convener:Ayako Seiki(Japan Agency for Marine-Earth Science and Technology), Tomoki Tozuka(Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo), Motoki Nagura(Japan Agency for Marine-Earth Science and Technology), Youichi Kamae(Faculty of Life and Environmental Sciences, University of Tsukuba), Chairperson:Ayako Seiki(Japan Agency for Marine-Earth Science and Technology), Motoki Nagura(Japan Agency for Marine-Earth Science and Technology)

Multi-scale ocean-atmosphere interaction in the tropics exerts a significant imprint on the global climate via atmospheric teleconnection. Since the 1980s, anchored by in-situ and satellite observations, improvements in modeling and theoretical understanding, various aspects of dominant modes of interannual (e.g., ENSO and IOD), intraseasonal (e.g., MJO) variabilities and their impacts on tropical (e.g., monsoons) and extra-tropical (e.g., North America) climate variations have received wide attention. Recent satellite-based salinity measurements indicate for an active role of salinity in the tropical ocean-atmosphere interaction. While recent studies suggest a possible link between interdecadal Pacific oscillation and global warming hiatus in 2000s, changes (if any) in the tropical ocean-atmosphere interaction are yet to be understood. Due to interactions between different time scales, between different ocean basins, and with the extratropics, the tropical ocean and atmosphere play a key role in shaping climate, its variability and change. To better understand and examine these challenging issues from various perspectives, this session offers a forum to discuss recent progress in observational, modeling and theoretical studies of multi-scale tropical ocean-atmosphere interaction.

Various aspects of climate system variability associated with ENSO

*Shuhei Maeda[1]

1. Climate Prediction Division, Japan Meteorological Agency

The El Niño-Southern Oscillation (ENSO) is the most dominant interannual climate variability in the Earth’ s climate system, and its pattern is characterized as zonal east-west see-saw of oceanic and atmospheric conditions in the tropical Pacific, and their associated teleconnections in the atmosphere to the extra-tropics. In addition, various aspects of climate system variability associated with ENSO are observed. For example, (1)vertical distribution of sea sub-surface temperature, (2)global average temperature, (3)energy budget at the top of atmosphere, (4)available potential energy in the atmosphere, (5)atmospheric meridional circulation such as Hadley and Ferrel circulations, (6) sub-tropical jet streams, (7)wave activities in the extra-tropics, and (8) polar vortex. In the presentation, I will review these aspects of climate system variability associated with ENSO, and discuss related mechanisms.

Influence and mechanism of the tropical Pacific variability on the Arctic and its seasonality

*Tsubasa Takigawa[1], Yu Kosaka[1], Bunmei Taguchi[1], Lea Svendsen[2]

1. Research Center for Advanced Science and Technology, University of Tokyo, 2. Bjerknes Centre for Climate Research, University of Bergen

Arctic temperature has increased about twice as fast as global mean surface temperature in recent decades. While anthropogenic influence on this Arctic warming is evident, potential contributions from internal climate variability remains to be examined. Svendsen et al. (2018) showed that Pacific decadal variability played a key role in the early twentieth century Arctic warming through a coupled model pacemaker experiments with historical forcing. It is still unclear, however, how much influence the Pacific internal variability induces on the Arctic and how this remote influence is conveyed.
This study investigates the relationship between Arctic climate and tropical Pacific variability (TPV) by using a pre-industrial control experiment with GFDL CM2.1, with the primary aim to quantify the effect of TPV in different timescales. The result shows that the surface temperature response at high latitudes is amplified at multi-decadal timescales compared to sub-decadal one. The Arctic temperature anomalies peak near surface and diminishes with height. Moreover, Arctic temperature and sea ice responses feature strong seasonality with peak in late winter, despite weak seasonality of the tropical SST anomalies associated with decadal TPV. These features bear similarity to radiatively induced Arctic warming, and suggest importance of local feedbacks in Arctic climate variability driven remotely by the TPV.

Subsurface nonlinear dynamical heating and ENSO asymmetry in CMIP5: Implications for anthropogenic tropical-warming uncertainties

*Michiya Hayashi[1], Fei-Fei Jin[1]

1. Department of Atmospheric Sciences, University of Hawaii at Manoa

El Niño-Southern Oscillation (ENSO) is a dominant interannual tropical variability, playing a key role in worldwide climate. Most climate models participating in CMIP5 (Coupled Model Intercomparison Project phase 5) can produce ENSO amplitude close to observations, but the asymmetry between its warm and cold phases is still poorly simulated in general. Here, using 25 CMIP5 historical simulations and multiple ocean reanalysis datasets, it is shown that the model-to-model diversity of ENSO asymmetry is mostly explained by the representation of nonlinear dynamical heating (NDH) in the subsurface ocean along the equatorial Pacific thermocline. The skewness of sea-surface temperature (SST) anomalies in the Niño-3 region linearly increases with respect to the variability of the subsurface NDH among the CMIP5 models (correlation of 0.8). The NDH variability in most CMIP5 models is under-simulated due to weak Equatorial Undercurrent variability.

Using a small subset of the models having the NDH variability greater than the CMIP5 average, the influence of ENSO amplitude change in CMIP5 anthropogenic warming scenarios is further assessed. The future change in ENSO amplitude still shows a large spread even within this subset. Nevertheless, the long-term change in climatological NDH mean follows the ENSO amplitude change, which is absent in the rest of the CMIP5 models having weak NDH variability. Hence, increasing the rectification effect of the subsurface NDH that deepens the mean-state thermocline to warm the SST can enhance the so-called "El Niño-like" global-warming pattern that exhibits the faster eastern-Pacific surface warming. In contrast, suppressing the subsurface rectification effect can cause a more "La Niña-like" warming pattern. These results suggest that properly simulating ENSO asymmetry and subsurface NDH in climate models is critical on projecting future climate.

Uncertainty in the projections of ENSO amplitude change under global warming: Role of the response of atmospheric circulation to SST anomalies

*Jun Ying[1]

1. Second institute of Oceanography, Ministry of Natural Resources

The study investigates the mechanism of the large inter-model uncertainty in the change of ENSO’s amplitude under global warming, based on 31 CMIP5 models. We find that the uncertainty in ENSO’s amplitude is significantly correlated to that of the change in the response of atmospheric circulation to SST anomalies (SSTAs) in the eastern equatorial Pacific Niño3 region. This effect of the atmospheric response to SSTAs mainly influences the uncertainty in ENSO’s amplitude during El Niño (EN) phases, but not during La Niña (LN) phases, showing pronounced nonlinearity. The effect of the relative SST warming and the present-day response of atmospheric circulation to SSTAs are the two major contributors to the inter-model spread of the change in the atmospheric response to SSTAs, of which the latter is more important. On the one hand, models with a stronger (weaker) mean-state SST warming in the eastern equatorial Pacific, relative to the tropical-mean warming, favor a larger (smaller) increase in the change in the response of atmospheric circulation to SSTAs in the eastern equatorial Pacific during EN. On the other hand, models with a weaker (stronger) present-day response of atmospheric circulation to SSTAs during EN tend to exhibit a larger (smaller) increase in the change under global warming. The result implies that an improved simulation of the present-day response of atmospheric circulation to SSTAs will be effective in lowering the uncertainty in ENSO’s amplitude change under global warming.

Impact of atmospheric variability on Indian Ocean Dipole mode

*Yuya Baba[1]

1. JAMSTEC Japan Agency for Marine-Earth Science and Technology

Some preceding studies investigated tropical atmospheric internal variability such as Madden-Julian oscillation on the formation of Indian Ocean Dipole mode (IOD), but still number of the studies remains few, and their relationship remains unknown. In this study, we focused on the impact of atmospheric variability especially intraseasonal variability. To reveal the impact, we conducted sensitivity experiments for the IOD during 1980-2009, using an ocean general circulation model and difference atmospheric forcing data, such as (1) climatological forcing, (2) same as (1) but with yearly anomalies, (3) same as (1) but with seasonal anomalies, (4) same as (1) but with monthly anomalies, (5) 90-day low-pass filtered forcing. The simulated Dipole mode index (DMI) indicates that the sensitivity case of (1) could not reproduced realistic DMI at all, (2) and (3) reproduced decreased DMI amplitudes, and (4) and (5) reproduced similar DMI which was simulated with daily forcing data. In this presentation, possible mechanisms that caused different features of simulated IODs will be explained, focusing on the relationship between the variabilities of ocean and atmosphere.

Do salinity anomalies matter for the evolution of the IOD? –Experimental assessments using a regional ocean model-

*Shoichiro Kido[1], Tomoki Tozuka[1], Weiqing Han[2]

1. Graduate School of Science, The University of Tokyo, 2. Department of Atmospheric and Oceanic Sciences, University of Colorado Boulder

The Indian Ocean Dipole (IOD), which is a dominant climate mode in the tropical Indian Ocean, is accompanied by significant surface and subsurface salinity anomalies. These salinity anomalies alter density field and stratification in the upper ocean, and thereby have potentials to affect the evolution of the IOD itself. Though many previous studies have attempted to estimate the impacts of the IOD-related salinity anomalies, no comprehensive assessments have been conducted. To this end, a series of sensitivity experiments using a regional ocean model is conducted with a novel experimental strategy. Results from these sensitivity experiments show that interannual salinity anomalies associated with the positive IOD tend to suppress the cooling in the eastern equatorial Indian Ocean by about 1.0˚C. Through an on-line heat budget analysis of each experiment, it is shown that weakening of the upwelling in the eastern Indian Ocean, which originates from the upward shift of the Equatorial Undercurrent, is the primary cause of the suppressed cooling there. These changes are induced by enhanced stratification in the eastern equatorial Indian Ocean associated with negative (positive) salinity anomalies near the surface (pycnocline). Momentum budget analysis and additional sensitivity experiments using a linear continuously stratified ocean model further support these ideas. Therefore, salinity plays an active role in the evolution of the IOD, rather than being passively influenced by atmospheric anomalies.

Mechanisms of future changes in equatorial upwelling: CMIP5 inter-model analysis

*Shoshiro Minobe[1,2], Mio Terada[2], Curtis Deutsch[3]

1. Earth and Planetary Sciences, Faculty of Science, Hokkaido University, 2. Graduate School of Science, Hokkaido University, 3. School of Oceanography, University of Washington

The future change in equatorial upwelling is investigated for the Pacific and Atlantic Oceans using data from 24 Coupled *Model* Intercomparison Project Phase 5 (CMIP5) models for the Representative Concentration Pathway 8.5 scenario until 2100. Three-dimensional velocity components of CMIP5 multi-models are used for the first time in an upwelling study, and allow to divide upwelling velocities into diapycnal and isopycnal velocities. This analysis, combined with inter-model regression, revealed that both the multi-model ensemble (MME) mean and the inter-model variability in the upwelling change in the eastern equatorial Pacific, where strong upwelling change occurs, are explained by two mechanisms. One is that the diapycnal upwelling decreases near the surface, which is associated with a weakened Ekman divergence. The other is that the isopycnal upwelling decreases at depths of 75–200 m around the core of the equatorial undercurrent (EUC) due to EUC flattening. Both the weakened Ekman divergence and the EUC flattening are induced by the locally weakened trade wind over the eastern Pacific basin. In the equatorial Atlantic, both the change in MME mean and the inter-model variability of upwellings are significantly related to the weakened trade wind and enhanced stratification, although these drivers are not independent. The results for the Pacific Ocean imply that future reduction in upwelling may impact the sea surface temperature and marine ecosystem by different mechanisms. The rapid warming of sea surface temperature in the eastern Pacific basin may be related to the near-surface diapycnal upwelling reduction, while the decrease in net community production, which is often measured by marine export production at a depth of 100 m, may be related to the isopycnal upwelling reduction.

The Indo-Pacific cross-basin interaction of the decadal climate variability under the progress of the global warming

*Yuma Miyaji[1], Youichi Tanimoto[2]

1. Hokkaido University, Graduate School of Environmental Science, 2. Hokkaido University, Faculty of Environmental Earth Science

We investigate a relationship of the decadal sea surface temperature (SST) variability between over the Indian Ocean and over the tropical Pacific based on the observed data sets and the multi-model climate simulations. In the present study, by subtracting the multi-model ensemble mean rather than the observed linear trend, we attempt to retain the decadal signals without the effect of the radiative forcing, in the observed long-term records of the ocean and atmosphere.
While several observational studies indicated that the simultaneous correlation coefficient of the long-term SST variability over the two basins changed from positive before 1985 into negative after 1985, our analysis always shows the positive correlation regardless of the selected decades, indicating that the internal dynamics of the Indo-Pacific ocean-atmosphere system for this cross-basin interaction. While the decadal variations of the surface winds over the Indian Ocean are influenced by the SST variability over the tropical Pacific, the SST formation processes by those surface winds are different among the regions north and south of 10˚S, respectively. The effect of the climatological meridional gradient in the thermocline depth on the different formation processes is discussed.

Air-sea flux observation by unmanned autonomous sea surface vehicle in the Tropics - Application of the Wave Glider -

*Iwao Ueki[1]

1. JAMSTEC Japan Agency for Marine-Earth Science and Technology

Air-sea fluxes of heat and momentum are fundamental variables for the ocean and atmosphere interaction, which influence weather and climate. The air-sea flux measurements; actually measurements of air temperature, humidity, sea surface temperature, winds, and radiations, are mainly conducted by research vessels, mooring buoys, and satellites. Based on these measurements, many types of global air-sea flux products are produced. However, these products still remain large biases and uncertainties in the global fields. Reducing inaccuracies in air-sea fluxes is important for improving long-term weather and climate predictions. For that purpose, we should consider about intensification of *in situ* measurements, which contribute to improve bulk algorithms, to understand mechanisms of flux variability, and to validate the products as proposed in Community White Papers of air-sea fluxes with a focus on heat and momentum in OceanObs’19. Due to the relatively high cost of research vessel and mooring buoy operations, number of in situ measurements is limited. The sparsity of the *in situ* measurement in present situation is one of obstacles to improve satellite algorithm development and product validation. Because of recent progress of unmanned autonomous ocean surface vehicles (UAVs) development, we can use these vehicles as a platform for air-sea flux observation. In this study, several field tests and evaluations of the acquired data through comparison with mooring buoys have been conducted especially in the tropical region. The present status of these activities will be introduced in the presentation.

Radar-derived Fresh water flux and its possible impact to the oceanic stratification observed during the Years of the Maritime Continent (YMC)

*Masaki Katsumata[1], Biao Geng[1], Satoru Yokoi[1], Shuichi Mori[1], Iwao Ueki[1]

1. Japan Agency for Marine-Earth Science and Technology

To investigate the air-land-sea interaction in the Maritime Continent (the world's largest archipelago bridging tropical Indian Ocean and tropical western Pacific), a series of the field campaign “YMC-Sumatra” was conducted as part of the project "Years of the Maritime Continent (YMC)". In “YMC-Sumatra 2017”, we deploy the research vessel "Mirai" at one station near the west coast of Sumatra Island to obtain time series.

The continuous dataset from C-band polarimetric radar is converted to the rainrate (i.e. fresh water flux) by utilizing the data from disdrometers and raingauges. The estimated fresh water flux is compared to the oceanic near-surface stratifications measured by the unmanned surface vehicle “wave glider”. The observed salinity at 0.2m and 6m depths differ under a precipitating event with weak wind (< 5 m/s). The event was followed by the strong wind (>10 m/s) precipitation. After the event, low salinity layer was captured down to 30~40 m depth for more than half days.

Driving Mechanism of Inter-Annual Precipitation Variability during Monsoon Season over the Northern Part of Sumatra Island, Indonesia

*Yahya Darmawan[1,2,3], Huang-Hsiung Hsu[2]

1. Taiwan International Graduation Program, Academia Sinica, 2. Research Center for Environmental Changes, Academia Sinica, 3. Indonesian Agency for Meteorology, Climatology and Geophysics (BMKG)

The precipitation variability of the Northern part of Sumatra Island in Indonesia has been driven by the complex tropical climate systems along with the local factors. The aim of this study is to investigate the driving mechanism of precipitation variability during the JJA-periods (June, July, and August) over the northern part of Sumatra. Moist Static Energy (MSE) budget analysis was used to model the source of energy which supports the precipitation anomalies. Composite analysis and statistical methods were used for confirming the result of MSE budget. By using 36 years of ERA-interim data, precipitation anomalies of JJA periods were classified into two categories, namely: wet years and dry years. Positive precipitation anomalies are found during the wet years which are supported by the upward motion of vertical velocity. During the wet years, the weaker easterly wind of Indian Summer Monsoon (ISM) associated with the westerly winds of a negative El Niño–Southern Oscillation (ENSO), a positive Indian Ocean Dipole (IOD), and a strong Western North Pacific Subtropical High (WNPSH). As a consequence, these anomalous circulations trigger a moisture flux convergence and positive precipitation anomaly. In the dry years, the downward of vertical velocity leads to negative precipitation anomaly. Generally, a stronger easterly wind of ISM was found during the dry years which is associated with a positive ENSO, a negative IOD, and a weak WNPSH. Even though the precipitation anomalies occur due to the collaboration of those winds, a new finding shows that WNSPH has a stronger impact to the precipitation anomalies than ENSO and IOD in the Northern part of Sumatra Island. In addition to those circulations, higher topography of the Barisan Mountains supports the ascending motion to moisten the lower troposphere and induces a positive precipitation anomaly in this maritime continent.

The impact of diurnal precipitation over the maritime continent on synoptic disturbances and its relation to the MJO

*Ayako Seiki[1], Satoru Yokoi[1], Masaki Katsumata[1], Kunio Yoneyama[1]

1. Japan Agency for Marine-Earth Science and Technology

Diurnal cycle has been known to contribute to a significant amount of precipitation over the maritime continent. In this study, the impact of diurnal precipitation over Sumatra Island, the Indonesian maritime continent, on synoptic disturbances over the surrounding ocean, especially the eastern Indian Ocean, is examined using the Global Satellite Mapping of Precipitation (GSMaP) data. High precipitation area observed over Sumatra in afternoon migrates offshore during night-time and reaches 500 km off the coast in average. Synoptic disturbances represented by eddy kinetic energy are enhanced south of the equator off Sumatra when the diurnal precipitation is strong, then they migrate poleward with cyclonic structures over the eastern Indian Ocean. These results suggest that the diurnal precipitation over Sumatra can excite synoptic disturbances over the eastern Indian Ocean.

Narrow corridors of moisture transport bands over the middle latitudes called atmospheric rivers (ARs) are important phenomena for hydrological cycle and natural disasters. Landfalling ARs associated with extratropical cyclones bring huge amount of rainfall over western coasts of North America and Europe. Previous studies pointed out that large-scale anomalies in atmospheric circulation associated with El Niño-Southern Oscillation (ENSO) are important factors for interannual variability in frequency of wintertime ARs over western North America. Recently, Kamae et al. (2017) revealed that ARs were also frequently observed over East Asia, especially during boreal summer. They also pointed out that preceding winter's El Niño results in anomalously-enhanced AR activity over summertime East Asia with a half-year lag. After the wintertime El Niño development, delayed warming over the Indian Ocean produces an anomalous anticyclone over the western North Pacific and associated increase in summertime AR frequency over East Asia. However, possible impacts of ENSO transition from preceding winter to concurrent summer on summertime AR activity over East Asia are still unclear. Here we extend our understanding on seasonal ENSO-AR relationship by compositing individual ENSO transition cases from winter to summer including rapid transitions from El Niño to La Niña. The rapid transition results in an anomalous AR activity over East Asia associated with the anomalous anticyclone over the western North Pacific. The anomalous anticyclone shifts northward compared to those found in years with sustained El Niño or decayed El Niño. We also found that the impacts of ENSO transition on ARs can be understood as a result of summertime teleconnection from the tropics favored by anomalous convective heating over the tropics associated with anomalous Walker circulation over the equatorial Pacific.

Impact of tropical Pacific sea surface temperature on the regional heavy rainfall events in Japan

*Yukiko Imada[1], Hiroaki Kawase[1], Masahiro Watanabe[2], Izuru Takayabu[1]

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Atmosphere and Ocean Research Institute, the University of Tokyo

To detect the impact of global-scale climate on regional extreme events is challenging especially for disastrous regional heavy rainfall events which are often strongly affected by local topography. Observed records are too short to obtain significant concurrent signals. General circulation models (GCMs) can represent background large-scale circulations causing regional heavy rainfall but cannot resolve the topography. On the other hand, high-resolution regional climate model can resolve orographic rainfall but cannot provide the information of key processes in larger-scale circulation. Here, we prepared a large-ensemble pair of GCM and nonhydrostatic regional model simulations covering 6800-year samples. It enables us to access local rainfall event directly and investigate cause-to-effect pathway to explain the impact of global scale climate. As an example, we cite 2-type heavy rainfall events around precipitous terrains in Japan: western Kyushu type and eastern Kyushu type. The western Kyushu type related to moisture transport is attributed to the development of the Pacific subtropical High which is often forced by an El Nino event during previous winter. On the other hand, the eastern Kyushu type is attributed to TC approach which correlates to the central Pacific El Ninos. Through this new flamework with large-ensemble pairs of global and regional simulations, we can verify various influence pathways of large-scale climate to specific regional extreme events.

The North Pacific pacemaker effect on historical ENSO and its mechanisms

*Yu Kosaka[1], Dillon J. Amaya[2], Wenyu Zhou[2], Yu Zhang[2], Shang-Ping Xie[2], Arthur J. Miller[2]

1. Research Center for Advanced Science and Technology, University of Tokyo, 2. Scripps Institution of Oceanography, University of California San Diego

Recent studies have indicated that North Pacific sea surface temperature (SST) variability can significantly modulate the evolution of the El Niño-Southern Oscillation (ENSO), but there has been little effort to put these extratropical-tropical interactions into the context of historical ENSO events. To quantify the role of the North Pacific in pacing the timing and magnitude of observed ENSO events, we use a fully-coupled climate model to produce the first ensemble of North Pacific Ocean-Global Atmosphere (nPOGA) SST pacemaker simulations. In nPOGA, SST anomalies in the North Pacific (>15˚N) are restored back to observations, but are free to evolve throughout the rest of the globe. We find that North Pacific SST variability has significantly influenced the observed trajectory of historical ENSO, accounting for approximately 15% of the total variance in boreal fall and winter. The interaction between the North and tropical Pacific is the result of two physical pathways: 1. A Wind-Evaporation-SST propagating mechanism in boreal spring, and 2. A convective response associated with the Seasonal Footprinting Mechanism in boreal fall. The latter accounts for 25% of the observed zonal wind variability around the equatorial dateline. On an event-by-event basis, nPOGA most closely reproduces the 2014-2015 and the 2015-2016 El Niño events. In particular, we show that the 2015 Pacific Meridional Mode event increased wind forcing along the equator by 20%, potentially contributing to the extreme nature of the 2015-2016 El Niño. Our results illustrate the significant role of extratropical noise in pacing the initiation and magnitude of ENSO events and may improve the predictability of ENSO on seasonal timescales.

Detection of the dry intrusions from the mid-latitudes to the Equator and their association with MJO

*Saki Yanagisawa[1], Akiyo Yatagai[1]

1. Hirosaki Univercity

Dry intrusion is a large-scale intrusion phenomenon of extremely dry air into tropics and it influences on the cumulus convection. However, their large-scale features and statistics have not been revealed yet. The purposes of this study are detecting the dry intrusions using a long-term reanalysis data (the ERA-Interim, 0.75˚ grid) and clarifying relationship between the appearance of the dry intrusions and the Madden-Julian Oscillation (MJO) activity.
First, we drew daily map of precipitable water (PW) from the ERA-interim for the year from 1998 to 2016 (total 10593 days), and we counted the appearance at every 20˚ longitudes according to the following conditions; 1) the dry intrusion arrives at 10˚S-10˚N and is maintained for 2-10 days, 2) It forms a crescent shape with an area that PW of less than 40 mm, 3) It includes areas with a PW of less than 30 mm and 4) The entire dry intrusion fits into an area of roughly 2000 km^2.
Among the 10593 days, we detected 1118 cases in all so the dry intrusions appear about 40 times a year in average, and appearance in the Northern Hemisphere are less (388 cases), and more in the Southern Hemisphere (730 cases). About 90% of the dry intrusions were detected in an area from the Indian Ocean to the western tropical Pacific in both hemispheres. The appearance of the dry intrusions has seasonal dependence; a lot of the dry intrusions are in winter and few are in summer in both hemispheres. Sometimes the dry intrusions by above definitions were appeared in association with the strong tropical cyclones, and they reach 8% of the total number of appearances of the dry intrusions.
We composited 700 hPa and 850 hPa zonal wind when the dry intrusions were appeared around the Indian Ocean, the Maritime Continent and the western tropical Pacific, respectively. As a result, a strong westerly wind blew around an area where dry intrusions were appeared in the Indian Ocean and the western tropical Pacific. In the Maritime Continent, a strong westerly wind blew on the west side of the Maritime Continent. Such wind fields occurred also at the MJO activity and it is called the Westerly wind burst (WWB). The WWB blew over the western tropical Pacific when the dry intrusions occurred in the Maritime Continent and the western tropical Pacific. Therefore, it may be had an association between a convection activity by the MJO and dry air intrusion. Over an entire period, 25.2% of all the dry intrusions detected in the western tropical Pacific occurred when the MJO was active in there and 14.8% occurred in the same area but the MJO was not active. The remaining 60.0% occurred when the MJO was active or non-active in other areas. This percentage has become lower in cases of the dry intrusions occurred in the Indian Ocean and the Maritime Continent.

Relationship between oceanic and atmospheric variations in the Philippine Sea and modulation of El Nino events

*Takuya Hasegawa[1], Akira Nagano[2], Iwao Ueki[2], Kentaro Ando[2]

1. Tohoku University, 2. JAMSTEC

Western Pacific Oscillator model (WPO model), which is the one of the ENSO theory models, shows strong anti-cyclonic anomalies over the wetern tropical Pacific (around Philippine Sea) after a mature phase of El Nino. To check this point, time series of sea level pressure (SLP) anomalies averaged over the Philippine Sea for boreal-winter (i.e., January to March) is made. The result shows that eastern-Pacific (EP)-El Nino events (1982.83, 1986/87, 1991/92, 1997/98) show strong positive SLP anomalies in line with the WPO model. On the other hand, central-Pacific (CP)-El Nino events (1994/95, 2002/03, 2004/05, 2006/07, 2009/10) show weak SLP anomalies. Next, composite maps for SLP and sea surface winds during boreal-winter in the year of occurrence of EP-El Nino and CP-El Nino are made, respectively. It is shown that positive SLP anomalies and related anti-cyclonic sea surface wind pattern appear over the Philippine Sea for EP-El Nino. In the south part of the Philippine Sea, easterly anomaly winds appear and it can lead poleward Ekman transport that decreases warm water volume in the western equatorial Pacific. This situation is consistent with that expected from the WPO model, that is, the equatorial cold Kelvin waves can be generated, and then will terminate the on-going El Nino event to start the next La Nina event. Analysis on the sea surface height anomalies also shows negative sea surface height anomalies in the western equatorial Pacific at that time. In contrast to the EP-El Nino, CP-El Nino does not show such patterns of SLP, sea surface wind, and sea surface height anomalies. Therefore, it can be said that WPO model does not well act after mature phase of CP-El Nino, while the model does well after mature phase of EP-El Nino.

Contribution of oceanic wave propagation from the tropical Pacific to asymmetry of the Ningaloo Nino/Nina

*Hidehiro Kusunoki[1], Shoichiro Kido[1], Tomoki Tozuka[1]

1. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo

Ningaloo Nino (Nina) is a climate mode associated with anomalously warm (cool) sea surface temperature (SST) off the Western Australian coast. Considering its large impacts on the local marine ecosystem and precipitation, better understanding of its mechanism and predictability is desirable. Existing studies suggest that both local air-sea interaction and remote forcing contribute to generation and amplification of the Ningaloo Nino/Nina. The latter forcing includes the atmospheric teleconnection and oceanic wave propagation through the Indonesian archipelago, mainly associated with the El Nino/Southern Oscillation (ENSO). One of the important characteristics of Ningaloo Nino/Nina is its asymmetry; the Ningaloo Nino is stronger than the Ningaloo Nina. This suggests the presence of some asymmetry in these processes. However, no studies to date focused on this topic.

Using a regional ocean modeling system (ROMS), the contribution of oceanic wave propagation to the amplitude and asymmetry of SST anomalies associated with the Ningaloo Nino/Nina is investigated. For these purposes, a sensitivity experiment in which oceanic lateral boundary conditions are replaced by the monthly climatology is conducted. The results suggest that downwelling (upwelling) Kelvin waves from the western tropical Pacific associated with La Nina (El Nino) that often co-occur with Ningaloo Nino (Nina) are stronger (weaker) and contribute to the asymmetry.

The life-cycle of annual waves in the Indian Ocean as identified by a seamless diagnosis for the energy flux

*Zimeng Li[1], Hidenori Aiki[2]

1. Graduate school of environmental studies, Nagoya university, 2. Institute for space-earth environmental research, Nagoya university

The role of synoptic-scale waves in tropical-extratropical interactions has been little investigated in terms of the transfers of wave energy, owing to the lack of an appropriate diagnosis scheme in previous studies. A recent theoretical study has derived a seamless scheme that is able to identify the direction of group velocity for both gravity and planetary waves at all latitudes. This new scheme has been used in the present study to provide a first-ever energetic view for the life-cycle of annual waves in the Indian Ocean in a set of shallow-water model experiments with climatological wind forcing. The new scheme is able to show, in particular for the second baroclinic mode, eastward energy fluxes associated with equatorial Kelvin waves (KWs) whose signal are found to span the full zonal extent of the tropical Indian Ocean. For the first and third baroclinic modes, eastward signals at the equator are found to appear in the western and eastern parts of the basin, respectively. Concerning the low-pass filtered time evolution the energy flux, eastward signals associated with equatorial KWs are found to culminate when zonal currents change direction (four times per year) according to monsoon winds. Waves in the tropical and subtropical regions are connected each other at the zonal boundaries of the Indian Ocean that has been viewed, for the first time in the history of geophysical fluid dynamics, in terms of the circulation of wave energy. Near the eastern boundary of the Indian Ocean, the incoming signals of equatorial KW bifurcate polewards along the coasts of Bay of Bengal and Australia and then transmit midlatitude Rossby waves, forming a basin-scale cyclonic energy circulation in each hemisphere. Near the western boundary of the Indian Ocean, the seasonal variations of both the Somali jet and the east African coastal current are found to yield equatorward energy fluxes along the African coast, forming a localized cyclonic energy circulation in each hemisphere. These results for the analysis of climatological annual waves provide a basis for the analysis of waves with interannual variations in a future study to better understand, for example, tropical-extratropical interactions during the Indian Ocean Dipole mode.

[A-CG38] Multi-scale ocean-atmosphere interaction in the tropical Indo-Pacific region

convener:Ayako Seiki(Japan Agency for Marine-Earth Science and Technology), Tomoki Tozuka(Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo), Motoki Nagura(Japan Agency for Marine-Earth Science and Technology), Youichi Kamae(Faculty of Life and Environmental Sciences, University of Tsukuba)

Multi-scale ocean-atmosphere interaction in the tropics exerts a significant imprint on the global climate via atmospheric teleconnection. Since the 1980s, anchored by in-situ and satellite observations, improvements in modeling and theoretical understanding, various aspects of dominant modes of interannual (e.g., ENSO and IOD), intraseasonal (e.g., MJO) variabilities and their impacts on tropical (e.g., monsoons) and extra-tropical (e.g., North America) climate variations have received wide attention. Recent satellite-based salinity measurements indicate for an active role of salinity in the tropical ocean-atmosphere interaction. While recent studies suggest a possible link between interdecadal Pacific oscillation and global warming hiatus in 2000s, changes (if any) in the tropical ocean-atmosphere interaction are yet to be understood. Due to interactions between different time scales, between different ocean basins, and with the extratropics, the tropical ocean and atmosphere play a key role in shaping climate, its variability and change. To better understand and examine these challenging issues from various perspectives, this session offers a forum to discuss recent progress in observational, modeling and theoretical studies of multi-scale tropical ocean-atmosphere interaction.

Impacts of seasonal transitions of ENSO on frequency of atmospheric rivers over East Asia

*Youichi Kamae[1], Moeka Naoi[2], Hiroaki Ueda[1]

1. Faculty of Life and Environmental Sciences, University of Tsukuba, 2. Graduate School of Life and Environmental Sciences, University of Tsukuba

Narrow corridors of moisture transport bands over the middle latitudes called atmospheric rivers (ARs) are important phenomena for hydrological cycle and natural disasters. Landfalling ARs associated with extratropical cyclones bring huge amount of rainfall over western coasts of North America and Europe. Previous studies pointed out that large-scale anomalies in atmospheric circulation associated with El Niño-Southern Oscillation (ENSO) are important factors for interannual variability in frequency of wintertime ARs over western North America. Recently, Kamae et al. (2017) revealed that ARs were also frequently observed over East Asia, especially during boreal summer. They also pointed out that preceding winter's El Niño results in anomalously-enhanced AR activity over summertime East Asia with a half-year lag. After the wintertime El Niño development, delayed warming over the Indian Ocean produces an anomalous anticyclone over the western North Pacific and associated increase in summertime AR frequency over East Asia. However, possible impacts of ENSO transition from preceding winter to concurrent summer on summertime AR activity over East Asia are still unclear. Here we extend our understanding on seasonal ENSO-AR relationship by compositing individual ENSO transition cases from winter to summer including rapid transitions from El Niño to La Niña. The rapid transition results in an anomalous AR activity over East Asia associated with the anomalous anticyclone over the western North Pacific. The anomalous anticyclone shifts northward compared to those found in years with sustained El Niño or decayed El Niño. We also found that the impacts of ENSO transition on ARs can be understood as a result of summertime teleconnection from the tropics favored by anomalous convective heating over the tropics associated with anomalous Walker circulation over the equatorial Pacific.

[A-CG39] Biogeochemical cycles in Land Ecosystem

convener:Tomomichi Kato(Research Faculty of Agriculture, Hokkaido University), Kazuhito Ichii(Chiba University), Takeshi Ise(FSERC, Kyoto University), Munemasa Teramoto(National Institute for Environmental Studies), Chairperson:Tomomichi Kato(Hokkaido University)

Terrestrial ecosystem influences global climate through cycles of water, carbon, and nitrogen between land surface and atmosphere. For better understanding of those behaviors, a great effort has been paid for developing varieties of approaches and techniques such as biometric survey, eddy and chamber methods, near and satellite remote sensing, biosphere modeling and so on.
 In particular, the JapanFlux, founded in 2006 as a researchers network of CO2, H2O and other trace gas flux measurement, has promoted the multi-disciplinal studies not only for flux measurement community, but also for remote sensing and biosphere modeling communities. Moreover, the Research-Group-on-Integrated-Land-Processes, which was founded in 2006, also has contributed to build networks between Japanese researchers to better understanding of physical and biological processes on interactions between terrestrial surface and atmosphere.
 This session unites those multi-disciplinal activities, and promotes the oral and poster presentations on the role of terrestrial ecosystem in material circulations of water, carbon, nitrogen, energy and other substances by any approaches and technics. This session takes over the former session in last year: A-CG40.

Laboratory examination of combined effects of temperature rising and increased water fluctuation on CO_2 release from volcanic ash soils

*Hirohiko Nagano[1], Mariko Atarashi-Andoh[1], Jun Koarashi[1]

1. Japan Atomic Energy Agency

Global warming will alter the precipitation pattern, resulting in the increase in seasonal fluctuation of soil water conditions. Both environmental factors of soil temperature and water fundamentally affect soil CO_2 release, a major carbon flux in terrestrial ecosystems. However, our understandings of soil CO_2 release under the increased temperature and fluctuated water conditions are still insufficient to infer the feedback of terrestrial carbon cycling in future worlds. In the present study, we are conducting laboratory incubation experiments for examining the combined effects of temperature rising and soil water fluctuation on CO_2 release from volcanic ash soils. Volcanic ash soil is the major soil type in Japan and is expected to have great ability to stabilize carbon as soil organic matter. We incubated volcanic ash soils under four combinatorial conditions of two temperatures (20 and 30 ˚C) and two water conditions (a continuously constant water and a fluctuated water conditions). The rate of CO_2 release was periodically measured during the incubation. Then, the ratio of CO_2 release at 20 ˚C to that at 30 ˚C, namely Q_{10}, was expressed as the temperature sensitivity of soil CO_2 release. The fluctuated water condition was maintained with multiple dry-wet cycles to achieve an average water content of 40% of water holding capacity which was equivalent to that under the continuously constant water condition. For the incubation at 20 ˚C, soil CO_2 release under the fluctuated water condition was up to 50% greater than that under the constant water condition. The excess of soil CO_2 release under the fluctuated water condition was, however, reduced to less than 10% for the incubation at 30 ˚C. Thus, Q_{10} under the fluctuated water condition (1.3 to 1.5) was equivalent to or lower than that under the continuously constant water condition (around 1.5). These preliminary results offer the needs of modifying basal CO_2 release extent and Q_{10} value for inferring the soil CO_2 release under increased temperature and fluctuated water conditions. The experiments are still ongoing and results and further insights will be presented at the meeting.

1. Introduction

Intense land-use change in tropical Asia has a significant influence on greenhouse gases (GHGs) budget in the region. Conversion of tropical peat swamp forest to both acacia and oil palm plantation is a typical land-use change in the region. To evaluate impact of the conversion on GHGs budget, we have to quantify many related processes, for example, enhanced decomposition of peat soil, N_2O emission from fertilization, biogas emission from palm oil mill effluent (POME) treatment ponds, etc. Oil mill facility is built adjacent to oil palm field because fresh oil palm fruit needs to be processed immediately after harvest. Oil palm plantation forms a stationary material cycle system as an integration of palm oil field and mill facility. POME treatment ponds is typical waste water treatment system in an oil palm plantation. Biogas contains high concentration of methane, because methane fermentation is an essential process in waste water purification in the ponds. Measured values of GHGs emission from POME treatment ponds is limited. We conducted field observation of GHGs emission from a POME treatment ponds in an oil palm plantation in tropical peatland as a joint research of National Institute for Environmental Studies and Sarawak Tropical Peat Research Institute.

2. Methods

We conducted field measurement of GHGs emissions from POME treatment ponds in an oil palm plantation on tropical peatland near Sibu Town, Sarawak, Malaysia. The life of the sampling equipment was assumed considerably short in POME treatment ponds due to the exposure to high concentration of corrosive hydrogen sulfide and pollution by oily scum. To quantify GHGs emission from the ponds, we had developed floating chamber system specialized to the POME ponds. The low cost and program controlled system made it possible to perform multi-point simultaneous sampling automatically in a short period of time. We collected biogas from the ponds into balloons of gas-barrier film using the chambers. We measured total amount of biogas in the balloons with modified water replacement method firstly, consequently measured concentration of gases (CH_4, CO_2, O_2, H_2, and H_2S) with portable gas monitor (BIOGAS 5000, Gastech, U.K.). We calculated gas fluxes from covered area, sampling duration, gas volume and gas concentrations. The gas fluxes measurements were conducted in eight ponds in upstream side of whole ten ponds during dry season (June 2018).

3. Results and discussions

Biogas from POME treatment ponds were mainly CO_2 and CH_4. Markedly large biogas flux was found in fourth pond from upper stream. About 65% of the biogas from the fourth pond was CH_4. This might be due to neutral pH and moderate temperature were suitable for methane fermentation in the pond. In the three upper-stream ponds, the pond water was acidic in which CO_2 dominated about 60% of biogas. Biogas flux was small in the ponds in lower-stream of the forth pond.

4. Summary

©2019. Japan Geoscience Union. All Right Reserved.

In the POME treatment ponds, decomposition process of organic matter in POME would be different in each stage because of differences in the various environmental factors such as pH, temperature, organic matter content, etc. It was successful in the integration of data in severe environmental condition in the POME treatment ponds despite various technical challenge. Oil palm plantation is a continuous and stationary material flow system as a whole including plant field, mill facility and POME treatment ponds. To fully understand the impact of land-use change on GHGs budget, it is very important to quantify the relationship between GHGs budget and material cycle in the whole plantation system. Besides field measurements, we also do interviews on material flow in the plantation with the cooperation of business entity of the plantation.
We will introduce the result of wet season (January 2019) during this presentation.

Soil CO_2 efflux dynamics with land-use changes in Southeast Asia

*HAJIME TOMIMATSU[1], NAISHEN LIANG[1], MUNEMASA TERAMOTO[1], JIYE ZENG[1], ZHAO XIN[1]

1. National Institute for Environmental Studies

Land use changes greatly affect carbon cycle of forest ecosystem. Since the 1970s, about 35% of tropical primary forests were lost due to disorderly commercial logging, plantation development such as oil palm and rubber in Southeast Asia. These rapid land use changes cause serious environmental problems such as soil erosion, decrease in soil fertility, and decrease in productivity. As a result, there will be a major change in the regional biochemical cycles.

Soil is an important source of information on the global carbon budget and it is a carbon sink, and soil respiration (R_s) is one of the most important elements of the carbon cycle in terrestrial ecosystems. Land use changes influence the dynamics of R_s. However, most studies on the effects of land use change on R_s focused on the boreal, temperate and subtropical ecosystems. In Southeast Asia, we have addressed the response of R_s to the land use changes, but mostly it is a short period with little spatial or temporal repetition, especially there are few long-term observations in lowland rainforests with no seasonal changes in temperature.

To examine the long-term response of R_s to land use change in Southeast Asia, we selected 4 research sites of different land use type, primary forest (PF), secondary forest (SF), oil palm plantation (OP), and rubber plantation (RP). In 2010, we installed total 30 soil collars (diameter 32 cm) in each site. The 30 collars were distributed in two rows, each with 15 collars and at 5 m intervals. R_s was measured every two weeks using a portable automatic opening and closing chamber system developed by the National Institute for Environmental Studies.

R_s showed synchronicity seasonal change among all sites, suggesting that it is controlled by both soil temperature and moisture. The apparent temperature sensitivity of R_s (Q_{10}) decreased from 4.86 in NF to 2.09 in SF, 2.14 in OP, 3.79 in GP. In addition, the annual average soil respiration rate decreased about 38% in SF, about 33% in OP and about 40% in GP compared with NF. Our results indicate that logging and/or conversions of primary forests to plantations lead severe soil degradation.

Individual-based analyses of the carry-over effects from recent climatic conditions on the interannual variability of LAI of an evergreen conifer stand

*Akihiro Sumida[1], Tsutomu Watanabe[1], Tomiyasu Miyaura[2]

1. Institute of Low Temperature Science, Hokkaido University, 2. Faculty of Science and Technology, Ryukoku University

The leaf area index (LAI) of a forest stand has been known to remain within a specific range after a peak at relatively young stand ages. For evergreen stands, however, little has been known about interannual variability of LAI and its effects on biomass increase. In this paper we introduce a series of studies ([1], [2]) in which interannual variability of the LAI and the growth rates of stem biomass were investigated with biological and climatic factors affecting them in an evergreen hinoki cypress (*Chamaecyparis obtusa*) stand between 21 and 40 years of stand age. In this long-term investigation, the stem diameter at the crown base (D_{CB}) was recorded for all living trees each year. This allowed us to estimate the leaf area of a tree (tree LA) using an allometric equation, which is known to be little affected by the difference in stand ages. Given the tapered shape of a tree stem within the crown, a rapid rise of the crown base height can lead to a decrease in D_{CB}, or a decrease in the tree LA. The other measurements also allowed us to estimate the stem dry mass for each tree in each year, and then the stand LAI and the stand stem biomass. The prediction intervals of LAI and stand stem biomass were evaluated for each year by propagating errors of those individual-based estimates. Monthly meteorological data were obtained using the climatic measurements recorded at the nearest weather station (AMeDAS).

The LAI varied between 7.1–8.8, with a relatively long fluctuation cycles over the observation period. This LAI range was maintained such that the gradual increase in the LA of the largest trees counterbalanced the gradual loss in LA of the smallest trees. The decrease in LA of the smallest trees resulted in their gradual death. Just before their death year, their tree LA had decreased to ~1% of the LAI of that year. Hence their death did not affect the LAI. These smallest trees were able to survive for many years even as their LA was decreasing, which would be important for LAI to be maintained without a sudden decrease. The total basal area decreased twice during the 20 years, whereas the stand stem biomass never decreased despite the death of trees. This was because the portion of the stem within the crown maintained a certain level of radial growth even in the trees with almost no stem radial growth at breast height.

There was a weak but significant positive relationship (r=0.40) between the LAI and the current-year mean summer temperature (July and August). This indicates that LAI tended to increase in the year with warm summer during which new leaves are produced. Further, we found that the moving average of the summer temperatures of 6 years (the current year and the previous 5 years) indicated a much stronger relationship (r=0.93) with the current-year LAI. According to a previous study in the same forest, the mean turnover time of the canopy leaves was estimated to be 4.3–6.3 years, suggesting that the summer temperature of the past years when the leaves in the current-year canopy accumulated was strongly influential in the LAI of the current year.

As canopy photosynthesis would generally be proportional to LAI, we had expected that the annual stem biomass increase rate (dB_{STEM}) would be greater in a year with a high LAI. However, the relationship

©2019. Japan Geoscience Union. All Right Reserved.

between them was not significant (r=0.09). Instead, dB_{STEM} had a positive significant relationship with the sum of precipitation of early summer (May-July) of the current year. Preceding studies of tree physiology have pointed out that a considerable portion of non-structural carbohydrates (NSC) from photosynthesis are used for purposes other than growth (e.g., maintenance of physiological homeostasis), and that the priority of the NSC to be allotted to growth would be lower than any other uses. This partly explains why dB_{STEM} was not correlated with LAI.

Carbon dioxide balance of an oil palm plantation on tropical peat

*Takashi Hirano[1], Frankie Kiew[2], Ryuichi Hirata[3], Guan Xhuan Wong[2], Edward Baran Aries[2], Kevin Kemudang[2], Joseph Wenceslaus[2], Lo Kim San[2], Lulie Melling[2]

1. Research Faculty of Agriculture, Hokkaido University, 2. Sarawak Tropical Peat Research Institute, 3. CGER, National Institute for Environmental Studies

Oil palm plantations have been expanding rapidly over recent decades especially in Indonesia and Malaysia, the two largest oil palm producers in the world. The greatest concern associated with such expansion is its environmental impact. Carbon rich tropical peat swamp forest is also not excluded from such expansion, because it is accessible for developers. Carbon dioxide (CO_2) release through accelerated oxidative peat decomposition is one of the main environmental concerns in the land conversion from peat swamp forest into oil palm plantations, which were drained and compacted to increase yield. Changes in aboveground biomass also might significantly alter the CO_2 exchange dynamics of the ecosystems. Despite the possible significant changes in the CO_2 balance through the land conversion, there is still no study on the ecosystem-scale CO_2 balance of oil palm plantations established on tropical peat. Thus, we have monitored CO_2 flux above an oil palm plantation established on tropical peatland in Sarawak, Malaysia by the eddy covariance technique since 2011. We quantify the annual CO_2 balance of the oil palm plantation and compare it with that of a secondary peat swamp forest in the same region.

The effect of heat wave in the summer of 2018 on carbon and water fluxes in an open black spruce forest in an interior Alaska

*Hideki Kobayashi[1], Robert Busey[2], Yongwon Kim[2], Sigrid Dengel[3], Stephen Chan[3]

1. Japan Agency for Marine-Earch Science and Technology, 2. International Arctic Research Center, University of Alaska, Fairbanks, 3. Lawrence Berkeley National Laboratory

Temperatures have been increasing at higher rate in the northern high latitudes than any other regions of the globe, especially over the land areas, and are projected to continue to do so during this century. In interior Alaska, where the majority of landscape is covered with evergreen needleleaf forest, an exceptionally hot dry summer heat wave was observed in July 2018. In this study, we investigated the eddy covariance carbon and water fluxes under the hot dry period in July 2018. The study was performed in an open black spruce forest site located in the Poker Flat Research Range in interior Alaska. Three eddy covariance systems (two enclosed path and one open path eddy covariance systems) were utilized in the study period. We found the significant down regulation of net ecosystem exchanges (NEE) during a high temperature period during DOY 201-206, 2018. We will introduce the results from the carbon and water fluxes with meteorological and spectral measurements in order to understand how the environmental conditions regulated the carbon and water fluxes and how these fluxes are related with the continuous spectral measurements.

Evaluation of feasibility of continental vegetation monitoring using Himawari-8.

*Kodai Hayashi[1], Kazuhito Ichii[1], Hiroki Yoshioka[2], Kazutaka Murakami[3], Reiko Ide[3], Kenlo Nasahara[4], Tomoko Akitsu[4], Tomoaki Miura[5]

1. Chiba Univ., 2. Aichi Prefectural Univ., 3. NIES, 4. Tsukuba Univ., 5. Univ. Hawaii

A new generation geostationary meteorological satellite, Himawari-8, began operation in July 2015. Due to newly attached multiple bands in the visible and near infrared wavelength ranges and improved observation frequency of onboard sensor, AHI (Advanced Himawari Imager), application to terrestrial monitoring is expected.
Himawari-8/AHI data are provided as the radiance or the reflectance at the top of atmosphere (TOA) level. In order to monitor terrestrial vegetation, conversion to surface reflectance (TOC: Top of canopy reflectance) is necessary. However, the methods to estimate and verify TOC reflectance of Himawari-8/AHI data has not yet been established. Furthermore, the TOC reflectance data of Himawari-8/AHI requires careful interpretation due to observational geometric conditions unique to geostationary orbit.
In order to understand the feature of the TOC reflectance and the normalized index by Himawari-8/AHI data and to evaluate the usefulness for terrestrial vegetation monitoring, first, we estimated the TOC reflectance from Himawari-8/AHI data with 6SV. The estimated TOC reflectance from Himawari-8/AHI was further evaluated using independent observations such as Terra, Aqua MODIS data and ground observations (HemiSpherical Spectro-Radiometer (HSSR) at Phenological Eyes Network (PEN) sites).
We compared the Himawari-8 TOA/TOC reflectances with the MODIS TOA/TOC reflectances from Terra and Aqua. In particular, in the shorter wavelengths such as blue and green, the R^2 was greatly improved by atmospheric correction. Furthermore, if we selected data only with similar illumination and geometric condition of AHI and MODIS, both TOC reflectances were very close to each other in all wavelength bands. Then, we checked the monthly variation in the TOC reflectances of AHI, MODIS, and HSSR. We found that the three TOC reflectances are similar in the first half of the year (spring and summer). However, after summer, the TOC reflectances of AHI were higher than those of MODIS and HSSR. It can be explained by the dominant backward scattering component in AHI in Japan. In particular, the difference in intensity between the backward scattering and the forward scattering increases toward winter seasons. Meanwhile normalized index such as NDVI could effectively reduce the anisotropic effect on the TOC reflectance and it can capture vegetation phenology similar to MODIS. As a result of cross-validation, Himawri-8 TOC reflectance estimated in this study was generally consistent with other data. However it is necessary to consider the observation conditions of the Himawari-8 TOC reflectance. In the next step, we will demonstrate how the high temporal resolution of Himawari-8 improve our understandings of terrestrial vegetation dynamics.

Estimation of global carbon dioxide emissions by fires

*Tomohiro Shiraishi[1], Ryuichi Hirata[1]

1. National Institute for Environmental Studies

Global warming accelerates snow melting and drying which cause forest fires. The forest fire gives positive feedback in global warming because large greenhouse gases are emitted into the atmosphere by the forest fire. The purpose of this study is to estimate carbon emissions caused by forest fire with high spatial and temporal resolution, which are 500 m and daily base.
In this study, we used several satellite observation data to estimate global carbon dioxide emissions by fires from 2001 to 2018. We used MODIS MOD14A 1 product for fire detection, MODIS MCD12Q1 product as land cover classification map, and above ground biomass map created by (Avitabile et al., 2016) in Wageningen university. Carbon dioxide emissions were estimated from burned area, biomass densities, burning efficiencies and emission factors for each land cover categories. The estimated carbon dioxide emissions through 18 years were 6159.77 [Tg/year] on yearly average and 607.26 [Tg/year] on standard deviation. These results underestimated to approximately 11% for GFED4.1s and FINN1.0, 8%, 36% for GFAS 1.0 and G-G (Shi et al., 2015), respectively.

Interactions between topography, permafrost, and vegetation in Siberian larch forest: a simulation study

*Hisashi Sato[1]

1. Institute of Arctic Climate and Environment Research, Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

In eastern Siberia, larches (Larix spp.) often exist in pure stands, constructing the world's largest coniferous forest, of which changes can significantly affect the earth's albedo and the global carbon balance. Siberian larch area locates on the environmental edge of existence of forest ecosystem, and hence small difference in environmental condition alters existence of larch trees.

Indeed, there is a quantitative pattern that topographic properties controls the abundance of larch forest via both drought and flooding stresses in this region; larch abundance appears to be controlled by drought stress in mountainous regions, while controlled by flooding stresses in plain areas (Sato& Kobayashi 2018). Besides, this region is underlaid by permafrost, vegetation productivity is constraint by depth of active layer; plant productivity becomes lower for shallower active layer by reducing liquid-state-water holding capacity (Beers et al. 2007). At the same time, active layer depth is a function of soil wetness, because wetland soil has larger ice content in active layer, which facilitates downward heat conduction to the permafrost, resulting in shallow thaw for the active layers (Woo & Xia 1996).

To reconstruct such complicated interactions between topography, permafrost, and vegetation in Siberian larch forest, the TOPMODEL, which is a physically based streamflow and water-table-depth computation scheme was implemented to a dynamic vegetation model SEIB-DGVM (Sato et al. 2016), which works with a thermohydrology model. In this presentation, I will talk how this integrated model reasonably works, and how it can be employed for future projection of environmental conditions of the Siberian larch region.

Data assimilation experiments with MODIS LAI observation and the dynamic global vegetation model SEIB-DGVM in Japan

*Hazuki Arakida[1], Shunji Kotsuki[1], Shigenori Otsuka[1], Takemasa Miyoshi[1]

1. RIKEN Center for Computational Science

In the previous study, Arakida et al. (2017) developed a data assimilation system with the SEIB-DGVM (Spatially Explicit Individual-Based Dynamic Global Vegetation Model), and assimilated satellite-observed Leaf Area Index (LAI) successfully over Siberia. In this study, we extend the experiment to a Japanese forest at the Takayama flux site and investigate the performance of the data assimilation system. We estimate the vegetation functions and structures, and model parameters related to the phenology of the deciduous broad-leaved tree and the undergrowth. For the climate forcing data, we used the global reanalysis dataset known as the ERA5. The original data assimilation system developed for Siberia turned out not to be suitable for the Japanese forest because of different LAI variabilities between Siberia and Japan. Namely, LAI stays at the saturated level for an extended period in Japan, while in Siberia, the LAI starts to drop soon after it reaches to the maximum value. Therefore, a model parameter which controls the saturated LAI level was considered for additional parameter estimation. In addition, the undergrowth was changed from deciduous to evergreen. The results show that the DA system performs generally well in Japan with the additional parameter estimation and the modification to the undergrowth.

Studying ecosystem dynamics with deep neural networks

*Takeshi Ise[1], Masanori Onishi[2]

1. FSERC, Kyoto University, 2. Grad. School of Agriculture, Kyoto University

Obtaining ecological data by field observation has been labor intensive. In this study, we present several approaches to obtain ecological bid data, using information technology. First, introduction to data-driven science and big-data science will be presented. As an example of these new approaches, deep learning with neural networks has various applications in ecological studies. In fact, digital images from satellite, UAV, or even smartphone can be the big data. We show how these big data are used to identify specific features of organisms and vegetation. Moreover, deep neural networks can be applied to analyze time-series data and project the future conditions.

Tue. May 28, 2019 1:45 PM - 3:15 PM JST | Tue. May 28, 2019 4:45 AM - 6:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_2

[A-CG39] Biogeochemical cycles in Land Ecosystem

convener:Tomomichi Kato(Research Faculty of Agriculture, Hokkaido University), Kazuhito Ichii(Chiba University), Takeshi Ise(FSERC, Kyoto University), Munemasa Teramoto(National Institute for Environmental Studies)

Terrestrial ecosystem influences global climate through cycles of water, carbon, and nitrogen between land surface and atmosphere. For better understanding of those behaviors, a great effort has been paid for developing varieties of approaches and techniques such as biometric survey, eddy and chamber methods, near and satellite remote sensing, biosphere modeling and so on.
 In particular, the JapanFlux, founded in 2006 as a researchers network of CO2, H2O and other trace gas flux measurement, has promoted the multi-disciplinal studies not only for flux measurement community, but also for remote sensing and biosphere modeling communities. Moreover, the Research-Group-on-Integrated-Land-Processes, which was founded in 2006, also has contributed to build networks between Japanese researchers to better understanding of physical and biological processes on interactions between terrestrial surface and atmosphere.
 This session unites those multi-disciplinal activities, and promotes the oral and poster presentations on the role of terrestrial ecosystem in material circulations of water, carbon, nitrogen, energy and other substances by any approaches and technics. This session takes over the former session in last year: A-CG40.

Soil respiration is the second largest carbon flux in terrestrial ecosystems and the global soil respiration is estimated to be 98 GtC yr^{-1}. Soil respiration consists of root respiration and heterotrophic respiration (R_h), and R_h contributes more than half of the soil respiration. It is commonly observed that R_h exponentially increases with temperature. Therefore, a small increase of temperature can result in a remarkable enhancement of R_h, indicating that it is an important positive feedback factor to accelerate global warming under a warmer environment. However, the long-term warming effect on R_h is not well understood especially in the humid Asian monsoon region.

To examine the long-term response of R_h to global warming in Asian monsoon forests, we set a multi-channel automated chamber measurement system in a beech forest on Mount Naeba in July 2007. We prepared 10 trenched chambers (90 cm ×90 cm ×50 cm) to continuously measure R_h. Half of those trenched chambers were artificially warmed by infrared heaters 1.6 m above the soil surface (+2.5ºC), and the influence of soil warming on R_h was examined by comparing control plots and warming plots. Measurements were conducted mainly during growing season from June to October.

Even though there was a large inter-annual variation, enhancement of R_h by soil warming was confirmed in all 8 years measurements. Soil temperature was the primary factor for the seasonal variation of R_h. The influence of soil moisture on seasonal variation of R_h was relatively small.

Simple approach to predict flowering and full blooming dates by bi-directional Self Organizing Maps

*Shin Nagai[1], Hiroshi Morimoto[2], Taku M Saitoh[3]

1. Research and Development Center for Global Change, Japan Agency for Marine-Earth Science and Technology, 2. Nagoya University, 3. River Basin Research Center, Gifu University

Accurate prediction of blooming phenology is important to evaluate spatio-temporal variability of ecosystem functions and services, and biodiversity under climate change. The process-based phenology models have been developed but they require suitable parameters to account for endodormancy and ecodormancy processes for each species. Our eco-physiological interpretation and observations of these processes are not still enough for various species. Here, we proposed a simple blooming phenology model by the bi-directional Self Organizing Maps (SOM). SOM, which is one of the data mining approaches, is a tool for categorizing patterns in n-dimensional observation data by forming a 2 dimensional lattice (https://clarkdatalabs.github.io/soms/SOM_NBA). The flowering and full blooming dates from 1953 to 2018 in 42 sites, Japan were predicted by the bi-directional SOM. We inputted daily mean air temperature during ecodormancy period (mainly from February to just before the flowering date) into input vectors and observed flowering or full blooming dates into a target vector. The mean absolute errors between predicted and observed flowering and full blooming dates were 2.78 to 4.33 days and 2.77 to 4.76 days, respectively. Compared with the process-based phenology model approach, our proposed approach have a little higher error. However, our approach has a merit that flowering and full blooming dates can be predicted with the very low cost of calculation without accounting for the endodormancy and ecodormancy processes. In this presentation, we show the latest result and discuss usability, uncertainty, and outlook of our proposed method.

Solar-induced chlorophyll fluorescence for detecting ecosystem photosynthetic activity by high-resolution spectrum measurement in a paddy field in Japan

*KANOKRAT BUAREAL[1], Tomomichi Kato[2], Keisuke Ono[3]

1. Graduate School of Global Food Resources, Hokkaido University, Sapporo, Japan, 2. Research Faculty of Agriculture, Hokkaido University, Sapporo, Japan, 3. National Institute for Agro-Environmental Sciences, Tsukuba, Ibaraki, Japan

The terrestrial ecosystem is the main sink of carbon storage through plant photosynthesis which can be expressed as gross primary productivity (GPP). Accurate tracking of photosynthesis in the ecosystem level is essential because it is involved in global carbon cycling and the carbon balance between land and atmosphere. Recently, Solar-Induced Chlorophyll fluorescence (SIF) has been used for tracking changes in plant photosynthesis at the global scale by satellite. However, the coarser spatial-temporal scale by satellite needs to be validated by performing a ground-based SIF assessment to better understand the dynamics of CO2 uptake by plants. The high-resolution spectrum for SIF detection was measured at the Mase eddy flux site (36.05˚N, 140.03˚E, 11 m ASL.) in Tsukuba, Japan. The study area is a rice paddy field (*Oryza sativa* L.; cultivar Koshihikari), which is a main Asia crop type. Transplanting seedlings and harvesting crop were processed in early-May and mid-September, respectively. The spectrum was measured from April to December in 2018 using five spectroradiometers; FLAME, HR4000 x 2, QE Pro x 2 (Ocean Optics, Dunedin, FL, USA) with 0.11-1.08 nm of the full-width at half maximum (FWHM). For recording the irradiance with 5 minutes interval time, the spectroradiometers were connected via fiber switches (FSM1x8, Piezosystem Jena GmbH, Jena, Germany, and MOL-1x8-600-H, LEONI Fiber Optics GmbH, Föritztal, Germany) to three optical fiber cables: the first one was set looking downward at a viewing zenith angle of 45˚ as bare fiber (field of view (FOV) of 25˚, cable length of 15m), the second one was vertically set looking downward with cosine corrector (FOV of 180˚, cable length of 15m), and the third one was vertically set looking upward to the sky with cosine corrector (FOV of 180˚, cable length of 6m). The SIF was calculated by multispectral methods derived from the Fraunhofer Line Depth (FLD) principle 2FLD, 3FLD, iFLD and Spectral Fitting Method (SFM). In this study, the preliminary results of SIF detection are shown together with other conventional vegetation indices such as the normalized difference vegetation index (NDVI) and Enhanced Vegetation Index (EVI) for evaluating their relationship and finally verifying the SIF to be a promising proxy of photosynthesis tracking in the paddy field ecosystem.

Environmental controls on anomalous variation in solar-induced fluorescence during the last 10 years

*Tomomichi Kato[1], Kazuki Mizuno[2]

1. Research Faculty of Agriculture, Hokkaido University, 2. Graduate School of Agriculture, Hokkaido University

Solar-Induced Chlorophyll Fluorescence (SIF) has been used to estimate the ecosystem photosynthesis (GPP) recently by Satellite remote sensing and by ground observations. The advantage of use of SIF is to be able to detect the photosynthetic activity on multiple scales. To examine the potential relationship in the anomalies between SIF and environmental factors including the VI, we investigated them from the currently available satellite monthly data from GOME-2 on 0.5o (Joiner et al., 2009) and other observation-based datasets including the inversion biosphere carbon uptake estimated by CarbonTracker, the ground surface CO2 concentration by GOSAT, the CRU climatology from UEA, and multiple climatic teleconnection indices (NiNO3, PDO, NAO etc.) for 10 years from 2007 to 2016.

The SIF and biosphere land carbon uptake by Carbon Tracker 2016 has a strong negative correlationship in Australia and Middle of North America, especially in summer (JJA) in grass, shrub and rangeland. High correlation between SIF and CO2 concentration showed seasonal change. This suggests that the photosynthesis in drier and less productive ecosystems showed directly positive reactions to leaf biomass change increase probably due to simple canopy structure.

Summer SIF anomaly showed relatively high correlation coefficients to the anomalies in temperature, diurnal temperature range, potential evapotranspiration, cloudiness and precipitation depending on region. SIF anomaly also responses strongly to NiNO3 and other teleconnections in Africa, Australia, East and Central Asia, and North America. Land Cover specific analysis shows that cloudiness has negative relationship to the sensitivity of anomalies in SIF to that in cloudiness and precipitation slopes except for desert. Precipitation does not show clear relationship. Temperature shows positive response to sensitivity to cloudiness and precipitation, and negative one to that to temperature.

Estimation of terrestrial carbon cycle in Asia using a machine learning and satellite data

*Riku Kawase[1], Kazuhito Ichii[2], Yusuke hayashi[1], Zhiyan Liu[1], Masahito Ueyama[3], Yuji Kominami[4]

1. Chiba University, 2. Center for Environmental Remote Sensing, Chiba University, 3. Osaka Prefecture University, 4. Forest Research and Management Organization

Gross Primary Productivity (GPP) and Ecosystem Respiration (RE) play an important role in the terrestrial carbon cycle. For large-scale estimation, empirical upscaling by machine learning using observation data is becoming one methodology because of expansion of ground observation network, improvement of satellite data, and development of machine learning [Yang et al. 2007; Jung et al. 2011; Kondo et al., 2015]. In Asia, spatio-temporal variations in terrestrial carbon fluxes were estimated using support vector regression by integrating ground observation network including JapanFlux [Ichii et al., 2017].
MODIS sensor data onboard Terra and Aqua satellite are one of the most widely used data for upscaling. The MODIS dataset used in many of the previous studies was an older version, Collection 5 (C5). C5 data was not able to adequately account for the secular change of sensor sensitivity, and it was improved by the new version, Collection 6 (C6) [Wang et al., 2012]. C5 data were mainly used in the large-scale estimation by machine learning so far. Therefore, we need to upgrade the dataset from C5 to C6.
In this study, we upgraded the MODIS data (from C5 to C6) from the existing study [Ichii et al. 2017]. We upgraded only MODIS data for site-level training and testing and large-scale model application. The satellite data used as input variables include the surface temperature, leaf area index, the vegetation index and the water index. GPP and NEE (Net Ecosystem Exchange) were estimated as output variables.
In the site-level model training and testing, there was no overall big difference in the result of the model (GPP, NEE) between C5 and C6. Spatial variations in GPP and NEE averaged over 2000-2015 were similar except for Southeast Asia. We also found differences in long-term trends in GPP and NPP over Asia. GPP and NEE using C6 shows more increase trends from 2000-2015. We need to evaluate which GPP and NEE changes are more realistic by comparing with other independent datasets.

Estimation of global solar-induced chlorophyll fluorescence (SIF) by terrestrial ecosystem model VISIT and comparison with SIF observed by GOSAT

*Tatsuya Miyauchi[1], Makoto Saito[1], Hibiki M Noda[1], Yukio Yoshida[1], Haruki Oshio[1], Akihiko Ito[1]

1. National Institute for Environmental Studies

Many studies for GPP model estimation improved by using solar-induced chlorophyll fluorescence (SIF) were reported after SIF was available from GOSAT's spectrum data. GOSAT-2 was launched in 2018 and SIF product is planted to provide. In this study we implemented the biochemical process for calculating SIF to terrestrial ecosystem model VISIT. Moreover, we estimated SIF for observation direction of GOSAT using a radiation transfer model for atmosphere-canopy. In our presentation, we will report details of model implementation and the method for converting the SIF calculated VISIT to the SIF of satellite-observed direction. We will show the comparison of SIF by VISIT and GOSAT.

Automatic vegetation identification in the satellite image using a convolutional neural network

*Watanabe Shuntaro[1], Kazuaki Sumi[2], Takeshi Ise[1,3]

1. Field Science Education and Research Center, Kyoto University, 2. Graduate School of Agriculture, Kyoto University, 3. PRESTO, Japan Science and Technology Agency

Image based object identification and classification would be a promising tool to implement the mapping the biodiversity with high spatio-temporal resolution. Since convolutional neural network (CNN) technique achieve highly accurate object detection and classification, it has become a new solution in the field of remote sensing. However, detection or classification of vegetation in the satellite images are still challenging task because vegetation in the satellite images often represents ambiguous and amorphous shape.

Recently, Ise et al., (2018) developed a method (chopped picture method) to conveniently classify the ambiguous and amorphous objects. This method dissects the images into numerous small squares and efficiently produces the training images. In this study, we investigated the potential for adapting the chopped picture method to classify the 3 vegetation types (Bamboo, Deciduous forest and Confer forest) in Google Earth images.
We obtained Google Earth images from three regions in Japan. By applying the deep convolutional neural network, the model successfully learned the features of each vegetation in Google Earth images, and the best trained model correctly classify the vegetation types. Our results also show that identification accuracy strongly depends on the image resolution and number of classification class. Our results suggest that CNN and the chopped picture method can potentially become a powerful tool for high accuracy automated detection and mapping of vegetation.

[A-CG39] Biogeochemical cycles in Land Ecosystem

convener:Tomomichi Kato(Research Faculty of Agriculture, Hokkaido University), Kazuhito Ichii(Chiba University), Takeshi Ise(FSERC, Kyoto University), Munemasa Teramoto(National Institute for Environmental Studies)

Terrestrial ecosystem influences global climate through cycles of water, carbon, and nitrogen between land surface and atmosphere. For better understanding of those behaviors, a great effort has been paid for developing varieties of approaches and techniques such as biometric survey, eddy and chamber methods, near and satellite remote sensing, biosphere modeling and so on.
 In particular, the JapanFlux, founded in 2006 as a researchers network of CO2, H2O and other trace gas flux measurement, has promoted the multi-disciplinal studies not only for flux measurement community, but also for remote sensing and biosphere modeling communities. Moreover, the Research-Group-on-Integrated-Land-Processes, which was founded in 2006, also has contributed to build networks between Japanese researchers to better understanding of physical and biological processes on interactions between terrestrial surface and atmosphere.
 This session unites those multi-disciplinal activities, and promotes the oral and poster presentations on the role of terrestrial ecosystem in material circulations of water, carbon, nitrogen, energy and other substances by any approaches and technics. This session takes over the former session in last year: A-CG40.

Long-term warming effect on heterotrophic respiration in a beech forest on Mount Naeba

*Munemasa Teramoto[1], Naishen Liang[1], Masaaki Naramoto[2], Jiye Zeng[1], Zhao Xin[1], Hajime Tomimastu[1]

1. Center for Global Environmental Research, National Institute for Environmental Studies, 2. Faculty of Agriculture, Shizuoka University

Soil respiration is the second largest carbon flux in terrestrial ecosystems and the global soil respiration is estimated to be 98 GtC yr^{-1}. Soil respiration consists of root respiration and heterotrophic respiration (R_h), and R_h contributes more than half of the soil respiration. It is commonly observed that R_h exponentially increases with temperature. Therefore, a small increase of temperature can result in a remarkable enhancement of R_h, indicating that it is an important positive feedback factor to accelerate global warming under a warmer environment. However, the long-term warming effect on R_h is not well understood especially in the humid Asian monsoon region.

To examine the long-term response of R_h to global warming in Asian monsoon forests, we set a multi-channel automated chamber measurement system in a beech forest on Mount Naeba in July 2007. We prepared 10 trenched chambers (90 cm ×90 cm ×50 cm) to continuously measure R_h. Half of those trenched chambers were artificially warmed by infrared heaters 1.6 m above the soil surface (+2.5ºC), and the influence of soil warming on R_h was examined by comparing control plots and warming plots. Measurements were conducted mainly during growing season from June to October.

Even though there was a large inter-annual variation, enhancement of R_h by soil warming was confirmed in all 8 years measurements. Soil temperature was the primary factor for the seasonal variation of R_h. The influence of soil moisture on seasonal variation of R_h was relatively small.

Simple approach to predict flowering and full blooming dates by bi-directional Self Organizing Maps

*Shin Nagai[1], Hiroshi Morimoto[2], Taku M Saitoh[3]

1. Research and Development Center for Global Change, Japan Agency for Marine-Earth Science and Technology, 2. Nagoya University, 3. River Basin Research Center, Gifu University

Accurate prediction of blooming phenology is important to evaluate spatio-temporal variability of ecosystem functions and services, and biodiversity under climate change. The process-based phenology models have been developed but they require suitable parameters to account for endodormancy and ecodormancy processes for each species. Our eco-physiological interpretation and observations of these processes are not still enough for various species. Here, we proposed a simple blooming phenology model by the bi-directional Self Organizing Maps (SOM). SOM, which is one of the data mining approaches, is a tool for categorizing patterns in n-dimensional observation data by forming a 2 dimensional lattice (https://clarkdatalabs.github.io/soms/SOM_NBA). The flowering and full blooming dates from 1953 to 2018 in 42 sites, Japan were predicted by the bi-directional SOM. We inputted daily mean air temperature during ecodormancy period (mainly from February to just before the flowering date) into input vectors and observed flowering or full blooming dates into a target vector. The mean absolute errors between predicted and observed flowering and full blooming dates were 2.78 to 4.33 days and 2.77 to 4.76 days, respectively. Compared with the process-based phenology model approach, our proposed approach have a little higher error. However, our approach has a merit that flowering and full blooming dates can be predicted with the very low cost of calculation without accounting for the endodormancy and ecodormancy processes. In this presentation, we show the latest result and discuss usability, uncertainty, and outlook of our proposed method.

Solar-induced chlorophyll fluorescence for detecting ecosystem photosynthetic activity by high-resolution spectrum measurement in a paddy field in Japan

*KANOKRAT BUAREAL[1], Tomomichi Kato[2], Keisuke Ono[3]

1. Graduate School of Global Food Resources, Hokkaido University, Sapporo, Japan, 2. Research Faculty of Agriculture, Hokkaido University, Sapporo, Japan, 3. National Institute for Agro-Environmental Sciences, Tsukuba, Ibaraki, Japan

The terrestrial ecosystem is the main sink of carbon storage through plant photosynthesis which can be expressed as gross primary productivity (GPP). Accurate tracking of photosynthesis in the ecosystem level is essential because it is involved in global carbon cycling and the carbon balance between land and atmosphere. Recently, Solar-Induced Chlorophyll fluorescence (SIF) has been used for tracking changes in plant photosynthesis at the global scale by satellite. However, the coarser spatial-temporal scale by satellite needs to be validated by performing a ground-based SIF assessment to better understand the dynamics of CO2 uptake by plants. The high-resolution spectrum for SIF detection was measured at the Mase eddy flux site (36.05˚N, 140.03˚E, 11 m ASL.) in Tsukuba, Japan. The study area is a rice paddy field (*Oryza sativa* L.; cultivar Koshihikari), which is a main Asia crop type. Transplanting seedlings and harvesting crop were processed in early-May and mid-September, respectively. The spectrum was measured from April to December in 2018 using five spectroradiometers; FLAME, HR4000 x 2, QE Pro x 2 (Ocean Optics, Dunedin, FL, USA) with 0.11-1.08 nm of the full-width at half maximum (FWHM). For recording the irradiance with 5 minutes interval time, the spectroradiometers were connected via fiber switches (FSM1x8, Piezosystem Jena GmbH, Jena, Germany, and MOL-1x8-600-H, LEONI Fiber Optics GmbH, Föritztal, Germany) to three optical fiber cables: the first one was set looking downward at a viewing zenith angle of 45˚ as bare fiber (field of view (FOV) of 25˚, cable length of 15m), the second one was vertically set looking downward with cosine corrector (FOV of 180˚, cable length of 15m), and the third one was vertically set looking upward to the sky with cosine corrector (FOV of 180˚, cable length of 6m). The SIF was calculated by multispectral methods derived from the Fraunhofer Line Depth (FLD) principle 2FLD, 3FLD, iFLD and Spectral Fitting Method (SFM). In this study, the preliminary results of SIF detection are shown together with other conventional vegetation indices such as the normalized difference vegetation index (NDVI) and Enhanced Vegetation Index (EVI) for evaluating their relationship and finally verifying the SIF to be a promising proxy of photosynthesis tracking in the paddy field ecosystem.

Environmental controls on anomalous variation in solar-induced fluorescence during the last 10 years

*Tomomichi Kato[1], Kazuki Mizuno[2]

1. Research Faculty of Agriculture, Hokkaido University, 2. Graduate School of Agriculture, Hokkaido University

Solar-Induced Chlorophyll Fluorescence (SIF) has been used to estimate the ecosystem photosynthesis (GPP) recently by Satellite remote sensing and by ground observations. The advantage of use of SIF is to be able to detect the photosynthetic activity on multiple scales. To examine the potential relationship in the anomalies between SIF and environmental factors including the VI, we investigated them from the currently available satellite monthly data from GOME-2 on 0.5o (Joiner et al., 2009) and other observation-based datasets including the inversion biosphere carbon uptake estimated by CarbonTracker, the ground surface CO2 concentration by GOSAT, the CRU climatology from UEA, and multiple climatic teleconnection indices (NiNO3, PDO, NAO etc.) for 10 years from 2007 to 2016.

The SIF and biosphere land carbon uptake by Carbon Tracker 2016 has a strong negative correlationship in Australia and Middle of North America, especially in summer (JJA) in grass, shrub and rangeland. High correlation between SIF and CO2 concentration showed seasonal change. This suggests that the photosynthesis in drier and less productive ecosystems showed directly positive reactions to leaf biomass change increase probably due to simple canopy structure.

Summer SIF anomaly showed relatively high correlation coefficients to the anomalies in temperature, diurnal temperature range, potential evapotranspiration, cloudiness and precipitation depending on region. SIF anomaly also responses strongly to NiNO3 and other teleconnections in Africa, Australia, East and Central Asia, and North America. Land Cover specific analysis shows that cloudiness has negative relationship to the sensitivity of anomalies in SIF to that in cloudiness and precipitation slopes except for desert. Precipitation does not show clear relationship. Temperature shows positive response to sensitivity to cloudiness and precipitation, and negative one to that to temperature.

Estimation of terrestrial carbon cycle in Asia using a machine learning and satellite data

*Riku Kawase[1], Kazuhito Ichii[2], Yusuke hayashi[1], Zhiyan Liu[1], Masahito Ueyama[3], Yuji Kominami[4]

1. Chiba University, 2. Center for Environmental Remote Sensing, Chiba University, 3. Osaka Prefecture University, 4. Forest Research and Management Organization

Gross Primary Productivity (GPP) and Ecosystem Respiration (RE) play an important role in the terrestrial carbon cycle. For large-scale estimation, empirical upscaling by machine learning using observation data is becoming one methodology because of expansion of ground observation network, improvement of satellite data, and development of machine learning [Yang et al. 2007; Jung et al. 2011; Kondo et al., 2015]. In Asia, spatio-temporal variations in terrestrial carbon fluxes were estimated using support vector regression by integrating ground observation network including JapanFlux [Ichii et al., 2017].
MODIS sensor data onboard Terra and Aqua satellite are one of the most widely used data for upscaling. The MODIS dataset used in many of the previous studies was an older version, Collection 5 (C5). C5 data was not able to adequately account for the secular change of sensor sensitivity, and it was improved by the new version, Collection 6 (C6) [Wang et al., 2012]. C5 data were mainly used in the large-scale estimation by machine learning so far. Therefore, we need to upgrade the dataset from C5 to C6.
In this study, we upgraded the MODIS data (from C5 to C6) from the existing study [Ichii et al. 2017]. We upgraded only MODIS data for site-level training and testing and large-scale model application. The satellite data used as input variables include the surface temperature, leaf area index, the vegetation index and the water index. GPP and NEE (Net Ecosystem Exchange) were estimated as output variables.
In the site-level model training and testing, there was no overall big difference in the result of the model (GPP, NEE) between C5 and C6. Spatial variations in GPP and NEE averaged over 2000-2015 were similar except for Southeast Asia. We also found differences in long-term trends in GPP and NPP over Asia. GPP and NEE using C6 shows more increase trends from 2000-2015. We need to evaluate which GPP and NEE changes are more realistic by comparing with other independent datasets.

Estimation of global solar-induced chlorophyll fluorescence (SIF) by terrestrial ecosystem model VISIT and comparison with SIF observed by GOSAT

*Tatsuya Miyauchi[1], Makoto Saito[1], Hibiki M Noda[1], Yukio Yoshida[1], Haruki Oshio[1], Akihiko Ito[1]

1. National Institute for Environmental Studies

Many studies for GPP model estimation improved by using solar-induced chlorophyll fluorescence (SIF) were reported after SIF was available from GOSAT's spectrum data. GOSAT-2 was launched in 2018 and SIF product is planted to provide. In this study we implemented the biochemical process for calculating SIF to terrestrial ecosystem model VISIT. Moreover, we estimated SIF for observation direction of GOSAT using a radiation transfer model for atmosphere-canopy. In our presentation, we will report details of model implementation and the method for converting the SIF calculated VISIT to the SIF of satellite-observed direction. We will show the comparison of SIF by VISIT and GOSAT.

Automatic vegetation identification in the satellite image using a convolutional neural network

*Watanabe Shuntaro[1], Kazuaki Sumi[2], Takeshi Ise[1,3]

1. Field Science Education and Research Center, Kyoto University, 2. Graduate School of Agriculture, Kyoto University, 3. PRESTO, Japan Science and Technology Agency

Image based object identification and classification would be a promising tool to implement the mapping the biodiversity with high spatio-temporal resolution. Since convolutional neural network (CNN) technique achieve highly accurate object detection and classification, it has become a new solution in the field of remote sensing. However, detection or classification of vegetation in the satellite images are still challenging task because vegetation in the satellite images often represents ambiguous and amorphous shape.

Recently, Ise et al., (2018) developed a method (chopped picture method) to conveniently classify the ambiguous and amorphous objects. This method dissects the images into numerous small squares and efficiently produces the training images. In this study, we investigated the potential for adapting the chopped picture method to classify the 3 vegetation types (Bamboo, Deciduous forest and Confer forest) in Google Earth images.
We obtained Google Earth images from three regions in Japan. By applying the deep convolutional neural network, the model successfully learned the features of each vegetation in Google Earth images, and the best trained model correctly classify the vegetation types. Our results also show that identification accuracy strongly depends on the image resolution and number of classification class. Our results suggest that CNN and the chopped picture method can potentially become a powerful tool for high accuracy automated detection and mapping of vegetation.

[A-CG40] Coastal Ecosystems - 1. Water Cycle and Land-Ocean Interactions

convener:Masahiko Fujii(Faculty of Environmental Earth Science), Makoto Yamada(Faculty of Economics, Ryukoku University), Jun Shoji(The University of Tokyo), Ryo Sugimoto(Faculty of Marine Biosciences, Fukui Prefectural University), Chairperson:Masahiko Fujii, Makoto Yamada

Substances from land which are brought by river and/or submarine groundwater discharge are important for the process of biological production in coastal areas. This session focuses on land-ocean interactions through water cycle. The aim of this session is to create interdisciplinary discussions on the research of connectivity of ecosystems, water cycles in terrestrial and coastal areas, fishery resources and biodiversity. Comprehensive discussion on the mechanisms that promote productivity and biodiversity in coastal ecosystems will be made from the viewpoint of land-ocean interactions. Presentations on water-material cycle in terrestrial and coastal areas, fishery resources, biodiversity and connectivity of the ecosystems are encouraged.
A companion session proposed as "Coastal Ecosystems - 2. Coral reefs, seagrass meadows, and mangroves" focuses on benthic communities in shallow-water ecosystems such as coral reefs, seagrass meadows and mangroves and is dedicated to promote researches on comprehensive assessment and monitoring of ecosystem functions and development of effective means for conservation and restoration. Main focuses of these two sessions are different. However, there are much of information that covers both sessions. Scientists who work on the related field will be able to obtain information and share them with other scientists if they attend to both of these sessions.

Discussion

Submarine groundwater discharge from Mt. Fuji in Suruga Bay(VI)

*Yasuhide Muranaka[1], Takafumi Kamitani[1], Noriaki Fushimi[1], Tomoya Oka[1], Masahiko Ono[2], Atsunao Marui[2]

1. Shizuoka Institute of Environment and Hygiene, 2. National Institute of Advanced Industrial Science and Technology

Around the foot of Mt. Fuji, the main flow passages of groundwater are thought to be in the Younger Fuji volcano, which consists of the pervious basaltic lavas in new volcanic stage. Most of rainfall and melted snow have been considered to be percolating into underground, turning to groundwater, flowing down in the layers of the Younger Fuji volcano and partly discharging from seabed in Suruga Bay. Especially, the Fujikawa-kako fault zone, which stretches south to north in the southwestern side of Mt. Fuji, has a potentially effect on the local groundwater flow system into Suruga Bay. Therefore, precipitation at Mt. Fuji have been considered to be discharging partly from seabed in Suruga Bayand making a impact on the biological production at the coastal sea area.

For the purpose of contribution to make sense of the rich coastal ecosystem in Suruga Bay, we conducted a survey for submarine groundwater discharge (SGD) in Oku-Suruga Bay: from the mouth of the Fuji River, at which the fault is found, to Tagonoura, where the lavas of the Younger Fuji volcano are distributed from 100 to 200 m below sea level. We detected SGD in the top of the cliff in the west of Tagonoura usinga remotelyoperatedvehicle(ROV), sampled seawater containing a high percentage of sea bottom spring water and conducted water quality analyses. In this presentation, we introduce our works noted above.

Relationship between the distribution of freshwater groundwater under the seabed at Obama Bay and the surrounding terrain of the land

*Makoto Yamada[1], Ryo Sugimoto[2], Toshimi Nakajima[3]

1. Faculty of Economics, Ryukoku University, 2. Fuculty of Marine Biosciences, Fukui Prefectural University, 3. Fukui Prefectural University

In Obama bay at north side of Obama City, Fukui Prefecture, research on submarine groundwater discharge (SGD) has been actively carried out so far, and it is clear that the SGD are discharging in Obama Bay. However, there are still many unclear points about the situation of SGD, that is, the distribution of freshwater groundwater under the seabed. Therefore, in this research, in order to clarify the distribution of freshwater groundwater under the seabed, we conducted the survey of resistivity distribution under the seabed by using a towing electric exploration system (SuperSting: Advanced Geosciences, Inc.). We discussed about relationship between the distribution of freshwater groundwater under the seabed and the surrounding terrain of the land from the results and the surrounding land topography.

The range indicated by the resistivity value under the seabed was approximately 0.1 to 6.2 Ohm-m. The place where the relatively high resistivity value of 1 Ohm-m or more was seen was mainly the place close to the land of the alluvial fan. At the north survey area, Observation towards the offshore direction revealed that the high resistivity area extended towards the offshore area. However, further offshore there was no place of high resistivity. These facts suggest that there is a possibility that freshwater groundwater is present in the high resistivity area extending about 500 m from the shoreline to the offshore.

At the estuary of the Kita-river in the south survey area, a high resistivity area was found at a distance of 1 km from the shoreline, suggesting the possibility that freshwater groundwater is present there. According to the bathymetric chart of Obama bay, the slope of the seabed at the offshore of Kita-river is gentle from estuary towards the ocean, which is considered to be covered with sediments derived from Kita-river. The place where high resistivity was observed corresponds to that part. In other words, it is considered that freshwater groundwater is present in the fan-shaped sediment. The above suggests that the groundwater flowing through the basement of the fan in land area may flow through the alluvial fan sediment under the seabed and supply freshwater groundwater under the seabed.
As a result, it was suggested that the distribution of freshwater groundwater under the seabed in Obama Bay was influenced by the spread of the alluvial sediment at the seabed and related to the shape of the alluvial fan in land area.

Influence of recirculated submarine groundwater discharge on phytoplankton dynamics in Moune Bay, Kesennuma

*Toshimi Nakajima[1], Takahiro Kusunoki[1], Yoshitake Takao[1], Ryo Sugimoto[1]

1. Fukui Prefectural University

Riverine inputs are often considered as the main terrestrial source of dissolved inorganic nitrogen (DIN), phosphorus (DIP), and silicon (DSi) in coastal seas. However, the fluxes of nutrients through submarine groundwater discharge (SGD) often exceed riverine inputs in different local and regional scale settings. Although the combined effects of riverine and SGD-derived nutrient inputs are crucial for sustaining marine productivity, a difference of nutrient composition in each source may result in a different response of phytoplankton dynamics in coastal seas. In this study, we evaluated the influence of each nutrient source on phytoplankton dynamics in the head of Kesennuma Bay in June, September and November 2018. Using the short-lived radium and radon isotopes, we quantified the contribution rates of four nutrient sources (river water, fresh SGD, recirculated SGD and offshore waters) on surface waters. Simultaneously, we evaluated productivity, biomass, apparent growth rates and species composition of phytoplankton. In brief results, DIP-enriched recirculated SGD affect significant impacts on phytoplankton dynamics. In the presentation, we will discuss more detailed results.

Estimation of contribution rate of Submarine Groundwater Discharge to *Ulva pertusa* using nitrogen stable isotope ratio analysis

*Tatsuhiro Ishida[1], Masaru Takeuchi[1], Toshimi Nakajima[1], Ryo Sugimoto[1], Shiho Kobayashi[2], Keisuke Koba[3], Keitaro Fukushima[3], Osamu Tominaga[1]

1. Fukui Prefectural University, 2. Kyoto University, 3. Center for Ecological Research,Kyoto Univrsity

In recent years, the influence of Submarine groundwater discharge (SGD) has attracted attention as a source of nutrient that supports biological production in the coastal area. However, the information about the direct influence of SGD on biological production is poor. In this study, in order to examine how much the groundwater contributes to primary production, we collected the primary producer *Ulva pertusa* in Yuza, Yamagata Prefecture, where the groundwater is abundant. On August 27, 2018, we collected sea water, ground water and ambient water around *Ulva* at five sites in the Yuza Coast and simultaneously measured salinity, water temperature, ^{222}Rn concentration which is the indicator of undergroundwater. We also analyzed the nutrient concentration, of sampled water and of *Ulva*. Finally, we estimated the contribution of groundwater to Ulva using two source Bayesian Mixing model. The value of nitrate nitrogen derived from SGD was low. In the high SGD sites (^{222}Rn concentration 427 ~ 22000 Bq/m^3) and the low SGD sites (^{222}Rn concentration 38.1 to 210.6 Bq/m^3), the of *Ulva* was 2.1 to 3.6 and 5.4 to 6.9, respectively. It was suggested that nutrient derived from SGD contributed to the production of *Ulva* in Yuza.

Evaluation of the environmental condition of Submarine Groundwater Discharge (SGD) using carbon and oxygen stable isotope ratio of the sessile bivalve *Crassostrea nippona* shell

*Osamu Tominaga[1], Takeuchi Masaru[1], Ryo Sugimoto[1], Ishida Tatsuhiro[1], Takeru Hirai[1], Toshimi Nakajima[1], Jun Shoji[2], Hisami Honda[4], Makoto Taniguchi[3]

1. Fukui Prefectural University, 2. Tokyo Univ. AORI, 3. RIHN, 4. Fukui Pref Gov

Submarine Groundwater Discharge (SGD) results in various biogeochemical changes in the coastal environments, such as coastal primary production, eutrophication, and benthic production. The SGD condition of 6 sites along volcanic mountain coast in northern Japan was evaluated by using carbon and oxygen stable isotope ratio ($\delta^{13}C$ and $\delta^{18}O$) in the shell of sessile bivalves *Crassostrea nippona*. In order to estimate the proportion of fresh water flow rate in SGD (FR) from the respective $\delta^{13}C$ and $\delta^{18}O$ of *C. nippona* shell, we used the three end member (sea water, riverine water and fresh underground water) bayesian stable isotope mixing model. The significant positive correlation was found between $\delta^{13}C$ and $\delta^{18}O$ of the shell and those of ambient water, respectively. FRs estimated from three source model were 3.1 -8.6% at low ^{222}Rn sites and 21.9-28.5% at high ^{222}Rn sites. At the site (Nishihama) of river mouth, the $\delta^{13}C$ and $\delta^{18}O$ of the shell collected were low (estimated FR 10.6-25.0%) and ^{222}Rn concentration was also low. The contribution of DIC in SGD and riverine water for shell formation was estimated to be 19.8 % and 7.8%, respectively. In the present study, we demonstrated the effectiveness of $\delta^{13}C$ and $\delta^{18}O$ of *C. nippona* shell as the tool for estimating FR.

Discussion

Influence of climate change on river and submarine groundwater discharge for three decades and the change of nutrient fluxes from the land to the coastal area

*Saki KATAZAKAI[1], Jing ZHANG[2], Kota NOJIMA[3]

1. Graduate School of Science and Engineer, University of Toyama, 2. Graduate School of Science and Engineering for Science, University of Toyama, 3. University of Toyama

In Toyama prefecture, 10 billion tons of river and submarine groundwater discharge annually flows in to Toyama Bay containing nutrients (Hatta et al., 2005) . Urasawa et al. (2016) shows that 20-40% of nitrate originated on land contributes to the coastal ecosystems. So it is important to evaluate the state of nutrient transport of from the land to the coastal area. However, global warming has caused an increase in rainfall and a decrease in snowfall in Hokuriku area and it is possible that the states of water and material fluxes has changed over the past years. The aim of this study is to clarify the change of nutrient fluxes via river and submarine groundwater discharge into the coastal area, analyzing hydrogen and oxygen stable isotopes as well as chemical composition.
Results of my analysis, should be, data in my study show that the stable isotopes decreased due to increasing rainfall and decreasing snowfall for three decades. Nitrate and phosphate fluxes are shown to have dramatically decreased as forest and paddy field decreased and the water treatment facilities increased over the years.
These results suggest that nutrient fluxes from the land to coastal zone in this region may continue to decrease due to ongoing climate change and the impact of human activities.

