is an active spreading ridge is subducting under the South America plate at CTJ and is the only ridge system that is currently subducting under trench in the world. Therefore this area is an important target to study the behavior of the active ridge just before subduction. And also, the mechanism and a possible driving force of the active ridge subduction are also to be studied by subsurface structure, age, development history, and so on through marine geophysical survey. The authors analysed total geomagnetic data from the tracks along the segments and attempted to obtain seafloor spreading rate at each segment and seafloor age from magnetic anomaly, and spreading stability in this area by the magnetic N/R boundary strikes derived from the three component magnetic data. Both the total force and the three-component magnetic data for this study were obtained from MR16-09 cruise by R/V MIRAI, Leg1 and Leg2. Marine Trackline data that were achived in National Geophysical Data Center were also used supplementarily. Seafloor spreading rate decrease is shown along almost all the tracks close to the trench, and comparison of several track data along the Segment SCR1 shows the same characteristics that spreading rate along the southern track is slower than that along the northern track. Moreover, the result from the other segments show that SCR1’s spreading rate (about3.0cm/yr) is higher than SCR3’s one (about 2.0cm/yr). These results show spreading rate is decreasing as the ridge is close to the trench. This mightbe due to declining of igneous activity and reduction of magma supply rate near the trench as Matsumoto et al (2013) showed. The reason why the young seafloor subducts early is that increasing of slab pull force caused by thickening of the oceanic lithosphere by cooling with closing the trench. Magnetic N/R boundary strike shows almost uniform trends, except near Guamblin fracture zone, so spreading stability is attained on the whole.

Newly Mapped Seamounts on the Antarctic Plate off Southern Chile

*Toshiya Fujiwara[1], Natsue Abe[2], Naomi Harada[3], Mirai MR16-09 Leg 2 Shipboard Science Party

1. Research and Development Center for Earthquake and Tsunami, Japan Agency for Marine-Earth Science and Technology, 2. Research and Development Center for Ocean Drilling Science, 3. Research and Development Center for Global Change

We conducted bathymetry, gravity, and magnetic survey of seamounts on the Antarctic Plate off southern Chile in the R/V Mirai MR16-09 Leg 2 cruise (January 20 - February 5, 2017: Puerto Montt - Punta Arenas). The survey including transit was an unprecedented opportunity to collect data in the regions of the Pacific Ocean where it has been sparsely surveyed.

A SeaBeam 3012 multibeam echo sounder was used for the bathymetric survey. The Micro-G LaCoste and Romberg S-116 shipboard gravity meter, a Geometrics G-882 cesium towing magnetometer, and a Tierra Tecnica SFG1214 shipboard three-component magnetometer were used for the gravity and magnetic surveys, respectively. Unfortunately, dredge rock sampling and seismic reflection survey was not conducted.

The seamounts are located on the Antarctic Plate. The mid-ocean ridge (Chile Ridge) was considered to be already subducted beneath the South American Plate. Magnetic Anomaly 6a was identified by Cande et al. (1982) on the seafloor in the vicinity of the seamounts. The crustal age around the seamounts is 18 Ma according to Muller et al. (2008). We observed magnetic anomaly stripes with amplitudes of about 400 nT, therefore, we will examine the crustal age and the seafloor spreading rate.

Since the seafloor was covered with a sedimentary layer, abyssal hills and their strikes could not be identified. The largest seamount was located at 51˚00'S, 79˚25'W. The seamount has a major axis of about 17 km, a minor axis of 10 km, and the strike of the major axis is N45˚W. The water depth of the base of the seamount is about 3900 m and the shallowest depth is about 2900 m, thus the relative height is about 1000 m. The seamount was surrounded by a moat with the maximum deep of 100 m. The basal area is about 160 square kilometers and the volume above the seafloor is about 70 cubic kilometers. The seamounts have calderas, and the depth and the diameter of the largest seamount are 200 m and 2.5 km, respectively.

The existence of the largest seamount was estimated by satellite altimetry and gravity observations. The relative height was estimated to be 364 m (Kim and Wessel (2011) seamount catalogue, ID: KW-05846). However, the accurate estimation of such a small seamount is difficult. We observed free-air gravity anomaly of about +20 mGal at the base of the seamount, and of about +50 mGal over the top of the seamount, thus the peak-to-trough amplitude of the gravity anomaly was 30 mGal. The gravity anomaly due to the seamount with 20 mGal larger amplitude was observed compared with a satellite-based gravity anomaly (Sandwell et al., 2014).

Surface-ship gravimetry on board MR16-09 Cruise by R/V MIRAI - Characteristrics of gravity anomaly around the Chile Triple Junction

*Takeshi Matsumoto[1], Takanori Ishihara[1]

1. Faculty of Science, University of the Ryukyus

MR16-09 cruise by R/V MIRAI traversed the Southeast Pacific and the Western Pacific from December 2016 to March 2017, with the portcall at Fiji, Chile, New Zealand and Mutsu. Gravity measurement was also carried out during the whole cruise except for within the EEZ of other countries.
During Leg2 of this cruise, the Segment SCR1 of the Chile Ridge, an active spreading ridge producing the Nazca plate and the Antarctica plate, was also surveyed in order to detect the characteristics of the gravity anomaly due to the subduction of the active mid-oceanic ridge below the South American Plate at the Chile Trench at the Chile Triple Junction (CTJ) located off Taitao Peninsula on the west coast of Chile.
The shipboard gravimeter used for the survey was a relative measurement system. Micro-g LaCoste air-sea gravity meter S-116 is equipped on board MIRAI. Normally, ‘gravity tie’ is carried out during the portcall at the wharf and the gravity base stations nearby where absolute value of gravity is known in order to obtain the absolute gravity value during the cruise. However, it was difficult to obtain accurate values after correcting the drift of the gravimeter because gravity tie was carried out only at 3 stations at the beginning (Shimizu), at the end (Sekinehama) and during the cruise (Punta Arenas). Therefore, correction of the value at the gravity measurement points on the survey lines was carried out using the latest global gravity 1’ grid data (Sandwell et al., 2014, Sandwell et al., 2013, Sandwell et al., 2009) derived from satellite altimetry data etc.

Let the grid intervals in the x and y directions of the grid data be dx and dy, respectively. Let g11, g21, g12, g22 be the gravitational values at the four corner points of this area (approximated by a rectangle) enclosed by x1, x2 (x1 < x2) for x-coordinate and y1, y2 (y1 > y2) for y-coordinate. The linearly interpolated value at the point (x, y) within this the area is

g1 = g11 * (x2 - x) * (y1 - y)

g2 = g21 * (x - x1) * (y1 - y)

g3 = g12 * (x2 - x) * (y - y2)

g4 = g22 * (x - x1) * (y - y2)

Then,

g = (g1 + g2 + g3 + g4) / (dx * dy).

Based on the difference between the gravity values obtained by this interpolation and the measured values, the drift rate at each leg was determined as,

Leg 1: 0.216 mgal/day

Leg 2: 0.520 mgal/day

©2019. Japan Geoscience Union. All Right Reserved.

Leg 3: -0.599 mgal/day

Leg 4: 0.562 mgal/day.

The measured gravity was corrected using these drift rates to obtain the final free air anomalies during the cruise.

Bouguer anomaly along the 3 survey lines on the Segment SCR1 (including the CTJ) of the Chile Ridge off the Chilean west coast was obtained by the two-dimensional calculation (assuming that the same seafloor topography and sub-seafloor structure are continuous along the trench/ridge axis direction) by use of the profiles of free air anomaly and seafloor topography along these survey lines. Regardless of the topographic undulation on the western side of the ridge/trench, the Bouguer anomaly decreased relatively uniformly towards the trench/ridge axis. This pattern is similar to that of the normal trenches and mid-ocean ridges. The rate of decrease as approaching the trench is about 1.5~2 mgal/km in the Western Pacific trench, <0.1 mgal/km for the Mid-Atlantic Ridge. However, the result of the current gravity survey shows that the decrease rate is 0.4~0.8 mgal/km.

In addition, geophysical traverses across the Tonga-Kermadec arc-trench, the southern East Pacific Rise (Leg1), the Bellingshausen Sea, the Amundsen Sea, the Eltanin-Udintzev fracture zones (Leg3), the South Fiji Basin, the Solomon arc-trench, and the West Caroline Plateau were obtained during the cruise.

Magnetic and Magnetotelluric surveys across the Afar depression, transition between continental rifting and sea-floor spreading

*Ryokei Yoshimura[1], Naoto Ishikawa[2], Tesfaye Kidane[3], Shin-ichi Kagashima[4], Nobutatsu Mochizuki[5], Ameha Atnafu Muluneh[3], Kirika Kitagawa[4], Taito Ikema[6]

1. Disaster Prevention Research Institute, Kyoto University, 2. Graduate School of Human and Environmental Studies, Kyoto University, 3. Addis Ababa University, 4. Faculty of Science, Yamagata University, 5. Priority Organization for Innovation and Excellence, Kumamoto University, 6. Faculty of Science, Kyoto University

The Afar area (Ethiopia) is well known as one of continental rifts transitioning to oceanic spreading centers. In order to delineate subsurface electric properties and document an initial stage of the formation process of magnetic stripes, we carried out wideband magnetotelluric (MT) measurements and ground magnetic survey along a common profile in 2016 and 2017. This profile, approximately 55km long, cuts across the Dabbahu rift in the Afar Depression. In magnetic survey on foot, we recorded total magnetic fields at 2.4 meters above the ground every 4 seconds by utilizing GSM-19 Overhauser magnetometer (GEM systems). In MT survey, we obtained electromagnetic and electric data at 14 sites using MTU-5A (Phoenix Geophysics) and ELOG1K-PHX (NT system design) systems. In this presentation, we will introduce the outline of our project and show results of magnetic and MT surveys.

Evolution of oceanic core complexes in the Shikoku Basin: when backarc basins cease to open

*Kyoko Okino[1], Yasuhiko Ohara[2,3], Masakazu Fujii[4], Tomoko Hanyu[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Japan Coast Guard, 3. Japan Agency for Marine-Earth Science and Technology, 4. National Institute of Polar Research

How and why backarc basins cease to open is one of the unsolved questions in plate tectonics. The Shikoku Basin is a typical backarc basin, that was formed behind the proto Izu-Bonin arc and stopped opening at ca.15 Ma. The post-spreading volcanism has formed a series of seamounts along the remnant spreading axis in the northern basin, whereas multiple oceanic core complexes have developed just before the spreading stop in the southern basin. Oceanic core complexes (OCC) are exposed lower crust and/or upper mantle materials along detachment faults, that are supposed to develop when melt supply rate M (=magmatic accommodation / plate separation) is around 0.5. The OCC is, therefore, a good indicator for temporal variation of melt supply when the backarc system died. During Yokosuka YK18-07 and Hakuho-maru KH-18-02 cruises in 2018 summer, we conducted the geophysical mapping (multibeam bathymetry, scalar and vector magnetics, and gravity) of an OCC at 23°50’ N, 138°50’ E in the southernmost Shikoku Basin and its adjusting areas. The OCC is tentatively named Mado Megamullion. We compiled these new datasets and previously collected data and analyzed detailed bathymetry and magnetic and gravity anomalies. In this presentation, we show the results and discuss the structure and evolutionary process of this OCC and its implications for demise of backarc opening system.

The Mado Megamulliion is about 20 km square domed high, located at the intersection of remnant ridge segment and transform fault. Its surface is characterized prominent corrugations parallel to flow lines. The mantle Bouguer anomaly is about 20mGal higher than the surroundings. This observation is consistent with the fact that high-density gabbro and peridotite samples were recovered both by Shinkai6500 dive in YK18-07 and dredge hauls in KH-18-02. A part of recovered rock samples show the deformation structure, suggesting that the surface of this OCC is a detachment fault surface. Magnetic anomaly distribution shows generally linear, positive and negative bands over the OCC as same as in the well-ordered abyssal hill area, suggesting continuous crust formation from ridge segments. The widths of lineations are, however, longer at the OCC, indicating clear asymmetric spreading during detachment faulting. The spreading asymmetry is often observed over world OCC areas. The equivalent magnetization value seems to be positively shifted, that may suggest the effect of induced magnetization of OCC massif. The result of vector magnetic field analysis shows clear, strong and ridge-parallel magnetic boundaries in well-ordered abyssal hill areas, that is consistent with normal seafloor spreading and block model. In contrast, the clear, systematic magnetic boundaries don’t exist. The estimated three dimensionality is not so strong. Within the rift valley south of the Mado Megamullion, a small domed high with high Bouguer anomaly exists. This is likely NTO (non-transform offset) massif, previously reported along mid-ocean ridges. Another corrugated surface is observed at neighboring segment, that shows typical detachment surface morphology but are not accompanied by gravity anomalies.
The structure and evolutionary process of the Mado Megamullion and the adjacent OCC-like massifs infer the temporal variation of melt supply on the final stage of backarc opening. Multiple core complexes including world largest Godzilla Megamullion are distributed along the Parece Vela Rift, south of the study area. The integrated analysis of these OCCs is a key to understand the demise of backarc systems.

Lithosphere-asthenosphere boundary (LAB) is a zone where heat, momentum, and materials are exchanged between conductive mantle and underlying convective mantle, and plays an important role in plate tectonics (McKenzie & Priestley, 2005; Fischer et al., 2010; Kawakatsu & Utada, 2017). Its internal structure and dynamic behavior are, however, far from understood. This study addresses this issue on the basis of petrological study of an orogenic peridotite complex. Lanzo massif in the western Alps, Northern Italy. We attempt to clarify temporal change of internal thermal structure of the complex during exhumation, from which the original thermal structures before exhumation may be estimated.
Lanzo massif is one of the largest mantle exposure thought to be a subcontinental lithospheric mantle exhumed related to the opening of the Jurassic Piedmont Sea between European continent and Adriatic continent, following slow spreading of the Atlantic mid ocean ridge (Müntener & Piccardo, 2003). The massif consists dominantly of plagioclase-bearing lherzolite, stable at the pressure lower than 1GPa, with subordinate amount of mafic rocks occurring as layers or dikes (Bodinier, 1988; Bodinier et al., 1991). The Lanzo massif divided into three bodies on the basis of petrographic characteristics: north, central and south. Previous studies argued that the northern part represents subcontinental lithospheric mantle and that the southern part may be of asthenospher origin (Bodinier, 1988; Bodinier et al. 1991). Therefore, the complex may represent a zone of lithosphere-asthenosphere boundary and can provide information on processes operated there (Bodinier, 1988; Bodinier et al., 1991; Kaczmarek & Müntener, 2008).
We examined plagioclase-bearing lherzolite collected from 16 localities covering the entire massif. Systematic variations of microstructures and mineral chemical compositions were confirmed, which is principally consistent with previous studies (Bodinier, 1988; Bodinier et al., 1991). All constituent minerals show chemical heterogeneity on grain scales, which is regarded as record of various processes the rocks underwent. Grain-scale zonings of Al and Ca in pyroxene, fluorescence-corrected Ca in olivine adjacent to pyroxenes, Cr and Al in spinel adjacent to plagioclase, and Ca and Na in plagioclase suggest that monotonous cooling and decompression accompanied by deformation occurred during decompression of the Lanzo massif. We quantified the space-dependent thermal history of Lanzo by using Ca-in-orthopyroxene geothermometer after Lindsley (1983) and Ca-in-olivine geothermometers calibrated on the basis of experimental results of Köhler & Brey (1990). All the estimated temperatures decrease from the southern body towards the northern body. The calculated temperatures were critically examined if they represent closure temperatures or a condition at which Lanzo resided for a certain period of time. The grain-scale zoning patterns indicate that the temperatures from core of orthopyroxene recorded a long residence, whereas those from rim of pyroxenes and both core and rim of olivine represent closure temperatures (Tc) at various timings during monotonous cooling. The decrease in temperatures of pyroxene cores from the south to the north by ~60K may represent a geotherm near LAB zone. All the Tc decrease from the north to the south and the difference of temperatures between the core and rim of orthopyroxene increases from the southern body to the northern body. This suggests that the cooler and probably shallower northern body cooled at slower rate at a wide temperature range (Tc=700-1100˚C) than the hotter and probably deeper southern body. A thermal gradient recorded in the Lanzo massif is estimated to be ~6K/km, which is greater than those estimated for deep subcontinental

lithosphere at steady thermal state (Mckenzie et al., 2005). We speculate that the high geotherm might have caused by thermal perturbation from asthenosphere.

Comparison of the back-arc basins of the South and the Central Ryukyus in the northwest Pacific

*Kohsaku Arai[1], Ayanori Misawa[1], Takahiko Inoue[1]

1. Institute of Geology and Geoinformation, National Institute of Advanced Industrial and Technology

The Ryukyu Arc, which extend for over 1200 km along the east coast of Asia from Kyushu to Taiwan, and the associated Ryukyu Trench, are products of the subduction of the Philippine Sea Plate (PSP) beneath the Eurasian Plate. The PSP is subducting northwestward beneath the Eurasian Plate at a convergence rate of 4–9 cm/yr (Seno et al., 1993). The major islands of the Ryukyu Arc are considered the forearc highs.
The Okinawa Trough is a back-arc basin located beside of the Ryukyu Arc that was formed in the late Miocene (Gungor et al., 2012) or the late Pliocene–early Pleistocene (Sibuet et al., 1998). Formation of the Okinawa Trough was a key geological event associated with complex tectonics and changes in the topographic configuration of the Ryukyu Arc. Geological Survey of Japan (GSJ), AIST has started the marine geological mapping project around Ryukyu Arc since the 2008 FY. Multi-channel (16 ch or 32 ch) high-resolution seismic profiles were acquired during these cruises by the GI-gun (355cu. inch) systems. In our investigation into the deformation of the Ryukyu Arc using the high-density seismic profiles, we found that the normal faults parallel to the trench axis are well developed on the back-arc side of the arc. Slope of northern off the Southern Ryukyu (Miyako-jima and Ishigaki-jima) is simply downthrown to the axis of Okinawa Trough and reach to 2000 m in depth. In the other hand, the Central Ryukyu, northwestern off the Okinawa-jima is characterized by the small basin structure which accompanies with active normal faults. The faults show ENE-WSW strike and dip to the north with clear half graben structure. We present the tectonics of these structure compare the back-arc basins of the South Ryukyu with the Central Ryukyu.