The assessment of human impacts on the distribution patterns of mangroves: a comparative study between the Rewa and Ba delta, Fiji

*Masahiko Fujii[1], Jone Ravuci Sassen[2]

1. Faculty of Environmental Earth Science, 2. Graduate School of Environmental Science

Mangrove ecosystems are among the most productive ecosystems on this planet. They are sources of livelihood to many people, the first walls of protection from storm waves, and nursery grounds for some marine organisms. Unfortunately, mangroves in Fiji are observed to have decreased over the years due to human (induced) activities. Moreover, apart from human impacts, there are several other natural impacts like tropical cyclones that may influence the distribution patterns of mangroves. The aims of this study are: (1) to elucidate changes of the distribution patterns of mangroves and the causes, and based on the results, and (2) to provide practical suggestions for sustainable use of mangroves and saving the ecosystems in Fiji.

To estimate changes in the area of mangroves, satellite imagery data from Landsat 7 and 8 were acquired and analyzed by using Geographic Information System (GIS) to produce land use classification maps for the Rewa delta (in 2002, 2005, 2016 and 2017) and Ba delta (in 2004, 2007, 2010 and 2017) in Fiji. A total of five land cover classes, i.e. mangrove, non-mangrove, urban, barren land, and water were used to classify the land cover. To elucidate causes of the changes in the area of mangroves, social survey was conducted in three villages of Kiuva, Muana I ra and Kinoya in the Rewa delta and three villages of Natutu, Nawaqarua and Votua of the Ba delta, respectively.

The trend in distribution patterns of mangroves was different between the study sites. In the Rewa delta, the area of mangroves has increased from 2002 to 2016 and decreased by 5 km² from 2016 to 2017. In Ba delta, on the other hand, the area decreased from 2004 to 2007, increased from 2007 to 2010, and again decreased from 2010 to 2017. The difference is considered to be caused by the difference in the dependency of people on mangrove ecosystems in the two sites, i.e. higher dependency on mangrove ecosystems for livelihood in the Ba delta with less access to urban centers than in the Rewa delta. Impacts of tropical cyclones and subsequent floods to mangrove ecosystems were also examined as possible climate change stressors, but the impacts were not found clearly in this study.

This study suggests that anthropogenic factors have continuously been major causes of mangrove degradation in Fiji. Mangrove protection in Fiji can be improved firstly by raising people’s awareness on the importance of mangroves to their lives. Secondly, amendment of current legislation might administer the protection of mangrove ecosystems by broadening its scope to monitor the domestic use as well as the commercial use of mangroves. Furthermore, mangrove areas are also required to be designated as “protected areas”, which can be an effective way to guard mangrove ecosystems from human impacts.

Mangroves are swamp forest ecosystem that predominates in low-energy brackish environment of subtropical and tropical coastal systems. Mangroves have a remarkable capacity to capture CO_2 by primary production and sequester organic carbon (OC) in the sediment, thereby contributing to climate change mitigation. Typical carbon sequestration rate and OC stock in top 1 m of mangrove sediment have been estimated to be 1030 kg C ha^{-1} $year^{-1}$ and 723 Mg C ha^{-1}, respectively (median values of available data; Alongi 2018). Mangroves have been vastly degraded by human activities and reclaimed and/or converted to aquacultures and agricultural fields for past a few centuries. Current global loss rate of mangroves has been estimated to be up to 2% per year, which corresponds to an emission of 0.27 to 0.59 Pg CO_2 $year^{-1}$ at the maximum, if OC in top 1 m of sediment is assumed to be entirely reoxidized after reclamation and conversion (Alongi 2018, Atwood et al. 2017). However, the degree to which and the rate at which sediment OC is returned to the atmosphere as CO_2 after degradation of mangroves are still uncertain, and presumably depend on land use pattern and hydrodynamic conditions after conversion. Some part of sediment OC may be reoxidized shortly after conversion, while other parts may remain unoxidized in the soil for long term or be flushed out to the ocean by tidal exchange. To estimate the rate of OC loss after degradation and conversion of mangroves and evaluate how the sediment OC stock may be recovered by reforestation, we are now conducting a multidisciplinary research project in coastal areas of Panay Island, Philippines, where various types of habitats typical to once degraded and converted mangroves are found, such as naturally recovered secondary mangroves, artificially reforested mangroves, artificial mangroves planted on originally seagrass-dominated habitats, and tidal marshes and shrubs growing on abandoned aquaculture plots. Here, we introduce first preliminary results on OC characteristics in sediment cores collected from a naturally-recovered secondary mangrove in an estuarine delta (Ibajay) and a replanted mangrove in a well-protected embayment (Batan Bay). Estimated OC stocks in top 1 m of sediment ranged from 40 Mg C ha^{-1} in lower estuary of Ibajay to 420 Mg C ha^{-1} in Batan Bay, which are significantly lower than the world-median OC stock for natural mangroves mentioned above. Radiocarbon dating showed that the cores from the lower estuarine secondary mangrove were predominated by modern carbon down to a depth of 1 m, which suggests that old OC originally stored in the primary mangrove had been reoxidized and/or washed out to the sea soon after the conversion. In contrast, sediment OC in the upper estuarine secondary mangrove showed a radiocarbon age of 400 –1200 yBP throughout the cores, suggesting that old OC stored in original mangroves persisted at least partially through conversion and subsequent regrowth of the forest. The OC loading, i.e. the amount of OC per unit surface area of sediment grains, seemed to be constrained by the hydrodynamic stability of sediment. This implies that detrital particles derived from mangrove litter was stored at the higher concentrations in sediment of the more protected environment. The curvilinear correlation of stable carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) isotope ratios to the OC loading suggests that

©2019. Japan Geoscience Union. All Right Reserved.

mangrove-derived detritus typically exhibits the $\delta^{13}C$ of −28‰ vs. VPDB and the $\delta^{15}N$ of +0.5‰ vs. atmospheric N_2. The other endmember of sediment OC, putatively marine seston, is represented by the $\delta^{13}C$ of around −25‰ and the $\delta^{15}N$ of +3‰ and tended to decrease with increasing sediment depth. Our results overall showed that both the persistence of old sediment OC and the accumulation of newly supplied detrital OC in secondary mangroves are strongly constrained by the hydrodynamic setting of habitat.

Multiple benefits of blue carbon ecosystems in promoting blue economy and reinforcing resilience in coastal communities

*Atsushi Watanabe[1]

1. The ocean policy research institute, The Sasakawa peace foundation

Blue carbon ecosystems (hereafter BCEs) such as seagrass beds and mangrove forests have recently been paid international attention due to their capability in effectively absorbing and storing carbon dioxide and thus mitigating climate change impacts when they are managed properly. BCEs could also be beneficial to the coastal communities in terms of preventing or minimizing climate change impacts, offering better environmental settings for aquaculture and fisheries, and in turn reinforcing their resilience. For instance ecosystem-based disaster risk reduction (Eco-DRR), sustainable food production through fisheries and aquacultures, and sustainable tourism could enhance adaptation capacity of the coastal community to climate change. The properly managed coastal ecosystems are thus the basis for the secure, safe, and circular coastal society, which is one of the main targets of the sustainable blue economy.
In this presentation, the definition and characteristics of BCEs such as mangrove forests, seagrass beds, coral reefs, and their interlinkages will be introduced first. Then some good examples and lessons learned from coastal communities in Japan as well as Palau will be introduced. Restoration of seagrass beds and coral reefs has involved multi-stakeholders and strengthened socioecological systems in Japanese coastal communities with some innovative ideas or continuing efforts of locals. In Palau, beautiful, unique marine ecosystems have attracted tourists from overseas and environmental fees paid by these tourists have contributed to the conservation and monitoring of these ecosystems in return. Through cataloguing and networking of these good examples from world coastal areas with similar natural or socioeconomic backgrounds, sustainable use of BCEs could be mainstreamed for promoting the blue economy and combating loss of these important ecosystems globally.

Significant storage of organic carbon in mineral matrix in both land and ocean and the role of Fe

*Rota Wagai[1]

1. NARO, Institute for Agro-Environmental Sciences

Land-ocean linkage is one of the least understood aspects in biogeochemistry and carbon (C) cycle, which presumably results from insufficient collaboration between land and ocean scientists as well as the inherent complexity of land-to-ocean processes. At a global scale, the largest C reservoir on land is soil (1500-2400 Pg C) in which major portions of C is stored as organic C (OC) in association with soil mineral particles. In ocean, sediment holds similar amounts of OC. Thus, OC stability and reactivity in soils and sediments have been a great concern as their strong impacts on global C cycle and climate change.

In this talk, I focus on the interaction of organic C with minerals (e.g., aluminosilicate clays, hydrous iron oxides) and discuss the similarity and difference in their interaction between soil and sediment based on my own studies and the literature. I also discuss mechanistic reasons why OC is stabilized in mineral matrix in both systems. An emphasis is given to iron-C interaction due to their high reactivity and ecological importance in both terrestrial and aquatic systems. For instance, OC cycle is linked to N and P cycling as many organic compounds contain N and P. Iron can control P cycle due to strong sorption of phosphate to Fe oxides.

I plan to end my talk by emphasizing that basic understanding of soil formation and biogeochemistry would greatly help when tackling C and nutrient-related questions in river and coastal water.

[A-CG40] Coastal Ecosystems - 1. Water Cycle and Land-Ocean Interactions

convener:Masahiko Fujii(Faculty of Environmental Earth Science), Makoto Yamada(Faculty of Economics, Ryukoku University), Jun Shoji(The University of Tokyo), Ryo Sugimoto(Faculty of Marine Biosciences, Fukui Prefectural University)

Substances from land which are brought by river and/or submarine groundwater discharge are important for the process of biological production in coastal areas. This session focuses on land-ocean interactions through water cycle. The aim of this session is to create interdisciplinary discussions on the research of connectivity of ecosystems, water cycles in terrestrial and coastal areas, fishery resources and biodiversity. Comprehensive discussion on the mechanisms that promote productivity and biodiversity in coastal ecosystems will be made from the viewpoint of land-ocean interactions. Presentations on water-material cycle in terrestrial and coastal areas, fishery resources, biodiversity and connectivity of the ecosystems are encouraged.
A companion session proposed as "Coastal Ecosystems - 2. Coral reefs, seagrass meadows, and mangroves" focuses on benthic communities in shallow-water ecosystems such as coral reefs, seagrass meadows and mangroves and is dedicated to promote researches on comprehensive assessment and monitoring of ecosystem functions and development of effective means for conservation and restoration. Main focuses of these two sessions are different. However, there are much of information that covers both sessions. Scientists who work on the related field will be able to obtain information and share them with other scientists if they attend to both of these sessions.

Submarine groundwater discharge and dissolved material fluxes quantified by radium isotopes in sandy beach, central Wakasa Bay

*Toshimi Nakajima[1], Ryo Sugimoto[1], Yuta Sumino[1], Makoto Taniguchi[2], Osamu Tominaga[1]

1. Fukui Prefectural University, 2. Research Institute for Humanity and Nature

Submarine groundwater discharge (SGD) is recognized as an important pathway for dissolved materials such as nutrients, carbon, alkalinity and trace metals from the land to the coastal sea. In the last decades, ^{222}Rn and Ra isotopes have been used as a proxy of groundwater discharge. In this study, we measured both SGD tracers (^{222}Rn, ^{223}Ra, ^{224}Ra, and ^{226}Ra) and nutrients, dissolved inorganic carbon (DIC), and total alkalinity (TAlk) of surface seawater and subterranean estuary in sandy beach of central Wakasa Bay to quantify the rate of groundwater discharge and associated material fluxes in May, July, and September 2018. Regardless of the sampling periods, ^{222}Rn, Ra isotopes, nutrients, DIC, and total alkalinity in subterranean estuary showed higher concentrations than in seawater. Activities of ^{222}Rn, ^{223}Ra, and ^{224}Ra in seawater decreased constantly from the tideline to offshore with little variation in salinity. This implies that recirculated saline groundwater seeps around the shoreline. Estimated SGD rates in May, July, and September by using the activities of ^{223}Ra and ^{224}Ra were 0.1 m^3 m^{-1} d^{-1}, 4.5 m^3 m^{-1} d^{-1}, 0.3 m^3 m^{-1} d^{-1} and 1.3 m^3 m^{-1} d^{-1}, 20.3 m^3 m^{-1} d^{-1}, 2.3 m^3 m^{-1} d^{-1}, respectively. High SGD rates in July would be due to heavy rain before the sampling date. If we assume that groundwater discharge occurs along the tideline of the beach (length: 887 m), mean SGD rates were 809.1 m^3 d^{-1} in May, 11192.4 m^3 d^{-1} in July, and 1186.2 m^3 d^{-1} in September. Fluxes of nutrients (DIN, DIP, and DSi), DIC, and TAlk, derived SGD were calculated by multiplying mean SGD rates by its mean concentration in subterranean estuary. Although the nutrients fluxes from SGD were < 1% of those from the Kita River, DIC flux of SGD in May, July, and September corresponds to 6.5%, 94.7%, and 7.7% of the Kita River, respectively. These results mean that DIC transport through groundwater may be significant for carbonate system of Wakasa Bay.

Influence of difference in river shape on heat supply to coastal area by hot spring drainage river

*Makoto Yamada[1], Taketoshi Mishima[2], Shinji Ohsawa[2]

1. Faculty of Economics, Ryukoku University, 2. Institute for Geothermal Sciences, Graduate School of Sciences, Kyoto University

In Beppu City, Oita Prefecture, it is clear that hot spring drainage flows into the river and affects the river ecosystem. On the mouth of the river where hot spring drainage flow into, there are many tropical fish due to the influence of the heat of hot spring drainage. However, even in rivers where hot spring drainage flow into, there are rivers where many of the native fish inhabits, and the influence of heat on the estuary is various. The river in Beppu city is flowing down a volcanic fan, and the length of the river is relatively short, but the shape differs for each river. Depending on the river, river stream is lined entirely with concrete, and the condition of the river is very different. In Beppu, hot spring drainage flows into mainly by the middle part of the river, so it is expected that the degree of heat supplied to the estuary will be different due to the difference in river conditions while reaching the estuary area. Therefore, in this study, in order to clarify the reason for the difference in the amount of heat supply to the coastal area, we compared the two rivers where the hot spring drainage remarkably flows into.
On both rivers, hot spring drainage flows into the river at the area of about 200 m in elevation, flows down about 3 km and reaches the mouth of the estuary. However, the river water temperature at the estuary is lower by 5 deg. C or more in the Haruki-river throughout the year. Compared to the Haruki River where some of the natural river remains, nearly all of the Hirata River is covered with concrete. In the presentation, in addition to these differences, topographical differences such as inclination and linearity, differences in flow rate etc. are compared and the reason why the difference in thermal influence of hot spring drainage at the mouth of the estuary occurs is considered.

Construction of an artificial outlet channel affects organic carbon accumulation in a coastal lagoon

*Kenta Watanabe[1], Tomohiro Kuwae[1]

1. Port and Airport Research Institute

Organic carbon (C_{org}) storage is one of the important functions of vegetated coastal ecosystems for mitigating the adverse effects of climate change. The artificial alteration of landforms by coastal constructions would impact on habitats, hydrological conditions, and sediment loads. However, how the coastal constructions change C_{org} accumulation in vegetated coastal ecosystems is poorly understood. In this study, the sediment profiles of geological and biogeochemical characteristics were measured in Komuke Lagoon, Hokkaido. Stable isotope ratios and ^{210}Pb profiles were used to investigate the origin of C_{org} and sediment age. We showed that C_{org} accumulation rates and the origin of accumulated C_{org} significantly changed after the construction of an artificial outlet channel. C_{org} accumulation was enhanced, the contribution of terrestrial-derived C_{org} decreased, and that of microalgae- and seagrass-derived C_{org} increased after the coastal construction at the site. These findings indicate that the construction of an artificial outlet channel alters the frequency of seawater exchange and affects habitat types and C_{org} accumulation.

Evaluation of the influence of swans, *Cygnus cygnus* on the distribution of seagrass, *Zostera japonica*

*Yoshiyuki TANAKA[1], Fumiyuki SATO[1]

1. Hachinohe Institute of Technology, Department of Life and Environmental Science

Distribution and biomass of seagrass are changed by various environmental factors. Grazing pressure by animals is one of the factors. It is pointed out that Zostera japonica growing on the shallow coast of Kominato in Aimori prefecture is affected by Grazing pressures of swans that come every winter. In this study, we investigated seasonal change of Z. japonica in the shallow area and seasonal change of biomass, and analyzed feces of swans, and evaluated the influence of swans on the distribution of Z. japonica. In July, October, November, December 2018, line transect survey was conducted to measure the presence or absence of seagrasses at 57 fixed points, and at some sites seagrass shoots within 20 cm * 20 cm frame were collected, shoot number and biomass was recorded. We also carried out aerial photographs using a drone. In February and March 2018, the feces of the swan was collected, the content of the feces was visually analyzed, and carbon and nitrogen stable isotope ratio analysis was also conducted. As a result of presence or absence survey, the distribution point decreased in November compared with October, and almost disappeared in December. A sharp decline was confirmed even in the Drone images. The shoot number of seagrass slightly decreased from July to October, while the weight of the underground part did not change much, whereas the weight of the aboveground part slightly increased. The shoots number of Z. japnonica in October to November, the weight of the aboveground and the belowground decreased sharply. Plant pieces and seaweed pieces were confirmed as fecal contents in February and rice hulls were confirmed in March and in the isotopic ratio analysis, changes in food quality were confirmed between February and March. It is inferred that the influence of predation by swans and other migratory birds was great for wide range and sudden reduction of distribution and biomass. Because biomass of the Z. japonica becomes extremely small in December, it is reasonable to think that the swans during overwintering depends on bait other than the Z. japonica. It was suggested that in December and March before and after paddy fields were covered with snow, it depended on the heading of paddy fields.

Assessment and future projection of variational characteristics of ocean warming and acidification proxies in Oshoro Bay, Japan

*Masahiko Fujii[1], Takuto Yamaka[2], Shintaro Takao[3]

1. Faculty of Environmental Earth Science, 2. Graduate School of Environmental Science, 3. National Institute of Polar Research

As ocean acidification proceeds, it is concerned difficult for calcium carbonate and magnesium carbonate to be produced in the ocean, and calcifying organisms such as corals and shellfish having these skeletons and shells may be adversely affected. Moreover, the diurnal, seasonal and interannual fluctuation are all considered more prominent in coasts than in the open ocean, because of relatively larger amount of sea grass beds and more direct and significant terrestrial impacts. On the other hand, in the subarctic coastal region, it is difficult to maintain observation due to stormy weather in winter, which yields paucity of observational data. In this study, long-term continuous monitoring of physical and biogeochemical parameters was conducted in Oshoro Bay, Otaru City, Hokkaido. Our results show that the timing of increase and decrease of pH and dissolved oxygen almost coincided with each other, and the diurnal variation of pH was larger in spring and summer than in fall and winter. The diurnal variation of pH was 0.1 or more on average from May to August. The variation was 0.15 on average and 0.26 at the maximum, respectively, in August. That was 0.03 on average and 0.07 at the maximum, respectively, in November. Thus, the seasonal difference in the diurnal variation was clear, suggesting significant effects of the photosynthesis in the daytime and the respiration in the nighttime by primary producers. The results suggest relatively predominant biological effects with larger biomass and higher solar radiation in summer compared to those in winter. Results of the temporal variability of the ocean warming and acidification proxies obtained by applying the Regional Ocean Model System (ROMS) to the site will be introduced in the presentation.

Evaluation of the influence of swans, *Cygnus cygnus* on the distribution of seagrass, *Zostera japonica*

*Yoshiyuki TANAKA[1], Fumiyuki SATO[1]

1. Hachinohe Institute of Technology, Department of Life and Environmental Science

Distribution and biomass of seagrass are changed by various environmental factors. Grazing pressure by animals is one of the factors. It is pointed out that Zostera japonica growing on the shallow coast of Kominato in Aimori prefecture is affected by Grazing pressures of swans that come every winter. In this study, we investigated seasonal change of Z. japonica in the shallow area and seasonal change of biomass, and analyzed feces of swans, and evaluated the influence of swans on the distribution of Z. japonica. In July, October, November, December 2018, line transect survey was conducted to measure the presence or absence of seagrasses at 57 fixed points, and at some sites seagrass shoots within 20 cm * 20 cm frame were collected, shoot number and biomass was recorded. We also carried out aerial photographs using a drone. In February and March 2018, the feces of the swan was collected, the content of the feces was visually analyzed, and carbon and nitrogen stable isotope ratio analysis was also conducted. As a result of presence or absence survey, the distribution point decreased in November compared with October, and almost disappeared in December. A sharp decline was confirmed even in the Drone images. The shoot number of seagrass slightly decreased from July to October, while the weight of the underground part did not change much, whereas the weight of the aboveground part slightly increased. The shoots number of Z. japnonica in October to November, the weight of the aboveground and the belowground decreased sharply. Plant pieces and seaweed pieces were confirmed as fecal contents in February and rice hulls were confirmed in March and in the isotopic ratio analysis, changes in food quality were confirmed between February and March. It is inferred that the influence of predation by swans and other migratory birds was great for wide range and sudden reduction of distribution and biomass. Because biomass of the Z. japonica becomes extremely small in December, it is reasonable to think that the swans during overwintering depends on bait other than the Z. japonica. It was suggested that in December and March before and after paddy fields were covered with snow, it depended on the heading of paddy fields.

Assessment and future projection of variational characteristics of ocean warming and acidification proxies in Oshoro Bay, Japan

*Masahiko Fujii[1], Takuto Yamaka[2], Shintaro Takao[3]

1. Faculty of Environmental Earth Science, 2. Graduate School of Environmental Science, 3. National Institute of Polar Research

As ocean acidification proceeds, it is concerned difficult for calcium carbonate and magnesium carbonate to be produced in the ocean, and calcifying organisms such as corals and shellfish having these skeletons and shells may be adversely affected. Moreover, the diurnal, seasonal and interannual fluctuation are all considered more prominent in coasts than in the open ocean, because of relatively larger amount of sea grass beds and more direct and significant terrestrial impacts. On the other hand, in the subarctic coastal region, it is difficult to maintain observation due to stormy weather in winter, which yields paucity of observational data. In this study, long-term continuous monitoring of physical and biogeochemical parameters was conducted in Oshoro Bay, Otaru City, Hokkaido. Our results show that the timing of increase and decrease of pH and dissolved oxygen almost coincided with each other, and the diurnal variation of pH was larger in spring and summer than in fall and winter. The diurnal variation of pH was 0.1 or more on average from May to August. The variation was 0.15 on average and 0.26 at the maximum, respectively, in August. That was 0.03 on average and 0.07 at the maximum, respectively, in November. Thus, the seasonal difference in the diurnal variation was clear, suggesting significant effects of the photosynthesis in the daytime and the respiration in the nighttime by primary producers. The results suggest relatively predominant biological effects with larger biomass and higher solar radiation in summer compared to those in winter. Results of the temporal variability of the ocean warming and acidification proxies obtained by applying the Regional Ocean Model System (ROMS) to the site will be introduced in the presentation.

[A-CG41] Promotion of Application and Utilization of Aircrafts for Earth sciences

convener:Nobuhiro Takahashi(Institute for Space-Earth Environmental Research, Nagoya University), Makoto Koike(Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo), Toshinobu Machida(National Institute for Environmental Studies), Taro Shinoda(Institute for Space-Earth Environmental Research, Nagoya University)

The problem of global environmental change such as global warming is a problem throughout the Earth and planetary sciences. To confront this problem, progresses of the observations that are dedicated for the monitoring Earth and for the process studies as well as the progresses of numerical prediction models. Aircraft observation has the great advantages of immediate and direct (in-situ) observations which cannot be achieved by Earth observing satellites or ground-based observations. Recently, the importance of aircraft observation is increasing in "in-situ measurements" such as concentration of greenhouse gases, aerosol and cloud particle size distribution, and chemical composition, and "remote sensing" such as three dimensional typhoon observation and observation on forests and vegetation. In addition, the application of aircraft observation to geodesy, study on earthquakes and volcanos are also progressing. However, steady and extensive aircraft observations to fulfill the requirements in Japan are not realized at the present time. Meanwhile, it is also a fact that the aircraft observations which have been carried out has cited the world leading results. In order to realize the effective research by using aircraft, it is necessary to have a close collaborations among researchers to promote aircraft observations, and it is also necessary to carry out as the master plan of national academic council of Japan. In this session, we will discuss the future aircraft observation through the latest research results with aircraft observations.

In situ measurements of aerosol and cloud microphysical properties and cloud seeding experiments over the UAE

*Narihiro Orikasa[1], Masataka Murakami[2,1], Takuya Tajiri[1], Yuji Zaizen[1], Taro Shinoda[2]

1. Meteorological Research Institute, 2. Nagoya Univ., ISEE

Our field campaign of aircraft observations had successfully been conducted over the UAE regions, as well as ferries between UAE and Japan, in the summer of 2017. This campaign has mainly two objectives. First, in situ measurements contribute to investigation on microphysical processes in seeded and unseeded clouds as well as elucidation of the mechanism responsible for precipitation augmentation. Secondly, the field observation data is useful to validate numerical simulations of cloud and precipitation and to improve the accuracy and reliability of numerical models.

We had deployed two aircraft whose base was Al Ain International Airport, as well as one ground-based observation site next to the aircraft hangar. One aircraft for in situ measurements was B200T operated by Diamond Air Service Inc., and the other for cloud seeding was C-90 operated by UAE National Center of Meteorology (NCM). We performed 14 research flights (~30 hours in total) from Sep. 5 to Sep. 24. Thirteen of the B200T flights were coordinated with the C-90 flights. As shown in Fig. 1, the B200T installed meteorological instruments, hot-wire water content probes, cloud microphysical probes for in situ measurements, aerosol size distribution instruments, sampling mesh device for electron microscopic analysis, cloud condensation nuclei (CCN) counter, and ice nucleating particle (INP) counter. The C-90 dispersed two types of seeding materials through burn-in-place flare racks: $CaCl_2$ hygroscopic (HYG) and silver iodide (AgI) flares.

As one of the flight patterns, seeding plumes generated from the C-90 were sampled and measured with the instrumented B200T which followed the C-90. We collected excellent data for background (BG) aerosols and seeding plume particles generated by HYG flares, AgI flares, or simultaneously generated by the both types of flares.

In order to investigate cloud seeding effects, the B200T measured the evolution of aerosols and cloud particles from cloud base to upper levels before and after the C-90's flare seeding. Based on the same strategy and method as in previous studies on Japanese field campaigns, the flight data quality check and data analysis have been processed, and results of initial cloud droplet size distributions in terms of the seeding signatures are shown from several cases. In general, it was difficult to find clear seeding signatures in any cases.

Except for the seeding experiments, several flights provided us in situ measurements of natural clouds. We sometimes encountered relatively developed clouds whose top temperature was warmer than -10 C, and most of such clouds had ice crystals and graupels. Those basic data will be useful to fully understand the mechanism of ice formation over the UAE regions and to verify the numerical simulations of cloud and precipitation.

In order to conduct an effective and efficient cloud seeding experiment, it is essential to know the physico-chemical properties of BG aerosols in the atmosphere and to observe their spatial and temporal distributions before the experiment. The vertical profiles of aerosol number concentrations (corrected for STP conditions) showed rather constant below cloud base height. The IN and CCN abilities of BG aerosols

©2019. Japan Geoscience Union. All Right Reserved.

are also essential information to accurately simulate cloud formation and precipitation development. The analysis of number concentrations of INP and CCN is shown from a few cases. The INP concentrations were typically ranged on the order of 1 to 10 L^{-1} and there were no significant height dependency. The CCN concentrations were typically several hundreds cm^{-3}_stp and generally depended on the space and time.

Analysis and Forecast Using Dropsonde Data from the Inner-Core Region of Tropical Cyclone Lan (2017) Obtained during the First Aircraft Missions of T-PARCII

*Kosuke Ito[1], Hiroyuki Yamada[1], Munehiko Yamaguchi[2], Tetsuo Nakazawa[2], Norio Nagahama[3], Kensaku Shimizu[3], Tadayasu Ohigashi[4], Taro Shinoda[5], Kazuhisa Tsuboki[5]

1. University of the Ryukyus, 2. Meteorological Research Institute, 3. Meisei Electric Co. LTD., 4. National Research Institute for Earth Science and Disaster Resilience, 5. Nagoya University

The inner core of Tropical Cyclone Lan was observed on 21–22 October 2017 by GPS dropsondes during the first aircraft missions of the Tropical Cyclones-Pacific Asian Research Campaign for the Improvement of Intensity Estimations/Forecasts (T-PARCII). To evaluate the impact of dropsondes on forecast skill, 12 36-h forecasts were conducted using a Japan Meteorological Agency non-hydrostatic model (JMA-NHM) with a JMANHM-based mesoscale four-dimensional data assimilation (DA) system. Track forecast skill improved over all forecast times with the assimilation of the dropsonde data. The improvement rate was 8–16% for 27–36-h forecasts. Minimum sea level pressure (Pmin) forecasts were generally degenerated (improved) for relatively short-term (long-term) forecasts by adding the dropsonde data, and maximum wind speed (Vmax) forecasts were degenerated. Some of the changes in the track and Vmax forecasts were statistically significant at the 95% confidence level. It is notable that the dropsonde-derived estimate of Pmin was closer to the realtime analysis by the Regional Specialized Meteorological Center (RSMC) Tokyo than the RSMC Tokyo best track analysis. The degeneration in intensity forecast skill due to uncertainties in the best track data is discussed.

On the Spatial Distribution of Freezing height of Typhoon Trami

*Nobuhiro Takahashi[1], Yuki Kaneko[2], Kazuhisa Tsuboki[1]

1. Institute for Space-Earth Environmental Research, Nagoya University, 2. Japan Aerospace Exploration Agency

Drop sonde observation from aircraft was conducted for typhoon Trami that occurred in September 2018. The drop sonde observation provides the vertical profile of the temperature and humidity in and around the eye of typhoon. Meanwhile, the global precipitation measuring (GPM) core satellite, which equips dual frequency precipitation radar (DPR), passed over Trami for several times, two of which captured the eye structure. In particular, the over flight case on September 27 by DPR is several hours after the drop sonde observation.

Since DPR can observe the vertical structure of the precipitation system, it is possible to estimate the freezing height in the stratiform precipitation region from the melting layer appearing as the so-called bright band, and an attempt was made to separate snowfall and rainfall by using dual frequency observation which gives information on altitude of transition from rain to snowfall in convective precipitation. In this report, freezing height pattern of typhoon Trami is estimated by combining information from drop sonde and DPR observation, especially around the eye of the typhoon. According to DPR's bright band information, the freezing height increases from 4500 m to 5400 m along the spiral band. Especially on the south side, it rose suddenly about 500 m around the inner core. In the vicinity of the inner core, which is a convective precipitation system, the region of large dual frequency ratio rises to about 6 km. On the other hand, from the observation of the drop sonde, the 0 ℃ altitude rose to about 6500 m in the eye.

Revision of Research Plan on “Promotion of Climate and Earth System Science Research by Aircraft Observation”

*Nobuhiro Takahashi[1], Makoto Koike[2]

1. Institute for Space-Earth Environmental Research, Nagoya University, 2. School of Science, The University of Tokyo

The Meteorological Society of Japan proposes on promotion of climate and Earth system science research by introducing a dedicated astronomical observation aircraft for Master Plan 2014 and 2017 of the Science Council of Japan with researchers in a wide field of the Earth and Planetary Sciences. In the Master Plan 2014 and 2017, this proposal was not selected as a priority plan. For Master Plan 2020, we strengthening cooperation with academic societies and researchers in the field of earth planetary science to consolidate the scientific purpose and also stated the cooperation with aeronautical engineering for future evolution of observation system. This research plan, which was originally prepared for the Master Plan 2017, revised to include the updated research field and issued as “Promotion of Climate and Earth System Science Research by Aircraft Observation.” In this presentation, overview of the research plan is introduced in terms of scientific purposes in the various field, proposed aircraft, cost and organization.

After the US aircraft reconnaissance in the western North Pacific was terminated in 1987, typhoon intensity is estimated by the Dvorak technique using satellite cloud pattern. Consequently, uncertainty of intensity estimation became large for very intense typhoons. Accurate intensity estimations are essential for prevention and mitigation of typhoon disaster. They are also important information for a study of long-term change of typhoon with the climate change. To improve this problem, the T-PARCII (Tropical cyclone-Pacific Asian Research Campaign for Improvement of Intensity estimations/forecasts) project performs an in situ observation of typhoons. In this project, Nagoya University and Meisei Electric Co., Ltd developed a new dropsonde and a four-channel dropsonde receiver. Using these systems on a jet aircraft, the T-PARCII project performed aircraft observations of very intense typhoons in 2017 and 2018. Typhoon Lan (2017) was the most intense typhoon in 2017 and was categorized as a supertyphoon by JTWC. It moved northeastward in the east of the Okinawa main island at 23 N on 21 October and at 28 N on October 22, 2017. In these two days, we made dropsonde observations inside of the eye and in the surrounding area of the eyewall. The T-PARCII team also made aircraft observations of Typhoon Trami (2018) during the period from 25 to 28 September 2018 in collaboration with the SATREPS ULAT group as well as Taiwan DOTSTAR. The observed dropsonde data were transmitted to GTS (Global Telecommunication System) in real time and were used for typhoon forecasts in 2018.

Because the height of dropsonde is derived from GPS, error of height data becomes large just before the dropsonde reaches to the sea surface. As a result, the sea level pressure is uncertain. Typhoon intensity is represented by the central sea level pressure. Accurate estimation of sea level pressure is necessary for a typhoon intensity information. We, therefore, developed two schemes to estimate the sea level pressure from dropsonde data. Temperature, humidity and pressure are measured by sensors of dropsonde. We assume that the accuracy of these data is sufficiently high and height is also accurate above ~500 m in height. In the scheme I, the sea level pressure is calculated by a pressure correction method from 50~100 observed points in 900~750 hPa. The final result is the average of these calculated sea level pressure values. In the scheme II, heights of observed pressure levels below 800 hPa are calculated by the hydrostatic equation using virtual temperature. The sea level pressure is corrected from the lowest grid point.

These schemes were examined by special observations around Minami-Daitojima comparing dropsonde observations with balloon sonde observations launched from Minami-Daitojima Island as well as the JMA surface observation. The maximum difference of sea level pressure is less than 3 hPa. The central sea level pressures of typhoons Lan and Trami were calculated by the schemes I and II. The results by these two schemes agreed well each other. We consider that the sea level pressures were estimated with a sufficient accuracy. They were compared with the JMA best track data. The difference of central pressure of typhoon Trami was about 5 hPa on September 25 when the typhoon was most intense. It was about 10 hPa on September 28 when the typhoon was weakened in the south of the Okinawa main island.

New observation strategies for typhoon intensity over the western North Pacific

*Hiroyuki Yamada[1], Kazuhisa Tsuboki[2], Taro Shinoda[2], Hisayuki Kubota[3], Yukihiro Takahashi[3], Norio Nagahama[4], Kensaku Shimizu[4], Tadayasu Ohigashi[5], Kosuke Ito[1], Munehiko Yamaguchi[6], Tetsuo Nakazawa[6]

Recent activities on typhoon intensity observation/estimation using aircraft reconnaissance and ground-based Doppler radars in the western North Pacific are introduced. Since aircraft reconnaissance by the US military was ceased in 1987, new techniques of intensity estimation using microwave radiometer and a geostationary satellite are used in this basin without enough verification. The major obstacle of aircraft reconnaissance is the difficulty of having a specially-designed propeller aircraft that withstands strong turbulence. Since wind speed in a typhoon is stronger in the lower troposphere, it takes a great deal of labor and expense to measure the center position and the central pressure of a typhoon through low-altitude flight with slow speed. On the other hand, since the winds become weaker in the upper troposphere, it is possible to fly into the typhoon center if the risks of heavy icing and severe turbulence in a convective burst can be avoided by using an airborne weather radar. During T-PARCII (Tropical Cyclone-Pacific Asian Research Campaign for Improvement of Intensity Estimations / Forecasts), we succeeded in observing the central pressure of two intense typhoons, Lan (2017) and Trami (2018), by using a commercial jet aircraft (Gulfstream-II) with a newly-developed GPS dropsonde system. These flight missions were made in the upper troposphere (43,000ft, approximately 13.7 km) and were marked by very weak turbulence during eyewall penetration. These flights demonstrated a possibility of typhoon intensity observation using a civil aircraft. In the Pacific coast of Japan and Philippines, Doppler radars became available in this decade. The combination of aircraft reconnaissance off the coast with the ground-based velocity track display (GBVTD) analysis near the coast will provide accurate information on typhoon intensity.

Meisei Electric, 5. Graduate School of Science, Hokkaido University, 6. Institute for Space-Earth Environmental Research, Nagoya University

Airborne typhoon observations were conducted for Typhoon Trami (2018) under Tropical cyclones-Pacific Asian Research Campaign for Improvement of Intensity estimations/forecasts (T-PARCII). Using the dropsonde data (zonal and meridional winds, temperature, and relative humidity) and the Japan Meteorological Agency Global Spectral Model (JMA/GSM, TL959L100) and 4 Dimensional Variational data assimilation (4DVAR, TL319L100), we performed Observing System Experiment (OSE) to see the impact of the newly available observational date on the track/intensity predictions by the JMA/GSM.

Three sets of numerical experiments, CNTL, EXP1 and EXP2, were performed. All the T-PARCII dropsonde and typhoon bogus data were used in the data assimilation in CNTL while T-PARCII dropsonde (typhoon bogus) data only were assimilated in the 4DVAR in EXP1 (EXP2). The period of the experiments is from 2018.09.25 00UTC to 2018.09.28 18UTC with a 6-hour data assimilation and forecasting cycle.

The error of the track predictions of EXP1 and EXP2 is smaller than that of CNTL. For example, the 3-day track prediction error of CNTL, EXP1 and EXP2 is 232, 201 and 218 km, respectively. A possible reason of the degradation of the track predictions by CNTL is that some dropsonde data were assimilated at the almost same locations as typhoon bogus data, which might deteriorate the initial structure of the typhoon.

In the operational configuration of the 4DVAR, all dropsonde data were assimilated irrespective of the existence of the typhoon bogus data. The results of a series of these numerical experiments may lead to improvement in the operational setting of dropsonde assimilation.

In this presentation, we will talk about the basic behaviors, microphysical and associated optical properties, and transport-and-removal processes of the tropospheric black carbon and iron oxide aerosol which have been elucidated mostly from aircraft measurements. We will clarify the scientific significance and contribution of these findings in the context of the related international research activities on atmospheric aerosols and climate change. In addition, we will suggest some related open problems which need to be investigated through in-situ aircraft measurements in future research.

Aerosol measurements around the ridge of East Antarctica using a Rogallo wing UAV

*Ryohei Haraguchi[1], Masahiko Hayashi[1], Keiichiro Hara[1], Naohiko Hirasawa[2], Koki Nakata[3], Kei-ichi Ozuka[4,1]

1. Fukuoka University, 2. National Institute of Polar Research, 3. kkt Inovate Co., Ltd, 4. Nippon Tungsten Co., Ltd

Meteorological observations using a UAV in the Antarctica have been carried out at S17 Air Base (69° 02’ S, 40° 06’ E, 606m a.s.l.), near Syowa Base by the 48th, 54th, and 56th Japanese Antarctic Research Expedition, (JARE). The JARE 58th planned to perform meteorological observations including snow, water vapor and aerosols budgets at S17 during December 22nd, 2016 and February 4th, 2017. One of main mission of the observation focused on aerosol processes using automated UAVs with a Rogallo wing, called Kite Planes. Two types of Kite Planes were used for different type observations. One is engine powered Kite Plane for horizontal observations with a condensation particle counter, an optical particle counter, and an aerosol sampler for SEM/EDX analyses. Another is a glider KitePlane supported by electric motor with an optical particle counter for vertical distribution observations. 22 flights were successfully carried out during the campaign of JARE 58th and obtained following results.

1. Uniformity in CN and Mie particle concentrations is very high during January in 2017.
2. Low CN concentrations were sometimes observed near surface.
3. High CN event with low Mie particle concentration from free troposphere was observed on January 23rd, suggesting caused by new particle formation.
4. High CN event with high Mie particle concentration from ocean area was observed on January 27th, 2017, suggesting hygroscopic growth of aerosols from marin boundary layer.

Wind Mesurements Based on In-situ Data -Direct Vector Calculation and Hodograph Analyses-

*Masahiko Hayashi[1], Tomoyuki Onohara[1], Ryohei Haraguchi[1,3], Kei-ichi Ozuka[2,4], Kazuo Okabe[3]

1. Faculty of Science, Fukuoka University, 2. Nippon Tungsten Co.,Ltd, 3. SkyRemote Co.,Ltd, 4. FIT-EH, Fukuoka University

Un-manned Aerial Vehicles have been developing rapidly and performance as observation platform are increasing. Our group have used Rogallo wing UAV, called KitePlane for aerosol measurement about 20 years ago. In-situ wind measurements have tested, becuase of importance for meteorological analyses and technical requirements for safety flight operations. There are two typical methods for atmospheric wind measurements based on in-situ data by in-flight airplane. One is direct calculation method by difference between gound speed and true air speed. The other is that drift of center of hodograph circle for ground speed coinsident with wind vector during flight.
Time and spatial resolutions for the direct calculations are around 1 second and 10 m respectively, and require high accuracy for true wind vectors. On the other hand, those for the hodograph methods are around 1 minuite and several hundreds meters, respectively, however the method only require position and time for calculations.
It will be presented based on actual flight by KitePlane that accuracies of wind speeds and directions are around 0.1m/sec and several degrees for both methods with recently developed small and precision sensors.

[J] Poster | A (Atmospheric and Hydrospheric Sciences)：A-CG Complex & General

Tue. May 28, 2019 10:45 AM - 12:15 PM JST | Tue. May 28, 2019 1:45 AM - 3:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_4

[A-CG44] Coastal Ecosystems 2 Coral reefs, seagrass and macroalgal beds, and mangrove

convener:Yu Umezawa(Tokyo University of Agriculture and Technology), Toshihiro Miyajima(Marine Biogeochemistry Group, Division of Ocean-Earth System Science, Atmosphere and Ocean Research Institute, The University of Tokyo), Atsushi Watanabe(The ocean policy research institute, The Sasakawa peace foundation), Tomihiko Higuchi(Atmosphere and Ocean Research Institute, The University of Tokyo)

Coastal marine ecosystems are complex open system interacting with surrounding watersheds, outer ocean, and the atmosphere, providing a wealth of various ecosystem services to human life. Simultaneously, they are also influenced strongly and often negatively by human activities. This session, together with a companion session dedicated for the water cycle and land-ocean interactions, aims to provide a platform for interdisciplinary discussion covering various aspects of frontiers in coastal ecosystem sciences. This session particularly focuses shallow-water benthic communities ranging from temperate to tropical regions, such as coral reefs, seagrass and macroalgal beds, and mangroves. All these communities are characterized by intrinsically high primary production, active material cycling, and biodiversity hot spots. However, increasing human demand for coastal marine resources and industrial development concentrating on coastal regions incur the risk of rapid degradation and diminishment. Comprehensive assessment and monitoring of ecosystem functions and development of effective means for conservation and restoration are urgently needed for such communities. This session is dedicated to organizing and promoting such research and management activities by sharing state-of-the-art science and technology among ecologists, geologists, geochemists, biogeographers, etc. Field-based and modeling studies concerning the following topics are especially welcome: material cycling and ecosystem functions; community connectivity; environmental changes such as global warming, ocean acidification, and sea-level rise; ecosystem services such as carbon sequestration, nutrient regulation, and fisheries production; broad-scale comparison; long-term ecological researches.

Characteristics of organic carbon in coastal carbonate sediment accompanied by seagrass meadows

*Toshihiro Miyajima[1]

1. Marine Biogeochemistry Group, Division of Ocean-Earth System Science, Atmosphere and Ocean Research Institute, The University of Tokyo

Seagrass meadows are submerged, highly productive ecosystem that occurs in sandy shallow coastal environments from tropical to boreal regions. Colonization of seagrasses in coastal habitats renders originally oligotrophic, organic-poor sandy sediment into a hot spot of organic carbon (OC) sequestration and storage. This function depends on a combination of several characteristics specific to seagrasses, such as very high and efficient photosynthetic ability, production of perennial belowground biomass, and physical attenuation effects of leaf blades and roots that enhance accumulation and stability of sediment. Recent estimates indicate that around 70% of global seagrass meadows are present in tropical and subtropical coastal habitats (Siikamäki et al. 2012), which are often covered with biogenic carbonate sediment especially in archipelagic regions. In fact, carbonate accumulated in global seagrass meadow sediments has been estimated to be up to five times greater than the amount of OC on the carbon basis (Mazarrasa et al. 2015). However, geochemical roles of carbonate sediment in OC sequestration in seagrass meadow sediments is not well understood.
This study focuses on the OC stock and its relationship to mineralogical properties of sediment such as carbonate content, specific surface area (SSA), and mesopore distribution in carbonate sediments accompanied by seagrass meadows in Japan and the Philippines. Here, typical carbonate sediment is defined as sediment with inorganic carbon (IC) content greater than 8 mmol IC g^{-1}(ca. 10%-IC w/w). Obtained results were compared with corresponding properties of temperate, non-carbonate (<0.5 mmol IC g^{-1}) seagrass meadow sediments. The ranges of OC concentration and stock, as well as the degree of accumulation of OC in seagrass meadows relative to adjacent non-vegetated sediment, were similar between carbonate and non-carbonate seagrass habitats. The OC concentration strongly correlated with SSA and total mesopore volume for both carbonate and non-carbonate sediments. However, average OC loading per unit surface area and unit mesopore volume was six-times and three-times greater for carbonate sediments than non-carbonate sediments, respectively. Carbon isotope abundance suggested that the fraction of seagrass-derived OC to total OC was often much greater for carbonate sediments than non-carbonate sediments. Nonetheless, OC tightly associated with carbonate minerals seemed to be derived mainly from non-seagrass sources. These findings as well as the differences between carbonate and non-carbonate sediments may be partially explained by characteristics specific to carbonate sediments, such as presence of basic OC inherited from organisms that originally produced the carbonate, different affinity to soluble organic matter, different mesopore shape and size distribution, and gradual dissolution during early diagenesis. However, what constrains the capacity of carbonate sediments to sequester OC is still unclear. Our results suggest that, although mineralogical control on sediment OC is significant in carbonate sediment, the classical sorptive preservation mechanism originally put forward for explaining the constant OC/SSA ratio in continental shelf sediments is not sufficient to explain the OC sequestration capacity of carbonate sediments supporting seagrass meadows.

Perceptions of Coastal Communities on Blue Carbon Ecosystems Services at the Municipalities of Eastern Samar and Western Visayas, Philippines

*Jay Mar Dioquito Quevedo[1], Yuta Uchiyama[1], Kaoru Kakinuma[1], Ryo Kohsaka[1]

1. Tohoku University

The blue carbon ecosystems (mangroves and seagrass) in the Philippines provide a wide range of benefits to the coastal communities; from provisional, regulating and cultural services ranging from supply of food and a natural fish nursery, carbon storage, protection against storm surges and as a tourism site. Existing studies in the Philippines have shown how local people in coastal areas affects the utilization and managing of the blue carbon ecosystems. However, little have recorded and evaluated the perception of people on the importance of these coastal ecosystems at the municipality level in relationship with rate of utilization to the different services these ecosystems provide. It is very important to understand the level of awareness and usage of mangrove, seagrass and associated resources because it can help in contextual formulation and implementation of management plan of coastal ecosystems in the municipality. In this study, household surveys, key informant interviews (KII), and focus group discussions (FGD) using semi-structured questionnaires will be utilized at coastal areas in select municipalities of Eastern Samar and Western Visayas. This study aims to determine the local knowledge of the coastal communities on blue carbon ecosystems, evaluate how they directly or indirectly use the services and identify potential local threats and destructive activities. It will also highlight the perception and evaluation of the existing efforts of the local government and their effectivity on the management of blue carbon ecosystems from local perspectives which has been largely overlooked.

Numerical simulation of typhoon events in Sekisei Lagoon, Okinawa, Japan using a coupled ocean-wave model

*Lawrence Patrick Cases Bernardo[1], Takashi Nakamura[1], Kazuo Nadoka[1]

1. Department of Transdisciplinary Science and Engineering, Tokyo Institute of Technology

Sekisei Lagoon is the site of Japan's largest coral reef area and is an important target site for conservation. However, it is affected to varying degrees by typhoons which approach yearly during the summer and autumn seasons. To closely investigate typhoon-driven hydrodynamics in Sekisei Lagoon, a modeling setup was developed using a nested Regional Ocean Modeling System (ROMS) configuration with an outer coarse scale regional model at 1.5 km grid resolution, and an inner model focused on the Sekisei Lagoon domain with a grid resolution of 300 meters. The inner model was configured using the Coupled Ocean-Atmophere-Wave-Sediment Transport (COAWST) modeling framework in order to couple the ROMS ocean model with the Simulating Waves Nearshore (SWAN) wave model. Initial conditions and ocean boundary forcing for the regional model were derived from the global 1/12° Hybrid Coordinate Modeling System analysis data (HYCOM GLBv0.08), and tidal forcing was added using data from the 1/30° OSU Topex/Poseidon Global Inverse tidal solution (TPXO9). Meteorological forcing was derived from Japan Meteorological Agency-Grid Point Value (JMA-GPV) mesoscale model results, and SWAN boundary forcing for the inner model was derived using outputs from the 5-km JMA Coastal Wave Model (CWM) for locations around the Yaeyama Islands where Sekisei Lagoon is located.

The modeling setup was run for specific typhoon events as well as for relatively calmer periods, and model performance was evaluated by comparing simulation results with in-situ observations from sensor deployments around Sekisei Lagoon conducted during the summer months of 2014, 2015, and 2016, as well as from a long term continuous monitoring setup in the Shiraho Reef area in Ishigaki Island. Modeled significant wave heights and peak wave periods at wave sensor locations for relatively calm periods had comparable ranges, but exact temporal trends could not yet be reproduced well. During modeled typhoon passages, trends in significant wave height, such as the timing of increase as the typhoon approached and the maximum wave height reached, were well-reproduced for a wave sensor located at the southeastern part of Sekisei Lagoon. However, the comparison was relatively poor for wave sensors deployed at the northwestern part of the lagoon and offshore of Shiraho Reef on the eastern side of Ishigaki Island, particularly in terms of the timing of wave height increase. In terms of simulating water temperature, running the inner ROMS model without SWAN resulted in Wilmott skill index (Wilmott 1981) scores ranging from 0.72 to 0.95 and root mean-square errors ranging from 0.46 to 1.52 deg C when compared with field observations conducted around Sekisei Lagoon from May to November in 2016. Modeling runs for the coupled ROMS-SWAN model were of shorter duration, but the simulated water temperatures showed some notable differences with the ROMS only case for some locations, suggesting that the influence of wave-driven flows on water temperature trends may need closer investigation.

Adjustments to the modeling setup are ongoing, especially in terms of more properly resolving bathymetric features, as some parts of the domain are characterized by complex barrier and fringing reef structures. Parameter tuning is also being conducted in relation to the physical processes considered in the SWAN wave model, such as the influence of bottom friction and depth-induced wave breaking. With further improvement, this modeling setup may serve as a potentially useful tool to gain further insight into the ways typhoons affect the hydrodynamic conditions in Sekisei Lagoon, as well as estimate potential damage levels, given that typhoon tracks and intensities vary. Even for the non-typhoon case, the setup

©2019. Japan Geoscience Union. All Right Reserved.

may also be useful to help clarify the influence of waves on the overall circulation in the area.

Study of macrobenthic community structure at mesophotic depths in the South Ryukyus based on ROV and AUV seafloor imaging

*Marc Humblet[1], Toshihiro Maki[2], Yasuo Furushima[3], Yukiyasu Noguchi[2], Hiroumi Horimoto[2], Hiroya Yatagai[2], Takashi Sakamaki[2], Shohei Ito[4], Sadao Suzuki[5]

1. Department of Earth and Planetary Sciences, Nagoya University, 2. Institute of Industrial Science, The University of Tokyo, 3. JAMSTEC, 4. FullDepth Co., Ltd., 5. ORE

Mesophotic coral reef habitats (30-150 m) are still largely unexplored despite their importance in biology (e.g., marine biodiversity studies, genetic connectivity between shallow and deep communities, ecological shift from photosynthetic to heterotrophic communities along a depth/light gradient) and in geology (e.g., study of sea-level changes and reef growth history during Quaternary sea-level lowstands). Here we report on new seafloor observations conducted by remotely operated vehicles (ROVs) and an autonomous underwater vehicle (AUV) at depths of 30-65 m around the Sekisei lagoon, Yaeyama Islands, South Ryukyus, Japan. In this study, new seafloor imaging was carried out at six sites along the northern (N1-N2) and southern (S1-S4) margins of the Sekisei Lagoon by two ROVs (BlueRov 2, Blue Robotics Inc., and FullDepth DiveUnit 300, FullDepth Co., Ltd.) and one AUV (HATTORI 2). HATTORI 2 is designed to acquire high-resolution video images of the seafloor at a constant elevation along a pre-programmed path, which enables the creation of a 3D topographic map of the seafloor based on structure-from-motion photogrammetry. In addition, HATTORI 2 was equipped with depth, temperature, salinity and light sensors. We combine these new observations with data obtained during previous ROV and AUV surveys to investigate the community structure of benthic organisms, particularly scleractinian corals, at mesophotic depths, and examine its relationship with water depth, seafloor topography, substrate type, and other major environmental parameters (i.e., light penetration, water temperature and salinity). Previous surveys revealed a clear bathymetric zonation at site S1 with a shift from a “coralgal” community (dominated by scleractinian corals and coralline algae) to a “mixed” community (including scleractinian corals, algae, octocorallians, sponges, and foraminifers) at a depth of ~60 m, and showed also that scleractinian corals become rare below 70 m. A preliminary analysis of images acquired during our latest survey indicates that coral cover in the upper mesophotic zone (30-40 m) varies greatly from one site to another: up to 100% in the area of sites N1 and N2 (*Leptoseris* and *Acropora* colonies locally abundant), 35% or less in the area of S1, close to 0% at sites S2 and S3, and 30-60 % at site S4. Our new data confirm that substrate type and seafloor topography are likely important factors controlling the distribution of corals at upper mesophotic depths (higher coral cover on hard rocky substrate and topographic highs), but they alone cannot explain the full range of our observations.

Enhancement of antioxidant activity of scleractinian coral *Galaxea Fascicularis* by feeding treatment.

*Hiroyuki Fujimura[1], Sayaka Higa[1], Toshihiro Miyajima[2], Tomihiko Higuchi[2], Sylvain Agostini[3], Ikuko Yuyama[3], Takashi Nakamura[4]

1. University of the Ryukyus, 2. The University of Tokyo, 3. Tsukuba University, 4. Tokyo Institute of Technology

In recent years, mass coral bleaching has been recognized around the world. Coral bleaching is a phenomenon that coral loses symbiotic algae “zooxanthellae” due to strong solar radiation and high water temperature, and white coral skeleton can be seen through the transparent its soft tissue. Coral bleaching is caused by a damage of photosynthetic system of zooxanthella by strong light and the damaged part is not repaired by the continuation of the high water temperature, leading to a generation of harmful reactive oxygen species by combining surplus electrons and surrounding oxygen.
Since a translocation of fixed carbon from zooxanthellae to coral decreases during bleaching event, corals are forced to consume the stored lipids in the tissues. Prolonged bleaching event eventually causes the death of coral. Corals that store enough energy by predation have more resistance against bleaching (Ferrier-Pages et al. 2010). An addition of a trace amount of inorganic metals to corals has shown an increase in antioxidant enzyme activity (Sasaki 2013). Feeding activity is not only energy supply for coral but also supply of trace metal elements that can be used for the active center of antioxidant enzyme as a cofactor. It is possible that heterotrophic feeding may improve a tolerance of coral bleaching. Therefore, the aim of this study is to investigate experimentally whether antioxidant capacity can be enhanced by heterotrophic nutrition.
Coral polyps of *Galaxea fascicularis* were incubated with and without a feeding condition for 20 days. Zooplankton was given to coral at the dawn when coral actively extends its tentacles and takes predatory behavior (AM 5: 00 - 8: 00). After 20 days, the water temperature was raised up to 31ºC within 3 days. Finally, all the coral polyps were sacrificed and separated into host tissues and zooxanthella. Superoxide dismutase (SOD) enzyme activity of the antioxidant and concentration of the metal element contained in the protein were measured, respectively.
As a result of feeding experiment, the SOD enzyme activity increased under feeding conditions of 27 ℃ and maintained the activity level after exposure to high water temperature, indicating the enhancement of the antioxidant activity of *G. fascicularis* by feeding process.

Effects of environmental stresses on coral bleaching

*Tomihiko Higuchi[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

Coral reefs are threatened by multiple environmental stresses at both the global and the local scales. Declining water quality in coastal reefs has been reported such as due to red soil runoff, agricultural fertilizers, and anti-fouling chemicals. Coral bleaching has been frequently reported and actively studied recently. The synergistic effects of multiple stressors have also been studied, with several studies reporting accelerated bleaching under conditions of high seawater temperature and low water quality. For example, enrichment of nitrate can accelerate coral bleaching under high light or high temperature conditions compared with single stress conditions. If the concentration of nitrate increases damage to coral reefs in coastal areas could significantly increase under high temperature or high light stress. Moreover, environmental bacteria, *Sulfitobacter* sp., which can be found in the seawater of coral reef, enhanced bleaching process under high temperature. These nitrate and bacteria did not affect corals severely under ambient temperature (not high temperature). To mitigate environmental stresses on coral reefs, it is important to evaluate risks due not only to global warming, but also to local stresses.

[J] Poster | A (Atmospheric and Hydrospheric Sciences)：A-CG Complex & General

Tue. May 28, 2019 5:15 PM - 6:30 PM JST | Tue. May 28, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_18

[A-CG44] Coastal Ecosystems 2 Coral reefs, seagrass and macroalgal beds, and mangrove

convener:Yu Umezawa(Tokyo University of Agriculture and Technology), Toshihiro Miyajima(Marine Biogeochemistry Group, Division of Ocean-Earth System Science, Atmosphere and Ocean Research Institute, The University of Tokyo), Atsushi Watanabe(The ocean policy research institute, The Sasakawa peace foundation), Tomihiko Higuchi(Atmosphere and Ocean Research Institute, The University of Tokyo)

Coastal marine ecosystems are complex open system interacting with surrounding watersheds, outer ocean, and the atmosphere, providing a wealth of various ecosystem services to human life. Simultaneously, they are also influenced strongly and often negatively by human activities. This session, together with a companion session dedicated for the water cycle and land-ocean interactions, aims to provide a platform for interdisciplinary discussion covering various aspects of frontiers in coastal ecosystem sciences. This session particularly focuses shallow-water benthic communities ranging from temperate to tropical regions, such as coral reefs, seagrass and macroalgal beds, and mangroves. All these communities are characterized by intrinsically high primary production, active material cycling, and biodiversity hot spots. However, increasing human demand for coastal marine resources and industrial development concentrating on coastal regions incur the risk of rapid degradation and diminishment. Comprehensive assessment and monitoring of ecosystem functions and development of effective means for conservation and restoration are urgently needed for such communities. This session is dedicated to organizing and promoting such research and management activities by sharing state-of-the-art science and technology among ecologists, geologists, geochemists, biogeographers, etc. Field-based and modeling studies concerning the following topics are especially welcome: material cycling and ecosystem functions; community connectivity; environmental changes such as global warming, ocean acidification, and sea-level rise; ecosystem services such as carbon sequestration, nutrient regulation, and fisheries production; broad-scale comparison; long-term ecological researches.

Characteristics of organic carbon in coastal carbonate sediment accompanied by seagrass meadows

*Toshihiro Miyajima[1]

1. Marine Biogeochemistry Group, Division of Ocean-Earth System Science, Atmosphere and Ocean Research Institute, The University of Tokyo

Seagrass meadows are submerged, highly productive ecosystem that occurs in sandy shallow coastal environments from tropical to boreal regions. Colonization of seagrasses in coastal habitats renders originally oligotrophic, organic-poor sandy sediment into a hot spot of organic carbon (OC) sequestration and storage. This function depends on a combination of several characteristics specific to seagrasses, such as very high and efficient photosynthetic ability, production of perennial belowground biomass, and physical attenuation effects of leaf blades and roots that enhance accumulation and stability of sediment. Recent estimates indicate that around 70% of global seagrass meadows are present in tropical and subtropical coastal habitats (Siikamäki et al. 2012), which are often covered with biogenic carbonate sediment especially in archipelagic regions. In fact, carbonate accumulated in global seagrass meadow sediments has been estimated to be up to five times greater than the amount of OC on the carbon basis (Mazarrasa et al. 2015). However, geochemical roles of carbonate sediment in OC sequestration in seagrass meadow sediments is not well understood.
This study focuses on the OC stock and its relationship to mineralogical properties of sediment such as carbonate content, specific surface area (SSA), and mesopore distribution in carbonate sediments accompanied by seagrass meadows in Japan and the Philippines. Here, typical carbonate sediment is defined as sediment with inorganic carbon (IC) content greater than 8 mmol IC g^{-1}(ca. 10%-IC w/w). Obtained results were compared with corresponding properties of temperate, non-carbonate (<0.5 mmol IC g^{-1}) seagrass meadow sediments. The ranges of OC concentration and stock, as well as the degree of accumulation of OC in seagrass meadows relative to adjacent non-vegetated sediment, were similar between carbonate and non-carbonate seagrass habitats. The OC concentration strongly correlated with SSA and total mesopore volume for both carbonate and non-carbonate sediments. However, average OC loading per unit surface area and unit mesopore volume was six-times and three-times greater for carbonate sediments than non-carbonate sediments, respectively. Carbon isotope abundance suggested that the fraction of seagrass-derived OC to total OC was often much greater for carbonate sediments than non-carbonate sediments. Nonetheless, OC tightly associated with carbonate minerals seemed to be derived mainly from non-seagrass sources. These findings as well as the differences between carbonate and non-carbonate sediments may be partially explained by characteristics specific to carbonate sediments, such as presence of basic OC inherited from organisms that originally produced the carbonate, different affinity to soluble organic matter, different mesopore shape and size distribution, and gradual dissolution during early diagenesis. However, what constrains the capacity of carbonate sediments to sequester OC is still unclear. Our results suggest that, although mineralogical control on sediment OC is significant in carbonate sediment, the classical sorptive preservation mechanism originally put forward for explaining the constant OC/SSA ratio in continental shelf sediments is not sufficient to explain the OC sequestration capacity of carbonate sediments supporting seagrass meadows.

Perceptions of Coastal Communities on Blue Carbon Ecosystems Services at the Municipalities of Eastern Samar and Western Visayas, Philippines

*Jay Mar Dioquito Quevedo[1], Yuta Uchiyama[1], Kaoru Kakinuma[1], Ryo Kohsaka[1]

1. Tohoku University

The blue carbon ecosystems (mangroves and seagrass) in the Philippines provide a wide range of benefits to the coastal communities; from provisional, regulating and cultural services ranging from supply of food and a natural fish nursery, carbon storage, protection against storm surges and as a tourism site. Existing studies in the Philippines have shown how local people in coastal areas affects the utilization and managing of the blue carbon ecosystems. However, little have recorded and evaluated the perception of people on the importance of these coastal ecosystems at the municipality level in relationship with rate of utilization to the different services these ecosystems provide. It is very important to understand the level of awareness and usage of mangrove, seagrass and associated resources because it can help in contextual formulation and implementation of management plan of coastal ecosystems in the municipality. In this study, household surveys, key informant interviews (KII), and focus group discussions (FGD) using semi-structured questionnaires will be utilized at coastal areas in select municipalities of Eastern Samar and Western Visayas. This study aims to determine the local knowledge of the coastal communities on blue carbon ecosystems, evaluate how they directly or indirectly use the services and identify potential local threats and destructive activities. It will also highlight the perception and evaluation of the existing efforts of the local government and their effectivity on the management of blue carbon ecosystems from local perspectives which has been largely overlooked.

Numerical simulation of typhoon events in Sekisei Lagoon, Okinawa, Japan using a coupled ocean-wave model

*Lawrence Patrick Cases Bernardo[1], Takashi Nakamura[1], Kazuo Nadoka[1]

1. Department of Transdisciplinary Science and Engineering, Tokyo Institute of Technology

Sekisei Lagoon is the site of Japan's largest coral reef area and is an important target site for conservation. However, it is affected to varying degrees by typhoons which approach yearly during the summer and autumn seasons. To closely investigate typhoon-driven hydrodynamics in Sekisei Lagoon, a modeling setup was developed using a nested Regional Ocean Modeling System (ROMS) configuration with an outer coarse scale regional model at 1.5 km grid resolution, and an inner model focused on the Sekisei Lagoon domain with a grid resolution of 300 meters. The inner model was configured using the Coupled Ocean-Atmophere-Wave-Sediment Transport (COAWST) modeling framework in order to couple the ROMS ocean model with the Simulating Waves Nearshore (SWAN) wave model. Initial conditions and ocean boundary forcing for the regional model were derived from the global 1/12° Hybrid Coordinate Modeling System analysis data (HYCOM GLBv0.08), and tidal forcing was added using data from the 1/30° OSU Topex/Poseidon Global Inverse tidal solution (TPXO9). Meteorological forcing was derived from Japan Meteorological Agency-Grid Point Value (JMA-GPV) mesoscale model results, and SWAN boundary forcing for the inner model was derived using outputs from the 5-km JMA Coastal Wave Model (CWM) for locations around the Yaeyama Islands where Sekisei Lagoon is located.

The modeling setup was run for specific typhoon events as well as for relatively calmer periods, and model performance was evaluated by comparing simulation results with in-situ observations from sensor deployments around Sekisei Lagoon conducted during the summer months of 2014, 2015, and 2016, as well as from a long term continuous monitoring setup in the Shiraho Reef area in Ishigaki Island. Modeled significant wave heights and peak wave periods at wave sensor locations for relatively calm periods had comparable ranges, but exact temporal trends could not yet be reproduced well. During modeled typhoon passages, trends in significant wave height, such as the timing of increase as the typhoon approached and the maximum wave height reached, were well-reproduced for a wave sensor located at the southeastern part of Sekisei Lagoon. However, the comparison was relatively poor for wave sensors deployed at the northwestern part of the lagoon and offshore of Shiraho Reef on the eastern side of Ishigaki Island, particularly in terms of the timing of wave height increase. In terms of simulating water temperature, running the inner ROMS model without SWAN resulted in Wilmott skill index (Wilmott 1981) scores ranging from 0.72 to 0.95 and root mean-square errors ranging from 0.46 to 1.52 deg C when compared with field observations conducted around Sekisei Lagoon from May to November in 2016. Modeling runs for the coupled ROMS-SWAN model were of shorter duration, but the simulated water temperatures showed some notable differences with the ROMS only case for some locations, suggesting that the influence of wave-driven flows on water temperature trends may need closer investigation.

Adjustments to the modeling setup are ongoing, especially in terms of more properly resolving bathymetric features, as some parts of the domain are characterized by complex barrier and fringing reef structures. Parameter tuning is also being conducted in relation to the physical processes considered in the SWAN wave model, such as the influence of bottom friction and depth-induced wave breaking. With further improvement, this modeling setup may serve as a potentially useful tool to gain further insight into the ways typhoons affect the hydrodynamic conditions in Sekisei Lagoon, as well as estimate potential damage levels, given that typhoon tracks and intensities vary. Even for the non-typhoon case, the setup

may also be useful to help clarify the influence of waves on the overall circulation in the area.

Study of macrobenthic community structure at mesophotic depths in the South Ryukyus based on ROV and AUV seafloor imaging

*Marc Humblet[1], Toshihiro Maki[2], Yasuo Furushima[3], Yukiyasu Noguchi[2], Hiroumi Horimoto[2], Hiroya Yatagai[2], Takashi Sakamaki[2], Shohei Ito[4], Sadao Suzuki[5]

1. Department of Earth and Planetary Sciences, Nagoya University, 2. Institute of Industrial Science, The University of Tokyo, 3. JAMSTEC, 4. FullDepth Co., Ltd., 5. ORE

Mesophotic coral reef habitats (30-150 m) are still largely unexplored despite their importance in biology (e.g., marine biodiversity studies, genetic connectivity between shallow and deep communities, ecological shift from photosynthetic to heterotrophic communities along a depth/light gradient) and in geology (e.g., study of sea-level changes and reef growth history during Quaternary sea-level lowstands). Here we report on new seafloor observations conducted by remotely operated vehicles (ROVs) and an autonomous underwater vehicle (AUV) at depths of 30-65 m around the Sekisei lagoon, Yaeyama Islands, South Ryukyus, Japan. In this study, new seafloor imaging was carried out at six sites along the northern (N1-N2) and southern (S1-S4) margins of the Sekisei Lagoon by two ROVs (BlueRov 2, Blue Robotics Inc., and FullDepth DiveUnit 300, FullDepth Co., Ltd.) and one AUV (HATTORI 2). HATTORI 2 is designed to acquire high-resolution video images of the seafloor at a constant elevation along a pre-programmed path, which enables the creation of a 3D topographic map of the seafloor based on structure-from-motion photogrammetry. In addition, HATTORI 2 was equipped with depth, temperature, salinity and light sensors. We combine these new observations with data obtained during previous ROV and AUV surveys to investigate the community structure of benthic organisms, particularly scleractinian corals, at mesophotic depths, and examine its relationship with water depth, seafloor topography, substrate type, and other major environmental parameters (i.e., light penetration, water temperature and salinity). Previous surveys revealed a clear bathymetric zonation at site S1 with a shift from a “coralgal” community (dominated by scleractinian corals and coralline algae) to a “mixed” community (including scleractinian corals, algae, octocorallians, sponges, and foraminifers) at a depth of ~60 m, and showed also that scleractinian corals become rare below 70 m. A preliminary analysis of images acquired during our latest survey indicates that coral cover in the upper mesophotic zone (30-40 m) varies greatly from one site to another: up to 100% in the area of sites N1 and N2 (*Leptoseris* and *Acropora* colonies locally abundant), 35% or less in the area of S1, close to 0% at sites S2 and S3, and 30-60 % at site S4. Our new data confirm that substrate type and seafloor topography are likely important factors controlling the distribution of corals at upper mesophotic depths (higher coral cover on hard rocky substrate and topographic highs), but they alone cannot explain the full range of our observations.

In recent years, mass coral bleaching has been recognized around the world. Coral bleaching is a phenomenon that coral loses symbiotic algae “zooxanthellae” due to strong solar radiation and high water temperature, and white coral skeleton can be seen through the transparent its soft tissue. Coral bleaching is caused by a damage of photosynthetic system of zooxanthella by strong light and the damaged part is not repaired by the continuation of the high water temperature, leading to a generation of harmful reactive oxygen species by combining surplus electrons and surrounding oxygen.
Since a translocation of fixed carbon from zooxanthellae to coral decreases during bleaching event, corals are forced to consume the stored lipids in the tissues. Prolonged bleaching event eventually causes the death of coral. Corals that store enough energy by predation have more resistance against bleaching (Ferrier-Pages et al. 2010). An addition of a trace amount of inorganic metals to corals has shown an increase in antioxidant enzyme activity (Sasaki 2013). Feeding activity is not only energy supply for coral but also supply of trace metal elements that can be used for the active center of antioxidant enzyme as a cofactor. It is possible that heterotrophic feeding may improve a tolerance of coral bleaching. Therefore, the aim of this study is to investigate experimentally whether antioxidant capacity can be enhanced by heterotrophic nutrition.
Coral polyps of *Galaxea fascicularis* were incubated with and without a feeding condition for 20 days. Zooplankton was given to coral at the dawn when coral actively extends its tentacles and takes predatory behavior (AM 5: 00 - 8: 00). After 20 days, the water temperature was raised up to 31ºC within 3 days. Finally, all the coral polyps were sacrificed and separated into host tissues and zooxanthella. Superoxide dismutase (SOD) enzyme activity of the antioxidant and concentration of the metal element contained in the protein were measured, respectively.
As a result of feeding experiment, the SOD enzyme activity increased under feeding conditions of 27 ℃ and maintained the activity level after exposure to high water temperature, indicating the enhancement of the antioxidant activity of *G. fascicularis* by feeding process.

Effects of environmental stresses on coral bleaching

*Tomihiko Higuchi[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

Coral reefs are threatened by multiple environmental stresses at both the global and the local scales. Declining water quality in coastal reefs has been reported such as due to red soil runoff, agricultural fertilizers, and anti-fouling chemicals. Coral bleaching has been frequently reported and actively studied recently. The synergistic effects of multiple stressors have also been studied, with several studies reporting accelerated bleaching under conditions of high seawater temperature and low water quality. For example, enrichment of nitrate can accelerate coral bleaching under high light or high temperature conditions compared with single stress conditions. If the concentration of nitrate increases damage to coral reefs in coastal areas could significantly increase under high temperature or high light stress. Moreover, environmental bacteria, *Sulfitobacter* sp., which can be found in the seawater of coral reef, enhanced bleaching process under high temperature. These nitrate and bacteria did not affect corals severely under ambient temperature (not high temperature). To mitigate environmental stresses on coral reefs, it is important to evaluate risks due not only to global warming, but also to local stresses.

Evaluation of mangrove ecosystems as a dissolved iron supplying system to tropical coastal waters

*Yasuhiro Nakanishi[1], Ko Hinokidani[1]

1. Tokyo University of Agriculture

Iron, one of the essential micro elements for plants, is normally contained in the insoluble forms in sea water, content of the dissolved forms greatly affects propagations of marine phytoplankton which are origins of the marine food chain and absorb CO_2 in sea water.

As one of the studies on natural systems for dissolved forms of iron from land to sea, we focused on mangrove ecosystems located at boundary between the land and sea in the tropical regions. To clarify the dissolved iron supplying systems, we have conducted studies on polyphenols content in leaves of some mangrove species and elution of dissolved iron generated in reactions between the polyphenols and mangrove floor soils. Additionally, we surveyed dissolved iron elution from the floor soils mixed with fecal materials of benthos, such as *Neosarmatium smith* and *Telebralia palustris* which feed on mangrove leaves.

Among different wetland habitats, mangroves are key source of dissolved organic matter (DOM) for the estuarine and coastal waters. However, the quantity and quality of DOM from both natural and rehabilitated mangroves sustained under contrasting hydro-climatological settings of tropical and subtropical regions have not been examined comprehensively. The present study was carried out in areas of such regions in the tropics (Panay and Palawan, Philippines) and sub-tropics (Ishigaki and Iriomote, Japan). Surface water sampling was performed along the salinity gradient of mangrove dominated rivers and estuaries in 2018, aiming to investigate the distribution, mixing and fate of dissolved organic carbon (DOC), δ^{13}C-DOC and optical properties such as chromophoric dissolved organic matter (as CDOM). Preliminary results showed that mean DOC concentration was ~2-fold higher in Ishigaki and Iriomote than Panay and Palawan mangroves (225±111 μM and 103±52 μM, respectively) due to dilution effect by increased rain water flux from the typhoon event during sampling in Panay and Palawan. Strong correlation between DOC and CDOM absorption coefficient at 412 nm was only evident for the Ishigaki and Iriomote mangroves, indicative of dominance of predominantly allochthonous DOM. In the Philippines, there were no significant variations of DOM properties observed between natural (Palawan) and rehabilitated (Panay) mangroves but their mixing pattern along the salinity transect differed significantly. Property-salinity relationship revealed regions of non-linear mixing of DOC for both sites demonstrating dynamic source-sink reaction processes within the river estuaries. During the course of transport to the sea, DOC was added to the waters in Palawan in contrast to the recruited mangroves of Panay reflecting higher mangrove material input for the former site. Other optical descriptors (like spectra slope between 275 nm and 295 nm, and slope ratio in the ranges of 275-295 nm and 350-400 nm) confirmed the shift in DOM origin from terrigenous to marine sources along the salinity transects of the river estuaries. The linear decreasing trend of specific UV absorption at 254 nm ($SUVA_{254}$) further indicated the loss of DOM aromaticity downstream to the sea. Further attempt will be made to better characterize the DOM molecular compositions and fluorescence properties from the same tropical and sub-tropical mangrove sites.

Modeling coral polyp-scale bleaching phenomenon and upscaling to reef-scale

*Takashi Nakamura[1], Tomihiko Higuchi[2], Toshihiro Miyajima[2], Lawrence Patrick Cases Bernardo[1], Kazuo Nadaoka[1], Atsushi Watanabe[1,3], Hiroyuki Fujimura[4]

1. School of Environment and Society, Tokyo Institute of Technology, 2. AORI, The University of Tokyo, 3. The ocean policy research institute, The Sasakawa peace foundation, 4. University of the Ryukyus

To elucidate the mechanism responsible for coral bleaching and to project the status of coral communities in the near future, a coral bleaching model was developed based on a reef-scale three-dimensional hydrodynamic–biogeochemical model coupled with a polyp-scale coral bleaching model.

The polyp-scale bleaching model was developed by incorporating the dynamics of photoinhibition, reactive oxygen species (ROS), and zooxanthella abundance based on a previously developed coral polyp model by Nakamura et al. (2013). The polyp-scale model assumes that ROS are produced by zooxanthellae and that corals expel zooxanthellae when the concentration of ROS in their tissues exceeds tolerable levels. When temperature increases, corals release more zooxanthellae because the ROS production rate per zooxanthella cell increases with increasing temperature. This mechanism accounts for coral bleaching at high temperatures. The model assumes that ROS are produced from excess electrons transferred from photosystem II (PSII) that are not used in the downstream photosynthetic process. Photoinhibition, which is a key factor in the transfer of electrons from PSII, was included in the model, and the temperature dependence of Rubisco activity was introduced as a blocking factor in the downstream photosynthetic process. The ROS dynamics include detoxification of ROS by antioxidant substances, and the zooxanthella population dynamics include reproduction, mortality, and the rate of zooxanthellae release, which depends on the ROS damage of the coral cell. Results of simulated incubation experiments under different temperature conditions by the bleaching model reproduced the temperature dependence of the coral bleaching phenomenon. Moreover, recovery process after bleaching was also reproduced, and the ability of the model to describe the recovery process is a unique feature. The model also reproduced the phenomenon that coral bleaching is effectively reduced by light shading. A comparison between photoinhibition and its absence revealed that photoinhibition effectively reduced electron transport from PSII and consequently reduced the production of excess electrons that form ROS. Photoinhibition therefore protects the photosystem and tissues from oxidative damage by ROS. A temperature-dependent repair delay from photoinhibition also reduces ROS production and thereby prevents coral bleaching. The delay may be strategically controlled by zooxanthellae.

The polyp-scale bleaching model was coupled with reef-scale hydrodynamic-biogeochemical model based on the model framework by Nakamura et al. (2018). The model was applied to both the Shiraho coral reef based on Nakamura et al. (2018), and Sekisei Lagoon based on Bernardo et al. (2017). The results of the model simulation confirmed that the model accurately reproduced the spatiotemporal variations of bottom water temperatures on the reef. In particular, the temperatures during the daytime were significantly higher on the reef crest and in shallow nearshore areas than in the offshore seawater. The model confirmed that the spatial pattern of zooxanthella density coincided with the spatial pattern of water temperature on the reef. The model can use the internal condition of the corals to output the parameters that characterize coral population dynamics, such as coral growth rates and mortality rates. The coupled model therefore has the potential to simulate long-term spatiotemporal changes in coral

©2019. Japan Geoscience Union. All Right Reserved.

coverage. Although the model still needs some improvement, incorporation of additional modules and improvement of the model will make it a useful tool for evaluating how corals respond to multiple environmental stresses on the reef-scale.

Reversal of surface ocean acidification and recovery potential of calcification: ecology of proton concentration control

*Kazuhiko Ichikawa[1]

1. (post) Graduate School of Environmental Earth Science, Hokkaido University

Surface ocean ecology is open system under anthropogenic effect on atmosphere. Coral reefs and individual coral polyps are interacting with surrounding watersheds. They are influenced strongly and often negatively by human activities. All the coordinates pointed out by atmospheric PCO2 and surface ocean pH were irregularly scattered at PCO2 > 290ppm under anthropogenic effect on surface ocean. The calcifying organism habitats of surface ocean are controlled by the proton dynamics and chemical physics of comprehensive global-environment. The surface oceans of calcifying organism habitats showed the proper base of ~8.0 < pH < ~8.3 at ~200ppm < P_{CO2} < ~290ppm under no anthropogenic effect on P_{CO2}. The calcifying organism habitats of surface ocean are controlled by the proton dynamics and chemical physics of comprehensive global-environment.Surface ocean ecology is open system under anthropogenic effect on atmosphere. Coral reefs and individual coral polyps are interacting with surrounding watersheds. They are influenced strongly and often negatively by human activities. All the coordinates pointed out by atmospheric PCO2 and surface ocean pH were irregularly scattered at PCO2 > 290ppm under anthropogenic effect on surface ocean. The calcifying organism habitats of surface ocean are controlled by the proton dynamics and chemical physics of comprehensive global-environment. The surface oceans of calcifying organism habitats showed the proper base of ~8.0 < pH < ~8.3 at ~200ppm < P_{CO2} < ~290ppm under no anthropogenic effect on P_{CO2}. The calcifying organism habitats of surface ocean are controlled by the proton dynamics and chemical physics of comprehensive global-environment.

Revisit of massive *Porites* coral growth under the outbreak of crown-of-thorns starfish and thermal stress in Sekisei Lagoon, Japan

*Kohki Sowa[1]

1. Japan Agency for Marine-Earth Science and Technology

Recently, shallow water coral reefs have come under high pressure because of the changes in climate due to global warming and water quality due to pollution. Coral reefs, which are distributed from the tropical to the temperate areas, consist of calcareous biotas such as scleractinian corals. As the coral skeletal growth is one of the candidate proxies for representing the whole coral reef health, it can provide vital information for developing effective conservation strategies for coral reefs. However, there are only a few studies on the long-term and *in-situ* verification of the relationships among coral skeletal growth, and changes in coral ecology and climate information.

Sekisei area is located between the Yaeyama Islands and the largest coral reef lagoon in Japan (approximately 400 km^2). Continual monitoring of coral and crown-of-thorns starfish (COTS) started in 1983, and the results revealed the negative effects of the outbreak of COTS and the thermal stress-induced severe damage to coral reef ecology. Massive *Porites* coral is one of the key species in the framework of coral reefs in North-West Pacific. The coral continuously precipitates carbonate skeleton over its previous frame, which provides us an opportunity to hindcast the skeletal growth for the long term. Therefore, massive *Porites* coral skeleton in Sekisei Lagoon offers an opportunity to verify whether their skeletal growth is an indicator of coral reef health.

This study shows the revisit of long-term massive *Porites* coral growth (extension rate) estimated from the coral cores in Sekisei Lagoon from 1965 to 2000 reported by Omata *et al.* (2002). Eighty-two coral cores were collected from 12 areas, including reef fronts and patch reefs in Sekisei Lagoon. This study then selected seventy-four coral cores. The average growth anomaly decreased from the 1980s to 1990, which corresponded to decreasing coral coverage. The results imply that the growth of *Porites* coral would be an indicator of the changes in coral coverage by biodisturbance in this area. On the contrary, there were several reductions in extension anomaly, but it did not entirely correspond to the coral bleaching events in 1983 and 1998. These results imply that the growth of *Porites* coral does not represent the coral bleaching events in this area.

[A-CG44] Coastal Ecosystems 2 Coral reefs, seagrass and macroalgal beds, and mangrove

convener:Yu Umezawa(Tokyo University of Agriculture and Technology), Toshihiro Miyajima(Marine Biogeochemistry Group, Division of Ocean-Earth System Science, Atmosphere and Ocean Research Institute, The University of Tokyo), Atsushi Watanabe(The ocean policy research institute, The Sasakawa peace foundation), Tomihiko Higuchi(Atmosphere and Ocean Research Institute, The University of Tokyo), Chairperson:Yu Umezawa(Tokyo University of Agriculture and Technology), Toshihiro Miyajima(The University of Tokyo), Atsushi Watanabe(Tokyo Institute of Technology), Tomihiko Higuchi(Atmosphere and Ocean Research Institute, The University of Tokyo)

Coastal marine ecosystems are complex open system interacting with surrounding watersheds, outer ocean, and the atmosphere, providing a wealth of various ecosystem services to human life. Simultaneously, they are also influenced strongly and often negatively by human activities. This session, together with a companion session dedicated for the water cycle and land-ocean interactions, aims to provide a platform for interdisciplinary discussion covering various aspects of frontiers in coastal ecosystem sciences. This session particularly focuses shallow-water benthic communities ranging from temperate to tropical regions, such as coral reefs, seagrass and macroalgal beds, and mangroves. All these communities are characterized by intrinsically high primary production, active material cycling, and biodiversity hot spots. However, increasing human demand for coastal marine resources and industrial development concentrating on coastal regions incur the risk of rapid degradation and diminishment. Comprehensive assessment and monitoring of ecosystem functions and development of effective means for conservation and restoration are urgently needed for such communities. This session is dedicated to organizing and promoting such research and management activities by sharing state-of-the-art science and technology among ecologists, geologists, geochemists, biogeographers, etc. Field-based and modeling studies concerning the following topics are especially welcome: material cycling and ecosystem functions; community connectivity; environmental changes such as global warming, ocean acidification, and sea-level rise; ecosystem services such as carbon sequestration, nutrient regulation, and fisheries production; broad-scale comparison; long-term ecological researches.

Florida Institute of Technology

This study aims to reveal the sedimentation process of the barrier reef lagoon in the Eastern Kume Island. We drilled at two sites (the south of Ooha island and the east of Eef beach)in Kume Island and obtained 4 cores. The penetration depth of cores were from 2.4 to 4.2 m. Unlithified sediments in coral reef lagoons in Kume Island were mainly composed of bioclast such as branching coral pebbles, foraminifera, shell, algae and lime mud.
We measured radiocarbon dating of 28 samples (18 coral pebbles and 10 foraminifera) in the cores and estimated their sedimentation rates. The results showed that the sedimentation rate was slow at the south of Ooha Island, but rapid at Eef beach. The timing of rapid sediment accumulation at Ooha Island coincided with the timing of relative sea-level rise around 6.7 ka and reached its highest level at Tonaki Island (Kan et al.,1997) locating next to Kume Island. The sediment accumulation at Eef Beach was from 4.1 to 3.2 ka and it lagged behind Ooha Island. It may be because the coastal plain was developed with three beach ridges behind Eef Beach (Kawana,1990) and the coring sites were located at the front of the coastal plain formation.
This study was supported by JSPS and the U.S. National Science Foundation.

Addressing challenges in long-term coral reef monitoring: Statistical tools to address the effect of new methods

*Iwao Fujii[1,2], Jennifer Selgrath[3,2], Amanda Vincent[2]

1. The Ocean Policy Research Institute of the Sasakawa Peace Foundation, 2. Project Seahorse, Institute of the Oceans and Fisheries, The University of British Columbia, 3. Hopkins Marine Station, Stanford University

Tracking how coral responds to marine protected areas (MPA) is critical for the effective coral reef management. Ideally, one method would be employed consistently throughout monitoring, but such longitudinal sampling can pose problems of methodology. Some possible reasons include a possibility of a current method found inappropriate in the course of monitoring or development of new preferred approaches over time. What happens when procedures are suboptimal and must be changed? Our project evaluated how data from two reef survey methods, line intercept transect (LIT) and photoquadrat (PQ), estimated coral cover. We then explored a way of combining data from different sources as one time-series dataset.

Data used in this study were collected in a three-year period of 18-year monitoring, where both LIT and PQ were executed. Monitoring surveys were conducted between 1998 and 2016 in dry and wet seasons (March ~ April, and September ~ October, respectively) at eight MPAs. LIT was used in the first half of monitoring (1998 ~ 2010) and PQ in the later half (2008 ~ 2016). Both methods were used between 2008 and 2010 as a transition period. In LIT, two 20 m transects were set up as fixed transects in each MPA; however, this method was replaced with PQ due to difficulties in maintaining the transects as fixed. In PQ, ten 23 m transects were placed haphazardly at each MPA. The surveys were conducted at the depth shallower than 5 m. LIT data were also sampled from areas between 5 and 10 m, but data from the deep areas were not included in this study.

In a comparison of data from the transition period, LIT showed higher mean percent coral cover than PQ (LIT mean: 40.5 %, PQ mean: 31.1 %). However, a difference between the two methods became insignificant after increasing sample sizes of LIT data by resampling (LIT mean after resampling: 39.0 %). In resampling, two 20 m LIT transects were subsetted by 1 m and thus, 40 samples were generated. In an analysis of coral cover change over time, PQ showed significant results (5.8 % decrease / year) whereas LIT exhibited insignificant results (1.8 % increase / year). This difference can be attributed to characteristics of PQ, where larger sample sizes were collected from wider areas. Although temporal patterns of LIT did not significantly change even after resampling, a comparability between the two methods can increase by adding deep LIT data, given there is no depth effect. These results confirmed that a difference in sample sizes and areas need to be carefully considered when data form different sources are analyzed. In addition, they indicated that resampling can be effective to improve comparability of different datasets. The results from this study can help improve the quality of monitoring data and thus, contributed to more powerful coral reef conservation.

Ocean currents and herbivory drive macroalgae-to-coral community shift under climate warming

*Naoki H. Kumagai[1], Jorge García Molinos[2], Hiroya Yamano[1], Shintaro Takao[1], Masahiko Fujii[2], Yasuhiro Yamanaka[2]

1. National Institute for Environmental Studies, 2. Hokkaido University

Range shifts in foundation species induced by global warming are likely to have ecosystem-wide implications for biodiversity, ecological functioning, biogeochemical cycling and resources used by humans. Corals and macroalgae are habitat-forming species in coastal ecosystems that co-occur and compete for space, and thus global degradation of coral reefs and macroalgal beds can have ecosystem-wide implications. However, recent studies in warm temperate zones have documented community shifts from macroalgae to corals, signaling a potential mechanism for coral conservation under climate warming at the expense of macroalgae under climate warming. Although such community shifts are expanding geographically, our understanding of the driving processes is still limited. Here, we reconstruct long-term climate-driven range shifts in 30 species of macroalgae (8 kelp and 22 fucoid species), 12 species of corals and three species of herbivorous fishes (records of overgrazing) from over 60 years records (mainly 1950–2015) stretching across 3,000 km of the Japanese archipelago from tropical to subarctic zones.

The direction and rate of the observed range shifts calculated for each species and coast during the study period showed considerable variation in both distribution centroids and range edges. Expansions were scarcer than contractions in macroalgae, whereas fishes and corals experienced expansions much more frequently than contractions. Expansions were fastest in fishes, followed by corals, fucoids and kelps, whereas macroalgae contracted their range faster than corals and fishes. Based on a revised coastal version of climate velocity trajectories and a Bayesian inference, we found that prediction models combining the effects of climate and ocean currents consistently explained observed community shifts significantly better than those relying on climate alone. Corals and herbivorous fishes performed better at exploiting opportunities offered by this interaction.

The contrasting range dynamics for these taxa suggest that ocean warming is promoting macroalgal-to-coral shifts both directly by increased competition from the expansion of tropical corals into the contracting temperate macroalgae, and indirectly via deforestation by the expansion of tropical herbivorous fish. Beyond individual species' effects, our results provide novel evidence on the important role that the interaction between climate warming and external forces conditioning the dispersal of organisms, such as ocean currents, can have in shaping community-level responses, with concomitant changes to ecosystem structure and functioning. Further, we found that community shifts from macroalgae to corals might accelerate with future climate warming, highlighting the complexity of managing these evolving communities under future climate change. Nevertheless, and although expansion rates are faster than contraction rates overall, we found that not only macroalgae but even corals might be unable to keep pace with climate change. This may suggest that the apparent expansion in overall range might be a transient effect potentially masking risk of metapopulation collapse with decreasing connectivity among local populations and future range collapses. Thus, future conservation of these communities might require of a more proactive management towards climate adaptation including abundance control of herbivorous fishes, artificial assistance for thermal adaptation through selection of thermal-tolerant lineages, or relocation and translocation into cooler areas.