Geochemistry and zircon U-Pb ages of mafic rocks in the Mikabu and Sorachi-Yezo belts: Comparison with the Shatsky Rise

*Naoto Kimura[1], Yuji Ichiyama[1], Shohei Takahashi[1], Hisatoshi Ito[2], Akihiro Tamura[3], Tomoaki Morishita[3]

Large igneous provinces (LIPs) are large volcanic edifices on the Earth, such as oceanic plateaus and continental traps. It is commonly believed that LIPs are formed by large-scale magmatism caused by the upwelling of unusually hot mantle plume from the deep mantle (e.g., Coffin and Eldholm, 1994). Therefore, the genesis and formation mechanisms of LIPs is crucial to understand the dynamics of the Earth’s interior and episodic global events. Recent studies have revealed that the fragments of accreted oceanic plateaus are preserved in orogenic belts as ophiolites and accretionary complexes (e.g., Kerr et al., 2000; Ichiyama et al., 2014). The investigation of accreted oceanic plateaus will help to enhance our understanding of LIPs.

The Mikabu belt in SW Japan and Sorachi-Yezo belt in central Hokkaido, North Japan contain large accreted fragments of a paleo-oceanic plateau (Kimura et al., 1994). Recently, Ichiyama et al. (2014) proposed that the Mikabu and Sorachi-Yezo picrites with highly magnesian olivine phenocrysts (up to Fo_{94}) were produced by an unusually hot mantle plume. They also suggested that these picrites are derived from the Late Jurassic oceanic plateau (hereafter named “Mikabu-Sorachi plateau”) formed on the Izanagi plate, which was possibly produced together with the Shatsky Rise at the Pacific-Izanagi-Farallon triple junction in the Pacific Ocean. However, the geochronological and geochemical comparison between the Mikabu-Sorachi and Shatsky Rise has been poorly constrained.

The Mikabu and Sorachi-Yezo mafic rocks are geochemically divided into depleted (D)-type and enriched (E)-type in the same manner as the picrites. The D-type is depleted in light rare earth elements (LREE), whereas the E-type is relatively enriched in LREE. These types were produced by higher degrees of partial melting (30-50%) than MORB. The U-Pb zircon analyses of gabbroic rocks in both belts yield the weighted mean $^{206}Pb/^{238}U$ zircon ages of 153.1-146.3 Ma for the Mikabu rocks and 146.2 and 137.6 Ma for the Sorachi-Yezo rocks.

A wide geochemical variety of basalts were recovered from the Shatsky Rise during the IODP Expedition 324 (Expedition 324 Scientists, 2010; Sano et al., 2012). The U1349-type and Normal-type basalts of the Shatsky Rise are closely similar in geochemical composition to the Mikabu-Sorachi D-type and E-type rocks, respectively. The radiometric ages of the Shastky Rise basalts show 144.6-133.9 Ma (Mahoney et al., 2005; Geldmacher et al., 2014). The magnetic anomaly lineations of the Shatsky Rise exhibit that the formation of the rise started at M21 (about 147 Ma). The zircon U-Pb ages of the Mikabu-Sorachi mafic rocks are almost coeval with the formation ages of the Shatsky Rise. However, the older radiometric ages than 147 Ma are shown in this study. Recently, Sawada et al. (2019) also report the zircon U-Pb age of 154.6 Ma for the Mikabu metabasite from the Toba area.

The magnetic anomaly lineation of M29 (about 157 Ma) drawn at the southwest of the Shatsky Rise implies that the triple junction was already present at 157 Ma. The Mikabu-Sorachi plateau was produced on the Izanagi plate before the Shatsky Rise at the triple junction. The igneous rocks in the Mikabu-Sorachi belt possibly record the information on initiation mechanisms of the triple junction and

Submersible magnetics reveals relationship between off-axis volcanism and hydrothermal systems of the Kairei and Yokoniwa fields at the Central Indian Ridge

*Masakazu Fujii[1], Kyoko Okino[2]

1. National Institute of Polar Research and SOKENDAI, 2. Atmosphere and Ocean Research Institute, The University of Tokyo

The Kairei (KHF) and Yokoniwa hydrothermal fields (YHF)are hosted in mafic as well as ultramafic rocks distributed at an off-axis volcanic knoll of the Central Indian Ridge. Despite intensive investigations, their geological and geophysical background is still debated. Here, we show the results of near-seafloor magnetic anomaly surveys conducted using a submersible. We investigated the bulk magnetization of the hydrothermally altered zone and the surrounding lava flows and evaluated their intensities compared with previously reported values at axial areas of seafloor spreading environments. The KHF is characterized by low coherence between observed and modeled anomalies and low values of magnetization. This result suggests that magnetic minerals within basaltic lava flows were likely altered by hydrothermal fluid circulation. The variation pattern in the observed magnetic anomalies above the lava flows is in phase with that of the modeled magnetic anomalies for the simple assumption that the magnetization direction is parallel to the geomagnetic field. This result suggests that these lava flows preserve normal magnetic polarity corresponding to the Brunhes Chron. The estimated magnetic-anomaly-derived absolute magnetizations (MADAM) show a reasonable correlation with the natural remanent magnetizations of rock samples collected from the seafloor of the same region; their relationship is consistent with previously reported datasets from the Mariana Trough and Mid-Atlantic Ridge. The estimated MADAM intensity reaches 20 A/m in the study area, which is clearly greater than those of previously reported off-axis areas, suggesting that recent volcanic eruption may have occurred in these off-axis areas. The high magnetization distributions are commonly observed at the bottoms of the western slope from the KHF and YHF. This finding provides new insight into the distribution of highly magnetized lava flows in the off-axis areas and indicates the distribution of recent off-axis volcanic activities, which is potentially linked to the sub-seafloor hydrothermal circulation.

Shipboard magnetic and gravity surveys around the Iheya North Knoll and the Iheya Minor Ridge in the Mid-Okinawa Trough: Preliminary results of KR18-14 Leg1/Leg2 cruises

*Kazuya Kitada[1], Takafumi Kasaya[1], Hisanori Iwamoto[1], Yoshifumi Nogi[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Institute of Polar Research

The Okinawa Trough, an active back-arc basin behind the Ryukyu trench, exhibits active rifting associated with extension of the continental margin. In the Mid-Okinawa Trough, more than 10 hydrothermal vent sites belonging to relatively large hydrothermal vent fields at the Iheya North Knoll, the Iheya Minor Ridge, the Izena Hole and etc., were discovered by previous studies (e.g., Halbach et al., 1989; Sakai et al., 1990; Momma et al., 1996; Kasaya et al., 2015; Nakamura et al., 2015). Although shipboard magnetic and gravity surveys are too low in resolution to investigate the hydrothermal sites, they are important for understanding the geological background of the hydrothermal systems across an entire region. As for the area off Kumejima Island in the Okinawa Trough, Kitada et al. (2018) revealed the characteristics of the submarine volcanic activity around a hydrothermal area by using dense magnetic and gravity data. In order to characterize sub-seafloor structures and the spatial distribution of the submarine volcanic activity around the Iheya North Knoll and the Iheya Minor Ridge, we conducted detailed magnetic and gravity surveys with a line spacing of 0.5 nmi aboard research vessel Kairei during the KR18-14 Leg1 and Leg2 cruises from October to November 2018. Additionally, we also compiled magnetic, gravity and bathymetric data which were collected during previous cruises by the Japan Agency for Marine-Earth Science and Technology (JAMSTEC) over the recent years. Magnetization intensities were estimated from observed magnetic anomalies, without applying annihilator. Bouguer gravity anomalies were calculated from free-air anomalies obtained. The distribution of magnetization intensity and variation in Bouguer gravity anomalies revealed the characteristics of submarine volcanic activity. Most of the knolls in the area show a relatively high magnetization (~1.0 to ~3.0 A/M) corresponding to the individual submarine knolls. Higher Bouguer gravity anomalies (~45 to ~55 mgal) implying the lower crustal thickness were observed in the Iheya graben. The knolls including the Iheya Minor Ridge, elongated in the ENE-WSW direction parallel to the graben, exhibit the ENE-WSW trending magnetization distribution with relatively high positive intensities, so volcanism appears to be constrained by normal faults forming the rift structure. On the other hand, the Iheya North Knoll have a relatively low magnetization of ~-1.0 to ~0.0 A/M with less variation of the magnetization. Although the data are sparse (the line spacing of ~1.5 to ~2 nmi), low magnetization (~1.5 A/M) with no prominent magnetic signature was also observed in the Izena Hole. Moreover, these knolls are located on the area where the Bouguer gravity anomaly is changed from ~30 to ~10 mgal and ~45 to ~30 mgal, respectively. The magmatism associated with submarine volcanic activity and back-arc rifting will be discussed based on the results obtained from these dense surveys.

A shallow seabed drilling was performed in February 2019 at Higashi Ensei Hydrothermal Field, Northern Okinawa Trough (Cruise ID: KM19-E01). Two localities were selected to investigate natures of sub-seafloor lithology with and without self-potential anomaly (SP anomaly) measured by near-bottom AUV survey. Here such a SP anomaly is to be resulted from a sub-seafloor orebody consisted of mainly sulfides. A seabed drilling apparatus, BMS (Boring machine system, Cellula Robotics Ltd.), was deployed twice from R/V Kaimei. At the first drilling in the cruise, the drilled hole reached to a formation 44m beneath the seafloor but stopped there due to significant venting through the drilled hole. Volcaniclastics with and without sulfide blocks or veins were sampled even poor recovery in the shallow part of the hole. Contrasting to it, the second drilled hole reached to 10 m beneath the seafloor where intact mafic-intermediate lava flow, i.e. volcanic basement, was sampled. In the second hole, little sulfide were retrieved except orange-colored one, probably realgar associating with orpiment and stibnite, in the first core, shallower than 1.5mbsf. On board IP measurement both as well as standard MSCL and visual core description were performed for the cores from the first hole. Further, an ROV dive observation was conducted within 16.5 hours after the drilling of the first hole. An exotic white sediment was recognized in the vicinity of the hole, similarly to the IODP exp.331 at Iheya-North Knoll, and successfully sampled. In this presentation, retrieved drilled samples as well as those sampled by ROV will be reported.

Hiruzen Institute for Geology and Chronology, 8. Faculty of Science, University of the Ryukyus, 9. Japan Agency for Marine-Earth Science and Technology

Intense hydrothermal activity associated with sulfide mineralization had been observed in the Gondou field, which is located at the seafloor around a water depth of 1330-1470 mbsl (meters below the sea level) at the western flank of the Daisan-Kume Knoll (Minami and Ohara, 2017; Ishikawaet al., 2016). Scientific drilling was performed by J-MARES during the SIP Integrated Ocean Resource Surveying System JM17-04 Cruise from October to November, 2017. Sediment cores were obtained from 5 sites in Southern area of the Gondou field by drilling using BMS (Benthic Multi-coring System) installed on *Shincho-maru*. Mineralogy and geochemistry of the obtained cores were studied based on VCD (Visual Core Description), microscopic observation, XRD (X-ray diffractometer) analysis, and electron probe microanalyzer (EPMA) analysis.
Most part of the obtained sediment, except for the surface hemipelagic sediment within a few mbsf (meters below the seafloor), was hydrothermally altered intensely. Abundant occurrence of illite (or illite/smectite mixed-layer mineral) was observed, which is common signature among hydrothermal alteration in hydrothermal fields in the Okinawa Trough. Whereas, occurrence of chlorite was limitedly recognized within a layer of 5-15 m thickness in each site. Kaolin minerals were identified in altered pumiceous volcaniclastic sediment in two sites. These specific occurrences may reflect subseafloor fluid migration of distinctive chemistry, based on the idea that chlorite formation would be related to interaction with heated seater-derived fluid while kaolin minerals formation would be related to interaction with acidic fluid. Occurrence of sulfate minerals such as anhydrite and barite is also limited, which may provide another information about subseafloor fluid migration.

Acknowledgements
This study was conducted under the framework of the Next-Generation Technology for Ocean Resources Exploration Project, Cross-ministerial Strategic Innovation Promotion Program (SIP) funded by the Japanese cabinet office. The sediment cores used in this study were provided from J-MARES (Research and Development Partnership for Next Generation Technology of Marine Resources Survey).

New type of self-potential anomaly observed near a hydrothermal site of Oomuro-dashi volcano, Izu-Ogasawara arc

*Yoshifumi Kawada[1,2], Takafumi Kasaya[2]

1. International Research Institute of Disaster Science, Tohoku University, 2. Japan Agency for Marine-Earth Science and Technology

Using a deep-towed electrode array, we identified a pair of positive and negative self-potential anomalies observed near an active hydrothermal field associated with a quarterly rhyolitic volcano, Oomuro-dashi, Izu-Ogasawara arc. Results with different rowed directions, the magnitude of both anomalies is of the order of millivolt. The negative anomaly is located immediately above the most active area; the positive self-potential anomaly is located a few hundreds of meters away from the most active hydrothermal area, where no apparent hydrothermal activity has been detected. The discovery of the positive self-potential anomaly in marine environments is probably the first time.

The origin of the negative self-potential anomalies may be explained by the geo-battery mechanism (Sato and Mooney, 1960), in which the presence of a conductive ore body crossing the redox gradient results in the upward electron transfer to give a negative self-potential anomaly above the body. Oxidized materials near the seafloor are reduced. In other words, an ore body near the seafloor behaves as a cathode. We have reported negative self-potential anomalies many times above hydrothermal areas of other sites (e.g., Sato et al., 2017; Kawada and Kasaya, 2017, 2018).

The origin of this newly founded positive self-potential anomaly is problematic. One possibility is that an anode of the geo-battery, where reduced materials are oxidized, is exhumed near to the seafloor. If this is true, shallow drilling or piston coring may confirm signals from oxidized chemical reactions around an anode. This is important for the understanding of the geo-battery because its anode is usually located far below the seafloor and cannot be accessed easily. Another possibility is the streaming potential, which is caused by a local charge imbalance due to the flow of electrolytes in the pore space. Although this mechanism is estimated to be minor in marine environments, a positive self-potential anomaly of the order of one millivolt may not be immediately rejected above an area of upward fluid flow. However, the area of this positive self-potential anomaly is away from the active hydrothermal site, where upward fluid discharge is expected.

Numerical simulation of submarine hydrothermal ore-deposits due to a coupled process of fluid migration and reactive geochemical transport

*Claudia Fujita[1], Hajime Yamamoto[1], Jun-ichiro Ishibashi[2], Takeshi Tsuji[3]

1. Taisei Corporation, 2. Department of Earth and Planetary Sciences, Faculty of Science, Kyushu University, 3. Department of Earth Resources Engineering, Faculty of Science, Kyushu University

Submarine hydrothermal ore-deposits are known to be rich in metal resources and are to be found abundant around the Japanese islands. In recent years, several studies (mostly field surveys) had been carried out and a lot of data on chemical, physical and biological properties of compounds have been gathered especially for hydrothermal fields in the Okinawa Trough. However, the mechanism of formation (hydrothermal fluid flow in combination with geochemical reaction) of these deposits is not yet clearly understood.

Hydrothermal ore-deposits are formed by precipitation of metal elements from hydrothermal fluid due to rapid cooling around the seafloor where the fluid discharges. Contrary to the hydrothermal systems in the mid-ocean ridges, hydrothermal systems in the Okinawa Trough has a fluid discharge region at the seafloor in sediment-rich environment. The sediment is often composed of two components; one is hemipelagic sediment possibly transported from the continental margin and the other is volcaniclastic sediment derived from felsic volcanism in the vicinity. Because these two components have quite different permeability, it is expected complicated fluid migration within the discharge region.

In this study, we investigated the above process using a numerical code TOUGHREACT V3.0 –OMP, which is for coupled non-isothermal multiphase fluid flow and geochemical reactive transport. A 2-dimensional radial model with the radius of 5 km and a depth of 1 km below the seafloor was chosen to represent a sufficient area of the discharge region around the hydrothermal vent. The center of the radial model represented a fluid conduit (10 cm diameter) where the venting hydrothermal fluid of 300 ˚C ascends from basal to the seafloor, with a flow rate of ~1000 t/day. Almost all model parameters are chosen based on available results of geophysical survey of the Iheya hydrothermal fields in the Okinawa Trough[1)]. The geological structures were set as having diverse permeability from 1×10^{-10} m^2 to 1×10^{-16} m^2, which reflects alternating pumiceous volcaniclastics layer and hemipelagic sediment layer. The initial thermal gradient was set to 4.8 ˚C/100 m. The top boundary (seafloor) was set to constant pressure condition (20 MPa) and a basal heat flux was also imposed at the bottom (5.6×10^{6} W/m^2), assuming a pumice thermal conductivity of 0.96 W-m/˚C.

The geochemical setting included initial concentrations of primary species, as, for instance, Na^{+}, SO_4^{-2}, H_4SiO_4, Ca^{+2}, S^{-2}, Zn^{+2}, HCO_3^{-} or NH_3 for seawater and hydrothermal fluid separately. Chemical reaction including precipitation of minerals) caused by mixing of the both fluids and cooling was considered in this setting. In order to simulate accumulation of mineral precipitations to form hydrothermal deposits over a long-time duration (an order of thousands of years), the numerical simulation was conducted for 10000 years.

As a result, the following features were clarified: First, high velocity venting hydrothermal fluid ascends to the seafloor through the fluid conduit at the center of the model, whereas nearby cold water percolates downward from the seafloor and convection occurs. Second, among the alternating layer structure, preferential horizontal flow is obvious for layers with high permeability, which resulted in primary sulfide precipitation with a lateral extend.