Estimation of temperature of seaweed bed vegetation boundary in the Western Seto Inland Sea using satellite SST

*Naoki Yoshie[1], Anri Kabe[1], Hiromori Shimabukuro[2], Goro Yoshida[2]

1. Center for Marine Environmental Studies, Ehime University, 2. Japan Fisheries Research and Education Agency

Seaweed bed is algal community in the coastal region, and important for the coastal fishing. It provides various ecosystem services to human society. However, it has been changing seriously, especially in the species and composition and habitat. Therefore, vegetation and distribution of seaweed in the near future is regarded as uneasiness by fisher men. Although several studies had reported the changes associated with the warming of sea surface temperature due to the climate change, they have some problems, such as low spatial-temporal resolution for the coastal region. Moreover, the boundary temperatures of the seaweed vegetation are not clear. In this study, I investigated the boundary temperature of seaweed vegetation in the Bungo Channel by using a satellite sea surface temperature data set (NOAA/AVHRR Pathfinder version5.3 level 3 collated global 4km sea surface temperature) which had enough resolution for the coastal region. The Bungo Channel has large gradient of sea surface temperature and various seaweed vegetation. First, I analyzed the accuracy of the satellite temperature in this region by comparing with ship board observation. The result shows that the accuracy of the satellite temperature in winter is enough high (RMSE<0.74℃), while the accuracy in summer is relative low (RMSE<1.25℃) compared with those in winter. Secondly, I analyzed the time series of the temperatures of three boundaries of seaweed vegetation both winter and summer. One is the restrictive temperature of the southern limit of temperate kelps habitat. Second is the restrictive temperature of the southern limit of the other temperate seaweeds habitat. Third is the restrictive temperature of the southern limit of the transition region between temperate and subtropical seaweeds (i.e., the northern limit of subtropical seaweeds). I found that the restrictive temperatures in winter were 14.5℃, 15.0℃, 16.0℃, and also the restrictive temperatures in summer were 26.0℃, 26.5℃, 27.0℃, respectively. The restrictive temperature of the southern limit of temperate kelps moved northward from 1989 when the winter temperature have been over 14.5℃. It was also affected by warm summer temperature changing in the 2000s. The restrictive temperature of the southern limit of the other temperate seaweed habitat was considered to be strongly affected by the warm winter temperature over 15.0℃ after the 1990s. Invasion of the subtropical seaweed seemed to be related with the disappearance of the temperate seaweed which lived in there after the 1990s.

Fate of macroalgal organic matter and its effects on in and outside of algal bed

*Shigeki Wada[1], Yuko Omori[1], Takeo Hama[1,2]

1. University of Tsukuba, 2. Dokkyo University

Macroalgal bed is known as one of the most productive biome on the earth’ s surface. Their habitat is limited to shallow coastal region, but the coastal environments are linked with the open oceans. A part of organic matter derived from macroalgae would be exported, and it contributes to ecosystem outside of algal bed. Dislodgement of algal body from their base provide drifting algae which would be partly utilized by organisms in offshore. Another fate of organic matter which is exported would be dissolved organic matter (DOM). DOM is exuded to body surface of macroalgae, and transported with mixing of water mass. Based on quantitative estimates of these fate of macroalgal products, we have tried to evaluate the ecological roles of macroalgae in large special scale.

Dislodgement of macroalgae

Dislodgement of macroalgal body would often happen due to wave action. In order to quantitatively estimate the amount of dislodgement, we labeled the body of *Ecklonia cava* which is dominant species in kelp forest around Shimoda, Izu Peninsula, Shizuoka, Japan. A part of labels was disappeared due to dislodgement, and it accounted for about 20-30% of fixed carbon by *E. cava*. In addition, we collected benthic organisms in offshore region with/without drifting algae, showing settlement of drifting algae increases species diversity of fauna on the seafloor.

Macroalgal DOM

Release rate of DOM is estimated by covering bag on blades of *E. cava*, and approximately 40% of fixed carbon is released as DOM. Horizontal distribution of DOM across algal bed to offshore showed a gradient of macroalgal DOM, being consistent with the fact that *E. cava* releases large amount of DOM in coastal region. We additionally examined the microbial and photochemical decomposition processes of the macroalgal DOM. Macroalgal DOM has a resistance for bacterial mineralization, while it was degraded by exposure to sunlight. Therefore, macroalgal DOM would be exported with mixing of water mass, and it is partly decomposed in surface layer. On the other hand, the fraction transported to deeper layer has resistance for bacterial decomposition, and contributes to carbon sequestration.

[A-CG45] Visible Remote Sensing of Hydrospheric Science and Its Application

convener:Joji Ishizaka(Institute for Space-Earth Environmental Research, Nagoya University), Mitsuhiro Toratani(School of Engineering, Tokai University), Yuji Sakuno(Graduate School of Engineering, Hiroshima University), Toru Hirawake(Faculty of Fisheries Sciences, Hokkaido University), Chairperson:Yuji Sakuno(広島大学大学院工学研究科)

Variety of visible remote sensing data for hydrospheric science is now available. For example, it is known that 20 years of long time series of 1 km resolution ocean color data from OCTS-SeaWiFS-MODIS is available. At the end of 2017, 250 m resolution SGLI (Shikisai) was launched by JAXA, and with 300 m resolution European OLSI it became possible to use high resolution and high frequency data. Furthermore, geostationary satellite data from Korean GOCI is also useful. Not only the satellite variety, diversity of products is also increasing from just phytoplankton pigment, chlorophyll-a, to primary production, phytoplankton community structure and even non-phytoplankton materials and optical properties. Those ocean color satellite data should be useful for various fields of hydrospheric science, combining with higher resolution LANDSAT as well as high frequency Himawari data. In this section, we will discuss the variety of new observations and applications of visible remote sensing in hydrospheric science.

Further information in the coastal areas from 250-m resolution multiple bands of GCOM-C “SHIKISAI”

*Hiroshi Murakami[1], Manabu Shimizu[2], Goh Onizuka[3]

1. Earth Observation Research Center, Japan Aerospace Exploration Agency, 2. Japan Fisheries Research and Education Agency, 3. National Research Institute of Fisheries and Environment of Inland Sea, Japan Fisheries Research and Education Agency

Generally, since the optical characteristics of a coastal area is more complicated than an open ocean, it is necessary to take into consideration the regionality of the in-water optical properties (absorption and scattering, and their spectral characteristics) in order to estimate biological variables like a chlorophyll-a concentration from satellite observations. On the other hand, the optical properties may be useful as new environment information if they can be derived correctly.

The Second-generation Global Imager (SGLI) boarded on Global Change Observation Mission - Climate (GCOM-C) has launched in Dec. 2017. Since SGLI has 19 observation channels with 250-m spatial resolution in the visible - infrared wavelengths, applications near the coastal areas are expected to be improved. The SGLI channels (380, 412, 443, 490, 530, 565, 672, and 867 nm) include a near-ultraviolet band (380 nm) and a pair of an absorption and a baseline in comparatively longer wavelengths (530 nm and 565 nm) which can improve estimate of high chlorophyll-a concentration since the absorption is not saturated with the high concentration in the wavelengths.

GCOM-C captured patches where water-leaving reflectance (r_w) of 565-nm, which is derived by the atmospheric radiative transfer code, Pstar-4 (Ota et al., 2010), were especially higher compared with r_w at 530 nm in the central part of the Seto Inland Sea on August 1, 5, and 13 2018. High a_ph/(a_ph+a_dg) ratio areas were captured (Fig. 1) through the in-water optical property model (Lyon and Hoge, 2006; Murakami, 2018) using average spectra of a_ph or a_dg in NOMAD dataset (Werdell, and Bailey, 2005). Generally, difference between absorption coefficients of phytoplankton at 530 nm and 565 nm (a_ph(530nm) - a_ph(565nm)) is larger than difference between absorption coefficient of CDOM + detritus at 530 nm and 565 nm (a_dg(530nm) - a_dg(565nm)). It may correspond to the redtide which has been reported around the area by Fisheries Agency (Fisheries Agency, 2018).

We will continue to make more precise water-leaving spectra to be used for useful information of coastal environment through improvement of correction aerosol absorption and so on.

Features of GCOM-C/SGLI standard atmospheric correction scheme and its processing results

*Mitsuhiro Toratani[1], Kazunori Ogata[2], Hajime Fukushima[3]

1. School of Engineering, Tokai University, 2. Japan Aerospace Exploration Agency/Earth Observation Research Center, 3. Tokai University

On December 23, 2017, the Second-generation Global Imager (SGLI) aboard the Global Climate Observation Mission-C (GCOM-C) satellite "Shikisai" was launched. SGLI has 11 observation bands in the visible and near-infrared region (380-870 nm), designed to detect slight change in water color (spectral water reflectance) with 250m spatial resolution. In order to retrieve accurate water reflectance, the correction of atmospheric absorption and scattering effects (atmospheric correction) is of vital importance. One feature of the JAXA standard atmospheric correction for SGLI is to combined use of the conventional atmospheric correction method for open ocean with the method that utilize the short wavelength infrared bands for coastal high suspended matter concentration waters. We demonstrate the processing results in comparison with MODIS results, and discuss the remaining issues.

The Second-generation Global Imager (SGLI) aboard the JAXA GCOM-C satellite was successfully launched on 23 December 2017. We conducted the first GCOM-C field campaign for the western North Pacific during 20–30 May 2018 aboard the R/V *Shinsei Maru*. During this expedition, in situ apparent optical property (AOP) measurements were made using a Compact-Optical Profiling System (C-OPS, Biospherical Instruments Inc.) in order to match up with SGLI data. Also, phytoplankton pigment samples were concomitantly collected from surface waters. A significant linear correlation (R^2 = 0.99, n = 6) was found between ultra-high performance liquid chromatography (UHPLC)-determined chlorophyll (Chl) *a* levels and those derived from C-OPS with the in-water algorithm OC3M6. However, the C-OPS values were underestimated by 32% as compared with the UHPLC data. This could be partly due to the higher pigment extraction efficiency of *N*,*N*-dimethylformamide (DMF) than other organic solvents such as methanol and acetone which are generally used in the world. During the field campaign, SGLI data were successfully matched up with in situ data at a station off Iwate Prefecture, Japan on 21 May. The SGLI-, C-OPS-, UHPLC- and Turner fluorometry-determined surface Chl *a* values were 0.546, 0.709, 0.847 and 1.21 mg m^{-3}, respectively. Other results obtained from the GCOM-C field campaign will also be shown in our presentation.

Toward a global retrieval of in-water optical properties using Deep Neural Network

*Salem Ibrahim Salem[1], Hiroto Higa[2], Kazuo Oki[1], Taikan Oki[1]

1. The University of Tokyo, 2. Yokohama National University

Reflected sunlight from water bodies, which records by ocean color sensors, contains information of optical properties of water bodies (e.g., chlorophyll-a concentrations, absorption and backscattering coefficients). During the last few decades, researches have been proposed many approaches for monitoring water bodies by retrieving their optical properties. These approaches include bands ratio, semi-analytical algorithms, and spectrum matching. However, there is no accurate continuous monitoring on a global scale, particularly over inland lakes and coastal regions. This is mainly due to the nonlinear complexity of water environment. In additions, there are a few studies that used the synthetic simulated reflectance to train artificial neural network (ANN) models to be applied on a global scale. However, the recent revaluation of these ANN models over the Japanese and European lakes revealed their limitation to provide accurate monitoring of these water bodies. These results could be attributed to two main reasons; (1) inappropriate ANN architecture with one hidden layer which could not be suitable to represent the complex situation of water bodies. (2) the limitation of the synthetic simulated reflectance that used to train these models. The deep neural network (DNN) with multiple hidden layers could provide a promising approach to overcome these complexities. Up to 2006, there is no way to accurately train a DNN due to a Vanishing gradient problem. the recent advances of DNN enable researchers to efficiently use the DNN models with low cost. During the current research, the performance of a DNN model with three-, five- and seven-hidden layers under different architecture conditions will be presented. These conditions include different activation functions (i.e., sigmoid, Relu and TanH), different optimization technique (i.e, Adam optimizer and stochastic gradient descent) and with/without applying dropout technique. The DNN model was designed to receive water leaving reflectance of several ocean color satellites (e.g., Global Change Observation Mission –Climate (GCOM-C)). Nine water quality parameters are generating from the DNN model. Two independent simulated datasets comprising 100,000 water leaving reflectance spectra each were generated for training and testing the DNN models. The two simulated datasets cover wide ranges of Chla (0.01–250 $mg \cdot m^{-3}$), NAP (0.01–250 $g \cdot m^{-3}$), and CDOM (0.001–10 m^{-1}) concentrations, representing the open ocean, coastal areas, and inland lakes. The proposed technique was also validated using in-situ datasets (e.g., NOMAD dataset, and many Japanese lakes and coastal bodies) that represent various trophic statuses. The results reveal the ability of proposed technique to provide accurate retrieval of in-water optical properties as will be discussed.

Development of atmosphere and in-water combining algorithm using GCOM-C/SGLI in Tokyo Bay

*Taiga Nakayama[1], HIROTO HIGA[1], Kazuki Ogata[2]

1. Yokohama National University, 2. Japan Aerospace eXploration Agency

GCOM-C / SGLI launched at the end of December 2017, has an excellent spatiotemporal resolution such as one time observation every two or three days at a resolution of 250 m on coastal area, is expected to monitor coastal areas where water environment change is siginificantly large and water area is comparatively small. However, high accuracy of water estimation is exceedingly difficult because coastal light environment in water changes complexly. In the traditional ocean color atmospheric correction algorithm, it is assumed that the water leaving radiance in the near infrared region is 0 and radiance due to air in the visible region is calcuration after estimating the radiance of atmospheric scattering. However, as in the coastal region, in the case of organic matter and inorganic matter increasing significantly, the water leaving radiance in the near infrared region increases and the assumption does not hold. Because of this, an aerosol reflectance is over estimated and an error occurs in the estimation of the water leaving reflectance in the visible region band. To improve this, there is a method of estimating aerosol reflectance while estimating water leaving reflectance in the near infrared region by the iterative method, and if the in-water model is suitable for the water area, highly accurate water leaving reflectance estimation Is possible. SGLI uses this iterative method in a low turbidity water such as the case1 water, and estimates atmospheric reflectance from a short-wavelength infrared channel without using an in-water model in a coastal area or other high turbidity water area, However, its accuracy is not as good as the high turbidity area.

In this study, we tried to develop a combination algorithm of atmospheric correction model, and in-water model which is adequate for coastal areas as a target of Tokyo Bay where organic matter is dominant. This is a modification of the in-water model used at the atmospheric correction stage to the Bio-Optical model created based on the measured SIOPs(Specific inherent optical properties) in Tokyo Bay, an selection aerosol model and estimation of reflectance at each wavelength are conducted by iterative calculation based on three parameters of Chl-a(Chlorophyll-a), CDOM(Color dissolvedorganic matter) and NAP(Non-algal particles). As a result, the suggested model became possible to estimate Chl-a and Rrs with high accuracy compared to normal SGLI atmospheric correction.

Analysis of the uncertainty of backscattering coefficient by radiative transfer simulation in coastal areas and lakes

*Hidehito Taki[1], Hiroto Higa[1], Yoshiyuki Nakamura[1], Takayuki Suzuki[1]

1. Graduate School of Urban Innovation, Yokohama National University

In coastal areas and lakes, the ocean color change is greatly complicated because of various substances which are derived from terrestrial and internal production coexist in the water. Therefore, in radiative transfer simulation in the water, the inherent optical properties per substance concentration, which is the basic parameter change greatly in spatiotemporal, resulting in errors in calculation accuracy. In particular, it has been pointed out that the uncertainty of the backscattering coefficient is one of the major error factors in radiative transfer simulation. (Lain et al., (2017)). In this study, we have conducted field observations to measure water quality, apparent optical properties and inherent optical properties which are basic parameters in radiative transfer simulation in coastal areas and lakes having different optical characteristics such as Tokyo Bay, Kasumigaura Lake, Thailand Bay, and Seto Inland Sea respectively. Furthermore, we tried to conduct radiative transfer simulation by using Hydrolight 4.1 (Mobley et al., (2000)) based on in-situ specific light absorption coefficient and specific backscattering coefficient in each water areas. As a result, it was found that the simulated remote sensing reflectance: R_{rs} (/str) is remarkably variable due to the fluctuation of backscattering probability expressing the particle scattering form in the water.
It was suggested that this result is because of not considering properly the variations of scattering form related to particle characteristics.

[A-CG45] Visible Remote Sensing of Hydrospheric Science and Its Application

convener:Joji Ishizaka(Institute for Space-Earth Environmental Research, Nagoya University), Mitsuhiro Toratani(School of Engineering, Tokai University), Yuji Sakuno(Graduate School of Engineering, Hiroshima University), Toru Hirawake(Faculty of Fisheries Sciences, Hokkaido University), Chairperson:Joji Ishizaka(名古屋大学宇宙地球環境研究所)

Variety of visible remote sensing data for hydrospheric science is now available. For example, it is known that 20 years of long time series of 1 km resolution ocean color data from OCTS-SeaWiFS-MODIS is available. At the end of 2017, 250 m resolution SGLI (Shikisai) was launched by JAXA, and with 300 m resolution European OLSI it became possible to use high resolution and high frequency data. Furthermore, geostationary satellite data from Korean GOCI is also useful. Not only the satellite variety, diversity of products is also increasing from just phytoplankton pigment, chlorophyll-a, to primary production, phytoplankton community structure and even non-phytoplankton materials and optical properties. Those ocean color satellite data should be useful for various fields of hydrospheric science, combining with higher resolution LANDSAT as well as high frequency Himawari data. In this section, we will discuss the variety of new observations and applications of visible remote sensing in hydrospheric science.

Discussion

Development of a blue tide estimation method based on the optical properties of sulfur colloid particles by geostationary ocean color satellite

*HIROTO HIGA[1], WATARU NAKAMURA[1]

1. Yokohama National University

Blue tides occurs every year from the summer to the fall in Tokyo Bay or Mikawa Bay, Japan. The blue tides occurs by upwelling sulfur colloid particles, which is generated by reacting oxygen with hydrogen sulfide in the hypoxic water at the bottom. The sulfur colloid particles scatter the light strongly at the surface and the ocean color changes to blue-white, therefore, it is called blue tide. When the magnitude of the blue tide is huge, mass mortality of shell and fish occurs and sometimes it is connected to damage of fisheries. Hence, the blue tides are recognized as an important water environment problem. Because the blue tide is short time scale phenomenon, it is difficult to monitor the spatial behavior adequately. Hence, the blue tide monitoring is expected by using geostationary ocean color satellite which spatio-temporal resolution is superior.
In the previous study, simple method of sulfur estimation method based on simple band of Rrs(Remote sensing reflectance) at 660 nm have been suggested(Higa et al., (2017)). However, it is impossible to separate the backscattering of sulfur and other detritus, respectively. In this study, we developed a bio-optical model, which is specialized in blue tide, based on the measured IOPs(Inherent optical properties) of Sulfur colloid particles. Furthermore, a sulfur estimation method was developed to separate the backscattering of sulfur and other detritus based on the QAA(Quasi-Analytical Algorithm).

Characteristics of water quality and red tide distribution in the Seto Inland Sea immediately after heavy rain in the western Japan by GCOM-C SGLI data

*Yuji Sakuno[1], Hiroto Higa[2], Hiroshi Kobayashi[3], Mitsuhiro Toratani[4]

1. Hiroshima University, 2. Yokohama National University, 3. Yamanashi University, 4. Tokai University

The heavy rain in western Japan disaster occurred in early July 2018. After this heavy rain, a large amount of sediment discharge from the river and damage of red tide occurred in the Seto Inland Sea. Meanwhile, Chla (Chlorophyll-a), TSM (Total Suspended Matter), CDOM (Color Dissolved Organic Matter), SST (Sea Surface Temperature), Rrs (Remote Sensing Reflectance) of GCOM-C SGLI launched at the end of December 2017 Standard product data with 250 m spatial resolution will be provided once every 2-3 days from JAXA (The Japan Aerospace Exploration Agency). In this research, the results of accuracy verification of these product data (Level 2) officially released in December 2018 will be reported. Secondly, a method for estimating the distribution of harmful red tides (mainly *Chattonella* and *Karenia*) occurred in the Seto Inland Sea from Rrs products will be examined. The study period is mainly from June to August 2018. As a result, the SGLI product satisfies the target accuracy even in this water area, and the characteristics of the water quality and red tide distributions in the Seto Inland Sea about one month after the heavy rainfall became clear.

Application of Satellite Remote Sensing to Monitor Eutrophication Status of Inland Lakes

*Wei Yang[1], Bunkei Matsushita[2]

1. Chiba University, 2. University of Tsukuba

Eutrophication of inland lakes is becoming a severe environmental issue all over the world. Routine monitoring of eutrophication status of inland lakes is essential for guaranteeing sustainable development of freshwater resources. The coupled spatial and temporal heterogeneity of water bodies often result in inadequate monitoring and characterization of water quality by using conventional sampling methods. On contrast, satellite remote sensing is quite flexible for monitoring the eutrophication status of inland lakes in terms of being able to cover large spatial areas at very frequent intervals. However, remote sensing of inland lakes has been far less successful than that of open oceans, due mainly to the complex interactions among optically active substances in the lake waters, as well as the difficulties in atmospheric correction. In this presentation, we will introduce our state-of-the-art remote sensing algorithms for estimating Chlorophyll-a concentrations (Chl-*a*) and Secchi disk depth (SDD), which have been widely used to evaluate the eutrophication status of lakes. These algorithms have been extensively validated using extensive in situ collected data sets, yielding satisfactory performances in overcoming the difficulties in remote sensing of turbid inland lakes. Application studies on satellite-based operational monitoring of Chl-*a* and SDD in several lakes of Japan will also be presented. Assessment results demonstrated that the proposed algorithms have the potential of being applied to operationally monitor water quality of inland lakes.

Exploring the Potentials of Google Earth Engine for Global Assessment of Coastal Eutrophication Based on Chlorophyll-*a* concentration

*Eligio de Raus Maure[1], Genki Terauchi[1], Joji Ishizaka[2]

1. Northwest Pacific Region Environmental Cooperation Center, 2. Institute for Space-Earth Environmental Research, Nagoya University

Eutrophication is either emerging or growing environmental issue in many parts of the global marine systems in the ocean. This deterioration in water quality in the coastal regions may at times result in the appearance of harmful algal blooms or hypoxic conditions that affects large spatial and temporal scales with serious damages to the environment and economy, and the marine ecosystem itself. To assess the coastal eutrophication the Special Monitoring and Coastal Environment Assessment Regional Activity Centre (of the Action Plan for the Protection, Management and Development of the Marine and Coastal Environment of the Northwest Pacific Region of the United Nations Environmental Programme) developed a screening procedure to detect symptoms of eutrophication based on satellite observations of chlorophyll-a concentration. The methodology was originally developed for the Toyama Bay, Japan and later applied to the whole Northwest Pacific region. In this presentation, we introduced the method and its applicability to the global ocean. Furthermore, we also introduce the potentials of the Google Earth Engine (GEE)—a cloud-based tool with planetary-scale analysis capability—for future coastal eutrophication assessment based on recent higher resolution ocean colour sensors such as SGLI on GCOM-C with 250 m or Sentinel-3 with 300 m spatial resolutions. Once the GEE is proven useful, it will be an important tool in providing rapid assessment of the status of marine systems in many regions where the information on the status and extent of coastal eutrophication is very limited.

Seasonal and interannual variability of seagrass distribution detected by Landsat TM, ETM+ and OLI images in western Nanao Bay

*Genki Terauchi[1]

1. Northwest Pacific Region Environmental Cooperation Center

Western Nanao Bay is known for being a home to massive seagrass beds. A massive die-off of seagrass was reported in 2012 in this area, possibly due to high water temperature in summer. Archive images of Landsat Thematic Mapper (TM), Enhanced Thematic Mapper Plus (ETM+) and Operational Land Imager (OLI) were obtained from USGS to detect seasonal and interannual variability of seagrass distribution. Ground truthing survey with an underwater video camera were carried out from a small boat to study sea floor substrates on June 1, 2 and 16 in 2016. Still photos were also taken from a Stand Up Paddleboard on June 1, 2016 to study seagrass species in a very shallow (< 1m) water area. Information of sea floor substrates obtained from the field survey was then used to classify sea floor types. Six classes of training data were then prepared for classifying the Landsat OLI image observed on June 1, 2016 namely: (1) dense seagrass, (2) dense seagrass with *Sargassum*, (3) *Sargassum*, (4) sandy bottom, (5) mud and (6) exposed sand. Supervised classification of the bottom substrates was carried out by the maximum likelihood method using bands of Red, Green and Blue or ratios of Green/Blue, Green/Red, Blue/Red and Green/Coastal bands corrected with the Depth Invariant Index (DII) method. Accuracy assessment showed better results in the DII corrected band ratios: overall accuracy of 0.73 and tau coefficient of 0.66.

To study seasonal and interannual variability for seagrass, past Landsat archive images were analyzed to detect seagrass distribution. Since past field data of seagrass distribution were not sufficient, the K means unsupervised classification technique with the six classes was applied for mapping the seagrass distribution from past Landsat archive images. The classification result of the Landsat OLI image on June 1, 2015 was used as a reference to determine seagrass distributions as it had a good compliance with the ground truth data. Since two out of the six classes obtained from the unsupervised classification corresponded to a distribution pattern of (1) the dense seagrass and (2) the dense seagrass with *Sargassum* classes from the June 1, 2015, these two classes were merged into one class to represent seagrass distribution in Western Nanao Bay. A comparison of seasonal patterns of seagrass distribution estimated by the unsupervised classification of the Landsat archive data from November 22, 1991 to June 1, 1992 and from November 21, 2014 to June 1, 2015 showed consistent similar seasonal pattern; indicating seagrass recovery between late fall to early summer, which corresponds to seagrass seed germination periods. The Landsat archive data during the seagrass seed germination periods were also obtained to study interannual variability of seagrass distribution. The obtained results showed that there are fewer seagrass years (1994, 1996 and 1999) and more seagrass years (2000, 2004, 2007 and 2008) during the seagrass seed germination periods, indicating the survival rate of seagrass varied depending on the year.

About GCOM-C/SGLI Ocean Standard Products

*Kazunori Ogata[1]

1. Japan Aerospace Exploration Agency

The Global Change Observation Mission - Climate "SHIKISAI" (GCOM-C) was launched on Dec. 23, 2017 by JAXA. The Second Generation Global Imager (SGLI) onboard GCOM-C is optical sensor which has 19 channels from near ultraviolet to thermal infrared wavelengths (380 nm to 12um).
SGLI Ocean standard products consist of 7 parameters and 2 processing levels. The parameters are composed of Normalized water Leaving Radiance (NWLR) at 380, 412, 443, 490, 530, 565 and 673.5 [W/m^2/sr/um], Aerosol optical Thickness (TAUA) at 673.5 and 868.5 [-], Photosynthetically Available Radiation (PAR) [Ein/m^2/day], Chlorophyll-*a* concentration (CHLA) [mg/m^3], Total Suspended Matter concentration (TSM) [g/m^3], Absorption coefficient of Colored dissolved Organic Matter (CDOM) at 412 [m^-1] and Sea Surface Temperature (SST) [degree C]. The processing levels consists of Level-2 and Level-3 from distinctions of time- and spatial resolutions.
After about one year of launch, all ocean standard products had achieved the thresholds of release accuracies, therefore, those products were started to provide on Dec. 20, 2018 from the JAXA G-Portal (https://gportal.jaxa.jp/gpr/).

Verification of GCOM-C/SGLI product in coastal area

*Joji Ishizaka[1]

1. Institute for Space-Earth Environmental Research, Nagoya University

GCOM-C/SGLI was launched on Decmber 2017, and the data distribution was started from December 2018. We obtained verification data of remote sensing reflectance, chlorophyll-a and others in the East China Sea, Ise Bay, Ariake Bay, etc. We will present the results of the verification of the products in the coastal area.

Marine phytoplankton plays an essential role in marine ecosystems as a primary producer. Generally, a trophic transfer food chain via large-sized phytoplankton can be found in the oceans at higher latitudes and/or in coastal waters. On the other hand, a trophic transfer via middle- and/or small-sized phytoplankton can be found in the oceans at lower latitudes. As a first approximation, a cell size of phytoplankton is associated with taxonomic groups (e.g. diatoms are often large in size whereas cyanobacteria are usually small). In addition, phytoplankton in a taxonomic group often possesses a characteristic photosynthetic and/or photoprotective pigment(s) (e.g. diatoms contain fucoxanthin while cyanobacteria zeaxanthin). As a result, a taxonomic group are linked as a first approximation to a specific size class and a pigment(s), so that the groups may be inferred from the size and pigments. Both of the cell size distribution and the pigments affects optical, or spectral signature of phytoplankton. Hence, once the spectral signature of phytoplankton is obtained, their taxonomic detection/classification may be possible. In the present technology, a radiometric observation, either in situ or from space, enables the detection of the signature. Currently, it is an open question what, and how many, spectral bands are required for the accurate detection/classification of the phytoplankton, especially when phytoplankton taxonomic composition is complex and when other optically-active components interplay in the radiometric measurements. In this presentation, a preliminary result towards answering the question is presented using in situ hyperspectral radiometric measurements obtained in the Atlantic Ocean. Our result shows that radiometric measurements at many spectral bands are correlated with each other. While the correlation strength differs among spectral bands in question, radiometric measurements at these bands are correlated to the concentration of chlorophyll-a, a pigment commonly found in phytoplankton groups. The correlation with chlorophyll-a was even found at spectral bands where chlorophyll-a little absorbs the light. This may be due to another correlation between the chlorophyll-a concentration and other phytoplankton pigments, the latter of which absorb the light at the spectral band where chlorophyll-a does not. The pigment co-variation implies that a correlation between the radiometric measurements and any pigment concentration does not guarantee the optical detection of the pigment signature, and a more careful analysis is required when the radiometric measurements are analyzed.

Improvement of absorption-based primary production model for SGLI/GCOM-C

*Toru Hirawake[1], Takuhei Shiozaki[2], Hisatomo Waga[1], Koji Suzuki[1]

1. Hokkaido University, 2. JAMSTEC

Net primary production (NPP) of phytoplankton is important to understand the global carbon cycle and marine ecosystem. While the majority of satellite NPP models use chlorophyll *a*(chl-*a*) concentration as a proxy of phytoplankton biomass, several NPP models use absorption coefficient of phytoplankton. An NPP models for Japanese new ocean color sensor, Second-generation GLobal Imager (SGLI), was developed based on the phytoplankton absorption to reduce estimation errors of chl-*a*due to pigment packaging and turbid water. However, sufficient validation in the open ocean has not been carried out. In this study, we obtained NPP data in the Pacific Ocean and compared with satellite-derived NPP applying the SGLI NPP model to MODIS data. The model overestimated the lower values of NPP less than 1000 mg m^2d^{-1}. Newly developed model considering response to daily averaged photosynthetically available radiation (PAR) showed better performance than previous one. However, bias and errors were still detected for a part of data. We will also discuss possibility of temperature dependency on this NPP model.

Attempt to distinguish river water influencing concentration of chlorophyll *a* off Miho Peninsula

*Akihiko Tanaka[1], Kyoko Takashima[2], Gen Fukuda[2], Takaaki Katsumata[1], Hiroyuki Tan[1], Masato Niki[2], Daisuke Takahashi[2]

1. Liberal Arts Education Center, Shimizu Campus, Tokai University, 2. School of Marine Science and Technology, Tokai University

In Suruga Bay, ocean color remote sensing shows that relatively higher chlorophyll a concentration in the western area than in the eastern part. One reason is that many large rivers flowing into Suruga Bay exist more in the west than the eastern side of Suruga Bay. The Miho Peninsula is located at the western part of Suruga Bay, that there are mouths of the Fuji River and the Okitsu River in the north, and the mouth of the Abe River in the south. High chlorophyll a concentration is also observed off Miho Peninsula. From the chlorophyll a concentration image by ocean color remote sensing, which river that influence high concentration of chlorophyll a off Miho Peninsula can be empirically discriminated, whereas it is sometimes difficult to distinguish with chlorophyll a concentration image. In Suruga Bay, the Ferry Fuji (Suruga Bay Ferry) cruises 4 times a day to Shimizu Port and Toi Port. It has been suggested that the current in the normal direction of the course can be estimated from the AIS (Automatic Identification System) information of the Ferry FUJI. Since the route of the Suruga Bay ferry is approximately in the east-west direction, it is possible to obtain the flow in the north-south direction. In this study, we attempt to distinguish river water affecting chlorophyll a concentration off Miho Peninsula by adding information of current estimated from AIS information to Chlorophyll a concentration image in the Suruga Bay.

Estimation of chlorophyll-a from RGB digital camera data collected in Ise-Mikawa Bay

*Akiko N. Mizuno[1], Joji Ishizaka[1]

1. Institute for Space-Earth Environmental Research, Nagoya University

Development for survey methods for phototrophs and/or environmental condition using RGB digital camera data has been increasingly studied for two decades. In examples for the ocean are studies of estimation of water quality using smart phone’ s camera (Goddijin et al. 2009, Leeuw and Boss 2018), detection of sea grass from aerial photo images and estimation of chlorophyll-a (Goddijn and White 2006). The portability and convenience of the digital camera are the reasons of interest for the RGB data. It is possible to be used as supplementary observation of satellite sensing because digital camera can use regardless of the cloud. Also, citizen participation surveys may be possible because anyone can take photographs using his or her digital camera.

Thus, we attempted to develop estimation method for chlorophyll-a from RGB digital camera data for Ise-Mikawa Bay, Japan. For Ise-Mikawa Bay, method of estimation of chlorophyll a concentration form SeaWiFS and MODIS data was developed by Hayashi et al (2015), but estimation method with digital camera data was not developed yet.

We used chlorophyll-a concentration, RGB data from photo images of surface water, sky and a photographer’ s 18% reflectance gray card during monthly survey cruises in Ise-Mikawa Bay. Spectral remote sensing reflectance data from RAMSES/TriOS was also obtained. We calculated RGB from spectral remote sensing reflectance data and compared RGB from digital camera. Digital camera RGB data was correlated with RGB from spectral data and in-situ chlorophyll-a concentration. In the future, we will reduce effect of reflection of sunlight from estimation of chlorophyll-a concentration using photographs of sky and gray card.

Science and Technology co., Ltd., 3-9-2, Koubai-cho, Showa, Nagoya, Aichi 466-0031, Japan.

Red tide occurs more frequently in the Ariake Bay since 1990s, and it has greatly damaged the local fisheries, especially the nori farms. Increase of water transparency and reduction of tidal currents were also reported recently, and they may be related to the increase of the frequency of red tides. It is also reported that another cause of the red tide is the river discharge. Satellite remote sensing is suggested to be used to monitor the red tide. In this study, the newly developed MODIS-derived chlorophyll-a (Chl-a) and total suspended matter (TSM) was used to investigate the relationship between Chl-a and TSM and the seasonal variations of influences of spring-neap tides and river discharge. We observed that 1) high Chl-a (>5 mg m^{-3}) and high TSM (>5 g m^{-3}) were generally distributed in the areas off Saga, Kumamoto and Yatsushiro, and Isahaya Bay where the main river systems discharge the fresh water; 2) the magnitude of Chl-a was highest in summer, and decreased gradually from autumn to spring, which corresponded to the amount of river discharge which concentrates in summer and early autumn (June-September); 3) in the spring-neap tidal cycle, TSM was much higher in neap to spring (NS) and spring (S) tide than in spring to neap (SN) and neap (N) tide, which was consistent with the tidal suspension. On the other hand, Chl-a was often increased after high river discharge peak and the variation of Chl-a was small when the river discharge peak was small, indicating that the variation of Chl-a was mainly influenced by the river discharge. The variation of TSM in the spring-neap tidal cycle was mainly regulated by the tidal suspension, whereas the variation of Chl-a was more controlled by the river discharge than the tidal resuspension.

Discrimination of green *Noctiluca scintillans* in the upper Gulf of Thailand using remote sensing techniques

*Jutarak Luang-on[1], Joji Ishizaka[2], Anukul Buranapratheprat[3], Jitraporn Phaksopa[4]

1. Graduate School of Environmental Studies, Nagoya University, 2. Institute for Space-Earth Environmental Research, Nagoya University, Japan, 3. Department of Aquatic Science, Faculty of Science, Burapha University, Thailand, 4. Department of Marine Science, Faculty of Fisheries, Kasetsart University, Thailand

Green *Noctiluca scintillans*, the peculiar single cellular heterotrophic organism containing green algae called *Pedinomonas noctilucae*, frequently causes harmful algal bloom (HAB) in the upper Gulf of Thailand (uGoT). The high density of green *Noctiluca* discolors the water to deep milky green, and it has the potential to generate low dissolved oxygen (hypoxia) in the water column resulting in massive fish mortality. The co-occurrence of green Noctiluca and other phytoplankton species (e.g., *Ceratium furca* and diatoms) was often reported. Heretofore, the behavior of red tides has not been clarified. In this study, we, therefore, focus on investigating the dominant spectral characteristics of each HAB species and developing an algorithm to discriminate green *Noctiluca* from the other harmful species. The ship observations (2017 –2018) were conducted to obtain the apparent and inherent optical properties as well as the pigment information of green *Noctiluca* blooms. Fortunately, the super green *Noctiluca* blooms (>1,500,000 cell L^{-1}) occurred near the west coast of the uGoT in July 2017. The remote sensing reflectance spectra measured by using the RAMSES hyperspectral radiometer (320 nm –950 nm) revealed the crucial features of green *Noctiluca* in near-infrared wavelengths. The different characteristics of green *Noctiluca* and other HAB species were also found in visible wavelengths. The investigated features were used in the discrimination method to detect the green *Noctiluca* bloom using satellite observation in the near future.

Monthly variability of Chlorophyll-a distribution in the Gulf of Thailand

*Dudsadee Leenawarat[1], Anukul Buranapratheprat[2], Joji Ishizaka[3]

1. Graduate School of Environmental Studies, Nagoya University, Japan, 2. Department of Aquatic Science, Faculty of Science, Burapha University, Thailand, 3. Institute for Space-Earth Environmental Research, Nagoya University, Japan

The Gulf of Thailand (GoT) is semi-enclosed sea located in the western part of the South China Sea. This area is important to fisheries production in this region. The satellite data can reveal the primary production through chlorophyll-a (Chl-a) which is basic for the food chain. The objectives of this study are to investigate the variation and spatial distribution patterns of Chl-a in the GoT by using long-term satellite data from SeaWiFS (1997-2010), MERIS (2002-2012), MODIS AQUA (2002-2018), and VIIRS (2012-2018) level 3 compared with oceanographic conditions from previous study and circulation model name Princeton Ocean Model (POM). Tide and climatological data of wind, salinity, temperature and river discharge are forcing in the model. The results from averaged monthly Chl-a concentration in the central GoT illustrate low Chl-a concentration occurred in transition periods (April-May, and October) by lowest in May when the water column was stratified. High Chl-a concentration occurred during the northeast monsoon (November to February) with the highest in December when the water column was well mixed, and a small peak was found during June to August. Hight Chl-a was found along the coast, especially near the northern coast in the southwest monsoon (June to October). During the northeast monsoon Chl-a near cape CaMau spread offshore, due to strong surface currents flew into GoT from the southern part of cape CaMau to the middle of GoT mouth.

AERONET-Ocean Color time series in Ariake Bay.

*yifei wu[1], Joji Ishizaka[2], Mengmeng Yang[1], Naoki Fujii[3], Masahiro Hori[4]

1. Graduate School of Environmental Studies, Nagoya University, 2. Institute for Space-Earth Environmental Research, Nagoya University, 3. Graduate School of Agriculture, Saga University, 4. EORC, JAXA

The AERONET (**AE**rosol **RO**botic **NET**work) project is a federation of ground-based remote sensing aerosol networks established by **NASA** and **PHOTONS** and is greatly expanded by networks from national agencies, institutes, universities, individual scientists. AERONET –Ocean Color (AERONET-OC) provides the additional capability of measuring the radiance emerging from the sea. In April 2018, a new station of AERONET-OC has been set by JAXA for GCOM-C validation in Ariake Bay located in Kyusyu, Japan where the seaweed (Nori) culture very famous. Aerosol Optical Depth (AOD) and remote sensing reflectance (Rrs) is considered as the most important products of AERONET-OC since the estimation of chlorophyll-a concentration by ocean color satellite is usually not so accurate in coastal areas because of the inaccurate satellite remote sensing reflectance (Rrs) influenced by aerosol. This study is to make a brief description of the time series of the AERONET-OC data from April 2018 to April 2019. Local Chl-a and TSM estimated by using radiances measured by the AERONET-OC is going to use to explain the phytoplankton bloom connect with factors such as precipitation and river discharge in Ariake Bay.

[J] Poster | A (Atmospheric and Hydrospheric Sciences)：A-CG Complex & General

Tue. May 28, 2019 5:15 PM - 6:30 PM JST | Tue. May 28, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_19

[A-CG45] Visible Remote Sensing of Hydrospheric Science and Its Application

convener:Joji Ishizaka(Institute for Space-Earth Environmental Research, Nagoya University), Mitsuhiro Toratani(School of Engineering, Tokai University), Yuji Sakuno(Graduate School of Engineering, Hiroshima University), Toru Hirawake(Faculty of Fisheries Sciences, Hokkaido University)

Variety of visible remote sensing data for hydrospheric science is now available. For example, it is known that 20 years of long time series of 1 km resolution ocean color data from OCTS-SeaWiFS-MODIS is available. At the end of 2017, 250 m resolution SGLI (Shikisai) was launched by JAXA, and with 300 m resolution European OLSI it became possible to use high resolution and high frequency data. Furthermore, geostationary satellite data from Korean GOCI is also useful. Not only the satellite variety, diversity of products is also increasing from just phytoplankton pigment, chlorophyll-a, to primary production, phytoplankton community structure and even non-phytoplankton materials and optical properties. Those ocean color satellite data should be useful for various fields of hydrospheric science, combining with higher resolution LANDSAT as well as high frequency Himawari data. In this section, we will discuss the variety of new observations and applications of visible remote sensing in hydrospheric science.

About GCOM-C/SGLI Ocean Standard Products

*Kazunori Ogata[1]

1. Japan Aerospace Exploration Agency

The Global Change Observation Mission - Climate "SHIKISAI" (GCOM-C) was launched on Dec. 23, 2017 by JAXA. The Second Generation Global Imager (SGLI) onboard GCOM-C is optical sensor which has 19 channels from near ultraviolet to thermal infrared wavelengths (380 nm to 12um).
SGLI Ocean standard products consist of 7 parameters and 2 processing levels. The parameters are composed of Normalized water Leaving Radiance (NWLR) at 380, 412, 443, 490, 530, 565 and 673.5 [W/m^2/sr/um], Aerosol optical Thickness (TAUA) at 673.5 and 868.5 [-], Photosynthetically Available Radiation (PAR) [Ein/m^2/day], Chlorophyll-*a* concentration (CHLA) [mg/m^3], Total Suspended Matter concentration (TSM) [g/m^3], Absorption coefficient of Colored dissolved Organic Matter (CDOM) at 412 [m^-1] and Sea Surface Temperature (SST) [degree C]. The processing levels consists of Level-2 and Level-3 from distinctions of time- and spatial resolutions.
After about one year of launch, all ocean standard products had achieved the thresholds of release accuracies, therefore, those products were started to provide on Dec. 20, 2018 from the JAXA G-Portal (https://gportal.jaxa.jp/gpr/).

Development for survey methods for phototrophs and/or environmental condition using RGB digital camera data has been increasingly studied for two decades. In examples for the ocean are studies of estimation of water quality using smart phone’ s camera (Goddijin et al. 2009, Leeuw and Boss 2018), detection of sea grass from aerial photo images and estimation of chlorophyll-a (Goddijn and White 2006). The portability and convenience of the digital camera are the reasons of interest for the RGB data. It is possible to be used as supplementary observation of satellite sensing because digital camera can use regardless of the cloud. Also, citizen participation surveys may be possible because anyone can take photographs using his or her digital camera.

Thus, we attempted to develop estimation method for chlorophyll-a from RGB digital camera data for Ise-Mikawa Bay, Japan. For Ise-Mikawa Bay, method of estimation of chlorophyll a concentration form SeaWiFS and MODIS data was developed by Hayashi et al (2015), but estimation method with digital camera data was not developed yet.

We used chlorophyll-a concentration, RGB data from photo images of surface water, sky and a photographer’ s 18% reflectance gray card during monthly survey cruises in Ise-Mikawa Bay. Spectral remote sensing reflectance data from RAMSES/TriOS was also obtained. We calculated RGB from spectral remote sensing reflectance data and compared RGB from digital camera. Digital camera RGB data was correlated with RGB from spectral data and in-situ chlorophyll-a concentration. In the future, we will reduce effect of reflection of sunlight from estimation of chlorophyll-a concentration using photographs of sky and gray card.

Red tide occurs more frequently in the Ariake Bay since 1990s, and it has greatly damaged the local fisheries, especially the nori farms. Increase of water transparency and reduction of tidal currents were also reported recently, and they may be related to the increase of the frequency of red tides. It is also reported that another cause of the red tide is the river discharge. Satellite remote sensing is suggested to be used to monitor the red tide. In this study, the newly developed MODIS-derived chlorophyll-a (Chl-a) and total suspended matter (TSM) was used to investigate the relationship between Chl-a and TSM and the seasonal variations of influences of spring-neap tides and river discharge. We observed that 1) high Chl-a (>5 mg m^{-3}) and high TSM (>5 g m^{-3}) were generally distributed in the areas off Saga, Kumamoto and Yatsushiro, and Isahaya Bay where the main river systems discharge the fresh water; 2) the magnitude of Chl-a was highest in summer, and decreased gradually from autumn to spring, which corresponded to the amount of river discharge which concentrates in summer and early autumn (June-September); 3) in the spring-neap tidal cycle, TSM was much higher in neap to spring (NS) and spring (S) tide than in spring to neap (SN) and neap (N) tide, which was consistent with the tidal suspension. On the other hand, Chl-a was often increased after high river discharge peak and the variation of Chl-a was small when the river discharge peak was small, indicating that the variation of Chl-a was mainly influenced by the river discharge. The variation of TSM in the spring-neap tidal cycle was mainly regulated by the tidal suspension, whereas the variation of Chl-a was more controlled by the river discharge than the tidal resuspension.

Discrimination of green *Noctiluca scintillans* in the upper Gulf of Thailand using remote sensing techniques

*Jutarak Luang-on[1], Joji Ishizaka[2], Anukul Buranapratheprat[3], Jitraporn Phaksopa[4]

1. Graduate School of Environmental Studies, Nagoya University, 2. Institute for Space-Earth Environmental Research, Nagoya University, Japan, 3. Department of Aquatic Science, Faculty of Science, Burapha University, Thailand, 4. Department of Marine Science, Faculty of Fisheries, Kasetsart University, Thailand

Green *Noctiluca scintillans*, the peculiar single cellular heterotrophic organism containing green algae called *Pedinomonas noctilucae*, frequently causes harmful algal bloom (HAB) in the upper Gulf of Thailand (uGoT). The high density of green *Noctiluca* discolors the water to deep milky green, and it has the potential to generate low dissolved oxygen (hypoxia) in the water column resulting in massive fish mortality. The co-occurrence of green Noctiluca and other phytoplankton species (e.g., *Ceratium furca* and diatoms) was often reported. Heretofore, the behavior of red tides has not been clarified. In this study, we, therefore, focus on investigating the dominant spectral characteristics of each HAB species and developing an algorithm to discriminate green *Noctiluca* from the other harmful species. The ship observations (2017 –2018) were conducted to obtain the apparent and inherent optical properties as well as the pigment information of green *Noctiluca* blooms. Fortunately, the super green *Noctiluca* blooms (>1,500,000 cell L^{-1}) occurred near the west coast of the uGoT in July 2017. The remote sensing reflectance spectra measured by using the RAMSES hyperspectral radiometer (320 nm –950 nm) revealed the crucial features of green *Noctiluca* in near-infrared wavelengths. The different characteristics of green *Noctiluca* and other HAB species were also found in visible wavelengths. The investigated features were used in the discrimination method to detect the green *Noctiluca* bloom using satellite observation in the near future.

Monthly variability of Chlorophyll-a distribution in the Gulf of Thailand

*Dudsadee Leenawarat[1], Anukul Buranapratheprat[2], Joji Ishizaka[3]

1. Graduate School of Environmental Studies, Nagoya University, Japan, 2. Department of Aquatic Science, Faculty of Science, Burapha University, Thailand, 3. Institute for Space-Earth Environmental Research, Nagoya University, Japan

The Gulf of Thailand (GoT) is semi-enclosed sea located in the western part of the South China Sea. This area is important to fisheries production in this region. The satellite data can reveal the primary production through chlorophyll-a (Chl-a) which is basic for the food chain. The objectives of this study are to investigate the variation and spatial distribution patterns of Chl-a in the GoT by using long-term satellite data from SeaWiFS (1997-2010), MERIS (2002-2012), MODIS AQUA (2002-2018), and VIIRS (2012-2018) level 3 compared with oceanographic conditions from previous study and circulation model name Princeton Ocean Model (POM). Tide and climatological data of wind, salinity, temperature and river discharge are forcing in the model. The results from averaged monthly Chl-a concentration in the central GoT illustrate low Chl-a concentration occurred in transition periods (April-May, and October) by lowest in May when the water column was stratified. High Chl-a concentration occurred during the northeast monsoon (November to February) with the highest in December when the water column was well mixed, and a small peak was found during June to August. Hight Chl-a was found along the coast, especially near the northern coast in the southwest monsoon (June to October). During the northeast monsoon Chl-a near cape CaMau spread offshore, due to strong surface currents flew into GoT from the southern part of cape CaMau to the middle of GoT mouth.

AERONET-Ocean Color time series in Ariake Bay.

*yifei wu[1], Joji Ishizaka[2], Mengmeng Yang[1], Naoki Fujii[3], Masahiro Hori[4]

1. Graduate School of Environmental Studies, Nagoya University, 2. Institute for Space-Earth Environmental Research, Nagoya University, 3. Graduate School of Agriculture, Saga University, 4. EORC, JAXA

The AERONET (**AE**rosol **RO**botic **NET**work) project is a federation of ground-based remote sensing aerosol networks established by **NASA** and **PHOTONS** and is greatly expanded by networks from national agencies, institutes, universities, individual scientists. AERONET –Ocean Color (AERONET-OC) provides the additional capability of measuring the radiance emerging from the sea. In April 2018, a new station of AERONET-OC has been set by JAXA for GCOM-C validation in Ariake Bay located in Kyusyu, Japan where the seaweed (Nori) culture very famous. Aerosol Optical Depth (AOD) and remote sensing reflectance (Rrs) is considered as the most important products of AERONET-OC since the estimation of chlorophyll-a concentration by ocean color satellite is usually not so accurate in coastal areas because of the inaccurate satellite remote sensing reflectance (Rrs) influenced by aerosol. This study is to make a brief description of the time series of the AERONET-OC data from April 2018 to April 2019. Local Chl-a and TSM estimated by using radiances measured by the AERONET-OC is going to use to explain the phytoplankton bloom connect with factors such as precipitation and river discharge in Ariake Bay.

Mechanical behaviors of geologic granular materials in shear provide fundamental insights into the mobility mechanisms related to the dynamics of landslides and tectonic faults. Some previous experimental studies have shown that the mineralogy of constituent materials plays a first-order control on the transitions of mechanical behaviors, including sliding stability or instability. Moreover, other laboratory investigations have demonstrated the importance of shear rate as a primary control on the strength properties, leading to rate-strengthening or rate-weakening. Despite these efforts, however, neither the knowledge of general relationships between material properties and failure modes nor the underlying processes are well understood. Here we report on a series of ring-shear friction experiments designed to investigate the shear surface morphology on the mechanical behaviors along pre-existing granular shear zones. Two kinds of commercial granular materials were used in our experiments, say, halite and silica. Results directly show that only inclusion a low proportion of granular halite can produce the transition from stable sliding to stick-slip instability. The visual observations of shear surfaces further indicate that the variations with halite content form different morphologies. By analyzing the shear displacement and acoustic emission data, the microslip precursors were identified to stick-slip instability. It is expected that the mechanical behavior transition may constrain the evolution of asperity mechanism in nucleating rupture instability along heterogeneous shear surfaces owing to breakage of grain interfaces.

On the Pre-failure Shear Behavior of Clayey Soil

*Chengrui Chang[1], Gonghui Wang[1]

1. Disaster Prevention Research Institute, Kyoto University

Introduction

Landslides are significant natural hazard that cause substantial economic loss and extensive loss of life. Triggering in landslides occurs as a result of highly dynamic processes and the hydrological state has a profound influence on the stability of the slopes. For rainfall-induced landslides, the increase of pore water pressure as a result of rainfall infiltration progressively reduces the normal effective stress of the slope materials acting on a potential shear surface and the shear resistance decreases as the inter-particle friction is reduced by the buoyancy force. Saito (1965) first proposed a linear trend when the inverse velocity before failure is plotted against time which has made a significant contribution to the understanding and monitoring of landslides (Voight, 1988, 1989; Fukozono, 1990). Many studies focusing on the deformation and pore water pressure noted that the rate of strain was initially small but showed a very rapid increase towards failure (Anderson & Sitar, 1995; Zhu & Anderson, 1998; Dai et al, 1999; Ng & Petley,

Methods

The aim of this study is to investigate experimentally the nature of the interactions between the pore pressure variation and the development of the displacement in the pre-failure stage. All the soil samples were taken from the Nishiwaki landslide, which was induced by the heavy rainfall accompanying the No. 21 Typhoon on Oct. 22rd, 2017 in Wakayama Prefecture. Subsequently, two different series of tests were undertaken under the combined condition of predefined normal stress and shear stress simulating consolidated nature slope in the ring shear apparatus. One series of test is the pore-pressure-controlled test, which uses a serially connected air tank and water tank to increase the pore water pressure (PWP) in the shear box of ring shear apparatus. This series of tests aims at simulating the effect of decreasing the effective stress state whilst holding constant shear stress to reproduce a slope undergoing heavy rainfall. The pore water pressure was increased deliberately and then hold or decrease the pore water pressure as a short-term movement was detected. Such a procedure has been repeated until the shear resistance dropped, which indicates the shear failure. The shear-stress-controlled series is aiming to investigate the shear displacement pattern with a gently cumulative increase in shear stress under undrained condition, which involves an increase of the shear stress in a flattened gradient after consolidation. Both series of tests are conducted in three kinds of consolidated conditions to examine the correlation between velocity and acceleration.

Results and discussions

In pore-pressure-controlled tests, the displacement shows a creep-like pattern before failure. During the whole test, several periods of constant velocity had been identified. We also found that shear swelling occurred in the drained shear test, therefore, we inferred that the possible infiltration of water into the shear zone may enable the continuous increase of pore water pressure so that the shear resistance will be lowered to initiate the accelerating movement. We also found that “stick-slip” behavior (short-term movements) occurred in the shear tests. We inferred that the increment of the PWP initiates the shear displacement rather than the amount of the PWP.

The results indicate that the increment of PWP can initiate larger and more rapid shear displacement when the level of the PWP is higher. A series of creep-like movements leads to final failure. The role of increasing pore water pressure in the initiation of the tertiary acceleration will be key for us to understand the creep behavior, and further tests and detailed examination on this issue will be continued.

GeoGuard: low-cost GNSS sensors for the continuous monitoring of landslides and structures

*Andrea Gatti[1], Giulio Tagliaferro[1], Eugenio Realini[1], Stefano Caldera[1]

1. Geomatics Research & Development srl

The United Nation Office for Disaster Risk Reduction warned that economic losses from landslides, floods, earthquakes, and drought will continue to escalate unless businesses take action to reduce their exposure to disaster risks. Structures can suffer structural deterioration due to aging, misuse or lack of proper maintenance. In addition, they are subject to exposure to natural hazards such as landslides, floods, and earthquakes. Traditional visual inspection techniques are both time consuming and expensive. They are also qualitative and can only assess outward appearance. Structures and natural hazard control and management are becoming one of the key issues in the approach to sustainable development of modern countries. In this framework, structural health monitoring is representing one of the most valuable approaches for the decision-making process. Global Navigation Satellite System (GNSS) technology can provide position information with accuracy to a few millimeters in near real-time. However, the widespread adoption of GNSS monitoring is hindered by the high cost of dual-/multi-frequency geodetic GNSS receivers.

In 2015, through a partnership with the Italian company Softeco, GReD started GeoGuard, an innovative end-to-end service for the continuous monitoring of landslides and structures by means of single-frequency GNSS low-cost receivers and antennas. GeoGuard provides accurate positioning with centimeter-level accuracy in near real-time, or millimeter-level accuracy for daily/sub-daily solutions. The GNSS network observations are processed by means of both Bernese software, and an ad-hoc evolution of goGPS, a free and open source positioning software package developed by the GReD team. A software platform was developed for the management of a GNSS positioning service, and for the visualization and delivery of results. Currently, GeoGuard uses GPS L1 observations for its operational activities; however, promising results are being obtained with the addition of Galileo E1 observations, especially for sites with limited sky visibility, and to improve the accuracy of sub-daily (e.g. hourly) solutions. Currently, the GeoGuard service is operational on two landslides, a highway bridge, a dam, and two penstocks.

Landslide Susceptibility Analysis in the Chenyulan River Watershed, Taiwan

*Po-Tsun Yeh[1], Kuang-Tsung Chang[1]

1. National Chung Hsing University, Taiwan

Many rainfall-triggered landslides occurred in the Chenyulan river watershed of central Taiwan during typhoon Morakot. In order to prevent rainfall-triggered landslide disasters, it is important to understand the relation of the disasters and the factors of rainfall, geology, and topography. In this study, the landslide susceptibility model of the Chenyulan river watershed was built and evaluated under the multiple logistic regression analysis based on slope units. These units were delineated by topography and 249 units out of them were chosen because orientation data of weak planes were included. The detection of the binary dependent variables (landslide and non-landslide samples) were based on the geomorphic change using satellite imageries before and after typhoon Morakot. Then the independent variables include geological, topographic and rainfall factors. Especially, we considered the orientation of weak planes and the spatial and temporal variability of rainfall. The result showed that the p-value of Hosmer-Lemeshow test and the Area Under the Curve of ROC are over 0.1 and 0.75, respectively. As the result, the chosen factors in the model could predict landslides in the Chenyulan river watershed effectively. It could be reference for follow-up research.

Investigating the Relationship Between Tree Height and Landslide Occurrence in the Ikawa Catchment, Central Japan

*Jamie Rhys Evans[1], Fumitoshi Imaizumi [1]

1. Faculty of Agriculture, Shizuoka University

The occurrence of landslides in forested terrain can have large impacts on the future productivity of soil and the quality of water that drains from a catchment, as well as damaging a valuable asset in the forest itself. The relationship between tree height and landslide occurrence in the Ikawa catchment, Northern Shizuoka prefecture, is investigated to gain a better insight into the distribution of landslides. Root depth profile, measured for trees of various height via trenches, is used in conjunction with tree height when assessing the distribution of landslides. Root tensile strength for unit areas of soil is calculated from individual root diameters to better understand the effect of the root network on slope stability. Landslide ratios in the Ikawa catchment show that landslides occur more frequently in shorter forests, with occurrence decreasing as tree height increases. This is likely due to stabilizing features of trees being accentuated as they grow, which is supported by both total root area and total root tensile strength data showing a significant increase between that of the 6.5m Kumashide, 8m Momi, and 12m Kumashide. The random distribution of results when comparing landslide depth to tree height suggests that while tree height, and hence total root tensile strength, has an impact upon whether a landslide is to occur or not, the depth of the landslides that do occur are independent of the height of trees. This suggests that slope stability increases alongside tree height and that landslide depth is not controlled by tree height so is therefore controlled by other factors. While there is no relationship between tree height and landslide depth, both Kumashide trees surveyed show decreases in total root tensile strength around the average depth of landslides in the Ikawa catchment of 0.46m.

Landslides induced by the knickpoint migration in the southern and the eastern margins of the Tibetan Plateau.

*Masahiro Chigira[1], Ching-Ying Tsou[2], Siyuan Zhao[4], Xiong Wu[3]

1. Disaster Prevention Research Institute, Kyoto University, 2. Hirosaki University, 3. Souithwest Jiaotong University, 4. Graduate School of Science, Kyoto University

Because of the collision of Indian plate to Eurasian continent, Himalaya, which is the southern margin of the Tibetan Plateau, is uplifting very rapidly and also the eastern margin of the Tibetan Plateau is uplifting. Those mountains are the sites of uplift and also the sites of rapid erosion and mass movements. We made field survey, using PRISM image with a resolution of 5 m and 5-m ALOS AW3D in both areas. We studied gravitational slope deformation and landslide, which are the response of mountain slopes to river incision, along the Kaligandaki River in Nepal Himalaya and the Minjiang River in Sichuan and found that gigantic landslides have occurred due to the slope instability made by the upstream migration of knickpoints and undercutting of the nearby slopes.

Along the Kaligandaki River, there are two outstanding knickpoints at Kalopani and Talbagar, respectively. The knickpoint at Kalopani is located at the largest landslide dam, which is called Kalopani landslide or Lete landslide. This landslide is inferred to be preceded by buckling deformation of calc gneiss. It is located near the lower margin of the glaciated area, and the slope could have been eroded by a glacier at the foot of the slope. Downstream of the Lete landslide are aligned 4 gigantic landslides, of which the most upstream one is the Talbagar landslide. It occurred on the left bank just downstream of an outstanding knickpoint of the Kali Gandaki River. This knickpoint propagated from downstream forming a slope break 200-400 m high from the riverbed. Talbagar landslide is a rock compound slide and the other three gigantic landslides were of two mica gneiss and occurred on slopes that had been toppled above the slope break.

There are two significant knickpoints along the Minjian River upstream of the Longmenshan fault. The effects of the knickpoint propagation and inner gorge formation on slope stability are dependent on the geometrical relationships between the river and geological structures. When the geological trend is normal or highly oblique to the river axis, landslides generally do not occur, but gigantic catastrophic landslides have occurred on one side of the Minjiang valley, which can be attributed to a wedge structure consisting of bedding planes and joints with intersections dipping valleyward and tight folds with hinges plunging valleyward. Diexi landslide, the largest landslide along the Minjian River was a wedge failure induced by this knickpoint migration.

The 2018 Hokkaido Eastern Iburi Earthquake struck the eastern Iburi region (epicenter: 42.691˚N, 142.007˚E, depth: 37.0km) of Hokkaido, Japan, at 3:07.59 JST, September 6, 2018 (18:07.59, September 5, 2018 UTC). Many shallow landslides and several large-scale deep-seated landslides, generating a landslide dam in the Hidaka-horonai River, were triggered by this magnitude 6.6 M_w (6.7 M_j) earthquake. The sedimentary rock in the affected area was covered by thick pyroclastic fall deposits derived from the Tarumae Volcano etc.. Landslides were densely distributed over hilly regions (elevation: 200–400 m) within an area of approximately 400 km^2 in Atsuma, causing 36 deaths, Abira and Mukawa, and representing the largest total area of earthquake-related landslides in Japan since the Meiji Era (1868–1912). The shallow landslides were characterized as follows: 1) pyroclastic fall deposits on sedimentary rock (basement complex) were moved by the strong seismic shock, 2) slip surface types included weathered tephra, weathered bedrock, and buried humus layers, 3) many occurred at relatively gentle slopes (< 30˚), 4) shallow landslides moving along valley type topography tended to travel longer than those moving along planar slope topography, and 5) concentrated shallow landslides occurred in tributary catchments of the Atsuma and Abira Rivers. Large-scale deep-seated landslides were characterized as follows: 1) rare occurrence and 2) slip surface within sedimentary rock.

On the coseismic landslides occurring on tephra slopes during the 2018 Hokkaido Eastern Iburi Earthquake

*Gonghui Wang[1], Gen Furuya[2]

1. Disaster Prevention Research Institute, Kyoto University, 2. Toyama Prefectural University

Numerous landslides were triggered by 2018 Hokkaido Eastern Iburi Earthquake on the tephra slopes, resulting in 36 casualties. Although one large landslide was initiated with its sliding surface being in the bedrock of sandstone and siltstone, most of them occurred on the tephra slope. To understand the initiation and movement mechanisms of these landslides occurring on tephra slopes, we performed field investigation (including geophysical survey, penetration test and field director shear box tests), and also conducted dynamic shear tests on the tephra samples taken from the sliding surface. The results will be presented in this report.

Seismological and geotechnical surveys on the landslides induced by the 2018 Hokkaido Eastern Iburi earthquake

*Issei Doi[1], Hikaru Osawa[2], Sumio Matsuura[1]

1. Disaster Prevention Research Institute, Kyoto University, 2. Mountain Science Center, University of Tsukuba

Atsuma Town, central part of Hokkaido, Japan, suffered from numerous landslides induced by the 2018 Hokkaido Eastern Iburi earthquake (Mw 6.7). We had a seismological and geotechnical surveys on some of the landslides. We selected a shallow landslide within tephra layers and a huge landslide of rockslide. Aftershock observation was conducted to grasp the vibration characteristics of the large landslide. Frequency components of ~2 Hz were dominant for S- and coda parts, with long durations of monochroic vibrations. Surface wave surveys, in both active and passive ways, were deployed to understand the vertical profile of the shallow landslide area. Very low (~ 50 m/s) Vs layers with the thickness ~ 1 m, which were consistent to the landslide depth, were detected along the survey line beside the landslide area, while such layers did not exist inside the landslide.

Acknowlegement: Hirokazu Fukui, a graduate student in Kyoto University, helped us for conducting the surveys.

[H-DS09] Landslides and related phenomena

convener:Masahiro Chigira(Disaster Prevention Research Institute, Kyoto University), Gonghui Wang(Disaster Prevention Research Institute, Kyoto University), Fumitoshi Imaizumi(Faculty of Agriculture, Shizuoka University), Chairperson:Fumitoshi Imaizumi, Chigira Masahiro

Mass movements, such as landslides, rockfalls, and debris flows, have been occurring extensively in a large number of countries, causing heavy damage. In order to understand them and mitigate induced disasters, we invite contributions that report and discuss on mass movements and related phenomena, focusing on improved understanding of their characteristics; new insights into landslide mechanisms; the development of new approaches to monitoring; novel approaches to behavior forecasting and prediction; studies of successful landslide management; and the development of methods for hazard and risk evaluation. In particular, papers about recent landslide hazards, induced by 2017 northern Kyushu rainstorm, 2018 Osaka earthquake, 2018 western Japan rainstorm, and 2018 Hokkaido earthquake are welcome.

Discussion

Initiation conditions of debris flows in Ohsawa landslide, Mt. Fuji

*Fumitoshi Imaizumi[1], Kazuki Yamamoto[1], Atsushi Ikeda[4], Okihiro Ohsaka[1], Hiroyuki Sugimoto[2], Satoru Suzuki[2], Shinichi Sato[2], Yoshiaki Kashiwabara[3], Naoki Nishimura[3]

1. Faculty of Agriculture, Shizuoka University, 2. Fuji Sabo Office, Ministry of Land, Infrastructure and Transport, 3. Asia Air Survey Co., Ltd., 4. Faculty of Life and Environmental Sciences, Tsukuba University

Initiation condition of the debris flow is generally explained only using rainfall threshold. However, the rainfall threshold possibly changes in cold seasons because of decreasing in the infiltration rate by freezing of the ground water. Snow cover and volume of unstable sediment in the debris flow torrent are also potential factor affecting the rainfall threshold. We have studied initiation condition of debris flow in Ohsawa landslide, Mt. Fuji, where the ground freezes for a long period due to high elevation. Snow cover period was estimated by the degree-day method. Progress of the freezing and melting of the groundwater toward deeper part of the ground was estimated using freezing degree days and degree days, respectively. In addition, effect of the freezing, snow cover, and volume of storage was studied by analyzing the rainfall and debris flow records over fifty years. Rainfall intensity and total rainfall needed for occurrence of debris flows in freezing periods is lower than that in the non-freezing periods. Rainfall threshold in the non-freezing periods with small volume of storage is lower than that in the non-freezing periods with large volume of storage. Influence of snow cover on the occurrence of debris flow and slash avalanche was not clear.

The role of thrust faults with incohesive clayey fault materials to generate deep-seated gravitational slope deformations and catastrophic landslides in the Shimanto accretionary complex

*Noriyuki Arai[1], Masahiro Chigira[1]

1. Disaster Prevention Research Institute,Kyoto University

The purpose of this study is to clarify the geological and geomorphological background of deep-seated catastrophic landslides (DCLs) and related gravitational slope deformations (DGSDs) that occur in mountain areas of accretionary complexes. We performed the detailed geological survey for the area of 25 km^2 in the Shimanto accretionary complex in the middle of the Kii Mountains, Japan. In this area, six DCLs were induced by the heavy rain of Typhoon Talas in 2011. Using the 1-m DTMs made from LiDAR data taken before and after the landslides by the Kinki Regional Development Bureau, Ministry of Land, Infrastructure, Transport and Tourism, and Nara Prefecture, we investigated the distribution of the thrust faults with the incohesive clayey fault materials in the mountain slopes and the inner structures of these thrusts. Mineralogy, permeability and shear strength were measured for the fault gouge.
As a result, we obtained the following results and conclusions.
1. Low-angle thrust faults with incohesive fault rocks thicker than approximately 1 m were newly found to develop at intervals of a few km in the study area.
2. Many of these thrust faults were different from previously reported thrust faults. The thrust faults with incohesive fault rocks include clayey crush materials that form a weak and impermeable layer, which becomes the base of a DGSD and would accommodate a sliding surface of a DCL.
3. The DGSDs and rain-induced DCLs in the study area preferentially occur in the hanging walls of those thrust faults and their areal alignments are controlled by the thrust faults.
4. Thrust faults commonly extend for kilometers as planar features but are sometimes locally folded with their nearby rocks. When a syncline involving thrust faults plunges valleyward, this structure also facilitates DGSDs.

Introduction

Earthquakes and earthquake induced landslides are the most threatening geological disasters in nature. Coseismic landslide, as a surface catastrophic effect induced by earthquakes, has drawn much scientific attention. The fact that seismic faults play a control role in the occurrence of landslide has been generally recognized. Many relating researches focused on the relationship between landslide distribution patterns and the distance to the co-seismic fault, peak ground acceleration (PGA) of the earthquake, and types of faults based on remote sensing interpretation and GIS method. Many statistical methods including fuzzy analytic hierarchy process, principal component analysis, and logistic regression, were used to evaluate landslide susceptibility in an earthquake event considering the main role of faults. However, how the faults affect the distribution patterns of coseismic landslides has not been clearly understood.Therefore, in this study we examined this issue based on a case study on the landslides triggered by the 2008 Wenchuan earthquake, in China.

Method

We selected Qingping part of Longmenshan faults generating the Ms 8.0 earthquake as a target region. First, measurements of rock mass structure were conduceted. In-situ field rock mass structure investigations, 2m*2m measurement network was used, in laboratory, fractures that were visible to the naked eye in the field were sketched and counted using a square frame (0.3 *0.3 m) along profiles oriented across the faults. Then fracture density was calculated to determine the characteristics of fractured system of the crustal rock mass in the fault zone area. Finally, Wenchuan earthquake landslides distribution patterns was combined to deeply discuss the effects of faults on landslides.

Result

The results of spatial variations in fracture density with increasing distance from the Jiangyou-Dujiangyan fault were shown in Fig 1. As can be seen in Fig. 1, fracture density is much higher in the faults zone than other areas and sharply decreases with further increase after it exceeds a certain distance (CD) from the main fault. In Yingxiu-Beichuan fault, this CD is 3030 m in hanging wall and 1170 m in footwall, while in Jiangyou-Dujiangyan fault, this CD is 1350m in the hanging wall. Fracture density also increases when subsidiary faults across. The results showed that occurrences of fractures are strongly concentrated around the faults zone, such as Yingxiu-Beichuan fault and Jiangyou-Dujiangyan fault, presence of secondary faults also has a strong relation with fracture density distribution. Most co-seismic landslides for wenchuan earthquake in the research area distributed on the concentration part of rockmass factures.

Discussion

In this study, we found that there are control effects confined to a certain range of huge faults on the surrounding regional rock mass structure, showing a great impact on rock mass structure in a large scale. A concept named “fracture zone” was defined to express this phenomenon.

The results suggest the existence of remarkable hanging wall effect of rock mass structure, since the width of fracture zone in the hanging wall is greater than that in the foot wall. The fracture zone of Yingxiu-beichuan fault hanging wall is much wider than that of Jiangyou-dujaingyan fault, indicating that

©2019. Japan Geoscience Union. All Right Reserved.

there is a stronger control effect on rockmass structure of Yingxiu-beichuan fault compared with Jiangyou-dujaingyan fault.

Most co-seismic landslides for wenchuan earthquake distributed on the concentration part of rockmass factures, namely fracture zone. Distinct “hanging wall” effect of rockmass structure is consistent with the distribution pattern of coseismic landslides in the research area. Results indicate that the control effect has directly impacts on the distribution pattern of Wenchuan coseismic landslides

Conclusion

1. A control effect confined to a certain range of huge faults on the structure of surrounding regional rock mass in the whole mountain by using fracture density method, this effect was defined as “fracture zone” effect, which has directly impacts on the distribution pattern of Wenchuan earthquake induced landslides.
2. The control effect on surrounding regional rock mass structure were also founded in other huge faults, we argue that this effect is universal, which could be also suitable for other huge faults. The control effect marks long-term dangerous zones, since fragmented rock mass is vulnerable to subjected to failure, which has implications for disaster prevention in mountainous areas where faults are active.

Fluidized landslides triggered by the liquefaction of subsurface volcanic deposits during the 2018 Iburi–Tobu earthquake, Hokkaido

*Jun Kameda[1], Hiro Kamiya[2], Hirokazu Masumoto[1], Tomonori Morisaki[1], Toru Hiratsuka[2], Chisaki Inaoi

1. Department of Natural History Sciences, Graduate School of Science, Hokkaido University, 2. Department of Earth and Planetary Sciences, School of Science, Hokkaido University

The Iburi–Tobu earthquake of M_w = 6.7 occurred at 3:07 AM (local time) on 6 September 2018, in southern Hokkaido, Japan. The earthquake caused power cuts and destroyed distribution networks across Hokkaido, creating widespread disruption. A total of 41 people were killed during the earthquake, with most of these (36 people) perishing in landslides near the epicenter. The hills in southwestern Hokkaido are widely covered by volcanic deposits, derived from the repeated eruptions of nearby volcanoes such as Tarumai, Eniwa, and Shikotsu (e.g., Nakagawa et al., 2018). On 4 September, Typhoon Jebi caused heavy rainfall in this area, which likely soaked and weakened the volcanic soils. Subsequent earthquake ground motion (with a maximum intensity of 7 on the intensity scale of Japan Meteorology Agency; Japan Meteorology Agency, 2018) may have triggered sudden whole-slope failures. The total number of the present landslides was ~6000 (Yamagishi and Yamazaki, 2018), and most of the recorded landslides are shallow and show features characteristic of fluidized landslides, such as long runouts of debris on a flat depositional area.
To investigate the mechanism generating the landslides triggered by the Iburi–Tobu earthquake, we conducted a field survey at a typical landslide in the Tomisato area of Atsuma, and we found a distinctive occurrence of liquefaction in the field, which could be a precursive condition for the generation of the fluidized landslides triggered by the earthquake. In the scarp of the landslide, an altered halloysite-bearing volcanic layer is observed at a level almost coincident with the sliding surface. The layer is intensely undulating and can be divided into an upper clay-rich layer and a lower pumice-rich layer, suggesting that the altered layer had liquefied as a result of the strong coseismic ground motion. The layer had been soaked by heavy rainfall just one day before the earthquake and could have liquefied by interstitial fluid pressurization, producing a weak and slippery plane, resulting in the catastrophic landslides in this area.

A comparison between the acoustic signals and seismic signals generated during a dam-break test

*Zheng-yi Feng[1], Hao-yang Huang[1], Chia-Ming Chuang[1]

1. Department of Soil and Water Conservation, National Chung Hsing University, Taichung, Taiwan

Natural events, such as landslide, sediment transport, flooding, etc., usually release energy to produce acoustic waves and seismic waves. Acoustic wave is transmitted through air and seismic wave is transmitted through geologic structure. Therefore, the characteristics of acoustic waves and the seismic waves induced by these events should be different. This study focus on the differences in the acoustic signals and seismic signals during a dam-break test performed by the authors. We built a model dam and slope in a creek for the test. We filled the dam with water and caused it to overflow. The overflow water caused the downward erosion of the dam. The flood due to the dam-break eroded the toe of the model slope causing the slope to collapse locally. We set up microphones to collect acoustic signals and installed accelerometers to collect vertical seismic signals generated by the flood and collapse events during the test. During the test we also used unmanned aerial vehicle (UAV) to continuously take photos for the collapsed areas for making the digital surface model (DSM) of the slope to analyze the volumes of the collapsed materials. We used Hilbert-Huang Transform (HHT) to obtain the time-frequency spectra for the acoustic signals and seismic signals. From the spectra, we compared the energy and frequency content of the two kinds of signals and their differences. The results show that the acoustic signal showing earlier indication of overtopping than that of the seismic signal. In addition, the acoustic and seismic signals generated during the flood can correspond to each other. The collapse events of the slope during the flood can be investigated also by examining the time-frequency spectrum of the seismic signal. Usually the signals of the collapse events can be distinguished from the flooding signals.

Evaluation of factors of safety and landslide risk for a watershed by Scoops3D

*Zheng-yi Feng[1], Chia-Ming Chuang[1], Hao-yang Huang[1]

1. Department of Soil and Water Conservation, National Chung Hsing University, Taichung, Taiwan

In this study, the Scoops3D code (USGS, 2015) is used to analyze the three-dimensional stability of the slopes in a watershed in Taiwan. To perform Scoops3D it requires the inputs such as digital elevation model (DEM), geological materials, groundwater level, earthquake, etc. The code calculates the minimum factor of safety (F.S.) and the associated potential failure volumes by using three-dimensional limit equilibrium method. We performed a comprehensive analysis of slope stability for the research areas using the Scoops3D code. The ArcMap software was used to present the F.S. that are less than unity as a 2D contoured map. We can observe this contoured map to understand the overall slope stability of the studied watershed. We perform a parametrical study by set three different sizes of sliding volume, “large”, “medium” and “small”, for evaluating the risk of landslide for the three different volume sizes.

Fuzzy Clustering Algorithms for Establishing Landslide Susceptibility Map

*Pei-hsun Tsai[1], Syuan-yi Wang[1], Jie-shin Cheng[1]

1. Chaoyang University of Technology

In recent years, the rainfall distribution is not uniform because of extreme weather events, the occurrence frequency of heavy rain increases. Coupled with steep terrain and complicated geological condition, so that the slope often occurred landslide when typhoon or heavy rain. Landslide susceptibility map delineates the potential zones for landslide occurrence. To develop the landslide model, we used several independent data layers that are recognized as effective factors in landslide occurrence, including slope, aspect, shear strength of rock or soil, dip and dip direction of stratum, and distance to road. All data layers were converted to raster layers with a 30 m ×30 m cell size. A total of 231336 cells were derived in study area. For assessing landslide susceptibility spatially, this study used fuzzy c-means clustering algorithm to classify the aforementioned data set in the study area into six clusters. Each cluster has similar natural environmental conditions and collapse situation. It is helpful to establish the monitoring management system and it can be applied to an early warning system in the landslide. Results of validation show that this model can accurately predict the occurrence of new landslides.

A Study on Landslides and Debris Flows Susceptibility Mapping Using Unmanned Aerial Vehicles

*Sheng-Jia Liu[1]

1. qwepoi13@gmail.com

The geology of Taiwan is generally vulnerable due to the natural adverse conditions such as younger strata, steep topography, active orogeny, frequent seismic activity, weathering and erosion, frequent typhoons, high rainfall, etc. Furthermore, the human factors like immature law and regulations, the weak execution, and improper land use and development also play an important role in reducing the slope stability. These factors to some degree worsen the slope conditions, lead to a more frequent natural disaster and cause the loss of life and property.

In order to effectively evaluate the landslide susceptibility and map the high risk areas, the Soil and Water Conservation Bureau of Taiwan Executive Yuan (SWCB) provides an assessment method for assessing the risk level of landslide susceptibility by selecting the combinations of impact factors that may trigger landslides. However, the accuracy and efficiency of data acquisitions, in a conventional way, for the assessment method are still limited.
With the advantages of UAVs, the digital image with high resolutions for a wider area without terrain restrictions can be obtained efficiently. Its applications have become more widespread, from battlefield detections and communications to forest management and mapping. This study utilizes the latest Dynamic Post-Processing Motion (PPK) positioning system to capture high-resolution image data from a chosen site in the northern part of Taiwan. The terrain information was extracted from aerial images using Pix4Dmapper with aerial triangulation techniques, thus the external direction of each image and the camera's internal direction parameters can be obtained, the point cloud data can be matched automatically, and a digital surface mode can be established. Further, a three-dimensional model with topographic map and landslide susceptibility evaluations can be established and performed by comparing with historical data and monitoring the slope conditions. A modified assessment method is proposed using the three factors (slope, the volume of soil and rock accumulations, and rainfall) to assess the landslide susceptibility of the study area. The evaluations made by the proposed method are in agreement with the SWCB method. The results from this study can be used in slope management and precaution, and rescue and recovery.

Largescale landslide induced by AD1586 Tensho-Earthquake in Gifu Prefecture, central Japan

*Takahiro Kurimoto[1], Yoshihiko Kariya[2], Kuniyasu Mokudai[3], Ryuji Yamada[4], Takashi Kimura[4]

1. Undergraduate Senshu University, 2. Department of Geography, Senshu University, 3. Japan Geoservice Incorporated, 4. National Research Institute for Earth Science and Disaster Resilience

On the basis of field investigation and topographic analysis by using GIS, we clarified the geological and geomorphological features of a large-scale landslide (V=2.2×10^7 m^3) called Mizore Landslide (ML) in Gujo City of Gifu Prefecture, central Japan. According to old documents, it is thought to ML was caused by AD1586 Tensho earthquake (generated from the Shokawa fault zone close to the ML and estimated M=7 to 8). However, there are few studies on geomorphological and geological basis. The main results are as follows: a) The ML holds a set of three head scarps and three landslide bodies both showing multiple activities of slope movement; b) The ML shows unique sedimentological and geomorphological characteristics such as a jigsaw crack structure in landslide deposits and hummocks and depressions upon the ground surface of the landslide bodies; c) Both involved buried soils in the landslide deposits and fossil wood logs in the dammed lake deposits enable us to date the landslide events; d) According to those ^{14}C dates of soils and logs, the latest landslide event is thought to occur in the period from cal AD1436 to 1650; e) The latest landslide event would be triggered by AD1586 Tensho earthquake. AD1596 Keicho-Fushimi earthquake occurred around Kyoto is a candidate event for further consideration.

Failure Probability of Lushan Landslide, Taiwan

*Wei-Ting Lin[1], Kuang-Tsung Chang[1]

1. National Chung Hsing University

The Lushan landslide located in the middle of Taiwan, has slid and damaged the road due to typhoons or heavy rainfalls for recent decades. It’ s seriously affecting the safety of life and property of the Lushan Hot Spring Tourist Area and local residents in the lower slope. In order to understand the probability of failure (Pf) of Lushan landslide, we built a numerical model by Plaxis2D, which is validated by the monitoring data of the 2009 typhoon Morakot. However, due to the lack of complete parameter data, uncertainties exist and may affect the simulation result of the collapse. With the back calculated friction angle (∅) and cohesion (c) from Plaxis2D, we used the Monte Carlo Simulation (MCS) to consider the friction angle and the cohesion of sliding body as random variables with uncertainty. The results are statistically analyzed to obtain the Probability Density Function (PDF) of the two parameters. Based on the parameter settings above, with the designed rainfall events at 24hr, 48hr and 72hr rainfall duration and 10, 25, 50, 100 and 200 years of recurrence interval, we calculate the factor of safety (SF) of the Lushan landslide in these 18 simulated rainfall events. Finally, we can obtain the distribution of factor of safety (SF) and probability of failure (Pf) of the Lushan landslide in different rainfall durations and recurrence intervals.

Keywords: probability of failure, Monte Carlo Simulation, uncertainty

Interpretation of landslide surface deformation in Kali Gandaki River watershed, Nepal using ALOS-2/PALSAR-2 InSAR image

*Hiroshi, P. Sato[1]

1. College of Humanities and Sciences, Nihon University

Previous studies have revealed and mapped glacial landform, fluvial terraces, and landslide landform in Thakkohla-Muktinath region, between Kagbeni and Ghasa along Kali Gandaki River, Nepal. And many attentions were paid to detect landslides that brock channels in the region, especially after Gorkha earthquake (25 Apr 2015; Mw7.8). Therefore, I tried to interpret landslide surface deformation on mountain slopes in Kali Gandaki River watershed after the earthquake, using Synthetic Aperture Radar interferometry (InSAR) image. The number of produced InSAR images was six, which is master image/slave image in order from ALOS-2/PALSAR-2 data, 08Oct2015/17Dec2015, 08Oct2015/30Nov2017, 25Feb2016/06Oct2016, 30Nov2017/24Jan2019, 08Mar2018/24Jan2019 and 31May2018/24Jan2019. In these InSAR images clear precursory landslide surface deformation was not interpreted on mountain slopes facing main stream of Kali Gandaki River. However, whose tributary watershed; i.e., Myagdi River watershed gave some landslide surface deformations (e.g., in 83.3983E, 28.4842N) clearly interpreted in the InSAR image of 08Oct2015/17Dec2015, which was relatively better coherence than the rest five images.

A depth-integrated model for granular flows on the transition of different bed conditions

*Ling-Yi Hsu[1], Chi-Yao Hung[1]

1. National Chung Hsing University

The different basal boundary conditions profoundly affected the flow behavior of debris flow. However, it is hard to have a general and straightforward model to describe the flow profile switching from different bed conditions. In this study, we purpose a new depth-averaged model to simulate the dense granular flow transition between the rigid and mobile bed. The model is based on mass conservation, momentum conservation, and kinetic energy conservation. We apply the linearized mu(I) rheology to describe granular deformation and assume Coulomb friction along the sidewalls. By incorporating the basal shear rate term into the equations, the theory can balance the extra force from rigid bed friction force. To check the model approach, we conducted an equilibrium and non-equilibrium heap flow experiments using the narrow see-saw channel, which can be tilted to different angles between runs or during flows. To compare the experimental results with the theory, the flow fields are monitored using high-speed video and particle-tracking velocimetry.

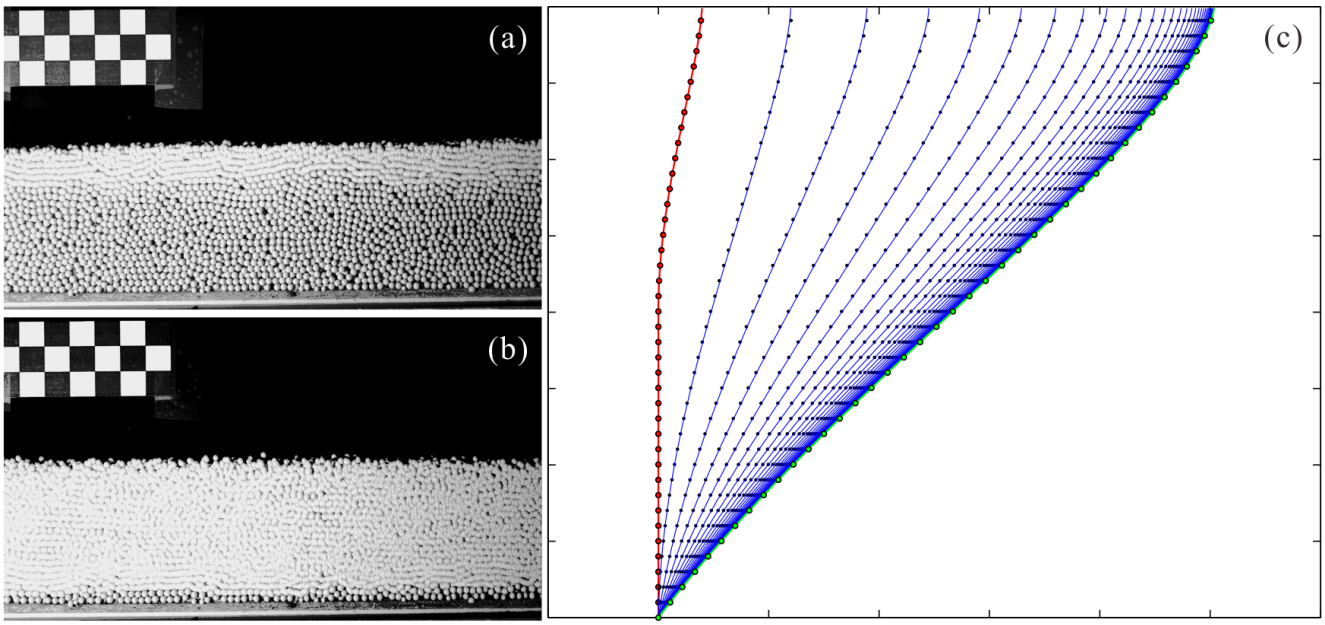

Fig.1 Experimental longexpousre image (a) over deposition bed; (b) over rigid bed; and (c) the transition velocity profile of theory prediction.

A viscous granular flow experiment with new refractive index matching material

*Tsai-Jung Lin[1], Chi-Yao Hung[1]

1. National Chung Hsing University

Entrainment rate at base controls how far the debris flow can travel and how large the debris flow becomes. Flow rheology of Refractive Index Matching (RIM) material are generally limited by the mono-particle properties (such as polymethyl methacrylate/liquid para-cymene etc.). In this study, a new RIM material (polyacrylamide polymer/18% Methanol solution) having a wide range of particle size distribution and viscosity (Fig. 1L) are purposed to visualize and measure the erosion process of mobile bed dam break experiments. Various rheology models may be formed by the different ratio of particle size. To improve the contrast between the particle phase and the liquid phase, a dye is used to make the particles bright under laser illumination. By varying the dye concentration, the entraining/detraining processes are easily distinguished (Fig. 1R). Granular motion is captured through a high-speed camera and Particle Tracking Velocimetry (PTV) method. Finally, an empirical relationship between the rheology and the entraining/ detraining process is developed.

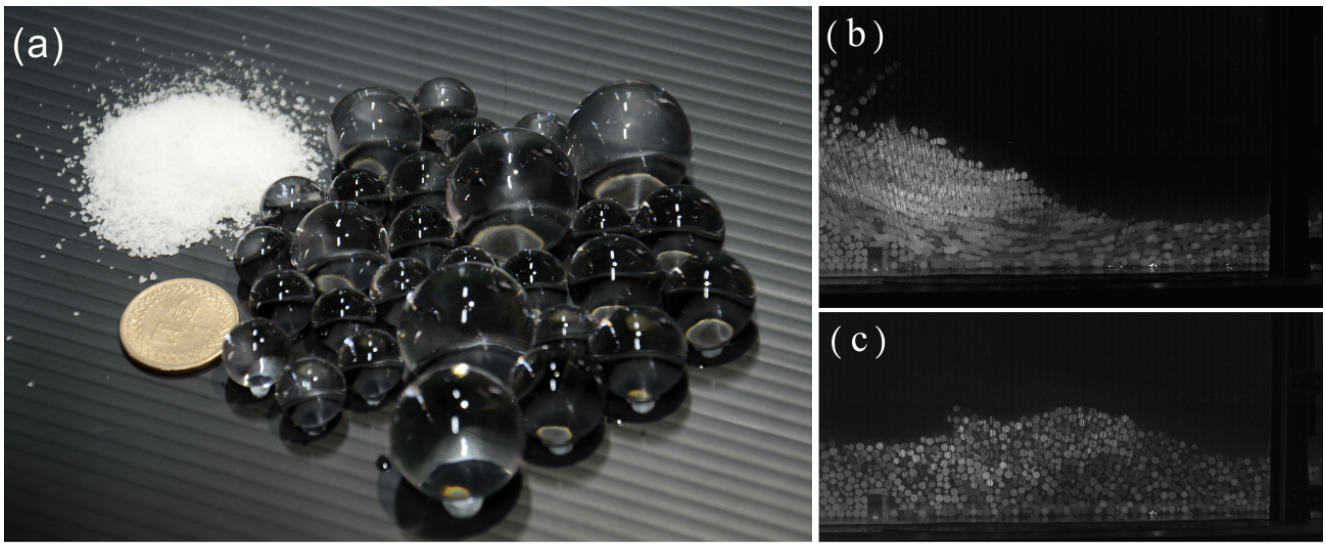

Fig.1 Experimental image (a)wide range of particle size; (b)longexposure image of dam break occurrence; (c)particles with different concentration of dye.