These results are likely to be consistent to recent field studies during scientific drilling into the submarine

Mineral composition and grain size distribution of REY-rich mud in the Minamitorishima EEZ: Implication for formation process of extremely REY-rich mud

*Sakai Takumi[1], Erika Tanaka[1], Kazutaka Yasukawa[1,2], Junichiro Ohta[2,1], Koichiro Fujinaga[2,1], Kentaro Nakamura[1], Yasuhiro Kato[3,1,2]

1. Department of Systems Innovation, School of Engineering, University of Tokyo, 2. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology, 3. Frontier Research Center for Energy and Resources, School of Engineering, The University of Tokyo

In 2011, it was reported that deep-sea sediments containing high concentrations of rare-earth elements and yttrium (REY) are widely distributed in the Pacific Ocean, and can constitute a new mineral resource for the industrially critical elements [1]. Moreover, the “extremely REY-rich mud” containing more than 5,000 ppm of total REY (ΣREY) was discovered within the Japanese exclusive economic zome (EEZ) around Minamitorishima Island [2], and various researches to reveal a detailed spatial distribution of the extremely REY-rich mud has been carried out [3]. However, the formation mechanism(s) of the extremely REY-rich mud have not been completely elucidated yet.

Recently, based on multi-elemental compositions of 49 piston core samples collected from the Minamitorishima EEZ, it was confirmed that the deep-sea sediments in the area could be classified into nine sedimentary units based on characteristic chemical compositions [4]. This chemostratigraphy indicated that there are at least three “ΣREY peaks” containing 2,000 ppm of ΣREY in the Minamitorishima EEZ [4]. A previous study targeting the extremely REY-rich mud corresponding to the 1st ΣREY peak (i.e, the shallowest ΣREY peak in the chemostratigraphy) demonstrated that grain sizes of biogenic Ca-phosphate (BCP) and authigenic phillipsite were largest in the horizon with the maximum ΣREY concentration, based on analyses of mineral composition and grain size distribution [5]. However, whether this feature is common in all of the ΣREY peak units remains uncertain. In addition, no systematic investigation of relationships between each chemostratigraphic unit and mineral composition and grain size distribution has been carried out.

Here, we aimed to characterize each chemostratigraphic unit from the perspectives of the mineral composition and grain size distribution, and also to provide a constraint on the formation process of the extremely REY-rich mud. We selected 80 sediment samples from the 17 piston cores collected within the Minamitorishima EEZ to cover all units of the chemostratigraphy. The mineral composition was estimated by microscopic observation following the standard protocols of the International Ocean Discovery Program. The grain size distribution was measured by using laser diffraction spectroscopy. As the result, we revealed systematic variations in mineral composition and grain size distribution of each chemostratigraphic unit, and confirmed that grain sizes of BCP and phillipsite in all the ΣREY peak units were coarser (i.e., more enriched in silt- to sand-sized fractions) than other units. The increased sizes of BCP grains as a common feature of the ΣREY peaks imply that a grain-size sorting by enhanced bottom currents concentrated coarse BCP grains on the seafloor and contributed to the formation of extremely REY-rich mud for multiple times throughout the sedimentary history of the area.

Geochemical and morphological features of manganese micronodules in REY-rich mud within the Minamitorishima EEZ, western North Pacific Ocean

*Satoshi Kino[1], Kazutaka Yasukawa[1,2], Keishiro Azami[1], Erika Tanaka[1], Koichiro Fujinaga[2,1], Kentaro Nakamura[1], Yasuhiro Kato[1,2]

1. Department of Systems Innovation, School of Engineering, University of Tokyo, 2. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology

Manganese micronodules are small grains (< 1 mm) composed of manganese oxides, and constitute one of the important components of pelagic sediments. The micronodules show high contents of various heavy metals, especially of some redox-sensitive transition metals [1]. In addition to chemical compositions, the abundance and texture of micronodules can be affected by sedimentation rates and/or redox conditions of the sediment column [1, 2]. Therefore, the micronodules have been regarded as a useful indicator of the sedimentary environment.

Recently, deep-sea sediment extremely enriched in rare-earth elements and yttrium (REY) was discovered within the Japanese exclusive economic zone (EEZ) around Minamitorishima Island [3]. Previous studies reported that the extremely REY-rich mud contains significant amounts of biogenic calcium phosphate, which is a main host of REY, and phillipsite grains [3, 4]. In addition to them, manganese micronodules were also recognized in the sediment column, which were especially abundant in the extremely REY-rich layer [3, 4]. However, detailed features of the micronodules in the REY-rich mud within the Minamitorishima EEZ have not been investigated yet. Manganese micronodules in the REY-rich mud are about μm –mm ferromanganese oxides. Because their abundance and chemical compositions are considered to reflect respectively the sedimentation rate and redox conditions when they were buried [4], the micronodules can provide important constraints on the depositional environment of the REY-rich mud.

In this study, therefore, to characterize the manganese micronodules in the REY-rich mud within the Minamitorishima EEZ, we implemented (1) microscopic observations of the shape, surface texture, and relative abundance of the micronodules, and (2) bulk chemical analysis of them by using ICP-MS. We compared the geochemical features of the micronodules with those of macronodules both on the seafloor of the Minamitorishima EEZ, and also with those of macro- and micronodules in other areas.

The Minamitorishima micronodules are generally characterized by diagenetic features, although showing a compositional shift towards hydrogenetic features in some samples. Based on the integration of the observational and analytical results, we will discuss the possible changes in the sedimentary environment (e.g., sedimentation rates and redox conditions) involving the formation of the extremely REY-rich mud.

Seafloor sediment thickness around the Japan and Kurile trenches obtained by traveltime analysis for PS converted wave recoded by ocean bottom seismograms

*Ryosuke Azuma[1], Genti Toyokuni[1], Ryota Takagi[1], Syuichi Suzuki[1], Makiko Sato[1], Takashi NAKAYAMA[1], Naoki Uchida[1], Ryota Hino[1]

1. Recearch Center for Prediction of Earthquake and Volcanic Eruption, Graduate School of Science, Tohoku University

seafloor observation network for earthquake and tsunamis has been working in the Japan and Kurile trench subduction zones since 2016 (S-net, installed by National Research Institute for Earth Science and Disaster Resilience). The seismograms recorded by such the ocean bottom observatories are very useful for a precise hypocenter estimation. On the other hand, to obtain precise location results, it is also necessary to take suitable correction for traveltime delay due to the presence of the thick low-velocity sediments below sites, because the thickness of sediments differs with sites.

This study aims to estimate thickness of the sedimentary layer below the sites of the S-net and pop-up-type ocean bottom seismometers (OBSs). We then focused on traveltime difference between direct P-waves and PS waves converted at the sedimentary basement.

In the analysis, we first estimated a sensor direction based on gravitational acceleration and particle motions of teleseismic surface waves on accelerograms and then transformed components of velocity waveforms from XYZ to UD, NS and EW (Takagi et al., this meeting). Next, we picked PS arrivals on horizontal components of velocity records, for thirty of intraslab earthquakes observed at twenty of the S-net sites located on the outer slope of the Kurile and Japan trenches and the landward slope of the Kurile trench (off Nemuro). As a result, we obtained PS-P traveltime difference of ~1.4 s at the most of sites, ~1.6 s near the Japan and Kurile trenches junction, and 1.8 and 2.7 s on the lower and upper portions of the landward slope of the Kurile trench. Considering the standard deviation of PS-P of ~0.15 s at each site, our result suggests that PS-P traveltimes at the junction and other trench-outer region differs significantly while that variation between neighbor sites seems to be small.

The obtained PS-P traveltime differences for the outer-trench sites is consistent with those by seismic surveys (1.0–1.5 s, Kodaira et al., 2014; Fujie et al., 2016) and OBS observations (0.9–1.2 s, Hino et al., 2009) at the outer rise of the Japan trench. Therefore, picked PS arrivals on the S-net records in this study coincide with those by the previous studies. Assuming a Vp/Vs ratio of 8.0 and an average Vp of 2.0 km/s in the sediments estimated by the wide-angle seismic surveys (Kodaira et al., 2014; Fujie et al., 2016) at the Japan and Kurile trench-outer rise regions, sediments thickness below the S-net sites would be 350~400 m, which is also consistent with results of the seismic reflection section (Kodaira et al., 2014; Fujie et al., 2016). By further analysis for PS converted wave at the inner-trench sites of OBSs and S-net besides off Nemuro, we will investigate the distribution of thickness of the sedimentary layer in the forearc region of the east Japan.

Examination of critical taper theory based on bathymetry data in subduction zones

*Hiroaki Koge[1], Juichiro Ashi[1], Jin-Oh Park[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

The fold-and-thrust belts and submarine accretionary wedges lie along compressive plate boundaries. The critical taper model has been recognized to be the most appropriate theory that describes the first-order mechanics of these structures. Applying the critical taper model in the subduction zones, we can estimate the frictional coefficient of the plate boundary fault with only simple topographical parameters from the cross-section. Thus, this model has been also used in discussions related to earthquakes.
However, in the critical taper model, the following two problems could be pointed out when acquiring the topographic parameters. 1) It is impossible to apply the critical taper model to the area without seismic cross-section. 2) In the depth conversion in the seismic cross-section, the depth of the plate boundary fault largely depends on the velocity model and affects the estimation of the décollement dip angle β. Thus, it is unreliable in terms of accurate comparison. Therefore, when comparing the result with various velocity models, the reliability is low in terms of accurate comparison.
Therefore, in this research, we developed a new method to obtain the topographical parameters only from bathymetry data instead of the seismic cross-section. We verified the validity of the method from the results, with comparing the result from the décollement dip angle β obtained from the seismic cross-sections and the result from the trench seaward slope angle β obtained from the bathymetry. We check the validity of the new method using the Nankai Trough as the target area. In the Nankai Trough, many seismic cross-sections have been acquired for the disaster mitigation of the large earthquake, and the observation based on various methods such as seismic waves or GPS has proceeded. Thus, it should be easy for acquiring the topographical parameters and interpreting the result of the critical taper model.
We found the theoretical blind spot of the critical taper model in the condition of the subduction zone under the sea. When a high pore pressure ratio is assumed for the whole wedge, the effect of β on the result is very small for the effective friction coefficient. Therefore, it is sufficiently possible to discuss the frictional distribution of the plate boundary fault with only the bathymetry data. It is although necessary to pay attention to relatively large error up to about 20%. Since the bathymetry data is spatially densely acquired data, it was possible to calculate the friction distribution of the shallow plate boundary fault along the trench axis in the high density.
As a preliminary interpretation of the results with the bathymetrical critical taper model , this metho is considered to be effective to contribute to earthquake/tsunami disaster mitigation in sea areas where seismic activity segments are not sufficiently studied.

Active structures of the Sagami Bay Fault by high-resolution sub-bottom profiling and pin-point core sampling

*Juichiro Ashi[1], Asuka Yamaguchi[2], Natsumi Okutsu[1], Ayanori Misawa[3]

1. Graduate School of Frontier Sciences, The University of Tokyo, 2. Atmosphere and Ocean Research Institute, The University of Tokyo, 3. National Institute of Advanced Industrial Science and Technology

Seafloor knolls called the Okinoyama Bank Chain are aligned in the eastern slope of the NW trending Sagami Trough. Existence of the Sagami Tectonic Line is estimated at the slope base and interpreted as a tectonic boundary of a subdution zone (Kimura, 1973, Kagaku). Ohkochi (1990, Chigaku Zasshi) reported active faults and an anticlinal fold based on seismic profiles. An eastward dipping reflector is recognized at the southeastern extension of the Kozu-Matsuda Fault by onshore-offshore integrated seismic imaging and interpreted as a splay fault of the plate boundary fault (Sato et al., 2010, Annual Meeting abstract of the Geological Society of Japan). However, Deformation of shallow sediment recording recent activity has not been clarified. The purpose of this study is to reveal recent fault activity by high resolution subbottom survey and sediment sampling. We carried out deep towed subbottom survey and pinpoint sediment sampling by remotely operqated vehicle NSS in the southwest slope of the Misaki Knoll during the Hakuho-maru cruises KH-10-3, KH-11-9 and KH-16-5. NSS can take piston cores at pinpoint accuracy by four propeller thrusters, video cameras and a payload fuck. Deep towed subbottom survey can obtain high resolution subsurface structure by pinging 1.1 to 1.6 kHz chirp frequency and receiving near the seafloor. Subbottom profiles across the southwest slope base of the Miura Knoll show a reflector suggesting a fault plane at the scarp base. The reflector dips 30 degree to northeast. Although the hanging wall shows structureless, the foot wall exhibits horizontal reflectors or chaotic suggesting talus deposit. We successfully obtained a 6-meter-long core after confirming a dipping reflector of a possible fault plane. The upper 1.2 meters of the core sample consists of alternation of dark green silty mud and pebbly mud with shell fragments of Calyptogena fossils. Thin silt layers are intercalated with dark green clay at about 15 cm intervals. A 5-mm thick zone, which suggesting a fault plane and consists of silty mud and granule size clasts, is recognized at 2.25 m from the core top. This zone, dipping 30 degree toward north to east after paleomagnetic restoration, is interpreted to correspond to the reflector of the fault plane on subbottom profiles. We also present shallow subsurface structures around the Miura Knoll.

Fault Distribution and Structural Characteristic in the Nankai Trough Area, Japan

*Rei Arai[1], Narumi Takahashi[1], Minako Katsuyama[1], Shigeyoshi Tanaka[1], Hiromi Kamata[1], Tomoyuki Sato[2], Takahiko Inoue[2], Yoshiyuki Kaneda[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Institute of Advanced Industrial Science and Technology, 3. Kagawa University

As part of “The Comprehensive Evaluation of Offshore Fault Information Project” by the Ministry of Education, Culture, Sports, Science and Technology, JAMSTEC has conducted collecting marine seismic reflection/refraction data, bathymetric data, well data acquired within the Japan EEZ and surrounding areas, and assembling a database to serve data for future scientific research.

Data includes 1) seismic reflection/refraction data acquired by JAMSTEC, AIST(Japan Geological Survey), and Japan Coastal Guard for purposes of geological investigation and research, and 2) seismic reflection data acquired for purposes of oil and gas exploration by Ministry of Economy, Trade and Industry and Japanese oil companies.

Since 2D multichannel seismic reflection were acquired and processed according to survey standards of the early era to the recent, the original data were re-processed by applying the state-of-the-art data processing methods to obtain unified high-quality seismic profile which capable of interpreting subsurface structures and fault morphology. Within the Nankai Trough and the Izu-Ogasawara area more than 180,000 km of 2D single/multichannel data and 4,800 km^2 of 3D multichannel data was collected to set for geological interpretation.

To identify a fault which caused earthquakes in geological history, a seismic profile must show not only geomorphological feature but also subsurface displacement or flexure in sedimentary layers and bed rocks. In order to determine the fault surface and morphology, the same structure must exist on other successive profiles, and bathymetric data also helps to trace lineament caused by fault activities.
The Nankai Trough is a part of plate boundaries where the Philippine Sea Plate subducts beneath the overlying the Eurasian Plate, and seismic reflection/refraction studied have been conducted to reveal the structure of the plate boundary and to understand the mechanics of seismic hazards. This project allows to use widely acquired data from scientific purposes to economic purposes in the Nankai Trough area, and as a result, the preliminary fault distribution on the area has been mapped. Offshore of Hamamatsu, Shizuoka Pref., seismic reflection profile shows compressive structures of the two known fault zones, the Enshu fault system and the Kodaiba fault system, which extends to offshore of Shima, Mie pref. Seismic reflection profiles which cross the trough shows that the beneath the forearc basin deposits and the old accretional prism a seismic reflector that dips landward iles just above the oceanic crust. This reflector is known as the spray fault (e.g. Park et al., 2002) and can be traced in other profile, with length of more than 50km.Off the Shikoku island to Hyuganada, seismic reflection data show very complex structures such as subsiding of a seamounts and ridges or mud domes which form along faults.

Seismicity in the central Ryukyu Trench by the Ocean Bottom Seismometers

*Ren Yakabu[1], Mamoru Nakamura[1], Yusuke Yamashita[2], Masanao Shinohara[3], Tomoaki Yamada[3], Hajime Shiobara[3], Kimihiro Mochizuki[3]

1. University of the Ryukyus, 2. DPRI, Kyoto University, 3. ERI, Tokyo University

We investigated the seismicity in the central Ryukyu Trench from the island of Amami to Okinawa between January 2015 and September 2016. Five ocean-bottom seismometers (OBSs) and 20 short-period seismometers of the Japan Meteorological Agency (JMA) were used. We analyzed the events with JMA magnitude over 3.0, which occurred near the trench running from Amami to Okinawa. The P and S arrivals were selected using the WIN system.

Subsequently, we determined the hypocenters. To achieve this, we first revised the 1-D velocity structure model in this region. For the velocity structure in the island arc area, we calculated the 1-D velocity structure with the Joint Hypocenter Determination method using the software VELEST (Kissling et al., 1994). We implemented the original model (JMA2001) first, then we adopted the revised model for the calculation of the travel time to the JMA stations. For the velocity structure beneath the OBSs, we built the velocity model based on a refraction survey performed near Okinawa (Kodaira et al., 1996; Nishizawa et al., 2017). Subsequently, we selected the PS-P time differences at each OBS station and computed the sediment layer correction. Using these values, we adopted the hypocenter determination modifying the software hypomh.

In addition, we investigated the seismicity for the earthquake swarm that occurred near the trench axis from May to June 2016. The swarm began with a M 5.7 earthquake at 12:44 (JST) on May 27th, 2016. We identified the P-S time difference of the earthquakes which were recorded at the NS02 of the OBS station from April 1st to May 27th, 2016.

The relocated hypocenters were shallower compared to those in the JMA catalog by 20-30 km, on average. The change in the depth is larger (approximately 60 km) near the trench axis. The relocated epicenters changed slightly with respect to the JMA epicenters in almost area near the trench. However, the relocated epicenters in the south of Okinawa moved trench-ward compared with the JMA epicenters.

In the P-S time diagram of the period preceding the 2016 earthquake swarm, we identified events with short-duration of P-S times approximately 12 h before the start of the swarm. Although this would constitute a foreshock activity of the swarm, it had not been recorded by the JMA seismic network. This suggests that the earthquake swarm had a precursor activity.

Seismic structure of subducted Philippine Sea plate beneath Kyushu inferred from Po/So waves

*Azusa Shito[1]

1. Institute of Seismology and Volcanology, Kyushu University

Po/So waves are oceanic Pn/Sn phases that are characterized by their high-frequency (f>2.5 Hz) content, long-duration, and great travel distances (up to 3000km) through the oceanic lithosphere [e.g., Linehan, 1940; Walker, 1977, 1982]. In our previous study [Shito et al., 2013], we demonstrated that Po/So waves develop from the multiple forward scatterings of P and S waves in oceanic lithosphere due to the laminated small-scale heterogeneities. Shito et al. [2015] analyzed Po/So waves in the Philippine Sea Plate, which consists of three regions with different lithospheric ages. They found that Po/So waves propagate more effectively in older regions and demonstrated that the increase in propagation efficiency of Po/So waves depending on the age of the oceanic lithosphere can be qualitatively explained by thickening of the oceanic lithosphere including small-scale heterogeneities and a reduction in the intrinsic attenuation. This study showed that Po/So waves are powerful tool to explore structural variations of the oceanic lithosphere.

Recently, such structural variations (e.g., thickness) of the incoming oceanic lithosphere are supposed to affect seismic and volcanic activity of the subduction zone [Yamamoto et al., 2013; Shibata et al., 2014]. However, it is poorly known that such structural variations of the oceanic lithosphere remain or dissipate after the subduction. In this study, we investigate the structural variations of the subducted Philippine Sea plate by using Po/So waves. We analyze Po/So waves from the earthquakes (mb>3.0, depth>50 km) that occurred in the subducted Philippine Sea slab beneath Kyushu. We compare Po/So waves propagating through different portion of the subducted Philippine Sea Plate and discuss the relation between observed features (velocity and energy) of the Po/So waves and the structural variations of the Philippine Sea plate. We verify that Po/So waves trace deeper extension of Kyushu-Palau Ridge (KPR) that is subducting beneath the Hyuga-nada region.

Acknowledgments
The data analyzed in this study were obtained from Hi-net (NIED) stations in Kyushu. The source parameters of the earthquakes were provided by JMA. This work was supported by JSPS KAKENHI Grant Number JP18K03807.

Slope failure features and their distribution in the forearc off northwestern Sumatra

*Kenji Hirata[1], Toshiya Fujiwara[2], Ayanori Misawa[3], Kohsaku Arai[3]

1. National Research Institue for Earth Science and Diaster resilience, 2. Japan Agency for Marine-Earth Science and Technology, 3. National Institute of Advanced Industrial Science and Technology

In Feb. 2005 and Oct. 2009, we conducted multi-narrow beam bathymetric (MNB) surveys during NT05-02 cruise with R/V Natsushima (NT05-02 scientific party, scientific party,http://www.jamstec.go.jp/jamstec-e/sumatra/ natsushima/bm/contents.html)and KY09-09 cruise with R/V KAIYO (Hirata et al.,2012, JAMSTEC report), respectively. Apporox. 1 degree angular intervals of multi narrow beams with both the R/Vs makes us possible to retrieve detailed bathymetry with high resolution of ~35 meters in azimuthal direction for seafloor of ~2000 meters in water depth beneath ship tracks. Hirata et al. integrated these multi-narrow beam bathymetric data to construct detailed bathymetric data (grid data of ~37 meters interval for the surveyed area with ~50 km x ~100 km, surrounded by latitudes 3˚50’ N and 5˚00’ N, and longitudes 93˚10’ E and 94˚10’ E). In this study, we identify slope failure features in the forearc region off the northwestern Sumatra, and discuss its spatial distribution in terms of the geological processes.

To identify bathymetric features clearly, we make four kinds of maps as follows; slope angle map, slope angle change map, slope (direction) azimuth map, as well as plain bathymetric map. Slope angle is defined by arctangent of dz/ds, where z is the water depth and s is unit distance vector projected the steepest descending direction on horizontal plain. Slope angle change is defined by arctangent of second derivative of a unit distance vector s. Slope (direction) azimuth is defined by arctangent of dx/dy, where x and y are due east and due north components, respectively, of unit distance vector projected the steepest descending direction on horizontal plain. As a sample, we show figures consisting of slope angle map ((b) in Fig), slope angle change map (c), slope (direction) azimuth map (d) as well as plain bathymetric map (a) for a small rectangular region in the forearc off northwest Sumatra. We finally interpret such kinds of maps to identify slope failure features, etc (e).

We can identify the upper portion of slope failure structures with an elevation difference of about 1 km which bounded the western edge of the outer arc high, although we cannot retrieve bathymetry of the Sumatra Trench at ~ 4500 meters water depth because the multi-narrow beam survey systems can sounding up to less than 3000 meters. The slope failure structures are created by several to more than ten of successive landslides in the region shown in Fig. The landslide features show uneroded and sharp crowns, implying that the landslide features nearby the Sumatra Trench are created “recently” in geological time scale. Slope failure features with weak to strong rounded crowns come to appear as our sample point migrates landward. This can be explained from the formation process of the outer arc high off northwestern Sumatra ; thick, upper sedimentary layers in the top of subducting Indo-Australia plate that are stripped off at the toe of the forearc obduct onto the outer arc high so that accretional process proceeds (Mosher et al.,2008, Mar.Geol.; Misawa et al., 2014, EPSL).This means that landward (eastward) of the outer arc high is accreted older than its seaward (westward).

©2019. Japan Geoscience Union. All Right Reserved.

On the one hand, there are exceptions to such a geological rule; we can find several slope failure features with uneroded, sharp crowns in a landward region where many slope failure features with weak and strong rounded crowns exist (e.g., two slope failure structures with a width of ~ 1 km around a location of4° 06’ N, 93°39’ E). These relatively fresh failure structures existing landward of the outer arc high possibly relate to recent activation of major thrusts proposed in the outer arc high off northwest Sumatra (Hirata et al., 2010, AGU).

Origin and migration of fluid in the Sumatra subduction input: application of a geochronological method using a long-lived radioisotope of dissolved iodine

*Satoko Owari[1], Hitoshi Tomaru[1]

1. Chiba university

Iodine has a strong biophilic character and is highly enriched in organic matter in the marine environment. Organic matter is decomposed by thermogenic and microbial processes during the sedimentation and releases iodine into the interstitial water. Iodine has one stable isotope (^{127}I) and one long-lived radio isotope (^{129}I) with the half-life of 15.7 Myr. Therefore, the ^{129}I/^{127}I ratio of marine interstitial water has been used for identifying the origin of fluid. We applied iodine geochronology to the interstitial waters extracted from the deep drilling cores recovered by IODP Exp. 362, where Sumatra subduction input sediments develop more than 1400 m without major fractures. The concentration and isotopic ratio (^{129}I/^{127}I) of iodine dissolved in the interstitial water were analyzed in order to characterize the source and potential age of iodine prior to the subduction and examine the basic geological factors controlling the fluid migration in the input sediment body.

Concentrations of iodine and methane increase and TOC decreases toward 200 meters below seafloor (mbsf) and 1250 mbsf, which indicate degradation of organic matter around that depth and subsequent release of iodine and methane into the interstitial water. Iodine gradient is controlled by the degradation of iodine-rich organic matter microbially in shallow sediment (at 200 mbsf) and geothermally in deep sediment (at 1250 mbsf), respectively. The ^{129}I/^{127}I ratios between 0 and 400 mbsf vary between 300 $\times 10^{-15}$ and 800 $\times 10^{-15}$, and the lowest ratio of 300×10^{-15} is found at 175 mbsf. There are some thick sand layers > 60 meters between 0 and 400 mbsf. These porous layers transport allochthonous dissolved iodine and interstitial water, which are relatively old. However ^{129}I/^{127}I of 1300×10^{-15} at 67 mbsf corresponding to the sediment age of 3 Ma at 200 mbsf which is the zone of degradation of organic matter. ^{129}I/^{127}I between 400 to 1480 mbsf decrease from 700 $\times 10^{-15}$ to 400×10^{-15}, resulting from mixing with deep (old) iodine and shallow (young) iodine. In the input sediment, iodine gradient is strongly controlled by degradation of organic matter and the migration is controlled by vertical diffusion which indicates poor fluid migration or slow migration rate. However, the horizontal advection/migration of interstitial water is significant within the thick-porous sandy layers.

Challenge to Future Deep-Water Mapping: Unmanned Bathymetric Survey Competition "Shell Ocean Discovery XPRIZE"

*MASANAO SUMIYOSHI[1]

1. Hydrographic and Oceanographic Department, Japan Coast Guard

Unmanned survey technology is utilized in the world of bathymetric survey in the present age, when unmanned technologies are developing in various fields. Especially Autonomous Underwater Vehicle (AUV) is actively used in order to acquire high resolution bathymetric data in the deep waters. The technological innovation is needed to further advance the unmanned and automated deep-water mapping, including AUV operations of launch and retrieval. In order to encourage such innovation, an international competition of unmanned deep-water mapping, "Shell Ocean Discovery XPRIZE" has been held for 3 years.
The University of New Hampshire actively develops many hydrographic and oceanographic survey technologies that will open a new era, and as a part of these efforts GEBCO-NF Alumni Team challenges the international unmanned deep-water competition. The author has been strongly pushing the research and development of technology of bathymetric survey for this challenge as a member of this team, who was studying abroad to this university until 2017 to learn the latest hydrographic survey technologies.
This team had passed through Round 1 (semi-final: ~ 2000 m) held in November 2017, and challenged Round 2 (final: ~ 4000 m) as one of the finalists in the last November. In this paper, we report our efforts and achievements of the GEBCO-NF Alumni team, including those in Round 2.

Prototype of deep-sea ocean bottom pressure recorder with self-calibration capability using “A-0-A” approach for detection of long-term crustal deformation

*Yusaku Ohta[1], Ryota Hino[1], Syuichi Suzuki[1], Makiko Sato[1], Yui Nishimagi[1], Hiroaki Kajikawa[2], Tokihiko Kobata[2]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University, 2. National Metrology Institute of Japan, National Institute of Advanced Industrial Science and Technology

Ocean bottom pressure gauge (OBP) can continuously observe the vertical crustal deformation in the seafloor. However, a nature of long-term drift of pressure sensors causes a serious problem in detection of the long-term crustal deformation. A possible approach to remove the sensor drift on the sea-floor is to use a dead-weight tester as the pressure standard to make in-situ calibration on the seafloor by periodically switching between the ambient pressure and the reference pressure (Sasagawa et al. 2016). Recently, an alternative approach, an “A-0-A” method, using the internal pressure of the instrument housing as the reference pressure was proposed (e.g. Wilcock et al., 2018). We investigated the long-term drift behavior and ability of “A-0-A” method by a laboratory experiment using dead-weight tester as a pressure standard (e.g. Nishimagi et al. AGU fall meeting, 2018). We regard the reading at high applied pressure as ambient pressure point (“A”) and that at atmospheric pressure as zero-point (“0”). Although the residual time series between the “A” and “0”, however, showed small discrepancy, we found drift characteristics of “A” and “0” are basically similar to each other.

Based on these laboratory experiment results, we have started to develop a proto-type of ocean bottom pressure recorder with self-calibration capability using “A-0-A” approach for deep-water (up to 7,000 m) deployment. We install all the equipments including a pressure sensor in a 17-in glass sphere. To measure both of the internal and external (water) pressure by a single sensor, we adopt 3-way a ball valve controlled by an electric actuator in front of the sensor, as in the previous self-calibrating system using a dead-weight tester. The actuator is operated by the microcomputer to switch by arbitrary interval. We also install alternative barometer to compare the internal pressure value recorded by the pressure sensor. The development is still under way, and we will show more detail characteristic of the prototype system and its potential abilites.

To achieve better performance of broadband ocean bottom seismometer (BBOBS) survey, we applied noise reduction analysis and dispersion measurements to the vertical component seismograms of the Normal Oceanic Mantle (NOMan) project arrays, which are previously analyzed by Takeo et al. (2018). Our noise reduction targets on the tilt noise that is significant for low-frequency (<0.1 Hz) BBOBS vertical records. Tilt noise is generated by the seafloor current which flows pass the BBOBS. It originally only dominates horizontal records, but the misalignment between the seismic sensor's vertical axis and gravitational direction allows projection of noisy horizontal tilt noise onto vertical records. Hence, vertical tilt noise can be estimated from the transfer function between horizontal and vertical records (Crawford and Webb, 2000). We developed a noise reduction method which is suitable for Japanese BBOBS based on the approach of Crawford and Webb (2000) and Bell et al. (2015). By performing noise reduction analysis, we achieved about 20 dB noise reduction at the frequency lower than 50 mHz and extracted lots of buried seismic signals. To verify the effect of noise reduction analysis, we compared array dispersion measurement results which derived from tilt noise removed and non-removed data. Using the method of Takeo et al. (2018), we measured average phase velocity and azimuthal anisotropy of fundamental mode Rayleigh waves to estimate isotropic and azimuthally anisotropic Vsv (βv) profiles. The results show that tilt noise removed data can provide us with more precise low-frequency measurements and the better-constrained structure at a depth of 80 km or deeper. Our results indicate that noise reduction preprocessing is important for improving Japanese BBOBS analysis.

High-tech dredge system for abyssal bedrock research; dredge system with acoustic real time monitoring on deep sea floor.

*Teruaki Ishii[1], Yukihiro - Kida[2], Izumi - Sakamoto[3], Shiki -- Machida[4]

1. Center for Integrated Research and Education of Natural Hazards, Sizuoka University, 2. JAMSTEC, 3. Toukai University, 4. Chiba Institute of Technology

It is very important to recover geological samples including hard rocks and soft materials from ocean floor to investigate bedrocks itself as well as sea floor environment on the basis of the material scientific aspects. Dredge haul methods being a simple and easy way with low costs, have been widely used for recovering the bedrocks. One of author (TI) has been working on the dredge hauls during about 40 years on the several Japanese and American Research Vessels (R/Vs), that is, R/V Tansei Maru, R/V Hakuho Maru, R/V Yokosuka, and R/V Kairei as well as R/V Atlantis-II, R/V Melville (2 times), R/V Moana Wave, and R/V Thomas Thompson, respectively. He has been proposing the (1) ORI-TI type dredge system, which has been improved and still improving on the basis of the better ideas gathered from the above mentioned all cruises. The dredge systems in the US Research Vessels have been continuing the conventional and basic technical methods, that is, box type chin-bag dredge (within or without fishing net) and using tension-meter as well as pinger.

On the other hand, Japanese scientists have been recently improving the traditional dredge systems with active introduction of high technique, for example, (2) transponder system and/or (3) deep sea TV camera system during dredge hauls. (4) new underwater acoustic transmission system of real-time TV-image.

(1)ORI-TI (Ocean Research Institute T. Ishii) type dredge system is composed of box type chain-bag dredge with steel bucket which can recover any sea bottom material including hard rocks as well as sand, mud and organisms(Ishii, 2017).

(2)Acoustic transponder attached on the dredge wire can mention real-time position of the dredge system on monitor showing pre-surveyed bathymetric map in the navigation room, This system helps safe and reliable rock sampling (Machida et al, 2011).

(3) Box-cage type dredge with installed deep sea TV camera system can record occurrence of bed rocks during dredge hauls (Sakamoto et al, 2017).

(4) New underwater acoustic transmission system of real-time TV -image with every 2 second from Shinkai 6500 to R/V Yokosuka put to practical use (Sakurai, 2018) on the basis of the new underwater acoustic communication system (Kida et al, 2018). If we can get low price (about USD$10,000) above mentioned system in a near future, it will be applied to the dredge hauls with real-time monitor on the sea bottom. The author (T.I.) assumes that its application fields are very wide; piston core, mooring system, ocean bottom seismometer, net fishing etc.

Construction of Database System on Offshore Faults around Japan

*Hiromi Kamata[1], Narumi Takahashi[1,2], Shigeyoshi Tanaka[1], Rei Arai[1], Minako Katsuyama[1], Ayako Nakanishi[1], Hiroyuki Fujiwara[2], Tsuneo Ohsumi[2], Takahiko Inoue[3], Tomoyuki Sato[3], Yoshiyuki Kaneda[4]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Research Institute for Earth Science and Disaster Resilience, 3. National Institute of Advanced Industrial Science and Technology, 4. Kagawa University

JAMSTEC has performed the project for “Comprehensive Evaluation of Offshore Fault Information” sponsored by the Ministry of Education, Culture, Sports, Science and Technology (MEXT) since FY2013. The project consists of three themes named “Sub-theme 1” gathering various kinds of existing geological/geophysical information and constructing offshore fault database system (DB), “Sub-theme 2” re-processing seismic data and interpreting offshore faults based on unified evaluation standard, and “Sub-theme 3” building offshore fault models conducted by NIED.

In Sub-theme 1, JAMSTEC has obtained or borrowed huge volumes of multi-channel seismic (MCS)/single-channel seismic (SCS) reflection data and ocean bottom seismometer (OBS) refraction data surveyed around Japan from various organizations including national research institutes and private enterprises, and has collected seismic velocity information, bathymetry data etc. After the quality check of these data, they are made into a database and unitary management of them are carried out. The final output of Sub-theme 1 is an offshore fault DB comprising the data sets of collected/re-processed seismic data and overall offshore fault information provided by Sub-theme 2 and Sub-theme 3. In Sub-theme 2, the past old-fashioned MCS data have been re-processed applying the latest sophisticated technology with de-multiple filtering and noise suppression for obtaining the high resolution profile of these seismic sections. Using the MCS/SCS data, offshore faults around Japan have been identified based on unified evaluation standard. Some geological horizons and a plate boundary have been also interpreted to model subsurface geometry and 3D velocity structure. The final output of Sub-theme 2 is to delineate the spatial distribution and continuity of identified faults on the high resolution bathymetric map such as a red relief image map, and to organize their features/parameters such as type, length, dipping direction, extension etc. after the seismic time–depth conversion using 3D velocity structure model. The 3D velocity structure has been modeled using collected OBS refraction data, velocity analysis results in MCS re-processing and some available published data. In Sub-theme 3, NIED has built the offshore fault models based on a fault information catalog completed by Sub-theme 2. The model validation for historical earthquake source faults with the magnitude over seven has been also conducted through ground motion and tsunami simulations.