Sandbox experiments of submarine landslide caused by water film in low permeability layer

*Shogo Kawakita[1], Daisuke Asahina[2], Keiji Kitajima[3], Mitsukazu Nakanishi[3]

1. Graduate School of Science & Technology, Nihon Univ., 2. National Institute of Advanced Industrial Science and Technology, 3. College of Science & Technology, Nihon Univ.

Submarine landslides can be serious geohazards since they potentially cause tsunamis and damage seafloor infrastructure. Submarine landslides can be larger in scale than landslides on land. Direct measurements/observations of submarine landslides at deep seafloor still remain a challenging task. Kokusho et al. (2000) proposed a water film effect and its mechanism on lateral flow with less frictional resistance to explain a driving force of large-scale submarine landslides

In this study, we conducted laboratory experiments to understand the relationship between sand liquefaction and lateral flow by water film, and investigate the influence of water film formation on lateral flow of upper layer. In general, it is difficult to observe the formations of liquefaction and lateral flow at the same time. This is because sand particles of sloping layer model start to move when vibration is applied, and inclination disappears before liquefaction. To solve this problem, we devised a mechanism to prevent the flow of the lower layer by providing a weir plate in inside the soil tank. This mechanism enables to distinguish and observe the movement of sand by the liquefaction and the lateral flow by the water film.

The results obtained in this study clearly show three stages: first, the lower layer was liquefied; then pore water was stored below the low permeability layer; and finally, the lateral flow was occurred by the water film effect. The experimental results show that there was no clear correlation between the increase in the angle of sloping layer and the travel distance or the maximum flow velocity. We also discuss the relationship between the layer angle and the location of sand boil. The location where sand soiling occurred moved to the upper side of the slope as the layer angle become larger.

Study on Creep Properties of Sand and Cemented Sand

*JIN-YI YU[1], KUANG-TSUNG CHANG[1]

1. National Chung Hsing University

In this study, we investigated the effects of creep on sand and cemented sand, using triaxial test. Sand represents a non-cohesive material, while cemented sand represents a brittle material. Before the failure of specimens, the deviator stress was fixed and the cyclic mean stress was applied to study the influence of creep on the materials. According to the test results, the axial strain accumulation of sand caused by creep is less, and the peak strength is larger than that of the monotonic loading when the axial loading is resumed. For cemented sand, creep causes microcracks inside the specimens, gradually forming a failure surface. When the axial strain accumulation is large enough, the reapplication of the axial loading shows a reduction of peak strength. We conclude that the influence of creep on non-cohesive material (sand) is limited, whereas creep can reduce the strength of the brittle material (cemented sand) and even cause failure.

The effects of seepage force and the Poisson’s ratio on slope stability

*Hirokazu Fukui[1], Tomomi Terajima[2]

1. Graduate school of Science, Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University

To predict accurately the timing of shallow landslide occurrence, we need to consider the direction and magnitude of seepage force and earth pressure. A model sandy slope (L: 9m, W:1m, H:4m) was used to measure the hydraulic gradient and seepage force with the tensiometers under the artificial rainfall of 80mm/h. We incorporated not only the seepage force but also the Poisson’s ratio into conventional slope stability analysis by the limit equilibrium method. As a result, the calculated timing of shallow landslide occurrence was almost agree with the timing of that in the experiment and also more accurate than the timing calculated by the Spenser method which took into account the magnitude and moment equilibrium of the force. These results imply that, based on both monitoring at fields and conducting more experiments by a real-size model slope, we need to verify the effects of seepage force and earth pressure as the important factors causing rainfall-induced slope instability.

Study on the factors of seepage erosion

*Szu-Wei Fu[1], Kuang-Tsung Chang[1]

1. National Chung Hsing University

The causes of many slope disasters are often related to the seepage behaviors of soil. For instance, groundwater seepage may cause internal erosion of the soil. The soil particles are taken away by seepage water to form void or pipe. In addition , the earth pressure leads to the collapse of the overlying soil.

In this study, we designed a set of apparatus that can add confining pressure to the outside of the specimen. In order to simulate the situation of sand in slopes, we investigated the critical seepage velocity of sands caused by seepage erosion failure under different confining pressure, with different particle size distributions, sizes of outflow, etc. Then a failure criterion for seepage erosion is developed based on the drag equation in fluid dynamics and confirm with experimental data.

The results show that the critical seepage velocity at failure is affected by the particle size distributions, sizes of outflow and the confining pressure. The theoretical results are compared well to the experimental data.

Deformation of slope models with different orientations of weak planes

*taeyuan tseng[1], Kuang-Tsung Chang[1]

1. National Chung Hsing University

Weak planes influence failure and deformation of slopes. We conducted experiments to simulate slopes of different orientations of weak planes, including cataclinal and analcinal slopes with 30˚ and 60˚ inclination angles of weak planes. We stacked artificial bricks to make small-sized slope models. The artificial bricks were made of gypsum, sand, cement and water with different weight proportion. In view of the scaling law, the artificial bricks were made less strength than natural rocks. The slope models were weakened under rainfall, resulting in deformation and final collapse. The slope deformation processes were photographed by a camera, and the displacement vector fields were analyzed using the Particle Image Velocimetry (PIV). The deformation and accumulated displacements were compared between slopes of different orientations of weak planes.

Keywords: cataclinal slope, analcinal slopes, rainfall, Particle Image Velocimetry (PIV), weak planes, deformation

[H-DS09] Landslides and related phenomena

convener:Masahiro Chigira(Disaster Prevention Research Institute, Kyoto University), Gonghui Wang(Disaster Prevention Research Institute, Kyoto University), Fumitoshi Imaizumi(Faculty of Agriculture, Shizuoka University)

Mass movements, such as landslides, rockfalls, and debris flows, have been occurring extensively in a large number of countries, causing heavy damage. In order to understand them and mitigate induced disasters, we invite contributions that report and discuss on mass movements and related phenomena, focusing on improved understanding of their characteristics; new insights into landslide mechanisms; the development of new approaches to monitoring; novel approaches to behavior forecasting and prediction; studies of successful landslide management; and the development of methods for hazard and risk evaluation. In particular, papers about recent landslide hazards, induced by 2017 northern Kyushu rainstorm, 2018 Osaka earthquake, 2018 western Japan rainstorm, and 2018 Hokkaido earthquake are welcome.

Fluidized landslides triggered by the liquefaction of subsurface volcanic deposits during the 2018 Iburi–Tobu earthquake, Hokkaido

*Jun Kameda[1], Hiro Kamiya[2], Hirokazu Masumoto[1], Tomonori Morisaki[1], Toru Hiratsuka[2], Chisaki Inaoi

1. Department of Natural History Sciences, Graduate School of Science, Hokkaido University, 2. Department of Earth and Planetary Sciences, School of Science, Hokkaido University

The Iburi–Tobu earthquake of M_w = 6.7 occurred at 3:07 AM (local time) on 6 September 2018, in southern Hokkaido, Japan. The earthquake caused power cuts and destroyed distribution networks across Hokkaido, creating widespread disruption. A total of 41 people were killed during the earthquake, with most of these (36 people) perishing in landslides near the epicenter. The hills in southwestern Hokkaido are widely covered by volcanic deposits, derived from the repeated eruptions of nearby volcanoes such as Tarumai, Eniwa, and Shikotsu (e.g., Nakagawa et al., 2018). On 4 September, Typhoon Jebi caused heavy rainfall in this area, which likely soaked and weakened the volcanic soils. Subsequent earthquake ground motion (with a maximum intensity of 7 on the intensity scale of Japan Meteorology Agency; Japan Meteorology Agency, 2018) may have triggered sudden whole-slope failures. The total number of the present landslides was ~6000 (Yamagishi and Yamazaki, 2018), and most of the recorded landslides are shallow and show features characteristic of fluidized landslides, such as long runouts of debris on a flat depositional area.
To investigate the mechanism generating the landslides triggered by the Iburi–Tobu earthquake, we conducted a field survey at a typical landslide in the Tomisato area of Atsuma, and we found a distinctive occurrence of liquefaction in the field, which could be a precursive condition for the generation of the fluidized landslides triggered by the earthquake. In the scarp of the landslide, an altered halloysite-bearing volcanic layer is observed at a level almost coincident with the sliding surface. The layer is intensely undulating and can be divided into an upper clay-rich layer and a lower pumice-rich layer, suggesting that the altered layer had liquefied as a result of the strong coseismic ground motion. The layer had been soaked by heavy rainfall just one day before the earthquake and could have liquefied by interstitial fluid pressurization, producing a weak and slippery plane, resulting in the catastrophic landslides in this area.

A comparison between the acoustic signals and seismic signals generated during a dam-break test

*Zheng-yi Feng[1], Hao-yang Huang[1], Chia-Ming Chuang[1]

1. Department of Soil and Water Conservation, National Chung Hsing University, Taichung, Taiwan

Natural events, such as landslide, sediment transport, flooding, etc., usually release energy to produce acoustic waves and seismic waves. Acoustic wave is transmitted through air and seismic wave is transmitted through geologic structure. Therefore, the characteristics of acoustic waves and the seismic waves induced by these events should be different. This study focus on the differences in the acoustic signals and seismic signals during a dam-break test performed by the authors. We built a model dam and slope in a creek for the test. We filled the dam with water and caused it to overflow. The overflow water caused the downward erosion of the dam. The flood due to the dam-break eroded the toe of the model slope causing the slope to collapse locally. We set up microphones to collect acoustic signals and installed accelerometers to collect vertical seismic signals generated by the flood and collapse events during the test. During the test we also used unmanned aerial vehicle (UAV) to continuously take photos for the collapsed areas for making the digital surface model (DSM) of the slope to analyze the volumes of the collapsed materials. We used Hilbert-Huang Transform (HHT) to obtain the time-frequency spectra for the acoustic signals and seismic signals. From the spectra, we compared the energy and frequency content of the two kinds of signals and their differences. The results show that the acoustic signal showing earlier indication of overtopping than that of the seismic signal. In addition, the acoustic and seismic signals generated during the flood can correspond to each other. The collapse events of the slope during the flood can be investigated also by examining the time-frequency spectrum of the seismic signal. Usually the signals of the collapse events can be distinguished from the flooding signals.

Evaluation of factors of safety and landslide risk for a watershed by Scoops3D

*Zheng-yi Feng[1], Chia-Ming Chuang[1], Hao-yang Huang[1]

1. Department of Soil and Water Conservation, National Chung Hsing University, Taichung, Taiwan

In this study, the Scoops3D code (USGS, 2015) is used to analyze the three-dimensional stability of the slopes in a watershed in Taiwan. To perform Scoops3D it requires the inputs such as digital elevation model (DEM), geological materials, groundwater level, earthquake, etc. The code calculates the minimum factor of safety (F.S.) and the associated potential failure volumes by using three-dimensional limit equilibrium method. We performed a comprehensive analysis of slope stability for the research areas using the Scoops3D code. The ArcMap software was used to present the F.S. that are less than unity as a 2D contoured map. We can observe this contoured map to understand the overall slope stability of the studied watershed. We perform a parametrical study by set three different sizes of sliding volume, “large”, “medium” and “small”, for evaluating the risk of landslide for the three different volume sizes.

Fuzzy Clustering Algorithms for Establishing Landslide Susceptibility Map

*Pei-hsun Tsai[1], Syuan-yi Wang[1], Jie-shin Cheng[1]

1. Chaoyang University of Technology

In recent years, the rainfall distribution is not uniform because of extreme weather events, the occurrence frequency of heavy rain increases. Coupled with steep terrain and complicated geological condition, so that the slope often occurred landslide when typhoon or heavy rain. Landslide susceptibility map delineates the potential zones for landslide occurrence. To develop the landslide model, we used several independent data layers that are recognized as effective factors in landslide occurrence, including slope, aspect, shear strength of rock or soil, dip and dip direction of stratum, and distance to road. All data layers were converted to raster layers with a 30 m ×30 m cell size. A total of 231336 cells were derived in study area. For assessing landslide susceptibility spatially, this study used fuzzy c-means clustering algorithm to classify the aforementioned data set in the study area into six clusters. Each cluster has similar natural environmental conditions and collapse situation. It is helpful to establish the monitoring management system and it can be applied to an early warning system in the landslide. Results of validation show that this model can accurately predict the occurrence of new landslides.

A Study on Landslides and Debris Flows Susceptibility Mapping Using Unmanned Aerial Vehicles

*Sheng-Jia Liu[1]

1. qwepoi13@gmail.com

The geology of Taiwan is generally vulnerable due to the natural adverse conditions such as younger strata, steep topography, active orogeny, frequent seismic activity, weathering and erosion, frequent typhoons, high rainfall, etc. Furthermore, the human factors like immature law and regulations, the weak execution, and improper land use and development also play an important role in reducing the slope stability. These factors to some degree worsen the slope conditions, lead to a more frequent natural disaster and cause the loss of life and property.

In order to effectively evaluate the landslide susceptibility and map the high risk areas, the Soil and Water Conservation Bureau of Taiwan Executive Yuan (SWCB) provides an assessment method for assessing the risk level of landslide susceptibility by selecting the combinations of impact factors that may trigger landslides. However, the accuracy and efficiency of data acquisitions, in a conventional way, for the assessment method are still limited.
With the advantages of UAVs, the digital image with high resolutions for a wider area without terrain restrictions can be obtained efficiently. Its applications have become more widespread, from battlefield detections and communications to forest management and mapping. This study utilizes the latest Dynamic Post-Processing Motion (PPK) positioning system to capture high-resolution image data from a chosen site in the northern part of Taiwan. The terrain information was extracted from aerial images using Pix4Dmapper with aerial triangulation techniques, thus the external direction of each image and the camera's internal direction parameters can be obtained, the point cloud data can be matched automatically, and a digital surface mode can be established. Further, a three-dimensional model with topographic map and landslide susceptibility evaluations can be established and performed by comparing with historical data and monitoring the slope conditions. A modified assessment method is proposed using the three factors (slope, the volume of soil and rock accumulations, and rainfall) to assess the landslide susceptibility of the study area. The evaluations made by the proposed method are in agreement with the SWCB method. The results from this study can be used in slope management and precaution, and rescue and recovery.

Largescale landslide induced by AD1586 Tensho-Earthquake in Gifu Prefecture, central Japan

*Takahiro Kurimoto[1], Yoshihiko Kariya[2], Kuniyasu Mokudai[3], Ryuji Yamada[4], Takashi Kimura[4]

1. Undergraduate Senshu University, 2. Department of Geography, Senshu University, 3. Japan Geoservice Incorporated, 4. National Research Institute for Earth Science and Disaster Resilience

On the basis of field investigation and topographic analysis by using GIS, we clarified the geological and geomorphological features of a large-scale landslide (V=2.2×10^7 m^3) called Mizore Landslide (ML) in Gujo City of Gifu Prefecture, central Japan. According to old documents, it is thought to ML was caused by AD1586 Tensho earthquake (generated from the Shokawa fault zone close to the ML and estimated M=7 to 8). However, there are few studies on geomorphological and geological basis. The main results are as follows: a) The ML holds a set of three head scarps and three landslide bodies both showing multiple activities of slope movement; b) The ML shows unique sedimentological and geomorphological characteristics such as a jigsaw crack structure in landslide deposits and hummocks and depressions upon the ground surface of the landslide bodies; c) Both involved buried soils in the landslide deposits and fossil wood logs in the dammed lake deposits enable us to date the landslide events; d) According to those ^{14}C dates of soils and logs, the latest landslide event is thought to occur in the period from cal AD1436 to 1650; e) The latest landslide event would be triggered by AD1586 Tensho earthquake. AD1596 Keicho-Fushimi earthquake occurred around Kyoto is a candidate event for further consideration.

Failure Probability of Lushan Landslide, Taiwan

*Wei-Ting Lin[1], Kuang-Tsung Chang[1]

1. National Chung Hsing University

The Lushan landslide located in the middle of Taiwan, has slid and damaged the road due to typhoons or heavy rainfalls for recent decades. It’ s seriously affecting the safety of life and property of the Lushan Hot Spring Tourist Area and local residents in the lower slope. In order to understand the probability of failure (Pf) of Lushan landslide, we built a numerical model by Plaxis2D, which is validated by the monitoring data of the 2009 typhoon Morakot. However, due to the lack of complete parameter data, uncertainties exist and may affect the simulation result of the collapse. With the back calculated friction angle (∅) and cohesion (c) from Plaxis2D, we used the Monte Carlo Simulation (MCS) to consider the friction angle and the cohesion of sliding body as random variables with uncertainty. The results are statistically analyzed to obtain the Probability Density Function (PDF) of the two parameters. Based on the parameter settings above, with the designed rainfall events at 24hr, 48hr and 72hr rainfall duration and 10, 25, 50, 100 and 200 years of recurrence interval, we calculate the factor of safety (SF) of the Lushan landslide in these 18 simulated rainfall events. Finally, we can obtain the distribution of factor of safety (SF) and probability of failure (Pf) of the Lushan landslide in different rainfall durations and recurrence intervals.

Keywords: probability of failure, Monte Carlo Simulation, uncertainty

Interpretation of landslide surface deformation in Kali Gandaki River watershed, Nepal using ALOS-2/PALSAR-2 InSAR image

*Hiroshi, P. Sato[1]

1. College of Humanities and Sciences, Nihon University

Previous studies have revealed and mapped glacial landform, fluvial terraces, and landslide landform in Thakkohla-Muktinath region, between Kagbeni and Ghasa along Kali Gandaki River, Nepal. And many attentions were paid to detect landslides that brock channels in the region, especially after Gorkha earthquake (25 Apr 2015; Mw7.8). Therefore, I tried to interpret landslide surface deformation on mountain slopes in Kali Gandaki River watershed after the earthquake, using Synthetic Aperture Radar interferometry (InSAR) image. The number of produced InSAR images was six, which is master image/slave image in order from ALOS-2/PALSAR-2 data, 08Oct2015/17Dec2015, 08Oct2015/30Nov2017, 25Feb2016/06Oct2016, 30Nov2017/24Jan2019, 08Mar2018/24Jan2019 and 31May2018/24Jan2019. In these InSAR images clear precursory landslide surface deformation was not interpreted on mountain slopes facing main stream of Kali Gandaki River. However, whose tributary watershed; i.e., Myagdi River watershed gave some landslide surface deformations (e.g., in 83.3983E, 28.4842N) clearly interpreted in the InSAR image of 08Oct2015/17Dec2015, which was relatively better coherence than the rest five images.

A depth-integrated model for granular flows on the transition of different bed conditions

*Ling-Yi Hsu[1], Chi-Yao Hung[1]

1. National Chung Hsing University

The different basal boundary conditions profoundly affected the flow behavior of debris flow. However, it is hard to have a general and straightforward model to describe the flow profile switching from different bed conditions. In this study, we purpose a new depth-averaged model to simulate the dense granular flow transition between the rigid and mobile bed. The model is based on mass conservation, momentum conservation, and kinetic energy conservation. We apply the linearized mu(I) rheology to describe granular deformation and assume Coulomb friction along the sidewalls. By incorporating the basal shear rate term into the equations, the theory can balance the extra force from rigid bed friction force. To check the model approach, we conducted an equilibrium and non-equilibrium heap flow experiments using the narrow see-saw channel, which can be tilted to different angles between runs or during flows. To compare the experimental results with the theory, the flow fields are monitored using high-speed video and particle-tracking velocimetry.

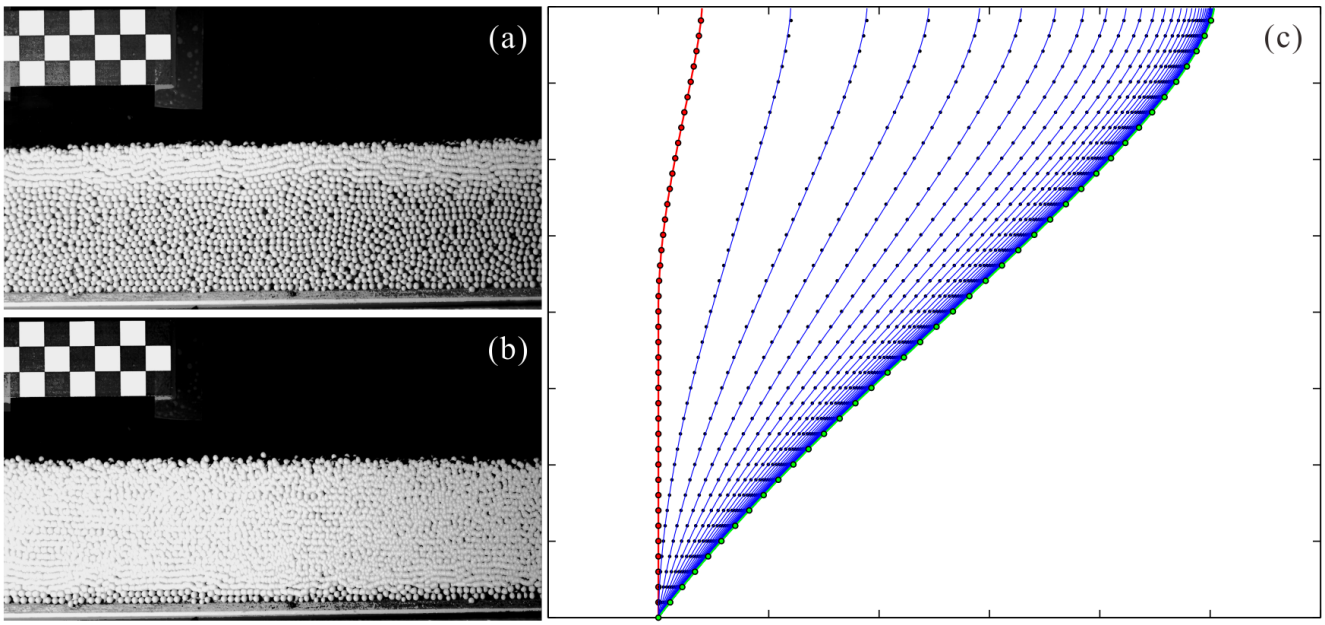

Fig.1 Experimental longexpousre image (a) over deposition bed; (b) over rigid bed; and (c) the transition velocity profile of theory prediction.

A viscous granular flow experiment with new refractive index matching material

*Tsai-Jung Lin[1], Chi-Yao Hung[1]

1. National Chung Hsing University

Entrainment rate at base controls how far the debris flow can travel and how large the debris flow becomes. Flow rheology of Refractive Index Matching (RIM) material are generally limited by the mono-particle properties (such as polymethyl methacrylate/liquid para-cymene etc.). In this study, a new RIM material (polyacrylamide polymer/18% Methanol solution) having a wide range of particle size distribution and viscosity (Fig. 1L) are purposed to visualize and measure the erosion process of mobile bed dam break experiments. Various rheology models may be formed by the different ratio of particle size. To improve the contrast between the particle phase and the liquid phase, a dye is used to make the particles bright under laser illumination. By varying the dye concentration, the entraining/detraining processes are easily distinguished (Fig. 1R). Granular motion is captured through a high-speed camera and Particle Tracking Velocimetry (PTV) method. Finally, an empirical relationship between the rheology and the entraining/ detraining process is developed.

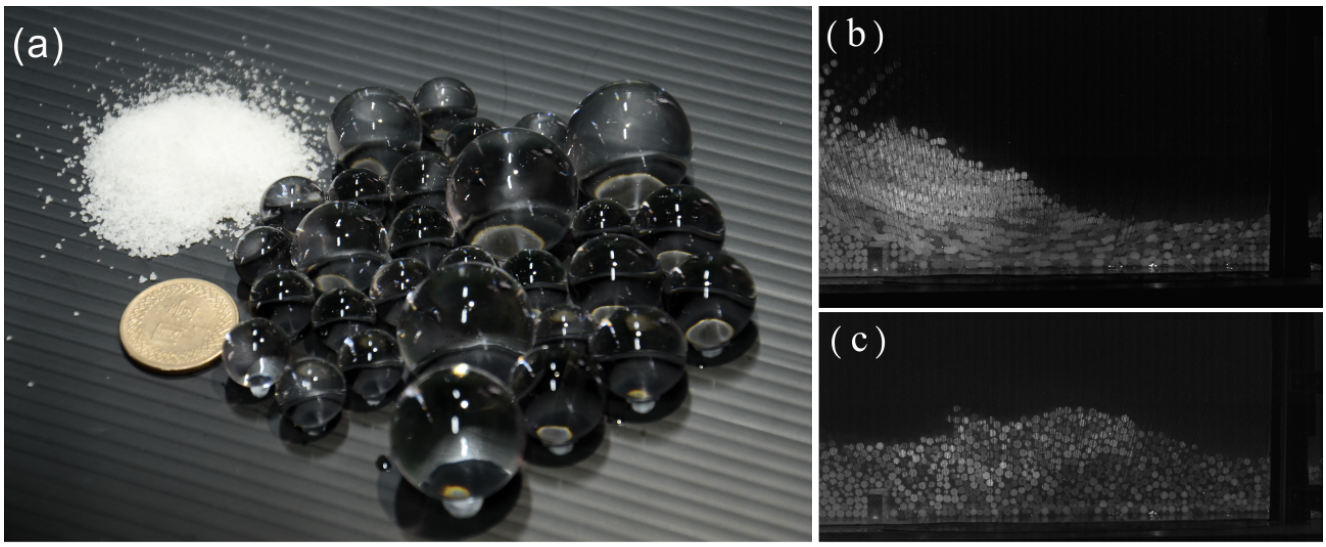

Fig.1 Experimental image (a)wide range of particle size; (b)longexposure image of dam break occurrence; (c)particles with different concentration of dye.

Sandbox experiments of submarine landslide caused by water film in low permeability layer

*Shogo Kawakita[1], Daisuke Asahina[2], Keiji Kitajima[3], Mitsukazu Nakanishi[3]

1. Graduate School of Science & Technology, Nihon Univ., 2. National Institute of Advanced Industrial Science and Technology, 3. College of Science & Technology, Nihon Univ.

Submarine landslides can be serious geohazards since they potentially cause tsunamis and damage seafloor infrastructure. Submarine landslides can be larger in scale than landslides on land. Direct measurements/observations of submarine landslides at deep seafloor still remain a challenging task. Kokusho et al. (2000) proposed a water film effect and its mechanism on lateral flow with less frictional resistance to explain a driving force of large-scale submarine landslides

In this study, we conducted laboratory experiments to understand the relationship between sand liquefaction and lateral flow by water film, and investigate the influence of water film formation on lateral flow of upper layer. In general, it is difficult to observe the formations of liquefaction and lateral flow at the same time. This is because sand particles of sloping layer model start to move when vibration is applied, and inclination disappears before liquefaction. To solve this problem, we devised a mechanism to prevent the flow of the lower layer by providing a weir plate in inside the soil tank. This mechanism enables to distinguish and observe the movement of sand by the liquefaction and the lateral flow by the water film.

The results obtained in this study clearly show three stages: first, the lower layer was liquefied; then pore water was stored below the low permeability layer; and finally, the lateral flow was occurred by the water film effect. The experimental results show that there was no clear correlation between the increase in the angle of sloping layer and the travel distance or the maximum flow velocity. We also discuss the relationship between the layer angle and the location of sand boil. The location where sand soiling occurred moved to the upper side of the slope as the layer angle become larger.

Study on Creep Properties of Sand and Cemented Sand

*JIN-YI YU[1], KUANG-TSUNG CHANG[1]

1. National Chung Hsing University

In this study, we investigated the effects of creep on sand and cemented sand, using triaxial test. Sand represents a non-cohesive material, while cemented sand represents a brittle material. Before the failure of specimens, the deviator stress was fixed and the cyclic mean stress was applied to study the influence of creep on the materials. According to the test results, the axial strain accumulation of sand caused by creep is less, and the peak strength is larger than that of the monotonic loading when the axial loading is resumed. For cemented sand, creep causes microcracks inside the specimens, gradually forming a failure surface. When the axial strain accumulation is large enough, the reapplication of the axial loading shows a reduction of peak strength. We conclude that the influence of creep on non-cohesive material (sand) is limited, whereas creep can reduce the strength of the brittle material (cemented sand) and even cause failure.

Keywords: creep, triaxial test, sand, cemented sand, strength, failure

The effects of seepage force and the Poisson’s ratio on slope stability

*Hirokazu Fukui[1], Tomomi Terajima[2]

1. Graduate school of Science, Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University

To predict accurately the timing of shallow landslide occurrence, we need to consider the direction and magnitude of seepage force and earth pressure. A model sandy slope (L: 9m, W:1m, H:4m) was used to measure the hydraulic gradient and seepage force with the tensiometers under the artificial rainfall of 80mm/h. We incorporated not only the seepage force but also the Poisson’s ratio into conventional slope stability analysis by the limit equilibrium method. As a result, the calculated timing of shallow landslide occurrence was almost agree with the timing of that in the experiment and also more accurate than the timing calculated by the Spenser method which took into account the magnitude and moment equilibrium of the force. These results imply that, based on both monitoring at fields and conducting more experiments by a real-size model slope, we need to verify the effects of seepage force and earth pressure as the important factors causing rainfall-induced slope instability.

Study on the factors of seepage erosion

*Szu-Wei Fu[1], Kuang-Tsung Chang[1]

1. National Chung Hsing University

The causes of many slope disasters are often related to the seepage behaviors of soil. For instance, groundwater seepage may cause internal erosion of the soil. The soil particles are taken away by seepage water to form void or pipe. In addition , the earth pressure leads to the collapse of the overlying soil.

In this study, we designed a set of apparatus that can add confining pressure to the outside of the specimen. In order to simulate the situation of sand in slopes, we investigated the critical seepage velocity of sands caused by seepage erosion failure under different confining pressure, with different particle size distributions, sizes of outflow, etc. Then a failure criterion for seepage erosion is developed based on the drag equation in fluid dynamics and confirm with experimental data.

The results show that the critical seepage velocity at failure is affected by the particle size distributions, sizes of outflow and the confining pressure. The theoretical results are compared well to the experimental data.

Deformation of slope models with different orientations of weak planes

*taeyuan tseng[1], Kuang-Tsung Chang[1]

1. National Chung Hsing University

Weak planes influence failure and deformation of slopes. We conducted experiments to simulate slopes of different orientations of weak planes, including cataclinal and analcinal slopes with 30˚ and 60˚ inclination angles of weak planes. We stacked artificial bricks to make small-sized slope models. The artificial bricks were made of gypsum, sand, cement and water with different weight proportion. In view of the scaling law, the artificial bricks were made less strength than natural rocks. The slope models were weakened under rainfall, resulting in deformation and final collapse. The slope deformation processes were photographed by a camera, and the displacement vector fields were analyzed using the Particle Image Velocimetry (PIV). The deformation and accumulated displacements were compared between slopes of different orientations of weak planes.

Keywords: cataclinal slope, analcinal slopes, rainfall, Particle Image Velocimetry (PIV), weak planes, deformation

Possible submarine landslides as sources of the 2018 Sulawesi tsunami

*Kenji Nakata[1], Akio Katsumata[1], Abdul Muhari[2]

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Ministry of Marine Affairs and Fisheries, Indonesia

Tsunami struck coastal areas of Palu bay, Slawesi Islands after an earthquake of Mw 7.5. Muhari et al. (2018) hypothesized that the tsunami was generated inside the Palu bay based on the evidence of tide gauge station records, videos, inundation distance, damage characteristics from post-tsunami surveys and so on. Furthermore, Arikawa et al. (2018) pointed out that subsidence of coastal areas may have related to tsunami generation, and that the tsunami heights were not high at the mouth of the Palu bay. While Heidarzadeh et al. (2018) reported that the tide gauge records in Palu bay were successfully simulated by the USGS’ s finite fault model, they also pointed out the possibility of the submarine landslide, following extremely large tsunamis. In this study we assumed that the recorded tsunami was caused by a submarine landslide. We investigated the possible locations and size of the submarine landslide that could express the waveform at the tide gauge station and the possibility of the tsunami generation at the shallow depth by tsunami simulations.
Results of tsunami simulation showed that it was necessary that tsunami wave source was at the shallow depth to simulate the observed period of tsunami wave. Calculated tsunami waveforms that closely matches the observed waveform was obtained at three locations in the bay. By calculating the landslide source for several fluidities, we reached a conclution sediments with low fluidity near coastal line was necessary for the landslide source.

Tsunami Data Assimilation of the 2015 Torishima Earthquake

*Yuchen Wang[1], Kenji Satake[1], Osamu Sandanbata[1], Takuto Maeda[2]

1. Earthquake Research Institute, University of Tokyo, 2. Graduate School of Science and Technology, Hirosaki University

The 2015 Torishima earthquake (M5.9) occurred at the Smith caldera, on May 2, 2015. It had a CLVD-type focal mechanism and generated larger tsunami waves compared to its seismic magnitude (Sandanbata et al., 2018). Therefore, it was regarded as a ‘volcanic tsunami earthquake’ –a tsunami earthquake with volcanic origin. The tsunami reached Hachijo Island, Boso Peninsula and Shikoku Island, and were recorded by tide gauges and ocean bottom pressure gauges (Kubota, 2018). Fukao et al. (2018) proposed an opening horizontal sill model to explain its origin. The abnormal mechanism makes it difficult to forecast tsunami from its seismic magnitude.

Tsunami data assimilation forecasts the tsunami by assimilating offshore observed data into a numerical simulation, without the need of calculating the initial sea surface height at the source (Maeda et al., 2015). In the Nankai region, the Dense Oceanfloor Network System for Earthquakes and Tsunamis (DONET) records the water pressure and has real-time data transmission. Synthetic experiments showed that this observational system was able to forecast the waveforms at Shikoku Island by tsunami data assimilation approach (Wang et al., 2018). Here, we performed this method to retroactively forecast the tsunami of the 2015 Torishima earthquake. We assimilated the observations of 16 DONET stations and two ocean bottom gauges off Muroto. The tsunami waveforms at the tide gauges Tosashimizu and Kushimoto were forecasted, and compared with the actual records.

The comparison between forecasted and observed waveforms at two tide gauges suggested that our method could forecast the tsunami amplitudes and arrival time accurately. The tsunami warning could be issued to local residents of Shikoku Island more than one hour before its arrival. Our method is merely based on offshore observations, and could be implemented for future tsunami warning systems.

Method for real-time estimation of tsunami sources using a network of dense ocean bottom pressure sensors

*Mayu Inoue[1], Yuichiro Tanioka[1], Yusuke Yamanaka[2]

1. Hokkaido University, 2. The University of Tokyo

After the 2011 hazardous tsunami, the Seafloor observation network for earthquakes and tsunamis along the Japan Trench (S-net) was installed by National Research Institute for Earth Science and Disaster Resilience in Japan (NIED). Various real-time tsunami-forecast methods using this S-net were developed by several researchers. The objective of this study is to develop a new method for real-time tsunami source estimation using S-net data, a simpler method than the previous methods. This study focuses on tsunami generated by great underthrust earthquakes at the plate interface off the Pacific coast of Hokkaido, Japan. First, we numerically computed tsunamis from fault models of M8.0 to M8.8 classes distributed along the plate interface along the Kurile Trench. Virtual observational waveforms at locations of sensors in S-net during each tsunami were estimated by converting the simulated tsunami waveform into a waveform of water pressure change. We tried to estimate a tsunami source area by classifying the virtual observational waveforms within 500 seconds after the origin time of the earthquake into the following three types. Type1 waveform goes down and stays down within 500 seconds. Type2 waveform includes one complete up-pulse waveform. All of the other waveforms were regarded as Type3. We found that a sensor with the type1 waveform is located in the initial uplifted area, and sensors with the type2 waveform is located not in the area but near the initial uplifted area, and the sensor with the type3 is located far from the initial uplifted area. After the tsunami source area was estimated, the magnitude of the earthquake can be estimated using the scaling relationship between the earthquake fault area and the magnitude of the earthquake. We tested four different scaling relationships suggested by previous studies to find the error of the magnitude estimation. The estimation error was found to be M ±0.08. Finally, this new method was applied to the 1952 Tokachi-oki earthquake and the 1968 Tokachi-oki earthquake source models. The tsunami source area and the magnitude of the earthquake were estimated well for both cases. Therefore, the new method should be useful for the rapid estimation of a tsunami source as a part of the tsunami early warning system.

Application of AI Technology for Tsunami Prediction by Oceanographic Radar

*hiromu yokosu[1], Yoshihito - Tanaka[1], Kenji - hayashi[2], Kentarou - Uehara[2]

1. Chubu Electric Power Co., Inc., 2. Japan Weather Association

At Hamaoka Nuclear Power Station, oceanographic radar (HF radar) is installed to detect the tsunami early.We can observe sea surface velocity distribution up to offshore of about 40 km approximately every minute.When a tsunami occurs, it is expected to capture the situation which the tsunami approaches and to predict the arriving tsunami.

Oceanographic radar observation captures a wide range of flow velocity distribution at once and obtains numerical result.By using the distribution situation of the change of the flow velocity on sea surface by the tsunami, we investigated the tsunami prediction by the image recognition method using AI technology.AlexNet (convolution neural network) was used for the image recognition method.

For the prediction of the tsunami, the tsunami height (first wave) and the arrival time are important, the tsunami height was classified into 1 m interval (tsunami height 10 m or less) or 2 m interval (tsunami height 10 m to 22 m), and the arrival time was classified as one minute interval (1 min to 22 min). The total was classified into 374 categories.Using the image recognition method, we examined the accuracy of the classification based on the observation situation.

In this study, the result of the tsunami simulation exceeding 5000 tsunami caused by the Nankai Trough earthquake which will have the most influence on Hamaoka Nuclear Power Station.Since the number of large-scale tsunami cases is small, we devised such as using data in seconds.Also, since AlexNet can handle color images (RGB), the current flow time change (current time, 1 minute before the current time, 2 minutes before the current time) of three steps in the learning data was applied to R, G, B.As a result, regularity such as time series of flow velocity and position information can be reflected, and the feature of image change (change in flow velocity distribution) became easier to capture.

Although the scale of the tsunami varies, it is important to predict a large-scale tsunami (tsunami height 10 m or more) at Hamaoka Nuclear Power Station, so the result of "Tsunami height 10 m or more" is described here.As for the verification of the AI prediction, the data (verification data) not used for learning data in simulation data was used.The ratio between learning data and verification data was set at about 80% and about 20%.The accuracy rate was about 77%.Regarding time, if one category (arrival time ±1 minute) is permitted, the accuracy rate improves to about 94%.So, it can be said that the error of the tsunami height is smaller than the arrival time with this image recognition method.

Keywords: tsunami prediction, oceanographic radar, AI, AlexNet

Development of the Tsunami Prediction System using fault plane solution of W-phase inversion

*Seolhan You[1], Mikyung Choi[1], Sun-Cheon Park[1], Hye-Won Lee[1], Duk Kee Lee[1]

1. Korea Meteorological Administration

Tsunami is a long-wave caused by earthquakes, submarine volcanoes or coastal landslides. The Korean Peninsula experienced tsunami damage followed by 1983 and 1993 Japan earthquakes. To respond to possible tsunamis in the surrounding seas, the Korea Meteorological Administration has operated tsunami warning system based on tsunami scenario database. Tsunami scenario database was constructed with the results (tsunami height and arrival time) of simulating tsunami assuming virtual earthquakes at each grid point spacing with 0.2˚ interval in surrounding seas of the Korean peninsula(120˚~142˚E, 25˚~45˚N) . Earthquakes were assumed with magnitude 6.0 to 9.0 having intervals of 0.2 on the fault plane which is from known information or which is assumed to generate higher tsunami in the coastal area. Therefore tsunami scenario database has a limitation that does not reflect the characteristics of earthquakes when they actually occur because the fault plane will be different from assumed one.
In this study, we have developed an algorithm for tsunami prediction capable of analyzing fault plane solution using W phase and simulating tsunami using the fault plane information. We tested the performance of the developed algorithm applying into the case of 1993 Japan tsunami. W phase inversion results were as follows: moment magnitude=7.7, depth=25.5km, strike=170.2˚, dip=45.3˚ and rake=77.8˚. As a result of tsunami simulation using the inversion results, the difference between the numerical results (tsunami height and arrival time) and measured data at tide stations was small. Therefore the algorithm for tsunami prediction may be used for tsunami warning as a complement to tsunami scenario database.

Keywords: tsunami, tsunami scenario database, W phase, tsunami prediction system

Can we detect tsunami magnetic signals at on-land observatories prior to tsunami arrivals? : From the perspective of numerical experiments

*Takuto Minami[1], Tungcheng Ho[1], Zhiheng Lin[2], Hiroaki TOH[2]

1. Earthquake Research Institute,The University of Tokyo, 2. Graduate School of Science, Kyoto University

Tsunami flow crossing the geomagnetic field generates electric currents in the ocean and associated secondary magnetic fields due to the electromotive force. This tsunami-generated magnetic (TGM) variations are observable not only at the seafloor (e.g. Toh et al. 2011) but also at on-land magnetic observatories on islands or along coastlines (e.g. Tatehata et al. 2015). Most of the TGM data reported in previous studies are from the seafloor observations since TGM signals are much stronger at the seafloor, which implies that usage of off-shore seafloor magnetic observations is a sensible solution for tsunami early warning. On the other hand, much cheaper on-land magnetic observations may be useful because the vertical component of the TGM field precedes the tsunami arrival by approximately a quarter of the tsunami period in shallow oceans (< ~ 1000 m; Minami et al. 2015). Previous studies have never carefully investigated possibilities of using on-land magnetic data in tsunami early warning, because of the difficulty in evaluating the effect of realistic topography on the TGM variations at on-land observatories.

We conduct three-dimensional simulations of TGM signals to investigate feasibility of using on-land magnetic data for tsunami early warning, with the aid of the finite element simulation code by Minami et al. (2017). This study focuses on three devastating tsunami events in the past, the 1960 Chilean tsunami (Mw 9.5), the 2011 Tohoku tsunami (Mw 9.0), and the 1707 Hoei tsunami (Mw 8.7). For the three tsunamis, we adopt the source models of Ho et al. (2019), Satake et al. (2013), and Furumura et al. (2010), respectively. Although all the three large tsunamis did extensive damage, features of their topographies are distinct from each other. One of the features of coastlines in Tohoku is ria coast, while Nankai area of Japan includes capes and bays. As for Chilean coast for the 1960 event, a straight long coastline is present in the vicinity of Santiago, Chile. We set many virtual magnetic observatories and tide stations along the coastlines and investigate arrival times of tsunamis and TGM signals. In the presentation, we compare the arrival times of tsunamis and TGM signals at each virtual observatory and to discuss feasibility of using on-land TGM signals for tsunami hazard mitigation.

Probability of Tsunami Inundation Estimated from Tsunami Database and G-R law

*Toru Takeda[1], Toshitaka Baba[1], Tsuneo Ohsumi[2], Hiroyuki Fujiwara[2]

1. Tokushima Univ, 2. NIED

Studies on probabilistic hazard assessments considering uncertainties such as the timing and magnitude of earthquake occurrence, diversity of heterogeneous slip, etc. are common in recent years. For tsunami, probabilistic tsunami height assessments along the coast were shown. But probabilistic tsunami inundation assessments are not shown yet because tsunami inundation modeling needs highly resolved topographic data (~10m) and probabilistic approach needs calculations from huge number of earthquake scenarios. Recent development of high-performance computers enables us to make a probabilistic tsunami inundation map if the study area narrowed down. In this study, we attempt to probabilistically assess tsunami inundation in an area of the Nankai subduction zone using a tsunami database and G-R law.

In the creation of the tsunami database, we used the Nankai earthquake slip models shown by Hirata et al. (2017). The propagation and inundation of the tsunami generated by each fault model were carried out by the nonlinear shallow water equations. A nesting algorism was applied to improve the spatial resolution in the study area. Coastal structures such as seawall were defined in the tsunami calculations, but they were disable if the tsunami height is higher than the height of seawall. We defined the relative weights among the earthquake fault models using the G-R law. The weights were used in superimposing of the all inundation maps to estimate probabilities of tsunami inundation.

As a result, it was confirmed that the probability of inundation depends on the topographic features, such as the region where the probability is high in the area end of the V-shaped bay and around the upstream area of the river. We will carry out an analysis that takes into consideration the uncertainty in earthquake occurrence and tsunami height estimations. We also investigate effects of costal structures on the inundation probability.

Keywords: probabilistically assess tsunami inundation, G-R law

The Detection of Tsunami Propagation Path by Using Sensitivity Kernel Distribution

*Norihiko Hashimoto[1], Kyosuke Okamoto[2], Seiji Tsuno[3]

1. ITOCHU Techno-Solutions Corporation, 2. National Institute of Advanced Industrial Science and Technology, 3. Railway Technical Research Institute

Predicting the inundation height and arrival time by tsunami propagation analysis are very important in the tsunami disaster prevention. On the other hand, it is also an important issue to elucidate tsunami propagation path. The tsunami propagation path has been commonly calculated by wave ray method, it has used in combination with the tsunami propagation analysis based on linear long wave theory and, shallow water theory. However, in the wave ray method, it’ s difficult to set an appropriate initial value and boundary conditions consistent with tsunami propagation analysis. So we must pay attention these characteristics in considering the analysis result.
Anyway, applying the sensitivity kernel distribution and adjoint field which used in seismic tomography to the tsunami wave field, we investigated the tsunami propagation path. In this method, it is also possible to detect a propagation path of the specific component extracted from a tsunami waveform by adding a routine for propagating a tsunami waveform in the reverse direction to the general tsunami propagation analysis code.
First, we verified this method whether it is possible to detect tsunami propagation path to the observed point in the ideal space. It was assumed water of constant depth and Gaussian distribution as an initial water level.
In addition, we used this method to detect how the far-field tsunami propagate to the Japan coast. We set the calculation target range that can be covered almost whole Pacific Ocean area whose mesh size is 10 sec, the wave source was the 1960 Chilean tsunami. Analyzing characteristics of tsunami is propagated which comes from Hawaiian island across the north-south, we confirmed the result as same as previous method by wave ray method.
An issue in the future, it’ s necessary to consider a practical method to extract and propagate specific components of the tsunami waveform, and verify the possibility of applying this method for the tsunami propagation analysis based on dispersive wave theory and shallow water theory. It is thought that they will be expanded the range of application.

Estimation of local seismic waves and rapid magnitudes for ‘slow tsunami earthquakes’ based on moment rate spectrum

*Takahito Nishimiya[1], Akio Katsumata[1]

1. Meteorological Research Institute, Japan Meteorological Agency

The tsunami height estimation at earliest stage in JMA is based on the estimated hypocenter and rapid magnitude (rapid-M) from local seismic wave data. The amplitudes of seismic waves from ‘slow tsunami earthquakes’ are usually smaller than those from normal earthquakes because those earthquakes radiate relatively low seismic energies in the short period range. Therefore it is difficult to estimate rapid-M of ‘slow tsunami earthquakes’ accurately. We would like to evaluate rapid-M of them quantitatively. However local seismic wave data of slow tsunami earthquakes is almost not available.

We estimated moment rate spectra of ‘slow tsunami earthquakes’ using tele-seismic wave data (in JpGU Meeting 2018), and calculated synthetic local seismic waves based on those spectra (in Seismological Society Fall Meeting 2018). We estimated rapid-M from the synthetic wave data here.

JMA magnitude (M_J) and M_{100} (Katsumata et al., 2013) are evaluated as the rapid-M. M_{100} is introduced by JMA to avoid underestimation of magnitude for huge earthquakes because M_J tends to indicate “magnitude saturation” for huge earthquakes. We calculated M_J and M_{100} from the synthetic wave data. REGARD (Kawamoto, 2017) based on GNSS data is also a kind of rapid-M. However we use seismic wave data from which smaller magnitude can be estimated compared with REGARD.

We assumed that a ‘slow tsunami earthquake’ occurs at the plate-boundary off the Pacific coast of Tohoku. It has the same moment rate spectrum as the Java tsunami earthquake (M_w7.8) in 1994. M_J estimated from those synthetic waves was smaller than M_w by more than 1.0. M_{100} is larger than M_J, but M_{100} is smaller than M_w by more than 0.5. We also evaluated magnitudes for an earthquake which has the same moment rate spectrum as the Sumatera tsunami earthquake (M_w7.8) in 2010. The difference from M_w reduced for the earthquake, while both M_J and M_{100} are lower than M_w.
USGS published M_s of significant earthquakes. M_s of the 1994 Java earthquake was lower than M_w by more than 0.5 although M_s of the 2010 Sumatera earthquake was about the same as M_w.

Our results suggest that big difference between M_{100} and M_J is useful for early discriminating ‘slow tsunami earthquakes’ from normal earthquakes. Even if M_{100} is much greater than M_J, M_{100} may be underestimated for slow tsunami earthquakes.

Development of tsunami simulator TNS and release of version 1.0

*Takayuki Miyoshi[1], Wataru Suzuki[1], Naotaka YAMAMOTO CHIKASADA[1], Shin Aoi[1], Sho Akagi[2], Toshihiko Hayakawa[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Mitsubishi Space Software Co.,Ltd.

A tsunami is a natural phenomenon in which disturbance generated in the sea by abrupt submarine deformation, propagates to the surrounding sea area with the gravity as restoring force, and often runs up to the land area. The National Research Institute for Earth Science and Disaster Resilience (NIED) has developed a software that can calculate a tsunami phenomenon including inundation on a computer by numerical simulation using finite-difference method (Miyoshi et al., 2018 JpGU). The software was named Tsunami Simulator (TNS: TsuNami Simulator).

Numerical codes of the TNS was developed to operate on the Central Processing Unit (CPU) and the Graphics Processing Unit (GPU), the main code of the CPU written in Fortran 90 and the GPU written in CUDA C in accordance with CUDA 7.5. The concept of the codes is basically equivalent to TUNAMI-N2 (Imamura et al., 2006), and tsunami propagation and inundation based on two-dimensional nonlinear long wave theory can be implemented using a nesting grid with a space grid ratio of 1: 3 in the Cartesian coordinate system. The initial wave height is calculated by the crustal movement in the semi-infinite medium with respect to a fault plane using the program DC3D (Okada, 1992 BSSA). Horizontal crustal movement (Tanioka and Satake, 1996 GRL) and hydraulic filters by Kajiura (1963, BERI) are also applicable. In the offshore boundary, the transmission boundary (Imamura et al., 2006) and the absorb area (e.g. Clayton et al., 1977 BSSA) are applied, and inundation boundary is used in the land side (Kotani et al., 1998 Coastal Engineering Journal). For distant tsunamis, a spherical coordinate system is introduced and connects to the region in the Cartesian coordinate where inundation simulation is carried out. In the spherical coordinate, Coriolis force and dispersion effect can be considered as the previous study, and loading effect (Inazu and Saito, 2013 EPS) can also be applied.

Real-time tsunami inundation forecast system using numerical database requires a large amount of tsunami scenario. From the TNS development version, we packaged the essential parts for constructing a tsunami scenario bank and released as TNS Version 1.0 (Miyoshi et al., 2019 Technical Note of the NIED). The users are assumed to be researchers, engineers, officers of local governments who is responsible for disaster prevention, and make it possible to calculate on the general Linux environment. The package included an operation guide, executable files precompiled on Linux, and some examples. The solver can conduct sequential computation by single CPU, and can conduct parallel computation using OpenMP, and the general-purpose computing on graphics processing units (GPGPU) in order to achieve reduction of calculation time.

A Study on Tsunami Inundation Simulation for the Nankai Trough Earthquake for Osaka City

*Kaoru Kawaji[1], Seiji Tsuno[2]

1. ITOCHU Techno-Solutions Corporation, 2. Railway Technical Research Institute

In planning disaster prevention measure against the tsunami, it is a very important factor how will the tsunami occur by occurrence of an earthquake and how it will attack. Since the Scenario of the Nankai Trough fault seismic source model was announced from the Cabinet Office as the maximum assumed wave source , various local governments and others are considering various disaster prevention measures and others. In this research, we carried out the tsunami inundation simulation for Osaka City using all 11 case fault models of the Nankai Trough's large earthquake model study meeting (2nd report) announced by the Cabinet Office in August 2012 , and examined the results.

Topographical model in tsunami inundation simulation was using topographic data published by the Cabinet Office, and we modeled with a 1215m grid about range of 1200km ×800km including from the fault to the coast. The calculation time was set to a maximum of 6 hours so that the maximum inundation area and the maximum inundation depth due to the tsunami could be calculated, and the calculation time interval was set to 0.01 second interval so that the calculation was stable.

If the parameters (slip angle, position, epicenter) etc in the fault seismic source model are different, the tsunami characteristics such as the tsunami wave height, the arrival time of the tsunami and the inundation range of tsunami should be different. However, it was different that the location of the large slip region and the epicenter in the fault model of 11 cases, but almost the same tsunami level and arrival time were found in the observation points in Osaka Bay in all cases. It was also found that the maximum wave height appearance time is within 30 minutes from the start of rupture regardless of the case. This trend can be seen similarly in the vicinity of the Kii Channel, off the coast of Osaka Bay, and this trend is thought to be the influence of the topographic of the intricate straits sandwiched between Kii Peninsula and Kochi / Kagawa. We will continue further multilateral investigation in the future and report on the results as well.

Database construction of Tsunami inundation simulation for large subduction earthquakes

*Mariko Korenaga[1], Seiji Tsuno[2], Kaoru Kawaji[1]

1. ITOCHU Techno-Solutions Corporation, 2. Railway Technical Research Institute

In the area facing the Nankai Trough, the danger of the tsunami caused by the large subduction earthquake is an urgent task. Because the earthquake occurrence area is too close, it is very important to grasp the possibility of inundation in advance, not after the earthquake occurred.

Therefore, from the viewpoint of tsunami protection against railway structures, databases of tsunami height near the coast and tsunami inundation zones were created, assuming a large number of scenario earthquakes for specific cities on the Pacific coast. Using this result we will investigate the risk of risk assessment due to the maximum inundation area and the delay time of evacuation compared to the coastal prediction results.

Coastal tsunami height tends to increase when large slip regions and super large slip regions exist in front of the coastline in each target area, but the spread of the inundation area is also related to the position in the dip direction of the large slip region. We would like to discuss what kind of information is important for mitigating tsunami damage from the standpoint of railroad disaster prevention while quantitatively examining the various inundated areas obtained.

Sediment Transport Modeling due to Tsunamis caused by the Nankai great earthquakes

*Takuya Saito[1], Kei Yamashita[2], Toshitaka Baba[1]

1. Tokushima Univ., 2. Tohoku Univ.

Tsunami that comes to the area in shallow water causes massive erosion and deposition of the coastal area. This causes damage such as collapse of coastal structures, burial of routes and blockage of water intakes at power stations. In the 2011 Tohoku Region Pacific Offshore Earthquake, collapses of coastal levees and burial of routes were caused by scouring. Damage caused by sediment transport will be prolonged, affecting recovery activities after the disaster. On the other hand, for disaster mitigations, it is necessary to accurately investigate the earthquakes and tsunamis back to the past as much as possible in order to estimate the maximum size of the earthquake and tsunami. Tsunami sediments are important information in studies of the historical earthquakes. Therefore, we simulated sediment transport using a numerical model developed by Takahashi et al. (1999, 2000, and 2011) for the great Nankai earthquakes.

The first study area is Tachibana-Bay classified as an important port having the rias coast in Shikoku, the southwestern Japan. In the simulation results, erosions were predicted in the straits between the islands, at the tip of the cape, near the estuary of the river and near the coastal levees. Sediment depositions were predicted in the vicinity. The maximum changes in erosion and sediment were about 10 m, about 6 m, respectively, for the great Nankai earthquakes (Mw 9.1). These were about 6 m and about 2 m, respectively, for the 1707 Hoei earthquake.

The other study area is a pond near the Cape Kamoda where tsunami sediment was found in the sediment layer about 2000 years ago (Okamura et al, 2012). However, all simulations we conducted in this study did not deposit sediment into the pond.

Acknowledgments: We thank Dr. Takahashi for providing us with the sediment transport software. This research is supported by Grant-in-Aid for Scientific Research 15H05718.

Tsunami model of the 2011 Tohoku Earthquake reproducing the wave gauge record offshore the Fukushima Daiichi NPP

*Toshimichi Kaneto[1], Ayumi Nishi[2], Tadashi Annaka[2]

1. Tokyo Electric Power Company Holdings,Inc, 2. Tokyo Electric Power Services Co,Ltd

1. Objectives of research
During the 2011 off the Pacific coast of Tohoku Earthquake, severe core damage accidents occurred in unit one, two and three in Fukushima Daiichi nuclear power plant due to the failure of core cooling after the reactor shutdown. For understanding the process of tsunami caused by the earthquake and for utilizing tsunami evaluation at the nuclear power plants, tsunami source model, L67, of the 2011 Tohoku Earthquake was determined based on the data of the tsunami waves, crustal deformation and run-up height.
Although the model L67 can simulate the first tsunami and the first crest of the secondary tsunami of wave gauge record offshore the Fukushima Daiichi NPP, it cannot reproduce the second crest of the secondary tsunami. Imamura et al. (2016) proposed the revised model of Sugino et al. (2013) which reproduce the second crest of the secondary tsunami. In this research we improve the reproducibility of the wave gauge record based on the following approach.

2. Contents of research
(1) Joint inversion of tsunami wave and 1-second sampling GPS data
For developing the model L67, we took the consideration of the problem that the slip process of the previous tsunami source models such as Cabinet office (2012), Sugino et al. (2013) and Satake et al. (2013), has long duration compared with those of models based on earthquake ground motion data and that of 1-second sampling GPS data by Geospatial Information Authority, Japan. In order to resolve this problem we used the short time window for inversion as 30 sec times 3. Consequently the slip process of the model L67 has shorter duration compared with the above tsunami source models.
In this research we conducted the joint inversion using tsunami wave and 1-second sampling GPS data. It seems that the duration of slip process will become naturally shorter by using the 1-second sampling GPS data.

(2) Inversion using “hypothetical tsunami records”
Non-linear effect is strong in the wave gauge record offshore the Fukushima Daiichi NPP. So we can use only initial portion of the record for the linear inversion. In order to improve the reproducibility of the wave gauge record, “a hypothetical tsunami record” at the depth of 50 m offshore the Fukushima Daiichi NPP was simulated using the initial fault model and the green functions and the adjusted hypothetical tsunami record was added to the inversion as observed record. The calculated tsunami wave became similar to the wave gauge record through a trial and error process.
The same approach was used for improving the K and kappa for the run-up height data.

3. Conclusions
The tsunami source model of the 2011 Tohoku Earthquake reproducing the wave gauge record offshore the Fukushima Daiichi NPP was determined based on the above inversion approach. The duration of slip process became naturally shorter by using the 1-second sampling GPS data. The reproducibility of the wave gauge record was much improved compared with the model L67 by using the “hypothetical tsunami record”. Goodness of fit for tsunami wave and run-up height is same as that for model L67.

Development of tsunami fragility curves on railway structures based on the 2011 off the Pacific coast of Tohoku earthquake

*Teppei Ono[1], Seiji Tsuno[2], Yuko Sato[2], Marioko Korenaga[1]

1. ITOCHU Techno-Solutions Corporation, 2. Railway Technical Research Institute

The Great Tsunami associated with the 2011 off the Pacific coast of Tohoku earthquake caused severe damage to railway structures on the coast of the Tohoku region in Japan. It is effective to obtain fragility curve from damaged data in this disaster to predict the risks of railway structures to the tsunami in the future. It is generally represented by a lognormal distribution or a normal distribution. In this study, we obtained fragility curve by integrating spatial damage data for railway structures and spatial inundation data accompanying the 2011 off the Pacific coast of Tohoku earthquake on GIS. The method of obtaining tsunami fragility curves were referred to Koshimura et al. (2009).
In this study, we collected the data of damage and location for railway structures located in the Tohoku region to refer multiple documents. First, the data of inundation depth at intervals of 100 meters of the 2011 off the Pacific coast of Tohoku earthquake published by the Ministry of Land, Infrastructure and Transport was utilized to grasp the inundation depth where the railway structure is located. Second, we used the railway data of MLIT and Geospatial Information Authority to grasp the location of the railway structure. The kinds of structure in railway structures are different from station, bridge, tunnel, railway crossing, roadbed, retaining wall, cage, embankments, cuts and so on. The kinds of material in railway structures are also such as soil, C, RC. The tsunami fragility curves were obtained by using the all data and the case of using only RC to consider the influence of the structural kind.
As a result, it was shown that the gradient of tsunami fragility curve becomes smaller as compared with the tsunami fragility curve for buildings in the 2011 off the Pacific coast of Tohoku earthquake shown at Koshimura and Gokon (2012). The reason is to obtain the tsunami fragility curve from various railway structures. Furthermore, tsunami damage probability for railway structure on Ishinomaki in Miyagi Prefecture and Shimanokoshi in Iwate Prefecture were shown to confirm the reproducibility of the obtained tsunami fragility curve by using the spatial inundation depth calculated by using the Cabinet Office model.

The characteristic of the cause of death in each city in Miyagi prefecture during the Great East Japan Earthquake

*Shuji SETO[1], Fumihiko IMAMURA[1]

1. IRIDeS, Tohoku University

About 20,000 people died in the Great East Japan Earthquake tsunami that occurred in 2011. According to the National Police Agency (2012), 90% of the victims in Iwate, Miyagi and Fukushima prefectures were drowned. Aoki et al. (2012) reported the results of questionnaires to physicians who actually examined in the affected areas. The questionnaire result showed that the National Police Agency's cause of death statistical result was reasonable, and that some physicians could not but describe it as drowning as a realistic problem.

This suggests that victims in a tsunami disaster may diefromcause of death other than drowning. According to Kahoku Shimpo(2011), the survivors witnessed the victims who died of symptoms like hypothermia after exposure to the tsunami. However, the details of the cause of death excluding drowning has not been elucidated yet.

Seto and Imamura(2019) classified the causes of death in Miyagi Prefecture during the 2011 Great East Japan Earthquake tsunami using victim information provided by Miyagi Prefecture Police Headquarters. As a result,the cause of death was classified into the following 12 kinds; Injuries to the head, Injuries to the neck, Injuries to the thorax, traumatic shock, Unspecified multiple injuries, Asphyxiation, Drowning, death due to fire, Hypothermia, Heart disease, Othrers and Unknown. And, they showed the proportion of each cause of death in Miyagi prefecture. The proportion in each city are needed to clarify the casualty in the Great East Japan Earthquake in more detail.

In this study, wecarried outthe analysis using the address data in victim information provided by Miyagi Prefecture Police Headquarters. The data are resident address and bodies found location. Combining each address data and the above 12 kinds of cause of death, we showed characteristics of each cause of death in each city in Miyagi prefecture.

The reflective south going current, accompanied by the third wave of Tsunammi at Iioka , Asahi City , Chiba Prefecture in 2011.

*Mitsuo Harukawa[1], Noboru Hashimoto[1], Fumio Ooshima[1]

1. The Group of Recording for Tsunami Damage of Asahi City in 2011

Shortly after the third wave of tsunami had gone to the north, Iioka was attacked abruptly by the south going current, which caused the disaster. The question is why the south going current occurred. The purpose of this thesis is to explain this issue.
After the disaster, we soon began to visit all the houses along the coast of Asahi City for interviews, and gathered about 650 personal experiences and eyewitness accounts. We found some of them very important. The summary is as follows.
When the third wave of tsunami reached the north coast of Iioka , it was reflected slightly eastward . Then the reflected current went down south along the seawall of west coast of Iioka. After a while, the south going current ran against the succeeding north going current that belonged to the third wave of tsunami. As a result of that collision, the wave height of south going current was increased so much that the wave got over the seawall and destroyed the houses from north to south.
By oblique mono photogrammetry, we calculated the strikes of the wave planes of south going current, and made a wave plane map, which we think proves the eyewitness accounts mentioned above to be right.
A TV program said that *the south going current was the edge wave of the first wave of tsunami*(April 9,2014 FNN), but we don't think it is the case. After the first wave of tsunami had gone, the tidal wave went far off the shore, leaving no seawater along the north coast of Iioka. The large area of the sea floor was visible. It is clear that no edge wave of the first wave stayed there.
Conclusion The south going current was not the edge wave of the first wave of tsunami. It was the reflective current of the third wave of tsunami.

Possible submarine landslides as sources of the 2018 Sulawesi tsunami

*Kenji Nakata[1], Akio Katsumata[1], Abdul Muhari[2]

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Ministry of Marine Affairs and Fisheries, Indonesia

Tsunami struck coastal areas of Palu bay, Slawesi Islands after an earthquake of Mw 7.5. Muhari et al. (2018) hypothesized that the tsunami was generated inside the Palu bay based on the evidence of tide gauge station records, videos, inundation distance, damage characteristics from post-tsunami surveys and so on. Furthermore, Arikawa et al. (2018) pointed out that subsidence of coastal areas may have related to tsunami generation, and that the tsunami heights were not high at the mouth of the Palu bay. While Heidarzadeh et al. (2018) reported that the tide gauge records in Palu bay were successfully simulated by the USGS’ s finite fault model, they also pointed out the possibility of the submarine landslide, following extremely large tsunamis. In this study we assumed that the recorded tsunami was caused by a submarine landslide. We investigated the possible locations and size of the submarine landslide that could express the waveform at the tide gauge station and the possibility of the tsunami generation at the shallow depth by tsunami simulations.
Results of tsunami simulation showed that it was necessary that tsunami wave source was at the shallow depth to simulate the observed period of tsunami wave. Calculated tsunami waveforms that closely matches the observed waveform was obtained at three locations in the bay. By calculating the landslide source for several fluidities, we reached a conclution sediments with low fluidity near coastal line was necessary for the landslide source.

Tsunami Data Assimilation of the 2015 Torishima Earthquake

*Yuchen Wang[1], Kenji Satake[1], Osamu Sandanbata[1], Takuto Maeda[2]

1. Earthquake Research Institute, University of Tokyo, 2. Graduate School of Science and Technology, Hirosaki University

The 2015 Torishima earthquake (M5.9) occurred at the Smith caldera, on May 2, 2015. It had a CLVD-type focal mechanism and generated larger tsunami waves compared to its seismic magnitude (Sandanbata et al., 2018). Therefore, it was regarded as a ‘volcanic tsunami earthquake’ –a tsunami earthquake with volcanic origin. The tsunami reached Hachijo Island, Boso Peninsula and Shikoku Island, and were recorded by tide gauges and ocean bottom pressure gauges (Kubota, 2018). Fukao et al. (2018) proposed an opening horizontal sill model to explain its origin. The abnormal mechanism makes it difficult to forecast tsunami from its seismic magnitude.

Tsunami data assimilation forecasts the tsunami by assimilating offshore observed data into a numerical simulation, without the need of calculating the initial sea surface height at the source (Maeda et al., 2015). In the Nankai region, the Dense Oceanfloor Network System for Earthquakes and Tsunamis (DONET) records the water pressure and has real-time data transmission. Synthetic experiments showed that this observational system was able to forecast the waveforms at Shikoku Island by tsunami data assimilation approach (Wang et al., 2018). Here, we performed this method to retroactively forecast the tsunami of the 2015 Torishima earthquake. We assimilated the observations of 16 DONET stations and two ocean bottom gauges off Muroto. The tsunami waveforms at the tide gauges Tosashimizu and Kushimoto were forecasted, and compared with the actual records.

The comparison between forecasted and observed waveforms at two tide gauges suggested that our method could forecast the tsunami amplitudes and arrival time accurately. The tsunami warning could be issued to local residents of Shikoku Island more than one hour before its arrival. Our method is merely based on offshore observations, and could be implemented for future tsunami warning systems.

Method for real-time estimation of tsunami sources using a network of dense ocean bottom pressure sensors

*Mayu Inoue[1], Yuichiro Tanioka[1], Yusuke Yamanaka[2]

1. Hokkaido University, 2. The University of Tokyo

After the 2011 hazardous tsunami, the Seafloor observation network for earthquakes and tsunamis along the Japan Trench (S-net) was installed by National Research Institute for Earth Science and Disaster Resilience in Japan (NIED). Various real-time tsunami-forecast methods using this S-net were developed by several researchers. The objective of this study is to develop a new method for real-time tsunami source estimation using S-net data, a simpler method than the previous methods. This study focuses on tsunami generated by great underthrust earthquakes at the plate interface off the Pacific coast of Hokkaido, Japan. First, we numerically computed tsunamis from fault models of M8.0 to M8.8 classes distributed along the plate interface along the Kurile Trench. Virtual observational waveforms at locations of sensors in S-net during each tsunami were estimated by converting the simulated tsunami waveform into a waveform of water pressure change. We tried to estimate a tsunami source area by classifying the virtual observational waveforms within 500 seconds after the origin time of the earthquake into the following three types. Type1 waveform goes down and stays down within 500 seconds. Type2 waveform includes one complete up-pulse waveform. All of the other waveforms were regarded as Type3. We found that a sensor with the type1 waveform is located in the initial uplifted area, and sensors with the type2 waveform is located not in the area but near the initial uplifted area, and the sensor with the type3 is located far from the initial uplifted area. After the tsunami source area was estimated, the magnitude of the earthquake can be estimated using the scaling relationship between the earthquake fault area and the magnitude of the earthquake. We tested four different scaling relationships suggested by previous studies to find the error of the magnitude estimation. The estimation error was found to be M ±0.08. Finally, this new method was applied to the 1952 Tokachi-oki earthquake and the 1968 Tokachi-oki earthquake source models. The tsunami source area and the magnitude of the earthquake were estimated well for both cases. Therefore, the new method should be useful for the rapid estimation of a tsunami source as a part of the tsunami early warning system.

Application of AI Technology for Tsunami Prediction by Oceanographic Radar

*hiromu yokosu[1], Yoshihito - Tanaka[1], Kenji - hayashi[2], Kentarou - Uehara[2]

1. Chubu Electric Power Co., Inc., 2. Japan Weather Association

At Hamaoka Nuclear Power Station, oceanographic radar (HF radar) is installed to detect the tsunami early.We can observe sea surface velocity distribution up to offshore of about 40 km approximately every minute.When a tsunami occurs, it is expected to capture the situation which the tsunami approaches and to predict the arriving tsunami.

Oceanographic radar observation captures a wide range of flow velocity distribution at once and obtains numerical result.By using the distribution situation of the change of the flow velocity on sea surface by the tsunami, we investigated the tsunami prediction by the image recognition method using AI technology.AlexNet (convolution neural network) was used for the image recognition method.

For the prediction of the tsunami, the tsunami height (first wave) and the arrival time are important, the tsunami height was classified into 1 m interval (tsunami height 10 m or less) or 2 m interval (tsunami height 10 m to 22 m), and the arrival time was classified as one minute interval (1 min to 22 min). The total was classified into 374 categories.Using the image recognition method, we examined the accuracy of the classification based on the observation situation.

In this study, the result of the tsunami simulation exceeding 5000 tsunami caused by the Nankai Trough earthquake which will have the most influence on Hamaoka Nuclear Power Station.Since the number of large-scale tsunami cases is small, we devised such as using data in seconds.Also, since AlexNet can handle color images (RGB), the current flow time change (current time, 1 minute before the current time, 2 minutes before the current time) of three steps in the learning data was applied to R, G, B.As a result, regularity such as time series of flow velocity and position information can be reflected, and the feature of image change (change in flow velocity distribution) became easier to capture.

Although the scale of the tsunami varies, it is important to predict a large-scale tsunami (tsunami height 10 m or more) at Hamaoka Nuclear Power Station, so the result of "Tsunami height 10 m or more" is described here.As for the verification of the AI prediction, the data (verification data) not used for learning data in simulation data was used.The ratio between learning data and verification data was set at about 80% and about 20%.The accuracy rate was about 77%.Regarding time, if one category (arrival time ±1 minute) is permitted, the accuracy rate improves to about 94%.So, it can be said that the error of the tsunami height is smaller than the arrival time with this image recognition method.

Development of the Tsunami Prediction System using fault plane solution of W-phase inversion

*Seolhan You[1], Mikyung Choi[1], Sun-Cheon Park[1], Hye-Won Lee[1], Duk Kee Lee[1]

1. Korea Meteorological Administration

Tsunami is a long-wave caused by earthquakes, submarine volcanoes or coastal landslides. The Korean Peninsula experienced tsunami damage followed by 1983 and 1993 Japan earthquakes. To respond to possible tsunamis in the surrounding seas, the Korea Meteorological Administration has operated tsunami warning system based on tsunami scenario database. Tsunami scenario database was constructed with the results (tsunami height and arrival time) of simulating tsunami assuming virtual earthquakes at each grid point spacing with 0.2˚ interval in surrounding seas of the Korean peninsula(120˚~142˚E, 25˚~45˚N) . Earthquakes were assumed with magnitude 6.0 to 9.0 having intervals of 0.2 on the fault plane which is from known information or which is assumed to generate higher tsunami in the coastal area. Therefore tsunami scenario database has a limitation that does not reflect the characteristics of earthquakes when they actually occur because the fault plane will be different from assumed one.
In this study, we have developed an algorithm for tsunami prediction capable of analyzing fault plane solution using W phase and simulating tsunami using the fault plane information. We tested the performance of the developed algorithm applying into the case of 1993 Japan tsunami. W phase inversion results were as follows: moment magnitude=7.7, depth=25.5km, strike=170.2˚, dip=45.3˚ and rake=77.8˚. As a result of tsunami simulation using the inversion results, the difference between the numerical results (tsunami height and arrival time) and measured data at tide stations was small. Therefore the algorithm for tsunami prediction may be used for tsunami warning as a complement to tsunami scenario database.

Can we detect tsunami magnetic signals at on-land observatories prior to tsunami arrivals? : From the perspective of numerical experiments

*Takuto Minami[1], Tungcheng Ho[1], Zhiheng Lin[2], Hiroaki TOH[2]

1. Earthquake Research Institute,The University of Tokyo, 2. Graduate School of Science, Kyoto University

Tsunami flow crossing the geomagnetic field generates electric currents in the ocean and associated secondary magnetic fields due to the electromotive force. This tsunami-generated magnetic (TGM) variations are observable not only at the seafloor (e.g. Toh et al. 2011) but also at on-land magnetic observatories on islands or along coastlines (e.g. Tatehata et al. 2015). Most of the TGM data reported in previous studies are from the seafloor observations since TGM signals are much stronger at the seafloor, which implies that usage of off-shore seafloor magnetic observations is a sensible solution for tsunami early warning. On the other hand, much cheaper on-land magnetic observations may be useful because the vertical component of the TGM field precedes the tsunami arrival by approximately a quarter of the tsunami period in shallow oceans (< ~ 1000 m; Minami et al. 2015). Previous studies have never carefully investigated possibilities of using on-land magnetic data in tsunami early warning, because of the difficulty in evaluating the effect of realistic topography on the TGM variations at on-land observatories.

We conduct three-dimensional simulations of TGM signals to investigate feasibility of using on-land magnetic data for tsunami early warning, with the aid of the finite element simulation code by Minami et al. (2017). This study focuses on three devastating tsunami events in the past, the 1960 Chilean tsunami (Mw 9.5), the 2011 Tohoku tsunami (Mw 9.0), and the 1707 Hoei tsunami (Mw 8.7). For the three tsunamis, we adopt the source models of Ho et al. (2019), Satake et al. (2013), and Furumura et al. (2010), respectively. Although all the three large tsunamis did extensive damage, features of their topographies are distinct from each other. One of the features of coastlines in Tohoku is ria coast, while Nankai area of Japan includes capes and bays. As for Chilean coast for the 1960 event, a straight long coastline is present in the vicinity of Santiago, Chile. We set many virtual magnetic observatories and tide stations along the coastlines and investigate arrival times of tsunamis and TGM signals. In the presentation, we compare the arrival times of tsunamis and TGM signals at each virtual observatory and to discuss feasibility of using on-land TGM signals for tsunami hazard mitigation.

Probability of Tsunami Inundation Estimated from Tsunami Database and G-R law

*Toru Takeda[1], Toshitaka Baba[1], Tsuneo Ohsumi[2], Hiroyuki Fujiwara[2]

1. Tokushima Univ, 2. NIED

Studies on probabilistic hazard assessments considering uncertainties such as the timing and magnitude of earthquake occurrence, diversity of heterogeneous slip, etc. are common in recent years. For tsunami, probabilistic tsunami height assessments along the coast were shown. But probabilistic tsunami inundation assessments are not shown yet because tsunami inundation modeling needs highly resolved topographic data (~10m) and probabilistic approach needs calculations from huge number of earthquake scenarios. Recent development of high-performance computers enables us to make a probabilistic tsunami inundation map if the study area narrowed down. In this study, we attempt to probabilistically assess tsunami inundation in an area of the Nankai subduction zone using a tsunami database and G-R law.

In the creation of the tsunami database, we used the Nankai earthquake slip models shown by Hirata et al. (2017). The propagation and inundation of the tsunami generated by each fault model were carried out by the nonlinear shallow water equations. A nesting algorism was applied to improve the spatial resolution in the study area. Coastal structures such as seawall were defined in the tsunami calculations, but they were disable if the tsunami height is higher than the height of seawall. We defined the relative weights among the earthquake fault models using the G-R law. The weights were used in superimposing of the all inundation maps to estimate probabilities of tsunami inundation.

As a result, it was confirmed that the probability of inundation depends on the topographic features, such as the region where the probability is high in the area end of the V-shaped bay and around the upstream area of the river. We will carry out an analysis that takes into consideration the uncertainty in earthquake occurrence and tsunami height estimations. We also investigate effects of costal structures on the inundation probability.

The Detection of Tsunami Propagation Path by Using Sensitivity Kernel Distribution

*Norihiko Hashimoto[1], Kyosuke Okamoto[2], Seiji Tsuno[3]

1. ITOCHU Techno-Solutions Corporation, 2. National Institute of Advanced Industrial Science and Technology, 3. Railway Technical Research Institute

Predicting the inundation height and arrival time by tsunami propagation analysis are very important in the tsunami disaster prevention. On the other hand, it is also an important issue to elucidate tsunami propagation path. The tsunami propagation path has been commonly calculated by wave ray method, it has used in combination with the tsunami propagation analysis based on linear long wave theory and, shallow water theory. However, in the wave ray method, it’ s difficult to set an appropriate initial value and boundary conditions consistent with tsunami propagation analysis. So we must pay attention these characteristics in considering the analysis result.
Anyway, applying the sensitivity kernel distribution and adjoint field which used in seismic tomography to the tsunami wave field, we investigated the tsunami propagation path. In this method, it is also possible to detect a propagation path of the specific component extracted from a tsunami waveform by adding a routine for propagating a tsunami waveform in the reverse direction to the general tsunami propagation analysis code.
First, we verified this method whether it is possible to detect tsunami propagation path to the observed point in the ideal space. It was assumed water of constant depth and Gaussian distribution as an initial water level.
In addition, we used this method to detect how the far-field tsunami propagate to the Japan coast. We set the calculation target range that can be covered almost whole Pacific Ocean area whose mesh size is 10 sec, the wave source was the 1960 Chilean tsunami. Analyzing characteristics of tsunami is propagated which comes from Hawaiian island across the north-south, we confirmed the result as same as previous method by wave ray method.
An issue in the future, it’ s necessary to consider a practical method to extract and propagate specific components of the tsunami waveform, and verify the possibility of applying this method for the tsunami propagation analysis based on dispersive wave theory and shallow water theory. It is thought that they will be expanded the range of application.

Estimation of local seismic waves and rapid magnitudes for ‘slow tsunami earthquakes’ based on moment rate spectrum

*Takahito Nishimiya[1], Akio Katsumata[1]

1. Meteorological Research Institute, Japan Meteorological Agency

The tsunami height estimation at earliest stage in JMA is based on the estimated hypocenter and rapid magnitude (rapid-M) from local seismic wave data. The amplitudes of seismic waves from ‘slow tsunami earthquakes’ are usually smaller than those from normal earthquakes because those earthquakes radiate relatively low seismic energies in the short period range. Therefore it is difficult to estimate rapid-M of ‘slow tsunami earthquakes’ accurately. We would like to evaluate rapid-M of them quantitatively. However local seismic wave data of slow tsunami earthquakes is almost not available.

We estimated moment rate spectra of ‘slow tsunami earthquakes’ using tele-seismic wave data (in JpGU Meeting 2018), and calculated synthetic local seismic waves based on those spectra (in Seismological Society Fall Meeting 2018). We estimated rapid-M from the synthetic wave data here.

JMA magnitude (M_J) and M_{100} (Katsumata et al., 2013) are evaluated as the rapid-M. M_{100} is introduced by JMA to avoid underestimation of magnitude for huge earthquakes because M_J tends to indicate “magnitude saturation” for huge earthquakes. We calculated M_J and M_{100} from the synthetic wave data. REGARD (Kawamoto, 2017) based on GNSS data is also a kind of rapid-M. However we use seismic wave data from which smaller magnitude can be estimated compared with REGARD.

We assumed that a ‘slow tsunami earthquake’ occurs at the plate-boundary off the Pacific coast of Tohoku. It has the same moment rate spectrum as the Java tsunami earthquake (M_w7.8) in 1994. M_J estimated from those synthetic waves was smaller than M_w by more than 1.0. M_{100} is larger than M_J, but M_{100} is smaller than M_w by more than 0.5. We also evaluated magnitudes for an earthquake which has the same moment rate spectrum as the Sumatera tsunami earthquake (M_w7.8) in 2010. The difference from M_w reduced for the earthquake, while both M_J and M_{100} are lower than M_w.
USGS published M_s of significant earthquakes. M_s of the 1994 Java earthquake was lower than M_w by more than 0.5 although M_s of the 2010 Sumatera earthquake was about the same as M_w.

Our results suggest that big difference between M_{100} and M_J is useful for early discriminating ‘slow tsunami earthquakes’ from normal earthquakes. Even if M_{100} is much greater than M_J, M_{100} may be underestimated for slow tsunami earthquakes.

Development of tsunami simulator TNS and release of version 1.0

*Takayuki Miyoshi[1], Wataru Suzuki[1], Naotaka YAMAMOTO CHIKASADA[1], Shin Aoi[1], Sho Akagi[2], Toshihiko Hayakawa[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Mitsubishi Space Software Co.,Ltd.

A tsunami is a natural phenomenon in which disturbance generated in the sea by abrupt submarine deformation, propagates to the surrounding sea area with the gravity as restoring force, and often runs up to the land area. The National Research Institute for Earth Science and Disaster Resilience (NIED) has developed a software that can calculate a tsunami phenomenon including inundation on a computer by numerical simulation using finite-difference method (Miyoshi et al., 2018 JpGU). The software was named Tsunami Simulator (TNS: TsuNami Simulator).

Numerical codes of the TNS was developed to operate on the Central Processing Unit (CPU) and the Graphics Processing Unit (GPU), the main code of the CPU written in Fortran 90 and the GPU written in CUDA C in accordance with CUDA 7.5. The concept of the codes is basically equivalent to TUNAMI-N2 (Imamura et al., 2006), and tsunami propagation and inundation based on two-dimensional nonlinear long wave theory can be implemented using a nesting grid with a space grid ratio of 1: 3 in the Cartesian coordinate system. The initial wave height is calculated by the crustal movement in the semi-infinite medium with respect to a fault plane using the program DC3D (Okada, 1992 BSSA). Horizontal crustal movement (Tanioka and Satake, 1996 GRL) and hydraulic filters by Kajiura (1963, BERI) are also applicable. In the offshore boundary, the transmission boundary (Imamura et al., 2006) and the absorb area (e.g. Clayton et al., 1977 BSSA) are applied, and inundation boundary is used in the land side (Kotani et al., 1998 Coastal Engineering Journal). For distant tsunamis, a spherical coordinate system is introduced and connects to the region in the Cartesian coordinate where inundation simulation is carried out. In the spherical coordinate, Coriolis force and dispersion effect can be considered as the previous study, and loading effect (Inazu and Saito, 2013 EPS) can also be applied.

Real-time tsunami inundation forecast system using numerical database requires a large amount of tsunami scenario. From the TNS development version, we packaged the essential parts for constructing a tsunami scenario bank and released as TNS Version 1.0 (Miyoshi et al., 2019 Technical Note of the NIED). The users are assumed to be researchers, engineers, officers of local governments who is responsible for disaster prevention, and make it possible to calculate on the general Linux environment. The package included an operation guide, executable files precompiled on Linux, and some examples. The solver can conduct sequential computation by single CPU, and can conduct parallel computation using OpenMP, and the general-purpose computing on graphics processing units (GPGPU) in order to achieve reduction of calculation time.

A Study on Tsunami Inundation Simulation for the Nankai Trough Earthquake for Osaka City

*Kaoru Kawaji[1], Seiji Tsuno[2]

1. ITOCHU Techno-Solutions Corporation, 2. Railway Technical Research Institute

In planning disaster prevention measure against the tsunami, it is a very important factor how will the tsunami occur by occurrence of an earthquake and how it will attack. Since the Scenario of the Nankai Trough fault seismic source model was announced from the Cabinet Office as the maximum assumed wave source , various local governments and others are considering various disaster prevention measures and others. In this research, we carried out the tsunami inundation simulation for Osaka City using all 11 case fault models of the Nankai Trough's large earthquake model study meeting (2nd report) announced by the Cabinet Office in August 2012 , and examined the results.

Topographical model in tsunami inundation simulation was using topographic data published by the Cabinet Office, and we modeled with a 1215m grid about range of 1200km ×800km including from the fault to the coast. The calculation time was set to a maximum of 6 hours so that the maximum inundation area and the maximum inundation depth due to the tsunami could be calculated, and the calculation time interval was set to 0.01 second interval so that the calculation was stable.

If the parameters (slip angle, position, epicenter) etc in the fault seismic source model are different, the tsunami characteristics such as the tsunami wave height, the arrival time of the tsunami and the inundation range of tsunami should be different. However, it was different that the location of the large slip region and the epicenter in the fault model of 11 cases, but almost the same tsunami level and arrival time were found in the observation points in Osaka Bay in all cases. It was also found that the maximum wave height appearance time is within 30 minutes from the start of rupture regardless of the case. This trend can be seen similarly in the vicinity of the Kii Channel, off the coast of Osaka Bay, and this trend is thought to be the influence of the topographic of the intricate straits sandwiched between Kii Peninsula and Kochi / Kagawa. We will continue further multilateral investigation in the future and report on the results as well.

Database construction of Tsunami inundation simulation for large subduction earthquakes

*Mariko Korenaga[1], Seiji Tsuno[2], Kaoru Kawaji[1]

1. ITOCHU Techno-Solutions Corporation, 2. Railway Technical Research Institute

In the area facing the Nankai Trough, the danger of the tsunami caused by the large subduction earthquake is an urgent task. Because the earthquake occurrence area is too close, it is very important to grasp the possibility of inundation in advance, not after the earthquake occurred.

Therefore, from the viewpoint of tsunami protection against railway structures, databases of tsunami height near the coast and tsunami inundation zones were created, assuming a large number of scenario earthquakes for specific cities on the Pacific coast. Using this result we will investigate the risk of risk assessment due to the maximum inundation area and the delay time of evacuation compared to the coastal prediction results.

Coastal tsunami height tends to increase when large slip regions and super large slip regions exist in front of the coastline in each target area, but the spread of the inundation area is also related to the position in the dip direction of the large slip region. We would like to discuss what kind of information is important for mitigating tsunami damage from the standpoint of railroad disaster prevention while quantitatively examining the various inundated areas obtained.

Sediment Transport Modeling due to Tsunamis caused by the Nankai great earthquakes

*Takuya Saito[1], Kei Yamashita[2], Toshitaka Baba[1]

1. Tokushima Univ., 2. Tohoku Univ.

Tsunami that comes to the area in shallow water causes massive erosion and deposition of the coastal area. This causes damage such as collapse of coastal structures, burial of routes and blockage of water intakes at power stations. In the 2011 Tohoku Region Pacific Offshore Earthquake, collapses of coastal levees and burial of routes were caused by scouring. Damage caused by sediment transport will be prolonged, affecting recovery activities after the disaster. On the other hand, for disaster mitigations, it is necessary to accurately investigate the earthquakes and tsunamis back to the past as much as possible in order to estimate the maximum size of the earthquake and tsunami. Tsunami sediments are important information in studies of the historical earthquakes. Therefore, we simulated sediment transport using a numerical model developed by Takahashi et al. (1999, 2000, and 2011) for the great Nankai earthquakes.

The first study area is Tachibana-Bay classified as an important port having the rias coast in Shikoku, the southwestern Japan. In the simulation results, erosions were predicted in the straits between the islands, at the tip of the cape, near the estuary of the river and near the coastal levees. Sediment depositions were predicted in the vicinity. The maximum changes in erosion and sediment were about 10 m, about 6 m, respectively, for the great Nankai earthquakes (Mw 9.1). These were about 6 m and about 2 m, respectively, for the 1707 Hoei earthquake.

The other study area is a pond near the Cape Kamoda where tsunami sediment was found in the sediment layer about 2000 years ago (Okamura et al, 2012). However, all simulations we conducted in this study did not deposit sediment into the pond.

Acknowledgments: We thank Dr. Takahashi for providing us with the sediment transport software. This research is supported by Grant-in-Aid for Scientific Research 15H05718.

Tsunami model of the 2011 Tohoku Earthquake reproducing the wave gauge record offshore the Fukushima Daiichi NPP

*Toshimichi Kaneto[1], Ayumi Nishi[2], Tadashi Annaka[2]

1. Tokyo Electric Power Company Holdings,Inc, 2. Tokyo Electric Power Services Co,Ltd

1. Objectives of research
During the 2011 off the Pacific coast of Tohoku Earthquake, severe core damage accidents occurred in unit one, two and three in Fukushima Daiichi nuclear power plant due to the failure of core cooling after the reactor shutdown. For understanding the process of tsunami caused by the earthquake and for utilizing tsunami evaluation at the nuclear power plants, tsunami source model, L67, of the 2011 Tohoku Earthquake was determined based on the data of the tsunami waves, crustal deformation and run-up height.
Although the model L67 can simulate the first tsunami and the first crest of the secondary tsunami of wave gauge record offshore the Fukushima Daiichi NPP, it cannot reproduce the second crest of the secondary tsunami. Imamura et al. (2016) proposed the revised model of Sugino et al. (2013) which reproduce the second crest of the secondary tsunami. In this research we improve the reproducibility of the wave gauge record based on the following approach.

2. Contents of research
(1) Joint inversion of tsunami wave and 1-second sampling GPS data
For developing the model L67, we took the consideration of the problem that the slip process of the previous tsunami source models such as Cabinet office (2012), Sugino et al. (2013) and Satake et al. (2013), has long duration compared with those of models based on earthquake ground motion data and that of 1-second sampling GPS data by Geospatial Information Authority, Japan. In order to resolve this problem we used the short time window for inversion as 30 sec times 3. Consequently the slip process of the model L67 has shorter duration compared with the above tsunami source models.
In this research we conducted the joint inversion using tsunami wave and 1-second sampling GPS data. It seems that the duration of slip process will become naturally shorter by using the 1-second sampling GPS data.

(2) Inversion using “hypothetical tsunami records”
Non-linear effect is strong in the wave gauge record offshore the Fukushima Daiichi NPP. So we can use only initial portion of the record for the linear inversion. In order to improve the reproducibility of the wave gauge record, “a hypothetical tsunami record” at the depth of 50 m offshore the Fukushima Daiichi NPP was simulated using the initial fault model and the green functions and the adjusted hypothetical tsunami record was added to the inversion as observed record. The calculated tsunami wave became similar to the wave gauge record through a trial and error process.
The same approach was used for improving the K and kappa for the run-up height data.

3. Conclusions
The tsunami source model of the 2011 Tohoku Earthquake reproducing the wave gauge record offshore the Fukushima Daiichi NPP was determined based on the above inversion approach. The duration of slip process became naturally shorter by using the 1-second sampling GPS data. The reproducibility of the wave gauge record was much improved compared with the model L67 by using the “hypothetical tsunami record”. Goodness of fit for tsunami wave and run-up height is same as that for model L67.

Development of tsunami fragility curves on railway structures based on the 2011 off the Pacific coast of Tohoku earthquake

*Teppei Ono[1], Seiji Tsuno[2], Yuko Sato[2], Marioko Korenaga[1]

1. ITOCHU Techno-Solutions Corporation, 2. Railway Technical Research Institute

The Great Tsunami associated with the 2011 off the Pacific coast of Tohoku earthquake caused severe damage to railway structures on the coast of the Tohoku region in Japan. It is effective to obtain fragility curve from damaged data in this disaster to predict the risks of railway structures to the tsunami in the future. It is generally represented by a lognormal distribution or a normal distribution. In this study, we obtained fragility curve by integrating spatial damage data for railway structures and spatial inundation data accompanying the 2011 off the Pacific coast of Tohoku earthquake on GIS. The method of obtaining tsunami fragility curves were referred to Koshimura et al. (2009).
In this study, we collected the data of damage and location for railway structures located in the Tohoku region to refer multiple documents. First, the data of inundation depth at intervals of 100 meters of the 2011 off the Pacific coast of Tohoku earthquake published by the Ministry of Land, Infrastructure and Transport was utilized to grasp the inundation depth where the railway structure is located. Second, we used the railway data of MLIT and Geospatial Information Authority to grasp the location of the railway structure. The kinds of structure in railway structures are different from station, bridge, tunnel, railway crossing, roadbed, retaining wall, cage, embankments, cuts and so on. The kinds of material in railway structures are also such as soil, C, RC. The tsunami fragility curves were obtained by using the all data and the case of using only RC to consider the influence of the structural kind.
As a result, it was shown that the gradient of tsunami fragility curve becomes smaller as compared with the tsunami fragility curve for buildings in the 2011 off the Pacific coast of Tohoku earthquake shown at Koshimura and Gokon (2012). The reason is to obtain the tsunami fragility curve from various railway structures. Furthermore, tsunami damage probability for railway structure on Ishinomaki in Miyagi Prefecture and Shimanokoshi in Iwate Prefecture were shown to confirm the reproducibility of the obtained tsunami fragility curve by using the spatial inundation depth calculated by using the Cabinet Office model.

The characteristic of the cause of death in each city in Miyagi prefecture during the Great East Japan Earthquake

*Shuji SETO[1], Fumihiko IMAMURA[1]

1. IRIDeS, Tohoku University

About 20,000 people died in the Great East Japan Earthquake tsunami that occurred in 2011. According to the National Police Agency (2012), 90% of the victims in Iwate, Miyagi and Fukushima prefectures were drowned. Aoki et al. (2012) reported the results of questionnaires to physicians who actually examined in the affected areas. The questionnaire result showed that the National Police Agency's cause of death statistical result was reasonable, and that some physicians could not but describe it as drowning as a realistic problem.

This suggests that victims in a tsunami disaster may diefromcause of death other than drowning. According to Kahoku Shimpo(2011), the survivors witnessed the victims who died of symptoms like hypothermia after exposure to the tsunami. However, the details of the cause of death excluding drowning has not been elucidated yet.

Seto and Imamura(2019) classified the causes of death in Miyagi Prefecture during the 2011 Great East Japan Earthquake tsunami using victim information provided by Miyagi Prefecture Police Headquarters. As a result,the cause of death was classified into the following 12 kinds; Injuries to the head, Injuries to the neck, Injuries to the thorax, traumatic shock, Unspecified multiple injuries, Asphyxiation, Drowning, death due to fire, Hypothermia, Heart disease, Othrers and Unknown. And, they showed the proportion of each cause of death in Miyagi prefecture. The proportion in each city are needed to clarify the casualty in the Great East Japan Earthquake in more detail.

In this study, wecarried outthe analysis using the address data in victim information provided by Miyagi Prefecture Police Headquarters. The data are resident address and bodies found location. Combining each address data and the above 12 kinds of cause of death, we showed characteristics of each cause of death in each city in Miyagi prefecture.

The reflective south going current, accompanied by the third wave of Tsunammi at Iioka , Asahi City , Chiba Prefecture in 2011.

*Mitsuo Harukawa[1], Noboru Hashimoto[1], Fumio Ooshima[1]

1. The Group of Recording for Tsunami Damage of Asahi City in 2011

Shortly after the third wave of tsunami had gone to the north, Iioka was attacked abruptly by the south going current, which caused the disaster. The question is why the south going current occurred. The purpose of this thesis is to explain this issue.
After the disaster, we soon began to visit all the houses along the coast of Asahi City for interviews, and gathered about 650 personal experiences and eyewitness accounts. We found some of them very important. The summary is as follows.
When the third wave of tsunami reached the north coast of Iioka , it was reflected slightly eastward . Then the reflected current went down south along the seawall of west coast of Iioka. After a while, the south going current ran against the succeeding north going current that belonged to the third wave of tsunami. As a result of that collision, the wave height of south going current was increased so much that the wave got over the seawall and destroyed the houses from north to south.
By oblique mono photogrammetry, we calculated the strikes of the wave planes of south going current, and made a wave plane map, which we think proves the eyewitness accounts mentioned above to be right.
A TV program said that *the south going current was the edge wave of the first wave of tsunami*(April 9,2014 FNN), but we don't think it is the case. After the first wave of tsunami had gone, the tidal wave went far off the shore, leaving no seawater along the north coast of Iioka. The large area of the sea floor was visible. It is clear that no edge wave of the first wave stayed there.
Conclusion The south going current was not the edge wave of the first wave of tsunami. It was the reflective current of the third wave of tsunami.

Today’s Japan has conducted immediate, wide-area tsunami forecasts using the quantitative tsunami forecasting system that databases results of numerous preliminary tsunami simulations. In the future, in order to conduct more accurate tsunami forecasts, it is necessary to verify the accuracy of the tsunami run-up calculation. However, there were few studies about the variation of run-up tsunami force by calculating on-site. In this study, we conducted the on-site tsunami run-up calculation using the two-dimensional simulator and analyzed the variation of run-up tsunami force.

We focused on the earthquake near Palu, Indonesia on September 28, 2018. We set some tsunami sources based on the results of the field study, (by Arikawa *et al.*) and conducted the 300 cases of two-dimensional tsunami run-up simulations by changing the fault parameters. Next, we investigated statistically the variation of the maximum inundation depth and Froude number at the maximum inundation depth. Using the calculation results of all cases we conducted, we made groups every 0.2m from the small inundation depth and made histograms of the maximum inundation depth and Froude number for each group.
As a result, the average of Froude number increased monotonically as the maximum inundation depth increased, and the variance of Froude number tended to increase about 4 times as the maximum inundation depth increased. This corresponds to a value of Froude number of 1.5 to 2.0 times. This indicates that even if the inundation depth is the same, there is a possibility that there is a difference in tsunami force, so it is necessary to investigate the variance of the Tsunami force in the area where the inundation depth is large. In addition, it is also necessary to further study the variance of the flow velocity in numerical calculation.

Tsunami Source of the 2018 Sulawesi Earthquake Estimated from Tsunami and InSAR Data

*Tungcheng Ho[1], Kenji Satake[1], Shingo Watada[1], Ray Y Chuang[2], Chih-Heng Lu[2]

1. Earthquake Research Institute,The University of Tokyo, 2. Department of Geography, National Taiwan University

An unexpected destructive tsunami struck Palu Bay after the Mw 7.5 strike-slip faulting earthquake in Sulawesi, Indonesia, on 28 September 2018. This tsunami impacted Palu city with 5 m to 10 m runup. The combined effects of the earthquake and tsunami caused a few thousand casualties. The tsunami waves were observed by two tide gauges in Sulawesi. One tide gauge at Pantoloan port in the bay recorded tsunami waves starting at about 5 minutes after the earthquake with amplitudes of up to 2 m. The other tide gauge at Mamuju port recorded tsunami waves after about 20 minutes with peaks of about 10 cm. To understand the mechanism of this unusual tsunami, we jointly utilized the tsunami records and InSAR data to analyze the source of this earthquake. The InSAR data observed by Sentinel-1 well resolved the offset of horizontal ground movement in the direction of the orbit azimuth along the fault strike. The data show a strike of about 358˚ in the north of the bay and about 352˚ in the south of the bay. The magnitude of the offsets varied from about 1 m in the north to up to 5 m in the south. Our simple modeling result suggests a slip of about 5 m at the north and a slip up to 8 m at the south to reproduce the observed tsunami waveform at Pantoloan. The southern asperity extended about 40 km from the bay with a width of about 16 km. Tsunami travel time analysis showed that the main tsunami arrived at the Mamuju station after about 45 minutes which means the first tsunami wave at this station was triggered by another source.

Source Models of the Two September and December 2018 Indonesia Tsunamis Based on Spectral Analyses and Numerical Modeling

*Mohammad Heidarzadeh[1], Abdul Muhari[2], Tomoya HARADA[3], Takeo Ishibe[4], Antonius Wijanarto[5]

1. Brunel University London, 2. Ministry of Marine Affairs and Fisheries, Jakarta 10110, Indonesia, 3. Earthquake Research Institute, The University of Tokyo, Japan, 4. Association for the Development of Earthquake Prediction, Tokyo, 101-0064, Japan, 5. Badan Informasi Geospasial, Cibinong, Indonesia

Indonesia was struck by two tsunamis in September and December 2018 in Sulawesi and Sunda strait, respectively. The combined fatalities from the two events were ~2500 people which made 2018 as one of the deadliest year for Indonesia in terms of natural disasters. The 2018 twin tsunamis were unique because both events were not generated by typical earthquake-generated seafloor deformation. The Sulawesi tsunami in September 2018 was most likely associated with a large submarine landslide (Heidarzadeh et al., 2018, Pure & Appl. Geophys. 176) and the Sunda event was of volcanic origin. Therefore, there have been intense speculations in the scientific community about the origins and mechanisms of these twin tsunamis without any clear clues about the source mechanisms so far (February 2019). Our methodology here to address the puzzle of the 2018 twin tsunamis is analyzing the observed tide gauges records of both events and then applying numerical simulations. For the Sulawesi tsunami, two tide gauge records were analyzed belonging to Pantoloan (inside the Palu Bay) and Mamuju (outside the Palu Bay). Maximum tsunami trough-to-crest heights of 380 and 24 cm, were measured in Pantoloan and Mamuju, respectively. Spectral analyses of the tide gauge records revealed dominating wave periods of 3.6–4.4 and 10 min at the aforesaid stations, respectively. Spectral results indicate that the tsunami source dimensions should have been most likely in the range of 3.4–4.1 km and 32.5 km, for inside and outside of the Palu Bay, respectively. We were able to reproduce the two observed tide gauge records using numerical simulations. However, the maximum simulated runup was approximately 2 m which was less than the observed runup of 11 m. It is likely that a secondary source, i.e. submarine landslide(s), has contributed to the tectonic source of the tsunami. We identify the southern part of the Palu Bay, around the latitude of -0.82°S, as the most likely location of a potential landslide based on our backward tsunami ray tracing analysis. For the Sunda tsunami, four tide gauges were analyzed revealing wave amplitudes in the range of 44-139 cm. The dominating period of the waves were ~7 min which are shorter than tsunamis generated by earthquakes. We have considered several landslide scenarios and conducted numerical modeling in order to reproduce the observed tsunami waves on the tide gauges and propose a source model for this tsunami.

Abrupt Large Uplift Caused by Volcanic Tsunami Earthquakes near the Kermadec Islands, New Zealand

*Osamu Sandanbata[1], Shingo Watada[1], Kenji Satake[1]

1. Earthquake Research Institute, the University of Tokyo

Abnormal non-double-couple (NDC) earthquakes are sometimes observed near volcanic or geothermal areas [e.g. Shuler et al., 2013, JGR], some of which generate large tsunamis despite their moderate seismic magnitudes, M5-6. The Torishima earthquakes are ones of the few examples and were attributed to a large crustal uplift associated with some volcanic activity at a submarine caldera edifice on Izu-Bonin Ridge [Fukao et al., 2018, Sci. Adv.; Sandanbata et al., 2018, PAGEOPH]. This type of earthquakes therefore can be regarded as "volcanic tsunami earthquakes."

Another series of volcanic tsunami earthquake were observed near the Curtis and Cheeseman Islands, parts of the Kermadec Islands, north of New Zealand, on 17 Feb 2009 and 8 Dec 2017 (UTC). Tsunamis were recorded at tide gauges and ocean bottom pressure gauges with a maximum amplitude of ~40 cm. The two earthquakes are remarkably similar in seismic magnitudes (M~6.0), focal mechanisms (dominant NDC components), centroid locations (gap of ~10 km) and observed tsunami waves.

In order to investigate their tsunami sources, we numerically solved two-dimensional Boussinesq-like equations with the simulation code, JAGURS [Baba et al., 2015, PAGEOPH]. We first located their source region in the vicinity of the Curtis and Cheeseman Islands, by assuming Gaussian-shaped sea-surface uplifts at 9 locations. We then conducted the tsunami waveform inversion with Green’s functions computed from cosine-tapered uplift distributed around the islands. The estimated tsunami source has a large sea-surface uplift concentrated just over a bathymetric depression that is a characteristic structure of calderas. This suggests a large uplift on seafloor was caused by the earthquakes associated with a volcanic activity of the submarine caldera.

Large uplift events called “resurgence” have been observed at calderas in nature and experiments, which are often attributed to reactivation of ring faults due to overpressure of a magma reservoir [e.g. Acocella et al., 2001, JVGR]. We modeled crustal deformation of a caldera with an interacted system of a ring-fault structure and a shallow sill-like magma reservoir [Liu et al., 2017, AGU Fall Meeting]. Our modeling suggests that the system can cause a large uplift concentrated just over the caldera. The uplift also reproduced tsunami waves similar to the observations, while the gap between seismic and tsunami magnitudes can be explained qualitatively. We therefore suggest that a ring-fault reactivation due to overpressure in a sill-like magma reservoir as a possible mechanism of the earthquakes and their resultant tsunamis.

Adaptive tsunami waveform inversion for estimating coseismic vertical displacements and slip distribution

*Iyan E. Mulia[1], Aditya Riadi Gusman[2], M. Jakir Hossen[3], Kenji Satake[1]

1. Earthquake Research Institute, The University of Tokyo, 2. GNS Science, 3. BRAC University

We developed an advanced two-step tsunami source inversion method with adaptive Green's functions by applying an optimization and a reciprocity principle (Mulia et al., 2018 JGR). In the first step, the method reconstructs the sea surface displacement from observed tsunami waveforms based on a superposition of Gaussian-shaped unit sources. Here, we optimize the unit source locations that give the best fit of waveforms to observations. This leads to non-equidistantly distributed unit sources, in which the synthetic waveforms from such sources to the observation points are generated using the reciprocity principle to save computational efforts of Green's functions. In the second step, the reconstructed sea surface displacement is used to estimate the slip on a finite fault plane. We also optimize the fault parameters that produce the closest displacement pattern to the first step result. Therefore, our method provides best fitting of waveforms and optimum fault parameters with automation for the process. The current method improves our previous studies, in terms of the construction of tsunami Green's functions using the reciprocity principle and determination of fault parameters through the optimizations.

We tested the proposed method using tsunami data of the 2004 Kii Peninsula, Japan event generated by an M_w 7.4 intraplate earthquake. Our result revealed a maximum initial displacement of approximately 0.5 m with the uplift region extended northwest to the epicenter. This value is slightly higher than that of most source models by the previous studies (e.g. Baba et al., 2005 EPS, Satake et al., 2005 EPS), but yields more accurate tsunami waveforms, particularly at the later phase of waveform recorded at a Global Positioning System buoy station off Cape Muroto. In terms of fault slip distribution, our model produced a maximum slip of 2.1 m, located at the uplift region of the coseismic displacement. Furthermore, the shallow fault depth resulted from our simulation is consistent with the more reliably relocated aftershock distribution by Bai et al. (2006 EPS).

Real-time tsunami prediction in a coastal zone, using a superposition of Green’ s function

*Seiji Tsuno[1], Norihiko Hashimoto[2]

1. Railway Technical Research Institute, 2. ITOCHU Techno-Solutions Corporation

Recently, S-net (Seafloor observation network for earthquakes and tsunamis along the Japan Trench) and DONET 1 & 2 (Dense Oceanfloor Network system for Earthquakes and Tsunamis) are installed off the Pacific Ocean, Japan by NIED (National Research Institute for Earth Science and Disaster Resilience) and JAMSTEC (Japan Agency for Marine-Earth Science and Technology); therefore, real-time tsunami forecasting methods using directly tsunami data observed in oceanfloor are proposed (e.g. Yamamoto, 2016; Tanioka, 2018). In this study, focusing on the immediacy and the robustness of tsunami forecasting, we investigated real-time tsunami prediction method in a coastal zone, using a superposition of previously calculated Green’ s function.

In this method, we divide the entire source area of tsunami into element sources (for example, 50 km x 50 km), and we, in advance, calculate the Green’ s function to a coastal point for the unit tsunami water level (1 m) in the element source. Assuming that the tsunami water level is the same within the element source when a tsunami occurs, we the Green’ s function to the element source –the coastal point for the maximum value of the tsunami water level observed at one point in the element source. By applying this to all the divided element sources and superimposing these Green’ s functions, we can obtain the tsunami water level in a coastal zone for the entire source area. Comparing the result predicted by this method to a tsunami simulation result simulated from source model proposed by the Cabinet Office, Government of Japan, for the 2011 off the Pacific coast of Tohoku earthquake, we confirmed that two results are in good agreements.

Moreover, to use the amount of tsunami water level in the source area due to heterogeneous fault rupture, we investigated the possibility to replace the time series of tsunami data observed at a point in the element source with the amount of tsunami water level within the element source area. We confirmed that the time series of tsunami data can be used for real-time tsunami prediction using a superposition of Green’ s functions by appropriately estimating the time when the tsunami propagates within the element source.

[J] Poster | H (Human Geosciences)：H-RE Resource and Engineering Geology

Tue. May 28, 2019 1:45 PM - 3:15 PM JST | Tue. May 28, 2019 4:45 AM - 6:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_5

[H-RE17] Application of earth science data towards the renewable energy field

convener:Hideaki Ohtake(National Institute of Advanced Industrial Science and Technology), Fumichika Uno(National Institute of Advanced Industrial Science and Technology), Teruhisa Shimada(Graduate School of Science and Technology, Hirosaki University), Daisuke Nohara(Central Research Institute of Electric Power Industry)

Renewable energy (RE) penetration is increasing dramatically in the world. RE power generations have made their presence felt in an electric power system. However, it is a challenge for RE to be stable power sources due in part to natural variability of RE and the distributed resources. For effective use of RE, a combination between power resources and energy storage technologies (e.g., pumped-storage power generation, storage battery system and electric vehicle) is required to provide power and energy flexibility. Therefore, we need to understand the amount of REs, causes of variation, and the predictability of power output. Then, enormous and diverse observation data sets and modeling technologies from earth science field should be analyzed and applied to power energy field to achieve easy use of earth science databases.
 This proposed session needs your presentation from the whole of RE fields (solar power, wind power, geothermal power, tidal power, wave power and biomass power generations). Our goal of this session is to exchange views with various researchers between RE field and earth science field (e.g., usage-trends of earth science datasets for RE field, the subjects in hand, earth science datasets availability, and cooperation between RE and earth science fields, and so on).

Evaluation of spring, groundwater and stream water quality for use as a cooling heat source at Iwaki volcano

*Seiichiro Ioka[1], Kazuyoshi Asai[2], Kazumi Asai[2]

1. Institute of Regional Innovation, Hirosaki University, 2. Geo Science Laboratory

There is a lack of existing research concerning cooling heat sources that are necessary for geothermal power development at Iwaki volcano. In this study, we evaluate the availability of spring water, groundwater and stream water as a cooling heat source for geothermal power generation. We are mainly concerned with water quality characteristics for geothermal binary power generation, and with scale formation more specifically.

We studied 10 spring water, two groundwater and 18 stream water samples from the Iwaki volcano area. We measured pH, electrical conductivity, water temperature, and flow rate. We conducted analyses for Li^+, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}, F^-, Cl^-, Br^-, NO_3^-, SO_4^{2-}, Fe, Mn, Sr, Ba, Cu, B, Si, alkalinity, dissolved organic carbon, $\delta^{18}O$ and δD in each sample. The evaluation of scale formation was carried out using PHREEQC Interactive Version 3.4.0.12927.

Scale formation was evaluated at an average temperature of 10 ˚C at the time of water sampling, as well as at a temperature of 15 ˚C assumed to be applicable to a scenario following utilization of the water as a cooling heat source. The saturation index results for calcite and amorphous silica indicated that all spring water, groundwater and stream water were undersaturated at 10 ˚C and 15 ˚C and scale formation was unlikely to occur. However, the saturation index for iron indicated oversaturation at an Fe concentration of 0.005 mg/L or higher, but concentrations of 0.1 mg/L or higher were only detected at two sites. We therefore conclude that these factors are not important provided that those two sites are not used. From the perspective of scale formation, this study indicates that spring water, groundwater and stream water in this area can be effectively utilized as a cooling heat source for geothermal power generation.

Characteristics of the confined groundwater based on the monitoring results in the western part of Osaka area: For thermal utilization of groundwater

*Hiroko Ito[1], Naoko Kitada[1], Tomoo Echigo[1], Teruyuki Fujiwara[1]

1. Geo-Research Institute

Utilization of renewable thermal energies has been promoted for several years in Japan. For the purpose of reduction of CO_2 emissions using renewable energies, thermal utilization of groundwater has been focused in Osaka area, where large amount of groundwater is potentially available for thermal sources. Recently, a demonstration experiment of Aquifer Thermal Energy Storage (ATES) system, which is one of the open-loop systems for large-scaled thermal utilization of groundwater, was performed at the redeveloped site near the Osaka Station. However, since widely ground subsidence was caused by excessive pumping of shallow groundwater in 1960’s, appropriate managements must be performed for effective use of groundwater. On the basis of these backgrounds, we observed groundwater chemistries, levels, and temperatures in order to clarify the initial characteristics and evaluate the possibilities of utilization for ATES system in the western part of Osaka area.

Pliocene to Quaternary sediments reach a maximum thickness of 1,500 m beneath the Osaka plain, and more than 20 marine clay layers deposited in association with cyclic global sea level changes are intercalated with freshwater sand and gravel layers. In this study, we investigated the confined groundwaters in Pleistocene sandy gravel layers so-called Dg1, Dg2 and Dg3. These three confined aquifers are widely distributed in the western part of Osaka Plain within the depth of 100 m from ground surface.

Seasonal variations of the chemical compositions were negligibly small. The analyzed groundwater samples mostly had reductive characteristics, e.g., about 80 % of iron was existed as dissolved ions. In order to long-term utilization of ATES system, it is necessary to maintain reductive groundwater condition to prevent precipitation of iron hydroxides which may cause clogging of well screens. All of sampled waters had Na^+-Cl^- type characteristic as major composition, however, the total concentrations of dissolved ions were higher in the groundwater samples of Dg1 than those of Dg2 and Dg3. Comparing the same aquifer, total concentrations of dissolved ions were lower in the northern part (Umeda-Fukushima area) than in the southern part (Nakanoshima area) of the studied area. Because groundwater chemistries were significantly different in each aquifer, pumped groundwater must be surely recharged into the original aquifer.

Groundwater levels had few variations at each monitoring site for all of the above three aquifers. Therefore, it is suggested that water flow velocities were very slow, stagnant groundwater environment. Artificial sharp declines in the groundwater levels of Dg2 were observed several times in 2017. Such remarkable declines of groundwater levels could not be observed in Dg1 and Dg3, i.e., these three aquifers must be independent at least in the studied area.

Groundwater temperatures were measured 4 times per year for every 1m depth. Both seasonal and locational variations were observed at the shallower than 30 m depth, however, the groundwater temperatures at the depth of more than 30 m showed constant trend around 18 celsius degree in the

©2019. Japan Geoscience Union. All Right Reserved.

western part of Osaka area. On the other hand, they were about 2 celsius degree higher in the northeastern part of Osaka city (near Uemachi Upland) than that of in the western regions.

Finally, this study is based on the results obtained from a “Renewable energy heat utilization technology development” project commissioned by the New Energy and Industrial Technology Development Organization (NEDO), a Japanese national agency.

Predictability of Wind Power Ramp Events based on Dynamical and Statistical Ensemble Prediction

*Daisuke Nohara[1], Takeshi Watanabe[1], Masamichi Ohba[1], Shinji Kadokura[1]

1. Central Research Institute of Electric Power Industry

Abrupt change in wind power generation, known as ramp events, due to fluctuating wind speeds present challenges to the stability of the electric power supply. In Japan, the ramp events are generally induced by extratropical cyclones along their track. Since prediction for the behavior of the cyclones entails uncertainty caused by nonlinear dynamics, probabilistic prediction is more effective. For this study, we developed a regional ensemble prediction method using the Weather Research and Forecasting model (WRF). To obtain dynamically consistent perturbations with a synoptic weather pattern, both initial and lateral boundary perturbations were determined by differences between the control and an ensemble member of the Japan Meteorological Agency (JMA)'s operational one-week ensemble forecast. This method provides 11 ensemble members with a horizontal resolution of 15 km for 75 hours at 30 minutes interval outputs by downscaling JMA's operational global forecast along with the perturbations. Wind power is projected using power curve which is estimated by relationship between area averaged wind speed and wind power generation. In addition to the dynamical ensemble, we expanded the ensemble member using Monte Carlo method to take account of the impact on uncertainty in the power curve. The expanded ensemble has 100 members. Forecast for the ramp events using the expanded ensemble exhibits high statistical consistency and reliability of ability to capture the ramp events compared with the dynamical ensemble prediction.

Offshore wind resource in the vicinity of Cape Erimo

*Teruhisa Shimada[1]

1. Graduate School of Science and Technology, Hirosaki University

Wind energy technology is rapidly developing and, above all, offshore wind energy is becoming a center of renewable energy in the world. In northern Japan, to examine the possibility of the offshore wind energy and to promote the development, detailed wind observations, examination for zoning, and plans to build offshore wind turbines are ongoing.

The latest offshore wind maps such as NeoWins (http://app10.infoc.nedo.go.jp/Nedo_Webgis/top.html) shows the largest wind energy resources in the vicinity of Cape Erimo, Hokkaido. Along the Japanese coast, there are only two offshore regions in which annual mean wind speeds exceed 10 m/s within approximately 20 km from the coast. One is the south of Cape Erimo.

However, few studies have paid attention to the strong winds in the vicinity of Cape Erimo and have investigated the mechanism of the strong winds or large wind energy. Although some studies demonstrated the strong winds which locally develops near the Cape Erimo by satellite wind observations (Shimada and Kawamura, 2004, 2007), there are remaining issues for further understanding of wind energy map and of the impact of the locally strong wind on the wind energy statistics. Therefore, this study investigate the locally strong wind developing near the Cape Erimo.

An Efficient Method for Estimating the Surface Solar Irradiance Based on Satellite-Observed Scattered Solar Radiation

*Keiichi Nishizawa[1]

1. Central Research Institute of Electric Power Industry

In order to estimate cloud optical thickness, which substantially affects the surface solar radiation, we intend to analyze the scattered solar radiation observed from satellites. For the inverse analysis of cloud optical thickness, “bidirectional reflectivity” of the earth-atmosphere system at 0.51 mm in wavelength has been calculated by using Rstar6b (a radiative transfer model developed by the University of Tokyo) for various sets of related parameters (i.e., cloud optical thickness, ice cloud fraction, solar zenith angle, satellite zenith angle, azimuth angle difference between sun and satellite, and surface albedo). The results from these calculations have been compiled into a six-dimensional look-up table. By using the table, the cloud optical thickness to reproduce the satellite-observed scattered solar radiation can be estimated very efficiently. When the surface global solar radiation is estimated from the obtained cloud optical thickness, however, uncertain variables, such as the surface albedo and ice cloud fraction, are anticipated causing considerable errors in the estimations.

Advance detection method of large forecast error on surface solar radiation considering atmospheric circulation patterns

*Fumichika Uno[1,3], Mio Matsueda[2], Takashi oozeki[1], Hideaki Ohtake[1,3], Yoshinori Yamada[3]

1. National Institute of Advanced Industrial Science and Technology, 2. University of Tsukuba, 3. Meteorological Research Institute

Prediction of surface solar radiation (SSR) using numerical weather prediction (NWP) models usually use at several hours to several days forecast. Large forecast errors (forecast busts) for SSR and therefore photovoltaic power generation may lead to either a shortage of power supply or production of excessive surplus power.

Previous study proposed the detection method of forecast busts using lognormal ensemble spread (standard deviation of ensemble forecast). This study also evaluates lognormal ensemble spread as the four NWP centers (Japan Meteorological Agency: JMA, European Centre for Medium-Range Weather Forecasts: ECMWF, National Centers for Environmental Prediction: NCEP, United Kingdom Met Office: UKMO) and a multi-center grand ensemble (MCGE). However, this study assessed the detectability each atmospheric circulation patterns. The detectability was assessed using ROC diagram. The study period is January 2014 to May 2017 in five winter months (January, February, May, November, December), and forecast lead time is from 24 to 144 hour every 24hours. The forecast busts were defined as the top 5, 10, 15, 20, 25, 30% absolute forecast error. The atmospheric circulation patterns are categorized Winter monsoon (WM), Winter Pacific (WP), High Pressure (HP), Low Pressure (LP), Southerly Flow (SF) using 500hPa height.

As the results, the proposed method in this study indicate higher detectability of forecast bust than the non-categorized detection (previous study) method. For instance, the WP and SF patterns are higher than the non-categorized detection method. Particularly, the hit rate on proposed method was improved more large forecast error event (top 5% forecast busts events), false alarm rate was improved almost all forecast lead time and fix forecast busts cases.

[H-RE17] Application of earth science data towards the renewable energy field

convener:Hideaki Ohtake(National Institute of Advanced Industrial Science and Technology), Fumichika Uno(National Institute of Advanced Industrial Science and Technology), Teruhisa Shimada(Graduate School of Science and Technology, Hirosaki University), Daisuke Nohara(Central Research Institute of Electric Power Industry)

Renewable energy (RE) penetration is increasing dramatically in the world. RE power generations have made their presence felt in an electric power system. However, it is a challenge for RE to be stable power sources due in part to natural variability of RE and the distributed resources. For effective use of RE, a combination between power resources and energy storage technologies (e.g., pumped-storage power generation, storage battery system and electric vehicle) is required to provide power and energy flexibility. Therefore, we need to understand the amount of REs, causes of variation, and the predictability of power output. Then, enormous and diverse observation data sets and modeling technologies from earth science field should be analyzed and applied to power energy field to achieve easy use of earth science databases.
 This proposed session needs your presentation from the whole of RE fields (solar power, wind power, geothermal power, tidal power, wave power and biomass power generations). Our goal of this session is to exchange views with various researchers between RE field and earth science field (e.g., usage-trends of earth science datasets for RE field, the subjects in hand, earth science datasets availability, and cooperation between RE and earth science fields, and so on).

Evaluation of spring, groundwater and stream water quality for use as a cooling heat source at Iwaki volcano

*Seiichiro Ioka[1], Kazuyoshi Asai[2], Kazumi Asai[2]

1. Institute of Regional Innovation, Hirosaki University, 2. Geo Science Laboratory

There is a lack of existing research concerning cooling heat sources that are necessary for geothermal power development at Iwaki volcano. In this study, we evaluate the availability of spring water, groundwater and stream water as a cooling heat source for geothermal power generation. We are mainly concerned with water quality characteristics for geothermal binary power generation, and with scale formation more specifically.

We studied 10 spring water, two groundwater and 18 stream water samples from the Iwaki volcano area. We measured pH, electrical conductivity, water temperature, and flow rate. We conducted analyses for Li^+, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}, F^-, Cl^-, Br^-, NO_3^-, SO_4^{2-}, Fe, Mn, Sr, Ba, Cu, B, Si, alkalinity, dissolved organic carbon, $\delta^{18}O$ and δD in each sample. The evaluation of scale formation was carried out using PHREEQC Interactive Version 3.4.0.12927.

Scale formation was evaluated at an average temperature of 10 ˚C at the time of water sampling, as well as at a temperature of 15 ˚C assumed to be applicable to a scenario following utilization of the water as a cooling heat source. The saturation index results for calcite and amorphous silica indicated that all spring water, groundwater and stream water were undersaturated at 10 ˚C and 15 ˚C and scale formation was unlikely to occur. However, the saturation index for iron indicated oversaturation at an Fe concentration of 0.005 mg/L or higher, but concentrations of 0.1 mg/L or higher were only detected at two sites. We therefore conclude that these factors are not important provided that those two sites are not used. From the perspective of scale formation, this study indicates that spring water, groundwater and stream water in this area can be effectively utilized as a cooling heat source for geothermal power generation.

Characteristics of the confined groundwater based on the monitoring results in the western part of Osaka area: For thermal utilization of groundwater

*Hiroko Ito[1], Naoko Kitada[1], Tomoo Echigo[1], Teruyuki Fujiwara[1]

1. Geo-Research Institute

Utilization of renewable thermal energies has been promoted for several years in Japan. For the purpose of reduction of CO_2 emissions using renewable energies, thermal utilization of groundwater has been focused in Osaka area, where large amount of groundwater is potentially available for thermal sources. Recently, a demonstration experiment of Aquifer Thermal Energy Storage (ATES) system, which is one of the open-loop systems for large-scaled thermal utilization of groundwater, was performed at the redeveloped site near the Osaka Station. However, since widely ground subsidence was caused by excessive pumping of shallow groundwater in 1960’s, appropriate managements must be performed for effective use of groundwater. On the basis of these backgrounds, we observed groundwater chemistries, levels, and temperatures in order to clarify the initial characteristics and evaluate the possibilities of utilization for ATES system in the western part of Osaka area.

Pliocene to Quaternary sediments reach a maximum thickness of 1,500 m beneath the Osaka plain, and more than 20 marine clay layers deposited in association with cyclic global sea level changes are intercalated with freshwater sand and gravel layers. In this study, we investigated the confined groundwaters in Pleistocene sandy gravel layers so-called Dg1, Dg2 and Dg3. These three confined aquifers are widely distributed in the western part of Osaka Plain within the depth of 100 m from ground surface.

Seasonal variations of the chemical compositions were negligibly small. The analyzed groundwater samples mostly had reductive characteristics, e.g., about 80 % of iron was existed as dissolved ions. In order to long-term utilization of ATES system, it is necessary to maintain reductive groundwater condition to prevent precipitation of iron hydroxides which may cause clogging of well screens. All of sampled waters had Na^+-Cl^- type characteristic as major composition, however, the total concentrations of dissolved ions were higher in the groundwater samples of Dg1 than those of Dg2 and Dg3. Comparing the same aquifer, total concentrations of dissolved ions were lower in the northern part (Umeda-Fukushima area) than in the southern part (Nakanoshima area) of the studied area. Because groundwater chemistries were significantly different in each aquifer, pumped groundwater must be surely recharged into the original aquifer.

Groundwater levels had few variations at each monitoring site for all of the above three aquifers. Therefore, it is suggested that water flow velocities were very slow, stagnant groundwater environment. Artificial sharp declines in the groundwater levels of Dg2 were observed several times in 2017. Such remarkable declines of groundwater levels could not be observed in Dg1 and Dg3, i.e., these three aquifers must be independent at least in the studied area.

Groundwater temperatures were measured 4 times per year for every 1m depth. Both seasonal and locational variations were observed at the shallower than 30 m depth, however, the groundwater temperatures at the depth of more than 30 m showed constant trend around 18 celsius degree in the

©2019. Japan Geoscience Union. All Right Reserved.

western part of Osaka area. On the other hand, they were about 2 celsius degree higher in the northeastern part of Osaka city (near Uemachi Upland) than that of in the western regions.

Finally, this study is based on the results obtained from a “Renewable energy heat utilization technology development” project commissioned by the New Energy and Industrial Technology Development Organization (NEDO), a Japanese national agency.

Predictability of Wind Power Ramp Events based on Dynamical and Statistical Ensemble Prediction

*Daisuke Nohara[1], Takeshi Watanabe[1], Masamichi Ohba[1], Shinji Kadokura[1]

1. Central Research Institute of Electric Power Industry

Abrupt change in wind power generation, known as ramp events, due to fluctuating wind speeds present challenges to the stability of the electric power supply. In Japan, the ramp events are generally induced by extratropical cyclones along their track. Since prediction for the behavior of the cyclones entails uncertainty caused by nonlinear dynamics, probabilistic prediction is more effective. For this study, we developed a regional ensemble prediction method using the Weather Research and Forecasting model (WRF). To obtain dynamically consistent perturbations with a synoptic weather pattern, both initial and lateral boundary perturbations were determined by differences between the control and an ensemble member of the Japan Meteorological Agency (JMA)'s operational one-week ensemble forecast. This method provides 11 ensemble members with a horizontal resolution of 15 km for 75 hours at 30 minutes interval outputs by downscaling JMA's operational global forecast along with the perturbations. Wind power is projected using power curve which is estimated by relationship between area averaged wind speed and wind power generation. In addition to the dynamical ensemble, we expanded the ensemble member using Monte Carlo method to take account of the impact on uncertainty in the power curve. The expanded ensemble has 100 members. Forecast for the ramp events using the expanded ensemble exhibits high statistical consistency and reliability of ability to capture the ramp events compared with the dynamical ensemble prediction.

Discussion

Application of geological dara to ground source heat pump systems with special reference to thermal conductivity of geological materials

*Masakatsu SASADA[1]

1. Geo-Heat Promotion Association of Japan

Ground source heat pump systems are getting popular in Japan. Ground source means low temperature energy in geological units shallower than 200 meters below the surface. A geothermal heat pump system is much more efficient than a conventional air source heat pump system. A ground source heat pump system also contributes to mitigating a heat island phenomenon in large urban areas like Tokyo, because it does not emit exhaust heat outside in summer.
Effective thermal conductivity is one of the most important parameters to design ground source heat pump systems. Thermal response tests result in effective thermal conductivity of geological units under the building site. The reference values of thermal conductivity for several geological units are also available to building designers.
The regulation of Energy Conservation Standards came into effect in April 2016. Under the regulation annual primary energy consumption for every type of building is standardized. An owner of building has to submit building certification application with data of annual energy consumption calculated by Web Program of Building Research Institute. When ground source heat pump systems are installed in the building, the thermal conductivity of the building site must be input the Web Program for calculation of annual primary energy consumption.
Thermal response test is the best method to estimate the thermal conductivity of the geological units under the building site. However, it is not always applied to residential houses and small size buildings. The reference data of thermal conductivity are usually applied to them. Since geological units are so diverse in the Japanese Islands that much more measured data of thermal conductivity are required for reference database.

Use of groundwater in the Nishi-Osaka Area and its activities.

*Naoko Kitada[1], Hiroko Ito[1], Tomoo Echigo[1], Teruyuki Fujiwara[1], Makoto Nishigaki[2]

1. Geo-Research Institute, 2. Okayama University

On the west side of Osaka plain, several clay layers accompanying repeated sea level change accumulate in layers, and the gravel layer between the clay layers forms a submerged aquifer where abundant underground water resides. On the other hand, due to the severe ground subsidence caused by the massive pumping up of factory water in the 1960s, pumping is currently strictly regulated. However, in recent years, especially in Osaka city, consideration is being made on effective utilization of groundwater, such as the promotion of underground water use project as regenerative thermal energy.

Therefore, we conducted survey of water level, water temperature, and water quality using existing observation holes near Nakanoshima from around Osaka Station for the purpose of acquiring background data on the properties of groundwater at the present time. The aquifer covered in this study is a sand gravel layer (1st aqueduct layer: Dg1) distributed beneath the clay layer (Ma13) of the Holocene, and the gravel layer (the second caught aquifer: Dg 2) distributed under the clay layer (Ma12). Regarding the water quality, we analyzed the composition of the principal components etc. for groundwater sampled 4 times in total in June, September, November 2016 and January 2017. As a result, it was revealed that both Dg 1 and Dg 2 were reductive and showed a Na - Cl type water quality composition, especially Dg 1 had a higher salt concentration.

Improvement of prediction of wind power ramp by using monitoring data

*Shinji Kadokura[1], Daisuke Nohara[1], Masamichi Ohba[1], Atsushi Hashimoto[1], Keisuke Nakao[1], Yasuo Hattori[1], Takeshi Watanabe[1], Hiromaru Hirakuchi[1]

1. Central Research Institute of Electric Power Industry

Introduction of power generation by renewable energy such as photovoltaics(PV) and wind power (WT) is worldwidely progressing. Since PV and WT power generation are markedly fluctuated due to the change of the wheather, there is concern about the stability of the electric power system. Therefore, we have been developing a prediction method of wind power generation output to contribute for the stabilization of electric power system. In this method, the numerical forecast value provided by the Japan Meteorological Agency is downscaled using the weather model WRF and CFD model to predict the wind speed at the wind turbine, and the power output is predicted using the power curve. By adding the generated power output for each wind turbine obtained, the total output of the area is obtained. In this study, we have improved the prediction of wind speed and power generation output by using the monitoring data for each wind turbine, by making correction based on multiple regression and by using empirical power curve. Furthermore, we have corrected the accuracy of the area total power output by sequentially correcting the windfarms where data for each windmill is not acquired. In addition, by performing multiple regression on the amplitude of the output change, we have improved the supplementation rate of the wind power generation rapid change henomenon, ramp.

A study of the use of meteorological data for energy management

*Hideaki Ohtake[1], Takashi Oozeki[1], Junichi Imura[2]

1. National Institute of Advanced Industrial Science and Technology, 2. Tokyo institute of technology

Recently, a large amount of photovoltaics (PV) power systems (approximately 45 GW as of June 2018) have been connected to a power grid in Japan. Electric power supply with PV power generation exceed electric power demand in a power grid. For safety control of an energy manage system (EMS) with variable PV power generation, optimal use of other power plants (thermal power plants etc) and battery systems will be required in a future energy network (Fig.1). PV power monitoring and forecasts based on a meteorological data can be useful information for an optimal control of other power systems. In our research group (referred as a HARPS in a JST CREST project), we developed a communication tool between meteorology and EMS research fields. Impacts of meteorological data have been also investigated in an EMS (e.g., optimal control of electrical power systems and battery systems) under large PV installations. Furthermore, real time monitoring of regional PV power estimation have been also tried using a new geostationary satellite, Himawari 8/9. In this presentation, we will introduce research topic of meteorological data in the EMS field.

[H-TT18] Development and application of environmental traceability methods

convener:Ichiro Tayasu(Research Institute for Humanity and Nature), Nobuhito Ohte(Department of Social Informatics, Graduate School of Informatics, Kyoto University), Gabriel J Bowen(University of Utah), Chairperson:Nobuhito Ohte(Kyoto University)

Modern society uses almost all the elements present in the natural world. Although there have long been calls for the sustainable use of the resources that provide these elements and the building of human societies that are in harmony with the environment, the survival of the human race is increasingly at risk as a result of qualitative changes to the environment as a whole. Implementation by the society of methodologies for diagnosing and tracking these various elements of the natural environment and their relationships with humans are now required.
Elements cycle within and among the Earth system spheres, human society and the human body. Information on the concentrations and stable isotopes of elements is powerful tool for tracing this cycling and has been applied in studies of atmosphere-hydrosphere circulation, ecological systems, and the life, health and history of humans. We propose a session to discuss development and applications of environmental traceability methods toward the goal of establishing traceability in natural and human systems.
We encourage the presentation of research integrating isotopic information in various disciplines, such as geochemistry, hydrology, ecology, geology, mineralogy, anthropology, food science, and forensics. Studies applying "Isoscapes", maps of spatial isotopic variation, in addition to traditional database-based approaches, are strongly encouraged.

Environmental traceability methodology by multi-isoscapes

*Ichiro Tayasu[1], Lei Fujiyoshi[1], Shiho Yabusaki[1], Ki-Cheol Shin[1], Takanori Nakano[1], Makoto Taniguchi[1]

1. Research Institute for Humanity and Nature

Stable isotope ratios of elements, together with the concentrations of elements, can trace a matter flow, the environmental condition of sites, ecosystem structure and food products. Spatio-temporal variation of multiple isotope ratios can be used for studying the earth systems from local to global point of view. By using the traceability function of the multiple isotope ratios, we can conduct research that contributes to solving global environmental problems covering various regions and time scales. Spatio-temporal variation of multiple isotope ratios can be used for studying earth systems, ranging from local to global scales. The information may serve as a key decision- making factor for local people to consider water, food and environmental security, all of which are fundamental for the sustainability of human society.

We are conducting a research for establishing a methodology for how to use the concept of environmental traceability. A combination of quantitative and qualitative tools, including “Multi-Isoscapes” (use of multiple elements and multiple isotope ratios, together with GIS-based mapping technique), social surveys, and workshops, are deployed to investigate the role of environmental traceability in confronting environmental issues. We hypothesize that the role and perception of traceability methods in transdisciplinary processes will differ among stakeholders and that the co-production of “Multi-Isoscapes” can act as an effective “bridging tool” for understanding and explaining variation in local environments. The ultimate objective of this research is to demonstrate the effectiveness of multi-isotopic information in solving global environmental issues. Research is taking place at sites in Ono City, Fukui; Otsuchi Town, Iwate; Saijo City, Ehime; Oshino Village, Yamanashi; the Chikusa river watershed, Hyogo; Lake Biwa and Yasu river watershed in Shiga; and Silang-Santa Rosa sub-watershed in the Philippines.

Exploring physical and biological connections using isoscapes

*Gabriel J Bowen[1]

1. University of Utah

Environmental chemistry data provide a wealth of information on Earth system processes, but perhaps one of the most general and widely useful applications of such data is in to identify within- and between-system connectivity. Chemical signatures have been used to establish hydrological connectivity, identify the provenance of geological materials, artefacts and forensic evidence, and trace the migration of humans and other animals. Particularly useful are spatial and temporal patterns of environmental isotope variation, which are often predictable based on large-scale databases and/or fundamental physio-chemical theory. I will review case studies demonstrating how the resulting quantitative data products, called isoscapes, have led to new advances and applications in fields as diverse as forensic science, water resources research, and aquatic ecology. I will also discuss how community data and computational infrastructure, including the Waterisotopes Database (wiDB; http://waterisotopes.org) and Isoscape Modeling, Analysis and Prediction tool (http://isomap.org) are facilitating and promoting the use of geochemical data in connectivity research and related outreach and education.

Spatial and temporal variations in stable isotopes and soluble ions on high mountain snow surface of Mt. Tateyama, Toyama Prefecture, Japan

*Nozomu Takeuchi[1], Ryo Sugiyama[1]

1. Chiba University

A great amount of snow accumulates during winter in mountain regions in Japan due to strong westerly of the Asian monsoon. Snow can preserve various aerosols in the atmosphere, such as sea spay, anthropogenic pollutants, mineral dust, and volcanic substances. Thus, studies of snow chemistry provide a means to understand spatial and seasonal variabilities of aerosols. Furthermore, soluble chemists in snow affect alpine vegetations and also affect microbes growing on snow surface during snow melting season. In this study, we investigated spatial variations in water stable isotopes and major soluble ions on snow surface of high alpine area of Mt. Tateyama (2300 - 2700 m a.s.l.) from spring to summer to understand sources and transportation of aerosols affecting the surface snow chemistry. The soluble ion concentrations in the surface snow are generally higher in April, when the surface snow did not melt yet, than those in May to August, when the snow melted significantly. We found high anomaly in Cl and stable isotope in the area along a small valley, called Raicho-zawa throughout the seasons. They are likely to originate from an active volcanic fumarole, called Jigokudani, located in this area. Results shows that the chemical conditions of the snow surface in this mountain area are mostly influenced by sea spay and anthropogenic pollutants supplied by westerly before melting season, and are also partially influenced by the volcanic fumarole of the mountain throughout the melting seasons.

Using Sr isotopes to determine the contribution of volcanic ash to Sr and Ca in stream waters in a chert watershed.

*Masami Koshikawa[1], Mirai Watanabe[1], Tomoyoshi Murata[1], Takejiro Takamatsu[1], Shingo Miura[1], Ki-Cheol Shin[2], Takanori Nakano[2]

1. National Institute for Environmental Studies, 2. Research Institute for Humanity and Nature

The sources of Ca in forest ecosystems in Japan have been considered to be sea salt, weathering product of bedrock, and weak-acid soluble minerals in Kosa (Asian dust). However, we believe that volcanic ash in soil also plays an important contributor of Ca in areas with volcanic ash soil (e.g., Andosols), especially in the regions where the Ca supply from bedrock is anticipated to be low. We reported the significant contribution of volcanic ash in soil to Ca in stream waters and plants in a granite watershed of Tsukuba area, using stable isotope of Sr, a good proxy of Ca (Koshikawa et al. 2016). To evaluate the contribution of volcanic substances to soil-vegetation-stream systems, we conducted a similar study at the forest on Mount Amamaki where volcanic ash in soil would be more abundant than Tsukuba area and chert with high resistance to chemical weathering are widely distributed. In this presentation, we report the concentrations of Sr and Ca and the isotope ratio of Sr in the 42 stream waters, and those of precipitation, bedrock and volcanic ash which are considered to be the end component, and estimate the contribution of volcanic ash to Sr and Ca in stream waters.

Keywords: Volcanic ash, Sr isotopes, Stream water, Ca sources, Chert

Influences of soil dust, sea salt and anthropogenic activities on ionic and Sr isotopic compositions of wet deposition in Iran

*Yoriko Yokoo[1], Kosuke Asai[1], Sae Horii[1], Ryo Anma[2], Shiva Mehrabani[3], KiCheol Shin[4]

1. Faculty of Science and Engineering, Doshisha University, 2. Tokushima University, 3. Kurdistan University, 4. RIHN

We collected monthly wet deposition in four western cities (Hamedan, Ilam, Shiraz and Ahvaz) from January 2014 to May 2017 and in three eastern cities (Mashhad, Birjand and Zahedan) from January 2016 to May 2017 and in Rezvanshahr from May 2016 to May 2017 in Iran, and determined their pH values, electrical conductivity (EC), major ionic concentration (Na^+, Mg^{2+}, K^+, Ca^{2+}, Cl^-, NO_3^-, SO_4^{2-} and HCO_3^-) and Sr isotope ratios ($^{87}Sr/^{86}Sr$) in order to elucidate the influences of soil dust, sea salt and anthropogenic activities on wet deposition chemistry. In no-rainfall months, we rinsed the sampler with ultrapure water and collected it to understand the influence of aerosols. The climate in Iran is semiarid, and the dry and wet seasons are from June to September and from October to May, respectively.
The wet deposition and rinsed water samples in western and eastern Iran were neutral to slightly alkaline ranging from 6.26 to 9.04 and from 6.71 to 11.08 in pH, respectively. Those in Rezvanshahr were neutral to acidic ranging from 3.88 to 7.48 in pH. The ionic compositions of most precipitation samples were enriched in $Ca^{2+}$and HCO_3^-. Although the pH of natural rain in equilibrium state with atmospheric CO_2 is typically 5.6, precipitation in western Iran is not acidic because of neutralization by aeolian minerals such as calcite originating from arid areas. The $^{87}Sr/^{86}Sr$ of samples fell in a narrow range of 0.708±0.001. These values were most likely due to the dissolution of calcite. Small, but detectable seasonal variation was found in the $^{87}Sr/^{86}Sr$ ratio that suggests different provenances of calcite/gypsum controlled by changing wind direction.
The ionic compositions of several samples were abundant in NO_3^- and SO_4^{2-} in Hamedan, Ilam, Shiraz and Mashhad. These samples were collected during dry season and wet season immediately after the dry season. These results suggest that the samples dissolved NO_3^- and SO_4^{2-} derived from anthropogenic activities and/or soil dust such as sulfate minerals concentrated in atmosphere during the dry season. The ionic compositions of samples in Ahvaz, Rezvanshahr, Birjand and Zahedan were relatively enriched in Na^+ and Cl^-. Ahvaz and Rezvanshahr are closer to the Persian Gulf and the Caspian Sea, respectively. These indicate that the wet deposition samples in Ahvaz and Rezvanshahr are subject to salt from sea and salt lake.

[H-TT18] Development and application of environmental traceability methods

convener:Ichiro Tayasu(Research Institute for Humanity and Nature), Nobuhito Ohte(Department of Social Informatics, Graduate School of Informatics, Kyoto University), Gabriel J Bowen(University of Utah), Chairperson:Gabriel Bowen(The University of Utah)

Modern society uses almost all the elements present in the natural world. Although there have long been calls for the sustainable use of the resources that provide these elements and the building of human societies that are in harmony with the environment, the survival of the human race is increasingly at risk as a result of qualitative changes to the environment as a whole. Implementation by the society of methodologies for diagnosing and tracking these various elements of the natural environment and their relationships with humans are now required.
Elements cycle within and among the Earth system spheres, human society and the human body. Information on the concentrations and stable isotopes of elements is powerful tool for tracing this cycling and has been applied in studies of atmosphere-hydrosphere circulation, ecological systems, and the life, health and history of humans. We propose a session to discuss development and applications of environmental traceability methods toward the goal of establishing traceability in natural and human systems.
We encourage the presentation of research integrating isotopic information in various disciplines, such as geochemistry, hydrology, ecology, geology, mineralogy, anthropology, food science, and forensics. Studies applying "Isoscapes", maps of spatial isotopic variation, in addition to traditional database-based approaches, are strongly encouraged.

Long-term increasing trend of line-conditioned excess in groundwater

*Masanori Katsuyama[1]

1. Graduate School of Agriculture, Kyoto University

The isotope composition in water is commonly used for the analysis of hydrological processes. According to the recently proposed two water world hypothesis, precipitation will separated into two water pools such as the stored portion in soil pore which is much evaporated and used by vegetation, and the rapidly infiltrated portion which is less affected by evaporation and recharge the stored ground- and stream water. The line-conditioned excess (or lc-excess) is an appropriate indicator to find these separation. This method defines the offset between a meteoric water line and each water samples, with a negative value indicate the effect of evaporation. The long-term observation of isotope composition is ongoing at the Kiryu Experimental Watershed (KEW). The isotope composition in the rain water does not have a clear increasing or decreasing trends for the observation period. The long-term trend of the lc-excess was also not found in soil water and shallow groundwater. On the other hand, the increasing trend of the lc-excess was found in deeper groundwater. This fact means that the effects of evaporation on the infiltrating water are decreasing. The d18O in the groundwater was slightly decreasing. If the global warming directly effects on the isotope composition in the groundwater, the d18O may increase. Thus, the decreasing d18O and the increasing lc-excess may be the results of the change of local hydrological processes. Recently, it is reported that the extreme rainfall events are increasing in Japan, including in KEW. Therefore, the trend of lc-excess in groundwater suggest that change of rainfall patterns cause the increase of rapid infiltration and recharge of groundwater body. Moreover, the long-term trend of groundwater isotope composition was observed at five locations, Hokkaido, Toyama, Yamanashi, Tottori, and Miyazaki prefectures in Japan and one location in California, USA using commercially available bottled waters. Within these locations, similar trend as KEW was found at Tottori and California. Although the depth and size of groundwater body and their residence time may effect on the patterns and trends of isotope composition, the results shown here suggest that the importance of the long-term monitoring of the groundwater. The effects of extreme rainfall events and vulnerability of each region should be evaluated based on the intensive observations at highly installed watersheds, as well as the utilization of easily available samples such as bottled waters.

Geochemistry of river water in the Okayama and Tottori Prefectures, Japan

*Katsuyuki Yamashita[1], Takahiro Kamei[1], Yuga Kishimoto[1], Masahiko Mori[1], Aya Ooi[2], Ayaka Onishi[2], Yoko Kurihara[2], Hitoshi CHIBA[1], Takanori Nakano[3], Ki-Cheol Shin[4]

1. Graduate School of Natural Science and Technology, Okayama University, 2. Faculty of Science, Okayama University, 3. Ono City, 4. Research Institute for Humanity and Nature

In order to evaluate the effect of water-soil (rock) interaction, as well as human impact on the geochemical nature of river water, we have collected 695 river water samples from 454 locations in the Okayama and Tottori Prefectures, Japan. The area is ideal for such study because (1) the geology of the area is well studied, (2) there is a sharp contrast in the amount of precipitation between the southern Okayama and northern Okayama to Tottori, and (3) the population density is highly variable. We have measured the major dissolved components, trace element concentrations, and O-H isotope ratios for all of the samples, along with Sr and S isotope ratios of the selected samples. Using these data, the high-resolution geochemical maps of the two prefectures were constructed.
Both the oxygen and hydrogen isotope ratios display a clear altitude effect. The d-excess, on the other hand, is high in the northern Okayama and Tottori Prefectures (>20), and gradually decreases towards the southern Okayama (5~15). This pattern can be explained by considering the O-H isotopic signatures of the precipitation (e.g Mao 2017), as well as the difference in the amount of precipitation in the two areas. The concentration of some elements seems to correlate well with the type of rocks exposed in the area. For example, Ca and Sr concentrations are high in the areas where limestones are exposed, whereas Cr and Ni concentrations are generally high in the areas dominated by ultra-mafic rocks. In the Mt. Daisen area of the western Tottori Prefecture where dacitic volcanic rocks are common, the concentration of Si, V, Rb, Cs is high. These observations suggest that the concentration of some elements in the river water is strongly controlled by the geochemistry of rocks exposed in the area. The concentration of some dissolved constituents such as SO_4 and NO_3, on the other hand, seem to correlate well with the population density. This may imply that human activity (industrial and agricultural) is responsible for the elevation of SO_4 and NO_3 concentrations in the river water.

Study on groundwater flow system at Oshino Village in Yamanashi Prefecture –Report 5. Estimation of the residence time in spring water and groundwater at Oshino Village.

*Shiho Yabusaki[1], Makoto Taniguchi[1], Ichiro Tayasu[1], Tomoya Akimichi[1], Noboru Ohomori[2], Ken Gotou[2], Souichirou Watanabe[2], Hitoshi Watanabe[2]

1. Research Institute for Humanity and Nature, 2. Oshino Village

Oshino Village is located in southern part of Yamanashi Prefecture, Japan. The elevation is 936 m a.s.l. and the area of village is about 8 km from east to west and about 4 km from north to south. The Oshino Hakkai springs that is registered as World Cultural Heritage Site are located in Oshino Village. It is suggested that the Oshino Hakkai springs are recharged at Mt. Fuji as a result of field observation. The objective in this study to clarify the detailed groundwater flow and residence time of spring water and groundwater in Oshino Village. In this presentation, the authors will report about average residence time of groundwater and spring water.

The water samples for estimating the residence time by using the CFCs and SF_6 have been collected at 2 spring water sites, 1 shallow groundwater site and 11 deep groundwater sites. For ^3H analysis, water samples have been collected at 4 spring water sites and 4 deep groundwater sites. In this study, “shallow groundwater” is defined as several meters to some dozen meters depth, and “deep groundwater” is defined as about 100 m to 400 m depth.

As a result of analysis, the average residence time of spring water is about 10 to 26 years, shallow groundwater is about 30 to 40 years and deep groundwater is about 40 to 60 years. In addition, it is estimated that the average residence time of spring water which show the specific water quality (Na-SO_4 type, $\delta^{18}O$ and δD is relatively low) is more than 70 years. We will consider the relation between average residence time and water quality/ stable isotopes in future.

The continuous observation of water temperature and EC at 2 sites of Oshino Hakkai has been implemented since August, 2018. We will continue the field observation of Oshino village at 2019, and estimate the groundwater flow system and residence time more clearly.

Keywords: Oshino Village, groundwater, water quality, stable isotopes, groundwater flow, residence time

The hydrogen and oxygen isotopic compositions of water in the Chikusa River

*Ken'ichi Ohkushi[1], Shiho Yabusaki[2], Ichiro Tayasu[2], Lei Fujiyoshi[2], Takanori Nakano[2], Ki-Cheol Shin[2], Tadashi Yokoyama[3], Hiromune Mitsuhashi[4], Masayuki Itoh[1], Kazuki Yasugi[1]

1. Kobe University, 2. The Research Institute for Humanity and Nature, 3. Ako School for Students with Special Ne, 4. University of Hyogo

Chikusa River is the class B river facing the Seto Inland Sea in southwest Japan. Because of heavy rain, this river sometimes flows over and its basin is damaged, so Hyogo prefecture has carried out river reforming works to improve the capacity of flow until May, 2016. But the works changed the environment of this river, the impact on the quality of river water and the river ecosystem is concerned and we need the basic data of this river to measure this impact scientifically. In this study, we analyzed concentrations of dissolved ion and trace elements, stable isotopic ratio of water (δ 2H, δ 18O). In addition, we plotted the result of analysis on a basin map with a geographical information system so that the result could be seen easily and we aimed to offer the basic data which was easy to use. Furthermore, we estimated the formation factor of dissolved ion, trace elements and stable isotopic ratio of the river water through a comparison between the result of analysis and the land use, geological features and topography of the basin.

In Chikusa River, Chikusa River Conservation Committee has been holding “The simultaneous survey of water temperature all around Chikusa River” in every August since 2002. In this survey, the committee and many local residents measure water temperature at 94 sites, from headwaters to river-mouth and some tributaries. From 2015, Research Institute for Humanity and Nature, Kobe University and University of Hyogo has joined in this survey and started collecting water samples. In the survey of 2018 (held in August 5, 13:00~16:00), we received the water samples from local residents and we filtered them at once, with cellulose acetate filters whose diameters of holds are 0.2 μm. After filtering, we subdivided the samples into some polyethylene bottles and a glass vial and stored them at 20℃ or -30℃. We analyzed stable isotopic compositions of water. Stable isotopic composition of water was lower in the upstream and higher from the middle reaches to the downstream. From the upstream toward the middle reaches, the ratio became lower as the altitude became higher because of the precipitation affected by the altitude effects. On the other hand, the ratio was higher from the middle reaches to the downstream in spite of the altitude. These areas’ river became shallower and wider in the river reforming works, so the effects of sunlight on the river became big and the evaporation from the surface of river became more active.

Dynamics of sulfate and nitrate inferred from stable isotope techniques in Chikusa river watershed, Hyogo Prefecture

*Lei Fujiyoshi[1], Ichiro Tayasu[1], Shiho Yabusaki[1], Takashi F Haraguchi[1], Chikage Yoshimizu[1], Ken'ichi Ohkushi[2], Fumiko Furukawa[2], Masayuki Itoh[2], Yudai Yamamoto[3], Tadashi Yokoyama[4], Hiromune Mitsuhashi[5]

1. The Research Institute for Humanity and Nature, 2. Kobe University, 3. Nagoya University, 4. Hyogo prefectural Ako School for Students with Special Needs, 5. University of Hyogo

The Chikusa river watershed is located in the southwestern part of Hyogo prefecture. Recent river improvement in the watershed has posed concerns about changes in water quality and river ecosystem. This study aims to clarify the dynamics of dissolved ions especially sulfate and nitrate using stable isotope techniques, and to contribute to the evaluation of water environment in the watershed.

Water samples were collected from headwaters to the river mouth in August (2015, 2016, and 2017) and in February (2018), and measured ion concentrations, sulfur (δ^{34}S) and oxygen (δ^{18}O) stable isotope ratios of sulfate, and nitrogen (δ^{15}N) and oxygen (δ^{18}O) stable isotope ratios of nitrate.

Sulfate concentration was lower upstream and higher downstream in all periods, and the nearest point to the river mouth showed topically high concentration (1156 mgl^{-1}). The δ^{34}S and δ^{18}O values of sulfate suggested that the sulfate was mainly derived from soil sulfate, and the sulfate near the river mouth was derived from the seawater. In contrast, nitrate concentration was higher upstream and lower downstream in August, however the trend reversed in February. The δ^{15}N and δ^{18}O values of nitrate imply that the contribution of primary production and/or denitrification in water caused the reversed trend of nitrate concentration. The spatial distribution of δ^{15}N of nitrate showed a significant correlation with the proportion of fertilized land use (paddy field, farmland, and golf course) in all periods, suggesting an influence of fertilization.

Chemistry and sulfur and oxygen isotope ratios of sulfate ion of water soluble component of suspended particulate matter at Okayama city.

*Hitoshi CHIBA[1], Tsubasa Yamamoto[1]

1. Graduate School of Natural Science and Technology, Okayama University

Suspended particulate matters (SPM and PM2.5) have been collected at Okayama University, Okayama city in order to elucidate their chemical nature, origin and relationship with sulfate ion in precipitation. SPM and PM2.5 were sampled once a month and duration of the sampling is 96 hours. Water soluble components of SPM and PM2.5 were extracted ultrasonically. Their chemical compositions were analyzed by ion chromatography and sulfur and oxygen isotope ratios were analyzed by EA-IRMS and TC/EA-IRMS, respectively.

Soluble components of PM and PM2.5 are overwhelmingly composed NH_4^+ and SO_4^{2-}, thus seems to be mainly $(NH_4)_2SO_4$. There is no significant compositional difference in SPM and PM2.5.

Sulfur isotopic ratio of sulfate in water soluble components in SPM and PM2.5 at Okayama city is high in winter and low in other seasons, similar to nss-sulfate in precipitation. However, their sulfur isotope ratios in autumn and winter are 1 to 2‰ higher than those of nss-sulfate in precipitation. High sulfur isotope ratios in winter seem to be affected by sulfur compounds originated from coal combustion in China. However, they are clearly lower than those of sulfate in total suspended particulate matter in Beijing (Han et al., 2016) and indicate that, even in winter, contribution of sulfur originated from coal-combustion in China seems to be small at Okayama city and local source may mainly contribute to sulfate of suspended particulate matter. Furthermore, sulfur isotope ratios of nss-sulfate in PM2.5 at Niigata city (Inomata et al., 2016) agree generally with our data at Okayama city.

Oxygen isotope ratios of soluble components in SPM and PM2.5 seem to be high in winter. Oxygen isotope ratios of nss-sulfate of precipitation is also high in spring. However, the cause of this phenomena is not clear now.

Present data suggests that the direct contribution of trans-border transport of SPM and PM2.5 from China is limited at Okayama city and/or that sulfur and oxygen isotope signatures of sulfate in water soluble components of SPM and PM2.5 are greatly altered during transport from China to Okayama.

[H-TT18] Development and application of environmental traceability methods

convener:Ichiro Tayasu(Research Institute for Humanity and Nature), Nobuhito Ohte(Department of Social Informatics, Graduate School of Informatics, Kyoto University), Gabriel J Bowen(University of Utah), Chairperson:Ichiro Tayasu(Research Institute for Humanity and Nature)

Modern society uses almost all the elements present in the natural world. Although there have long been calls for the sustainable use of the resources that provide these elements and the building of human societies that are in harmony with the environment, the survival of the human race is increasingly at risk as a result of qualitative changes to the environment as a whole. Implementation by the society of methodologies for diagnosing and tracking these various elements of the natural environment and their relationships with humans are now required.
Elements cycle within and among the Earth system spheres, human society and the human body. Information on the concentrations and stable isotopes of elements is powerful tool for tracing this cycling and has been applied in studies of atmosphere-hydrosphere circulation, ecological systems, and the life, health and history of humans. We propose a session to discuss development and applications of environmental traceability methods toward the goal of establishing traceability in natural and human systems.
We encourage the presentation of research integrating isotopic information in various disciplines, such as geochemistry, hydrology, ecology, geology, mineralogy, anthropology, food science, and forensics. Studies applying "Isoscapes", maps of spatial isotopic variation, in addition to traditional database-based approaches, are strongly encouraged.

Do mountain-climbing mammals protect plants from global warming by their vertical seed dispersal?

*Shoji NAOE[1], Ichiro Tayasu[2]

1. Forestry and Forest Products Research Institute, Forest Research and Management Organization, 2. Research Institute for Humanity and Nature

Today, global warming is progressing rapidly, and attention is focused on how trees that make up the forest respond. The easiest and most powerful means for trees to escape from global warming is to move to colder areas, that is, higher altitude or latitude, by seed dispersal. Considering that the temperature drop with increasing altitude is one hundred to a thousand times larger than that of the equivalent latitudinal distance, vertical seed dispersal seems a key process for plant escape from warming temperatures. However, no study has evaluated vertical seed dispersal itself due to technical difficulty or high cost. By using negative correlation between altitudes and oxygen isotope ratio of seeds, we evaluated the vertical seed dispersal of summer-fruiting wild cherry and autumn-fruiting wild kiwi by mammals in central Japan. The results were contrasting: while seeds of cherry were dispersed toward mountain tops (by bear; mean +307.2, marten; +193.0 m), seeds of kiwifruit were dispersed toward the foot of mountains (by bear; -393.1, monkey; -98.5, raccoon dog; +4.5, marten; -226.9 m). These were probably because mammals followed plant phenology in temperate zone which proceeds from the foot to the top of mountains in spring to summer and from the top to the foot in autumn to winter. Downhill seed dispersal will likely lead to a serious population decrease of plants under global warming, because their performance is strongly reduced by novel competitive plants in the lower altitude environment. Considering that many of trees depend on animals and fruit in autumn to winter, forest composition in temperate zone might dramatically change under global warming due to biased vertical seed dispersal by animal.

Keywords: seed dispersal, global warming, temperate forest, mammal, cherry, kiwi

Spatial distribution of nitrogen stable isotope ratio in deer feces in an agro-environment, Osaka

*Takashi F Haraguchi[1], Ryosuke Koda[2], Ichiro Tayasu[1]

1. Research Institute for Humanity and Nature, 2. RIEAF, Osaka

A rapid increase in the number of sika deer (*Cervus nippon*) in the last decades aroused needs for quantitatively estimating crop herbivory by them, in order to evaluate how much damage they cause to agriculture. Analysis of ingredients in deer feces using observation under microscopes or molecular techniques is useful to reveal whether they consumed crops. Nevertheless, these techniques in common tend to underestimate crop herbivory, because crops are usually digested more easily than wild plants and less likely to remain in the feces. Measurement of fecal nitrogen stable isotope ratio (fecal δ^{15}N) can be a complement to the molecular technique, considering that application of fertilizer leads to distinctively higher δ^{15}N values of crops than the adjacent wild plants. In our previous study using captive deer individuals, we estimated the fecal δ^{15}N values are 2.0 to 3.5‰ lower than those of deer diets. Based on the test using captive individuals, the uncertainties of the fecal δ^{15}N values associated with the variations in isotopic fractionation were far less than the difference of δ^{15}N values between fertilized crops and wild plants. In this study, for a field validation of the fecal δ^{15}N measurements as an indicator of crop consumption, we examined the spatial distribution of the fecal δ^{15}N, assuming the crop consumption should occur in the individuals of sika deer inhabiting close to cropland.

Deer feces were collected in 80 forested sites in the northern part of Osaka prefecture in the 2014 to 2015 winter period. The fecal samples, which were dried at 60℃, ground, and homogenized for each of the fecal mass, were used for δ^{15}N measurements. Based on GPS telemetry of sika deer in the region (Ishizuka et al., 2007), we assumed that short-time moving range of sika deer is around 500 m in radius and the accessibility of crops for the deer is reflected by surrounding land use within the distance from sampling points. Land use surrounding sampling points were categorized into four components; forest, crop field, herbal vegetation, residential area and area of each component were calculated. Land use data are obtained from MoE National Surveys on the Natural Environment and area (m^2) of the surrounding sampling points. We conducted Spatial AutoRegressive model (SAR) and PCNM-RDA analyses to analyze the effects of surrounding areas of these landscape components on the fecal δ^{15}N values and concentrations of nitrogen in the feces.

The surrounding area of crop field was selected as a single variable to explain the fecal δ^{15}N values, and the positive correlation between the fecal δ^{15}N values and crop field area indicated the availability of crop to deer was a factor of the increase in the fecal δ^{15}N values. Based on the result, this study supported our hypothesis that fecal δ^{15}N values are an effective indicator of crop consumption by sika deer. In our presentation, we will further discuss about the relationships among concentration of nitrogen in the feces, which is known as an indicator of nutritional status of the defecated individual, estimated deer population density, and land use to elucidate factors inducing crop consuming behavior of sika deer.

Nutrient supply from forest to river in eastern Toyama: carbon and nitrogen isotopic composition of Epilithic Organic Matter

*JING ZHANG[1], Ryosuke Masuda[1], SAKI KATAZAKAI[1], Tamihisa Ohta[1], OSAMU INAMURA[2], Fumiko Nakagawa[3]

1. University of Toyama, 2. Uozu Aquarium, 3. Nagoya University

River water has higher concentrations of dissolved components than precipitation because dissolved components are added when precipitation passes through forest areas interacting with rocks and vegetation. To clarify the supply of nutrients from the forest area to the river, in this study we focused on catchment areas and conducted research at river upstream areas in eastern Toyama prefecture where there is with very little human influence. River waters and Epilithic Organic Matter (EOM) were collected from 2016 to 2018. We measured the concentration of major chemical components, stable isotope composition of oxygen and hydrogen (d18O, dD) in water samples, and stable carbon and nitrogen isotopic ratios of EOM. Analysis results are discussed together with topographical data and the vegetation map obtained by GIS. The results are as follows.

1) Judging from d18O values and dD values, river waters were formed by a mixture of precipitation in summer and in winter in an altitude range of 300 ~ 2000 m.

2) There was a correlation between d13C values of EOM and both Calcium and bicarbonate concentration. This suggests that Ca in river water is supplied by carbonate (CaCO3) weathering of rock and soil in the catchment area. Ca, Na, K and Mg concentrations showed a significant positive correlation with the coniferous proportion, it suggests that these chemicals are added into river water when passing through the forest area. Compared to rain water, chemical components were higher in rivers, about 200 times for Ca, 6 times for Na, 8 times for K and 10 times for Mg respectively.

3) A negative correlation exists between riverine nitrate concentration and evergreen percentage of vegetation in the catchment, and more than 90% of nitrate in river water is derived from the forest using oxygen isotopic ratio Δ17O of nitrate. It means the amount of nitrate in precipitation is trapped in the forest and then the forest originated nitrogen discharges into the rivers.

4) Δ15N in EOM, which possibility “records" the nitrogen supply information for several days to weeks when using nitrate from river water, is bounded at the altitude of 1500 m and reflects the vegetation within the catchment areas. In addition, the δ15N value showed a positive correlation with the evergreen percentage in the Catchment area, suggesting that vegetation affects nitrate outflow to rivers.

Investigation on the possibility of the identification of air pollutant sources using stable isotope ratios of lead and strontium

*Shinji Sakurai[1], Takao Nakagiri[1], Kosuke Tanaka[1], Haruhiko Horino[1], Ki-Cheol Shin[2], Ichiro Tayasu[2], Shiho Yabusaki[2]

1. Osaka Prefecture University, 2. Research Institute for Humanity and Nature

In Japan, transboundary air pollution coming from neighboring countries is concerned as one of the serious threads on the health. However, it is not easy to assess the actual impact because of difficulty to identifying the detailed transport path and the source of pollutants. Although it is expected that stable isotope ratios (hereafter, isotope ratios) of lead (Pb) and strontium (Sr) can be used as environment tracers to identify the pollutant source, even the basic information on their characteristics such as chronological and/or seasonal variations at resolution of rainfall event as well as the relationship between the ratios and other water quality parameters is still not enough to consider the possibility.
In our study, rainwater was collected in a polyethylene bottle, on the top of which a polypropylene funnel was set, separately in every rainfall event from June 2016 to August 2018 at the campus of Osaka Prefecture University in Sakai, Osaka, Japan. The isotope ratios of Pb and Sr ($^{207}Pb/^{206}Pb$, $^{208}Pb/^{206}Pb$, and $^{87}Sr/^{86}Sr$) in the rainwater samples were measured using a multi-collector inductively coupled plasma mass spectrometer. Concentrations of heavy metals (Fe, Mn, Cd, Cu, Ni, and Pb), inorganic ions, pH, EC, TOC, COD, T-N, and T-P were measured as water quality parameters. Rainfall amount was measured with a rain gauge set near the rainwater sampling point. Other meteorological data needed to investigate and estimate the pollutant sources, such as air temperature, wind direction, and duration of drought, were obtained from the Japan Meteorological Agency.
There was no obvious trend either chronologically or seasonally for $^{207}Pb/^{206}Pb$ or $^{87}Sr/^{86}Sr$. The values of the $^{207}Pb/^{206}Pb$ ratio declined slightly during the observation period, but the $^{87}Sr/^{86}Sr$ ratio did not show this chronological variation.
There was no obvious correspondence between most of water quality parameters and each isotope ratio. The $^{207}Pb/^{206}Pb$ varied widely during events in which Cr and Fe concentrations were low, but was close to 0.871 as the concentrations of these metals were getting higher. There is similar tendency in $^{87}Sr/^{86}Sr$ for Fe and Cr. It was suggested that these metals might be derived from the same source.
For correspondence with meteorological factors, the monthly rainfall amount weighted average of $^{207}Pb/^{206}Pb$ fluctuated when the wind from the west or the west-southwest was dominant, while it took almost a unique value for the south-southwest. It was suggested that Pb was originated from various sources with the west wind.
Plots of the obtained data on the $^{207}Pb/^{206}Pb$ vs. $^{208}Pb/^{206}Pb$ were distributed upside and parallel to the lead isotope growth curve. When comparing our plots with the previous global studies, we found that ours were distributed in a manner similar to those from China and Russia. It was indicated that it is difficult to identify pollutant sources from these countries, which are thought to cause transboundary pollution in Japan.
Further research, including the collection of data on isotope ratios as environmental tracers, is necessary to identify pollutant sources using isotope ratio of Pb and/or Sr.

Magnesium and zinc stable isotopes in stream ecology

*Kai Nils Nitzsche[1], Yoshikazu Kato[1], Ki-Cheol Shin[1], Hiromitsu Kamauchi[1], Ichiro Tayasu[1]

1. Research Institute for Humanity and Nature

Magnesium (Mg) and zinc (Zn) play important roles in biological production in stream ecosystems. Aquatic organisms take up metals from the diet and the water; however, relative contributions are largely unknown, which is assumed to depend on feeding habits. We determined Mg and Zn stable isotope ratios (δ^{26}Mg, δ^{66}Zn) of aquatic macroinvertebrates and of small goby, and their potential Mg and Zn sources (periphyton, plant litter, stream water) from upper and lower reaches of two temperate streams in the Lake Biwa catchment. Our goal was to understand Mg and Zn sources to aquatic organisms, and to explore δ^{26}Mg and δ^{66}Zn variations across feeding habits. δ^{26}Mg and δ^{66}Zn did not correlate with each other indicating that Mg and Zn sources differ across functional feeding groups and/or different degrees of isotopic fractionation during Mg and Zn uptake. Grazers, shredders and predators showed offsets to higher δ^{26}Mg values compared to metal sources indicating isotope fractionation during Mg accumulation, while stream water was the main Mg source to filter-feeders. In contrast, δ^{66}Zn of grazers and filter-feeders indicated Zn was often a mixture between periphyton and stream water, while δ^{66}Zn of shredders and predators gave evidence for Zn isotopic fractionation. Our results demonstrate the usefulness of applying non-traditional isotopes to understand metal sources to aquatic organisms, which could be used to trace the ultimate origin of metals from the catchment.

A mechanitic metabolic model of nitrogen stable isotope dynamics in trophic processes

*Reiichiro Ishii[1], Maki Noguchi Aita[2], Eitaro Wada

1. Research Institute for Humanity and Nature, 2. Japan Agency for Marine-Earth Science and Technology

Stable isotope analysis of nitrogen and carbon have been a powerful tool used for identifying trophic structure of ecosystems. Our previous studies suggested that the ratios of trophic fractionation of carbon and nitrogen isotopes ($Dd^{15}N/Dd^{13}C$) throughout food chain are similar in various ecosystems (Aita et al. 2011, Wada et al. 2013), although the general mechanisms determining isotopic incorporation rates and discrimination factors are not understood mechanistically yet. On the other hand, recent studies revealed the 15N enrichment factor for trophic processes varies among amino acids from which new method of estimation of the trophic level of animal samples (e.g., Chikaraishi et al. 2009).
Based on these observations, we developed a simple dynamic model of the isotopic fractionation in nitrogen metabolic processes that are common to animals composing most grazing food chains. Particularly, we focused on and incorporated the transamination and deamination processes of two classes of amino acid, essential and non-essential, respectively into the model. With this model we investigated how d15N signatures of the two amino acid classes and whole-body change. Preliminary result suggests that the instant isotopic composition of animals are sensitive to the change of their diet composition and growth rate, but on the other hand, the isotopic composition converges as the integrating period becomes long. Based on this model we will discuss possible negative feedback processes in isotopic enrichment for nitrogen to explain the commonly observed trophic-step 15N-enrichment factor through many food chains.

[H-TT18] Development and application of environmental traceability methods

convener:Ichiro Tayasu(Research Institute for Humanity and Nature), Nobuhito Ohte(Department of Social Informatics, Graduate School of Informatics, Kyoto University), Gabriel J Bowen(University of Utah)

Modern society uses almost all the elements present in the natural world. Although there have long been calls for the sustainable use of the resources that provide these elements and the building of human societies that are in harmony with the environment, the survival of the human race is increasingly at risk as a result of qualitative changes to the environment as a whole. Implementation by the society of methodologies for diagnosing and tracking these various elements of the natural environment and their relationships with humans are now required.
Elements cycle within and among the Earth system spheres, human society and the human body. Information on the concentrations and stable isotopes of elements is powerful tool for tracing this cycling and has been applied in studies of atmosphere-hydrosphere circulation, ecological systems, and the life, health and history of humans. We propose a session to discuss development and applications of environmental traceability methods toward the goal of establishing traceability in natural and human systems.
We encourage the presentation of research integrating isotopic information in various disciplines, such as geochemistry, hydrology, ecology, geology, mineralogy, anthropology, food science, and forensics. Studies applying "Isoscapes", maps of spatial isotopic variation, in addition to traditional database-based approaches, are strongly encouraged.

Isotopic study on seasonal nitrogen dynamics at Lake Biwa

*Takaaki Ishibashi[1], Ken'ichi Osaka[1], Keisuke Koba[2], Takashi Nakamura[3], Kei Nishida[3]

1. Department of ecosystem study, University of Shiga Prefecture, 2. Center for Ecological Research, Kyoto University, 3. International Research Center for River Basin Environment, University of YAMANASHI

To clarify nitrogen dynamics in Lake Biwa, we measured the concentrations of nitrogen compounds and their nitrogen stable isotopic ratios in 14 depths in north basin of Lake Biwa. In the lake, particulate nitrogen (PN), such as phytoplankton, is generally decomposed to dissolved nitrogen (DN); in order of dissolved organic nitrogen (DON), ammonia nitrogen (NH_4^+) and nitrate nitrogen (NO_3^-). These dissolved nitrogen compounds are taken up by phytoplankton again, and the nitrogen circulation in the lake is established. To predict the water quality in future, it is necessary to understand the nitrogen cycle in the lake, as well as nutrient load to the lake.

In this study, we collected lake water sample at 14 depths in north basin of Lake Biwa (water depth is 90 m) in 1-2 months interval. The lake waster sample was analyzed for the concentration of PN, PC, DN, NO_3^-, NO_2^- and NH_4^+, $d^{15}N$ of PN, DN and NO_3^-.

NO_3^- concentration was lower in the surface layer (0-20m), and higher in the deep layer (20-90m) during the stratification period, whereas NO_3^- concentration was constant in all layers during the circulation period. PN concentration also increased in the surface layer from April to June, decreased sharply in July. These indicate that phytoplankton which grew on the surface layer from April to June used NO_3^-, thereafter, NO_3^- was depleted after June, then, phytoplankton decreased after July respectively. On the other hand, NO_3^- concentration is considered to be increased by decomposition of the precipitated PN from surface layer. It is considered that the NO_3^- concentration became constant in all layers because of mixing of deep layer and the surface layer.

The weighted average $d^{15}N_{DN}$, $d^{15}N_{NO3}$ in the unit water columns decreased about 3‰ in the circulation period, in the circulation period, then, increased during the stratification period. The decrease of $d^{15}N_{DN}$, $d^{15}N_{NO3}$ at the water column during circulation period can not be explained by mixing of deep layer and the surface layer. We will discuss the mechanisms of $d^{15}N_{DN}$, $d^{15}N_{NO3}$ decrease during circulation period in the presentation.

Relationship between residence time, water quality, and stable isotopes of spring water and groundwater in coastal area of Fukushima prefecture

*Shiho Yabusaki[1], Kazuyoshi Asai[2]

1. Research Institute for Humanity and Nature・Faculty of Symbiotic Systems Science, Fukushima University, 2. Geo Science Laboratory

After the Great East Japan Earthquake occurred, the investigation near the coast area in northern part of Fukushima prefecture has been carried out to clarify the groundwater flow and residence time in this area. The measuring of EC, pH, water temperature, ORP and sampling of groundwater, spring water and river water have been carried out several times at Shinchi town, Soma city, Minamisoma city, Namie town, Okuma town, Iitate village and Date city since September in 2012. The inorganic ions, stable isotopes of oxygen and hydrogen, trace elements were analyzed for all samples by using the IC (ICS-3000), CRDS (Picarro L2130-i) and ICP-MS (Agilent 7500cx). For estimating the residence time, tritium concentration, CFCs and SF_6 measurements were made in several samples.

The water quality of river water and shallow groundwater indicates mainly Ca-HCO_3 type. In the part of the flooded area by a tsunami, the water quality of shallow groundwater and spring water is Na-Cl type. The Ca-SO_4 type and mixed type were also confirmed in some sites. In the case of deep groundwater, the water quality shows the Na-HCO_3 type and Ca-HCO_3 type. The concentration of Fe, Mn and Al were relatively high in some parts of deep groundwater. It is considered that the origin of these trace elements is soil.

The stable isotopes of oxygen and hydrogen ($\delta^{18}O$ and δD) in river water of Niida river, Mano river and Kamimano river indicate altitude effect. Because the stable isotopes in deep groundwater is relatively low, it is anticipated the recharge are of deep groundwater is about 300 m higher than that of shallow groundwater. It is expected that the recharge area of deep groundwater is around the Abukuma Mountains.

The average residence time of deep groundwater and spring water which indicate the Na-HCO_3 type is about 60 to 70 years. On the other hand, the average residence time of shallow groundwater which indicate the Ca-HCO_3 type is less than 10 years.

The information of groundwater flow is useful for considering the groundwater use with revival of the coastal area. We will continue the investigation of coastal area and make clear the groundwater flow system.

Applicability evaluation of CIA due to river and lake

*yusuke hataya[1], SEIKI KAWAGOE[1], Shiho Yabusaki[2], KEN Suzuki[1]

1. fukushima university, 2. Research Institute for Humanity and Nature

Water resources management must be further attention because extreme weather condition generate to predict climate change. However, a water area have the various regional characteristics. Therefore a universal way may not also be able to indicate the effect management. If categorized basin tool is developing to obtain characteristic, it is possible to choose suitable management technique in water areas. We tried to develop database to manage basin as chemical and geographical information. In this research, Water factors (Chemical condition, land use condition, soil condition and geological condition) between basins (rivers and reservoirs) were compared to develop data base. Especially, we applied to Chemical Index of Alteration (CIA) as chemical condition factor. As results, It was possible to obtain the basin area scale to apply CIA.

Chemical property analysis of short time scale to determine snowfall source

*Suzuki hiromichi[1], SEIKI KAWAGOE[1], SHO ADACHI[1], Shiho Yabusaki[2]

1. Fukushima University, 2. Research Institute for Humanity and Nature

Occurrence of the strange weather phenomenon is predicted from the current state depending on climate change. To ask this influence, we have to advance the match which raises the future predictability. And, we have to mark a phenomenon of the current state detail. This study targets to obtain chemically snow environment. The aim of this study was to analyse and predict the stable water isotopic composition of the snow cover at specific basin (Agano river). In addition, the dependence of short time step isotopic composition of the entire snow cover was analysed. Snow in 3 catchments was sampled at the end of the accumulation period from December 2016 to April 2018. The observed variability of short time step isotopic composition of the snow cover was analysed chemical verification. Especially, basin The Inawashiro-Lake north side of the northern upstream region indicated the low chemical feature (Suzuki et al 2018). I'm working on the investigation analysis to grasp the chemical special quality of the snow event of the short time scale at present based on this result (2016-2018). It was that a chemical analysis makes the sample which sampled and acquired it by each day the time of a snowfall at Fukushima, Hibara and Yonezawa located in an upstream region in a basin, and we tried to follow up a snowfall origin of the short time scale.

As results, a strong pressure pattern of southern high and northern low could admit January 22nd-the 25th, the result obtained from the result of analysis also reacted to the weather situation sensitively. And influence of a characteristic snowfall origin was admitted at 3 spots. The difference in the spatial time lags was done clearly.

Analyzing the origin of surface water in the Saijo Plain, Japan, based on the antimony concentration in the water

*Minoru TOKUMASU[1,2], Ki-Cheol SHIN[3], Yoshihiro YAMADA[4]

1. The United Graduate School of Agricultural Sciences, Ehime University, 2. Saijo City, 3. The Research Institute for Humanity and Nature (RIHN) , 4. Kagawa University, Faculty of Agriculture

1. Introduction

The flow of river water in many medium and small rivers is managed for water use and flood control. However, it is almost impossible to understand how the water taken from the rivers circulates throughout a basin. The source of water in the Saijo Plain in Ehime Prefecture is from the Kamo River surface water flow, shallow groundwater (unconfined ground water), and deep groundwater (confined ground water). Therefore, it is necessary to quantitatively clarify the source of water for sustainable water use. In this study, we tried to quantify the origin of river water in the plain based on the concentration of some chemical elements. In particular, antimony (Sb) was used as the main trace element because of large differences in its concentration between the water sources.

2. Materials and Methods

On November 25 and 26, 2017, during the non-irrigation period and on the 27th and 28th of July, 2018, during the irrigation period, surface water was collected at a total of 43 sites on small and medium rivers and waterways in the Saijo Plain. Multi-element analysis was carried out on the collected water using ICP-MS 7500 cx.

3. Results and Discussion

There was a large difference in the concentration of Sb among the sites. The highest concentration was found in the water from the Ichino River (Stn. 2) at 113 (2017) and 158 μg/L (2018). There was once an antimony mine in the Ichino River basin, so high concentrations of the element in the river water can be regarded as reflecting the influence of the geology. In the main stream of the Kamo River before joining the Ichinose River (Stn. 1), the Sb concentration was as low as 0.2 μg/L, and after the junction of the two rivers (Stn. 3), the concentration increased to 4.3 (2017) and 7.2 μg/L (2018). The concentration was 4.2 (2017) and 7.2 μg/L (2018) at Stn. 4 of the Kamo River, 11.6 (2017) and 11.7 μg/L (2018) in the unconfined ground water (average of Stns. 13, 14, 15), and 0.4 (2017) and 0.5 μg/L (2018) in the confined ground water (average of Stns. 28, 29, 40, 41, 43). The concentration of Si was 2.7 (2017) and 3.2 mg/L (2018) at Stn. 4 of the Kamo River, 3.4 (2017) and 2.9 mg/L (2018) in the unconfined ground water (average of Stns. 13, 14, 15), and 4.1 (2017) and 3.9 mg/L (2018) in the confined ground water (average of Stns. 28, 29, 40, 41, 43).
The ratio of water origin at each survey site was estimated using the above three sources as end members. In the upstream area, the irrigation water taken from the Kamo River occupied most of the surface water. In the middlestream area, the ratio of water taken from the rivers was smaller, and the contribution of

©2019. Japan Geoscience Union. All Right Reserved.

unconfined ground water exceeded 80%. In the downstream area, the confined ground water contribution exceeded 40% at many sites. In the Saijo Plain, the water origins are different in the upstream, middlestream, and downstream areas, where the contribution of irrigation water is small overall, and the contribution of the confined ground water is large.

Basic kinetic study on stable isotope ratios of nitrogen compounds: a case study for groundwater in the Kathmandu Valley, Nepal

*Ken Yokozawa[1,2], Kei Nishida[1,3], Takashi Nakamura[1,3], Ken'ichi Osaka[4]

1. University of Yamanashi, 2. Special Graduate Program on River Basin Environmental Science,, 3. ICRE, 4. Department of ecosystem study Univercity of Shiga prefecture

Groundwater is a valuable source of water in developing countries where water demand is increasing with population increase. At the same time, nitrogen contamination by industrial wastewater, domestic wastewater and agricultural activities has been reported. In underground environments, it is not unusual to identify sources of contamination since the forms and the concentrations of nitrogen compounds vary at different water flow or microbial metabolism. Stable isotopic analysis is one of the effective methods to detail the variations. However, the isotope value is also greatly affected by environmental conditions, and the theoretical enforcement for describing the variation of the isotope value is needed. In this study, we aimed to quantitatively understand and identify the factors of mixing and isotopic fractionation that determine the stable isotope ratio with a case study on groundwater contamination in the Kathmandu Valley, Nepal.

The data used for the analysis was obtained from the groundwater survey of the Kathmandu Valley conducted from September 2014 to August 2018. Based on the stable isotope ratios of nitrogen and oxygen of nitrate, the contamination patterns were roughly categorized. The mixing line and the denitrification line were prepared based on the dynamic fractionation for the stable isotope ratios of nitrate nitrogen, and the spatial distribution of denitrification-related samples was examined on the map. In addition, assuming that the reactants exist sufficiently and homogeneously in the system, an equilibrium fractionation model was formulated by combining nitrification and denitrification for oxygen stable isotope ratios of nitrate and water. The range of the model parameters were determined by using the measured data from the filed survey, the influence of each process on the stable oxygen isotope ratio of nitrate was quantified.