This poster presentation focuses on the offshore fault DB constructed by Sub-theme 1 of the project. JAMSTEC has finished the clarification of faults in the Sea of Japan, and around the sea area of the Nansei Islands and Izu-Ogasawara Islands by FY2017. We are currently working on the interpretation of subsurface structure and fault distribution in the Nankai Trough area, and continue to register MCS/SCS reflection time/depth sectional figures, 3D velocity models, NIED’s fault models and their parameters into the DB sequentially. The trial operation of the DB has been also done at the subcommittee of the Headquarters for Earthquake Research Promotion of MEXT. The DB is highly expected to become a useful tool that contribute to tsunami hazard evaluation and disaster management conducted by Japanese government and local authorities, and that improve the public awareness against disaster prevention.

An integration method for multiple sets of seafloor backscatter intensity data

*Shiki Machida[1,2], Taichi Sato[3], Kazutaka Yasukawa[2]

1. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology, 2. University of Tokyo, 3. AIST

Acoustic backscattering of the seafloor is thought to provide a useful signal representing the existence of hard materials, such as lava flows with ferromanganese crust along the slope of seamount or knoll [1, 2], and ferromanganese nodules on the seafloor [3]. Previous investigations using vessel-equipped multi-narrow beam echo sounder (MBES) [1–3] identified variations of distributions over an area of tens or hundreds of square kilometres. Therefore, vessel-equipped MBES can provide a more economical exploration for vast areas than that provided by underwater apparatuses such as a deep-towed side scan sonar. However, a disadvantage inhibiting its use is that the different physical and technical parameters, such as sounder characteristics, observation period, and processing, yield different absolute values of backscatter intensity for the same area. As a solution, we propose a generally applicable method for obtaining the widespread distribution of deep-sea solid materials using a combination of several datasets of vessel-equipped MBES.

The Japanese exclusively economic zone (EEZ) around Minamitorishima Island in the western North Pacific is the best candidate area in which to analyse vessel-equipped multibeam backscatter data. This is due to the fact that several research cruises, operated by the Japan Agency for Marine-Earth Science and Technology (JAMSTEC), have obtained multiple sets of backscatter data, combined with bathymetry mapping. These data were obtained with an identical MBES (SeaBeam 3012. multibeam system) for each of the four cruises of *R/V Mirai*(MR14-E02, MR15-E01 Legs 2 and 3, and MR15-02) in 2014 and 2015, and with the other MBES (SeaBeam 2112.004 multibeam system) during a cruise of *R/V Yokosuka* (YK10-05) in 2010.

We identified two important components for successfully integrating several sets of backscatter intensity data collected by vessel-equipped MBES, as follows. (1) The folding points in the trend of the second-order differential values of the histogram of backscatter data correspond to the boundaries between different types of geology, e.g. barren pelagic sediment and dense ferromanganese nodules. (2) These thresholds each indicate that the same geologic boundaries appear at similar intervals in the histogram, even if the absolute values of intensity are different for each dataset. In particular, this latter component ensures linear fitting of the thresholds used to adjust each dataset to the arbitrary standard data. We need the confirmation of the geographical distributions of the identified boundary intensities between the different datasets. In this presentation, we will show an example of data integration for nine datasets to map the backscatter intensity of a region of approximately 155,500 km^2in the Japanese EEZ around Minamitorishima Island.

A precise calculation of average depth for ETOPO1

*Yasushi Harada[1], Sae Horiuchi[1]

1. School of Marine Science and Technology, Tokai University

NOAA calculated global ocean average depth as -3688m (https://www.ngdc.noaa.gov/mgg/global/etopo1_ocean_volumes.html) , but in their method, there are deviations for distribution of sampling points, especially at high latitude area. Generally, perfect uniform sampling points are needed to calculate precise average depth using digital elevation data such as ETOPO1.

We tried a different method for creating uniform sampling points on spherical surface. Yamaji(2001) created this software called GSS generator(GSS). The GSS makes almost perfect uniform sampling points on sphere, but not on WGS84 ellipsoid. Therefore we compared the two methods, and performed a statistical analysis for both methods.

We found that the two methods produced similar average depth values and the errors, and that the average depth of ETOPO1 is 3685.9 ±0.5m and about 2m shallower than NOAA’s 3688m value.

[J] Oral | S (Solid Earth Sciences)：S-CG Complex & General

Mon. May 27, 2019 10:45 AM - 12:15 PM JST | Mon. May 27, 2019 1:45 AM - 3:15 AM UTC | A05 TOKYO BAY MAKUHARI HALL

[S-CG60] Investigation of inputs to subduction zones: Influence of tectonic processes on the incoming plate

convener:Makoto Yamano(Earthquake Research Institute, the University of Tokyo), Tomoaki Morishita(School of Geoscience and Civil Engineering, College of Science and Technology, Kanazawa University), Gou Fujie(Japan Agency for Marine-Earth Science and Technology), Chairperson:Shigeaki Ono(Japan Agency for Marine-Earth Science and Technology)

Various tectonic processes occur on the seaward side of the trench associated with bending of the incoming oceanic plate, e.g., fracturing of oceanic crust, infiltration of water, and intraplate volcanism. Investigation of these processes and their influence on the incoming plate provides important information on the boundary condition at the trench, inputs to subduction zones. Variation in inputs should significantly affect geophysical/geological phenomena around the plate interface and geochemical cycles in subduction zones. We welcome contributions from a broad range of earth science (geophysics, geology, petrology, and so on) discussing topics related to inputs to subduction zones such as occurrence of tectonic processes due to bending of the incoming plate, modification of the incoming plate by the processes, relationship between the processes and the inherited structure of the incoming plate, and influence of the processes on the subduction plate interface. We hope discussions are made on studies of a variety of subduction zones, including the Japan Trench and the Nankai Trough, and comparative studies among different subduction zones.

The Chile triple junction (CTJ) is a unique place where a spreading center of mid-ocean ridge is subducting near the Taitao peninsula. Around CTJ, presence of high heat flow on the continental slope (Cande et al., 1987, J. Geophys. Res.) and near-trench young granitic rocks on the Taitao peninsula (Anma and Orihashi, 2013, Geochem. J.) suggests the thermal and petrological impact of subducting ridge on the continental side. The tectonic history of the southeast Pacific since early Cenozoic to the present suggests that ridge subduction continuously occurred along the Chile trench, which migrated northward (Cande and Leslie, 1986, J. Geophys. Res.), which can contribute to growth of the continental crust (Iwamori, 2000, EPSL).
In January 2019, the MR18-06 cruise Leg 2 was conducted at the Chile Triple Junction, as a part of 'EPIC' expedition by using R.V Mirai of JAMSTEC. During the leg, we completed 4 SCS lines, 6 piston coring, 6 heat flow measurements, 2 dredges, and underway geophysics observations, as well as deployment of 13 OBSs. The primary object of heat flow measurement at CTJ is to better constrain the thermal regime around CTJ by adding new data right above CTJ. The key question is whether CTJ is thermally dominated by ridge activity (magmatic, tectonic, and/or hydrothermal) or by subduction initiation (tectonic thickening, accretion, and/or erosion). The ultimate goal is to model the temperature at the plate interface from the heat flow and other data, and to infer how the thermal regime at CTJ contributes the seismogenic behavior at the M~9 megathrust zone.
Our preliminary analysis shows high and variable heat flow around CTJ. It is generally consistent with previous heat flow along line 751 (Cande et al., 1987). With SCS and piston core data, a reasonable thermal model can be constructed around CTJ. (Acknowledgment) we thank the Hydrographic Department of Chile (SHOA), for allowing to enter the Chilean EEZ and territory for our survey.

Heat flow measurement on the seaward side of the Kuril Trench off Hokkaido

*Kouta Sasaki[1], Makoto Yamano[1], Yoshifumi Kawada[2], Masataka Kinoshita[1], Kiichiro Kawamura[3]

1. Earthquake Research Institute, the University of Tokyo, 2. International Research Institute of Disaster Science, Tohoku University, 3. Yamaguchi University

To understand thermal structure of subduction zone, heat flow on the surface of incoming oceanic plate serves as an important boundary condition. On the surface of oceanic plate, observed value of heat flow is generally consistent with prediction of the plate cooling model (e.g., Stein and Stein, 1992). Yamano et al. (2014) revealed extensive high heat flow anomaly on the seaward side of the Japan Trench, where the very old Pacific plate (~135 Myr) subducts beneath northeast Japan, and some possible causes of the anomaly have been examined. Fujie et al. (2013, 2015) pointed out seismic velocity structure anomalies in the crust and the uppermost mantle seaward of the Japan and Kuril trenches and attributed them to increase in water content as a result of bending of the incoming oceanic plate. Kawada et al. (2014) examined influence of hydrothermal circulation in a permeable layer in the oceanic crust as a possible source of the high heat flow anomaly. They showed that hydrothermal circulation in the permeable layer thickening toward the trench axis in concordance with the seismic velocity anomaly pumps up heat efficiently and raises heat flow on the seafloor.

Infiltration of water into the crust is inferred seaward of the Kuril Trench as well based on the seismic velocity anomaly. Nakanishi (2011) argued that the direction of bending-related faults on the oceanward slope of the Kuril and Japan trenches is well correlated with the angle between the trench axis and the ancient spreading ridge axis, which varies along the trenches. It is also speculated that the trench-ridge angle is a major controlling factor of incoming plate hydration (Fujie et al., 2018). These studies suggest that it is indispensable to examine heat flow distribution seaward of the Kuril Trench, where few data have been obtained, for investigation of water and heat transport processes associated with plate bending.

In this study, we conducted heat flow measurement on the seaward of the Kuril trench off Hokkaido on KH-18-5 cruise of R/V Hakuho-maru. We measured geothermal gradient with a 3 m long temperature probe at eight sites and with a piston corer at four sites within about 120 km of the trench axis. We attempted penetration of the temperature probe several times at each site at intervals of 300 to 500 m. Few penetrations were successful within 60 km of the trench axis probably because thick layers of volcanic ash prevented the probe from penetrating into the sediment. Thermal conductivity was measured on piston core samples.

Most of the obtained 25 new heat flow values are roughly consistent with typical values for ocean basins older than 100 Myr (~50 mW/m^2), while high heat flow, 90 to 100 mW/m^2, was observed at one station about 70 km from the trench axis. This result indicates that the degree of heat flow anomaly on the seaward side of the Kuril Trench is lower than that in the counterpart of the Japan Trench.

Comparison of experimental and intermediate-depth earthquake b-value: difference in hydration degree of the oceanic mantle between Tohoku and Hokkaido

*Saeko Kita[1], Thomas P. Ferrand[2]

1. International Institute of Seismology and Earthquake Engineering, BRI, 2. ERI, University of Tokyo

We examine b-values of the lower-plane events than beneath Tohoku. Using the acoustic emission (AE) experimental result, the b-values for intermediate-depth intraslab earthquakes in the Pacific slab beneath the Tohoku and Hokkaido regions, northeastern Japan and find a difference in the b-values of lower-plane events in the double seismic zone. Lower-plane events reveal significantly larger b-values beneath Tohoku (0.96) than Hokkaido (0.86), implying that the brittle deformation beneath Hokkaido is more localized and leads to higher ratio of relatively large lower-plane events by Ferrand et al. [2017, Nature Communications], we also found that the b-values for experimental earthquakes increase with increasing antigorite content in serpentinized peridotite. A comparison of experimental and natural earthquake b-values implies that lower- plane peridotite is more hydrated beneath the Tohoku region, which is consistent with the difference in oceanic-plate velocity structures near the trench identified in Ocean Bottom Seismometer studies off Tohoku and Hokkaido by Fujie et al. [2017, Nature communications]. Since the density of fracture zones offshore Tohoku is larger than offshore Hokkaido, the extent of hydration of the oceanic mantle beneath Tohoku could be larger than beneath Hokkaido.

Variations in bend faulting and the nature of the incoming oceanic plate off northeast Japan arc

*Gou Fujie[1], Koichiro Obana[1], Yojiro Yamamoto[1], Tomoaki Yamada[2], Takehi Isse[2], Shuichi Kodaira[1], Seiichi Miura[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Earthquake Research Institute, Univ. of Tokyo

As the inputs to subduction zone, the nature of the incoming oceanic plate, such as relief, thermal state, lithology, and the water content, affects subduction zone processes, including arc magmatism and interplate and intraplate seismic activities. Thus, regional variations in the nature of the incoming oceanic plate have a potential to cause regional variations in such subduction zone processes.

To reveal the nature of the incoming oceanic plate and its regional variations off northeastern Japan arc, we have conducted extensive controlled-source seismic experiments at the northwestern margin of the oceanic Pacific plate. First, we conducted seismic experiments at around the junction of the Kuril and Japan trenches. We observed seismic structural changes owing to the plate bending-related faults just prior to subduction at both trenches and found the structural changes caused by bend faulting are more significant in the Japan trench side than that in the Kuril Trench side, indicating that plate hydration before subduction is remarkably higher in the Japan Trench than in the Kuril Trench. These observed differences can be explained by the type of the bend faults, newly created faults (Japan Trench) or reactivated abyssal-hill faults (Kuril Trench). As the type of bend faults are determined by the angle between the current trench and the ancient spreading ridge, this angle is one of key factors controlling the hydration of the incoming oceanic plate.

In 2017 and 2018, we conducted additional seismic experiment at the trench-outer rise areas of the southern Japan Trench off Fukushima. This was our first seismic survey in the trench-outer rise region of the southern Japan trench. The strike of the Japan trench differs between the northern part and the southern part, indicating that the angle between the current trench axis and the ancient spreading ridge also differs between the northern part and the southern part. In addition, unlike the northern part of the Japan trench, a large seamount chain exists in the trench-outer rise region of the southern Japan Trench. The primary aim of our new seismic survey in the southern part of the Japan Trench is to clarify the differences between the northern and the southern part of the Japan trenches.

We applied traveltime tomographic inversion to the wide-angle reflection and refraction seismic data and developed a P-wave velocity (Vp) model. The obtained Vp model clearly shows the reduction in Vp near the trench axis caused by bend faulting. The Vp reduction patterns are closely akin to that in the northern Japan trench area. The angle between the current trench and the ancient ridge axis differs between the northern and the southern Japan trench, but the type of bend faults are the same. Our new observation confirmed that the type of bend faults is a key controlling factor on the bend faulting and plate hydration prior to subduction.

In addition to the structural changes caused by bend faulting, we observed curious features in crustal Vp structure. In the area far from the trench axis off Fukushima, our Vp model shows velocity reversal within the oceanic crust which is suggested by the "shadow zones" of the crustal refractions. We have observed similar velocity reversal within the oceanic crust in the areas far off Iwate, but not in the areas far off Miyagi. These observations suggest that the oceanic crust are intrinsically inhomogeneous in the

©2019. Japan Geoscience Union. All Right Reserved.

northwestern part of the Pacific plate.

In this presentation, we will show the variations in the Vp model in the northwestern part of the Pacific plate including the structural changes caused by bend faulting and the velocity reversal within the crust, and discuss the possible impact as the subduction inputs.

Seismicity in the trench-outer rise region off Fukushima and Ibaraki, southern Japan Trench

*Koichiro Obana[1], Gou Fujie[1], Yojiro Yamamoto[1], Yuka Kaiho[1], Yasuyuki Nakamura[1], Seiichi Miura[1], Tsutomu Takahashi[1], Shuichi Kodaira[1]

1. Research and Development Center for Earthquake and Tsunami, Japan Agency for Marine-Earth Science and Technology

After the 2011 Tohoku-oki earthquake, seismicity within the incoming Pacific plate is active in the trench-outer rise region along the Japan Trench. These earthquakes were characterized by normal-faulting focal mechanisms and could provide information about potential source faults of large outer-rise normal-faulting earthquakes. We have conducted earthquake observations in the southern part of the Japan Trench, off Fukushima and Ibaraki region(36º—38º N) by using ocean bottom seismographs (OBSs). The observations were conducted from March to July, 2017. We have deployed 35 OBSs including 14 ultra-deep type OBSs, which can be deployed in the trench-axis area where the maximum water depth was about 7800 m. Earthquakes were detected from continuous OBS records and phase arrival times were picked manually. Then, we relocated earthquakes by using double-difference tomography technique. In the tomography analysis, we used the initial velocity model based on an active seismic study conducted in the study area. Finally, we have obtained hypocenter location of about 1400 earthquakes. We also estimated focal mechanisms by using P-wave first-motion polarities in vertical component seismograms. The results show several linear earthquake clusters in the trench-outer rise region extended in roughly N-S and NNE-SSW directions. Pre-dominance of the normal-faulting focal mechanisms indicate that the earthquakes in the trench-outer rise region were explained by bending-related normal-faulting. The earthquake cluster oriented N-S direction was almost parallel to the strike of the northern Japan Trench, whereas NNE-SSW oriented linear clusters were almost parallel to the strike of the southern Japan Trench. Although the strike of the Japan trench changes from N-S in the north to NNE-SSW in the south at around 38º N, linear clusters parallel to both directions suggest existence of the complicated fault system in the trench-outer rise region in this area. Previous OBS observations along the Japan Trench showed that there was almost no seismicity along the plate boundary and within the overriding plate closed to the trench axis. The trench landward seismicity close to the trench axis observed only within the subducting Pacific plate. However, shallow earthquakes, which could occur along the plate boundary or within the overriding plate, close to the trench axis were observed landward slope of the Japan Trench south of 36.7º N. Seafloor geodetic studies indicated that seaward motion in the landward slope along the southern part of the Japan Trench, while landward motion were observed along the central part of the Japan trench. The characteristic shallow seismicity beneath the landward slope close to the trench axis might relate to the different displacement of the trench landward slope in the southern part of the Japan Trench.