The result showed that the nitrate in shallow groundwater partially originated from the atmospheric source through infiltration of rainwater. A characteristic of denitrification was observed, which was initiated and proceeded over the valley. Additionally, the correspondent isotopic fractionation differed at the location and the season, particularly controlled by ammonia oxidation, nitrite reduction and oxygen exchange between nitrite and water.

Usefulness of strontium isotope composition for determining the geographical origin of wasabi and potato

*Takafumi Kamitani[1], Ki-Cheol Shin[2], Sachiko Nakamura[1], Rika Koda[1], Tomoya Oka[1], Noriaki Fushimi[1], Yasuhide Muranaka[1]

1. Shizuoka Institute of Environment and Hygiene, 2. Research Institute for Humanity and Nature

Originally, the use of strontium isotope ratios ($^{87}Sr/^{86}Sr$) was restricted to geology and petrology, but they have been used as a particularly effective tracer of geographical food origin, as plants reflect the strontium isotope composition of the regionally based rock, soil, and water. This study aims to evaluate the usefulness of $^{87}Sr/^{86}Sr$ for determining the geographical origin of wasabi (Japanese horseradish) and potato, which are specialty crops in Shizuoka Prefecture, Japan.

Wasabi is cultivated in springs and streams located at the top of rivers, where dissolved element and isotopic compositions in water would reflect the geological characteristics without the effects of atmospheric deposition and human activity. We collected wasabi and water samples from 40 locations of major production areas in Japan: Shizuoka, Iwate, Nagano, Tokyo, and Shimane. These samples were subjected to trace elements and $^{87}Sr/^{86}Sr$ analyses. The $^{87}Sr/^{86}Sr$ values differed, based on the geological characteristics of their site locations, and the value of wasabi was well accorded with that of water in the same location. The wasabi samples collected from Izu Peninsula and Mt. Fuji regions in Shizuoka, where young volcanic rocks such as Quaternary basalts are distributed, had low $^{87}Sr/^{86}Sr$ (below 0.7040), whereas those from Nagano and Tokyo, where older rocks such as Mesozoic granites and accretionary complex are distributed, showed higher ratios (over 0.7095). We conclude that $^{87}Sr/^{86}Sr$ value of wasabi allowed us to distinguish the production area clearly.

On the other hand, the $^{87}Sr/^{86}Sr$ values of crops cultivated in the field are considered to be partly affected by precipitation and fertilizer. Therefore we conducted field survey and planter test for potato in Shizuoka. Field survey was conducted at Mishima, in eastern part of Shizuoka prefecture, and at Mikatahara, in western part of it, and $^{87}Sr/^{86}Sr$ of potato and soil exchangeable fraction were compared. As a result, there was a correlation between potato and soil in $^{87}Sr/^{86}Sr$, although the effects of precipitation and fertilizer were observed. The planter test suggests that the influence of fertilizer on $^{87}Sr/^{86}Sr$ varies depending on the amount of exchangeable Sr contained in the original soil.

Reconstruction of sea surface temperature and salinity for the Medieval Climatic Anomaly using a long-lived fossil coral collected at Ishigaki Island, southwestern Japan

*Osamu Abe[1], Maki Morimoto[2], Ryuji Asami[3], Takeshi Nakatsuka[1,4]

1. Graduate School of Environmental Studies, Nagoya University, 2. School of Education, Gifu University, 3. Graduate School of Science, Tohoku University, 4. Research Institute for Humanity and Nature

The period between 950 and 1250CE is called as the Medieval Climate Anomaly (MCA; Masson-Delmotte et al., 2013), at the time when the warmer climate seemed dominant globally (Bradley et al., 2003). Recent investigations based on the proxy record such as tree-ring widths, speleothems, ice cores, and historical documents indicated that a significant climate change occurred during the latter half of the 10th century. Mann et al. (2009) found that an increase of the average air temperature in the northern hemisphere at the late 10c. coincided with an increase of sea surface temperature at northern subpolar oceans. Yan et al. (2011) indicated that atmospheric environments in the equatorial Pacific shifted from the La Nina like condition to the El Nino like condition around 1000CE. In East Asia, Zhang et al. (2008) and Ge et al. (2013) described that the activity of East Asian Summer Monsoon (EASM) had been enhanced during the late 10c., then the climate in China shifted to warmer and wetter. Whereas Lie et al. (2014) showed that the EASM had been weakened during the 11th century. In addition, the climate in southern China was reported as relatively dry (Chen et al., 2015).

These studies demonstrated that a large climatic shift occurred around 1000CE, however, most of them have relied on records collected on land. There is little long-term high-resolution marine record during the MCA.

We reconstructed sea surface temperature (SST) and salinity with a temporal resolution of one month for 300 years using a long-lived fossil coral collected at Ishigaki Island, southwestern Japan. Based on the U/Th dating in the youngest part of the coral skeletons as well as the band counting, this coral sample had lived between 845 and 1130CE, largely covered the MCA period. Skeletal Sr/Ca and oxygen isotopic composition were analyzed for about 4,000 samples.

The empirical equations between Sr/Ca and water temperature; between oxygen isotopic composition of coral skeleton and seawater, and water temperature, were established using the present coral records, observed water temperature and oxygen isotopic composition of seawater. With these equations and the relationship between seawater salinity and oxygen isotopic composition, proposed by Abe et al. (2009), SST and seawater salinity from 845 to 1130CE were reconstructed from the fossil coral Sr/Ca and oxygen isotopic composition.

Through the entire period, average summer and winter SSTs were 2 and 1 deg. C higher than the present, respectively. In addition, SST increased significantly after 1040CE; 0.9 for the annual average, 0.7 for summer and 1.1 for winter. Salinity also increased after 990CE; 0.8 all for the annual average, summer and winter. Salinity was significantly higher through the entire period than the present, however, its absolute value seems unconfirmed yet.

©2019. Japan Geoscience Union. All Right Reserved.

Increasing SST and salinity found in this study during ca. 1000 and 1130CE were consistent with the weakening of EASM during the 11th and 12th centuries shown by Liu et al. (2014). They argued the weakening occurred as a consequence of weakening of the solar activity and the decrease of SST at the western Pacific warm pool. In this study region, the decrease of precipitation during the Baiu period induced the increase of salinity as well as local SST increase due to the decrease of the cloud cover. Our results were also consistent with the warming of China in the late 10c. (Ge et al., 2013), and a drier condition in southern China (Chen et al., 2015).

The periodicity of SST and salinity based on the spectral analysis will be discussed in the presentation.

Development of the analytical method for sulfur isotope in SO_2 gas

*Masaaki Takahashi[1], Hiroyuki Sase[1], Tsuyoshi Ohizumi[1]

1. Asia Center for Air Pollution Research

1. Introduction

Sulfur is a major source of acid deposition. Usually sulfur is emitted as SO_2 and it is oxidized to SO_4^{2-} in atmosphere. S isotopic analysis of water and particulate samples were conducted in many studies. But gaseous SO_2 was rarely used for isotopic study. Isotopic ratio of SO_2 is strongly influenced by emission source near the sampling point. Because most of SO_2 emitted far from sampling point is oxidized to SO_4^{2-} during transportation. It is possible to distinguish domestic emission from transboundary emission. Moreover, dry deposition processes of SO_2 and particulate SO_4^{2-} and their interactions with tree canopy could be discussed more precisely. Isotopic analysis of SO_2 is considered as a powerful method to investigate the behavior of S in the atmosphere and ecosystems. We studied about the analytical method for S isotope in SO_2.

2. Method

(1) Equipment

SO_2 concentration in Japan is very low (e.g. annual 0.02ppb at Sado). We need to collect air sample at least $1m^3$ that is the amount we can obtain 1.2mg of $BaSO_4$ precipitation enough for isotopic analysis. High volume air sampler is generally used to collect around $1m^3$ of air sample. It uses filter, so we examined filter collection of SO_2 by K_2CO_3 filter generally used to collect SO_2 in filter-pack method.

(2) Filters

We used quarts filter for particulate SO_4^{2-} and K_2CO_3 filter for gaseous SO_2 next to it. K_2CO_3 filter is made on the basis of EANET manual. But to get enough flow rate for high volume air sampler, the size of K_2CO_3 filter is larger (20×26 cm, same size with quarts filter) than the manual and already dried before sampling.

(3) Flow rate/leak test

Under flow rate 100~400 L/min in this system, we confirmed weather sampling can be carried out stably. And we checked leak using two K_2CO_3 filters.

(4) Sample treatment

©2019. Japan Geoscience Union. All Right Reserved.

On the basis of EANET manual, the sample was extracted with 0.05% H_2O_2aq and filtered. Then 2N HCl was added and concentrated to remove CO_3^{2-}. Next 1%(w/w)$BaCl_2$ was added. We filtered forming $BaSO_4$ precipitation. We examined the method to get $BaSO_4$ precipitation and to remove the components from K_2CO_3 filter.

3. Results

(1) Sampling and sample treatment

Sampling could be conducted under flow rate 100~400 L/min. Sampling efficiency was about 80%..

Several conditions to get $BaSO_4$ precipitation ware examined, it could be gotten by the method as below.

Filter was cut and ultrasonic extracted with 0.05% H_2O_2aq 30 minutes and filtered. 2.5 ml of 2N HCl was added and concentrated to around 10 ml. Then 1 ml of heated 1 %(w/w) $BaCl_2$ was added under pH 4~6. Next evaporated all solvent and added 10 ml of water. $BaSO_4$ precipitation was observed. After put for one night, the precipitation was separated by centrifuge 3,600 rpm for 10 minutes and we removed the solvent. The precipitation was washed twice by 10 ml of water and filtered. At last the filter was ashed for four hours in muffle furnace in 800 ℃ .

(2) Actual analysis

We used two K_2CO_3 filters and collected 2160.2 m^3 of air sample under flow rate 300 L/min. 3.80 mg of particular SO_4^{2-} and 0.89 mg (first) and 0.14 mg (second) of SO_4^{2-} from SO_2 were obtained. $\delta^{34}S$ of particular SO_4^{2-} was 8.64 ‰and that of SO_2 from the first filter was -1.54 ‰. The amount of precipitation from second filter was not enough for isotopic analysis. This difference was caused by effect of sea salt mainly. But nss- $\delta^{34}S$ of particular SO_4^{2-} was 4.78 ‰. It was still higher than SO_2. It suggested that nss- SO_4^{2-} contains both transboundary SO_4^{2-} and domestic SO_4^{2-}. According to the relevant literature, domestic SO_2 may have negative isotopic values because of imported oil from Middle East. Considering that this sampling was carried out in January, possible effect of transboundary SO_2 with higher isotopic values should also be taken into account for source identification of the collected SO_2.
We would like to discuss at the conference with the latest data.

Zinc isotope analysis on human tooth enamel samples to reconstruct diet of the Jomon period.

*Soichiro Kusaka[1], Ki-Cheol Shin[2]

1. Tokai Univ., 2. Research Institute for Humanity and Nature

This study investigates zinc isotope ratios in tooth enamels of human skeletal remains of the Jomon period in Japan. Carbon and nitrogen isotope analysis on bone collagen were traditionary used to reconstruct diet and trophic levels on prehistoric people. The progress of isotope measurements using MC-ICP-MS enables us to analyze isotope ratios of zinc and other metals. Some researches report that the zinc isotope ratios of animals reflect dietary sources and vary according to trophic levels. This study newly develops zinc isotope analysis on human tooth enamels. The zinc isotope analysis has great potential to reconstruct dietary information from inorganic materials of archaeological bones or fossils.

The material used in this study is SRM1400 (bone ash), six samples of human tooth enamels from the Yoshigo and Inariyama shell mounds of Aichi prefecture, and faunal remains (six deer enamels, three boar enamels, six marine fish bones, and six modern plant leaves). Zinc was purified from these samples using anion exchange resin. Zinc isotope ratios were measured by MC-ICP-MS with the zinc standard solution of AA-ETH. The mass bias was corrected with Cu standard solution added to all standards and samples. The zinc isotope ratios of SRM1400 showed similar value with the value previously reported. The difference of zinc isotope ratios between washed and unwashed samples with acetic acids were very small, suggesting no significant diagenetic alteration. The deer and marine fish samples showed the value expected from their dietary ecology. The zinc isotope ratios of Jomon skeletal remains was higher than those of plants, but lower than deer and marine fish. This result indicates that sources of zinc for humans were terrestrial and marine meat as well as terrestrial plants.

Zinc stable isotope analysis of environmental reference materials

*Ki-Cheol Shin[1]

1. Research Institute for Humanity and Nature

Zinc has atomic number 30 and atomic mass 65.39. It is a trace element of terrestrial rocks and widely distributed throughout the lithosphere and biosphere. It is chalcophile features and has rich coordination chemistry, participates in a large number of important biological compounds and reactions. The zinc plays an important role as an essential trace metal in all living systems from bacteria to humans. Zn has five stable isotopes ^{64}Zn, ^{66}Zn, ^{67}Zn, ^{68}Zn, and ^{70}Zn. Their isotopic fractionation could provide valuable information about environmental processes, especially in biological processes.

With the advent of multi-collector ICP-MS, it is possible to measure the precise value of ^{66}Zn/^{64}Zn in Zn solution. To promote the environmental stable isotope traceability, RIHN is desired to determine the isotope ratios of zinc for environmental reference materials with high precision and accuracy, rapidness, and convenience.

Here, I report a simple and efficient method for zinc isotope analysis. The various environmental samples over 20 types were used for the study. All samples have purified with an anion exchange resin to separated Zn and Fe at a time. Zinc isotope ratios were measured by MC-ICP-MS (NEPTUNE plus) with AA-ETH, which is a new zinc isotopic standard solution reported by Archer et al. (2017). The mass bias correction conducted with Cu standard solution (NIST SRM 976).

[E] Poster | H (Human Geosciences)：H-TT Technology & Techniques

Tue. May 28, 2019 5:15 PM - 6:30 PM JST | Tue. May 28, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_23

[H-TT18] Development and application of environmental traceability methods

convener:Ichiro Tayasu(Research Institute for Humanity and Nature), Nobuhito Ohte(Department of Social Informatics, Graduate School of Informatics, Kyoto University), Gabriel J Bowen(University of Utah)

Modern society uses almost all the elements present in the natural world. Although there have long been calls for the sustainable use of the resources that provide these elements and the building of human societies that are in harmony with the environment, the survival of the human race is increasingly at risk as a result of qualitative changes to the environment as a whole. Implementation by the society of methodologies for diagnosing and tracking these various elements of the natural environment and their relationships with humans are now required.
Elements cycle within and among the Earth system spheres, human society and the human body. Information on the concentrations and stable isotopes of elements is powerful tool for tracing this cycling and has been applied in studies of atmosphere-hydrosphere circulation, ecological systems, and the life, health and history of humans. We propose a session to discuss development and applications of environmental traceability methods toward the goal of establishing traceability in natural and human systems.
We encourage the presentation of research integrating isotopic information in various disciplines, such as geochemistry, hydrology, ecology, geology, mineralogy, anthropology, food science, and forensics. Studies applying "Isoscapes", maps of spatial isotopic variation, in addition to traditional database-based approaches, are strongly encouraged.

Isotopic study on seasonal nitrogen dynamics at Lake Biwa

*Takaaki Ishibashi[1], Ken'ichi Osaka[1], Keisuke Koba[2], Takashi Nakamura[3], Kei Nishida[3]

1. Department of ecosystem study, University of Shiga Prefecture, 2. Center for Ecological Research, Kyoto University, 3. International Research Center for River Basin Environment, University of YAMANASHI

To clarify nitrogen dynamics in Lake Biwa, we measured the concentrations of nitrogen compounds and their nitrogen stable isotopic ratios in 14 depths in north basin of Lake Biwa. In the lake, particulate nitrogen (PN), such as phytoplankton, is generally decomposed to dissolved nitrogen (DN); in order of dissolved organic nitrogen (DON), ammonia nitrogen (NH_4^+) and nitrate nitrogen (NO_3^-). These dissolved nitrogen compounds are taken up by phytoplankton again, and the nitrogen circulation in the lake is established. To predict the water quality in future, it is necessary to understand the nitrogen cycle in the lake, as well as nutrient load to the lake.

In this study, we collected lake water sample at 14 depths in north basin of Lake Biwa (water depth is 90 m) in 1-2 months interval. The lake waster sample was analyzed for the concentration of PN, PC, DN, NO_3^-, NO_2^- and NH_4^+, $d^{15}N$ of PN, DN and NO_3^-.

NO_3^- concentration was lower in the surface layer (0-20m), and higher in the deep layer (20-90m) during the stratification period, whereas NO_3^- concentration was constant in all layers during the circulation period. PN concentration also increased in the surface layer from April to June, decreased sharply in July. These indicate that phytoplankton which grew on the surface layer from April to June used NO_3^-, thereafter, NO_3^- was depleted after June, then, phytoplankton decreased after July respectively. On the other hand, NO_3^- concentration is considered to be increased by decomposition of the precipitated PN from surface layer. It is considered that the NO_3^- concentration became constant in all layers because of mixing of deep layer and the surface layer.

The weighted average $d^{15}N_{DN}$, $d^{15}N_{NO3}$ in the unit water columns decreased about 3‰ in the circulation period, in the circulation period, then, increased during the stratification period. The decrease of $d^{15}N_{DN}$, $d^{15}N_{NO3}$ at the water column during circulation period can not be explained by mixing of deep layer and the surface layer. We will discuss the mechanisms of $d^{15}N_{DN}$, $d^{15}N_{NO3}$ decrease during circulation period in the presentation.

Relationship between residence time, water quality, and stable isotopes of spring water and groundwater in coastal area of Fukushima prefecture

*Shiho Yabusaki[1], Kazuyoshi Asai[2]

1. Research Institute for Humanity and Nature・Faculty of Symbiotic Systems Science, Fukushima University, 2. Geo Science Laboratory

After the Great East Japan Earthquake occurred, the investigation near the coast area in northern part of Fukushima prefecture has been carried out to clarify the groundwater flow and residence time in this area. The measuring of EC, pH, water temperature, ORP and sampling of groundwater, spring water and river water have been carried out several times at Shinchi town, Soma city, Minamisoma city, Namie town, Okuma town, Iitate village and Date city since September in 2012. The inorganic ions, stable isotopes of oxygen and hydrogen, trace elements were analyzed for all samples by using the IC (ICS-3000), CRDS (Picarro L2130-i) and ICP-MS (Agilent 7500cx). For estimating the residence time, tritium concentration, CFCs and SF_6 measurements were made in several samples.

The water quality of river water and shallow groundwater indicates mainly Ca-HCO_3 type. In the part of the flooded area by a tsunami, the water quality of shallow groundwater and spring water is Na-Cl type. The Ca-SO_4 type and mixed type were also confirmed in some sites. In the case of deep groundwater, the water quality shows the Na-HCO_3 type and Ca-HCO_3 type. The concentration of Fe, Mn and Al were relatively high in some parts of deep groundwater. It is considered that the origin of these trace elements is soil.

The stable isotopes of oxygen and hydrogen ($\delta^{18}O$ and δD) in river water of Niida river, Mano river and Kamimano river indicate altitude effect. Because the stable isotopes in deep groundwater is relatively low, it is anticipated the recharge are of deep groundwater is about 300 m higher than that of shallow groundwater. It is expected that the recharge area of deep groundwater is around the Abukuma Mountains.

The average residence time of deep groundwater and spring water which indicate the Na-HCO_3 type is about 60 to 70 years. On the other hand, the average residence time of shallow groundwater which indicate the Ca-HCO_3 type is less than 10 years.

The information of groundwater flow is useful for considering the groundwater use with revival of the coastal area. We will continue the investigation of coastal area and make clear the groundwater flow system.

Applicability evaluation of CIA due to river and lake

*yusuke hataya[1], SEIKI KAWAGOE[1], Shiho Yabusaki[2], KEN Suzuki[1]

1. fukushima university, 2. Research Institute for Humanity and Nature

Water resources management must be further attention because extreme weather condition generate to predict climate change. However, a water area have the various regional characteristics. Therefore a universal way may not also be able to indicate the effect management. If categorized basin tool is developing to obtain characteristic, it is possible to choose suitable management technique in water areas. We tried to develop database to manage basin as chemical and geographical information. In this research, Water factors (Chemical condition, land use condition, soil condition and geological condition) between basins (rivers and reservoirs) were compared to develop data base. Especially, we applied to Chemical Index of Alteration (CIA) as chemical condition factor. As results, It was possible to obtain the basin area scale to apply CIA.

Chemical property analysis of short time scale to determine snowfall source

*Suzuki hiromichi[1], SEIKI KAWAGOE[1], SHO ADACHI[1], Shiho Yabusaki[2]

1. Fukushima University, 2. Research Institute for Humanity and Nature

Occurrence of the strange weather phenomenon is predicted from the current state depending on climate change. To ask this influence, we have to advance the match which raises the future predictability. And, we have to mark a phenomenon of the current state detail. This study targets to obtain chemically snow environment. The aim of this study was to analyse and predict the stable water isotopic composition of the snow cover at specific basin (Agano river). In addition, the dependence of short time step isotopic composition of the entire snow cover was analysed. Snow in 3 catchments was sampled at the end of the accumulation period from December 2016 to April 2018. The observed variability of short time step isotopic composition of the snow cover was analysed chemical verification. Especially, basin The Inawashiro-Lake north side of the northern upstream region indicated the low chemical feature (Suzuki et al 2018). I'm working on the investigation analysis to grasp the chemical special quality of the snow event of the short time scale at present based on this result (2016-2018). It was that a chemical analysis makes the sample which sampled and acquired it by each day the time of a snowfall at Fukushima, Hibara and Yonezawa located in an upstream region in a basin, and we tried to follow up a snowfall origin of the short time scale.

As results, a strong pressure pattern of southern high and northern low could admit January 22nd-the 25th, the result obtained from the result of analysis also reacted to the weather situation sensitively. And influence of a characteristic snowfall origin was admitted at 3 spots. The difference in the spatial time lags was done clearly.

Analyzing the origin of surface water in the Saijo Plain, Japan, based on the antimony concentration in the water

*Minoru TOKUMASU[1,2], Ki-Cheol SHIN[3], Yoshihiro YAMADA[4]

1. The United Graduate School of Agricultural Sciences, Ehime University, 2. Saijo City, 3. The Research Institute for Humanity and Nature (RIHN) , 4. Kagawa University, Faculty of Agriculture

1. Introduction

The flow of river water in many medium and small rivers is managed for water use and flood control. However, it is almost impossible to understand how the water taken from the rivers circulates throughout a basin. The source of water in the Saijo Plain in Ehime Prefecture is from the Kamo River surface water flow, shallow groundwater (unconfined ground water), and deep groundwater (confined ground water). Therefore, it is necessary to quantitatively clarify the source of water for sustainable water use. In this study, we tried to quantify the origin of river water in the plain based on the concentration of some chemical elements. In particular, antimony (Sb) was used as the main trace element because of large differences in its concentration between the water sources.

2. Materials and Methods

On November 25 and 26, 2017, during the non-irrigation period and on the 27th and 28th of July, 2018, during the irrigation period, surface water was collected at a total of 43 sites on small and medium rivers and waterways in the Saijo Plain. Multi-element analysis was carried out on the collected water using ICP-MS 7500 cx.

3. Results and Discussion

There was a large difference in the concentration of Sb among the sites. The highest concentration was found in the water from the Ichino River (Stn. 2) at 113 (2017) and 158 μg/L (2018). There was once an antimony mine in the Ichino River basin, so high concentrations of the element in the river water can be regarded as reflecting the influence of the geology. In the main stream of the Kamo River before joining the Ichinose River (Stn. 1), the Sb concentration was as low as 0.2 μg/L, and after the junction of the two rivers (Stn. 3), the concentration increased to 4.3 (2017) and 7.2 μg/L (2018). The concentration was 4.2 (2017) and 7.2 μg/L (2018) at Stn. 4 of the Kamo River, 11.6 (2017) and 11.7 μg/L (2018) in the unconfined ground water (average of Stns. 13, 14, 15), and 0.4 (2017) and 0.5 μg/L (2018) in the confined ground water (average of Stns. 28, 29, 40, 41, 43). The concentration of Si was 2.7 (2017) and 3.2 mg/L (2018) at Stn. 4 of the Kamo River, 3.4 (2017) and 2.9 mg/L (2018) in the unconfined ground water (average of Stns. 13, 14, 15), and 4.1 (2017) and 3.9 mg/L (2018) in the confined ground water (average of Stns. 28, 29, 40, 41, 43).
The ratio of water origin at each survey site was estimated using the above three sources as end members. In the upstream area, the irrigation water taken from the Kamo River occupied most of the surface water. In the middlestream area, the ratio of water taken from the rivers was smaller, and the contribution of

©2019. Japan Geoscience Union. All Right Reserved.

unconfined ground water exceeded 80%. In the downstream area, the confined ground water contribution exceeded 40% at many sites. In the Saijo Plain, the water origins are different in the upstream, middlestream, and downstream areas, where the contribution of irrigation water is small overall, and the contribution of the confined ground water is large.

Basic kinetic study on stable isotope ratios of nitrogen compounds: a case study for groundwater in the Kathmandu Valley, Nepal

*Ken Yokozawa[1,2], Kei Nishida[1,3], Takashi Nakamura[1,3], Ken'ichi Osaka[4]

1. University of Yamanashi, 2. Special Graduate Program on River Basin Environmental Science,, 3. ICRE, 4. Department of ecosystem study Univercity of Shiga prefecture

Groundwater is a valuable source of water in developing countries where water demand is increasing with population increase. At the same time, nitrogen contamination by industrial wastewater, domestic wastewater and agricultural activities has been reported. In underground environments, it is not unusual to identify sources of contamination since the forms and the concentrations of nitrogen compounds vary at different water flow or microbial metabolism. Stable isotopic analysis is one of the effective methods to detail the variations. However, the isotope value is also greatly affected by environmental conditions, and the theoretical enforcement for describing the variation of the isotope value is needed. In this study, we aimed to quantitatively understand and identify the factors of mixing and isotopic fractionation that determine the stable isotope ratio with a case study on groundwater contamination in the Kathmandu Valley, Nepal.

The data used for the analysis was obtained from the groundwater survey of the Kathmandu Valley conducted from September 2014 to August 2018. Based on the stable isotope ratios of nitrogen and oxygen of nitrate, the contamination patterns were roughly categorized. The mixing line and the denitrification line were prepared based on the dynamic fractionation for the stable isotope ratios of nitrate nitrogen, and the spatial distribution of denitrification-related samples was examined on the map. In addition, assuming that the reactants exist sufficiently and homogeneously in the system, an equilibrium fractionation model was formulated by combining nitrification and denitrification for oxygen stable isotope ratios of nitrate and water. The range of the model parameters were determined by using the measured data from the filed survey, the influence of each process on the stable oxygen isotope ratio of nitrate was quantified.

The result showed that the nitrate in shallow groundwater partially originated from the atmospheric source through infiltration of rainwater. A characteristic of denitrification was observed, which was initiated and proceeded over the valley. Additionally, the correspondent isotopic fractionation differed at the location and the season, particularly controlled by ammonia oxidation, nitrite reduction and oxygen exchange between nitrite and water.

Usefulness of strontium isotope composition for determining the geographical origin of wasabi and potato

*Takafumi Kamitani[1], Ki-Cheol Shin[2], Sachiko Nakamura[1], Rika Koda[1], Tomoya Oka[1], Noriaki Fushimi[1], Yasuhide Muranaka[1]

1. Shizuoka Institute of Environment and Hygiene, 2. Research Institute for Humanity and Nature

Originally, the use of strontium isotope ratios ($^{87}Sr/^{86}Sr$) was restricted to geology and petrology, but they have been used as a particularly effective tracer of geographical food origin, as plants reflect the strontium isotope composition of the regionally based rock, soil, and water. This study aims to evaluate the usefulness of $^{87}Sr/^{86}Sr$ for determining the geographical origin of wasabi (Japanese horseradish) and potato, which are specialty crops in Shizuoka Prefecture, Japan.

Wasabi is cultivated in springs and streams located at the top of rivers, where dissolved element and isotopic compositions in water would reflect the geological characteristics without the effects of atmospheric deposition and human activity. We collected wasabi and water samples from 40 locations of major production areas in Japan: Shizuoka, Iwate, Nagano, Tokyo, and Shimane. These samples were subjected to trace elements and $^{87}Sr/^{86}Sr$ analyses. The $^{87}Sr/^{86}Sr$ values differed, based on the geological characteristics of their site locations, and the value of wasabi was well accorded with that of water in the same location. The wasabi samples collected from Izu Peninsula and Mt. Fuji regions in Shizuoka, where young volcanic rocks such as Quaternary basalts are distributed, had low $^{87}Sr/^{86}Sr$ (below 0.7040), whereas those from Nagano and Tokyo, where older rocks such as Mesozoic granites and accretionary complex are distributed, showed higher ratios (over 0.7095). We conclude that $^{87}Sr/^{86}Sr$ value of wasabi allowed us to distinguish the production area clearly.

On the other hand, the $^{87}Sr/^{86}Sr$ values of crops cultivated in the field are considered to be partly affected by precipitation and fertilizer. Therefore we conducted field survey and planter test for potato in Shizuoka. Field survey was conducted at Mishima, in eastern part of Shizuoka prefecture, and at Mikatahara, in western part of it, and $^{87}Sr/^{86}Sr$ of potato and soil exchangeable fraction were compared. As a result, there was a correlation between potato and soil in $^{87}Sr/^{86}Sr$, although the effects of precipitation and fertilizer were observed. The planter test suggests that the influence of fertilizer on $^{87}Sr/^{86}Sr$ varies depending on the amount of exchangeable Sr contained in the original soil.

Reconstruction of sea surface temperature and salinity for the Medieval Climatic Anomaly using a long-lived fossil coral collected at Ishigaki Island, southwestern Japan

*Osamu Abe[1], Maki Morimoto[2], Ryuji Asami[3], Takeshi Nakatsuka[1,4]

1. Graduate School of Environmental Studies, Nagoya University, 2. School of Education, Gifu University, 3. Graduate School of Science, Tohoku University, 4. Research Institute for Humanity and Nature

The period between 950 and 1250CE is called as the Medieval Climate Anomaly (MCA; Masson-Delmotte et al., 2013), at the time when the warmer climate seemed dominant globally (Bradley et al., 2003). Recent investigations based on the proxy record such as tree-ring widths, speleothems, ice cores, and historical documents indicated that a significant climate change occurred during the latter half of the 10th century. Mann et al. (2009) found that an increase of the average air temperature in the northern hemisphere at the late 10c. coincided with an increase of sea surface temperature at northern subpolar oceans. Yan et al. (2011) indicated that atmospheric environments in the equatorial Pacific shifted from the La Nina like condition to the El Nino like condition around 1000CE. In East Asia, Zhang et al. (2008) and Ge et al. (2013) described that the activity of East Asian Summer Monsoon (EASM) had been enhanced during the late 10c., then the climate in China shifted to warmer and wetter. Whereas Lie et al. (2014) showed that the EASM had been weakened during the 11th century. In addition, the climate in southern China was reported as relatively dry (Chen et al., 2015).

These studies demonstrated that a large climatic shift occurred around 1000CE, however, most of them have relied on records collected on land. There is little long-term high-resolution marine record during the MCA.

We reconstructed sea surface temperature (SST) and salinity with a temporal resolution of one month for 300 years using a long-lived fossil coral collected at Ishigaki Island, southwestern Japan. Based on the U/Th dating in the youngest part of the coral skeletons as well as the band counting, this coral sample had lived between 845 and 1130CE, largely covered the MCA period. Skeletal Sr/Ca and oxygen isotopic composition were analyzed for about 4,000 samples.

The empirical equations between Sr/Ca and water temperature; between oxygen isotopic composition of coral skeleton and seawater, and water temperature, were established using the present coral records, observed water temperature and oxygen isotopic composition of seawater. With these equations and the relationship between seawater salinity and oxygen isotopic composition, proposed by Abe et al. (2009), SST and seawater salinity from 845 to 1130CE were reconstructed from the fossil coral Sr/Ca and oxygen isotopic composition.

Through the entire period, average summer and winter SSTs were 2 and 1 deg. C higher than the present, respectively. In addition, SST increased significantly after 1040CE; 0.9 for the annual average, 0.7 for summer and 1.1 for winter. Salinity also increased after 990CE; 0.8 all for the annual average, summer and winter. Salinity was significantly higher through the entire period than the present, however, its absolute value seems unconfirmed yet.

©2019. Japan Geoscience Union. All Right Reserved.

Increasing SST and salinity found in this study during ca. 1000 and 1130CE were consistent with the weakening of EASM during the 11th and 12th centuries shown by Liu et al. (2014). They argued the weakening occurred as a consequence of weakening of the solar activity and the decrease of SST at the western Pacific warm pool. In this study region, the decrease of precipitation during the Baiu period induced the increase of salinity as well as local SST increase due to the decrease of the cloud cover. Our results were also consistent with the warming of China in the late 10c. (Ge et al., 2013), and a drier condition in southern China (Chen et al., 2015).

The periodicity of SST and salinity based on the spectral analysis will be discussed in the presentation.

Development of the analytical method for sulfur isotope in SO_2 gas

*Masaaki Takahashi[1], Hiroyuki Sase[1], Tsuyoshi Ohizumi[1]

1. Asia Center for Air Pollution Research

1. Introduction

Sulfur is a major source of acid deposition. Usually sulfur is emitted as SO_2 and it is oxidized to SO_4^{2-} in atmosphere. S isotopic analysis of water and particulate samples were conducted in many studies. But gaseous SO_2 was rarely used for isotopic study. Isotopic ratio of SO_2 is strongly influenced by emission source near the sampling point. Because most of SO_2 emitted far from sampling point is oxidized to SO_4^{2-} during transportation. It is possible to distinguish domestic emission from transboundary emission. Moreover, dry deposition processes of SO_2 and particulate SO_4^{2-} and their interactions with tree canopy could be discussed more precisely. Isotopic analysis of SO_2 is considered as a powerful method to investigate the behavior of S in the atmosphere and ecosystems. We studied about the analytical method for S isotope in SO_2.

2. Method

(1) Equipment

SO_2 concentration in Japan is very low (e.g. annual 0.02ppb at Sado). We need to collect air sample at least $1m^3$ that is the amount we can obtain 1.2mg of $BaSO_4$ precipitation enough for isotopic analysis. High volume air sampler is generally used to collect around $1m^3$ of air sample. It uses filter, so we examined filter collection of SO_2 by K_2CO_3 filter generally used to collect SO_2 in filter-pack method.

(2) Filters

We used quarts filter for particulate SO_4^{2-} and K_2CO_3 filter for gaseous SO_2 next to it. K_2CO_3 filter is made on the basis of EANET manual. But to get enough flow rate for high volume air sampler, the size of K_2CO_3 filter is larger (20×26 cm, same size with quarts filter) than the manual and already dried before sampling.

(3) Flow rate/leak test

Under flow rate 100~400 L/min in this system, we confirmed weather sampling can be carried out stably. And we checked leak using two K_2CO_3 filters.

(4) Sample treatment

©2019. Japan Geoscience Union. All Right Reserved.

On the basis of EANET manual, the sample was extracted with 0.05% H_2O_2aq and filtered. Then 2N HCl was added and concentrated to remove CO_3^{2-}. Next 1%(w/w)$BaCl_2$ was added. We filtered forming $BaSO_4$ precipitation. We examined the method to get $BaSO_4$ precipitation and to remove the components from K_2CO_3 filter.

3. Results

(1) Sampling and sample treatment

Sampling could be conducted under flow rate 100~400 L/min. Sampling efficiency was about 80%..

Several conditions to get $BaSO_4$ precipitation ware examined, it could be gotten by the method as below.

Filter was cut and ultrasonic extracted with 0.05% H_2O_2aq 30 minutes and filtered. 2.5 ml of 2N HCl was added and concentrated to around 10 ml. Then 1 ml of heated 1 %(w/w) $BaCl_2$ was added under pH 4~6. Next evaporated all solvent and added 10 ml of water. $BaSO_4$ precipitation was observed. After put for one night, the precipitation was separated by centrifuge 3,600 rpm for 10 minutes and we removed the solvent. The precipitation was washed twice by 10 ml of water and filtered. At last the filter was ashed for four hours in muffle furnace in 800 ℃ .

(2) Actual analysis

We used two K_2CO_3 filters and collected 2160.2 m^3 of air sample under flow rate 300 L/min. 3.80 mg of particular SO_4^{2-} and 0.89 mg (first) and 0.14 mg (second) of SO_4^{2-} from SO_2 were obtained. $\delta^{34}S$ of particular SO_4^{2-} was 8.64 ‰and that of SO_2 from the first filter was -1.54 ‰. The amount of precipitation from second filter was not enough for isotopic analysis. This difference was caused by effect of sea salt mainly. But nss- $\delta^{34}S$ of particular SO_4^{2-} was 4.78 ‰. It was still higher than SO_2. It suggested that nss- SO_4^{2-} contains both transboundary SO_4^{2-} and domestic SO_4^{2-}. According to the relevant literature, domestic SO_2 may have negative isotopic values because of imported oil from Middle East. Considering that this sampling was carried out in January, possible effect of transboundary SO_2 with higher isotopic values should also be taken into account for source identification of the collected SO_2.
We would like to discuss at the conference with the latest data.

Zinc isotope analysis on human tooth enamel samples to reconstruct diet of the Jomon period.

*Soichiro Kusaka[1], Ki-Cheol Shin[2]

1. Tokai Univ., 2. Research Institute for Humanity and Nature

This study investigates zinc isotope ratios in tooth enamels of human skeletal remains of the Jomon period in Japan. Carbon and nitrogen isotope analysis on bone collagen were traditionary used to reconstruct diet and trophic levels on prehistoric people. The progress of isotope measurements using MC-ICP-MS enables us to analyze isotope ratios of zinc and other metals. Some researches report that the zinc isotope ratios of animals reflect dietary sources and vary according to trophic levels. This study newly develops zinc isotope analysis on human tooth enamels. The zinc isotope analysis has great potential to reconstruct dietary information from inorganic materials of archaeological bones or fossils.

The material used in this study is SRM1400 (bone ash), six samples of human tooth enamels from the Yoshigo and Inariyama shell mounds of Aichi prefecture, and faunal remains (six deer enamels, three boar enamels, six marine fish bones, and six modern plant leaves). Zinc was purified from these samples using anion exchange resin. Zinc isotope ratios were measured by MC-ICP-MS with the zinc standard solution of AA-ETH. The mass bias was corrected with Cu standard solution added to all standards and samples. The zinc isotope ratios of SRM1400 showed similar value with the value previously reported. The difference of zinc isotope ratios between washed and unwashed samples with acetic acids were very small, suggesting no significant diagenetic alteration. The deer and marine fish samples showed the value expected from their dietary ecology. The zinc isotope ratios of Jomon skeletal remains was higher than those of plants, but lower than deer and marine fish. This result indicates that sources of zinc for humans were terrestrial and marine meat as well as terrestrial plants.

Zinc stable isotope analysis of environmental reference materials

*Ki-Cheol Shin[1]

1. Research Institute for Humanity and Nature

Zinc has atomic number 30 and atomic mass 65.39. It is a trace element of terrestrial rocks and widely distributed throughout the lithosphere and biosphere. It is chalcophile features and has rich coordination chemistry, participates in a large number of important biological compounds and reactions. The zinc plays an important role as an essential trace metal in all living systems from bacteria to humans. Zn has five stable isotopes ^{64}Zn, ^{66}Zn, ^{67}Zn, ^{68}Zn, and ^{70}Zn. Their isotopic fractionation could provide valuable information about environmental processes, especially in biological processes.

With the advent of multi-collector ICP-MS, it is possible to measure the precise value of ^{66}Zn/^{64}Zn in Zn solution. To promote the environmental stable isotope traceability, RIHN is desired to determine the isotope ratios of zinc for environmental reference materials with high precision and accuracy, rapidness, and convenience.

Here, I report a simple and efficient method for zinc isotope analysis. The various environmental samples over 20 types were used for the study. All samples have purified with an anion exchange resin to separated Zn and Fe at a time. Zinc isotope ratios were measured by MC-ICP-MS (NEPTUNE plus) with AA-ETH, which is a new zinc isotopic standard solution reported by Archer et al. (2017). The mass bias correction conducted with Cu standard solution (NIST SRM 976).

[H-TT22] New Developments in Shallow Geophysics

convener:Kyosuke Onishi(Public Works Research Institute), Kunio Aoike(Oyo corporation), Keisuke Inoue(National Agriculture and Food Research Organization), Tishiyuki Yokota(National Institute of Advanced Industrial Science and Technology), Chairperson:Toshiyuki Yokota, Keisuke Inoue

The session of shallow geophysics calls many research contributions on geophysical exploration techniques for the near surface. Our target depth is strictly restricted in the depth zone from 5 cm to 30 m (or from 2 in to 100 ft) below the surface of the ground. It may be the closest unknown territory for human society and advanced societies cannot have controlled yet to avoid disasters caused by dynamics in the shallow near surface. Peoples require techniques to manage levee, landslide and earth constructions also knowledge to control groundwater, liquefaction and soil pollution. The near surface has many geotechnical, environmental and hydrogeologic problems.
Major survey techniques are surface wave method, electric exploration, ground-penetrating radar and land streamer, but any methods will be discussed if your target is located in the specified depths. This session welcomes to discuss laboratory tests and rock physics for unconsolidated porous media in the vadose zone. Also, we will welcome not only cutting-edge technologies but also classic theory, if the knowledge is useful for human living.

High-frequency seismic reflection measurements for imaging internal structure of a sabo dam damaged by a huge debris flow

*Tomio INAZAKI[1], Hiroshi Kisanuki[2], Takanori Ogahara[1], Takeshi Shimizu[1], Naoki Fujimura[1]

1. Public Works Research Institute, Tsukuba Central Institute, 2. PWRI (Present address: OYO Corporation)

We conducted high-frequency, high-resolution seismic reflection measurements on the rear face of a sabo dam which had been damaged by a huge debris flow attack in July 9, 2014. The debris flow swept away the top 5 m part of the dam and segmented the dam body into several blocks associated with horizontal cracks. Estimated surface dislocation was at most 20 cm.
iezoelectric type high-frequency accelerometers were pasted on the surface at 10 cm intervals, and manual hit using a rock hammer was employed for generating high-frequency signals. High-performance data acquisition systems were also employed to obtain high-resolution and high sampling seismic data. Minimum sampling rate was set to 2 microseconds. We set 5 horizontal lines and 1 vertical line on the rear surface during December 2014 to April 2016. Relative height was about 5 m between the first and the last horizontal line. Assuming the RMS velocity to the constant value to 2,500 m/s, which was the typical S-wave velocity of concrete, we processed the dataset to reconstruct migrated depth sections. Clear flat reflection events appeared at 10 m and 7 to 5 meters. The former or deeper reflection event was correlated to the frontal face of the dam. The latter events were possible to be correlated to a horizontal joint which had dislocated the dam body caused by the debris flow attack. A gently dipping reflector, which started from the point just the survey line intersected a vertical fracture, was recognized in the lowest depth section.
In conclusion, field measurements demonstrated that high-frequency and high-resolution seismic reflection surveying was helpful to image the internal fracture distributions in a damaged concrete dam body.

Development and applications of 3D ambient noise tomography

*Chisato Konishi[1], Koichi Hayashi[1]

1. OYO Corporation

In a microtremor array measurement, receivers are usually placed on a center and the circumference of a circle or a center and the vertexes of a triangle to observe ambient noise from omni-directions for 1D S-wave velocity delineation. We developed 2D/3D ambient noise tomography as an extension of the normal microtremor array method, and we have conducted several field experiments. Cable-less seismographs including GPS clock, AD converter, battery, and SD card memory are used for the survey, and that makes a receiver array deployment flexible. Additionally, the estimated phase velocity is not affected by a specific direction of the ambient noise because several tens of receivers are deployed in X and Y directions on the ground surface. Furthermore, high quality data can be obtained due to a stacking of the multiple receiver pairs even if the observation time is limited.
CMP-SPAC analysis that is a modification of the CMPCC analysis in the 2D surface wave method is used in the 3D ambient noise tomography. SPAC coefficients are calculated for all possible pairs of the receiver arrays, and these are stacked and sorted by receiver separations at each CMP bin to make CMP-SPAC gathers. The frequency versus phase velocity image is obtained by comparing the CMP-SPAC gather with Bessel function. Dispersion curve is obtained from the frequency versus phase velocity image at all CMPs. By the same procedure to the 2D surface wave method, 1D S-wave velocity structure can be estimated by an inversion based on the non-linear least square method. And then 3D S-wave velocity is created by interpolating the 1D velocity structure at all CMPs. The computation time for this analysis is comparable to the 2D surface wave method, so we can easily obtain the 3D S-wave velocity.
Several field experiments have been conducted and the results almost agree with the existing geological information and other geophysical survey results. We found that the accuracy of the estimated S-wave velocity structure is lower around the edge of the survey area, and the estimated phase velocity around the edge might be affected by the direction of the ambient noise due to the limited receiver pairs. Nevertheless, we can eliminate this issue by extending the survey area, which is a usual countermeasure in most of geophysical surveys. Another finding is that even if the ambient noise does not include high frequency or short-wave length, we can investigate the shallow subsurface by adding a manmade vibration around the receiver array easily.

Keywords: Microtremor, S-wave velocity, 3D exploration

An Attempt to Estimate the Level of Non-confind Groundwater by Earthing Resistance (I) - Outline of Theory -

*Kunihiro Ryoki[1]

1. Polytechnic University

1. Introduction

In the Musashino district of the Kanto plain, some loam layers for several meters with good permeability cover the Musashino gravel layer. The groundwater under no pressure here uses the Musashino gravel layer as the main aquifer. However, the seasonal recharge may raise the water level to the upper loam layer. The impermeable layer, which has a clay-rich lens shape, is often present in the loam layer (Kakuda, 2017). As the perchied water level rises to near the surface of the earth, flood damage is brought about occasionally (for example, Tokyo Metropolitan Geological Survey Association, 2000). Therefore, observation of such groundwater level fluctuation at many points is required to prepare for flood damage. Ohshima *et al*. (2015) examined the stability of these earthing resistances, in order to use the housing foundation as the earthing electrode to ensure safety for the electrical equipment, using a small model foundation of about 2 m ×2 m or the building foundation of a real scale housing. According to this, it was shown that there is a seasonal fluctuation in earthing resistance of about 200% in the small model or about 20% to 30% in the real scale. It is thought that this fluctuation is caused by the characteristic accompanying the temperature change. On the other hand, the observations of groundwater level at the wells around Inokashira pond, from the beginning of December 1988 until March 2001, showed that the peak-to-peak annual change of 2 m to 3 m (Kokubu, 2005). These variation in the groundwater level makes to change the earthing resistivity, and it becomes a factor of changing the earthing resistance of the electrode (Ryoki, 2019). In this memoir, the conseption is introduced, and then, it has been proposed that a method for estimating the level, based on the contribution of the variation of the groundwater level to the earthing resistance.

2. Theory

Consider the point current I flowing from the origin O to the ground of the semi-infinite medium with the resistivity ρ, the potential V_r, that is created on the surface of the distance r, is $V_r=\rho I/2\pi r$. When the hemispherical metal electrode of the radius a, which instead of the point current source, is grounded, the potential in the metal becomes equal to the potential $V_a=\rho I/2\pi a$ on the surface. Therefore, R, as the resistance of the origin O (*eq*. the resistance value of the hemispherical metal electrode) viewed from infinity, is expressed as follows; $R=V_a/I=\rho/2\pi a$. This is the earthing resistance of the hemispherical metal electrode.

Next, let us consider the ground potential when the earth is regarded as a horizontal two-layers structure. According to the mirror image method (Figure 1) shown by Hagiwara (1951), the potential $V_{0(r,\,z=0)}$ on the ground surface, z=0, at the distance r made by the point current source is as follows; $V_{0(r,\,z=0)}=\rho_1 I(1/r+2\Sigma^{\infty}_{k=1}(Q^k/(r^2+(2kd)^2)^{1/2}))/2\pi$. Where Q is the reflection coefficient with respect to the current density; $Q=(\rho_2-\rho_1)/(\rho_2+\rho_1)$. ρ_1 and ρ_2 are the resistivities of the first layer and the second layer, respectively. d is the layer thickness of the first layer. Now, consider R_a, the earthing resistance of the earth electrode on the two-layer structure, as in the case of Wenner's method which is a vertical electrical prospecting, letting $r=a$; $R_a=V_a/I=\rho_1(1/a+2\Sigma^{\infty}_{k=1}(Q^k/(a^2+(2kd)^2)^{1/2}))/2\pi$. This is able to call the equivalent earthing resistance. Consider the ratio of R_a to the earthing resistance R_1 which is in the semi-infinite medium consisting only of the first layer of resistivity ρ_1; $R_a/R_1=1+2\Sigma^{\infty}_{k=1}(Q^k/(1+4k^2(d/a)^2)^{1/2})$. This is able to call the apparent resistivity with respect to the equivalent earthing resistance.

©2019. Japan Geoscience Union. All Right Reserved.

Fig. 2 shows the relationship between d/a and R_a/R_1, here, d: thickness of the first layer, a: radius of the hemispherical conductive electrode. Shown in Fig. 2, it is able to understand that the equivalent earthing resistance takes a change when the groundwater level varies. Therefore, it is able to expect that variations in groundwater level is sensed by monitoring fluctuation of earthing resistance.

3. Future plans

In order to verify the method introduced here, the observation well will be drilled, and the fluctuation of the groundwater level *etc.* will be measured there. Then, the earthing resistance of the earth electrode for safety of electrical equipment will be continuously measured. The planned observations are (1) the groundwater level, (2) also the temperature, (3) also the electrical conductivity, (4) the apparent resistivity of the earth, and (5) the earthing resistance. Preliminary measurement results will be shown at the JpGU meeting.

Experimental and Theoretical Studies for Seafloor Survey by Ground Penetrating Radar

*Jun Sonoda[1], Tomoyuki Kimoto[2]

1. National Institute of Technology, Sendai College, 2. National Institute of Technology, Oita College

The electromagnetic wave (EM) do not propagate in the seawater because of high conductivity. In recent, the ultrasonic wave is widely used in the sea, such as the fish-finder, the side-scan sonar, and so on. We have used the ground penetrating radar (GPR) by several hundred MHz to search missing persons and rubbers in the sea after the tsunami caused by the Great East Japan earthquake. In this study, we have studied the under seawater prospecting using 350/400 MHz GPR in Hiroura Bay, Natori city, in Isohama fisher port, and off the coast of Sakamoto, Yamamoto town, Miyagi prefecture. At first, frequency characteristics of complex permittivity of several seawater samples by the time domain reflectometry (TDR), and conductivity in the depth of seawater by the conductivity temperature depth profiler (CTD) have been shown. Also, it is shown that the reflected wave from several objects at the about 10 meters depth has been observed using the 350 MHz GPR. Finally, the EM wave propagation in the seawater has been analyzed using the FDTD method with the graphics processing unit (GPU).

Evaluation of the 3-D Distribution of Fractures in a Rock Mass using Directional Borehole Radar Data from a Horizontal Borehole

*Kazuhiko Masumoto[1], Tomoaki Matsushita[2], Suguru Shirasagi[1], Takashi Ueki[3], Shinsuke Karasawa[3], Daiki Makino[3], Kazushige Wada[4]

1. Kajima Technical Research Institute, 2. Kajima Corporation, 3. Matsunaga Geo-Survey Co., Ltd., 4. Mitsui Mineral Development Engineering Co., Ltd.

Evaluation of the distribution of fractures in a rock mass ahead of a tunnel face is required for safe and reasonable tunnel excavation. To evaluate not only the position of fractures, but also their inclination before tunnel excavation, a directional borehole radar may be a suitable technique. A directional borehole radar can determine the inclination of fractures with a single pilot boring because it can estimate the arrival direction of the waves reflected by fractures, which are measured by a dipole array antenna with multiple elements. This study first examined the application of a directional borehole radar to investigate within a horizontal pilot boring. Next, field test using the directional borehole radar was conducted in a horizontal borehole drilled in the sidewall of a tunnel in order to confirm the applicability of the directional borehole radar for evaluating the three-dimensional distributions of fractures.

To apply the borehole radar for horizontal pilot boring in a tunnel, a casing is needed to prevent collapse of the borehole. Because the steel casing pipe which is typically used for pilot borings cannot be used for radar measurements, the applicability of a glass fiber reinforced plastic (GFRP) tube was verified as the borehole casing in this study. As the results of the experimental study, it could be concluded that GFRP tubes with steel joint couplers can be used as a borehole casing for measurements with radar.

Next, a directional borehole radar was applied to the survey of fractures in granite in a horizontal borehole drilled in the sidewall of a tunnel in order to confirm its applicability for evaluating the three-dimensional distribution of fractures. The results indicated that the strike and dip of each reflector estimated by the directional borehole radar measurements approximately corresponded to the fractures observed with a borehole scanner. Therefore, it was concluded that a survey with a directional borehole radar in a horizontal borehole could evaluate the three-dimensional distribution of fractures surrounding the borehole.

Automatic Detection of Deteriorated Concrete Bridge Deck using 2 GHz Horn Antennae

*Kunio Aoike[1], Shogo Tanaka[2], Naoto Takase[1], Akio Matsuyama[1], Masaya Yamauchi[1], Yoshinori Uno[1]

1. OYO Corporation, 2. Professor Emeritus of Yamaguchi Univ.

In 10 years, about 40% road bridges in Japan will become over 50 years old after the construction. Although many inspections have been conducted to the aged road bridges, the upper part of the bridge deck is impossible to inspect visually because of the asphalt concrete layer covering the bridge decks. It is becoming an important problem that slab deterioration is often generated in the upper part of the aged concrete bridge deck. Thus, it is becoming urgently necessary for the deterioration of the aged concrete bridge deck to be detected and repaired to elongate the life of the bridge. Ground penetrating radar (GPR) mounted on a vehicle is one of the effective non-destructive methods, which enables us to inspect the deterioration under no traffic control. A high pulse resolution is required to the GPR to detect anomalies beneath the asphalt concrete layer of the thickness of about 8cm. Adding to it, both a high scan rate in data acquisition and a safe mounting way of the GPR on vehicle are required to achieve the accurate and high-resolution inspection with a high speed traveling of the inspection cars. We adopted the horn antenna, produced by GSSI, whose central frequency is 2 GHz. The antenna can detect reflection waves from the boundary between the asphalt layer and the concrete bridge deck, and also can distinguish them from the surface reflection wave of the asphalt surface. SIR-30 type radar system having 8 channels enables us to realize 989 scans per second with 512 samples, thus it can realize the inspection under the vehicle speed up to 80km/h. We also mount the GPR antennae to the height of 45cm (i.e., lift off) from the road surface. This mounting is important for safe traveling of the inspection vehicle. 8 antennae are mounted on a boat trailer towed by vehicle and aligned in the transverse line to the moving direction. It allows us to scan about 1.7m width at one time. For the inspection of the deterioration of the concrete bridge deck, we developed an automatic processing system. This method predicts a received signal by using two empirical reflection waveforms. We acquired in advance surface reflection waveform and asphalt bottom reflection waveform from an experiment using a real size physical model. We determined the arrival time and the amplitude for each empirical waveform by matching the linear combination of the two empirical waveforms and the actual received signal. To visualize the anomaly distribution of the concrete bridge deck and to inspect the deterioration, we made three types of 2 dimensional maps on thickness of asphalt layer, relative reflectivity at the asphalt bottom, and the fitness between the received and the predicted waveforms. As the results, we could successfully detect the anomalies and delineate their extents. Fig. 1 shows an example of the processing results on a concrete bridge deck model which simulated slab deterioration. We have a plan to continue to modify and update the proposed method by applying the method to real road bridges as a future work.

[H-TT22] New Developments in Shallow Geophysics

convener:Kyosuke Onishi(Public Works Research Institute), Kunio Aoike(Oyo corporation), Keisuke Inoue(National Agriculture and Food Research Organization), Tishiyuki Yokota(National Institute of Advanced Industrial Science and Technology)

The session of shallow geophysics calls many research contributions on geophysical exploration techniques for the near surface. Our target depth is strictly restricted in the depth zone from 5 cm to 30 m (or from 2 in to 100 ft) below the surface of the ground. It may be the closest unknown territory for human society and advanced societies cannot have controlled yet to avoid disasters caused by dynamics in the shallow near surface. Peoples require techniques to manage levee, landslide and earth constructions also knowledge to control groundwater, liquefaction and soil pollution. The near surface has many geotechnical, environmental and hydrogeologic problems.
Major survey techniques are surface wave method, electric exploration, ground-penetrating radar and land streamer, but any methods will be discussed if your target is located in the specified depths. This session welcomes to discuss laboratory tests and rock physics for unconsolidated porous media in the vadose zone. Also, we will welcome not only cutting-edge technologies but also classic theory, if the knowledge is useful for human living.

The shallow structure imaging of integrated geophysical surveying of GPR and ERT at Oyunuma in the Goshougake geothermal area, northeast of Japan

*Inoue Yusuke[1], Tomoki Tsutsui[1], Shinya Sakanaka[1]

1. Graduate School of International Resource Sciences in Akita University

The Goshougake geothermal area is surrounded in active volcanoes of Akita Yakeyama volcanoes and Hachimantai volcanoes. In this area, we can observe active geothermal phenomena, such as hot springs, high temperature water marshes including Oyunuma, and mud volcanoes. In this field, a part of sidewalk was broken by mud volcanic eruption, and has closed to walk since autumn 2016. The event inspires our motivation to research the shallow structure at the field by geophysical method.
The previous studies with geophysical methods were applied to the area including the Goshougake geothermal area. The gravitational survey, magnetic survey, electrical survey, and seismic survey in the north Hachimantai area were carried out by Yora and Ito (1974). Airborne electromagnetic survey, MT survey, and electrical survey were carried out by Uchida and Mitsuhata (1995). The research target of these studies focused on the wide area and the studies imaging shallow structure have never reported at Oyunuma in the in the Goshougake geothermal area. Our research purpose is revealing the shallow structures at Oyunuma in the Goshougake geothermal area by the integrated geophysical surveying of GPR (Ground Penetrating Radar) and ERT (Electrical Resistivity Tomography).
In GPR survey, a line of 172 m long was arranged on the southeast of Oyunuma. We used 4 different antennas of 100 MHz, 270 MHz, 400 MHz, and 900 MHz with the GPR equipment SIR-3000 made by GSSI (Geophysical Survey System, Inc.) and adopted the profile measurement with keeping interval of transmitter and receiver antennas. In ERT, a line of 188 m long was arranged along the GPR survey line. We used the equipment SYSCAL Pro made by IRIS Instruments and adopted the array system of the dipole-dipole method. The number of electrode is 48 and the intervals of the electrodes were 4 m.
A series of the GPR analysis, that is, time-zero correction, background removal, bandpass filter (BPF), autocorrelation, predictive deconvolution, velocity analysis, and depth conversion were applied to the obtained data. Clear reflections appeared at two way time of 75-100 ns in the time sections derived by BPF in the records of 4 kinds of antennas. Especially, clear reflections appeared in the reflection record of 270 MHz antenna. We picked up 4 blocks (sections) with remarkably clear reflections in the GPR survey line and carried out detailed analyses on each classified block.
The reflection records obtained in GPR survey are presented in the time sections. In order to convert them in the depth sections, it is necessary to know the exact EM (electromagnetic) wave velocity. We developed an original computer program for the EM velocity analysis which can be applicable for GPR profiling using Visual Studio 2015 C#. Based on calculation using the program, we can draw the contour chart of velocity spectrum which evaluates the most appropriate mean velocity by the semblance values. The semblance value is the ratio of the energy of stacked waves included in a time window to the total input energy of the waves in the same window (Honda, 2014). The exact mean EM velocity in ground medium is estimated to be 0.093-0.147 m/ns for each block. When multiple reflectors appear in reflection records, appropriate velocities are obtained by the predictive deconvolution processing. The original program also calculates the autocorrelation function which is the parameter used in the predictive deconvolution processing. Using the EM velocity by the velocity analysis, we can convert GPR data to the depth sections and the clear reflections revealed in the depth of 4-5 m from the surface of the sidewalk.
The 2D resistivity inversion by the finite difference method is used in the analysis of ERT. The part of the

continuity of an extreme low resistivity zone to the ground surface matches the location of the outcrop of the vents of sulfur gas. Consequently, the zone of the extreme low resistivity is suggested to be a layer of the pass of thermal water.
Comparing the results of GPR and ERT in the depth sections, the clear reflections in the blocks (from block1 to block 4) in GPR sections are located at the area steeply changing from the low resistivity to the high resistivity in ERT section. We can conclude that the some features of the shallow structure in Goshougake geothermal area obtained by the geophysical methods provide the key to elucidate the mechanism and the prediction of the eruption of mud volcanoes.

The P and S wave velocity and geological conditions of shallow surrounding tunnel ground by velocity logging on tunnel side wall

*Kenji OKAZAKI[1], Toshiyuki KURAHASHI[1], Hiroumi NIWA[2]

1. Civil Engineering Research Institute for cold region, Public Works Research Institute, 2. FUJITA corporation

In the tunnel maintenance, the information for the condition of tunnel ground may be necessary to grasp its loosening or deterioration of the surrounding tunnel ground. One way method to estimate these condition is velocity logging. The velocity logging is a method of measuring P and S wave velocity in a borehole, and the condition of the tunnel ground can be estimated based on the velocity distribution. Normally, the S-wave velocity is measured by applying a top load to a thick plate placed horizontally on the ground surface and tapping it. However, in order to measure the S-wave velocity in a horizontal ground in a tunnel, it is necessary to vibrate the concrete surface of the side wall, and it is necessary to fix the thick plate used for its vibration to the side wall surface is there. Touyama et al. 2018 show the results of striking with a thick plate fixed to the ground by a spike of 30 cm in length, and clear and equivalent waveforms are measured compared with the case where it is not fixed by spikes, and the amplitude of the S-wave has been amplified to about 2 times.

In this study, a core drill (Niwa et al. 2017) at the two points A and B on the side wall part covers 5.0 meters at point A, 3.8 meters at point B was excavated and the these core were collected in the tunnel that constructed by the sheet pile construction method. In addition, velocity logging by the downhole method was performed in each hole, and the correspondence between the properties of the excavation core and the P and S wave velocity was compared. The P-wave velocity was measured by directly hitting the concrete surface of the side wall around the boring hole with a steel hammer. The S-wave velocity was measured by driving four anchors on the concrete surface of the side wall, fixing the thick plate so as to be in close contact with a screw type anchor bar, and hitting a thick plate with a hammer from both directions.

As a result of drilling by the core drill, at the point A, the andesite was confirmed on the back side of the liner concrete of 0.87 m. An andesitic rocks were collected as rod-shaped cores that emit metal sounds somewhat by hammer consultation. At point B, we also confirmed the andesitic rocks at the back of the liner concrete of 0.75 m in the same way. The andesite was collected as a short columnar core up to about 40 cm which emits a voiced sound at hammering consultation. As a result of velocity logging, the P-wave velocity at point A was 2170 m/s and the S-wave velocity was 1050 m/s. In addition, it was confirmed that inverted waveforms could be measured symmetrically with S-waves hit from both directions. The P-wave velocity at point B was 980 m/s and the S-wave velocity was 550 m/s, confirming a tendency lower than point A. It is thought that this is due to the fact that the same andesite is distributed at both sites, but the site B is in a situation with more degradation and cracks than at point A. It was confirmed that the inverted waveform of S-wave at point B was also measured symmetrically. In this survey, we measured the S-wave velocity for the ground in the horizontal direction of the tunnel with the vertical surface of the side wall concrete on tunnel, and we were able to obtain good waveform. By the simple method like this survey, we could grasp the velocity distribution of the shallow part of the tunnel and obtained information to evaluate the condition of the surrounding tunnel ground.

Rock physical interpretation of the relationship between S-wave velocity and fluid saturation in rocks

*Toru Takahashi[1]

1. Fukada Geological Institute

There have been many studies on the relationship between seismic velocity and fluid (water) saturation in rocks. As for the S-wave velocity, it is reported that it increases and decreases with the increase of the saturation degree, and it shows a more complicated aspect than the P wave velocity. In recent years, the application of seismic exploration and monitoring methods using surface waves has rapidly expanded and the importance of S-wave velocity of rocks which governs surface wave propagation is further increasing. In this study, to understand and model the relationship between S-wave velocity and fluid saturation, the data on the relationship between seismic velocity, especially S-wave velocity, and fluid saturation obtained in the laboratory tests are analyzed. It is also examined whether the observation data as described above can be explained or not by the proposed model. As a result, it is confirmed that the relationship between the S-wave velocity and fluid saturation is changed according to the type and age of the rock, and that the relationship can be represented by the rock physical model.

Estimation of Rayleigh wave group velocities in Zushi City using seismic interferometry in the short period range

*jun ueno[1], Yoshiya - Oda[1]

1. Tokyo Metropolitan University

To estimate Rayleigh wave group velocities in the short period range from microtremor data, we have applied seismic interferometry method to microtremor data observed in Zushi City, Kanagawa, Japan. The group velocities for the 82 station pairs from 58 observation points have been calculated by using the multiple filter analysis. As the result, we found that there is a good correlation with the results of microtremor array method carried out at the same area.

Acquiring distributions of phase velocity for wave frequency to use DAS for surface wave method

*Kyosuke Onishi[1], Kobayashi Takayuki[1], Takanori Ogahara[1], Tomio INAZAKI[1]

1. Public Works Research Institute

Recently, the distributed acoustic sensing (DAS) technology has been developed and the development speed is accelerated. Test surveys using test wells of petroleum production are frequency reported. In shallow geophysics, DAS will be useful technology for a low-cost sensor to monitor for long ranges. The main method of geophysical exploration using elastic wave for river banks and shallow soil structures is surface wave method. When we want to use DAS technology to survey shallow soil structure, it is important to acquire and analyze surface waves. We acquired events of surface wave on DAS records using optical fiber set in shallow ground in our research institute (PWRI, Tsukuba). DAS records show lower s/n than the records from standard geophones, but we can find propagation of surface wave on the DAS records. We analyzed phase velocities on different frequencies using CMP-CC method and acquired fine images of dispersion property. The minimum wave length we specified is about 6.5 m to acquire phase velocity. However, we cannot analyze phase velocity in some CMP points and we search reasons to improve analysis methods. When phase velocity curves will be stably acquired, surface wave method is applied by DAS technology and development of DAS for shallow geophysics will be accelerated.

Imaging of deteriorated floor slabs using a test model by ground-penetrating radar

*Kyosuke Onishi[1]

1. Public Works Research Institute

The concrete floor slab of bridge sometimes has special deterioration, which is faster than standard deteriorations. Previous detecting methods without visual examination will be developed for sudden problems. Ground-penetrating radar (GPR) is frequently and widely used for survey underground cavities and it becomes one of effective tools to detect deterioration areas of floor slabs. However, GPR is difficult to detect deterioration of a concrete slab in many situations. One of the reasons is that the target depth is shallow. The deterioration of concrete slab occurs from the top surface. The depth of the top surface from the surface of road is decided from the thickness of pavement. The value of pavement thickness is frequently ranged from 5 cm to 10 cm. The thickness values is travel time including direct waves in air and on ground, which becomes difficult to separate important event signals. We made a model of floor slab and measured several GPR equipment. We show some results of GPR records. The model has a special design to remove an asphalt pavement layer and to easily change conditions of a concrete slab. We find GPR can detect anomalous areas in the upper zone with deterioration of a concrete slab, when dielectric characteristic shows enough different from around areas. However, it is difficult to detect abnormal conditions, such as thickness, particle size, moisture from characteristic signals detected on GPR records. We conclude that tests of slab model and numerical simulations should be used to understand characteristic signals of many conditions and to use them to interpret actual data acquired from bridges.

The number of electrode is 48 and the intervals of the electrodes were 4 m.
A series of the GPR analysis, that is, time-zero correction, background removal, bandpass filter (BPF), autocorrelation, predictive deconvolution, velocity analysis, and depth conversion were applied to the obtained data. Clear reflections appeared at two way time of 75-100 ns in the time sections derived by BPF in the records of 4 kinds of antennas. Especially, clear reflections appeared in the reflection record of 270 MHz antenna. We picked up 4 blocks (sections) with remarkably clear reflections in the GPR survey line and carried out detailed analyses on each classified block.
The reflection records obtained in GPR survey are presented in the time sections. In order to convert them in the depth sections, it is necessary to know the exact EM (electromagnetic) wave velocity. We developed an original computer program for the EM velocity analysis which can be applicable for GPR profiling using Visual Studio 2015 C#. Based on calculation using the program, we can draw the contour chart of velocity spectrum which evaluates the most appropriate mean velocity by the semblance values. The semblance value is the ratio of the energy of stacked waves included in a time window to the total input energy of the waves in the same window (Honda, 2014). The exact mean EM velocity in ground medium is estimated to be 0.093-0.147 m/ns for each block. When multiple reflectors appear in reflection records, appropriate velocities are obtained by the predictive deconvolution processing. The original program also calculates the autocorrelation function which is the parameter used in the predictive deconvolution processing. Using the EM velocity by the velocity analysis, we can convert GPR data to the depth sections and the clear reflections revealed in the depth of 4-5 m from the surface of the sidewalk.
The 2D resistivity inversion by the finite difference method is used in the analysis of ERT. The part of the

©2019. Japan Geoscience Union. All Right Reserved.

continuity of an extreme low resistivity zone to the ground surface matches the location of the outcrop of the vents of sulfur gas. Consequently, the zone of the extreme low resistivity is suggested to be a layer of the pass of thermal water.
Comparing the results of GPR and ERT in the depth sections, the clear reflections in the blocks (from block1 to block 4) in GPR sections are located at the area steeply changing from the low resistivity to the high resistivity in ERT section. We can conclude that the some features of the shallow structure in Goshougake geothermal area obtained by the geophysical methods provide the key to elucidate the mechanism and the prediction of the eruption of mud volcanoes.

The P and S wave velocity and geological conditions of shallow surrounding tunnel ground by velocity logging on tunnel side wall

*Kenji OKAZAKI[1], Toshiyuki KURAHASHI[1], Hiroumi NIWA[2]

1. Civil Engineering Research Institute for cold region, Public Works Research Institute, 2. FUJITA corporation

In the tunnel maintenance, the information for the condition of tunnel ground may be necessary to grasp its loosening or deterioration of the surrounding tunnel ground. One way method to estimate these condition is velocity logging. The velocity logging is a method of measuring P and S wave velocity in a borehole, and the condition of the tunnel ground can be estimated based on the velocity distribution. Normally, the S-wave velocity is measured by applying a top load to a thick plate placed horizontally on the ground surface and tapping it. However, in order to measure the S-wave velocity in a horizontal ground in a tunnel, it is necessary to vibrate the concrete surface of the side wall, and it is necessary to fix the thick plate used for its vibration to the side wall surface is there. Touyama et al. 2018 show the results of striking with a thick plate fixed to the ground by a spike of 30 cm in length, and clear and equivalent waveforms are measured compared with the case where it is not fixed by spikes, and the amplitude of the S-wave has been amplified to about 2 times.

In this study, a core drill (Niwa et al. 2017) at the two points A and B on the side wall part covers 5.0 meters at point A, 3.8 meters at point B was excavated and the these core were collected in the tunnel that constructed by the sheet pile construction method. In addition, velocity logging by the downhole method was performed in each hole, and the correspondence between the properties of the excavation core and the P and S wave velocity was compared. The P-wave velocity was measured by directly hitting the concrete surface of the side wall around the boring hole with a steel hammer. The S-wave velocity was measured by driving four anchors on the concrete surface of the side wall, fixing the thick plate so as to be in close contact with a screw type anchor bar, and hitting a thick plate with a hammer from both directions.

As a result of drilling by the core drill, at the point A, the andesite was confirmed on the back side of the liner concrete of 0.87 m. An andesitic rocks were collected as rod-shaped cores that emit metal sounds somewhat by hammer consultation. At point B, we also confirmed the andesitic rocks at the back of the liner concrete of 0.75 m in the same way. The andesite was collected as a short columnar core up to about 40 cm which emits a voiced sound at hammering consultation. As a result of velocity logging, the P-wave velocity at point A was 2170 m/s and the S-wave velocity was 1050 m/s. In addition, it was confirmed that inverted waveforms could be measured symmetrically with S-waves hit from both directions. The P-wave velocity at point B was 980 m/s and the S-wave velocity was 550 m/s, confirming a tendency lower than point A. It is thought that this is due to the fact that the same andesite is distributed at both sites, but the site B is in a situation with more degradation and cracks than at point A. It was confirmed that the inverted waveform of S-wave at point B was also measured symmetrically. In this survey, we measured the S-wave velocity for the ground in the horizontal direction of the tunnel with the vertical surface of the side wall concrete on tunnel, and we were able to obtain good waveform. By the simple method like this survey, we could grasp the velocity distribution of the shallow part of the tunnel and obtained information to evaluate the condition of the surrounding tunnel ground.

Rock physical interpretation of the relationship between S-wave velocity and fluid saturation in rocks

*Toru Takahashi[1]

1. Fukada Geological Institute

There have been many studies on the relationship between seismic velocity and fluid (water) saturation in rocks. As for the S-wave velocity, it is reported that it increases and decreases with the increase of the saturation degree, and it shows a more complicated aspect than the P wave velocity. In recent years, the application of seismic exploration and monitoring methods using surface waves has rapidly expanded and the importance of S-wave velocity of rocks which governs surface wave propagation is further increasing. In this study, to understand and model the relationship between S-wave velocity and fluid saturation, the data on the relationship between seismic velocity, especially S-wave velocity, and fluid saturation obtained in the laboratory tests are analyzed. It is also examined whether the observation data as described above can be explained or not by the proposed model. As a result, it is confirmed that the relationship between the S-wave velocity and fluid saturation is changed according to the type and age of the rock, and that the relationship can be represented by the rock physical model.

Estimation of Rayleigh wave group velocities in Zushi City using seismic interferometry in the short period range

*jun ueno[1], Yoshiya - Oda[1]

1. Tokyo Metropolitan University

To estimate Rayleigh wave group velocities in the short period range from microtremor data, we have applied seismic interferometry method to microtremor data observed in Zushi City, Kanagawa, Japan. The group velocities for the 82 station pairs from 58 observation points have been calculated by using the multiple filter analysis. As the result, we found that there is a good correlation with the results of microtremor array method carried out at the same area.

Acquiring distributions of phase velocity for wave frequency to use DAS for surface wave method

*Kyosuke Onishi[1], Kobayashi Takayuki[1], Takanori Ogahara[1], Tomio INAZAKI[1]

1. Public Works Research Institute

Recently, the distributed acoustic sensing (DAS) technology has been developed and the development speed is accelerated. Test surveys using test wells of petroleum production are frequency reported. In shallow geophysics, DAS will be useful technology for a low-cost sensor to monitor for long ranges. The main method of geophysical exploration using elastic wave for river banks and shallow soil structures is surface wave method. When we want to use DAS technology to survey shallow soil structure, it is important to acquire and analyze surface waves. We acquired events of surface wave on DAS records using optical fiber set in shallow ground in our research institute (PWRI, Tsukuba). DAS records show lower s/n than the records from standard geophones, but we can find propagation of surface wave on the DAS records. We analyzed phase velocities on different frequencies using CMP-CC method and acquired fine images of dispersion property. The minimum wave length we specified is about 6.5 m to acquire phase velocity. However, we cannot analyze phase velocity in some CMP points and we search reasons to improve analysis methods. When phase velocity curves will be stably acquired, surface wave method is applied by DAS technology and development of DAS for shallow geophysics will be accelerated.

Imaging of deteriorated floor slabs using a test model by ground-penetrating radar

*Kyosuke Onishi[1]

1. Public Works Research Institute

The concrete floor slab of bridge sometimes has special deterioration, which is faster than standard deteriorations. Previous detecting methods without visual examination will be developed for sudden problems. Ground-penetrating radar (GPR) is frequently and widely used for survey underground cavities and it becomes one of effective tools to detect deterioration areas of floor slabs. However, GPR is difficult to detect deterioration of a concrete slab in many situations. One of the reasons is that the target depth is shallow. The deterioration of concrete slab occurs from the top surface. The depth of the top surface from the surface of road is decided from the thickness of pavement. The value of pavement thickness is frequently ranged from 5 cm to 10 cm. The thickness values is travel time including direct waves in air and on ground, which becomes difficult to separate important event signals. We made a model of floor slab and measured several GPR equipment. We show some results of GPR records. The model has a special design to remove an asphalt pavement layer and to easily change conditions of a concrete slab. We find GPR can detect anomalous areas in the upper zone with deterioration of a concrete slab, when dielectric characteristic shows enough different from around areas. However, it is difficult to detect abnormal conditions, such as thickness, particle size, moisture from characteristic signals detected on GPR records. We conclude that tests of slab model and numerical simulations should be used to understand characteristic signals of many conditions and to use them to interpret actual data acquired from bridges.

[H-CG28] Implementing Integrated Research for Sustainable Future

convener:Yukio Himiyama(Emeritus Professor, Hokkaido University of Education), Akihiko Kondoh(Center for Environmental Remote Sensing, Chiba University), Takeshi Sakurai(Graduate School of Agricultural and Life Sciences, The University of Tokyo), Kenichi Abe(Research Institute for Humanity and Nature)

The world global environmental studies are being re-organized in the framework of Future Earth, which is considered to be an important driver to achieve the Sustainable Development Goals (SDGs) set by UN in 2015. Geoscience, which has traditionally been concerned about the dynamic nature and phenomena of the Earth, including lithosphere, hydrosphere, atmosphere and biosphere, is now increasingly committed to human sphere and human dimensions of global change, assuming unique roles in Future Earth and the SDGs. The session is intended to discuss the crucial issues related with them, particularly in reference to such SDGs as good health and well-being, quality education, clean water and sanitation, sustainable cities and communities, climate action, life below water and life on land. Those interested in Future Earth, SDGs, and ESD (Education for Sustainable Development) particularly those who have already started or are about to start related projects, or are interested in Future Earth Knowledge-Action Networks (KANs), such as Ocean, Food-Water-Energy Nexus, Health, Disasters, Cities, Natural Assets, will find this Session an ideal place to present his/her research results, to exchange information and ideas, and to seek new collaborative relations with other research groups and even with partners in the society.

Ground Motion Instrumentation Network and Earthquake Early Warning System for Uttarakhand

*Pankaj Kumar[1,2], Ashok - Kumar[1,2], Ajay - Gairola[1,2]

1. Indian Institute of Technology Roorkee, India, 2. Earthquake Early Warning Laboratory, Centre of Excellence in Disaster Mitigation & Management, IIT Roorkee

An Earthquake Early Warning System (EEWS) has been developed by Indian institute of Technology Roorkee (IIT Roorkee) for Uttarakhand, a Himalayan province of India. The region behind to set up first EEWS in India for Uttarakhand is that the main central thrust (MCT) and main boundary thrust (MBT) passes through it and central seismic gap exists in its region and seismologist envisaged a big earthquake will hit this region in near future. Under this project, 155 accelerometers have been installed in 53,483 km^2 area in the Himalayan part of Uttarakhand. These accelerometers are installed on the ground floor of government owned offices of Bharat Sanchar Nigam Limited (BSNL) mobile towers and State Wide Area Network (SWAN) available in the province. The average station to station distance is kept between 10 to 20 km which ensure the triggering of more than 6 accelerometers if an earthquake of magnitude greater than 6 triggers in the region. The data is streamed at the central server located in Earthquake Early Warning Laboratory at Centre of Excellence in Disaster Mitigation & Management in IIT Roorkee through private network of BSNL and SWAN on 24 ×7 basis. The location of installed accelerometers and their streaming at the Earthquake Early Warning Laboratory is shown in figure 1. Whole system is automatic and the early warning parameter is peak displacement (Pd). When an earthquake of magnitude greater than 6 will strike in the instrumented region an earthquake warning will be issued to public through the sirens. The early warning sirens are installed in the public offices, government buildings, schools, colleges of the two major cities, Dehradun and Haldwani, and all 13 district emergency operation center of the province. After hearing, earthquake alarm, people can take necessary precautionary measures. This paper presents the details of instrumentation and working of the EEWS.

Fig 1. Installed accelerometers are shown in Uttarakhand’ s map. MCT and MBT passes through the Himalayan province. Streaming of the data from accelerometer to central server at EEW laboratory is shown in the snapshot.

Linking Socioeconomic and Geographical Model to Analyze Land Use Changes in the Jakarta - Bandung Mega Urban Regions

*Didit Okta Pribadi[1,2]

1. Center for Regional Systems Analysis, Planning and Development (CrestPent) - IPB University, 2. Research Center for Plant Conservation and Botanic Gardens - Indonesian Institute of Sciences

Continuing rapid urbanization has led to escalating socio-economic and physical interaction between two adjacent megacities in Indonesia namely Jakarta and Bandung megacity. Physically, enhancing the connection over time has formed urban corridors that stimulate rapid land use changes as well as the expansion of urban-rural land use mixture in the vast area between the two big cities. As land use composition is essential to achieve urban sustainability, modelling land use changes is required as a tool for decision makers to assess the sustainability of different urban form. Nowadays, land use changes model has been rapidly developed owing to increasing computation capacity which is capable of incorporating previous trend of land use changes (e.g. Markov Chain), spatial correlation (e.g. Cellular Automata), and related driving factors (e.g. Logistic Regression or Neural Network) within the model. However, this model is too focused on geographical aspect, while lacking to consider socio-economic factors which spatially might have distinctive properties such as spatial heterogeneity, spatial network, and spatial multiplier effect. This paper aims to combine socioeconomic and geographical factors to analyze complex and dynamic land use systems as found in Jakarta-Bandung Megacity corridors. Land Change Modeler (LCM) from Idrisi Tersset software as a combination of Neural Network and CA-Markov model would be enhanced by incorporating socioeconomic aspects analyzed by GWR (Geographical Weighted Regression) for detecting spatial heterogeneity, gravity model for analyzing spatial network, and spatial autocorrelation model (SAM) for defining spatial multiplier effect. This model would be compared to the results of LCM as a single approach. A new model is suggested as an enhanced approach to understand multiple factors that influence land use changes in Jakarta-Bandung megacity corridors, thus more comprehensive policies can be formulated.

Development of an Integrated Model for Evaluation of Pasture Carrying Capacity and its Vulnerability based on Water Resources in Arid and Semi-arid Regions------A Case Study in Mongolia

*Qinxue Wang[1], Tomohiro Okadera[1], Tadanobu Nakayama[1], Deni Eer[1], Ochirbat Batkhishig[2], Dorjgotov Battogtokh[2], Uudus Bayasaikhan[3]

1. National Institute for Environmental Studies, 2. Institute of Geography and Geoecology, Mongolian Academy of Sciences, 3. School of Arts and Sciences, National University of Mongolia

Arid and semi-arid regions cover 41% of the global land area and near 2 billion people (34.7%) live there, where fragile environment is getting more vulnerable due to climate change and human activities. Pasture carrying capacity and its vulnerability can be recognized as the integrated indicators for SDGs in arid and semi-arid regions. Our previous study revealed that climate change in past few decades caused the obvious degradation of permafrost, the water deficit of land-surface, and then the decrease of pasture productivity and carrying capacity. However, beside climate change, land use/cover changes caused by human activities such as urbanization, cultivation and mining industry may also have a large influence on pasture carrying capacity. In such regions, it is essential for us to develop some indicators to be used for sustainable management of pasture ecosystems.

In this study, we have developed an integrated model based on water resources to evaluate the pasture Carrying Capacity (CC), Grazing Pressure (GP) and Vulnerability Index (VI) under the influences of both climate change and land use/cover changes, such as urbanization, cultivation and mining & so on (Figure 1). The input data include the pasture net primary production, land use, gradient of slope and grazing density, etc. In order to evaluate the impact of land use/cover changes, we applied the model to four target areas: urban area (Ulaanbaatar City) and steppe area (Altanbulag Soum) in semi-arid regions of northern Mongolia and mining area (Khanbogd Soum) and desert (Manlai Soum) in arid regions of southern Mongolia, and the estimated result was shown in Figure 2, which indicates:

Carrying Capacity (CC): steppe area > urban area > desert area > mining area
Grazing Pressure (GP): urban area > steppe area > mining area > desert area
Vulnerability Index (VI): urban area > mining area > desert area > steppe area

We also applied the model to the Soum level in Mongolia and found that the areas with high vulnerability expanded rapidly, especially in central Mongolia in last decades. We are now trying to use the model to do sensitivity analysis to parameters, such as water accessibility, harvest index and so on, to be able to evaluate the efficiency of adaptation strategies, such as well construction for enhancing groundwater usage, forage plantation for enhancing harvest index and so on.

Influence of land use histories on vegetation and ecosystem services of restored wetlands in Tumen River basin, China

*CAO GUANGLAN[1], Kazuaki Tsuchiya[1], Weihong Zhu[2], OKURO TOSHIYA[1]

1. The University of Tokyo, 2. Yanbian University

Wetlands are among the world’ s most productive and valuable ecosystems. They are important habitats for a variety of flora and fauna, and are vital ecosystems that provide diverse services. They not only are essential for ecological functions such as maintaining biodiversity, controlling floods, and removing pollutants, but also serve necessary economic functions in rice and fish production, transport, and hydropower energy. Despite this, they have suffered a loss of 54%–57% of their area worldwide, which continues under pressures from agriculture, urban expansion, industrialization, and resource extraction. Conservation and restoration of wetland ecosystems is important issues for conservation biodiversity and sustainable use of ecosystem services. In this study, we focus on the lower of Tumen River, Northeast China where the wetlands decreased dramatically because of reclamation. Our objective was to determine the influence of land use and management histories on vegetation structure and ecosystem services and future analyse their associations with environmental factors. The results of this study are of great significance to the impact of management measures on wetland ecosystems, as well as the analysis and evaluation of vegetation restoration.

The spatial flow of freshwater ecosystem services: A case study of Tumen River watershed

*JIAN ZHANG[1], Shizuka hashimoto[1], Kazuaki Tsuchiya[1], Weihong Zhu[2], OKURO TOSHIYA[1]

1. The University of Tokyo, 2. Yanbian University

Freshwater is widely regarded as the most essential natural resource underpinning the well-being of human society, and while scientists translate it into ecosystem services' valuable processes, the supply of clean freshwater has the highest value among various provisioning services. However, due to the land-use intensification and projected warming climate, an increasing likelihood of persistent drought condition, and inadequate conservation, freshwater scarcity issues continue to gain urgency in science and policies. The fusion of the concept of ecosystem services with natural resources management nowadays represents a new conservation paradigm, but still faces notable limitations. Some scientists, noticing the occurrence of spatial mismatch between the supply and demand of ecosystem services, put forward the concept of ecosystem services flow to deal with the problem. Ecosystem services flow research brings out a spatio-temporal connection between the supply and demand, and an deepened understanding about when ,where, and how those benefits were enjoyed. Many papers also suggested that studies at landscape scale may offer a better understanding of ecosystem processes, ecosystem functions, ecosystem services and link them from one to another, as landscape patterns have long been discussed as tools for explaining numerous ecological consequences. In 2017, the annual meeting of IALE in USA as well emphasized the pressing need of integrating landscape patterns to ecosystem services. Thus the study attempt to conduct an analysis of freshwater ecosystem services flow in an intact watershed with the combination of landscape ecology theories. The conceptual framework and progress of this study will be introduced.

Development of an Integrated Model for Evaluation of Pasture Carrying Capacity and its Vulnerability based on Water Resources in Arid and Semi-arid Regions------A Case Study in Mongolia

*Qinxue Wang[1], Tomohiro Okadera[1], Tadanobu Nakayama[1], Deni Eer[1], Ochirbat Batkhishig[2], Dorjgotov Battogtokh[2], Uudus Bayasaikhan[3]

1. National Institute for Environmental Studies, 2. Institute of Geography and Geoecology, Mongolian Academy of Sciences, 3. School of Arts and Sciences, National University of Mongolia

Arid and semi-arid regions cover 41% of the global land area and near 2 billion people (34.7%) live there, where fragile environment is getting more vulnerable due to climate change and human activities. Pasture carrying capacity and its vulnerability can be recognized as the integrated indicators for SDGs in arid and semi-arid regions. Our previous study revealed that climate change in past few decades caused the obvious degradation of permafrost, the water deficit of land-surface, and then the decrease of pasture productivity and carrying capacity. However, beside climate change, land use/cover changes caused by human activities such as urbanization, cultivation and mining industry may also have a large influence on pasture carrying capacity. In such regions, it is essential for us to develop some indicators to be used for sustainable management of pasture ecosystems.

In this study, we have developed an integrated model based on water resources to evaluate the pasture Carrying Capacity (CC), Grazing Pressure (GP) and Vulnerability Index (VI) under the influences of both climate change and land use/cover changes, such as urbanization, cultivation and mining & so on (Figure 1). The input data include the pasture net primary production, land use, gradient of slope and grazing density, etc. In order to evaluate the impact of land use/cover changes, we applied the model to four target areas: urban area (Ulaanbaatar City) and steppe area (Altanbulag Soum) in semi-arid regions of northern Mongolia and mining area (Khanbogd Soum) and desert (Manlai Soum) in arid regions of southern Mongolia, and the estimated result was shown in Figure 2, which indicates:

Carrying Capacity (CC): steppe area > urban area > desert area > mining area
Grazing Pressure (GP): urban area > steppe area > mining area > desert area
Vulnerability Index (VI): urban area > mining area > desert area > steppe area

We also applied the model to the Soum level in Mongolia and found that the areas with high vulnerability expanded rapidly, especially in central Mongolia in last decades. We are now trying to use the model to do sensitivity analysis to parameters, such as water accessibility, harvest index and so on, to be able to evaluate the efficiency of adaptation strategies, such as well construction for enhancing groundwater usage, forage plantation for enhancing harvest index and so on.

Influence of land use histories on vegetation and ecosystem services of restored wetlands in Tumen River basin, China

*CAO GUANGLAN[1], Kazuaki Tsuchiya[1], Weihong Zhu[2], OKURO TOSHIYA[1]

1. The University of Tokyo, 2. Yanbian University

Wetlands are among the world’ s most productive and valuable ecosystems. They are important habitats for a variety of flora and fauna, and are vital ecosystems that provide diverse services. They not only are essential for ecological functions such as maintaining biodiversity, controlling floods, and removing pollutants, but also serve necessary economic functions in rice and fish production, transport, and hydropower energy. Despite this, they have suffered a loss of 54%–57% of their area worldwide, which continues under pressures from agriculture, urban expansion, industrialization, and resource extraction. Conservation and restoration of wetland ecosystems is important issues for conservation biodiversity and sustainable use of ecosystem services. In this study, we focus on the lower of Tumen River, Northeast China where the wetlands decreased dramatically because of reclamation. Our objective was to determine the influence of land use and management histories on vegetation structure and ecosystem services and future analyse their associations with environmental factors. The results of this study are of great significance to the impact of management measures on wetland ecosystems, as well as the analysis and evaluation of vegetation restoration.

The spatial flow of freshwater ecosystem services: A case study of Tumen River watershed

*JIAN ZHANG[1], Shizuka hashimoto[1], Kazuaki Tsuchiya[1], Weihong Zhu[2], OKURO TOSHIYA[1]

1. The University of Tokyo, 2. Yanbian University

Freshwater is widely regarded as the most essential natural resource underpinning the well-being of human society, and while scientists translate it into ecosystem services' valuable processes, the supply of clean freshwater has the highest value among various provisioning services. However, due to the land-use intensification and projected warming climate, an increasing likelihood of persistent drought condition, and inadequate conservation, freshwater scarcity issues continue to gain urgency in science and policies. The fusion of the concept of ecosystem services with natural resources management nowadays represents a new conservation paradigm, but still faces notable limitations. Some scientists, noticing the occurrence of spatial mismatch between the supply and demand of ecosystem services, put forward the concept of ecosystem services flow to deal with the problem. Ecosystem services flow research brings out a spatio-temporal connection between the supply and demand, and an deepened understanding about when ,where, and how those benefits were enjoyed. Many papers also suggested that studies at landscape scale may offer a better understanding of ecosystem processes, ecosystem functions, ecosystem services and link them from one to another, as landscape patterns have long been discussed as tools for explaining numerous ecological consequences. In 2017, the annual meeting of IALE in USA as well emphasized the pressing need of integrating landscape patterns to ecosystem services. Thus the study attempt to conduct an analysis of freshwater ecosystem services flow in an intact watershed with the combination of landscape ecology theories. The conceptual framework and progress of this study will be introduced.

Keywords: freshwater ecosystem services, services flow, andscape pattern, watershed

[E] Oral | H (Human Geosciences)：H-CG Complex & General

Tue. May 28, 2019 3:30 PM - 5:00 PM JST | Tue. May 28, 2019 6:30 AM - 8:00 AM UTC | 302 3F

[H-CG28] Implementing Integrated Research for Sustainable Future

convener:Yukio Himiyama(Emeritus Professor, Hokkaido University of Education), Akihiko Kondoh(Center for Environmental Remote Sensing, Chiba University), Takeshi Sakurai(Graduate School of Agricultural and Life Sciences, The University of Tokyo), Kenichi Abe(Research Institute for Humanity and Nature), Chairperson:Ernan Rustiadi(Bogor Agricultural University), Qinxue Wang(National Institute for environmental Studies), takeshi sakurai

The world global environmental studies are being re-organized in the framework of Future Earth, which is considered to be an important driver to achieve the Sustainable Development Goals (SDGs) set by UN in 2015. Geoscience, which has traditionally been concerned about the dynamic nature and phenomena of the Earth, including lithosphere, hydrosphere, atmosphere and biosphere, is now increasingly committed to human sphere and human dimensions of global change, assuming unique roles in Future Earth and the SDGs. The session is intended to discuss the crucial issues related with them, particularly in reference to such SDGs as good health and well-being, quality education, clean water and sanitation, sustainable cities and communities, climate action, life below water and life on land. Those interested in Future Earth, SDGs, and ESD (Education for Sustainable Development) particularly those who have already started or are about to start related projects, or are interested in Future Earth Knowledge-Action Networks (KANs), such as Ocean, Food-Water-Energy Nexus, Health, Disasters, Cities, Natural Assets, will find this Session an ideal place to present his/her research results, to exchange information and ideas, and to seek new collaborative relations with other research groups and even with partners in the society.

3:30 PM - 3:45 PM JST | 6:30 AM - 6:45 AM UTC

[HCG28-01] Implementing Integrated Research for Sustainable Future - a human geoscience perspective

Implementing Integrated Research for Sustainable Future - a human geoscience perspective

*Yukio Himiyama[1]

1. Emeritus Professor, Hokkaido University of Education

Global environmental programmes are re-organized under the framework of Future Earth, which is intend to play a leading role in guiding or coordinating world research communities for sustainability. Human geoscience, which has been built on geoscience which studies dynamic nature and phenomena of the Earth including its resources, geo-hazards and environmental changes, is uniquely committed to human sphere, where human, the environment, environmental problems and disasters are, and to the world sustainability. It hence has strong human/social scientific, as well as physical scientific, viewpoint, and assumes important roles in Future Earth, SDGs (Sustainable Development Goals), and other programmes for global sustainability or disaster risk reduction. This session is intended to discuss crucial issues related with them, and to seek right ways to implement needed integrated research for sustainable future in human geoscience perspective.

Application of environmental carrying capacity analysis and land cover change scenarios in collaborative spatial planning process: The Jakarta Megacity Case

*ERNAN RUSTIADI[1], Andrea Emma Pravitasari[2], Diar Shiddiq[1], Laode Syamsul Iman[1], Setyardi Pratika Mulya[2], Mia Ermyanila[1], Nur Etika Karyati[1]

1. Center for Regional System Analysis, Planning and Development, Bogor Agricultural University , 2. Department of Soil Science and Land Resource, Faculty of Agriculture, Bogor Agricultural University

In the National Spatial Plan, the Jabodetabekpunjur area (Jakarta Megacity) is designated as a national strategic area. Due to the increasing environmental problems, the Indonesian government carried out a revision process of spatial plan based on an environmental carrying capacity assessment. This research is intended to explain how the study of land-based carrying capacity assessment was applied to the spatial planning process. First, this research is carried out by developing scenarios for land cover changes. Projections of land use change are carried out by extrapolating 20-year time series data on land cover change backward to forecast 20 years of future land use. The study of environmental carrying capacity against current and future conditions is based on the concept of land capability, land suitability, and multi-criteria analysis. The results of the study of carrying capacity were then used to revise existing spatial plans. The decision-making process on revising spatial plan was carried out by a collaborative process involving relevant stakeholders in serial workshop processes by considering the results of the carrying capacity study.

Does the Market Economy Save the Local Natural Resources While Improving Human Welfare? The Case of 101 Natural Forests in the Middle Hills of Nepal

*Takeshi Sakurai[1], Towa Tachibana[2], Santosh Rayamajhi [3]

1. The University of Tokyo, 2. Chiba University , 3. Tribhuvan University

To pursue a sustainable human development, while expanding human frontiers into space, we need to conserve the natural environment of our mother planet. In low-income countries, deterioration of local natural resources such as forests for firewood, inshore fishery for home and local consumption has been the most urgent environment issue. Various measures have been taken to stem excessive harvesting of local natural resources in the course of the population increase: e.g., community management. Little attention has been paid, however, to the seemingly most powerful lifesaver for the overuse of local natural resources: the market economy. Out-migration from the marginally productive rural areas along with the investments in urban areas would attain both the conservation of natural resources and improvements in human welfare. With 101 randomly-sampled natural forests in the Middle Hills of Nepal, we compare the impacts of community management and those of out-migration on forest conditions. Forest condition was evaluated by forest inventory conducted in 1997-1999 and 2014-2016.

Academic-public-private partnerships for sustainable herding under increasing frequency of climate hazards

*Masato Shinoda[1]

1. Graduate School of Environmental Studies Nagoya University

Socio-ecological damage from climate-related disasters has increased worldwide, including a slow-onset cold-season disaster that is unique to Mongolia, known as *dzud*. *Dzuds* are defined, bio-geophysically, as anomalous climatic and/or land-surface (i.e. snow) conditions that lead to reduced accessibility and/or availability of pastures, and ultimately to significant livestock mortality during winter–spring. Our studies showed that recent *dzuds* were caused by a half-to-half combination of multi-climate hazards and man-made vulnerability, including inadequate pasture management, poverty, and insufficient winter preparedness. With this background, for the first time, our academia produced a new *dzud* risk map to predict risky areas at the national level for the 2015/2016 winter. Subsequently, the early warning system developed together with the risk map has been implemented and successfully applied for sustainable herding under the framework of partnerships among universities/research institutes, Mongolian government, international aid organizations, and herders. This action was supported by the Grant-in-Aid for Scientific Research from the Japan Society for the Promotion of Science ‘Integrating Dryland Disaster Science’ and nominated as a top case study of early warning early action at the Asian Ministerial Conference on Disaster Risk Reduction in July 2018.

Land use after death and funeral of citizen mainly based on public cemeteries in modern Beijing city

*Haruhiro Doi[1], Yanwei Chai[2], Peiwei Xu[3]

1. Faculty of Education, Oita University, 2. Peking University, 3. Beijing Normal University

After death, a person builds a graveyard by occupying a certain land, such as by relatives left behind. Therefore, in urban areas of China where economic growth and population growth continue, the demand for the land used for the deceased is large, so controlling the cemetery area as part of the management of land resources is an important policy task.
In modern Beijing City, large-scale public cemeteries have been developed throughout the city over the last few decades in order to cope with the increasing demand for land use after death. These public cemeteries are mainly located in rural areas that are relatively adjacent to built-up areas and suitable fountains on Feng shui in suburban areas (Doi and Chai, 2017).
The present report intends to examine the history of maintenance of these public cemeteries and its relations with neighboring rural communities and to consider the relationship between the funeral of the ethnic minorities other than the Han tribe in modern Beijing.

Restoration and sustainable land management of degraded landscapes in Asia and Africa

*OKURO TOSHIYA[1]

1. Graduate School of Agricultural and Life Sciences, The University of Tokyo

Land degradation causes reduction or loss of the biological or economic productivity and complexity, resulting from land uses or from processes arising from human activities and habitation patterns. As land degradation is also defined as “the processes of landscape changes caused by miss-match between natural land conditions and land use by human”, it is necessary to reconstruct new land use systems based on new human-environment relations which can realize sustainable use of ecosystem services. This paper introduces case studies on the sustainable land management (SLM) approaches, focusing on human-environment relations, or social-ecological systems in rangelands of Asia and Africa. Firstly, I show a modelling of trade-offs in ecosystem services and assessment of effectiveness of countermeasures on land restoration. Secondly, I show a concept and methodology of grassland management systems in consideration of biodiversity-ecosystem functioning relationships. Finally I propose future perspectives, possible research topics which should be further developed, and implication to SDGs.

Keywords: social-ecological system, threshold, biodiversity, ecosystem functioning, sustainable land management, non-equilibrium

[S-GD01] Gravity and Geoid

convener:Tokuro Kodama(Geospatial Information Authority of Japan), Daisuke Oka(Geological Survey of Hokkaido, Environmental and Geological Research Department, Local Independent Administrative Agency, Hokkaido Research Organization)

Recent precise gravity measurements lead to advances in many kinds of applications, e.g., geophysical exploration of internal structure of the Earth and Moon, studies of earthquake, volcano, subsidence, landslide and tsunami, monitoring ice mass balance, and so on.
In this session, we call wide range of papers related to topics of gravity and geoid, including theory of gravity field, absolute/relative gravity measurements, data analysis of satellite gravity missions, and development of gravity sensors.

An Improved GRACE time-varying gravity field model and its application in China and Antarctica

*Yunlong Wu[1], Yi Zhang[1], Zhengbo Zou[1], Minzhang Hu[1]

1. Institute of Seismology, China Earthquake Administration

A cross correlation analysis is carried out on the time-varying gravity field models derived from GRACE observations and provided by CSR, GFZ, JPL and ITSG. This is used to propose an improved weight determination method for producing a combined time-varying gravity field model. Taking the Antarctic region as a test area, the reliability and accuracy of the combined model is verified by comparing the changes of Antarctic ice sheet mass inferred from it and the other gravity field solutions considered. The results show that the minimum difference in mass changes (expressed as equivalent water height) between the combined model and the ITSG inversion is concentrated between -0.2 cm to 0.4 cm. To further verify the new method, China’ s Three Gorges region, the North China Plain region, and the Tianshan region are assessed. The results indicate that the new combined time-varying gravity field model is consistent with those models published by CSR, GFZ and JPL, and conforms best to ITSG. The combined time-varying gravity field model proposed in this paper provides a reference for the application of such models and the optimization of time-varying gravity field for future gravity satellite missions.

Numerical modeling of crustal deformation and gravity change caused by glacier melting in Southeast Alaska

*Kazuhiro Naganawa[1], Takahito Kazama[1]

1. Graduate School of Science, Kyoto University

Glacier melting caused by global warming is of great interest as a factor of sea level rise. Spatiotemporal variations in glacier melting have been monitored by geodetic observations such as altimetry, gravimetry and GNSS. However, since these observations contain various responses of solid earth, many devices are necessary in order to estimate glacier melting from observation data. As one of the devices, it is considered to construct numerical model of solid earth deformations caused by glacier melting. Because glacier melting involve variation of mass distribution in earth’ s surface and deformation of solid earth (GIA : Glacial Isostatic Adjustment), glacier melting cause various spatiotemporal deformations such as sea level change, crustal deformation, and gravity change. Therefore, in order to quantify the present spatiotemporal variations in glacier melting directly, it is necessary to improve numerical model regularly.

In Southeast Alaska that is the main area of this study, about 16 km^3/yr of glaciers melt at present (Larsen et al., 2007) and those melting speed may be accelerated these days (Arendt et al., 2002). GNSS stations has been installed in this area since the 2000s, and they observed large ground uplift of up to 3 cm/yr associated with GIA (Larsen et al., 2004). The spatial variation of the uplift was already modeled by Larsen et al. (2005) and Sato et al. (2012) numerically. On the other hand, absolute gravity values have been measured in this area sinse 2006, and absolute gravity changes of -4~-7 microGal/yr were detected (Sun et al., 2010). However, any previous studies have not considered the observed gravity changes in their numerical model, so the gravity variations are not reproduced quantitatively as of now.

Therefore, we numerically model spatiotemporal variations in crustal deformation and gravity change derived from GIA in Southeast Alaska as follows. Both of crustal deformation and gravity change are mainly composed of two effects: the elastic deformation due to the present glacier melting, and the viscoelastic deformation due to the past glacier melting. Gravity change is additionally caused by the time variation in the attraction effect due to the present glacier melting. We here estimate these effects expected at six absolute gravity points in Southeast Alaska, by numerically computing the spatiotemporal integral of the present-day ice melting model (Larsen et al., 2007) and the ice melting history model (e.g., ICE-6G; Peltier et al., 2015). We compare the estimated results with the data observed in Southeast Alaska until 2015, to discuss the present glacier melting in this area.

Keywords: glacier melting, glacial isostatic adjustment, Alaska, gravity change, crustal uplift

Gravity gradient variations considered to have occured 3 months before the Tohoku-Oki earthquake

*Naoki Hasumi[1], Kosuke Heki[1]

1. Hokkaido University Graduate School of Science

Since the launch in 2002, the Gravity Recovery And Climate Experiment (GRACE) satellite system has been measuring global gravity field of the Earth. It has produced various scientific results by measuring redistribution of land water storage and snow/ice as time-variable gravity. Fault dislocations associated with earthquakes also redistribute mass and cause subtle changes of gravity. GRACE has also enabled observations of coseismic and postseismic gravity changes of recent megathrust earthquakes, contributing to seismology (Tanaka & Heki, 2017). Preseismic gravity changes have not been considered a target of researches with GRACE. Recently, Panet et al. (2018) reported possible detection of significant change of gravity gradients around Japan a few months before the Mw9.0 2011 Tohoku-Oki earthquake. Their approach differs from conventional studies in several ways. First, they analyzed gravity gradients, which has better spatial resolution than gravity. Second, they searched for signals over wide range of temporal and spatial scales. Third, they concentrated on components with wavelengths of 800-1600 km. We tried to reproduce the results of Panet et al. (2018) by analyzing GRACE level-2 data (Stokes' coefficients) and examining gravity gradient changes a few months before the 2011 Tohoku-Oki earthquake. We could obtain preseismic gravity gradient changes fairly similar to Panet et al. (2018), although we still see certain differences due to unknown reasons. We will also report if we see similar gravity gradient changes before the other two M9 class earthquakes, 2004 Sumatra-Andaman and 2010 Maule earthquakes.

Density structure inferred from gravity and airborne gravity gradiometry data in the northwestern part of Kuju volcano, Oita prefecture

*Jun Nishijima[1], Yasuhiro Fujimitsu[1]

1. Department of Earth Resources Engineering, Graduate School of Engineering, Kyushu University

There are many geothermal fields, hot springs and the geothermal power plants (Otake, Hatchobaru and Takigami) in the northwestern part of Kuju volcano, Oita prefecture. This area is included in the Hohi geothermal area. Many geothermal explorations have been conducted in this area since 1960. The gravity data which is measured by many institute, company and university was recorded in some gravity database. Moreover, an airborne gravity gradiometry (AGG) survey was conducted by the Japan Oil, Gas and Metals National Corporation (JOGMEC) in 2012 and 2017. The underground density structure is estimated by the gravity and AGG data inversion analysis using VOXI Earth modeling on Geosoft Oasis montaj. This result is integrated with the other geological, geophysical and geochemical data on the GIS software. Finally, the conceptual hydrothermal model is estimated by the integrated interpretation using GIS software.The high-density (2400 –2550 kg/m^3) areas were estimated below the middle and late Pleistocene volcanoes in the shouthern part of the study area at a depth of 0 to 2000 m below sea level. These high-density areas correspond to the distributions of the older Hohi volcanic rocks. Moreover, the depression structure was detected in the western side of Mt. Waita. Some hot springs (Yamakawa, Asozuru, Nuruyu and Tsuetate) are located on the edge of this structure.

On the effect of higher-order terms in the gravity sensor of the superconducting gravimeter

*Yuichi Imanishi[1], Kazunari Nawa[2], Yoshiaki Tamura[3], Hiroshi Ikeda[4]

1. Earthquake Research Institute, The University of Tokyo, 2. AIST, 3. NAOJ, 4. University of Tsukuba

The superconducting gravimeter CT #036 operated at the VERA Ishigakijima station, Okinawa, Japan, indicates several kinds of behaviors characteristic to this site. Imanishi et al. (2018), by developing a theoretical model for the static and dynamic properties of the gravity sensor, showed that the effect of the movements of a nearby VLBI antenna on the gravimeter is explained quantitatively by the coupling between the horizontal and vertical components in the gravity sensor. However, it remained unresolved whether the apparent gravity increase associated with enhanced ground noise, as typically seen when typhoons approach the Ishigakijima island, is explained by the same model, because the magnitude of the higher-order terms representing vertical nonlinearity were unknown. Here we will report our result on the measurements of the higher-order terms obtained by injecting artificial signals to CT #036, and discuss its impact on the dynamic properties of the gravity sensor.

Keywords: superconducting gravimeter, Ishigakijima, nonlinearity

Gravity Effect of Local Snow Accumulation obtained from Superconducting Gravimeter and UAV survey at Syowa Station

*Akihisa Hattori[1], Yuichi Aoyama[1,2], Koichiro Doi[1,2], Hajime Oishi[3], Jun Nishijima[4], Hiroshi Ikeda[5]

1. SOKENDAI (The Graduate University of Advanced Studies), 2. National Institute of Polar Research, 3. NEC Networks & System Integration Corporation, 4. Kyushu University, 5. University of Tsukuba

Continuous gravity observation has been conducted with a superconducting gravimeter (SG) at the Japanese Antarctic station, Syowa Station (69°0.2646' S, 39°34.9074' E) since 1993. The first SG, TT70#016, was replaced by the second SG, CT#043, in 2003, then CT#043 was replaced by the third OSG#058 in 2010, and OSG#058 is in operation. It is considered that the gravity observations with SGs, which have a high sensitivity, are detecting the gravitational signal of local snow accumulation in Syowa Station. It is necessary to correct the accumulated snow effect for monitoring the geophysically important but weak signals, such as one associated with Glacial Isostatic Adjustment (GIA).

The distribution of snow depth in Syowa Station was estimated from digital surface models (DSMs) made from unmanned aerial vehicle (UAV) photographic survey by applying structure from motion (SfM) processing methods to the aerial photographs. In the 59th Japanese Antarctic Research Expedition (JARE-59) activity (2017-2019), we conducted aerial photogrammetry by the fixed-wing drone "senseFly eBee Plus," which has dual-frequency GNSS receiver, over Syowa Station in January (austral summer season). Besides, we have conducted aerial photogrammetry by the rotary wing drone "DJI Inspire 2" and "DJI Phantom" in the same area, about every one month from May to November (austral winter season). The DSM and the orthomosaic photo were generated from each set of the geotagged photos using the SfM software "Pix4D."

For improving the accuracy of DSM, we used the geodetic triangulation survey points operated by GSI (Geospatial Information Authority of Japan) as GCP (ground control points) in SfM analysis. We also calibrated the height of DSM by using the ground area uncovered by snow characterized by Brown color as fixed height sites. Thereby, we obtained the time-series of snow depth distributions by calculating height differences among DSMs.

We calculated the attractive changes on OSG#058 estimated from the obtained snow depth distribution. Consequently, it was revealed that the local snow accumulation changes in the Syowa Station caused a seasonal gravity variation of at least 0.1-0.3 μGal (1 μGal = 10^{-8} m/s^2).

In this presentation, we show the details of observed changes in snow distribution, and discuss the comparison between the estimated gravity effect of local snow accumulation and the gravity change observed by OSG#058.

[S-GD01] Gravity and Geoid

convener:Tokuro Kodama(Geospatial Information Authority of Japan), Daisuke Oka(Geological Survey of Hokkaido, Environmental and Geological Research Department, Local Independent Administrative Agency, Hokkaido Research Organization)

Recent precise gravity measurements lead to advances in many kinds of applications, e.g., geophysical exploration of internal structure of the Earth and Moon, studies of earthquake, volcano, subsidence, landslide and tsunami, monitoring ice mass balance, and so on.
In this session, we call wide range of papers related to topics of gravity and geoid, including theory of gravity field, absolute/relative gravity measurements, data analysis of satellite gravity missions, and development of gravity sensors.

An Improved GRACE time-varying gravity field model and its application in China and Antarctica

*Yunlong Wu[1], Yi Zhang[1], Zhengbo Zou[1], Minzhang Hu[1]

1. Institute of Seismology, China Earthquake Administration

A cross correlation analysis is carried out on the time-varying gravity field models derived from GRACE observations and provided by CSR, GFZ, JPL and ITSG. This is used to propose an improved weight determination method for producing a combined time-varying gravity field model. Taking the Antarctic region as a test area, the reliability and accuracy of the combined model is verified by comparing the changes of Antarctic ice sheet mass inferred from it and the other gravity field solutions considered. The results show that the minimum difference in mass changes (expressed as equivalent water height) between the combined model and the ITSG inversion is concentrated between -0.2 cm to 0.4 cm. To further verify the new method, China’ s Three Gorges region, the North China Plain region, and the Tianshan region are assessed. The results indicate that the new combined time-varying gravity field model is consistent with those models published by CSR, GFZ and JPL, and conforms best to ITSG. The combined time-varying gravity field model proposed in this paper provides a reference for the application of such models and the optimization of time-varying gravity field for future gravity satellite missions.

Numerical modeling of crustal deformation and gravity change caused by glacier melting in Southeast Alaska

*Kazuhiro Naganawa[1], Takahito Kazama[1]

1. Graduate School of Science, Kyoto University

Glacier melting caused by global warming is of great interest as a factor of sea level rise. Spatiotemporal variations in glacier melting have been monitored by geodetic observations such as altimetry, gravimetry and GNSS. However, since these observations contain various responses of solid earth, many devices are necessary in order to estimate glacier melting from observation data. As one of the devices, it is considered to construct numerical model of solid earth deformations caused by glacier melting. Because glacier melting involve variation of mass distribution in earth’ s surface and deformation of solid earth (GIA : Glacial Isostatic Adjustment), glacier melting cause various spatiotemporal deformations such as sea level change, crustal deformation, and gravity change. Therefore, in order to quantify the present spatiotemporal variations in glacier melting directly, it is necessary to improve numerical model regularly.

In Southeast Alaska that is the main area of this study, about 16 km^3/yr of glaciers melt at present (Larsen et al., 2007) and those melting speed may be accelerated these days (Arendt et al., 2002). GNSS stations has been installed in this area since the 2000s, and they observed large ground uplift of up to 3 cm/yr associated with GIA (Larsen et al., 2004). The spatial variation of the uplift was already modeled by Larsen et al. (2005) and Sato et al. (2012) numerically. On the other hand, absolute gravity values have been measured in this area sinse 2006, and absolute gravity changes of -4~-7 microGal/yr were detected (Sun et al., 2010). However, any previous studies have not considered the observed gravity changes in their numerical model, so the gravity variations are not reproduced quantitatively as of now.

Therefore, we numerically model spatiotemporal variations in crustal deformation and gravity change derived from GIA in Southeast Alaska as follows. Both of crustal deformation and gravity change are mainly composed of two effects: the elastic deformation due to the present glacier melting, and the viscoelastic deformation due to the past glacier melting. Gravity change is additionally caused by the time variation in the attraction effect due to the present glacier melting. We here estimate these effects expected at six absolute gravity points in Southeast Alaska, by numerically computing the spatiotemporal integral of the present-day ice melting model (Larsen et al., 2007) and the ice melting history model (e.g., ICE-6G; Peltier et al., 2015). We compare the estimated results with the data observed in Southeast Alaska until 2015, to discuss the present glacier melting in this area.

Gravity gradient variations considered to have occured 3 months before the Tohoku-Oki earthquake

*Naoki Hasumi[1], Kosuke Heki[1]

1. Hokkaido University Graduate School of Science

Since the launch in 2002, the Gravity Recovery And Climate Experiment (GRACE) satellite system has been measuring global gravity field of the Earth. It has produced various scientific results by measuring redistribution of land water storage and snow/ice as time-variable gravity. Fault dislocations associated with earthquakes also redistribute mass and cause subtle changes of gravity. GRACE has also enabled observations of coseismic and postseismic gravity changes of recent megathrust earthquakes, contributing to seismology (Tanaka & Heki, 2017). Preseismic gravity changes have not been considered a target of researches with GRACE. Recently, Panet et al. (2018) reported possible detection of significant change of gravity gradients around Japan a few months before the Mw9.0 2011 Tohoku-Oki earthquake. Their approach differs from conventional studies in several ways. First, they analyzed gravity gradients, which has better spatial resolution than gravity. Second, they searched for signals over wide range of temporal and spatial scales. Third, they concentrated on components with wavelengths of 800-1600 km. We tried to reproduce the results of Panet et al. (2018) by analyzing GRACE level-2 data (Stokes' coefficients) and examining gravity gradient changes a few months before the 2011 Tohoku-Oki earthquake. We could obtain preseismic gravity gradient changes fairly similar to Panet et al. (2018), although we still see certain differences due to unknown reasons. We will also report if we see similar gravity gradient changes before the other two M9 class earthquakes, 2004 Sumatra-Andaman and 2010 Maule earthquakes.

Density structure inferred from gravity and airborne gravity gradiometry data in the northwestern part of Kuju volcano, Oita prefecture

*Jun Nishijima[1], Yasuhiro Fujimitsu[1]

1. Department of Earth Resources Engineering, Graduate School of Engineering, Kyushu University

There are many geothermal fields, hot springs and the geothermal power plants (Otake, Hatchobaru and Takigami) in the northwestern part of Kuju volcano, Oita prefecture. This area is included in the Hohi geothermal area. Many geothermal explorations have been conducted in this area since 1960. The gravity data which is measured by many institute, company and university was recorded in some gravity database. Moreover, an airborne gravity gradiometry (AGG) survey was conducted by the Japan Oil, Gas and Metals National Corporation (JOGMEC) in 2012 and 2017. The underground density structure is estimated by the gravity and AGG data inversion analysis using VOXI Earth modeling on Geosoft Oasis montaj. This result is integrated with the other geological, geophysical and geochemical data on the GIS software. Finally, the conceptual hydrothermal model is estimated by the integrated interpretation using GIS software.The high-density (2400 –2550 kg/m^3) areas were estimated below the middle and late Pleistocene volcanoes in the shouthern part of the study area at a depth of 0 to 2000 m below sea level. These high-density areas correspond to the distributions of the older Hohi volcanic rocks. Moreover, the depression structure was detected in the western side of Mt. Waita. Some hot springs (Yamakawa, Asozuru, Nuruyu and Tsuetate) are located on the edge of this structure.

On the effect of higher-order terms in the gravity sensor of the superconducting gravimeter

*Yuichi Imanishi[1], Kazunari Nawa[2], Yoshiaki Tamura[3], Hiroshi Ikeda[4]

1. Earthquake Research Institute, The University of Tokyo, 2. AIST, 3. NAOJ, 4. University of Tsukuba

The superconducting gravimeter CT #036 operated at the VERA Ishigakijima station, Okinawa, Japan, indicates several kinds of behaviors characteristic to this site. Imanishi et al. (2018), by developing a theoretical model for the static and dynamic properties of the gravity sensor, showed that the effect of the movements of a nearby VLBI antenna on the gravimeter is explained quantitatively by the coupling between the horizontal and vertical components in the gravity sensor. However, it remained unresolved whether the apparent gravity increase associated with enhanced ground noise, as typically seen when typhoons approach the Ishigakijima island, is explained by the same model, because the magnitude of the higher-order terms representing vertical nonlinearity were unknown. Here we will report our result on the measurements of the higher-order terms obtained by injecting artificial signals to CT #036, and discuss its impact on the dynamic properties of the gravity sensor.

Gravity Effect of Local Snow Accumulation obtained from Superconducting Gravimeter and UAV survey at Syowa Station

*Akihisa Hattori[1], Yuichi Aoyama[1,2], Koichiro Doi[1,2], Hajime Oishi[3], Jun Nishijima[4], Hiroshi Ikeda[5]

1. SOKENDAI (The Graduate University of Advanced Studies), 2. National Institute of Polar Research, 3. NEC Networks & System Integration Corporation, 4. Kyushu University, 5. University of Tsukuba

Continuous gravity observation has been conducted with a superconducting gravimeter (SG) at the Japanese Antarctic station, Syowa Station (69°0.2646' S, 39°34.9074' E) since 1993. The first SG, TT70#016, was replaced by the second SG, CT#043, in 2003, then CT#043 was replaced by the third OSG#058 in 2010, and OSG#058 is in operation. It is considered that the gravity observations with SGs, which have a high sensitivity, are detecting the gravitational signal of local snow accumulation in Syowa Station. It is necessary to correct the accumulated snow effect for monitoring the geophysically important but weak signals, such as one associated with Glacial Isostatic Adjustment (GIA).

The distribution of snow depth in Syowa Station was estimated from digital surface models (DSMs) made from unmanned aerial vehicle (UAV) photographic survey by applying structure from motion (SfM) processing methods to the aerial photographs. In the 59th Japanese Antarctic Research Expedition (JARE-59) activity (2017-2019), we conducted aerial photogrammetry by the fixed-wing drone "senseFly eBee Plus," which has dual-frequency GNSS receiver, over Syowa Station in January (austral summer season). Besides, we have conducted aerial photogrammetry by the rotary wing drone "DJI Inspire 2" and "DJI Phantom" in the same area, about every one month from May to November (austral winter season). The DSM and the orthomosaic photo were generated from each set of the geotagged photos using the SfM software "Pix4D."

For improving the accuracy of DSM, we used the geodetic triangulation survey points operated by GSI (Geospatial Information Authority of Japan) as GCP (ground control points) in SfM analysis. We also calibrated the height of DSM by using the ground area uncovered by snow characterized by Brown color as fixed height sites. Thereby, we obtained the time-series of snow depth distributions by calculating height differences among DSMs.

We calculated the attractive changes on OSG#058 estimated from the obtained snow depth distribution. Consequently, it was revealed that the local snow accumulation changes in the Syowa Station caused a seasonal gravity variation of at least 0.1-0.3 μGal (1 μGal = 10^{-8} m/s^2).

In this presentation, we show the details of observed changes in snow distribution, and discuss the comparison between the estimated gravity effect of local snow accumulation and the gravity change observed by OSG#058.

Seasonal variation of gravity values at the Ishioka Geodetic Observing Station

*Akira Tomiyama[1], Tokuro Kodama[1], Shuichi Oomori[1], Yoshifumi Hiraoka[1], Toshihiro Yahagi[1]

1. GSI of Japan

Conventionally consistency between absolute gravimeters has been confirmed through the International Comparison of Absolute Gravimeters (ICAG) which is offered by the Comité International des Poids et Mesures (CIPM) with supports of the International Association of Geodesy (IAG). In order to extent the consistency to inside Japan, the Domestic Comparison of Absolute Gravimeters (DCAG) has been conducted by the Geospatial Information Authority of Japan (GSI) since 2002. Thanks to the opening of a new facility of GSI, named the Ishioka Geodetic Observing Station, the DCAG has been held there with inviting several domestic organizations which own absolute gravimeters. In order to evaluate validity of obtained data, it is necessary to collect data inside the Ishioka station and to examine influences of external factors. Therefore, we carried out periodic measurements using one of our FG5 absolute gravimeters for about one week every month throughout one year at the fundamental gravity point, “Ishioka FGS”, which is installed inside the Ishioka station. In this presentation, we will report the seasonal variation of gravity values obtained from our verification work.

Installation of the First Gravity Station in the Mount Fuji Research Institute, and the Phase-Free gravity measurement

*Ryo Honda[1], Yuichi Imanishi[2], Kazunari Nawa[3], Toshiyuki Tanaka[4], Tokuro Kodama[5], Akira Tomiyama[5]

1. MFRI, Yamanashi Prefectural Government, 2. ERI, University of Tokyo, 3. GSJ, AIST, 4. TRIES, ADEP, 5. GSI

Mount Fuji is an active volcano, the difficult situation is that we can’ t tell where the vent will open. Moreover, the eruption is thought to occur rapidly after the precursors such as grand deformations or increase of the seismic activities, because of its low viscosity magma. As a part of the volcano monitoring system, we are now constructing the gravity monitoring network. We are planning to install multiple continuous gravity monitoring stations. We installed the First Gravity Station in Mount Fuji Research Institute (MFRI) last year, where the absolute gravity value is measured by GSI. We are going to start the continuous observation in this station. Although low frequency events or tremors are observed sporadically, Mount Fuji is quiet at this point of time. So, the purpose of our observation at the beginning is to comprehend the precipitation and ground water effect, including snow melting effect in the spring time.

There is another interesting point for the gravity observation in Mount Fuji. The gravity difference between MFRI and the fifth station of the Yoshida trail is about 320 mGal, and the travel time between two points is about 30 minutes. It means that this is a good observation line for the verification of the gravimeters. Now we suggest the "phase-free" gravity measurement (https://phasefree.org/). The idea of "phase-free" is to eliminate the social phases (time, state) of normal times and disasters, so that goods or services normally used can be appropriately used at the time of disaster. If we continuously use the gravity observation line for the verification by various gravimeters in the normal time, that will be the important data for the volcano monitoring when the Mount Fuji is starting to prepare the eruption.

Absolute gravity and GNSS measurements on bedrock outcrops in Dronning Maud Land, East Antarctica

*Takahito Kazama[1], Yuichi Aoyama[2], Yoichi Fukuda[1], Koichiro Doi[2]

1. Graduate School of Science, Kyoto University, 2. National Institute of Polar Research

The Antarctic ice sheet plays a significant role in the long-term global climate change, so the spatiotemporal variations in the Antarctic ice sheet should be precisely monitored to forecast future climate changes. The ice sheet variations can be detected as loading deformations of the solid Earth, which are composed of the elastic deformation due to the present-day ice melting and the viscoelastic deformation due to the past ice melting. These effects can be separated by measuring both of the crustal deformation and land gravity variation, but enough gravity data has not been collected in the Antarctic region as of now. In order to understand more about the ice sheet variations in terms of solid-earth geophysics, land gravity data should be repeatedly measured at more sites in the Antarctic region.
We therefore collected new absolute gravity data using the FG5-210 absolute gravimeter at two stations located on bedrock outcrops in Dronning Maud Land, East Antarctica in November-December 2018. We first stayed at the Norwegian station, Troll (72.01S, 2.53E) from November 13 to 26, and installed the gravimeter on the benchmark (Troll AA) of the gravity hut. We needed to take more time to vacuum the dropping chamber of the gravimeter during the installation, because vacuuming pumps did not work normally, mainly associated with the cold weather in Troll Station. We started to measure absolute gravity values on November 18, and obtained the average gravity value of 982,360,741.41 +/- 1.16 +/- 1.82 microGal from the 178 sets of the gravity data collected for 5 days. We also stayed at the Indian station, Maitri (70.77S, 11.73E) from November 26 to December 4, and started to measure gravity values on the benchmark (Maitri AB) of the gravity hut on November 28. We obtained the 112 sets of the gravity data for 4 days, and determined the average gravity value of 982,576,883.10 +/- 1.23 +/- 1.83 microGal.
Our absolute gravity values collected in November-December 2018 was found to be smaller than those obtained in January-February 2012 (Dr. Jaakko Mäkinen, personal communication) by -4.4 and -4.2 microGal at Troll and Maitri stations, respectively. The gravity decrease may be caused by ground subsidence and/or ice mass decrease around the stations. The cause of the gravity decrease will be investigated in detail by analyzing the GNSS data which was collected simultaneously with the absolute gravity data at two stations.

Capability of ICA Method for separating GIA and Ice Mass Signals in Antarctica

*SHI TIANYAN[1], Yoichi Fukuda[1]

1. Graduate School of Science, Kyoto University

The Gravity Recovery and Climate Experiment (GRACE) mission provided global gravity change data with a spatial resolution of a few hundred kilometers and a temporal resolution of 30 days. The GRACE data revealed the total mass changes in Antarctica and contributed to Antarctic Ice Sheet (AIS) mass balance researches. However, there are large uncertainties in Glacial Isostatic Adjustment (GIA) effects, which should be removed from the GRACE data, for estimating the AIS mass balance. While many studies have been conducted for estimating or removing the GIA effects thus far, we try to use a statistical analysis method called Independent Component Analysis (ICA) and investigated its capability of separating GIA and AIS mass signals.

We primarily employed GRACE RL05 mascon data provided by NASA Jet Propulsion Laboratory (JPL) of all the GRACE available period from January 2002 to June 2017 with the spatial coverage of all Antarctica. And we used three ICA methods, namely, spatial ICA (sICA), temporal ICA (tICA), and spatio-temporal ICA (stICA), for testing the characteristics and/or the capabilities of the methods.

The results showed that the GIA like signal can be recovered successfully with sICA which separated GIA signals and AIS mass change signals into two statistical independent components. On the other hand, tICA decomposed the GIA signal into two independent components. This suggested that tICA could not solve the signals mixing problem completely. Nevertheless, tICA detected an extra anomaly snow-fall signal around 2010. This shows that tICA may have the potential to separate long-term trend signals with different time scales. The results of stICA suggested that its characteristics could be seen as a combination of the above two methods. Thus, an appropriate combination of the methods should be examined.

We also tested other datasets and revealed the different datasets and/or pre-processing of the datasets largely affected the obtained results. It is impossible to assess the validity of the results only using the GRACE data. Therefore, additional information should be necessary to validate and interpret the results.

Preliminary result of continuous observation with an iGrav superconducting gravimeter at the Teshikaga observatory, eastern Hokkaido, Japan

*Kazunari Nawa[1], Hiroaki Takahashi[2], Mako Ohzono[2], Kazumi Okada[2], Teruhiro Yamaguchi[2], Daisuke Oka[3], Noritoshi Okazaki[3], Ryo Honda[4], Hiroshi Ikeda[5]

1. National Institute of Advanced Industrial Science and Technology, 2. Hokkaido University, 3. Geological Survey of Hokkaido, 4. Mount Fuji Research Institute, 5. University of Tsukuba

In November, 2018, continuous observation with the iGrav type superconducting gravimeter (# 017) was started at the Teshikaga Observatory of the Hokkaido University in order to carry out high spatiotemporal resolution gravity monitoring in the caldera / volcanic area in eastern Hokkaido. The gravity meter used in CCS project of Tomakomai site was temporarily relocated to the Minami-shinkawa Observatory in September of the same year and then moved to the Teshikaga Observatory from Minami-shinkawa at the timing before entering the snowy season . We report what kind of record is obtained by the superconducting gravimeter at each observatory in wide frequency band from the seismic to the geodetic band. The observation data will be registered in the Crustal Deformation Database of Hokkaido University for the purpose of archive, distribution and comparative analysis with other principle data.

On the anomalous temporal gravity change between VERA and F-net stations at Ishigakijima, Japan

*Kazunari Nawa[1], Yuichi Imanishi[2], Yoshiaki Tamura[3], Hiroshi Ikeda[4], Takeshi Kimura[5]

1. National Institute of Advanced Industrial Science and Technology, 2. Earthquake Research Institute, The University of Tokyo, 3. National Astronomical Observatory of Japan, 4. University of Tsukuba, 5. National Research Institute for Earth Science and Disaster Resilience

Continuous gravity and hydrological observations at Ishigakijima revealed that the gravity difference between the F-net station (gPhone) and the VERA station (superconducting gravimeter) is closely related with the change in the soil water content near the F-net station. It was also noted, however, that the gravity difference did not indicate significant changes on some occasions of heavy rainfall. In addition, our precipitation response model did not predict the observed gravity change well for a particular period expanding a few tens of days. Here we reexamine our data of precipitation, soil moisture, and underground water level as well as gravity, to refine our model of the hydrological effects on gravity at Ishigakijima.

Discussion

Absolute gravity signals at the Sakurajima volcano since 2009 through 2018

*Shuhei Okubo[1], Keigo Yamamoto[2], Masato Iguchi[2], Yoshiyuki Tanaka[3], Yuichi Imanishi[1], Ryuichi Nishiyama[1], Miwako Ando[1], Atsushi Watanabe[1]

1. Earthquake Research Institute, The University of Tokyo, 2. Disaster Prevention Research Institute, Kyoto University, 3. Graduate School of Science, The University of Tokyo

In this paper, we present gravity signals based on continuous absolute gravity measurements since 2009 through 2018. During this period, several hundreds to a thousand eruptions/explosions were observed every year during 2009 through 2015 (phase 1). Significant seismicity and crustal deformations were observed on Aug. 15, 2015 (phase 2), followed by unusual quiescence since August 2015 (phase 3). Gravity signal after eliminating groundwater disturbance showed remarkable features according to the phase of volcanic activity as described below. During the phase 1 characterized by frequent vulcanian eruptions from the Showa crater, gravity fluctuated about a mean with rather small amplitude of 10 microgals, suggesting dynamic equilibrium is achieved at the magma chamber; magma supply from deeper interior is balanced with mass loss through eruptions. The phase 2 is interpreted as a dyke intrusion event, which causes elastic deformation and short-term gravity change almost simultaneously. In the current phase 3 (2016-2018), gravity shows monotonous increase of 10 microgal/yr, suggesting deflation of magma.

Seismic waves radiating from an earthquake rupture induce density perturbations of the medium, which in turn generate widespread transient gravity perturbations before the arrival of P-waves. Recently, signal detections of such prompt gravity perturbations from the 2011 Tohoku-Oki earthquake were reported. However, the data used for the detections were only a small subset of the available data, and the statistical significance of the signals were not sufficient nor discussed. In this study, we optimized multi-channel data recorded by several instruments and searched for the signals from the 2011 event. Though the single-trace records did not show any signal, the stacked trace of the broadband seismometer array data in Japan showed a signal clearly standing above the noise level, and this detection was confirmed with a sufficient statistical significance. This result provides the first constraint on the amplitude of prompt gravity signals by observation and will work as a reference for future detections.

Evaluation of atmospheric attraction effect using local-scale objective analysis (LANAL)

*Toshiyuki Tanaka[1]

1. Tono Research Institute of Earthquake Science, Association for the Development of Earthquake Prediction

Tono Research Institute of Earthquake Science (TRIES) has been conducting continuous gravity observations both above the ground and below the ground of Mizunami Underground Research Institute in order to monitor the underground mass fluctuation including groundwater (Tanaka and Honda, 2018, doi: 10.1002 / 2017EA000311). The mass fluctuation between these two gravimeters can be evaluated from the difference between the two gravimeter values. Also, the sum of the two gravimeter values reflects the gravitational effects both from above the ground gravimeter position and from the below the underground gravimeter position. In order to extract the gravity fluctuation related to earthquake phenomena, that is, the gravitational effect only from below the subsurface gravimeter position, it is necessary to correct the atmospheric attraction effects above the ground gravimeter. Here, for the sake of simplicity, it is assumed that the atmospheric loading deformation effects and the existence of high altitude near the observation point are negligible. TRIES has been used the meso-scale objective analysis (MANAL) to calculate the atmospheric attraction effect in the range of 10 ˚×10 ˚×100 hPa–surf (approximately, 900 km in latitudinal direction ×1100 km in longitudinal direction ×16 km in altitudinal direction) centered on a gravity observation point before now. This attraction effect accounts for approximately 60% of the time-variating amplitude of the global summation. Local-scale objective analysis (LANAL) began publishing since 2018. The lattice spacing was 5 km, the same as MANAL, but LANAL increased the number of isobaric surfaces by 1 (975 hPa surface) from MANAL. This increase improved the spatial resolution of the altitude close to the observation point. Moreover, the time resolution improved as time interval changed from three hours of MANAL to one hour. Therefore, the updating from MANAL to LANAL to calculate the atmospheric attraction effect have to been evaluated quantitatively. Like other objective analysis data, LANAL is also offered in GRIB 2 format. We accessed LANAL using the GrADS software (http://cola.gmu.edu/grads/), but as it was seen in MANAL, it was not possible to display correctly with the control file generated by the g2clt or alt_g2ctl commands. In the PDEF line of the control file, you need to change the jref variable set to 1 to the value of the jsize variable. Also, from the necessity both of atmospheric density calculation on the topographic surface and comparison between isobaric surfaces and a topographic altitude, we use the enclosed terrain data (4-byte real binary). This feature is also the same specification as MANAL, and the GrADS draws the North-South direction reversed figure. In order to correct this problem, the data stored with the northwest end as the starting point was restored as the start point at the southwest end (byte swapping is necessary depending on the processing system). After that, the atmospheric attraction effect was calculated according to the procedure developed for MANAL. At the time of this writing, it was an evaluation for only one month in March 2018. The standard deviation of the difference of simultaneous numerical values between MANAL and LANAL was 0.66 microGal, and the maximum difference of instantaneous values was 2.4 microGal. It turned out that there was a significant difference. In the future, we would like to evaluate the difference from using MANAL by applying to gravity observation data.

Airborne gravity survey for establishment of a new precise gravimetric geoid model

*Tokuro Kodama[1], Akira Tomiyama[1], Shuichi Oomori[1], Erika Wada[1], Toshihiro Yahagi[1], Yoshifumi Hiraoka[1], Hiroshi Kawawa[1]

1. GSI of Japan

The vertical datum of Japan has been maintained by the Geospatial Information Authority of Japan (GSI) since more than 130 years ago. Basically it has been realized by conducting periodical leveling surveys in order to determine orthometric height of benchmarks, which are installed at approximately 2 km intervals along main national highways, based on the mean sea level of the Tokyo Bay. However, since this method takes much time and costs a lot, it is quite difficult to reflect vertical land movements quickly caused by such as plate motions and big earthquakes.

In order to tackle this situation, the GSI established a geoid model, called GSIGEO2011+2000, in April 2013 and also implemented a new manual for utilizing the model for public surveys in order to obtain orthometric height from GNSS data. It in fact played a certain role in improving the efficiency of surveying. Geoid models released by the GSI so far are all hybrid, which are constructed of a gravimetric geoid model and geoid heights directly measured by GNSS/leveling surveys, in order to compensate the lack of precision of the gravimetric geoid model. However, since the GNSS/leveling data are based on results of the leveling surveys, they are unavailable once crustal deformation occurs until the leveling surveys are conducted again. In order to improve the precision of the gravimetric geoid model, it is necessary to prepare high quality gravity data all over Japan. But current gravity data contain some problems such as blank areas in both mountainous areas and coastal waters , age of data and inaccuracy of location information decided by topographic map.

In order to solve these problems and make it possible to measure precise orthometric height more quickly, the GSI has been carrying out a new airborne gravity survey project since FY2018. First, we will collect high quality nationwide gravity data using aircraft, then calculate a new precise gravimetric geoid model combined the airborne gravity data with other ones such as terrestrial, marine and satellite gravity data. We are planning to introduce a new height system based on this new geoid model and ellipsoidal heights obtained from GEONET by 2014. Since the geoid model is basically very stable against the crustal deformation, it is expected to update the orthometric height immediately by GNSS data even if crustal deformation occurs.

In this presentation, we will review our future vision of the new height system and report the progress of GSI’ s airborne gravity survey project.

[S-GD02] Engineering Application of Space Geodesy

convener:Seiichi Shimada(Graduate School of Frontier Sciences, University of Tokyo Nippo Co. Ltd.), Shuichi Rokugawa(The University of Tokyo), Basara Miyahara(GSI of Japan), Toshiaki Tsujii(Department of Aerospace Engineering, Osaka Prefecture University), Chairperson:Masaatsu Aichi, Kazuki Sakai

In the space geodetic community in Japan, geoscience and other scientific researches, such as seismology, volcanology and meteorology, are predominant. However, engineering application researches are also actively conducted in academic societies abroad. Recent advances in GNSS and InSAR measurement techniques are progressing towards widely engineering usage of space geodetic measurements even in domestic Japan. In addition, the Geospatial Information Authority of Japan (GSI) is about to shift from conventional leveling survey to space geodetic surveying such as GNSS levelling, and the space geodetic method could spread rapidly even in many engineering fields using conventional leveling survey. In this session, we introduce advanced engineering research using space geodetic measurements such as ground measurement / self-driving in particular to young earth scientists. We will also welcome a wide range of general presentations on measurements/research in engineering fields using space geodetic technology.

*Toshihiro Yahagi[1], Kensuke Kokado[1], Kenji Yoshida[1], Takashi Toyofuku[1], Masao Iwata[1], Basara Miyahara[1]

1. GSI of Japan

Global Navigation Satellite System (GNSS) are conventionally used for determining reference positions in Japan by static survey activities following a uniform standard based on the survey low. In recent years, thanks to improvement of satellite positioning techniques, the utilization of GNSS positioning has been expanded to various real-time positioning services such as autonomous driving system, intelligent construction, smart agriculture and drone delivery. This trend would accelerate in the future due to new services like Centimeter Level Augmentation Service (CLAS) offered by Quasi-Zenith Satellite System (QZSS) or Precise Point Positioning (PPP) provided by private companies. Basically those kind of real-time positioning data give us ‘current’ location though most geospatial information, represented by maps, are built based on the certain ‘past’ epoch. The difference between them becomes larger year by year because of active crustal deformation in Japan. The more precise the real-time position are decided, the more careful we should treat this difference.

Therefore GSI has been developing a new system for correcting this difference in order to fully utilize the real-time positioning data by keeping consistency between existed geospatial information. The prototype of the system was offered to public from January to March in 2019 to collect feedbacks from stakeholders. We plan to launch this system officially until 2020.

It is also important to obtain precise elevation for three dimensional positioning. Historically the height system in Japan has been maintained by conducting nationwide split leveling surveys for more than 130 years. However, since it needs a lot of time and cost, it is necessary to prepare a precise geoid model for determining an orthometric height directly from an ellipsoidal height obtained by GNSS data. Hence GSI launched a new airborne gravity survey project in 2018 to collect high quality gravity data all over Japan, which is necessary to construct a new precise gravimetric geoid model within several centimeters precision. It is expected to introduce a new height system based on the new geoid model and GNSS data up to 2014. It will enable users to determine reasonable elevation data by GNSS without leveling surveys.

Through these efforts, GSI will contribute to realize the future society which fully utilize precise three dimensional position data for various geospatial information services. In this presentation, we will review the current actions of GSI and share a future vision derived from them.

Preliminary study on the application of satelite-based monitoring for land surface displacement to inverse analyses of groundater flow/land subsidence modeling

*Masaatsu Aichi[1]

1. Graduate School of Frontier Sciences, The University of Tokyo

Incerasing land subsidence monitoring data with InSAR and GNSS techniques are expected to improve a calibration process of groundwater flow/land subsidence model. However, the observed data possibly includes the displacement caused not only by known groundwater abstraction but also natural displacements such as seismic/post-seismic crustal motion. Then, it is not straight forward to use the observed data for inverse analysis. It is important to separate known and unknown components from monitoring data with a simultaneous
calibration of land subsidence model.
This study presents a new method based on the prior assumption that the crustal deformation is smooth in space relative to land subsidence cone caused by groundwater abstraction. It consists of the iteration of the following three steps. In the first step, the map of difference between the observed data and the calculated result of the land subsidence model with assumed parameters. In the next step, the spatial roughness of difference map is evaluated from the rotational energy. In the final step, the model parameters are modified to minimize the spatial roughness of unknown components.
This method was tested by a synthetic data composed of land subsidence from the assumed groundwater abstraction, the assumed sudden and long-term displacement like earthquake and post seismic motion. The proposed method successfully separated the land subsidence caused by groundwater abstraction and other components, and exactly found the model parameters. The results suggest that the porposed method has the possibility to enhance the application of satellite-based land subsidence monitoring data to the calibration of land subsidence models.

Monitoring of ground deformation all over Japan by InSAR and utilizing 2.5-D analysis

*Kazuki Sakai[1], Kyonosuke Hayahsi[1], Masaki Kuwahara[1], Tatsuya Yamashita[1], Masaki Honda[1], Hiroshi Munekane[1]

1. GSI of Japan

GSI (Geospatial Information Authority of Japan) has been conducting SAR interferometry (InSAR) analysis with ALOS-2 data to monitor ground deformation all over JAPAN. In addition, we have conducted InSAR urgent analyses once natural disasters such as volcanic crisis or large earthquakes occur. We provide InSAR-derived deformation data to the Earthquake Research Committee, the Coordinating Committee for Prediction of Volcanic Eruptions and others. Furthermore, we publish those data on GSI website for general users.

InSAR analysis with a pair of observation data can reveal only line-of-sight (LOS) deformation. However, quasi-up-down and quasi-east-west component deformation may be calculated by combining LOS deformations observed from both east and west direction. This analysis method is called 2.5-D analysis (Fujiwara et al., 2000). “Quasi” means that the directions of obtained deformation by 2.5-D analysis are slightly different from up-down and east-west.

LOS deformation from InSAR analysis is usually represented in rainbow color, and is difficult to understand intuitively. Furthermore, deformation direction can’t be identified from such InSAR image. On the other hand, 2.5-D analysis image is easier to understand and deformation direction can be identified. GSI has been considering a way to make InSAR image more understandable to general public, and 2.5-D analysis is one of the candidates. The 2018 Hokkaido Eastern Iburi Earthquake is an example of utilizing 2.5-D analysis. The quasi-up-down component deformation was utilized in setting a recovery survey area.

In this presentation, we will introduce ground deformations detected by InSAR analysis and some examples of 2.5-D analysis derived from earthquakes and volcanic activities.

*Acknowledgment

ALOS-2 data were provided based on the joint research agreement with JAXA (Japan Aerospace Exploration Agency). The ownership of ALOS-2 data belongs to JAXA.

Resource Exploration using Interferometric Synthetic Aperture Radar Measurement Technology

*Shuichi Rokugawa[1], Takako Nakamura[1]

1. The University of Tokyo

InSAR using synthetic aperture radar (SAR) is a technology that enables the detection of the earth surface deformation without any observation points on the ground. The L-band SAR mounted on ALOS / PALSAR-2 is effective even in the vegetated areas because of relatively long wavelength of the sensor. InSAR has the potential to be used in the various technical applications. This technique has been primarily used to analyze fluctuations due to natural disasters and large-scale deformations such as crustal movement caused by earthquakes and volcanic eruptions. However, the extraction of the small deformation is also possible by continuously monitoring the ground deformation. Compared with the leveling and global navigation satellite system, InSAR provides the advantage of wide range observation capability. However, accumulating a certain amount of data is required for this kind of analysis. In this study, the second largest oil filed in Kuwait and East Kanto gas field in the Chiba prefecture, were analyzed as case study fields. InSAR data from 2004 to 2010 are applied to derive the surface deformation. The results of the detailed analysis confirmed remarkable ground deformation mainly at four locations in Kuwait. It was confirmed that each of these four points coincided with the positions of the Burgan, Minagishu, Umm Gudair and the Wafra oil fields, respectively. Therefore, it was discovered that InSAR can accurately grasp the ground deformation near the oil production wells. Moreover, these results reveal that there was a linear correlation between the influence range of the oil and the production amount of the oil field. A high correlation was also observed between the subsidence amount of the oil field and the actual production amount. Therefore, it is established that the InSAR analysis results can be applicable in production management, as well. Similarly, in Chiba prefecture, the InSAR time series analysis was conducted to grasp the spatial distribution of the ground change in time series. It also demonstrate the possibility of the tools for monitoring and management of the actual oil/gas fields.

The application example of GNSS for natural gas development together with PDCA Management Method

*Yoshiyuki Muramoto[1], Susumu Hayatsu[1], Michiharu Hiyama[1], Daisuke Murai[1], Shoji Kunisue[1]

1. KANTO NATURAL GAS DEVELOPMENT CO., LTD

[Background]
We have been developing the Southern Kanto gas field for many years. This field which contains natural gas dissolved in water is located primarily under Chiba prefecture, and it extends across a wide area of the Kanto region, including Ibaraki, Saitama and Kanagawa prefectures as well as Tokyo Metropolis. This field's recoverable reserves are estimated 368.5 billion cubic meters, making it the largest field of gas dissolved in water in Japan. The gas is dissolved in formation water which is called brine, so it is produced together with brine. Commercial production of natural gas has been conducted in Chiba prefecture since 1931 and has contributed to the growth in the region. Formerly, it was mainly used for industrial gas, but now most common usage is for city gas. On the other hand, land subsidence has been confirmed in Kujukuri area, east of Chiba prefecture. Brine production is considered as one of possible causes of it. Companies producing natural gas in this area including our company have made a land subsidence prevention agreement with the Chiba prefectural government to prevent and control land subsidence. Also, from the technical point of view, we conduct joint study on environmental issues with other gas production companies as a member of "Environmental Technology Research Association for Natural Gas Dissolved in Water".

[Observation of land subsidence]
The Chiba prefectural government has conducted leveling every year. We also have conducted it, but it takes a lot of time to get the survey result because we have to revise the observation data based on the leveling result conducted by local government. On the other hand, GNSS observation which is one of the surface level observation techniques has been prevailed recently. The advantage of GNSS is that continuous observation is possible at the place where it is installed. In Japan, the Geographical Survey Institute has established GEONET (GNSS Earth Observation Network System) throughout the country. We installed GNSS stations in our operating area and analyze these data together with GEONET's since 2013 to get circumstance of land subsidence quickly.

[Application example of GNSS for natural gas production]
We installed GNSS station to monitor the land subsidence in a certain area where natural gas is newly developed. The reason for that is because we need to adjust the brine production rate based on land subsidence. We use GNSS data in "PDCA Management for Land Subsidence Control", one method for controlling land subsidence systematically. This method consists of four elements. "P", Plan, means making of production plan based on the simulation result. "D", Do, means production of natural gas based on the production plan. "C", Check, means observation and evaluation of land subsidence by GNSS and leveling. "A", Act, means update of simulation model. By repeating this method every year, we will improve the way of subsidence management.
In the presentation, we will introduce the application example of GNSS for natural gas development together with PDCA Management Method.

New threats and countermeasures in the aviation field where the use of GNSS satellite navigation expands

*Takeshi Fujiwara[1], Toshiaki Tsujii[2]

1. Japan Aerospace Exploration Agency, 2. Osaka Prefecture University

To contribute to the realization of the next-generation air transportation system, JAXA is promoting the research and development project named DREAMS (Distributed and Revolutionary Efficient Air-safety Management System). Research and development of high precision and reliable navigation system is one of the most important targets of this project. In this paper, the impact of the plasma bubble, a kind of ionospheric anomalies, on the availability of GBAS precision approach is investigated based on the collected data under the actual plasma bubbles and the mathematical models of the plasma bubbles are introduced to be used in the Monte-Carlo simulations to estimate the availability.

1. Introduction

We have obtained the RINEX data of the electronic reference points of the Geospatial Information Authority of Japan every day from 2008, and automatically process it using GAMIT/GLOBK software and accumulate the coordinate data of day value and week value (Shimada et al., 2014; 2015). We used ITRF 2005 from April 2008 to October 2011, ITRF 2008 from October 2011 to May 2017, and ITRF 2014 from May 2017 onwards so that the reference coordinate system of that analysis conforms to the latest coordinate system as much as possible. In the processing, observation data of 30 IGS points around Japan is used as reference points for constraining to the ITRF coordinate system, and it is solved together with electronic reference point data in Japan. In addition, we processed using Bernese Ver. 5.2 under the same conditions, and checked whether or not there is no difference in the results depending on processing software.

2. Application to dynamic map (4 dimensional map) management for engineering use

By using the above data, as the Japanese Information System of Land Deformation (JISLaD), changes in the position of the electronic reference point and the baseline length have already been disclosed. We also plan to announce the results of monitoring the fluctuation of area distortion etc.
Furthermore, we plan to calculate the fluctuation speed of an arbitrary point from the fluctuation at the GEONET point. Specifically, we are considering application to dynamic map management which is a 4-dimensional map.

As one of the items of the Cross-ministerial Strategic Innovation Promotion Program (SIP), an automatic driving system is mentioned in both the first and second phases. Automatic traveling system is a system to combine various technologies, but high-precision digital map is an important item among them. For self-location estimation for automatic driving, it is important to recognize self-position using satellite positioning information etc. However, if there is no map corresponding to it, it is meaningless only by self-position recognition.

Needless to say, the crustal deformation in Japan is intense. Therefore, once you have made a precise digital map you cannot use the map forever.

The idea of crustal deformation in Japan's map is based on semi-dynamic system. In other words, the idea is to decide the initial stage and to take the correspondence with the map by returning the latest position coordinates measured at the present time to the value of the coordinates of the original period, based on the observation of the crustal deformation.

Although this system is suitable for use such as the registration of land, it is not suitable for the automatic traveling system which corresponds the position and the map of the car every moment in the Japanese

islands where the crustal deformation is intense. Therefore, we consider the dynamic map which makes the coordinates of the map itself new every day considering the change accompanying the crustal deformation, considering application of JISLaD data to dynamic map management. In the Tohoku region, the postseismic movements exceed 10 cm per year continues still after the 2011 Tohoku Earthquake. We believe that an accuracy of about 10 cm is necessary as a basic map used for automatic driving, which means that even if crustal deformation due to a new earthquake does not occur, update the map at least once a year is necessary in the Tohoku region.

This way of thinking is not limited to cars with both roads and autonomous driving, it is important for all engineering applications where acquisition of precise coordinates is considered to be effective, especially for aircraft using electronic navigation and airport. It is a very important thing for checking the positional relationship etc.

Utilization of Interferometric Synthetic Aperture Radar Time Series Analysis Technology for Disaster Prevention

*Takako Nakamura[1], Shuichi Rokugawa[1]

1. The University of Tokyo

In this research, we investigate the possibility of extraction and monitoring of the ground changes before and after disasters such as landslides using interference synthetic aperture radar (InSAR) time series analysis. An analysis was conducted using the satellite image data obtained before and after the occurrence of the disaster from the location with a past disaster occurrence. The obtained results may be effective in predicting to some extent the occurrence timing of the sediment-related disasters in hazardous areas caused due to frequent earthquakes, volcanic eruptions, and local heavy rains in recent years. Several regions affected due to these sediment-related disasters were considered and a ground deformation analysis was performed on a model area using the InSAR analysis technology.
The Miyazaki prefecture Mimikawa upper basin, southwestern part of the Hiroshima prefecture, Kyushu Northwest and a few other regions were considered for analysis. These are the areas with landslide risks and past occurrences of sediment-related disasters. The image data of a HH polarized wave with an incident angle of 34.3˚ acquired during the satellite operation period was retrieved from the archive data of ALOS/PALSAR and used for the analysis.
Interference SAR time series analysis enables the detection of minute fluctuations using smoothing restraint inversion method for integrally analyzing the interference images of multiple orbits. We also performed a 2.5 dimensional analysis using two orbits of descending and ascending nodes. During the analysis, strong displacements were observed not only in the collapse track, but also at other points in the upper stream of the Mimi River. Those points that demonstrated a high possibility of collapse were then extracted. Such a phenomenon was also observed in some instances of other analyses. From the 2.5 dimensional analysis of the area around the affected area in the southwestern part of Hiroshima Prefecture, actual sediment-related disasters were extracted, almost pinpoint, from the variation diagram of the eastern component. In the area, the faults in the northeast and the southwest directions were dominant and the continuous slope of the mountain extended in the same directions. The characteristic topography of these areas possibly affected the direction of the ground surface fluctuation. In the northwestern part of Kyushu, several points with earlier occurrences of landslides were detected in addition to the actual landslide site by employing the median filter plus histogram extraction processing and Laplacian filter processing together. As a result, it was determined that various measures were necessary for the interference SAR time series analysis to extract the fine ground fluctuation immediately before the disaster, as these fluctuations are unlike the relatively large fluctuations that occur during the disaster.
To actually implement monitoring using the InSAR analysis, it is important to sufficiently consider the geology of the target area and its topographical features and accumulate and maintain the base information on the target area in times of peace. In case of emergencies, the latest observation data can be obtained immediately by retrieving from the archives to perform the required analysis.

The annual and secular movements of vertical component in GEONET sites caused by groundwater usages

*Seiichi Shimada[1], Masaatsu Aichi[1]

1. Graduate School of Frontier Sciences, University of Tokyo

Annual and secular movements are observed in vertical components of many GEONET sites caused by the groundwater usage. Observation of vertical movements associated with groundwater drawing is an indispensable observation element for establishing groundwater circulation model, as well as observations of groundwater level and meteorological factors. The Geospatial Information Authority of Japan plans to switch the monitoring method of vertical movements from conventional leveling survey to the space geodetic techniques such as GNSS measurements, and in the near future vertical movement monitoring by GNSS observations is likely to become an observation tool indispensable for groundwater usage and management through groundwater circulation model. In order to observe ground subsidence, one of the largest obstacles in the groundwater usage, installation of antenna pillar for GNSS observations will become indispensable near the water well that pumps a large amount of groundwater, in the near future.

In this presentation, we show examples of annual and long-term secular variations associated with groundwater usage, which we find by the analyses of GEONET sites in the Kanto region and Niigata prefecture. In the analysis, we determine at first the daily coordinates of the GEONET sites with 23 fiducial sites of IGS network in East Asia and the surrounding area. We apply the ITRF 2014 coordinates and the VMF1 mapping function as well as 10° cutoff elevation angle. We estimate every hourly zenith delay and every four-hourly atmospheric gradient simultaneously with the site coordinates and ambiguities. Then we apply the 30-day window Kalman filter to eliminate the short cycle fluctuation and clarify the annual/semi-annual and secular vertical movements from long-term observation data.

In the GEONET sites in the Kanto region, vertical movements due to agricultural usage of ground water are detected in the central to northern part of the Kanto plain, centering on Saitama prefecture. For example, at the Tsukuba1 site (92110 site) in the campus of the Geospatial Information Authority of Japan, annual variations that subside in summer are observed caused by the groundwater usage of the rise field around the site, that are harmonious with VLBI and groundwater level observations (Tobita et al., 2004; Munekane et al., 2010; Shimada et al., 2017).

In the Kujukuri area, a large amount of subsiding is observed caused by the groundwater mining for refining natural gas. At the Oami-Shirasato site (93027 point) and the Chosei site (93033 site) in this area, in addition to the annual variation subsiding in the winter, the long-term ground subsidence are detected harmonizing with the level survey and the InSAR observations (Harada, 2018; Shimada et al., 2018).

In Niigata prefecture including the Niigata plain, groundwater usage for snow melting is widespread, and vertical subsidence is observed caused by the groundwater usage. For example, at the Niigata Sakae site (970810 site) in Sanjo city, as well as the annual variation that settling in winter, progress of inelastic secular subsidence is seen especially in the years when the amount of snow fall is large and the amount of ground subsidence also large (Shimada, 2018).

[S-GD02] Engineering Application of Space Geodesy

convener:Seiichi Shimada(Graduate School of Frontier Sciences, University of Tokyo Nippo Co. Ltd.), Shuichi Rokugawa(The University of Tokyo), Basara Miyahara(GSI of Japan), Toshiaki Tsujii(Department of Aerospace Engineering, Osaka Prefecture University)

In the space geodetic community in Japan, geoscience and other scientific researches, such as seismology, volcanology and meteorology, are predominant. However, engineering application researches are also actively conducted in academic societies abroad. Recent advances in GNSS and InSAR measurement techniques are progressing towards widely engineering usage of space geodetic measurements even in domestic Japan. In addition, the Geospatial Information Authority of Japan (GSI) is about to shift from conventional leveling survey to space geodetic surveying such as GNSS levelling, and the space geodetic method could spread rapidly even in many engineering fields using conventional leveling survey. In this session, we introduce advanced engineering research using space geodetic measurements such as ground measurement / self-driving in particular to young earth scientists. We will also welcome a wide range of general presentations on measurements/research in engineering fields using space geodetic technology.

1. Introduction

We have obtained the RINEX data of the electronic reference points of the Geospatial Information Authority of Japan every day from 2008, and automatically process it using GAMIT/GLOBK software and accumulate the coordinate data of day value and week value (Shimada et al., 2014; 2015). We used ITRF 2005 from April 2008 to October 2011, ITRF 2008 from October 2011 to May 2017, and ITRF 2014 from May 2017 onwards so that the reference coordinate system of that analysis conforms to the latest coordinate system as much as possible. In the processing, observation data of 30 IGS points around Japan is used as reference points for constraining to the ITRF coordinate system, and it is solved together with electronic reference point data in Japan. In addition, we processed using Bernese Ver. 5.2 under the same conditions, and checked whether or not there is no difference in the results depending on processing software.

2. Application to dynamic map (4 dimensional map) management for engineering use

By using the above data, as the Japanese Information System of Land Deformation (JISLaD), changes in the position of the electronic reference point and the baseline length have already been disclosed. We also plan to announce the results of monitoring the fluctuation of area distortion etc.
Furthermore, we plan to calculate the fluctuation speed of an arbitrary point from the fluctuation at the GEONET point. Specifically, we are considering application to dynamic map management which is a 4-dimensional map.

[S-SS06] Nankai Trough Seismogenic Zone Experiment: Logging and sampling the seismogenic megathrust

convener:Kyuichi Kanagawa(Graduate School of Science, Chiba University), Demian M Saffer(Pennsylvania State University), Masataka Kinoshita(Earthquake Research Institute, University of Tokyo), Chairperson:Kyuichi Kanagawa(Graduate School of Science, Chiba University), Demian Saffer(Department of Geosciences, Pennsylvania State University), Masataka Kinoshita(Earthquake Research Institute, the University of Tokyo)

The Nankai Trough Seismogenic Zone Experiment (NanTroSEIZE) is a multidisciplinary investigation of fault mechanics and seismogenesis along the megathrust at the Nankai Trough subduction zone, and includes reflection and refraction seismic imaging, direct sampling by drilling, in situ measurements, and long-term monitoring in conjunction with laboratory and numerical modeling studies. During the past 12 IODP expeditions off Kii Peninsula since 2007, 15 sites have been drilled by D/V "Chikyu" down to depths from 100s of meters to more than 3000 meters below seafloor, where the inner and outer wedge of the Nankai margin has been logged and sampled extensively, and three state-of-the-art real-time downhole observatories are now in operation. The final NanTroSEIZE expedition aiming to log and sample the seismogenic megathrust at ~5200 meters below seafloor is now ongoing from October, 2018 to March, 2019.
In this session, we expect presentations not only on scientific outcomes from the past NanTroSEIZE expeditions, but also on the exciting preliminary results of the final NanTroSEIZE expedition. We welcome presentations on, but are not limited to, seismic imaging, borehole logging and monitoring, chemical analyses of pore water and mud gas, lithology, structures, physical properties and laboratory experiments of cuttings and core samples, and theoretical and numerical modeling.

Geoscientific information about plate boundary along the Nankai Trough provided by the GNSS-A

*Yusuke Yokota[1], Tadashi Ishikawa[2]

1. Institute of Industrial Science, The University of Tokyo, 2. Hydrographic and Oceanographic department, Japan Coast Guard

In the last decade, many geophysical implications were provided by the GNSS-A seafloor geodetic network. Along the Japan Trench, coseismic and postseismic deformations following the 2011 Tohoku-oki earthquake were detected [Sato et al., 2011, Science; Watanabe et al., 2014, GRL; Tomita et al., 2017, Sci. Adv.]. Coseismic monitoring result was applied for many seismological research [e.g., Ozawa et al., 2012, JGR] and geological research and monitoring plan. Postseismic viscoelastic behavior and afterslip event [Sun et al., 2016, Nature; Iinuma et al., 2016, Nature Comm.] could not be identified without our monitoring results.

After 2015, more important geoscientific suggestions were obtained from monitoring in the Nankai Trough. Yokota et al. [2016, Nature] showed undersea interseismic coupling condition. This observation result has been broadly applied to various geophysical studies while being modified [e.g., Nishimura et al., 2018, Gesphere; Noda et al., 2018, JGR] and constrains earthquake prediction research including numerical simulation and submarine drilling research.

In addition, recently, we improved the GNSS-A technology and upgraded observation frequency and precision [Yokota et al., 2017, Rep. Hydro. Ocean. Res; Yokota et al., 2018, MGR]. With the present observation ability, yearly time change of the amount of undersea crustal deformation was newly unclosed. This new version data suggests that there were longer-term sequences of slow slip events (SSEs) around strong coupling regions [Yokota and Ishikawa, this JpGU meeting].

These results provide several suggestions about property and condition on the plate boundary. The simple and biggest question is what is the reason for separating strong coupling and SSE conditions. Since the difference between the generation patterns of SSE and other slow earthquakes is also considered to be due to physical properties, some dominant factor can be assumed. Differences and similarities between deep and shallow SSEs are also important. What physical properties control the behaviors of deep and shallow SSEs?

For answering these questions, additional experiments and observations from many different viewpoints will be necessary. At the same time, continuous GNSS-A monitoring and upgrading its density and accuracy are required for understanding shallow coupling conditions and SSEs.

Deep Drilling at the Nankai Trough: IODP NanTroSEIZE Expedition 358 Summary and First Results

*Harold Tobin[1], Takehiro Hirose[7], Matt Ikari[5], Kyuichi Kanagawa[10], Gaku Kimura[3], Masataka Kinoshita[8], Hiroko Kitajima[6], Demian M Saffer[4], Asuka Yamaguchi[9], Lena Maeda[2], Nobu Eguchi[2], Sean Toczko[2]

1. Department of Earth and Space Sciences, University of Washington, 2. JAMSTEC-CDEX, 3. Tokyo Un. of Marine Science-Technology, 4. Penn State University, 5. MARUM Un. of Bremen, 6. Texas A&M University, 7. JAMSTEC-KCC, 8. Un. of Tokyo Earthquake Research Institute, 9. Un. of Tokyo AORI, 10. Chiba University

IODP Expedition 358 was carried out beginning October 10, 2018 and scheduled to continue until March 31, 2019. The primary objective was to sample and make geophysical measurements in and around the megasplay fault/plate boundary fault at Site C0002, by extending the riser borehole (Hole C0002P) established during previous Integrated Ocean Drilling Program NanTroSEIZE expeditions. After Expedition 348 in 2014, Hole C0002P was left suspended, with steel casing in pace holding the borehole open to 2922 meters below the sea floor (mbsf). The primary seismic reflector target interpreted as the main plate boundary fault zone was estimated to lie at a little more than 5000 mbsf, necessitating a plan to re-enter that hole and then add about 2000 meters of new depth drilling to reach and cross it.

Drilling commenced with a sidetracking operation to establish Hole C0002Q, which was advanced to 3263 mbsf, but operational difficulties precluded going any deeper. Two more attempts were made to advance the riser hole over many weeks, but ultimately did not result in further progress toward the objective. At the time of this writing, coring operations are ongoing at the site at a depth of about 2900 mbsf, in deformed and steeply-dipping mid-Miocene age inner accretionary wedge rocks. There are plans to end riser operations at Site C0002 at the end of February 2019 despite not reaching the primary target, and instead commence drilling at a new site to target the frontal thrust portion of the plate boundary near previous IODP Site C0006. First results from the expedition will be reviewed in this presentation, and a preliminary assessment of the scientific outcomes will be made.

It was believed that sediment strengthened irreversibly with depth, and same lithology has same strength in same depth. It was found that quite soft portions were developed within hard sedimentary rock at deep Nankai accretionary prism, southwest Japan, during the NanTro Seize Project, IODP Expedition 348 and 358.

The site C0002 is located at the Tonankai Earthquake (1944 M=8.0) area and penetrates 3262 m below sea floor (mbsf) through the Kumano basin and Nankai accretionary prism. The porosity decreases, and hardness increases with depth gradually. Deeper than approximately 2000 mbsf, the Silty claystone of dark gray lithified hard rock with low porosity less than 20% is occurred for main lithology. Interleaved between this hard rock, the Fine silty claystone with high porosity upper than 30% was observed deeper than 2360 mbsf (Tobin et al., 2015). This soft sediment is similar with the Silty claystone in grain size and mineral assemblages, but strength is totally difference. Such soft stuffs are commonly generated during drilling. In this site, various types of drill tools of bit and reamers were operated due to unstable hole condition. However, no relationship was found between drilling tool and occurrence of the Fine silty claystone. Optical microscope and micro X-CT observations revealed that some sedimentary laminations and burrows of benthos were preserved within the Fine silty claystone. These show that the fine silty claystone is natural sediment, but not drilling induced artifact.

The reason for coexistence of soft and hard sediments in same depth can be explained by conceptual idea as below. In initial state of diagenesis, some crystals will grow larger having smaller surface energy than the other. This surface energy difference in same solution causes that smaller crystal dissolution and larger crystal grow further. Resulting of this process, well crystalline and less crystalline parts probably have marked contrast in strength. This implies that present of heterogeneous strength distribution around the initiation depth of diagenesis.

Stress and strain should be crucial parameter to understand preparation/generation cycle of mega-thrust earthquakes which repeatedly occur along subduction zone. Recent studies suggest that seismic approach (c.f. seismic anisotropy analysis and seismic velocity monitoring) could be alternative tool to monitor stress/strain field in the seismogenic zone. The IODP Exp. 358, which includes deep riser drilling by D/V Chikyu around the IODP C0002 hole in the Nankai Trough region, is a great opportunity to observe the seismic dataset, which would be used to discuss the relationship between seismic parameters and stress field before, after and while the deep borehole drilling.

We performed a series of seismic experiments including passive and active surveys. The experiments include: 1) Seismic velocity monitoring near the C0002 hole by seismic interferometry using drilling/vessel noise. 2) Seismic anisotropy survey around the C0002 hole by air-gun circular shooting. 3) Microearthquakes and tremors monitoring to identify stress condition around the borehole. In this region, real-time borehole seismic observatory and seafloor seismic observatory, named LTBMS (Long-Term Borehole Monitoring System) and DONET (Dense Oceanfloor Network system for Earthqukae and Tsunamis), have been already installed and operated. These observatories can be used as seismic receivers for this experiment. 10 OBSs (Ocean Bottom Seismicmeter) were additionally deployed near the C0002 hole for dense seismic observation within 10 km from the C0002 hole. 6 OBSs were deployed by R/V Yokosuka during the YK18-14 cruise. Another 4 OBSs were deployed by Chikyu’s ROV (Remotely Operated Vehicle) with distances of 90 m to 300 m from the C0002 hole. These OBSs will be recovered from May to Oct. 2019. As active seismic survey, R/V Kaimei fired circular shooting line around the C0002 hole during the KM18-10 cruise. The air-gun signals were clearly observed by LTBMS seismometer and seafloor DONET seismometers. The observed data show clear seismic events which should be caused by seismic anisotropy. Since 2013 to 2016, we have performed the same survey around the C0002 hole by R/V Kairei in every year. Therefore, time-lapse discussion on seismic anisotropy should be possible by using the newly and existing dataset.

Phase analysis and beam-forming processing would be possible by using the OBS array dataset to discuss distributions of microearthquake and tremors. OBS array data can be also used for seismic interferometry analysis to discuss velocity structure monitoring during the drilling. In this presentation, we will show initial data observed by OBS if the data were available after the recovery. Also, we will show initial results of active seismic survey observed by LTBMS and DONET seismometers including time-lapse discussion on seismic anisotropy.

Microfabric analysis of damaged zone of principal shear zone in the frontal megathrust in the Nankai Trough

*Gaku Kimura[1], Asuka Yamaguchi[2], Yohei Hamada[3], Suguru Yabe[4]

The outer wedge of the Nankai forearc is located to the south of the splay fault, which is the traditional southern margin of the seismogenic rupture zone. The evidence for seismo-tsunamigenic slip was, however, recognized on the basis of a thermal anomaly along ~2 mm thick fault gouge indicative of frictional heating at the frontal thrust. This fact suggested a rupture propagation to the Nankai Trough in the past. Recently, slow slips along the megathrust beneath the outer wedge were observed and an intimate relationship between the coseismo-tsunamigenic large and fast slip and interseismic slow slips is a matter of great concern.

The underlying micro-mechanical processes responsible for the fast or slow slips are, however, poorly known.

We revisited the recovered core sample of the frontal thrust and added further micro-textural observations for damaged zone to already reported principal shear zone. The detailed mineralogical, chemical and micro fabric analysis for a principal shear zone presents the nearly complete transformation from smectite to illite, which is consistent with frictional heating. The observed micro-texture of the gouge and its surroundings of damaged zone is characteristic of experimentally-produced brittle textures for slow slip. This suggests an overprint of slow slip on the previous seismo-tsunamigenic fast slip. This micro-tectonic based interpretation is consistent with the recent observation of inter-sesimic slow slip beneath the outer wedge and around the frontal megathrust. We suggest that the illite-smectite lithology of gouge and surrounding is conditionally stable, allowing it to transition from co-seismic rapid slip to inter-seismic slow slip at different times.

Seismic Imaging of Mud Diapirs in Northern Kumano Basin, Nankai Trough

*Gregory F Moore[1], Miho Asada[2], Shuichi Kodaira[2], Achim Kopf[3]

1. University of Hawaii at Manoa, 2. JAMSTEC, 3. MARUM

Mud volcanoes (MV), the surface expression of deeper-seated diapirs are now well known in Kumano Basin. Fifteen years ago, Morita et al. (2004) published a seismic line across the basin showing mud diapirs sourcing the MVs, but the extent of these diapirs has remained underappreciated. We present JAMSTEC 2D seismic lines across and along the basin axis showing that significant deformation of the shallow sedimentary section in the northern part of the basin is caused by mud diapirs. The diapirs feed at least 11 MVs in the northern part of the basin, all of which have been surveyed with multibeam bathymetry, high-resolution sonar and sampling. The diapirs range in diameter from 4-6 km and have seismic expression to at least 2-3 km below the seafloor. Older sedimentary layers are tilted upward adjacent to the diapirs and have internal onlap features that indicate several stages of uplift. Bottom simulating reflections (BSRs) that cross-cut the sediment and diapirs are locally disrupted under the MVs, indicating upward migration of fluids through the methane hydrate layers to the surface. Morita et al. (2004) report that mudstone fragments carried to the surface by the MVs range in age from 18.2-13.6 Ma (late Early Miocene –early Middle Miocene), indicating that the mud diapirs, which probably originate within the underlying accretionary prism, passed through the older layers of the forearc basin.

[S-SS06] Nankai Trough Seismogenic Zone Experiment: Logging and sampling the seismogenic megathrust

convener:Kyuichi Kanagawa(Graduate School of Science, Chiba University), Demian M Saffer(Pennsylvania State University), Masataka Kinoshita(Earthquake Research Institute, University of Tokyo)

The Nankai Trough Seismogenic Zone Experiment (NanTroSEIZE) is a multidisciplinary investigation of fault mechanics and seismogenesis along the megathrust at the Nankai Trough subduction zone, and includes reflection and refraction seismic imaging, direct sampling by drilling, in situ measurements, and long-term monitoring in conjunction with laboratory and numerical modeling studies. During the past 12 IODP expeditions off Kii Peninsula since 2007, 15 sites have been drilled by D/V "Chikyu" down to depths from 100s of meters to more than 3000 meters below seafloor, where the inner and outer wedge of the Nankai margin has been logged and sampled extensively, and three state-of-the-art real-time downhole observatories are now in operation. The final NanTroSEIZE expedition aiming to log and sample the seismogenic megathrust at ~5200 meters below seafloor is now ongoing from October, 2018 to March, 2019.
In this session, we expect presentations not only on scientific outcomes from the past NanTroSEIZE expeditions, but also on the exciting preliminary results of the final NanTroSEIZE expedition. We welcome presentations on, but are not limited to, seismic imaging, borehole logging and monitoring, chemical analyses of pore water and mud gas, lithology, structures, physical properties and laboratory experiments of cuttings and core samples, and theoretical and numerical modeling.

Crustal structure in the Nankai Trough seismogenic zone based on renewed depth images and seismic attribute analysis

*Kazuya Shiraishi[1], Yasuhiro Yamada[1], Masataka Kinoshita[2], Gaku Kimura[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. Earthquake Research Institute, The University of Tokyo, 3. Tokyo University of Marine Science and Technology

To better understand geological structure in the Nankai Trough seismogenic zone, we investigate deformations in the accretionary prism based on renewed depth images and seismic attribute analyses. We reprocessed subareas of the Kumano-nada 3D MCS data acquired in 2006: 25 km x 12 km area including IODP C0002 site in Phase 1 (2015-2016) and 20 km x 12 km area including IODP C0006 site in Phase 2 (2017-2018). We also reprocessed 2D MCS data along a 50-km line crossing C0002 site in NW-SE direction, which was selected from a 2D survey ODKM03 in 2003 with a longer streamer cable (6 km) than streamer cables of the 3D survey (4.5 km). Quality improvement of reflection signals was achieved by applying recent broadband processing and advanced process to attenuate noise and multiple reflections. Depth domain reflection images were obtained after applying new pre-stack depth migration methods. Then, we calculated several seismic attributes from the 3D reflection image volumes, such as coherence and structure dips which are useful to interpret structural features.
As a result of our investigation, deformed structure within the inner accreted sediments and its relation with the megathrust fault are clearer than before. Anticlines are identified just below the Kumano forearc basin and fragmented reflections can be seen below the anticlines. Characteristic patterns of folds can be recognized on the horizontal section of the coherence cube, which are corresponding to the anticlines on the vertical sections. These reflection features imply development of fold structures due to thrust faults with branched minor faults. In the reprocessed 2D section, curved reflectors with stepwise displacement are imaged in the region of 4 - 6 km depth. These reflectors may represent multiple thrust faults with back-thrusts, and the thrust faults are consistent with the structural features in the 3D images. The detachments of the thrust faults seem to converge to wavy points on the megathrust fault surface. Furthermore, details of deformation and fracture in the outer accretionary prism are imaged clearer than the previous images. Lithological boundaries with displacement along imbricated thrusts can be traced beyond the fault, and conjugate faults due to horizontal compression which cut the in-sequence thrusts are recognized on the horizontal section from superimposed view of the coherence and dip angles. Reflectors within underthrusted sediments beneath the imbricated thrust layer are clearly imaged. Some of the reflectors can be identified as parts of detachment of the thrust faults. The topographic relief of the oceanic crust should be considered when the deformed structures in the overburden sediments and distribution of décollement are revisited.

Along-strike variations in protothrust zone characteristics at the Nankai Trough subduction margin

*Hannah Tilley[1], Gregory F Moore[1], Mikiya Yamashita[2], Shuichi Kodaira[2]

1. University of Hawaii at Manoa, 2. JAMSTEC

Protothrust zones (PTZs) are assumed to control the development of new frontal thrusts at subduction zones. PTZs are areas of incipient thrust faulting between the deformation front and the frontal thrust. However, limited resolution of previous seismic studies has hindered the study of their role in subduction accretion. New high-resolution seismic reflection surveys enabled detailed analysis of the PTZ along the Nankai Trough, SE Japan. Seventeen multichannel seismic reflection lines were collected perpendicular to the trench axis between Cape Ashizuri and Cape Muroto using a 1200m long, 192 channel hydrophone cable and a 380 in^3 (5.24L) cluster airgun array. These lines were processed using pre-stack depth migration. PTZs only existed where a turbidite sequence was present beneath the trench wedge. The PTZs consisted of closely spaced, sub-parallel protothrusts that decreased in spacing and increased in length landward. Where the turbidites were truncated by basement topography, there was a transitional PTZ heterogeneous protothrusts and small displacement thrust faults. We hypothesize that elevated pore pressures due to the low permeability hemipelagic sediment inhibit the formation of PTZs and favor small displacement thrusts in a narrow trench wedge. Conversely, turbidite layers within the hemipelagic sediment allow drainage and reduce the pore pressure. This increases the effective stress and shear strength on faults, resulting in strain localizing protothrusts. This implies that the changes in pore pressure imposed by differences in the sediment permeability control the style of deformation in the trench wedge and consequently, the geometry of the accretionary wedge.

Temporal change in seismic velocity in the Nankai subduction zone from cross-correlation analysis of ambient noise

*Tatsunori Ikeda[1], Takeshi Tsuji[1]

1. Kyushu University

To investigate the temporal variation of stress or strain in the Nankai subduction zone, we estimated the temporal variation of seismic velocity by using cross-correlations of ambient noise in the frequency range 0.7–2.0 Hz, which was dominated by ACR waves, recorded by the DONET offshore seismic network from 1 October 2014 to 30 November 2017. The 1 April 2016 Off-Mie earthquake (M_W 5.9) and its aftershocks occurred beneath the seismic network.

Our results document a clear decrease in seismic velocity at the time of the earthquake. These coseismic velocity drops were correlated with peak ground velocities at each station, suggesting that dynamic stress changes due to strong ground motions are a primary factor in coseismic velocity variations. Differences in the sensitivity of seismic velocity changes to peak ground velocity may reflect subsurface conditions at each station, such as geological structures and effective pressure conditions. We also observed a long-term increase in seismic velocities, independent of the 2016 earthquake, that may reflect tectonic strain accumulation around the Nankai subduction zone. After removing the long-term trend, we found that the coseismic velocity drops had not completely recovered by the end of the observation period, possibly indicating nonlinear effects of the 2016 earthquake. Our results suggest that ambient noise cross-correlation might be used to monitor the stress state in the Nankai accretionary prism in offshore environments, which would contribute to a better understanding of earthquake processes.

Strength profile of the Nankai accretionary prism evaluated from drilling parameters

In-situ rock strength with depth under the ground/seafloor is a critical parameter for various studies in geology and seismology. The measurements on rock/core samples, however, hardly have been done with success due to lack of drilled cores and sufficient knowledge about the in situ conditions. We proposed a new indicator of the strength, equivalent strength (EST) developing previous mechanical parameter (Mechanical specific energy: Teal, 1964) from the oil industry, which is converted only from drilling performance parameters such as drillstring rotational torque, bit depth and drillstring rotational per minute. The data processing was applied to the data taken from International Ocean Discovery Program (IODP) expeditions in the Nankai Trough (sites C0002 and C0023). The depth profiles of the EST at Site C0002 are drawn from 0 to 3000 meter-below-seafloor (mbsf), across the forearc basin and the accretionary prism, and the values of the calculated EST are consistent with compressive strength measured on core samples under estimated in situ stress conditions in laboratory. The high (~20 MPa) EST in the forearc basin sediments corresponds to the high $CaCO_3$ content indicating the carbonate is cementing the shallow formation. The EST did not show a significant increase at the forearc basin–accretionary prism boundary, however clearly increased within the prism, ca. below 1500 mbsf. This result may indicate that even the shallow accretionary prism has been strengthened by horizontal compression derived from plate subduction. At the site C0023, where the toe of the accretionary prism area off Cape Muroto, the EST trend increases with depth and suddenly changes between 600–650 mbsf, 840–870 mbsf, and 1120 ~ mbsf, corresponding to tuff0rich zone, top of the subducting sediments and the basement igneous rocks, respectively. This EST trend shows good agreement with P-wave velocity curve measured on core samples. The EST decreases from ~20 MPa to 5 MPa below the frontal decollement with sharp negative peak. This low-EST zone probably indicate the existence of excess fluid pressure.

Paleotemperature anomalies deduced from thermal-maturity parameters within the décollement, off Cape of Muroto, Japan

*Nana Kamiya[1,2], Takehiro Hirose[2], Yuzuru Yamamoto[2], Yohei Hamada[2], Stephen A Bowden[3], Man-Yin Tsang[4], Kiho Yang[5], Satoshi Tonai[6], Weiren Lin[1,2]

1. Graduate School of Engineering, Kyoto University, 2. JAMSTEC, 3. University of Aberdeen, 4. University of Toronto, 5. Yonsei University, 6. Kochi University

Heat flow is characteristically high at the toe of the Nankai accretionary prism, off cape Muroto, and this is considered to be a consequence of the subduction of a hot and active ridge (e.g. Yamano et al., 2003). Despite present-day heat flow being known, how heat has changed over time in this area remains uncertain and is poorly constrained. To address this question, we have investigated palaeotemperatures using thermal maturity parameters measured on cores collected during IODP Expedition 370. Paleotemperature data were evaluated within the context of present-day heat flow and expected changes in temperature with respect to depth; e.g., numerical constraint whether present-day temperatures are too hot or cold to explain thermal maturity measurements, and whether there are anomalies with respect to depth. This is particularly important for Expedition 370 (T-limits) which selected the Muroto-site (Site C0023) because of its high heat flow and the chance this offers to investigate the habitability of the deep biosphere with respect to the temperature. Site C0023 is located 120 km from Cape Muroto, and is in the protothrust-zone of the Nankai accretionary prism. The hole encountered the décollement at 758-795 mbsf, and present-day temperatures were measured down to ~350 mbsf. Vitrinite reflectance was used to estimate maximum paleotemperatures and to look for thermal anomalies. The vitrinite reflectance increases with depth from 0.2 to 0.6 % from 200 to 700 mbsf, typical of conventional burial metamorphism, but changes little from 700 to 1000 mbsf (values stay about 0.6 %). There is a notable high value at 1090 mbsf (about 1%). There are anomalously high values of both vitrinite reflectance and sterane and hopane biomarker data at about 800 mbsf. For heating durations of 400, 4000, 40000 and 400000 years, and assuming thermal maturation using the EasyVit model of Burnham and Sweeny (1990), temperatures of 40~140 ℃ can explain data between 200 to 750 mbsf. To match measurements of vitrinite reflectance at 750 mbsf, a maximum paleotemperature of 140 ℃ is required. At 1090 mbsf, temperatures as high as ~200 ℃ could be needed. The difference between the paleo- and present-day temperatures is the notably the greatest at the décollement, strongly suggesting an elevated heat flow at some time. A heating duration of 400 years, an elevated a heat flow of 130 ±90 mW/m^2 and a temperature > 150 ℃ can explain the observations on the vitrinite reflectance. Considering the scales of space and time of thermal advection, a high-temperature fluid along the décollement zone is our currently preferred explanation.