Influence of water–rock interactions on the strength of outer-rise faults

*Ken-ichi Hirauchi[1]

1. Department of Geosciences, Faculty of Science, Shizuoka University

Knowledge of the amount of water stored in oceanic plates is important for understanding subduction zone water budgets (e.g., Hatakeyama et al., 2017, *Sci. Rep.*). Beneath the outer rise, the incoming oceanic plate bends down into the trench, resulting in the formation of extensional normal faults (i.e., outer-rise faults). Seismic reflection studies have shown that these normal faults penetrate into the upper mantle and act as a permeable fluid pathway. How deep outer-rise faults can develop primarily depends on the depth extent of strain localization within the oceanic lithosphere. Infiltration of seawater into outer-rise faults may promote the growth of mechanically weak hydrous phases such as talc and serpentines, perhaps leading to further strain localization. In order to understand effects of water–rock interactions on the strength of the upper mantle, I have conducted high-pressure deformation experiments on simulated peridotite fault gouges in the presence of hydrothermal water (Hirauchi et al., 2016, *Nat. Commun.*). I found that at a temperature of 500˚C and a confining pressure of 1 GPa, the development of talc-bearing, localized shear zones leads to an order-of-magnitude reduction in strength. This finding indicates that water–rock interactions along outer-rise faults play a role in deepening the fault depth and increasing water budgets in the oceanic upper mantle.

[S-CG60] Investigation of inputs to subduction zones: Influence of tectonic processes on the incoming plate

convener:Makoto Yamano(Earthquake Research Institute, the University of Tokyo), Tomoaki Morishita(School of Geoscience and Civil Engineering, College of Science and Technology, Kanazawa University), Gou Fujie(Japan Agency for Marine-Earth Science and Technology), Chairperson:Makoto Yamano(Earthquake Research Institute, University of Tokyo)

Various tectonic processes occur on the seaward side of the trench associated with bending of the incoming oceanic plate, e.g., fracturing of oceanic crust, infiltration of water, and intraplate volcanism. Investigation of these processes and their influence on the incoming plate provides important information on the boundary condition at the trench, inputs to subduction zones. Variation in inputs should significantly affect geophysical/geological phenomena around the plate interface and geochemical cycles in subduction zones. We welcome contributions from a broad range of earth science (geophysics, geology, petrology, and so on) discussing topics related to inputs to subduction zones such as occurrence of tectonic processes due to bending of the incoming plate, modification of the incoming plate by the processes, relationship between the processes and the inherited structure of the incoming plate, and influence of the processes on the subduction plate interface. We hope discussions are made on studies of a variety of subduction zones, including the Japan Trench and the Nankai Trough, and comparative studies among different subduction zones.

The structure of an incoming oceanic plate influences various seismic behavior in subduction zones. In the outer-rise region of the Japan Trench, young intraplate volcanism, called “petit-spot” volcanism, has been reported (e.g., Hirano et al., 2006). However, to date, only a few geophysical studies have focused on petit-spot volcanism and its modifying effects on the structure of the oceanic crust. In 2017, Japan Agency for Marine-Earth Science and Technology (JAMSTEC) conducted an active-source seismic survey in the trench-outer-rise region of the Japan Trench during cruise KM17-05 of R/V *Kaimei* (Ohira et al., 2018). For refraction studies, a large tuned airgun array with a total volume of 10,600 cubic inches was towed at 10 m depth and fired every 100 m. The seismic data were recorded on 40 OBSs deployed along a 100-km-long line (line A4) with a spacing of 2 km. The multi-channel seismic (MCS) reflection data were collected by R/V *Kairei* using a 6,000-m-long, 444-channel streamer cable during cruise KR11-05 and KR15-07. On the MCS reflection section, we imaged opaque reflections at the top of the oceanic crust and a weak or absent Moho reflection under petit-spot volcanoes. The P-wave velocity model obtained from first-arrival traveltime tomography showed the large velocity reduction at the top of the oceanic crust near petit-spot volcanoes. This velocity reduction can be interpreted as fractures, hydration, and high porosity associated with petit-spot volcanic activity, as well as by the development of bend faulting (e.g., Fujie et al., 2018) and ancient fractures (Fujie et al., 2016). Our results suggest that petit-spot volcanism is one of the contributing factors leading to structural variation and modification of the incoming oceanic plate prior to its subduction. In 2018, additional new seismic reflection data from 25 –50 km interval of profiles were acquired during cruise KM18-06 of R/V Kaimei to cover the outer-rise region from 38°N to 36°N at the south of the petit-spot region. The new data provide along-strike structural variations attributed to petite-spot, bend fault and seamount.

Dependence of calculation parameters on tsunami height from the outer-rise earthquakes

*Toshitaka Baba[1], Naotaka YAMAMOTO CHIKASADA[2], Yasuyuki Nakamura[3], Gou Fujie[3], Koichiro Obana[3], Seiichi Miura[3], Shuichi Kodaira[3]

1. Graduate School of Science and Technology, Tokushima University, 2. National Research Institute for Earth Science and Disaster Resilience, 3. Japan Agency for Marine-Earth Science and Technology

Huge subduction zone earthquakes often induced outer-rise earthquakes occurring on the sea side from the trench axis. An outer-rise earthquake of M8 class which becomes a pair of the 2011 Tohoku earthquake has not yet been occurred. We should pay much attention on the next outer-rise earthquakes and resulting tsunamis in the Japan Trench. A data base (DB) retrieval type system is common for real-time tsunami prediction. It is necessary to incorporate various kinds of earthquake scenarios into DB without deficiencies. However, we have no clear answer to questions such as to how many every kilometer to be set in the depth of the fault stored in the DB in order to guarantee the prediction accuracy of a tsunami. Therefore, in this study, sensitivity analysis of calculation parameters was carried out for tsunamis caused by the outer-rise earthquakes.

We set nine basic fault models of the outer-rise earthquakes with reference to the results of crustal structure surveys and ocean bottom seismic observations. Each basic fault model was composed of multiple small subfaults of about 20 km in length, and the top end of the small subfaults were all set to be 0.1 km under the seafloor, the slope angle was 60 ˚, and the rake angle was 270 ˚. The strike angle of the subfaults were based on seafloor topography and crustal structure surveys. Magnitude (M) of the modeled outer-rise earthquake was calculated from the total fault length (L) using an outer-rise earthquake scaling law complied by Álvarez-Gómez et al. (2012). The fault width (W) was constrained at the lower end of the seismogenic layer, but it was given as L/W = 1 until reaching the lower end. The thickness of the seismogenic layer was set at 35 km. Slip amount was calculated from the fault area and M. Crustal deformation due to the faulting was calculated assuming a semi-infinite homogeneous elastic medium (Okada, 1985). The initial sea surface distribution was obtained considering the effect of tsunami excitation by horizontal movement of the slope (Tanioka and Satake, 1996) and the hydraulic filter (Kajiura, 1963) on the calculated seafloor crustal deformation. For tsunami calculations, the nonlinear shallow water equations were solved on a finite difference scheme.

Tsunamis were calculated by changing the calculation parameters and methods of the basic model one by one. The investigated cases were when using the dip angle of (1) 45 ˚or (2) 75 ˚against the dip angle of 60 ˚of the basic model, (3) when using the model approximated by single subfault, (4) when ignoring the effect of horizontal movement of the slope , (5) when ignoring the hydraulic filter, (6) when using different fault scaling laws, and (7) when using the nonlinear dispersive equations in the tsunami calculations. For the coastal tsunami height, the residuals from the basic model were evaluated by the root mean square error normalized by average tsunami height (NRMSE).

In this study, the difference in the coastal maximum tsunami height between the basic model and the derived model was large when (6) the fault scaling law was different (NRMSE ~ 0.50). This is followed by (7) without dispersion (NRMSE = 0.28), (5) without hydraulic filter (NRMSE = 0.21), (1)(2) when using the different dip angle in the subfault (NEMSE ~ 0.15), and (3) when approximating with a single fault (NRMSE = 0.10). Since the outer rise earthquake is a high-angle fault occurring in the relatively flat ocean, the effect of horizontal movement of the slope is relatively small (NRMSE = 0.025).

Bathymetry data analysis and multi-channel seismic reflection survey in the 1933 Sanriku earthquake (Mw 8.4) rupture region

*Tomoko Hanyu[1], Jin-Oh Park[1], Yukari Kido[2]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Japan Agency for Marine-Earth Science and Technology

In the northern part of the Japan Trench, the 1933 Showa-Sanriku earthquake (Mw 8.4), a normal-faulting earthquake such as large tensional outer-rise earthquake, occurred 37 yr after the 1896 Meiji-Sanriku tsunami earthquake (Mw 8.0) that ruptured plate-interface. Both earthquakes generated tsunamis that caused serious damages along the Sanriku coast of northeast Japan. As such, similar large-scale outer-rise earthquake is predicted to occur after the 2011 Tohoku-Oki earthquake (Mw 9.0). However, evolution process of the outer-rise earthquake fault has been poorly understood so far. From seismological data, Kanamori (1971) indicated that the faulting, with the average slippage on the fault plane, dipping 45˚ towards N 90˚W, amounts to 3.3 m, took place over the entire thickness of the lithosphere that caused the Showa-Sanriku earthquake. However, the large fault that penetrated from seafloor to upper mantle has not been identified yet. In order to obtain detailed images of the normal faults that cause the outer-rise earthquakes of the Japan Trench, we will carry out a multi-channel seismic reflection survey using R/V Shinsei-maru in April 2019. Before the survey, fine scale bathymetry data sets (90 meters grid), which were compiled and provided by JAMSTEC (after Kido et al., 2011), are used for the analysis of seafloor structure. In this study, we applied second-order differentiation to detect the horst-graben structures with slope at a steep angle.

The characteristics of horst-graben structures and inherited seafloor spreading fabric in our study are well concordant to those of Nakanishi (2011). In the region between 37.5˚N–40˚N, the horst-graben structures with trend of N20˚E–N30˚E are sometime broken continuity by the abyssal hills with trend of N50˚E–N70˚E and fault structures with trend of N20˚W. In a part of this region, between 38˚N–39˚N, was considered that this region was formed as a result of the ridge propagation (Nakanishi, 2011). The structure boundary on the crustal surface and Moho is observed by the OBS survey (Fujie et al., 2016) that located at a fracture zone associated with the ridge propagation, although the length of the distorted crustal surface and Moho across the fracture zone is extended about 60 km. Note that, Nakanishi (2011) suggested that the fault structures with trend of N20˚W are inherited seafloor spreading fabric and reactivated by the subduction. On the other hand, Kobayashi et al. (1998) interpreted that these faults are formed by the orientation change of the plate strength which is caused by the trend change of the trench axis from south to north along the Japan Trench. A few faults with slope angle of more than 50 degrees are recognized, but there is lack of continuity. Around the 39.5˚ N, continuous horst-graben structures with slope angle of about 30 degrees are confirmed. These continuous horst-graben structures have average vertical displacement of about 200 m. The longest horst-graben structure has length of about 250 km, and the northern portion of this fault reaches the hypocenter of Showa-Sanriku earthquake. It remains uncertain whether this structure is actually continuous or just apparently continuous. Because of the overlying sediment and lower resolution than that of seismic reflection data, the accurate slope angle and vertical displacement could not be obtained from only the bathymetry data. While, the large horst-graben structures could be detected by the bathymetry data and analysis of the bathymetric data is useful for planning the observation lines and pick-up the specific observation data set from the database. We will present the results of the bathymetry data analysis and preliminary results of the multi-channel seismic reflection survey in April 2019, and discuss the normal fault behavior associated with the outer-rise earthquakes.

Sedimentation process and deformation process before sinking of sediment on oceanic plate: examples in northwest Pacific Ocean and Sumatra

*Kiichiro Kawamura[1]

1. Yamaguchi University

The sediments covering subducting oceanic plate are pressed into continents. Sometimes it forms an accretionary prism, and they may collapse into submarine landslides in some cases. Also, it may become a fault zone during the further subducting process. Thus, the sediment on the subducting oceanic plate plays an important role in the continental deformation process in the subduction zones. From the above viewpoint, it is a currently required research topic to compare sedimentological, mineralogical and mechanical characteristics of sediment on the subducting plate before and after subducting. In this paper, I report the characteristics of sediments before subducting in the Northwest Pacific and off Sumatra in detail.

As a sedimentary feature, in the northwest Pacific, the effect of the bottom current is large, and it appears in sediments and ocean bathymetry as shown below. In this area, the Pacific plate is subducting into the Izu-Ogasawara Trench on the south part, the Japan Trench and the Kuril Trench in the northern part. In this area, a strong north - south bottom current along the trench axis has been observed at about 6000 m in water depth (Lee et al., 2003, etc), from the north to the south on the land side (Owens and Warren, 2001). Furthermore, in the deep ocean of the Pacific Ocean, flow from west to east is reported (Fujio and Yanagimoto, 2005).

18 sediment samples have been collected using a 4-m piston corer system. The samples are composed mainly of diatomaceous hemipelagic clay and volcanic ash layers. The volcanic ash layer is dated using the glass refractive index measurement. Various sedimentary structures are found in the clay layer, and in particular, on the trench axis, eroded surfaces are seen, suggesting the influence of bottom currents along the trench axis. The effect of the bottom current also is detected in the magnetic susceptibility anisotropy data. In addition, it is suggested that topographical features by the bottom current is also found from an asymmetric depression and/or moat (depth of several tens of meters, width of several kilometers) around a knoll. Thus, from sediments and submarine topography, The sediment and topographic features would suggest that we could understand the predominant bottom current directions in the northwest Pacific during the geological time scale of several thousand years.

As a mechanical feature, burial consolidation and/or diagenesis are one of the important processes in sediments before subducting. It is known that when deposits are consolidated during burial, dehydration progresses in response to stress and the microstructure gradually changes accordingly. They are called to be a card house structure in the shallow part, a book house structure in the middle part, and a shale-like (preferred horizontally orientation) structure in the deep part. They would be proceed by creeping by particle rotation and sliding and are generally considered to be secondary consolidation that occurs after primary compaction caused by reduction of excess pore fluid pressure. Burial consolidation causes gradual hardening of sediments, but the rate of change of its mechanical properties varies depending on various factors such as deposition rate, geothermal gradient, pore water chemical composition, particle composition. For example, the shale-like structure occurs at an void ratio of about 1.0 in the input

©2019. Japan Geoscience Union. All Right Reserved.

sediments of the Izu-Ogasawara trench and occurs at about 0.5 off Sumatra. In addition, in the Izu-Ogasawara Trench and the input sediments off the coast of Sumatra, various deformation structures of the normal fault system are observed as a deformed structure before subducting.

By clarifying the sedimentary features such as the input sediments and the surrounding seabed topography, it is possible to interpret the difference of the deposition rate, the distribution area of the layer thickness of the sediment and so on. In addition, the mechanical characteristics represent the pre-additional deformation process before subducting, that is, in the area where the accretionary prism body is developing. The detailed characteristics of the sediments before subducting as described above will be important information for comparing deposits after subducting.

Exploring more asthenospheric melt: the preliminary report of KS-18-9 cruise, R/V Shinseimaru

*Naoto Hirano[1], Taku Yutani[2,1], Yuki Katsuragi[1], Jeffrey Anthony Oalmann[3], Fidel Costa Rodriguez[3], KS-18-9 Onboard Scientific Party

1. Tohoku University, 2. University of Bayreuth, 3. Nanyang Technological University

The petit-spot magmas originate from the asthenosphere, ascending along the flexed zone of the outer-rise prior to plate subduction (Hirano *et al.*, 2006, *Science* 313, 1426; Valentine & Hirano, 2010, *Geology* 38, 55; Yamamoto *et al.*, 2014, *Geology* 42, 967; Machida *et al.*, 2015, *EPSL* 426, 267). This forms a unique opportunity to examine the asthenosphere below the ocean in a region outside of the well-examined but spatially restricted areas of MORs and hotspots. Recent researches, however, indicates that most of petit-spot erupted on concavely flexed plate are highly reacted with the depleted lithosphere during the magma ascending to surface. Geochemical composition of entrained xenolith from depleted mantle is disturbed by wall-rock interaction (Pilet *et al.*, 2016, *Nature Geosci.* 9, 898). From the observation that silica-poor alkaline melt is shifted to silica-rich subalkaline melts as a result of metasomatic interaction with lithospheric peridotite, the wall-rock interaction with silica-poor and strongly alkaline melts produces melts such as the majority of those at petit-spot lavas in NW Pacific (Pilet *et al.*, 2008, *Science* 320, 916). Experimental studies conducted by Machida *et al.* (2017, *Nature Comm.* 8, 14302), moreover, reported that the NW Pacific petit-spot melts were last equilibrated with peridotite at 1.5–2 GPa corresponding to the mid-depth or lower part of NW Pacific lithosphere as well. The melt fractionation must occur at depths greater than the mid-lithosphere because the geobarometer of peridotitic xenoliths shows the deepest 43 km (Yamamoto *et al.*, 2014) in spite of the lack of olivine phenocrysts. The most of petit-spot magma fractionated in mid- or lower lithosphere with some metasomatic reactions with depleted mantle at lower lithosphere during the magma-ascending to surface.

We newly discovered the directly ascending petit-spot melt from asthenosphere (Sato *et al.*, 2018, *Int'l. Geol. Rev.* 60, 1231). The lavas, silica-poor and strongly alkaline with phenocrystic olivines, are completely discriminated from the majority of previously reported petit-spot. They selectively erupt atop the outer-rise wherein the lithosphere behaves entirely in an extensional regime during the ascent of melt from asthenosphere. We conducted several dredge samplings in order to access the asthenosphere more directly, by the research cruise KS-18-9, R/V *Shinseimaru*, in August 2018, supported by AORI, Tokyo University, and the JSPS Japanese-German Graduate Externship. Special thanks to shipboard scientific party (S. Machida, N. Akizawa, T. Ishii, A. Matsumoto, M. Kaneko, Y. Sato, Y. Nakano, T. Yutani, K. Azami, S. Sakai, Y. Katsuragi), captain A. Tsuji, and crews on KS18-09, R/V Shinsei.

The petit-spot rocks are dredged at a lava field displayed by multibeam survey without any topographic highs, which are small blocks surrounding very fresh glass with less palagonitic alteration and manganese coating, implying the lavas are quite young. The quenched glass rinds were analysed for major and trace elements by an electoron microprobe at University of Bayreuth, Germany (co-work with T. Yutani), and an inductively coupled plasma–mass spectrometer (LA-ICP-MS) at Nanyang Technological University, Singapore (co-work with F. Rodriguez, J. Oalmann, Y. Katsuragi), respectively. As we gained "directly ascending petit-spots" from several volcanoes on this cruise, it is possible to recognize their source and melting process from their geochemical variations. The strongly alkaline lavas, directly ascending petit-spot, show clear trend in Zr/Hf, Sm/Hf ratios and HREEs, implying the carbonatite addition with the depth in source mantle. We present here the several processes of lithospheric flexure, metasomatized

lithosphere, magma-fractionation, and finally, upwelling directly from asthenosphere occur prior to trench-oceanward slope, which would be significant components into the incoming oceanic plate.

Inputs of Argon on oceanic plate at subduction zones

*Shigeaki Ono[1]

1. Japan Agency for Marine-Earth Science and Technology

It is known that noble gases are key tracers to understand the evolution of the mantle because of their inertness nature and isotope variations. However, a mechanism of recycle of noble gases in the deep mantle is still open question. Argon is one of noble gases and has three isotopes, ^{36}Ar, ^{38}Ar, and ^{40}Ar. Holland and Ballentine [2006] proposed that Ar from the mantle is identical to seawater component. This indicates that the seawater recycling dominates a behavior of Ar in the mantle. In contrast, the systematic analysis for noble gases indicates that ocean island basalt has a primordial signature which is different from atmosphere component [Mukhopadhyay 2012]. The recycling of Ar between the Earth’s surface and the deep mantle has been discussed using the isotope data of noble gases. However, it is difficult to understand a mechanism of recycling of Ar because of a lack of knowledge for physical and chemical properties of Ar at high pressure and high temperature.

In this study, we used density functional theory to investigate the melting temperature and thermal pressure of Ar. We also performed the high-pressure experiments to determine the room-temperature equation of state for Ar. The combination of the first-principles molecular dynamics calculations and the high-pressure experiments led us to determine reliable physical properties, such as the equation of state and the melting temperature, over a wide range of pressures and temperatures.

The equation of state of Ar has been investigated to 382 GPa and 3000 K using the diamond anvil cell experiments and the first-principles molecular dynamics method. A large volume dependence of the thermal pressure of Ar was revealed at pressures higher than 200 GPa. A significant temperature dependence of the calculated effective Grüneisen parameters was confirmed at high pressures. This indicates that the conventional approach to analyze thermal properties using the Mie-Grüneisen approximation is likely to have a significant uncertainty in determining the equation of state for Ar, and that an intrinsic anharmonicity should be considered to analyze the equation of state. A melting temperature of Ar was estimated from calculation data, and a significant pressure dependence was confirmed. If the pressure-temperature path of the subducted slab is lower than critical condition, ~750 K and ~7.5 GPa, solid Ar can be carried down into the deep mantle. Melting of solid Ar in the upwelling mantle plume occurs at the bottom of the transition zone.

[S-CG60] Investigation of inputs to subduction zones: Influence of tectonic processes on the incoming plate

convener:Makoto Yamano(Earthquake Research Institute, the University of Tokyo), Tomoaki Morishita(School of Geoscience and Civil Engineering, College of Science and Technology, Kanazawa University), Gou Fujie(Japan Agency for Marine-Earth Science and Technology)

Various tectonic processes occur on the seaward side of the trench associated with bending of the incoming oceanic plate, e.g., fracturing of oceanic crust, infiltration of water, and intraplate volcanism. Investigation of these processes and their influence on the incoming plate provides important information on the boundary condition at the trench, inputs to subduction zones. Variation in inputs should significantly affect geophysical/geological phenomena around the plate interface and geochemical cycles in subduction zones. We welcome contributions from a broad range of earth science (geophysics, geology, petrology, and so on) discussing topics related to inputs to subduction zones such as occurrence of tectonic processes due to bending of the incoming plate, modification of the incoming plate by the processes, relationship between the processes and the inherited structure of the incoming plate, and influence of the processes on the subduction plate interface. We hope discussions are made on studies of a variety of subduction zones, including the Japan Trench and the Nankai Trough, and comparative studies among different subduction zones.

Tsunami Simulations of the 2006 and 2007 Kuril Earthquakes

*Keiji Akai[1]

1. Graduate School of Advanced Technology and Science, Tokushima University

On November 15, 2006, an earthquake (Mw8.3) occurred off the Kuril Islands (the 2006 Kuril earthquake). Following tsunami was observed in the coastal region in Japan, Hawaii and North, Central and South America. About 2 month later, on January 13, 2007, another earthquake (Mw8.1) occurred and the tsunami was also observed (the 2007 Kuril earthquake). At the 2006 Kuril earthquake, tsunami warning had been cancelled in Japan before the maximum wave arrived. After the 2010 Chile Maule tsunami and the 2011 Tohoku tsunamis, technology simulating far-field tsunami was well developed including effect of elastic deformation of the Earth during tsunami propagation. In this study, using the new simulation method for the far-field tsunami, we revisited at the 2006 and 2007 Kuril earthquakes. The new simulation method has not been validated on tsunami cause by the outer-rise earthquakes, so that, especially, we focus on the 2007 Kuril earthquake because it was an outer-rise event.

In the tsunami calculations, tsunami sources were calculated by fault parameters from IISEE HP and Fujii and Satake (2008) with analytical solution using homogeneous elastic media. Tsunami propagations were solved by nonlinear shallow water equations with effects of dispersion, elastic loading and sea water density stratification on a finite difference scheme. We used GEBCO data resampled by 5 arc-min. and time step with of 5 s to calculate tsunami for 24 hours. The calculated tsunamis were compared with observed data by DARTs. As the results, the 2006 Kuril tsunami had been well modelled at the DART observation points in terms of arrival time and the maximum amplitude. However, for the 2007 Kuril tsunami, the agreement between the calculated and observed data were not good as the 2006 Kuril tsunami. The misfit became large as the lapse of time. This discrepancy may be caused by insufficient resolution of bathymetric data because the outer-rise earthquakes generate tsunami shorter wavelength than that of the subduction zone earthquakes.

The variation of seismic attributes about incoming oceanic crust in Nankai Trough using multi-channel seismic reflection data

*Mikiya Yamashita[1], Seiichi Miura[1], Ayako Nakanishi[1], Jin-Oh Park[2], Shuichi Kodaira[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Department of Ocean Floor Geoscience, Atmosphere and Ocean Research Institute, The University of Tokyo

The physical properties of seismic reflection profiles include many geological information with tectonic setting. Nankai Trough is one of the best places to reveal the characteristics about plate boundary of subducting oceanic plate for understanding the large disaster earthquake because there are many exploration data. Japan Agency for Marine-Earth Science and Technology carried out high-resolution multi-channel seismic reflection (MCS) survey in Shikoku Basin along the Nankai Trough by using R/V Kaiyo with high-resolution portable system in 2012 and 2014. To reveal the characteristics of the subducting oceanic plate is important to evaluate the property of plate boundary for understanding the large disaster earthquake. We evaluate not only structure of MCS profiles, but also the variations of reflection strength about the top of oceanic crust of incoming plate.

MCS profiles of lines KY12-4 and SB01 were obtained along the Nankai Trough. These data were valuable for case study by comparison about physical properties from seismic attribute of top of oceanic crust. In order to extract the physical properties from the reflector of top of oceanic crust, we apply seismic attributes analysis for these data. Seismic attributes are measured from seismic data that can be analyzed in order to enhance information that might be well understanding in a traditional seismic image (Tarner et al. 1979). The seismic envelope attributes often use the reflection strength of the reflector (e.g. Tsuji et al. 2007). The envelope of seismic attributes means the envelope of seismic signal. These attributes are good for looking at packages of amplitudes. We select the second derivative of single envelope as reflection strength of top of oceanic crust. Although calculated seismic attributes of reflection strength indicate the high intensities in the central part of Shikoku Basin, the west and east part of Shikoku Basin where is initial stage of spreading of Shikoku Basin have the small intensities. This suggests that the reflection strength of top of oceanic crust is affected by the created condition of oceanic crust. We also discuss about the relationship between the reflection strength of top of oceanic crust and the thickness of sediments of Shikoku Basin.
This study is part of 'Research project for compound disaster mitigation on the great earthquakes and tsunamis around the Nankai trough region' funded by Ministry of Education, Culture, Sports, Science and Technology, Japan.

Bending-Related Topographic Structures of the Subducting Plate in the Southeastern Pacific Ocean

*Reno Kotate[1], Masao Nakanishi[2]

1. Chiba University Graduate School Science and Engineering Dvision of Earth and Environmental Scienes Department of Earth Sciences, 2. Chiba University Graduate School Faculty of Science

Oceanic plates bend near trenches before subduction. The bending causes elongated topographic structures such as ridges and escarpments on the incoming oceanic plate. The elongated topographic structures facilitate the infiltration of seawater into the oceanic plate. The amount of water in the subducting plate is one of the important properties controlling subduction. Therefore, the study of bending-related topographic structures on the incoming plate is one of the imperative studies of the subduction zone.

The strike of bending-related topographic structures on the oceanward trench slopes is parallel to the trench axis or inherited seafloor spreading fabric (Kobayashi et al.,1995,1998). Nakanishi (2017) pointed out the following rule for the topographic structures.

1. Most of bending-related topographic structures near the trenches in the northwestern Pacific Ocean are limited to less than about 80 km from the trench axis.

2. Seafloor spreading fabric is reactivated where the angle between the fabric and trench axis is less than about 30˚.

3. The above rules are not applicable to curved trenches and trenches near seamounts or other volcanic edifices constructed by off-ridge volcanism.

To find out that the above rule is appropriate to the whole trenches in the southeastern margin of the Pacific Ocean, we made the bathymetric maps and described the bending-related topographic structures from Middle America Trench to Peru-Chile Trench.

The bending-related topographic structures are limited to less than 60 km from the trench axis for the Peru Trench and the northern part of the Peru-Chile Trench. In the southern part of Peru-Chile Trench, elongated topographic structures parallel to the magnetic anomaly lineation are confirmed more than 150 km from the trench axis. The throw of the structures doesn’ t increase toward the trench axis, implying that it is difficult to distinguish the structures are made by reactivation of seafloor spreading fabric. Elongated topographic structures in the Middle America Trench are found more than 250 km from the trench axis. The structures are parallel to the magnetic anomaly lineations. The throw of the structures starts to increase from the distance of 150 km to the trench axis. This indicates that the elongated structures are grown by reactivation of seafloor spreading fabric and the bending-related topographic structures are limited to less than 150 km from the trench axis in the Middle America Trench.

The bending-related topographic structures in the Middle America Trench and the southern part of the Peru Trench are parallel to the magnetic anomaly lineations. The angle between the structures and the trench axis is less than 30˚. The bending-related topographic structures in the northern parts of the Peru and Peru-Chile Trenches are parallel to the trench axis. The angle between the structures and the trench

Detailed tectonic structure of the Japan Trench subduction zone off Miyagi by 2D pre-stack depth migration imaging

*GUO CHEN[1], Jin-Oh Park[1]

1. The University of Tokyo

The 2011 Tohoku earthquake (Mw 9.0) has been extensively examined by many geophysical data from state-of-the-art observational networks deployed both globally and locally. There were lots of studies to investigate the tectonic structure of the 2011 coseismic rupture zone. However, there were a few detailed seismic reflection images about both shallow and deep structure, because of the complicated geologic structure. In order to figure out detailed geologic structure and P-wave velocity modelof the Japan Trenchsubduction zone off Miyagi, northeast Japan, we tried to do 2D pre-stack depth migration (PSDM) imaging using multi-channel seismic (MCS) reflection data acrossthe2011 Tohoku coseismic rupture zone. Pre-processing to get CDP gathers with high S/N ratio includes trace editing, pre-filtering, spherical divergence correction, debubbling, deghosting, and surface-related multiple attenuation (SRMA).After air gun shots, a main pulse and following bubble oscillations were recorded, even though the air gun was tuned. In order to suppress the periodic bubble oscillations, we designed debubble filter. We used shot gather data with gain, trace header modification, sort and static application to extract the bubble signature from the raw MCS data, eventually producing a filter with ~30 Hz bubble waveform.In marine MCS data acquisition, source (air gun) and receiver (streamer cable) ghosts are recorded as notches in power spectrum. These secondary wavefield usually corrupts the raw data, depending on offset, time and geologic dip. We designed deghost filter to reduce the source and receiver ghosts. Like no other time before, we used both horizon-based tomography and grid-based tomography during the PSDM processing. Horizon-based tomography and grid-based tomography are global approaches which involve a solution of simultaneous set of equations for calculating the updating parameters of the velocity-depth model. In the horizon-based tomography, we built a depth-velocity model along which the residuals were picked, and updated both the depth surfaces and velocity of each layer. The updates are calculated at equally spaced spline nodes and then interpolated. After the horizon-based tomography, we inputted this velocity section into 2D auto-picker and calculated the QC semblance for defining a complete depth surface and updated for velocity at equally spaced points on a 2D grid. We recognize a bright reflector as the topmost oceanic crust (i.e., plate interface) of the Pacific plate subducting beneath the overlying Okhotsk plate, which can be traceable to more than 100 km landward from the Japan Trench axis. The seaward Pacific plate is characterized by horst and graben structure with normal faults. A strong reflector of Moho discontinuity, which is observed beneath the oceanic crust before subduction, is also observed even after subduction of the Pacific plate, up to more than 100 km landward from the Japan Trench axis. In the upper plate, we identify the Neogene sedimentary layer overlying the Cretaceous erosional unconformity, andseverallargereversefaultsdevelopingwithin theCretaceous basement. The backstop interface showshigh amplitude and negative polarityreflection that may be indicative offluid-rich fault. We observe a reflection of Arc Moho at depth of about 20 km. We can also observe megalens structure along plate interface at about 15-20 km depth, which is similar in Costa Rica subduction zone.

Conductive zone of incoming Pacific Plate in the outer rise region off Japan trench

*Shinya Sato[1], Tada-nori Goto[1], Takafumi Kasaya[2], Hiroshi Ichihara[3], Makoto Yamano[4]

1. Kyoto Univesity, Graduate School of Engineering, 2. Japan Agency for Marine-Earth Science and Technology, 3. Nagoya University, Graduate School of Environmental Studies, 4. University of Tokyo, Earthquake Research Institute

Various geophysical surveys have been operated in order to expose the subsurface structure of incoming Pacific plate in the outer rise region off Japan trench. One of the targets is existence of water in the plate, and two geophysical surveys (seismic surveys and heat flow measurements), which were conducted independently, in the outer rise region reported recently the possibility of water existence in the plate. The seismic surveys (e.g., Fujie et al., 2016; Fujie et al., 2018) visualized the subsurface structure indicating low velocity in the oceanic crust and below the boundary between crust and lithosphere (i.e., Moho) although there are high pressures. Also, the heat flow measurements (e.g., Yamano and Kawada, 2017) reported high heat-flow anomalies in the region, and suggested the possibilities that the anomalies were triggered by the water through the permeable layer in the plate. However, the existence of water in the deep portion below the oceanic crust has not been well known, and the source of water is now being discussed. A marine magnetotelluric (MT) survey was conducted in the outer rise region with distant of 100 –200 km from the Japan trench. This survey' s target is to verify the existence of water in the oceanic mantle visualizing the subsurface resistivity structure. We recorded electromagnetic data (MT data) for the analysis of subsurface resistivity structure at four locations with water depth of about 5500 m. Unfortunately, one of four data failed to record the MT data appropriately, and the other data included large noises, whose source were possibly the instruments themselves. We applied the noise-reduction method based on Frequency Domain Independent Component Analysis (Sato et al., 2017) for the estimation of MT responses at the three sites. The resistivity structure was visualized using a 2D inversion code by Uchida and Ogawa (1993) from the derived MT responses. The visualized structure showed two features: i) the boundary between resistive lithosphere and conductive asthenosphere and ii) the conductive zones below the oceanic crust. At the presentation, we will not only show them but discuss the source of conductive zones based on electromagnetic environment, whose model includes the effect of trench or coast.

Geochemical variations of the asthenosphere inferred from the geochemistry of petit-spot lavas in the NW Pacific plate

*Yuki Katsuragi[1], Naoto Hirano[1], Kenji Shimizu[2], Fidel Costa[3], Jaffrey Oalmann[3], Taku Yutani[1]

1. Tohoku University, 2. Kochi Core Center, Kochi University / JAMSTEC, 3. Nanyang Technological University

The low seismic velocity and high electrical conductivity of the asthenosphere may be due to the presence of volatile materials (e.g. CO_2 and H_2O) (e.g. Gairrard et al., 2008; Hirschmann, 2010). Recently, the so-called “petit-spot volcanism” which is characterized by submarine eruptions that occur in oceanic plates in response to lithospheric flexures, has been proposed to result from melts directly ascending from the asthenosphere (Hirano et al., 2006; Sato et al., 2018). The lava samples (foidite to trachybasalt) show high vesicularity despite the eruption occurring under high hydrostatic pressure at approximately 6000 meters below sea level (Sato et al., 2018). Here we discuss the volatile, bulk, and Sr-Nd isotopic compositions of quenched glass rinds of petit-spot lavas from the NW Pacific plate, supported by the JSPS Japanese-German Graduate Externship.

The glass has higher volatile contents (H_2O, CO_2, and halogens) than most MORBs and lacks chlorine alteration by seawater. Some samples are clearly oversaturated in CO_2 and H_2O at 60 MPa, which is the submarine hydrostatic pressure. The glass also shows negative anomalies of Zr, Hf and Ti, implying that there is a carbonatitic component in the mantle source. Moreover, Nd and Sr isotope ratios, and some geochemical trends with volatile elements indicate that the magma was derived from an EM1-like mantle component. Therefore, the compositions of the petit-spot lavas can possibly be explained by mixing of DMM and recycled EM1 material with carbonates. The degree of EM1 signature for each eruptive location gradually decreases toward the trench. We suggest that the variation of volatile compositions and Sr-Nd isotopic systematics of petit-spot magmas reflect their temporal and spatial transition in the asthenosphere along the NW Pacific plate track.

[S-CG60] Investigation of inputs to subduction zones: Influence of tectonic processes on the incoming plate

convener:Makoto Yamano(Earthquake Research Institute, the University of Tokyo), Tomoaki Morishita(School of Geoscience and Civil Engineering, College of Science and Technology, Kanazawa University), Gou Fujie(Japan Agency for Marine-Earth Science and Technology)

Various tectonic processes occur on the seaward side of the trench associated with bending of the incoming oceanic plate, e.g., fracturing of oceanic crust, infiltration of water, and intraplate volcanism. Investigation of these processes and their influence on the incoming plate provides important information on the boundary condition at the trench, inputs to subduction zones. Variation in inputs should significantly affect geophysical/geological phenomena around the plate interface and geochemical cycles in subduction zones. We welcome contributions from a broad range of earth science (geophysics, geology, petrology, and so on) discussing topics related to inputs to subduction zones such as occurrence of tectonic processes due to bending of the incoming plate, modification of the incoming plate by the processes, relationship between the processes and the inherited structure of the incoming plate, and influence of the processes on the subduction plate interface. We hope discussions are made on studies of a variety of subduction zones, including the Japan Trench and the Nankai Trough, and comparative studies among different subduction zones.

The variation of seismic attributes about incoming oceanic crust in Nankai Trough using multi-channel seismic reflection data

*Mikiya Yamashita[1], Seiichi Miura[1], Ayako Nakanishi[1], Jin-Oh Park[2], Shuichi Kodaira[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Department of Ocean Floor Geoscience, Atmosphere and Ocean Research Institute, The University of Tokyo

The physical properties of seismic reflection profiles include many geological information with tectonic setting. Nankai Trough is one of the best places to reveal the characteristics about plate boundary of subducting oceanic plate for understanding the large disaster earthquake because there are many exploration data. Japan Agency for Marine-Earth Science and Technology carried out high-resolution multi-channel seismic reflection (MCS) survey in Shikoku Basin along the Nankai Trough by using R/V Kaiyo with high-resolution portable system in 2012 and 2014. To reveal the characteristics of the subducting oceanic plate is important to evaluate the property of plate boundary for understanding the large disaster earthquake. We evaluate not only structure of MCS profiles, but also the variations of reflection strength about the top of oceanic crust of incoming plate.

MCS profiles of lines KY12-4 and SB01 were obtained along the Nankai Trough. These data were valuable for case study by comparison about physical properties from seismic attribute of top of oceanic crust. In order to extract the physical properties from the reflector of top of oceanic crust, we apply seismic attributes analysis for these data. Seismic attributes are measured from seismic data that can be analyzed in order to enhance information that might be well understanding in a traditional seismic image (Tarner et al. 1979). The seismic envelope attributes often use the reflection strength of the reflector (e.g. Tsuji et al. 2007). The envelope of seismic attributes means the envelope of seismic signal. These attributes are good for looking at packages of amplitudes. We select the second derivative of single envelope as reflection strength of top of oceanic crust. Although calculated seismic attributes of reflection strength indicate the high intensities in the central part of Shikoku Basin, the west and east part of Shikoku Basin where is initial stage of spreading of Shikoku Basin have the small intensities. This suggests that the reflection strength of top of oceanic crust is affected by the created condition of oceanic crust. We also discuss about the relationship between the reflection strength of top of oceanic crust and the thickness of sediments of Shikoku Basin.

Bending-Related Topographic Structures of the Subducting Plate in the Southeastern Pacific Ocean

*Reno Kotate[1], Masao Nakanishi[2]

1. Chiba University Graduate School Science and Engineering Dvision of Earth and Environmental Scienes Department of Earth Sciences, 2. Chiba University Graduate School Faculty of Science

Oceanic plates bend near trenches before subduction. The bending causes elongated topographic structures such as ridges and escarpments on the incoming oceanic plate. The elongated topographic structures facilitate the infiltration of seawater into the oceanic plate. The amount of water in the subducting plate is one of the important properties controlling subduction. Therefore, the study of bending-related topographic structures on the incoming plate is one of the imperative studies of the subduction zone.

The strike of bending-related topographic structures on the oceanward trench slopes is parallel to the trench axis or inherited seafloor spreading fabric (Kobayashi et al.,1995,1998). Nakanishi (2017) pointed out the following rule for the topographic structures.

1. Most of bending-related topographic structures near the trenches in the northwestern Pacific Ocean are limited to less than about 80 km from the trench axis.

2. Seafloor spreading fabric is reactivated where the angle between the fabric and trench axis is less than about 30˚.

3. The above rules are not applicable to curved trenches and trenches near seamounts or other volcanic edifices constructed by off-ridge volcanism.

To find out that the above rule is appropriate to the whole trenches in the southeastern margin of the Pacific Ocean, we made the bathymetric maps and described the bending-related topographic structures from Middle America Trench to Peru-Chile Trench.

The bending-related topographic structures are limited to less than 60 km from the trench axis for the Peru Trench and the northern part of the Peru-Chile Trench. In the southern part of Peru-Chile Trench, elongated topographic structures parallel to the magnetic anomaly lineation are confirmed more than 150 km from the trench axis. The throw of the structures doesn’ t increase toward the trench axis, implying that it is difficult to distinguish the structures are made by reactivation of seafloor spreading fabric. Elongated topographic structures in the Middle America Trench are found more than 250 km from the trench axis. The structures are parallel to the magnetic anomaly lineations. The throw of the structures starts to increase from the distance of 150 km to the trench axis. This indicates that the elongated structures are grown by reactivation of seafloor spreading fabric and the bending-related topographic structures are limited to less than 150 km from the trench axis in the Middle America Trench.

The bending-related topographic structures in the Middle America Trench and the southern part of the Peru Trench are parallel to the magnetic anomaly lineations. The angle between the structures and the trench axis is less than 30˚. The bending-related topographic structures in the northern parts of the Peru and Peru-Chile Trenches are parallel to the trench axis. The angle between the structures and the trench

In the upper plate, we identify the Neogene sedimentary layer overlying the Cretaceous erosional unconformity, andseverallargereversefaultsdevelopingwithin theCretaceous basement. The backstop interface showshigh amplitude and negative polarityreflection that may be indicative offluid-rich fault. We observe a reflection of Arc Moho at depth of about 20 km. We can also observe megalens structure along plate interface at about 15-20 km depth, which is similar in Costa Rica subduction zone.

Various geophysical surveys have been operated in order to expose the subsurface structure of incoming Pacific plate in the outer rise region off Japan trench. One of the targets is existence of water in the plate, and two geophysical surveys (seismic surveys and heat flow measurements), which were conducted independently, in the outer rise region reported recently the possibility of water existence in the plate. The seismic surveys (e.g., Fujie et al., 2016; Fujie et al., 2018) visualized the subsurface structure indicating low velocity in the oceanic crust and below the boundary between crust and lithosphere (i.e., Moho) although there are high pressures. Also, the heat flow measurements (e.g., Yamano and Kawada, 2017) reported high heat-flow anomalies in the region, and suggested the possibilities that the anomalies were triggered by the water through the permeable layer in the plate. However, the existence of water in the deep portion below the oceanic crust has not been well known, and the source of water is now being discussed. A marine magnetotelluric (MT) survey was conducted in the outer rise region with distant of 100 –200 km from the Japan trench. This survey' s target is to verify the existence of water in the oceanic mantle visualizing the subsurface resistivity structure. We recorded electromagnetic data (MT data) for the analysis of subsurface resistivity structure at four locations with water depth of about 5500 m. Unfortunately, one of four data failed to record the MT data appropriately, and the other data included large noises, whose source were possibly the instruments themselves. We applied the noise-reduction method based on Frequency Domain Independent Component Analysis (Sato et al., 2017) for the estimation of MT responses at the three sites. The resistivity structure was visualized using a 2D inversion code by Uchida and Ogawa (1993) from the derived MT responses. The visualized structure showed two features: i) the boundary between resistive lithosphere and conductive asthenosphere and ii) the conductive zones below the oceanic crust. At the presentation, we will not only show them but discuss the source of conductive zones based on electromagnetic environment, whose model includes the effect of trench or coast.

The low seismic velocity and high electrical conductivity of the asthenosphere may be due to the presence of volatile materials (e.g. CO_2 and H_2O) (e.g. Gairrard et al., 2008; Hirschmann, 2010). Recently, the so-called “petit-spot volcanism” which is characterized by submarine eruptions that occur in oceanic plates in response to lithospheric flexures, has been proposed to result from melts directly ascending from the asthenosphere (Hirano et al., 2006; Sato et al., 2018). The lava samples (foidite to trachybasalt) show high vesicularity despite the eruption occurring under high hydrostatic pressure at approximately 6000 meters below sea level (Sato et al., 2018). Here we discuss the volatile, bulk, and Sr-Nd isotopic compositions of quenched glass rinds of petit-spot lavas from the NW Pacific plate, supported by the JSPS Japanese-German Graduate Externship.

The glass has higher volatile contents (H_2O, CO_2, and halogens) than most MORBs and lacks chlorine alteration by seawater. Some samples are clearly oversaturated in CO_2 and H_2O at 60 MPa, which is the submarine hydrostatic pressure. The glass also shows negative anomalies of Zr, Hf and Ti, implying that there is a carbonatitic component in the mantle source. Moreover, Nd and Sr isotope ratios, and some geochemical trends with volatile elements indicate that the magma was derived from an EM1-like mantle component. Therefore, the compositions of the petit-spot lavas can possibly be explained by mixing of DMM and recycled EM1 material with carbonates. The degree of EM1 signature for each eruptive location gradually decreases toward the trench. We suggest that the variation of volatile compositions and Sr-Nd isotopic systematics of petit-spot magmas reflect their temporal and spatial transition in the asthenosphere along the NW Pacific plate track.

[S-CG61] Dynamics in mobile belts

convener:Yukitoshi Fukahata(Disaster Prevention Research Institute, Kyoto University), Toru Takeshita(Department of Natural History Sciences, Graduate School of Science, Hokkaido University), Hikaru Iwamori(Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology), Chairperson:Toru Takeshita, Kenta Kobayashi

The dynamic behaviours of mobile belts are expressed across a wide range of time scales, from the seismic and volcanic events that impact society during our lifetimes, to orogeny and the formation of large-scale fault systems which can take place over millions of years. Deformation occurs on length scales from microscopic fracture and flow to macroscopic deformation to plate-scale tectonics. To gain a physical understanding of the dynamics of mobile belts, we must determine the relationships between deformation and the driving stresses due to plate motion and other causes, which are connected through the rheological properties of the materials. To understand the full physical system, an integration of geophysics, geomorphology, and geology is necessary, as is the integration of observational, theoretical and experimental approaches. In addition, because rheological properties are greatly affected by fluids in the crust and fluid chemical reactions, petrological and geochemical approaches are also important. After the 2011 great Tohoku-oki earthquake, large-scale changes in seismic activity and regional scale crustal deformation were observed, making present-day Japan a unique natural laboratory for the study of the dynamics of mobile belts. This session welcomes presentations from different disciplines, such as seismology, geodesy, tectonic geomorphology, structural geology, petrology, and hydrology, as well as interdisciplinary studies, that relate to the dynamic behaviours of mobile belts.

Fault zone development in the West Tottori area, Japan

*Kenta Kobayashi[1]

1. Department of Geology, Faculty of Science, Niigata University

Several kinds of investigations were carried out in the NW-SE trending aftershock area of the 2000 Tottori-ken Seibu earthquake (Mj7.3) and along the Nichinanko lineament (L=15km) which runs the SW of the aftershock area. The earthquake occurred in a place where no active fault is identified, with the exception of some short lineaments (e.g. Kanayama lineament: L=2km) in the direction of NW-SE. After the earthquake, many NW-SE to WNW-ESE trending surface ruptures were found in the aftershock area (e.g. Ryokusuien in central part of the area). They indicated sinistral slip sense. On the other hand, brittle fault rock zones are distributed in Late Cretaceous to Paleogene granitic rocks. Miocene rhyolite, basalt-andesite and aplite dikes intrude the granitic rocks, also deformed along the faults. Most fault planes with WNW strike indicate sinistral slip, and most of those with ENE strike show dextral slip. The determined paleo stress field is strike slip type of N-S tension, congruents with the 2000 Tottori-ken Seibu earthquake. However, along a few fault planes with WNW strike the early dextral slip is detected (e.g. Ryokusuien). Brittle fault rock zones are also distributed along the NW-SE trending Nichinanko lineament. Along the lineament, a wider mixture zone is formed. Fault planes with NW strike indicate sinistral slip.

XRD analysis showed that the gouge in the central part of the aftershock area is mainly composed of illite and chlorite (Kobayashi et al., 2006; Manaka et al., 2012), while the gouges in the NW and SE parts of the aftershock area (Kaneki et al., 2019) and those along the Nichinanko lineament (Manaka et al., 2012) are rich in halloysite. Chemical processes are different between these fault rock zones. In the central part of the aftershock area, most gouges were formed at a higher temperature than the neighborhood. On the other hand, the latest gouge is rich in smectite at Ryokusuien.

These facts suggest that the maturity of the fault zone along the aftershock area has been a low level, WNW strike fault planes (R1 shears) and ENE strike fault planes (R2 shears) formed predominantly. Therefore, the early kinematic (dextral) and chemical (illite-chlorite forming hydrothermal alteration) processes are remained. On the other hand, the activity along the Nichinanko lineament has been a higher level in a shallower depth (halloysite-smectite forming environment), NW strike fault planes (Y surfaces) formed predominantly, the remarkable Nichinanko lineament developed. In addition, the Komachi-Ohdani lineament system (L=12km) which runs the NE of the aftershock area also developed. How these fault zones have developed over a long period of time will be discussed.

Inerastic deformation around focal area of the 2000 Western Tottori EQ (M7.3) detected by “0.1 manten” Hyper Dense Seismic Observation (2)

*Satoshi Matsumoto[1], Yoshihisa Iio[2], Shin'ichi Sakai[3], Aitaro Kato[3], Takuo Shibutani[2], Yuto Hayashida[4], Group for 0.1 manten Hyper dense seismic observation

Seismic observation with high resolution and sensitivity is a key to solve a question how the crust deforms inelastically and accumulate stress in the seismogenic zone. We have completed a seismic observation for one year at one thousand sites (0.1 Manten seismic observation) in an aftershock area of the 2000 Western Tottori earthquake (M7.3). The seismic network with radius of about 18 km covered entire aftershock area of the M7.3 event. Automatic-detecting procedure was applied to the seismograms in order to detect small earthquakes. Over 5000 events of natural earthquakes were obtained during the observation. Sensitivity of the network is high and its detection limit for small earthquake was about magnitude of -1.0. Focal mechanism of the earthquake with magnitude range below zero could be determined. In this study, we showed inelastic deformation due to seismic activity of the small earthquake around the fault of the main shock.
The detected aftershock activity is higher at north of the large slip area of the main shock than at other area. Taking into account the activity just after the main shock, we found inelastic strain rate inferred from the aftershock reveals spatial heterogeneous distribution. The rate is smaller than inverse of the lapse time from the main shock, indicating that inelastic deformation due to the aftershock continue long duration compared with other part of the fault. This area corresponds to the hypocentral area of the preceding activity toward the main shock of the Western Tottori earthquake. These suggests that the high inelastic strain rate area at the north of the asperity of the main shock behaved as low strength area relaxing stress at the part and resulted stress loading to the asperity. Comparing the rate with it estimated from the preceding activity to the main shock, the rate at present is similar order to one before the mainshock. It suggests a possibility that loading processes exists below the low-decay rate zone where seismic activity observed prior to the main shock.

Non-double couple micro-earthquakes in the focal area of the 2000 Western Tottori earthquake (M7.3) by "0.1 manten" hyper dense seismic observation

*Yuto Hayashida[1], Satoshi Matsumoto[2], Yoshihisa Iio[3], Shin'ichi Sakai[4], Aitaro Kato[4], Group for "0.1 Manten" hyper dense seismic observation Group registration

Earthquakes with non-double couple (NDC) component could provide information such as geometric fault complexity, tensile failure, and fluid flow in faulting.

In this study, we found definite micro-earthquakes with NDC in the aftershock area of the 2000 Western Tottori earthquake (M 7.3) based on polarity analysis for first P-wave motion data from “0.1 manten” hyper dense seismic observation. The observation composed of a thousand seismic stations successfully provided with high resolution focal mechanisms of a lot of micro-earthquakes in the area.

We attempted to model the events with NDC by tensile-shear faulting, shear-tensile faulting, and multiple events with pure double couple focal mechanisms. We analyzed 8 events that distributes the entire after shock area.

Plausible models for the events occurring at shallower and deeper depth are the faulting with tensile crack and the multiple shear faulting models, respectively. The results suggest that fluid contributes to the crack opening at the shallow part. In contrast, fluid pressure does not sufficient to open tensile crack at the deep part. Therefore, the depth of the boundary may relate to the pressure of fluid at the earthquake fault. In addition, the events with large NDC component were located around co-seismic large slip area of the mainshock of the Western Tottori earthquake. This suggests that fluid exits around the co-seismic slip area.