Modelling thermal maturity of an accretionary wedge

Utsav Mannu[2], *Masataka Kinoshita[1], Taras Gerya[3]

1. Earthquake Research Institute, University of Tokyo, 2. Department of Earth and Climate Science, IISER Pune, 3. Institute of Geophysics, ETH Zürich

In accretionary margins, the estimation of peak heating through the thermal maturity of organic material reveals differentiated deformational pathways in the adjoining sections of the wedge. As the thermal maturity of the deformed structures is a function of both the geothermal gradient and the duration of time it has been exposed to different gradients, the distribution of vitrinite reflectance (the measure of thermal maturity) in the wedge does not necessarily reveal the temporal deformational pathway of the individual pockets. As a result, the different portions of the accretionary wedge exhibit different correlations between the thermal maturity and a unique deformational pathway. These different correlations can be explored through the means of geodynamic modelling which can then be used in the field to ascertain a more holistic picture of deformation in an accretionary wedge. Therefore, in this study, we use a 2D plate subduction thermomechanical model, to simulate formation of accretionary wedge and the track the evolution of the vitrinite reflectance in the accretionary wedge.

To better understand geological structure in the Nankai Trough seismogenic zone, we investigate deformations in the accretionary prism based on renewed depth images and seismic attribute analyses. We reprocessed subareas of the Kumano-nada 3D MCS data acquired in 2006: 25 km x 12 km area including IODP C0002 site in Phase 1 (2015-2016) and 20 km x 12 km area including IODP C0006 site in Phase 2 (2017-2018). We also reprocessed 2D MCS data along a 50-km line crossing C0002 site in NW-SE direction, which was selected from a 2D survey ODKM03 in 2003 with a longer streamer cable (6 km) than streamer cables of the 3D survey (4.5 km). Quality improvement of reflection signals was achieved by applying recent broadband processing and advanced process to attenuate noise and multiple reflections. Depth domain reflection images were obtained after applying new pre-stack depth migration methods. Then, we calculated several seismic attributes from the 3D reflection image volumes, such as coherence and structure dips which are useful to interpret structural features.
As a result of our investigation, deformed structure within the inner accreted sediments and its relation with the megathrust fault are clearer than before. Anticlines are identified just below the Kumano forearc basin and fragmented reflections can be seen below the anticlines. Characteristic patterns of folds can be recognized on the horizontal section of the coherence cube, which are corresponding to the anticlines on the vertical sections. These reflection features imply development of fold structures due to thrust faults with branched minor faults. In the reprocessed 2D section, curved reflectors with stepwise displacement are imaged in the region of 4 - 6 km depth. These reflectors may represent multiple thrust faults with back-thrusts, and the thrust faults are consistent with the structural features in the 3D images. The detachments of the thrust faults seem to converge to wavy points on the megathrust fault surface. Furthermore, details of deformation and fracture in the outer accretionary prism are imaged clearer than the previous images. Lithological boundaries with displacement along imbricated thrusts can be traced beyond the fault, and conjugate faults due to horizontal compression which cut the in-sequence thrusts are recognized on the horizontal section from superimposed view of the coherence and dip angles. Reflectors within underthrusted sediments beneath the imbricated thrust layer are clearly imaged. Some of the reflectors can be identified as parts of detachment of the thrust faults. The topographic relief of the oceanic crust should be considered when the deformed structures in the overburden sediments and distribution of décollement are revisited.

Along-strike variations in protothrust zone characteristics at the Nankai Trough subduction margin

*Hannah Tilley[1], Gregory F Moore[1], Mikiya Yamashita[2], Shuichi Kodaira[2]

1. University of Hawaii at Manoa, 2. JAMSTEC

Protothrust zones (PTZs) are assumed to control the development of new frontal thrusts at subduction zones. PTZs are areas of incipient thrust faulting between the deformation front and the frontal thrust. However, limited resolution of previous seismic studies has hindered the study of their role in subduction accretion. New high-resolution seismic reflection surveys enabled detailed analysis of the PTZ along the Nankai Trough, SE Japan. Seventeen multichannel seismic reflection lines were collected perpendicular to the trench axis between Cape Ashizuri and Cape Muroto using a 1200m long, 192 channel hydrophone cable and a 380 in^3 (5.24L) cluster airgun array. These lines were processed using pre-stack depth migration. PTZs only existed where a turbidite sequence was present beneath the trench wedge. The PTZs consisted of closely spaced, sub-parallel protothrusts that decreased in spacing and increased in length landward. Where the turbidites were truncated by basement topography, there was a transitional PTZ heterogeneous protothrusts and small displacement thrust faults. We hypothesize that elevated pore pressures due to the low permeability hemipelagic sediment inhibit the formation of PTZs and favor small displacement thrusts in a narrow trench wedge. Conversely, turbidite layers within the hemipelagic sediment allow drainage and reduce the pore pressure. This increases the effective stress and shear strength on faults, resulting in strain localizing protothrusts. This implies that the changes in pore pressure imposed by differences in the sediment permeability control the style of deformation in the trench wedge and consequently, the geometry of the accretionary wedge.

Temporal change in seismic velocity in the Nankai subduction zone from cross-correlation analysis of ambient noise

*Tatsunori Ikeda[1], Takeshi Tsuji[1]

1. Kyushu University

To investigate the temporal variation of stress or strain in the Nankai subduction zone, we estimated the temporal variation of seismic velocity by using cross-correlations of ambient noise in the frequency range 0.7–2.0 Hz, which was dominated by ACR waves, recorded by the DONET offshore seismic network from 1 October 2014 to 30 November 2017. The 1 April 2016 Off-Mie earthquake (M_W 5.9) and its aftershocks occurred beneath the seismic network.

Our results document a clear decrease in seismic velocity at the time of the earthquake. These coseismic velocity drops were correlated with peak ground velocities at each station, suggesting that dynamic stress changes due to strong ground motions are a primary factor in coseismic velocity variations. Differences in the sensitivity of seismic velocity changes to peak ground velocity may reflect subsurface conditions at each station, such as geological structures and effective pressure conditions. We also observed a long-term increase in seismic velocities, independent of the 2016 earthquake, that may reflect tectonic strain accumulation around the Nankai subduction zone. After removing the long-term trend, we found that the coseismic velocity drops had not completely recovered by the end of the observation period, possibly indicating nonlinear effects of the 2016 earthquake. Our results suggest that ambient noise cross-correlation might be used to monitor the stress state in the Nankai accretionary prism in offshore environments, which would contribute to a better understanding of earthquake processes.

Strength profile of the Nankai accretionary prism evaluated from drilling parameters

*Yohei Hamada[1], Manami Kitamura[2], Takehiro Hirose[1], Yasuhiro Yamada[1], Yoshinori Sanada[1], Takamitsu Sugihara[1], Saneatsu Saito[1], KYAW MOE[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Institute of Advanced Industrial Science andTechnology

In-situ rock strength with depth under the ground/seafloor is a critical parameter for various studies in geology and seismology. The measurements on rock/core samples, however, hardly have been done with success due to lack of drilled cores and sufficient knowledge about the in situ conditions. We proposed a new indicator of the strength, equivalent strength (EST) developing previous mechanical parameter (Mechanical specific energy: Teal, 1964) from the oil industry, which is converted only from drilling performance parameters such as drillstring rotational torque, bit depth and drillstring rotational per minute. The data processing was applied to the data taken from International Ocean Discovery Program (IODP) expeditions in the Nankai Trough (sites C0002 and C0023). The depth profiles of the EST at Site C0002 are drawn from 0 to 3000 meter-below-seafloor (mbsf), across the forearc basin and the accretionary prism, and the values of the calculated EST are consistent with compressive strength measured on core samples under estimated in situ stress conditions in laboratory. The high (~20 MPa) EST in the forearc basin sediments corresponds to the high $CaCO_3$ content indicating the carbonate is cementing the shallow formation. The EST did not show a significant increase at the forearc basin–accretionary prism boundary, however clearly increased within the prism, ca. below 1500 mbsf. This result may indicate that even the shallow accretionary prism has been strengthened by horizontal compression derived from plate subduction. At the site C0023, where the toe of the accretionary prism area off Cape Muroto, the EST trend increases with depth and suddenly changes between 600–650 mbsf, 840–870 mbsf, and 1120 ~ mbsf, corresponding to tuff0rich zone, top of the subducting sediments and the basement igneous rocks, respectively. This EST trend shows good agreement with P-wave velocity curve measured on core samples. The EST decreases from ~20 MPa to 5 MPa below the frontal decollement with sharp negative peak. This low-EST zone probably indicate the existence of excess fluid pressure.

Paleotemperature anomalies deduced from thermal-maturity parameters within the décollement, off Cape of Muroto, Japan

*Nana Kamiya[1,2], Takehiro Hirose[2], Yuzuru Yamamoto[2], Yohei Hamada[2], Stephen A Bowden[3], Man-Yin Tsang[4], Kiho Yang[5], Satoshi Tonai[6], Weiren Lin[1,2]

Heat flow is characteristically high at the toe of the Nankai accretionary prism, off cape Muroto, and this is considered to be a consequence of the subduction of a hot and active ridge (e.g. Yamano et al., 2003). Despite present-day heat flow being known, how heat has changed over time in this area remains uncertain and is poorly constrained. To address this question, we have investigated palaeotemperatures using thermal maturity parameters measured on cores collected during IODP Expedition 370. Paleotemperature data were evaluated within the context of present-day heat flow and expected changes in temperature with respect to depth; e.g., numerical constraint whether present-day temperatures are too hot or cold to explain thermal maturity measurements, and whether there are anomalies with respect to depth. This is particularly important for Expedition 370 (T-limits) which selected the Muroto-site (Site C0023) because of its high heat flow and the chance this offers to investigate the habitability of the deep biosphere with respect to the temperature. Site C0023 is located 120 km from Cape Muroto, and is in the protothrust-zone of the Nankai accretionary prism. The hole encountered the décollement at 758-795 mbsf, and present-day temperatures were measured down to ~350 mbsf. Vitrinite reflectance was used to estimate maximum paleotemperatures and to look for thermal anomalies. The vitrinite reflectance increases with depth from 0.2 to 0.6 % from 200 to 700 mbsf, typical of conventional burial metamorphism, but changes little from 700 to 1000 mbsf (values stay about 0.6 %). There is a notable high value at 1090 mbsf (about 1%). There are anomalously high values of both vitrinite reflectance and sterane and hopane biomarker data at about 800 mbsf. For heating durations of 400, 4000, 40000 and 400000 years, and assuming thermal maturation using the EasyVit model of Burnham and Sweeny (1990), temperatures of 40~140 ℃ can explain data between 200 to 750 mbsf. To match measurements of vitrinite reflectance at 750 mbsf, a maximum paleotemperature of 140 ℃ is required. At 1090 mbsf, temperatures as high as ~200 ℃ could be needed. The difference between the paleo- and present-day temperatures is the notably the greatest at the décollement, strongly suggesting an elevated heat flow at some time. A heating duration of 400 years, an elevated a heat flow of 130 ±90 mW/m^2 and a temperature > 150 ℃ can explain the observations on the vitrinite reflectance. Considering the scales of space and time of thermal advection, a high-temperature fluid along the décollement zone is our currently preferred explanation.

Modelling thermal maturity of an accretionary wedge

Utsav Mannu[2], *Masataka Kinoshita[1], Taras Gerya[3]

1. Earthquake Research Institute, University of Tokyo, 2. Department of Earth and Climate Science, IISER Pune, 3. Institute of Geophysics, ETH Zürich

In accretionary margins, the estimation of peak heating through the thermal maturity of organic material reveals differentiated deformational pathways in the adjoining sections of the wedge. As the thermal maturity of the deformed structures is a function of both the geothermal gradient and the duration of time it has been exposed to different gradients, the distribution of vitrinite reflectance (the measure of thermal maturity) in the wedge does not necessarily reveal the temporal deformational pathway of the individual pockets. As a result, the different portions of the accretionary wedge exhibit different correlations between the thermal maturity and a unique deformational pathway. These different correlations can be explored through the means of geodynamic modelling which can then be used in the field to ascertain a more holistic picture of deformation in an accretionary wedge. Therefore, in this study, we use a 2D plate subduction thermomechanical model, to simulate formation of accretionary wedge and the track the evolution of the vitrinite reflectance in the accretionary wedge.

Tue. May 28, 2019 10:45 AM - 12:15 PM JST | Tue. May 28, 2019 1:45 AM - 3:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_6

[S-SS10] Seismicity

convener:Kei Katsumata(Institute of Seismology and Volcanology, Hokkaido University)

This session aims to improve our understanding on seismicity. Any contribution on behavior of earthquakes as a cluster, such as regional seismicity and aftershocks, are welcomed. We also welcome contribution on temporal and spatial interactions that control seismicity, and tectonic processes, and geological and thermal structures that regulate seismicity.

Spatial-temporal and seismogram characteristics of foreshock and aftershock activities for tsunami earthquakes

*Yifeng Liu[1], Yoshihiro Ito[2], Kazuaki Ohta[2], Satoshi Katakami[1]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, 2. Disaster Prevention Research Institude, Kyoto University

A tsunami earthquake is an abnormal earthquake type causing a large tsunami compared to the magnitude measured by short-period seismic waves. There is a high risk to induce a massive tsunami damage for the reason that people who live in the coastal area do not feel quakes a lot, and it is difficult to keep themselves safe after the unusual earthquake happened. Additionally, as for the tsunami earthquakes, their observation cases are much fewer than ordinary earthquakes, so the mechanism of its occurrence is still an open question. To address spatio-temporal features and the mechanism of tsunami earthquakes, we focus on three typical examples of tsunami earthquake and their foreshock & aftershock sequences, which are (Nicaragua (1992/09/02, Mw 7.7), Jawa island (2006/07/17, Mw 7.7) and Mentawai (2010/10/25, Mw 7.8)). We also investigated whether a small earthquake showing the same characteristics as the tsunami earthquake is contained in the foreshock and aftershock activity.

First, we use seismic catalogs and waveform recording provided by ISC/USGS and IRIS respectively to extract the foreshock and aftershock activity, then evaluate the spatio-temporal features. We have found that four foreshock sequences (1992/08/10 06:09:20 Mb 5.2, 1992/08/10 06:34:14 Mb4.7, 1992/08/11 05:23:51 Mb 5.1, 1992/08/13 08:41:17 Mb 4.7) near the epicenter of mainshock area were observed before the occurrence of the Nicaragua mainshock. We have also analyzed the regional and spatio-temporal characteristics of three tsunami earthquake regions by dividing the area of 5*5 around the epicenter into twenty-five segments with the size of 1*1. As a result, in each of the three regions, we have found out that there is a seismic quiescence period in the vicinity of the mainshock area in each tsunami earthquake. Meanwhile, regarding aftershocks of the Nicaragua earthquake, seismic quiescence area is still detected in the same segment as the foreshock.

Migration phenomenon is observed in the foreshock activity near the focal region of the mainshock, especially before the mainshock of the Nicaragua earthquake. Meanwhile, the waveforms of aftershocks occurring in the same area as the events included in the migration have been compared with those of the mainshock. Next, we have calculated the ratio of maximum absolute amplitude of surface wave to that of body wave, in order to address features on waveforms of tsunami earthquake. As a result, the ratio of the mainshock, such as the tsunami earthquake shows extremely high value, whereas for the foreshocks and aftershocks, it does not show the same characteristic as the tsunami earthquake does. This suggests that small earthquakes occurring within the tsunami seismogenic region show the same phenomenon as ordinary earthquakes, but only the mainshock has the characteristics of the tsunami earthquake.

Successively occurring large earthquakes in the world –comparison of real cases with expectations by the space-time ETAS

*Tetsuo Hashimoto[1], Takashi YOKOTA[2]

1. Seismology and Tsunami Research Department, Meteorological Reaserch Institute, 2. Aichi Institue Technology

In the government for evaluating criteria on abnormal phenomena along the Nankai Trough for disaster prevention measures, they made the criteria for events to announce the Nankai Trough Earthquake Information. In order to implement specific ways of disaster prevention, they discussed about specific criteria for what kind of phenomenon corresponds to the abnormal event. In this time, we presented the real cases of the successive occurrence of large earthquakes in the world on the newly revised ISC-GEM version 5.1 data (1904-2014) for contributing to the above discussion. And we estimated the large earthquakes occurrence by using the space-time ETAS (Ogata and Zhuang, 2006).The 103 earthquakes of Mw 8.0 over were extracted about the earthquakes in the world for about the last 100 years. There were 9, 10 and 13 earthquakes which were accompanied with the earthquake of Mw 7.8 over occurred within the epicentral distances 500 km within 3 days, 7 days and 30 days, respectively.We estimated occurrences earthquakes from summations of expectations by the space-temporal ETAS which was applied with the parameters around Japan of Ogata and Zhaung (2006) and b=0.92 estimated with the JMA earthquake catalog. And then there were 5.3, 6.5 and 8.0 earthquakes of Mw 8 over which accompanied to the earthquake of Mw 7.8 over within the epicentral distances 500km within 3days, 7days and 30 days, respectively.The expected frequency of occurrence and the decreasing trend accompanying the elapsed time since the preceding earthquake were generally consistent with the above actual case.Acknowledgment: We used ISCGEMver 5.1 from ISC. In addition, we received great cooperation from the Earthquake Prediction and Information Division, Seismology and Volcanology Department, Japan Meteorological Agency.

Seismicity beneath stable oceanic plate

*Yasushi Ishihara[1]

1. R&D Center for Earthquake and Tsunami, JAMSTEC

Stable oceanic plate has low seismic activity generally. Real tectonic deformation is also stable? To survey this topics, high quality and long-term observation. Pacific21 broadband seismic network deploys stations in Micronesia area. At present five islands station are under operation. Two of all have already telemetered to our data center via internet connection and transfer to other organization and institute.
In this year new telemeter station (station code: CHUK) is completed successfully. Chuuk (Truk) island locates on old oceanic plate about 900-1,000km southeast of Mariana trench and Guam. CHUK station locates inside deep tunnel made in more than 70 years ago, WWII era. The site condition is fine in basalt mountain, under stable temperature and on rigid floor. We deployed STS-2 broadband sensor in sensor room, high-resolution data logger and stable power supply system. CHUK station will contribute monitor and location of earthquake around Mariana trench and outer rise area.
Though CHUK station locates in small oceanic island and records strong ocean microseism, background noise level is lower level than standard model. CHUK station is excellent site to monitor including small local earthquake. CHUK station operates for about four years. We review continuous data and pick up local regional seismic events. Not only outer rise region but also Chuuk island area and hidden tectonic zone has active seismicity. By trial analysis, depth of these seismic events is beneath 20km. It implies stress concentration in oceanic plate and its deformation.

Relation between long-term slow slip events and correlation between tidal triggering effect and deep low-frequency earthquakes in Bungo Channel: Part 2

*Fuyuki Hirose[1], Akio Kobayashi[1], Kenji Maeda[2]

1. Seismology and Tsunami Research Department, Meteorological Research Institute, 2. Seismology and Volcanology Department, Japan Meteorological Agency

Long-term slow slip events (LSSEs) have occurred with the interval of 5-6 years beneath the Bungo Channel [e.g., Kobayashi, 2017, EPS]. Deep low-frequency tremors and earthquakes (LFEs) have synchronized with the LSSEs and have activated [Hirose et al., 2010, Science]. It is pointed out that tremors have high tidal correlation [Ide, 2010, Nature; Ide & Tanaka, 2014, GRL]. There is no study that investigated long-term changes of the tidal correlation of LFEs.
On the other hand, the correlation between regular seismicity and tide also have been investigated energetically, and then there is a report that the tidal correlation became higher before the large earthquake around the focal region and became lower after the mainshock [e.g., Tanaka et al., 2012, GRL]. In addition, it is also pointed out that a leading period of high tidal correlation corresponded with the magnitude of a following earthquake.
Accordingly, we investigated temporal changes of tidal correlation of LFEs before and after LSSEs beneath the Bungo Channel on the analogy of tidal correlation of background seismicity before and after large earthquakes.
We extracted LFEs from the earthquake catalog unified by Japan Meteorological Agency (JMA) that occurred beneath the Bungo Channel from 2000 to March 21, 2018. Accuracy of locations of LFEs is lower than that of regular earthquakes. Note that hypocenter determination method for LFE by JMA changed since March 22, 2018, and then detection level also changed at the border. Taking int consideration that the change is not suitable in order to investigate long-term changes of tidal correlation of LFEs, we selected LFEs data.
It is necessary to set fault parameters in order to estimate the theoretical below-ground tidal response. Because our study area was narrow area with 15 km square, we set one fault plane (strike angle 237˚, dip angle 16˚, and rake angle 103˚) taking into consideration the plate configuration [Hirose et al., 2008, JGR] and MT solutions of deep very LFEs [Ide & Yabe, 2014, GRL]. In addition, we set hypocenters of LFEs to the common location (longitude 132.254˚, latitude 33.142˚, and depth 32 km). We used only occurrence times of LFEs determined by the JMA.
We summed temporal variations of the solid and oceanic tide loading effects for six independent components of the strain tensor, as estimated at the hypocenter of each event. Then we converted them to temporal variations of volumetric strain (ΔV) at the hypocenter, and shear stress ($\Delta\tau$), normal stress ($\Delta\sigma$), and the Coulomb failure function (ΔCFF) on the assumed fault plane. In the ΔCFF calculation, we assumed values of 0.1, 0.4, and 0.7 for the apparent friction coefficient μ'. In the case of ΔV and $\Delta\sigma$, we defined expansion/dilatation as positive and contraction/compression as negative; consequently, positive $\Delta\sigma$ values promote fault slip. We also defined $\Delta\tau$ and ΔCFF as positive when they promote fault slip. Using the time series of tidal stress (strain) levels, we assigned phase angles of −180˚ and 180˚ to the minimum tidal stress (strain) levels before and after an event, respectively, and 0˚ to the maximum tidal stress (strain) that occurred between these two minima. The phase angle at the earthquake occurrence time was estimated by linear interpolation in the time interval between −180º and 0˚ or between 0˚ and 180˚. The possible occurrence of LFEs at certain tidal phase angles was evaluated using the *p* value, as

©2019. Japan Geoscience Union. All Right Reserved.

calculated by Schuster [1897].
We found that LFEs tended to occur near a tidal phase angle of 0° for $\Delta\tau$ (when the tidal force promoted fault slip). This result indicates extremely low μ' and high pore pressure, being consistent with the existence of fluid inferred from the seismic velocity structure [Hirose et al., 2008]. LSSEs occurred three times (in 2003-2004, 2009-2011, and 2014) during the study period. Temporal changes of *p* value showed to tend to become lower before the LSSEs and become higher after ones (Tidal correlation tended to become higher before the LSSEs and become lower after ones). This result is similar to temporal changes of *p* value for background seismicity before and after large earthquakes. Accordingly, temporal tidal correlation of LFEs indicates to be affected by stress perturbation associated with LSSEs. Note that *p* value at March in 2018 falls to a level just before past LSSEs.

Arrival-time and hypocenter determination using S-net

*Tomomi Okada[1], Ryota Takagi[1], Takashi NAKAYAMA[1], Syuichi Suzuki[1], Ryosuke Azuma[1], Genti Toyokuni[1], Keisuke Yoshida[1], Naoki Uchida[1], Ryota Hino[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

Hypocenter distribution is basic information for understanding seismogenesis.
For east off Honshu from Hokkaido, Tohoku, Kanto, S-net has been deployed by NIED. S-net is expected to improve accuracy of hypocenter location. In this study, we show a preliminary result of hypocenter determination using S-net and onshore stations.
We used hypomh (Hirata and Matsu’ura (1984)) with seismic velocity structure of Hasegawa et al. (1978). In our case, we used waveform converted to vertical, north-south, east-west components by Takagi et al. (this meeting).
For the earthquake near coast line, we can determine reliable hypocenter location, which is correspond to the location determined by F-net CMT or AQUA catalog. However, large travel time residuals over 3 seconds earlier are estimated for distant stations including the stations east of trench. This would mainly be due to the high velocity Pacific plate (e.g., Toyokuni et al., this meeting). To improve the velocity structure and use station correction are necessary for further study.

Acknowledgements: We used S-net, Hi-net and stations by universities (Hokkaido, Hirosaki, Tokyo and others), Aomori and Tokyo Pref., ADEP (Association for the development of earthquake prediction) and JMA. Profs. Matsuzawa, Zhao, Umino and Hasegawa and Mr. Hirahara give us valuable suggestions.

Focal mechanisms of the double seismic zone in the Pacific plate, off Boso: Temporal change after the 2011 Tohoku EQ

*Guanyu Chen[1], Toshinori Sato[2], Tomoharu Sato[1], Asami Terada, Masanao Shinohara[3], Kimihiro Mochizuki[3], Tomoaki Yamada[3], Kenji Uehira[4], Takashi Shimbo[5], Shuichi Kodaira[5], Yuya Machida[5], Ryota Hino[6], Ryosuke Azuma[6], Yoshio Murai[7], Yoshihiro Ito[8], Hiroshi Yakiwara[9], Kenji Hirata[4], Akinori Hashima[3], Andrew M. Freed[10]

1. Introduction

The Pacific plate and the Philippine Sea plate subduct off the Boso Peninsula, and the Pacific plate has a double seismic zone at this place (e.g. Terada et. al., JpGU, 2016). Sato et. al. (JpGU, 2018) revealed that most focal mechanisms for the lower surface events have down-dip extension before the 2011 Tohoku EQ, and down-dip compression during 3 months after the EQ using land and ocean bottom seismic observations. This presentation shows 1 year temporal change of focal mechanisms for the double seismic zone’ s events after the 2011 Tohoku EQ.

2. Data and analysis

The used data are waveform data from Hi-net by NIED, and the aftershock survey of the 2011 Tohoku EQ using ocean bottom seismometers (2011/3/15-2012/3/31). We select events in the double seismic zone, and pick polarities of the P wave first motions. We calculate emergent azimuth and dip of each event-receiver pair using a 3D structure determined by Terada et al. (JpGU, 2016), and search optimal focal mechanisms using a grid search method.

3. Results

During 1 year after the 2011 Tohoku EQ, most focal mechanisms have down-dip compression for the upper surface events. For the lower surface events, on the other hand, most focal mechanisms have down-dip compression by July, 2011, and many mechanisms have down-dip extension after September, 2011. This may indicate that a compressional stress change occurred at the depth of the Pacific plate just after the 2011 Tohoku EQ, because the EQ moved the Pacific plate downward at the shallower part, and compressed the deeper part of the plate. After that, the compressional stress may had relaxed about a half a year.

Acknowledgements

We thank captains and crew of aftershock observation cruises of the 2011 Tohoku Earthquake. We used waveform data from Hi-net by NIED.

Ocean bottom seismographic observation and similar earthquake detection in the northern part of the Nansei Islands

*Yukihiro Nakatani[1], Hiroshi Yakiwara[1], Shuichiro Hirano[1], Reiji Kobayashi[2], Hiroki Miyamachi[2], Shigeru Nakao[2], Kazunari Uchida[3], Takeshi Matsushima[3], Hiroshi Shimizu[3], Kazuo Nakahigashi[4], Yusuke Yamashita[5], Hideji Abe[6], Tomoaki Yamada[6], Masanao Shinohara[6]

Earthquake Research Institute, the University of Tokyo

The Ryukyu Trench subduction zone is seismically active region. In the northern part of the Nansei Islands, both seismic and aseismic events have occurred along the subducting plate interface. Spatial distribution of small local earthquakes in this region seems to show some seismic clusters and gaps. Short-term slow slip events and shallow low-frequency tremors have been also observed by recent onshore seismic and geodetic data. However, patterns of their slip behavior and spatiotemporal relationship between regular and slow earthquakes are less well understood because seismic stations are located only at the islands that are linearly arranged; at least 100 km away from the Ryukyu Trench.
We have therefore conducted repeating long-term ocean bottom seismographic observation off the northern part of the Nansei Islands since 2014. First, we deployed three pop-up type ocean bottom seismometers (OBSs) in April 2014. Then, three more OBSs were added to the network in July 2015, and after that deployment and retrieval of OBSs at the same position have been repeatedly carried out every about one year. The station interval is about 40–60 km.
In this study, we focus on regular local earthquakes, particularly seismic clusters beneath the central part of the observation network. In order to obtain key properties of the clusters and to detect missing earthquakes, we apply a matched-filter technique to OBS continuous waveform data. As template event waveforms, we select events determined by Nansei-Toko Observatory for Earthquakes and Volcanoes, Kagoshima University. The hypocenters of the template events are relocated by merging manual pick data of P phases and S phases recorded on the OBSs with those on the onshore stations. As a preliminary result, we achieve detection of missing earthquakes using example template events and a threshold rule based on the median absolute deviation of the mean correlation coefficient. In this presentation, we further discuss the characteristics of waveform similarity of the OBS data.

Seismicity and crustal structure in the Okinawa Trough

*Azusa Nishizawa[1], Takeshi Kimura[1], Kentaro Kaneda[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Japan Coast Guard

The Okinawa Trough is an active backarc basin of the Nansei-Shoto (Ryukyu) island arc–trench system, where the crustal thinning caused by backarc rifting is currently in progress in the entire trough. The characteristics of the seismic activity around the Ryukyu Trench and the Okinawa Trough are not enough investigated due to several reasons; 1) the number of large earthquakes related to the plate subduction along the Ryukyu Trench is not many compared with those in the Nankai Trough and the Japan Trench, 2) the coupling of the plate boundary is considered to be weak, and 3) the sparse distribution of the seismic stations on the Nansei-Shoto island arc makes difficult to obtain enough seismic data in the Ryukyu subduction zone and the Okinawa Trough.

The distribution of the shallow earthquakes in the Okinawa Trough by obtained Japan Metrological Agency during 1923–2018 is spatially inhomogeneous and shows several clusters. The seismic activity in the trough should be related to the seismic crustal structures. Recently, the Japan Coast Guard has reported the detailed seismic structure in the Okinawa Trough. We compared the active seismic areas with the seismic crustal models. The *M*7.1 Satsuma-hanto Seiho-oki Earthquake occurred on Nov. 14, 2015, in the western margin of the northern trough, the transition area between the East China Sea shelf and the Okinawa Trough, where the crust is thinner than the center of the trough with the deepest water. The source mechanisms of the main shock and intense aftershock activity compiled in the NIED (National Research Institute for Earth Science and Disaster Resilience) F-net moment tensor catalog have NW–SE extension axis, indicating that the area is undergoing tectonic rifting.

The largest shallow earthquakes with depths < 30 km observed in the trough is the 1938 Miyako-jima–Hokusei-oki Earthquake (*M*7.2) near the north of Miyako-jima Island and a tsunami with a height of 1.5 m hit Miyako-jima Island. The location of the hypocenter is estimated at the structurally discontinuous area where the northern extension of the Yaeyama Rift, the deepest elongated depression in the Okinawa Trough, meets Miyako Seamount, a fragment of the continental crust of the East China Sea shelf. Active seismicity including three events with $M > 6$ on Apr. 20, 2007 was observed in the Miyako Rift to the north of Miyako Seamount. Multichannel seismic profiles show many normal faults and deformation in sedimentary layers beneath the Miyako Rift. However, the accuracy of hypocenter locations in this region is poor, and the CMT locations are different over 20 km at the maximum between the NIED F-net and Global CMT.

The P-wave velocity models beneath the Okinawa Trough generally show an extended arc crust of the Ryukyu Islands which consists of upper, middle, and lower crusts. Although the crustal thickness becomes thinner from the north to the south, the crust is thicker than those of typical oceanic crusts or backarc basin crusts such as the Shikoku Basin. Therefore, the seismogenic layer in the Okinawa Trough is thicker than in mid-oceanic ridges, indicating that larger earthquakes could occur in the trough.

Time series analyses of the seismic activities in southwestern Japanese Island to southeastern Korean Peninsula excited by the deep fluid heat flow

*Takayuki Kawabe[1]

1. Faculty of Education, Arts and Sciences, Yamagata University

More than eight series of large damaging earthquakes occurred since November 2015 in southwestern Japanese Islands. They are as follows;
1) 2015/11/15 earthquakes of Northwestern margin of Okinawa Trough N31.33050˚, E128.71733˚, Depth: 9.4km, M5.9.
Foreshock: M5.1 (11/14), largest aftershock: M5.5 (2016/05/07).
2) 2016/04/16 2016 Kumamoto Earthquakes N32.75450˚ E130.76300˚, Depth: 12.45km, M7.3.
Foreshock: M6.5 (04/14), M6.4 (04/15), largesrt aftershock: (04/16) M5.9.
3) 2016/09/12 earthquake of Southeastern Korean Peninsula N35.79817˚ E129.27167˚, Depth: 36.0km, M5.8.
Foreshock: M5.2 (40 minutes before), Largest aftershock: M5.2 (2017/11/15).

4) 2016/10/21 earthquake of Central Tottori in 2016 N35.38050˚ E133.85617˚, Depth: 10.61km, M6.6.
Foreshocks: low frequency earthquakes, aftershocks: containing low frequency earthquakes.
5) 2017/11/15 earthquake of Southeastern Korean Peninsula N36.19584˚ E129.39417˚, Depth: 11.0km, M5.6.
6) 2018/02/11 earthquake of Southeastern Korean Peninsula N36.09883˚ E129.45700˚, Depth: 4.0km, M4.6.
7) 2018/04/09 earthquake of Western Shimane Prefecture in 2018 N35.18467˚ E132.58667˚, Depth: 12.13km, M6.1.
8) 2018/06/18 Northern Osaka Earthquake in 2018 N34.84433˚ E135.62167˚, Depth: 12.98km, M6.1.

Positions of the formar four eathquakes and the later four earthquakes shift from the west to the east. The number and scale of the earthquakes of Northwestern margin of Ryukyu Trough is reduced just several days berore the 2016 Kumamoto Earthquakes, and the number and scale of them is just restored after the 2016 Kumamoto Earthquakes. This seems to have a strong relationship between the earthquakes of Northwestern margin of Okinawa Trough and the 2016 Kumamoto Earthquakes. This suggests that such two strongly related earthquakes may be drived by the migration of thermal enargy because the earthquake activities are restored.
Seismic activity contined more than two years in the case of the earthquakes of Southeastern Korean Peninsula and large eathquakes often recured there. Their hypocenters show remarkable distribution. That is to say, they distribute not along any plane but along three dimensionally bent lines. on the lines, earthquakes occurred from the bellow to the upper in the lower to the upper crust. This means that the earthquakes of southeastern Korean Peninsula occurred not in an elastomechanical system but other system as thermal energy. Next earthquakes, just after the earthquakes of southeastern Korean Peninsula, occuring in the central Tottori in 2016 contains large number of low frequency earthquakes through the foreshocks to the aftershocks. The main shock of the ceentral Tottori in 2016 is actually drived by the thermal liquid enargy.
According to such evidences of the liquid flow causing the earthquakes, the large earthquakes occuring in

©2019. Japan Geoscience Union. All Right Reserved.

the upper crust of Southwest Japan would be driven by the eastward transmigrating thermal energy in the upper mantle (Tsunoda et al., 2013).

Integrated monitoring of seismicity in and around the Suruga Bay using Ocean Bottom Seismometers and inland stations.

*Yannis Panayotopoulos[1], Hisatoshi Baba[2], Takahito Nishimiya[3], Taiyo Sotani[4], Nakao Nagisa[4]

1. Association for the Development of Earthquake Prediction, 2. Department of Marine and Earth Science, Tokai University, 3. Meteorological Research Institute, Japan Meteorological Agency, 4. Tokai University

The Suruga bay is located in the western flank of the Izu Peninsula in central Japan. It marks the easternmost boundary of the Nankai trough, of the Philippine Sea plate subduction zone. The Fujikawa fault zone located at the northern tip of the Suruga Bay is considered to be the landward extension of the megathrust boundary between the Philippine Sea plate and the Eurasia plate (e.g.: Yamazaki, 1992). This megathrust boundary produced the M8.4 Ansei-Tokai Earthquake (e.g.: Ishibashi, 1981), and is assumed to be the source region of the next Tokai Earthquake. We closely monitored the seismicity in the vicinity of the Suruga Trough axial region from May, 2018 to September, 2018, using 6 pop-up type Ocean Bottom Seismometers (OBS). In recent years, several moderate size earthquakes have occurred in the Suruga Trough axial region (M6.5 in 2009 and M6.2 in 2011), that resulted in a prominent excitation of seismicity in the area. Using the inland routine observation network alone, those earthquakes are estimated to have occurred on the subduction zone of the Philippine Sea Plate. However, there is a considerable amount of hypocenter depth location error due to the lack of stations in the sea areas.

In this study, we will report the results of the OBSs observations, which enabled us to make more accurate estimations of the frequency and hypocenter depth distribution of the earthquakes occurring in the Suruga Trough axial region.

Linear distribution of the intraslab earthquakes in Tokai

*Sadaomi Suzuki[1]

1. Tono Research Institute of Earthquake Science, Association for the Development of Earthquake Prediction

Figure 1 show an epicenter map of the earthquakes shallower than 60 km in the Tokai area occurring from June 2002 to April 2018. The intraslab earthquakes were shown by yellow, green, or blue small circles, because they occurred in the depth from 30 −50 km. They distribute not homogeneously but linearly as shown in the epicenter map. Elongated ellipses by broken lines show linear distributions (LDs) of the intraslab earthquakes. LD-A and LD-d arranged NW-SE are main distribution in the Tokai area. On the east of them there are small LD-e and LD-f. In contrast LD-B which is arranged NNE from near the port of Nagoya makes an angle of 70° with LD-A. There is small LD-c on the west of LD-B. LD-B and LD-c may be suggested by Miyoshi and Obara (2010a). We studied focal mechanism solutions of 12 earthquakes (Group A) belonging to LD-A and 146 earthquakes (Group B) belonging to LD-B, respectively, using JMA data. We obtained the average values of the azimuths of P- and T-axis for each group as the following. The average values for Group A are 171° and 350° in P-axes and 91° and 256° in T-axes, respectively (see Figure 1). The average values for Group B are 172° and 358° in P-axes and 82° and 254° in T-axes, respectively (see Figure 1). There are no large differences in their corresponding values between Group A and B. This result suggests that there is no large difference in the average stress generating earthquakes between Group A and B. We, therefore, have to consider other reasons for causing those linear distributions.

Figure 2 is a seismological cross section that crosses the Tokai area from NNW to SSE referred from Suzuki et al., 2018. Schematic interpretation of seismic structures including S wave tomography (Nakajima and Hasegawa, 2016) and two earthquake groups consisiting of LFEs and intraslab earthquakes are represented. The most of intraslab earthquakes distributes in the low velocity area of *S* wave in the uppermost oceanic mantle. The relatively low velocities of *S* wave in the subducting oceanic crust and its surrounding areas are interpreted as being indicative of fluids released by progressive metamorphic dehydration reactions in the oceanic crust (e.g., Abers et al., 2013) under increasing temperature and pressure conditions. We suppose that the intraslab earthquakes occur because these fluids penetrate into the uppermost oceanic mantle. Therefore the pore fluids may penetrate from the oceanic crust into not homogeneously but linearly in plane. It is presumed that old fracture zones that had been formed before the Philippine Sea plate subducted below the Tokai area existed at the uppermost oceanic mantle.

The stress change of Chubu region before and after the 2011 Tohoku-oki Earthquake(Mw9.0)

*Yuki Susukida[1], Kei Katsumata[1]

1. Institute of Seismology and Volcanology, Hokkaido University

Great subduction-zone earthquakes occur frequently off coast of the Pacific Ocean in Japan. And the Chubu region (central part of Honshu, Japan) has risk not only subduction-zone earthquake but also inland earthquake. In 1891, Nobi earthquake (M8.0) occurred at Neodani fault system in Chubu region, which is the largest inland earthquake in Japan. (Milne 1893) Furthermore, after Tohoku-oki earthquake, seismicity of northern part of Neodani fault system was activated. (Toda et al, 2011) In this study, I examined effect of Tohoku-oki earthquake on seismicity around the Neodani fault system by inferring of stress change before and after Tohoku-oki earthquake.

At first, I demonstrated the stress field inversion method (Hardebeck & Michael, 2006) by synthetic data to check the performance of this inversion method. As a result, I found that the inversion method will analyze real data well.

Next, I conduct stress field inversion for the joint observation data by eight Universities in Japan and NIED (National Research Institute for Earth Science and Disaster Resilience in Japan) in the Chubu region between 2009 and 2013. As a result, I found the stress field in Neodani fault system didn’ t change significantly before and after Tohoku-oki earthquake.

Repeating earthquake activity off Miyagi Prefecture triggered by the 2011 Tohoku-oki earthquake

*Kenshiro Tsumura[1]

1. Association for Developement of Earthquake Prediction

A remarkable repeating earthquke activity off Miyagi Prefecture tiggered by the 2011 Tohoku-oki earthquake was analized in detail. The epicenters of repeating earthquakes ditributed in a very small area with a diameter of about 1km , centered at 38°38′N and 141°54′E, and with depth 46-49km. The recurrence intervals were about 20 days in the initial period then gradually changed longer, about 100 days in 2018. Magnitude of earthquake was about 4.0 in the initial period then gradually changed smaller, about 3.5 in 2018. For this activity, based on its repeating regularity, mid-term prediction was tried and obtaied good result for a certain period.

Seismic Moments of Inland Small Earthquakes in Japan: Spectral Analyses Using the Hi-net

*Tomotake Ueno[1], Tatsuhiko Saito[1]

1. National Research Institute for Earth Science and Disaster Resilience

Seismic moments and moment magnitudes are one of the most important quantities in characterizing earthquakes. NIED reports moment magnitudes for moderate and large earthquakes (M_W > ~3.5) using the F-net or the KiK-net/K-NET. However, the moment magnitudes of small earthquakes (M_W < 3.5) aren't well determined because of sparse station distributions of the F-net and low sensitivity sensors of the KiK-net/K-NET. These earthquakes' magnitudes are determined using maximum amplitudes of the seismograms of the Hi-net, a dense seismic observations with high-sensitivity sensors. Such high sensitivity seismometers are also used to estimate seismic moments (e.g., Uchide and Imanishi, 2018). This study estimated seismic moments and moment magnitudes for inland earthquakes in Japan using the Hi-net.

We calculated seismic moment for inland earthquakes shallower than 20 km deep with magnitudes from 3 to 4 occurred in 2013 to 2017. Firstly, we calculated a source spectrum from waveform data during 1s before to 9s after the S-wave arrival time. Then, correcting path, site, and the instrumental response, we estimated source spectra. Comparing the observed source spectra with a theoretical one supposing the ω^2 model, we obtained the seismic moment.

The Hi-net detected 455 inland earthquakes with the magnitude from 3 to 4 in 2017. We successfully estimated the seismic moments more than 90 % of those earthquakes. We could estimate the moment magnitudes more than 90 % except 2016. Because the aftershocks of the Kumamoto earthquakes contaminated Hi-net records, we calculated the seismic moments only for 70 % of the 1730 earthquakes in 2016. We compared the moment magnitudes determined by the Hi-net with those by a moment tensor inversion of the F-net. The moment magnitude of Hi-net was smaller than those of the F-net by 0.13±0.11. On the other hand, the magnitude using the maximum amplitude of the Hi-net was larger than the F-net by 0.06±0.21.

Spatiotemporal variations of stress field in the 2016 Kumamoto earthquake (M 7.3) area

*Dapeng Zhao[1], Zhiteng Yu[2], Jiabiao Li[2], Zhouchuan Huang[3]

1. Department of Geophysics, Tohoku University, 2. State Oceanic Administration, 3. School of Earth Sciences and Engineering, Nanjing University

Focal mechanism solutions of 349 local crustal earthquakes and stress tensors in central-north Kyushu are determined using a large number of P-wave polarity data and a 3-D velocity model. The obtained tensional ($\sigma 3$) axis trends NNW-SSE or N-S horizontally, and the compressive ($\sigma 1$) axis trends WSW-ENE or E-W. The direction of the $\sigma 3$ axis is consistent with the spreading direction at the Okinawa Trough. The stress field in the 2016 Kumamoto earthquake area is attributed to rollback of the Philippine Sea plate and northward extension of the Okinawa Trough. The orientation of the $\sigma 3$ axis is quite stable, whereas the $\sigma 1$ and $\sigma 2$ axes are distributed in a wide range. With the 3-D velocity model, the principal stress axes can be better determined by inverting a large number of FMSs. Spatial and temporal variations of the stress field are well revealed in the Kumamoto source area. The $\sigma 3$ axis significantly rotated counterclockwise after the M 6.5 foreshock, and rotated clockwise after the M 7.3 mainshock on the Futagawa fault segment. The stress rotation suggests a small magnitude of deviatoric stress in the source area, which indicates a small friction coefficient on the seismogenic faults. In addition, a generally small value of friction (~0.4) on the faults is obtained by the stress inversions, indicating that the faults in the Kumamoto earthquake area are weak. The fault weakening may be caused by the arc magma and fluids ascending from the mantle wedge associated with the dehydration reactions of the subducting Philippine Sea slab.

Seismicity and crustal deformation following the 2016 Kumamoto earthquakes

*Kazuyoshi Nanjo[1], Jun Izutsu[2], Yoshiaki Orihara[3], Masashi Kamogawa[4], Toshiyasu Nagao[3]

1. University of Shizuoka, 2. Chubu University, 3. Tokai University, 4. Tokyo Gakugei University

The 2016 Kumamoto earthquakes include a magnitude *M*7.3 mainshock that struck April 16, 2016, as well as *M*6-class foreshocks (*M*6.5 and *M*6.4) and many *M*5-class aftershocks. This seismicity that fulfils sections along the Futagawa and Hinagu faults, is still being active. Seismicity and crustal deformation in the Kumamoto region were investigated to get implications of future seismic-activity trends.

We referred our previous work (Nanjo et al., 2016) that examined the spatial and temporal trend in *b* value of the Gutenberg-Richter's law, based on seismicity prior to the Kumamoto earthquakes. For the spatial distribution of *b* values, which shows data for a post-period (January 2017-January 2019), excluding the active aftershock period, we found a zone with low *b* values (130.6-130.8˚E, 32.5-32.6˚N), which lays further to the southwest of the *M*6.5 and *M*6.4 foreshocks along the Hinagu fault. A comparison with the spatial distribution of *b* values calculated for the seismicity from January 2000 to immediately before the Kumamoto earthquakes (Nanjo et al., 2016) reveals a zone where the *b* value decreased. This zone coincides with the low-*b*-value locations seen for seismicity after 2017. We compared the spatial distribution of earthquakes with *M*>5 in the Kumamoto sequence and the *b*-value distribution based on seismicity after 2017. Earthquakes with *M*> 5 have not occurred in the low-*b*-value zone.

While referring previous studies of crustal deformation associated with the Kumamoto earthquakes by GEONET (e.g., Hiyama et al., 2016), we investigated baseline changes of control stations near the Futagawa and Hinagu faults (the period from January 2013 until the end of 2018, with the "Misumi" (Shimane pref.) taken as a fixed station). A step-like change associated with the mainshock occurrence, followed by gradual changes associated with postseismic formation, is seen for all the baselines investigated. The same is true for the control station "Izumi" (130.79˚E, 32.58˚N), located in the low-*b* -value zone identified for seismicity after 2017, although the postseismic deformation is coming to an end. Therefore, active seismicity is expected to continue in the future.

Our method pinpointed the zone of low *b* values along the Hinagu fault, and this is the only one where the *b* value has decreased, compared to before the Kumamoto earthquakes. Nanjo et al. (2016) compared the *b*-value map with the sequence of foreshocks, mainshock, and aftershocks with *M*5 or greater, and showed that areas of low *b* values contained a high percentage (84%) of the sequence. If the *b* value is regarded, for the Kumamoto region, as an indicator for estimating the occurrence location of a relatively large earthquake in the future, the current low-*b*-value zone shows the high likelihood of "seismic gap", a segment considered to suffer a future *M*>5 earthquake.

The unique characters of intensity distribution of the 2018 Sep. 6 Mw6.6 Earthquake of Iburi region in Hokkaido, Japan

*Ritsuko S. Matsu'ura[1], Hiroto Tanaka[2], Mitsuko Furumura[1], Tsutomu Takahama[2]

1. Earthquake Research Center, Association for the Development of Earthquake Prediction, 2. Kozo Keikaku Engineering Inc.

On Sep. 6, 2018, the Mw6.6 (M_{JMA}6.7) earthquake of 35km depth (JMA depth 37km) occurred in the eastern part of Iburi region, Hokkaido, Japan. Waves from this event are characterized by the very high level in high frequency part. Although it is just an Mw6.6 earthquake, and the shortest distance to the land is larger than its depth, Japanese Instrumental Seismic Intensity (JISI) 7 was recorded at Shikanuma station, 43km away from the source. The comparison of observed waves with the various prediction equations of PGV or PGA for Japan, such as Si and Midorikawa(1999) shows that the observation was remarkably larger than most equations in distances less than 50km [e.g. Nishimura and Miyakoshi (2018)].

We applied the new prediction equation of JISI, which was classified by the physical source types, and in which the surface ground effect was removed by the term dependent on AVS30 of each station [Matsu'ura et al. (2018)], to this event. The equation for the PAC-intra type fits well to stations in distances less than 100km, while the equation for the PAC-inter type fits well to further stations in Iwate or southeastern part of Hokkaido (Fig.). It apparently shows the high stress-drop source feature like an event of intra slab, but the abnormal intensity effect due to the PAC is weaker than that of the PAC-intra type, and similar to that of the PAC-inter type. These features are well explained when this Mw6.6 event occurred within the rather cold shallow mantle overriding on the slab on the western foot of Hidaka Mountains. The high frequency waves were transferred very efficiently from the source to the PAC slab like those from interplate events, which suggests that the source lies in fairly homogeous area than the ordinary Japanese crust.

This study was done as a part of the Supporting Project for the Headquarters for Earthquake Research Promotion (HERP) sponsored by the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan.

Determination of Hypocenter Location in Sumani and Sianok Fault Segments, West Sumatra region Using Oct-Tree Importance Sampling Method

*Ade Surya Putra[1], Nanang Tyasbudi Puspito[2], Andri Dian Nugraha[2], Pepen Supendi[3,1]

1. Geophysical Engineering, Faculty of Mining and Petroleoum Engineering, Institute of Technology Bandung, 2. Global Geophysics Research Group, Faculty of Mining and Petroleoum Engineering, Institute of Technology Bandung, 3. Agency of Meteorology, Climatology and Geohysics (BMKG), Indonesia, Bandung, Indonesia

Sumani and Sianok segments are two of the many fault segments in Sumatra Fault Zone (SFZ) that have a considerable history of seismicity and cause significant impacts. An important effort to overcome this problem is the need to analyze tectonic structures in detail through one of them by elaborating an accurate hypocenter location. In this study, we conducted hypocenter determination by using a non-linear approach with the oct-tree importance sampling method through NonLinLoc software by using local velocity components for earthquakes in Sumani and Sianok Segments in the range of 2009-2017. The results of hypocenter determination in this study indicate an improvement in picking arrival time of P and S wave. The increment is denoted by the results of residual picking P and S wave arrival times using oct-tree sampling method that dominant at frequency of 0.1 seconds and there is a correlation between hypocenter location cluster in this study with a location of major earthquakes that have occurred in Sumani and Sianok Segments.

1D Seismic Velocity Modelling and Hypocenter Relocation around Central and East Java Region: Preliminary Result

*Faiz Muttaqy[1], Andri Dian Nugraha[2], Nanang Tyasbudi Puspito[2]

1. Geophysical Engineering Study Program, Faculty of Mining and Petroleum Engineering, Institut Teknologi Bandung,
2. Global Geophysics Research Group, Faculty of Mining and Petroleum Engineering, Institut Teknologi Bandung

Central and East Java are part of Sunda Arc which has relatively high seismicity and complex geological system as a result of Indo-Australian plate that subducted under the Eurasian plate. The early stage of seismic tomography study in order to obtain a reliable geometry about the velocity structure beneath the study area is to define the precise earthquake location and 1D seismic velocity model. In this study, we manually picked P- and S-wave arrival time recorded by BMKG network for the time period from January 2009 to September 2017. We determined the hypocenter location around Central and East Java region by using an NLLoc program. We also conducted a velocity inversion using the VELEST program to obtain an updated 1D velocity model in the study area. Afterward, the hypocenters were relocated using the double-difference algorithm and the updated 1D velocity model to improve the accuracy of the hypocenter locations. Our results indicate that the seismicity around Central and East Java is generally distributed in the southern part of the island, such as in the south of Kebumen, Yogyakarta, Pacitan, Malang, and Banyuwangi that associated with the subduction activity. Moreover, the shallow seismicity is probably controlled by the presence of active inland faults, such as Opak Fault and Kendeng Thrust. As further studies, we will determine the focal mechanism of selected events related to the active inland fault in this region and conduct 3D seismic tomography imaging beneath Central and East Java region.

Seismicity and Tectonics of the Bingöl Area: Eastern Anatolia

*Dogan Kalafat[1]

1. Bogazici University Kandilli Observatory and Earthquake Research Institute Cengelkoy, Istanbul Turkey

In this study, Bingöl Earthquakes which have occurred in recent years have been evaluated from seismological point of view. The Eastern Anatolia Region is the most seismologically deformed area of the Anatolian plate and is under compression due to the relative movement of the Arabian and Eurasian plates in general. The Anatolian plate bounded by the North Anatolian Fault Zone (NAFZ) and Eastern Anatolian Fault Zones (EAFZ) moves relatively westward. Bingöl Earthquakes are located within the Eastern Anatolian Fault Zone and this fault zone occurs due to the movement of the parts. Bingöl and the surrounding area is the most active regions in Turkey in terms of seismicity. The most important earthquakes in Bingöl during the instrumental period were the 1971 and 2003 earthquakes. Bingöl Fault starts from the south of Bingöl and extends along the Göynuk stream valley. This fault length is about 75 km. which is northern part of the Eastern Anatolian Fault Zone and joins the North Anatolian Fault Zone after passing through the villages of Serpmekaya and Sakaören. During the 1971 Bingöl Earthquake, about 38 km surface rupture occured which it started from Ormanardi to the southeast of Bingöl and extends to the N45ºE degree in the southwestern direction of Goynuk. The observed faults showed a strike-slip and a left lateral movement and the fault plane solutions supported the field observations.
The other important earthquake occurred on May 1, 2003. In this earthquake, 176 citizens were killed and 521 citizens were injured in various places. In particular, public buildings were severely damaged. The episantr area is between the Balikcay village plateau, Hanocayiri-Kurtulus and Sudugunu Plateau. Stepped fractures with NW-SE trending N20-30ºW trending were observed in Hanocayiri, which is one of the closest settlements of earthquake. As a result of earthquake, a great deal of collapses and mud currents were formed due to the effect of groundwater pressure. The fault traces in the region continued on the slopes of the NW-SE trending Kade mountains. Liquefaction, sitting, collapse and faulting samples were seen together in Hanocayiri hamlet. The earthquake caused severe damage, destruction and death in the buildings located on the alluvial terrace of Göynuk Creek in Bingöl province. During the earthquake, the Celtiksuyu Boarding School of Bingöl province was completely destroyed and 84 students died under the rubble. In addition, many public buildings were damaged. The macroseismic epicenter of the earthquake is approximately 12 km. distance between the district of Elcagini-Elmacayiri and Sudugunu plateaus. The area is mountainous and there are no frequent settlements. The nearest settlements are Balikcay, Hanocayiri Village, Elmacayiri village and Kurtulus village. It was observed that the epicenter of Bingöl Earthquake was highly compatible with the NW-SE trending faults. The fault of N-NW, which passes between Kurtulus-Elmacayiri-Hanocayiri and towards the Balikcay-Cimenli villages, was defined as the fault which was broken by the 2003 Bingöl Earthquake. In this study, 12 earthquakes fault plane solutions have given (magnitude Mw> 5.0) between 1971-2015 time period in Bingöl. The fault plane solution of 6 earthquakes was conducted within the scope of the study. The stress analysis shows that the dominant stress axes in the region are dominated by NW-SE directional compression and strike-slip faulting which are characterized by NE-SW extension axes.
The recent earthquakes showed that the ongoing deformation in the region continued with the strike-slip fault systems as the dominant. Structural heavy damages caused by earthquakes were mostly due to poor soil conditions, improper production, low quality and missing materials.

Seismicity along the North Anatolian Fault beneath the Marmara Sea, deduced from long-term ocean bottom seismographic observations

*Yojiro Yamamoto[1], Narumi Takahashi[2,1], Dogan Kalafat[3], Ali Pinar[3], Remzi Polat[3], Zeynep Coskun[3], Haluk Ozener[3], Yoshiyuki Kaneda[4]

1. Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 2. NIED, 3. KOERI, Bogaziti University, 4. Kagawa University

The North Anatolian Fault (NAF) beneath the Marmara Sea is recognized as a seismic gap for M >7 earthquake during more than 100 years. Earthquake hazard and disaster mitigation studies in Marmara region are sensitive to detailed information on fault geometry and its coupling status beneath the Marmara Sea. Although hypocenter distribution could help us to estimate them, it is difficult to obtain precise hypocenter location from only onshore permanent seismic stations. Thus, we have started a series of long-term ocean bottom seismographic (OBS) observations beneath the western and central Marmara Sea since 2014. We have installed 10~15 OBSs along the Main Marmara Fault(MMF) for each observation phases, and observation length is about 10 or 11 months. Based on the first phase observation, conducted from 2014 to 2015, Yamamoto et al. (2017) identified a segment boundary of the MMF beneath the central basin of the Marmara Sea (28.05˚E). Besides, they proposed that the zones of no seismicity within the upper crust appear to indicate locked sections of the MMF.
In this study, we analyze the second (from 2015 to 2016) and third phases (from 2016 to 2017) observation data. The OBS distribution of second phase is same as first phase,whereas that of third phase is about 20 km shifted to eastward relative to first and second phases. The tentative result shows that the feature of hypocenter distribution, including the location of no seismicity zones obtained by Yamamoto et al. (2017), is not changed for all phases, suggesting that the coupling status along the fault is almost same during at least three years. In the west of 28.05˚E, seismicity located not only the upper but also lower crust. On the other hand, the lower limit of the seismogenic zone in the east of 28.05˚E is about 15 km, shallower than the Conrad discontinuity. The largest no seismicity zone extended over the upper crust is located between 28.45˚E and 28.65˚E, where strong coupling is suggested from seafloor geodetic observation (Sakic et al., 2016).
According to the spatial relationship between the epicenter of microearthquakes and fault trace on the sea floor (Armijo et al., 2005) suggests that the MMF around 28.75˚E is near vertical to slightly northward dipping. Since previous study indicates that the east of 28.05˚E MMF is southward dipping (Yamamoto et al., 2017), there might be another segment boundary west of 28.75˚E. We also find an active seismic cluster around 40.8˚N, 28.7˚E, 14 km depth. There is a possibility that this cluster relates to the southern branch of NAF.

Microseismic Monitoring of the Sultandagi Fault Zone: Western Turkey

*Dogan Kalafat[1], Yavuz Gunes[1], Mehmet Kara[1], Kivanc Kekovali[1]

1. Bogazici University Kandilli Observatory and Earthquake Research Institute Cengelkoy, Istanbul Turkey

Western Turkey is one of the seismically active region in Turkey. The high seismic activity is a result of the complex tectonic deformation of the Anatolian plate which has been dominated by the N–S extensional tectonic regime in the western edge. In western Turkey, relatively 3 major earthquakes (Mw≧6.0) were identified on the Sultandagi Fault Zone (Afyon-Aksehir Graben) between years of 2000–2002. In this study, mentioned local earthquake activity, have been investigated to understand their nature and relation of the regional seismic activity and tectonic deformation on the Sultandagi Fault Zone (SFZ) in western Turkey. Due to these activities along the SFZ it is decided to monitor microseismic activity (M<2.5) by establishing low-magnitude threshold seismic network. For this purpose, 3 new broadband (BB) seismic stations were temporarily established to control the northern part of the Sultandagi Fault Zone, and the micro-seismicity of the fault zone was started to be observed in July 2017. Thus, the earthquake activity in the region started to be monitored sensitively. So we started to get 2 times more earthquakes than permanent stations in the region. The one of the biggest primary outcome by this study that there is a significant microseismic activity (M<2.5) at the SFZ which was not seen from prior studies and long-term seismicity catalogues from permanent network (M>2.5). At first, we started to analyze the distribution of micro-earthquakes in the region. During the data analysis, it was predicted that some intensive micro-earthquake activity in the project area could be caused by quary-blasting and some locations were visited during the field study. Relocation of common earthquakes recorded by KOERI and the study was carried out, and the earthquake epicenters were displaced approximately as ±0.8–6 km. There were also some positive changes in the depth distribution of earthquakes. Consequently, thanks to the stations established within the scope of the study, horizontal (distance) and vertical error (depth) margins of the events in the region have been reduced. As a result of the evaluation of the data obtained, it was observed that the Sultandagi Fault Zone has especially intense seismic activity in the middle and northwest part. In addition, a significant seismic activity was observed in NW-SE direction at the north of Isparta city .
This research is funded by Bogazici University Research Fund within the scope of Project Number 12280. We thank to Bogazici University Research Fund Commission and members.

Analysis of radiated seismic energy distributing in aftershock sequences at the Guerrero, Mexico subduction zone.

*Raymundo Omar Plata Martinez[1], Xyoli Pérez Campos[2], Krishna Shri Singh[2]

1. Kyoto University, 2. Geophysics Institute, UNAM

Radiated seismic energy is valuable parameter in seismic source studies, as it can be a good criterion to evaluate earthquakes size but also very useful to analyze the dynamics of the rupture process. Significant large thrust earthquakes have occurred over the last decades at the Mexican, subduction zone, however just a few researches have been done to understand the distribution of seismic energy release in the area. For this purpose, we calculated source spectra to estimate radiated seismic energy of three large earthquakes and their aftershocks (*M* larger than 4.0) in the Guerrero segment of the Mexican subductions zone; the 2012 Ometepec-Pinotepa Nacional (*Mw* 7.5), the 2014 Papanoa (*Mw* 7.2) and the 2018 Pinotepa Nacional (*Mw* 7.2) earthquakes. We found a mean value of the log of radiated seismic energy scaled with the seismic moment (Mo/Es) of -5.05 ±0.25, as well as, regional estimations tend to be higher than the teleseismic estimations by a factor of 1.3 to 6.3. A small dependence of scaled seismic energy with distance from the trench was seen, however distribution of seimsic energy seems to be spatially heterogeneous along the trench. We found four different regions with characteristic behaviors in energy release. One of the regions reveals recurrent low energies with possible slow rupturing close to the trench. Opposingly, high energy seismicity was present, adjacent to the Guerrero gap, which has not had a large earthquake in over 115 years. This suggests that radiated seismic energy can be highly influenced by complexities at the plate interphase, variations on the shear strength and/or coupling at the interface where seismic slip interacts over previous rupture patches.

[J] Poster | S (Solid Earth Sciences)：S-SS Seismology

Tue. May 28, 2019 5:15 PM - 6:30 PM JST | Tue. May 28, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_29

[S-SS10] Seismicity

convener:Kei Katsumata(Institute of Seismology and Volcanology, Hokkaido University)

This session aims to improve our understanding on seismicity. Any contribution on behavior of earthquakes as a cluster, such as regional seismicity and aftershocks, are welcomed. We also welcome contribution on temporal and spatial interactions that control seismicity, and tectonic processes, and geological and thermal structures that regulate seismicity.

Spatial-temporal and seismogram characteristics of foreshock and aftershock activities for tsunami earthquakes

*Yifeng Liu[1], Yoshihiro Ito[2], Kazuaki Ohta[2], Satoshi Katakami[1]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, 2. Disaster Prevention Research Institude, Kyoto University

A tsunami earthquake is an abnormal earthquake type causing a large tsunami compared to the magnitude measured by short-period seismic waves. There is a high risk to induce a massive tsunami damage for the reason that people who live in the coastal area do not feel quakes a lot, and it is difficult to keep themselves safe after the unusual earthquake happened. Additionally, as for the tsunami earthquakes, their observation cases are much fewer than ordinary earthquakes, so the mechanism of its occurrence is still an open question. To address spatio-temporal features and the mechanism of tsunami earthquakes, we focus on three typical examples of tsunami earthquake and their foreshock & aftershock sequences, which are (Nicaragua (1992/09/02, Mw 7.7), Jawa island (2006/07/17, Mw 7.7) and Mentawai (2010/10/25, Mw 7.8)). We also investigated whether a small earthquake showing the same characteristics as the tsunami earthquake is contained in the foreshock and aftershock activity.

First, we use seismic catalogs and waveform recording provided by ISC/USGS and IRIS respectively to extract the foreshock and aftershock activity, then evaluate the spatio-temporal features. We have found that four foreshock sequences (1992/08/10 06:09:20 Mb 5.2, 1992/08/10 06:34:14 Mb4.7, 1992/08/11 05:23:51 Mb 5.1, 1992/08/13 08:41:17 Mb 4.7) near the epicenter of mainshock area were observed before the occurrence of the Nicaragua mainshock. We have also analyzed the regional and spatio-temporal characteristics of three tsunami earthquake regions by dividing the area of 5*5 around the epicenter into twenty-five segments with the size of 1*1. As a result, in each of the three regions, we have found out that there is a seismic quiescence period in the vicinity of the mainshock area in each tsunami earthquake. Meanwhile, regarding aftershocks of the Nicaragua earthquake, seismic quiescence area is still detected in the same segment as the foreshock.

Migration phenomenon is observed in the foreshock activity near the focal region of the mainshock, especially before the mainshock of the Nicaragua earthquake. Meanwhile, the waveforms of aftershocks occurring in the same area as the events included in the migration have been compared with those of the mainshock. Next, we have calculated the ratio of maximum absolute amplitude of surface wave to that of body wave, in order to address features on waveforms of tsunami earthquake. As a result, the ratio of the mainshock, such as the tsunami earthquake shows extremely high value, whereas for the foreshocks and aftershocks, it does not show the same characteristic as the tsunami earthquake does. This suggests that small earthquakes occurring within the tsunami seismogenic region show the same phenomenon as ordinary earthquakes, but only the mainshock has the characteristics of the tsunami earthquake.

Successively occurring large earthquakes in the world –comparison of real cases with expectations by the space-time ETAS

*Tetsuo Hashimoto[1], Takashi YOKOTA[2]

1. Seismology and Tsunami Research Department, Meteorological Reaserch Institute, 2. Aichi Institue Technology

In the government for evaluating criteria on abnormal phenomena along the Nankai Trough for disaster prevention measures, they made the criteria for events to announce the Nankai Trough Earthquake Information. In order to implement specific ways of disaster prevention, they discussed about specific criteria for what kind of phenomenon corresponds to the abnormal event. In this time, we presented the real cases of the successive occurrence of large earthquakes in the world on the newly revised ISC-GEM version 5.1 data (1904-2014) for contributing to the above discussion. And we estimated the large earthquakes occurrence by using the space-time ETAS (Ogata and Zhuang, 2006).The 103 earthquakes of Mw 8.0 over were extracted about the earthquakes in the world for about the last 100 years. There were 9, 10 and 13 earthquakes which were accompanied with the earthquake of Mw 7.8 over occurred within the epicentral distances 500 km within 3 days, 7 days and 30 days, respectively.We estimated occurrences earthquakes from summations of expectations by the space-temporal ETAS which was applied with the parameters around Japan of Ogata and Zhaung (2006) and b=0.92 estimated with the JMA earthquake catalog. And then there were 5.3, 6.5 and 8.0 earthquakes of Mw 8 over which accompanied to the earthquake of Mw 7.8 over within the epicentral distances 500km within 3days, 7days and 30 days, respectively.The expected frequency of occurrence and the decreasing trend accompanying the elapsed time since the preceding earthquake were generally consistent with the above actual case.Acknowledgment: We used ISCGEMver 5.1 from ISC. In addition, we received great cooperation from the Earthquake Prediction and Information Division, Seismology and Volcanology Department, Japan Meteorological Agency.

Seismicity beneath stable oceanic plate

*Yasushi Ishihara[1]

1. R&D Center for Earthquake and Tsunami, JAMSTEC

Stable oceanic plate has low seismic activity generally. Real tectonic deformation is also stable? To survey this topics, high quality and long-term observation. Pacific21 broadband seismic network deploys stations in Micronesia area. At present five islands station are under operation. Two of all have already telemetered to our data center via internet connection and transfer to other organization and institute.
In this year new telemeter station (station code: CHUK) is completed successfully. Chuuk (Truk) island locates on old oceanic plate about 900-1,000km southeast of Mariana trench and Guam. CHUK station locates inside deep tunnel made in more than 70 years ago, WWII era. The site condition is fine in basalt mountain, under stable temperature and on rigid floor. We deployed STS-2 broadband sensor in sensor room, high-resolution data logger and stable power supply system. CHUK station will contribute monitor and location of earthquake around Mariana trench and outer rise area.
Though CHUK station locates in small oceanic island and records strong ocean microseism, background noise level is lower level than standard model. CHUK station is excellent site to monitor including small local earthquake. CHUK station operates for about four years. We review continuous data and pick up local regional seismic events. Not only outer rise region but also Chuuk island area and hidden tectonic zone has active seismicity. By trial analysis, depth of these seismic events is beneath 20km. It implies stress concentration in oceanic plate and its deformation.

Relation between long-term slow slip events and correlation between tidal triggering effect and deep low-frequency earthquakes in Bungo Channel: Part 2

*Fuyuki Hirose[1], Akio Kobayashi[1], Kenji Maeda[2]

1. Seismology and Tsunami Research Department, Meteorological Research Institute, 2. Seismology and Volcanology Department, Japan Meteorological Agency

Long-term slow slip events (LSSEs) have occurred with the interval of 5-6 years beneath the Bungo Channel [e.g., Kobayashi, 2017, EPS]. Deep low-frequency tremors and earthquakes (LFEs) have synchronized with the LSSEs and have activated [Hirose et al., 2010, Science]. It is pointed out that tremors have high tidal correlation [Ide, 2010, Nature; Ide & Tanaka, 2014, GRL]. There is no study that investigated long-term changes of the tidal correlation of LFEs.
On the other hand, the correlation between regular seismicity and tide also have been investigated energetically, and then there is a report that the tidal correlation became higher before the large earthquake around the focal region and became lower after the mainshock [e.g., Tanaka et al., 2012, GRL]. In addition, it is also pointed out that a leading period of high tidal correlation corresponded with the magnitude of a following earthquake.
Accordingly, we investigated temporal changes of tidal correlation of LFEs before and after LSSEs beneath the Bungo Channel on the analogy of tidal correlation of background seismicity before and after large earthquakes.
We extracted LFEs from the earthquake catalog unified by Japan Meteorological Agency (JMA) that occurred beneath the Bungo Channel from 2000 to March 21, 2018. Accuracy of locations of LFEs is lower than that of regular earthquakes. Note that hypocenter determination method for LFE by JMA changed since March 22, 2018, and then detection level also changed at the border. Taking int consideration that the change is not suitable in order to investigate long-term changes of tidal correlation of LFEs, we selected LFEs data.
It is necessary to set fault parameters in order to estimate the theoretical below-ground tidal response. Because our study area was narrow area with 15 km square, we set one fault plane (strike angle 237˚, dip angle 16˚, and rake angle 103˚) taking into consideration the plate configuration [Hirose et al., 2008, JGR] and MT solutions of deep very LFEs [Ide & Yabe, 2014, GRL]. In addition, we set hypocenters of LFEs to the common location (longitude 132.254˚, latitude 33.142˚, and depth 32 km). We used only occurrence times of LFEs determined by the JMA.
We summed temporal variations of the solid and oceanic tide loading effects for six independent components of the strain tensor, as estimated at the hypocenter of each event. Then we converted them to temporal variations of volumetric strain (ΔV) at the hypocenter, and shear stress ($\Delta\tau$), normal stress ($\Delta\sigma$), and the Coulomb failure function (ΔCFF) on the assumed fault plane. In the ΔCFF calculation, we assumed values of 0.1, 0.4, and 0.7 for the apparent friction coefficient μ'. In the case of ΔV and $\Delta\sigma$, we defined expansion/dilatation as positive and contraction/compression as negative; consequently, positive $\Delta\sigma$ values promote fault slip. We also defined $\Delta\tau$ and ΔCFF as positive when they promote fault slip. Using the time series of tidal stress (strain) levels, we assigned phase angles of −180˚ and 180˚ to the minimum tidal stress (strain) levels before and after an event, respectively, and 0˚ to the maximum tidal stress (strain) that occurred between these two minima. The phase angle at the earthquake occurrence time was estimated by linear interpolation in the time interval between −180º and 0˚ or between 0˚ and 180˚. The possible occurrence of LFEs at certain tidal phase angles was evaluated using the *p* value, as

©2019. Japan Geoscience Union. All Right Reserved.

calculated by Schuster [1897].
We found that LFEs tended to occur near a tidal phase angle of 0° for $\Delta\tau$ (when the tidal force promoted fault slip). This result indicates extremely low μ' and high pore pressure, being consistent with the existence of fluid inferred from the seismic velocity structure [Hirose et al., 2008]. LSSEs occurred three times (in 2003-2004, 2009-2011, and 2014) during the study period. Temporal changes of *p* value showed to tend to become lower before the LSSEs and become higher after ones (Tidal correlation tended to become higher before the LSSEs and become lower after ones). This result is similar to temporal changes of *p* value for background seismicity before and after large earthquakes. Accordingly, temporal tidal correlation of LFEs indicates to be affected by stress perturbation associated with LSSEs. Note that *p* value at March in 2018 falls to a level just before past LSSEs.

Arrival-time and hypocenter determination using S-net

*Tomomi Okada[1], Ryota Takagi[1], Takashi NAKAYAMA[1], Syuichi Suzuki[1], Ryosuke Azuma[1], Genti Toyokuni[1], Keisuke Yoshida[1], Naoki Uchida[1], Ryota Hino[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

Hypocenter distribution is basic information for understanding seismogenesis.
For east off Honshu from Hokkaido, Tohoku, Kanto, S-net has been deployed by NIED. S-net is expected to improve accuracy of hypocenter location. In this study, we show a preliminary result of hypocenter determination using S-net and onshore stations.
We used hypomh (Hirata and Matsu’ura (1984)) with seismic velocity structure of Hasegawa et al. (1978). In our case, we used waveform converted to vertical, north-south, east-west components by Takagi et al. (this meeting).
For the earthquake near coast line, we can determine reliable hypocenter location, which is correspond to the location determined by F-net CMT or AQUA catalog. However, large travel time residuals over 3 seconds earlier are estimated for distant stations including the stations east of trench. This would mainly be due to the high velocity Pacific plate (e.g., Toyokuni et al., this meeting). To improve the velocity structure and use station correction are necessary for further study.

Acknowledgements: We used S-net, Hi-net and stations by universities (Hokkaido, Hirosaki, Tokyo and others), Aomori and Tokyo Pref., ADEP (Association for the development of earthquake prediction) and JMA. Profs. Matsuzawa, Zhao, Umino and Hasegawa and Mr. Hirahara give us valuable suggestions.

Focal mechanisms of the double seismic zone in the Pacific plate, off Boso: Temporal change after the 2011 Tohoku EQ

*Guanyu Chen[1], Toshinori Sato[2], Tomoharu Sato[1], Asami Terada, Masanao Shinohara[3], Kimihiro Mochizuki[3], Tomoaki Yamada[3], Kenji Uehira[4], Takashi Shimbo[5], Shuichi Kodaira[5], Yuya Machida[5], Ryota Hino[6], Ryosuke Azuma[6], Yoshio Murai[7], Yoshihiro Ito[8], Hiroshi Yakiwara[9], Kenji Hirata[4], Akinori Hashima[3], Andrew M. Freed[10]

Institute of Seismology and Volcanology, Faculty of Science, Hokkaido University, 8. Disaster Prevention Research Institute, Kyoto University, 9. Nansei-toko Observatory for Earthquakes and Volcanoes, Kagoshima University, 10. Purdue University

1. Introduction

The Pacific plate and the Philippine Sea plate subduct off the Boso Peninsula, and the Pacific plate has a double seismic zone at this place (e.g. Terada et. al., JpGU, 2016). Sato et. al. (JpGU, 2018) revealed that most focal mechanisms for the lower surface events have down-dip extension before the 2011 Tohoku EQ, and down-dip compression during 3 months after the EQ using land and ocean bottom seismic observations. This presentation shows 1 year temporal change of focal mechanisms for the double seismic zone’ s events after the 2011 Tohoku EQ.

2. Data and analysis

The used data are waveform data from Hi-net by NIED, and the aftershock survey of the 2011 Tohoku EQ using ocean bottom seismometers (2011/3/15-2012/3/31). We select events in the double seismic zone, and pick polarities of the P wave first motions. We calculate emergent azimuth and dip of each event-receiver pair using a 3D structure determined by Terada et al. (JpGU, 2016), and search optimal focal mechanisms using a grid search method.

3. Results

During 1 year after the 2011 Tohoku EQ, most focal mechanisms have down-dip compression for the upper surface events. For the lower surface events, on the other hand, most focal mechanisms have down-dip compression by July, 2011, and many mechanisms have down-dip extension after September, 2011. This may indicate that a compressional stress change occurred at the depth of the Pacific plate just after the 2011 Tohoku EQ, because the EQ moved the Pacific plate downward at the shallower part, and compressed the deeper part of the plate. After that, the compressional stress may had relaxed about a half a year.

Acknowledgements

We thank captains and crew of aftershock observation cruises of the 2011 Tohoku Earthquake. We used waveform data from Hi-net by NIED.

Ocean bottom seismographic observation and similar earthquake detection in the northern part of the Nansei Islands

*Yukihiro Nakatani[1], Hiroshi Yakiwara[1], Shuichiro Hirano[1], Reiji Kobayashi[2], Hiroki Miyamachi[2], Shigeru Nakao[2], Kazunari Uchida[3], Takeshi Matsushima[3], Hiroshi Shimizu[3], Kazuo Nakahigashi[4], Yusuke Yamashita[5], Hideji Abe[6], Tomoaki Yamada[6], Masanao Shinohara[6]

1. Nansei-Toko Observatory for Earthquakes and Volcanoes, Kagoshima University, 2. Graduate School of Science and Engineering, Kagoshima University, 3. Institute of Seismology and Volcanology, Faculty of Science, Kyushu University, 4. Tokyo University of Marine Science and Technology, 5. Disaster Prevention Research Institute, Kyoto University, 6. Earthquake Research Institute, the University of Tokyo

The Ryukyu Trench subduction zone is seismically active region. In the northern part of the Nansei Islands, both seismic and aseismic events have occurred along the subducting plate interface. Spatial distribution of small local earthquakes in this region seems to show some seismic clusters and gaps. Short-term slow slip events and shallow low-frequency tremors have been also observed by recent onshore seismic and geodetic data. However, patterns of their slip behavior and spatiotemporal relationship between regular and slow earthquakes are less well understood because seismic stations are located only at the islands that are linearly arranged; at least 100 km away from the Ryukyu Trench.
We have therefore conducted repeating long-term ocean bottom seismographic observation off the northern part of the Nansei Islands since 2014. First, we deployed three pop-up type ocean bottom seismometers (OBSs) in April 2014. Then, three more OBSs were added to the network in July 2015, and after that deployment and retrieval of OBSs at the same position have been repeatedly carried out every about one year. The station interval is about 40–60 km.
In this study, we focus on regular local earthquakes, particularly seismic clusters beneath the central part of the observation network. In order to obtain key properties of the clusters and to detect missing earthquakes, we apply a matched-filter technique to OBS continuous waveform data. As template event waveforms, we select events determined by Nansei-Toko Observatory for Earthquakes and Volcanoes, Kagoshima University. The hypocenters of the template events are relocated by merging manual pick data of P phases and S phases recorded on the OBSs with those on the onshore stations. As a preliminary result, we achieve detection of missing earthquakes using example template events and a threshold rule based on the median absolute deviation of the mean correlation coefficient. In this presentation, we further discuss the characteristics of waveform similarity of the OBS data.

Seismicity and crustal structure in the Okinawa Trough

*Azusa Nishizawa[1], Takeshi Kimura[1], Kentaro Kaneda[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Japan Coast Guard

The Okinawa Trough is an active backarc basin of the Nansei-Shoto (Ryukyu) island arc–trench system, where the crustal thinning caused by backarc rifting is currently in progress in the entire trough. The characteristics of the seismic activity around the Ryukyu Trench and the Okinawa Trough are not enough investigated due to several reasons; 1) the number of large earthquakes related to the plate subduction along the Ryukyu Trench is not many compared with those in the Nankai Trough and the Japan Trench, 2) the coupling of the plate boundary is considered to be weak, and 3) the sparse distribution of the seismic stations on the Nansei-Shoto island arc makes difficult to obtain enough seismic data in the Ryukyu subduction zone and the Okinawa Trough.

The distribution of the shallow earthquakes in the Okinawa Trough by obtained Japan Metrological Agency during 1923–2018 is spatially inhomogeneous and shows several clusters. The seismic activity in the trough should be related to the seismic crustal structures. Recently, the Japan Coast Guard has reported the detailed seismic structure in the Okinawa Trough. We compared the active seismic areas with the seismic crustal models. The *M*7.1 Satsuma-hanto Seiho-oki Earthquake occurred on Nov. 14, 2015, in the western margin of the northern trough, the transition area between the East China Sea shelf and the Okinawa Trough, where the crust is thinner than the center of the trough with the deepest water. The source mechanisms of the main shock and intense aftershock activity compiled in the NIED (National Research Institute for Earth Science and Disaster Resilience) F-net moment tensor catalog have NW–SE extension axis, indicating that the area is undergoing tectonic rifting.

The largest shallow earthquakes with depths < 30 km observed in the trough is the 1938 Miyako-jima–Hokusei-oki Earthquake (*M*7.2) near the north of Miyako-jima Island and a tsunami with a height of 1.5 m hit Miyako-jima Island. The location of the hypocenter is estimated at the structurally discontinuous area where the northern extension of the Yaeyama Rift, the deepest elongated depression in the Okinawa Trough, meets Miyako Seamount, a fragment of the continental crust of the East China Sea shelf. Active seismicity including three events with $M > 6$ on Apr. 20, 2007 was observed in the Miyako Rift to the north of Miyako Seamount. Multichannel seismic profiles show many normal faults and deformation in sedimentary layers beneath the Miyako Rift. However, the accuracy of hypocenter locations in this region is poor, and the CMT locations are different over 20 km at the maximum between the NIED F-net and Global CMT.

The P-wave velocity models beneath the Okinawa Trough generally show an extended arc crust of the Ryukyu Islands which consists of upper, middle, and lower crusts. Although the crustal thickness becomes thinner from the north to the south, the crust is thicker than those of typical oceanic crusts or backarc basin crusts such as the Shikoku Basin. Therefore, the seismogenic layer in the Okinawa Trough is thicker than in mid-oceanic ridges, indicating that larger earthquakes could occur in the trough.

Time series analyses of the seismic activities in southwestern Japanese Island to southeastern Korean Peninsula excited by the deep fluid heat flow

*Takayuki Kawabe[1]

1. Faculty of Education, Arts and Sciences, Yamagata University

More than eight series of large damaging earthquakes occurred since November 2015 in southwestern Japanese Islands. They are as follows;
1) 2015/11/15 earthquakes of Northwestern margin of Okinawa Trough N31.33050˚, E128.71733˚, Depth: 9.4km, M5.9.
Foreshock: M5.1 (11/14), largest aftershock: M5.5 (2016/05/07).
2) 2016/04/16 2016 Kumamoto Earthquakes N32.75450˚ E130.76300˚, Depth: 12.45km, M7.3.
Foreshock: M6.5 (04/14), M6.4 (04/15), largesrt aftershock: (04/16) M5.9.
3) 2016/09/12 earthquake of Southeastern Korean Peninsula N35.79817˚ E129.27167˚, Depth: 36.0km, M5.8.
Foreshock: M5.2 (40 minutes before), Largest aftershock: M5.2 (2017/11/15).

4) 2016/10/21 earthquake of Central Tottori in 2016 N35.38050˚ E133.85617˚, Depth: 10.61km, M6.6.
Foreshocks: low frequency earthquakes, aftershocks: containing low frequency earthquakes.
5) 2017/11/15 earthquake of Southeastern Korean Peninsula N36.19584˚ E129.39417˚, Depth: 11.0km, M5.6.
6) 2018/02/11 earthquake of Southeastern Korean Peninsula N36.09883˚ E129.45700˚, Depth: 4.0km, M4.6.
7) 2018/04/09 earthquake of Western Shimane Prefecture in 2018 N35.18467˚ E132.58667˚, Depth: 12.13km, M6.1.
8) 2018/06/18 Northern Osaka Earthquake in 2018 N34.84433˚ E135.62167˚, Depth: 12.98km, M6.1.

Positions of the formar four eathquakes and the later four earthquakes shift from the west to the east. The number and scale of the earthquakes of Northwestern margin of Ryukyu Trough is reduced just several days berore the 2016 Kumamoto Earthquakes, and the number and scale of them is just restored after the 2016 Kumamoto Earthquakes. This seems to have a strong relationship between the earthquakes of Northwestern margin of Okinawa Trough and the 2016 Kumamoto Earthquakes. This suggests that such two strongly related earthquakes may be drived by the migration of thermal enargy because the earthquake activities are restored.
Seismic activity contined more than two years in the case of the earthquakes of Southeastern Korean Peninsula and large eathquakes often recured there. Their hypocenters show remarkable distribution. That is to say, they distribute not along any plane but along three dimensionally bent lines. on the lines, earthquakes occurred from the bellow to the upper in the lower to the upper crust. This means that the earthquakes of southeastern Korean Peninsula occurred not in an elastomechanical system but other system as thermal energy. Next earthquakes, just after the earthquakes of southeastern Korean Peninsula, occuring in the central Tottori in 2016 contains large number of low frequency earthquakes through the foreshocks to the aftershocks. The main shock of the ceentral Tottori in 2016 is actually drived by the thermal liquid enargy.
According to such evidences of the liquid flow causing the earthquakes, the large earthquakes occuring in

©2019. Japan Geoscience Union. All Right Reserved.

the upper crust of Southwest Japan would be driven by the eastward transmigrating thermal energy in the upper mantle (Tsunoda et al., 2013).

Integrated monitoring of seismicity in and around the Suruga Bay using Ocean Bottom Seismometers and inland stations.

*Yannis Panayotopoulos[1], Hisatoshi Baba[2], Takahito Nishimiya[3], Taiyo Sotani[4], Nakao Nagisa[4]

1. Association for the Development of Earthquake Prediction, 2. Department of Marine and Earth Science, Tokai University, 3. Meteorological Research Institute, Japan Meteorological Agency, 4. Tokai University

The Suruga bay is located in the western flank of the Izu Peninsula in central Japan. It marks the easternmost boundary of the Nankai trough, of the Philippine Sea plate subduction zone. The Fujikawa fault zone located at the northern tip of the Suruga Bay is considered to be the landward extension of the megathrust boundary between the Philippine Sea plate and the Eurasia plate (e.g.: Yamazaki, 1992). This megathrust boundary produced the M8.4 Ansei-Tokai Earthquake (e.g.: Ishibashi, 1981), and is assumed to be the source region of the next Tokai Earthquake. We closely monitored the seismicity in the vicinity of the Suruga Trough axial region from May, 2018 to September, 2018, using 6 pop-up type Ocean Bottom Seismometers (OBS). In recent years, several moderate size earthquakes have occurred in the Suruga Trough axial region (M6.5 in 2009 and M6.2 in 2011), that resulted in a prominent excitation of seismicity in the area. Using the inland routine observation network alone, those earthquakes are estimated to have occurred on the subduction zone of the Philippine Sea Plate. However, there is a considerable amount of hypocenter depth location error due to the lack of stations in the sea areas.

In this study, we will report the results of the OBSs observations, which enabled us to make more accurate estimations of the frequency and hypocenter depth distribution of the earthquakes occurring in the Suruga Trough axial region.

Figure 1 show an epicenter map of the earthquakes shallower than 60 km in the Tokai area occurring from June 2002 to April 2018. The intraslab earthquakes were shown by yellow, green, or blue small circles, because they occurred in the depth from 30 −50 km. They distribute not homogeneously but linearly as shown in the epicenter map. Elongated ellipses by broken lines show linear distributions (LDs) of the intraslab earthquakes. LD-A and LD-d arranged NW-SE are main distribution in the Tokai area. On the east of them there are small LD-e and LD-f. In contrast LD-B which is arranged NNE from near the port of Nagoya makes an angle of 70° with LD-A. There is small LD-c on the west of LD-B. LD-B and LD-c may be suggested by Miyoshi and Obara (2010a). We studied focal mechanism solutions of 12 earthquakes (Group A) belonging to LD-A and 146 earthquakes (Group B) belonging to LD-B, respectively, using JMA data. We obtained the average values of the azimuths of P- and T-axis for each group as the following. The average values for Group A are 171° and 350° in P-axes and 91° and 256° in T-axes, respectively (see Figure 1). The average values for Group B are 172° and 358° in P-axes and 82° and 254° in T-axes, respectively (see Figure 1). There are no large differences in their corresponding values between Group A and B. This result suggests that there is no large difference in the average stress generating earthquakes between Group A and B. We, therefore, have to consider other reasons for causing those linear distributions.

Figure 2 is a seismological cross section that crosses the Tokai area from NNW to SSE referred from Suzuki et al., 2018. Schematic interpretation of seismic structures including S wave tomography (Nakajima and Hasegawa, 2016) and two earthquake groups consisiting of LFEs and intraslab earthquakes are represented. The most of intraslab earthquakes distributes in the low velocity area of *S* wave in the uppermost oceanic mantle. The relatively low velocities of *S* wave in the subducting oceanic crust and its surrounding areas are interpreted as being indicative of fluids released by progressive metamorphic dehydration reactions in the oceanic crust (e.g., Abers et al., 2013) under increasing temperature and pressure conditions. We suppose that the intraslab earthquakes occur because these fluids penetrate into the uppermost oceanic mantle. Therefore the pore fluids may penetrate from the oceanic crust into not homogeneously but linearly in plane. It is presumed that old fracture zones that had been formed before the Philippine Sea plate subducted below the Tokai area existed at the uppermost oceanic mantle.

The stress change of Chubu region before and after the 2011 Tohoku-oki Earthquake(Mw9.0)

*Yuki Susukida[1], Kei Katsumata[1]

1. Institute of Seismology and Volcanology, Hokkaido University

Great subduction-zone earthquakes occur frequently off coast of the Pacific Ocean in Japan. And the Chubu region (central part of Honshu, Japan) has risk not only subduction-zone earthquake but also inland earthquake. In 1891, Nobi earthquake (M8.0) occurred at Neodani fault system in Chubu region, which is the largest inland earthquake in Japan. (Milne 1893) Furthermore, after Tohoku-oki earthquake, seismicity of northern part of Neodani fault system was activated. (Toda et al, 2011) In this study, I examined effect of Tohoku-oki earthquake on seismicity around the Neodani fault system by inferring of stress change before and after Tohoku-oki earthquake.

At first, I demonstrated the stress field inversion method (Hardebeck & Michael, 2006) by synthetic data to check the performance of this inversion method. As a result, I found that the inversion method will analyze real data well.

Next, I conduct stress field inversion for the joint observation data by eight Universities in Japan and NIED (National Research Institute for Earth Science and Disaster Resilience in Japan) in the Chubu region between 2009 and 2013. As a result, I found the stress field in Neodani fault system didn’ t change significantly before and after Tohoku-oki earthquake.

Repeating earthquake activity off Miyagi Prefecture triggered by the 2011 Tohoku-oki earthquake

*Kenshiro Tsumura[1]

1. Association for Developement of Earthquake Prediction

A remarkable repeating earthquke activity off Miyagi Prefecture tiggered by the 2011 Tohoku-oki earthquake was analized in detail. The epicenters of repeating earthquakes ditributed in a very small area with a diameter of about 1km , centered at 38°38′N and 141°54′E, and with depth 46-49km. The recurrence intervals were about 20 days in the initial period then gradually changed longer, about 100 days in 2018. Magnitude of earthquake was about 4.0 in the initial period then gradually changed smaller, about 3.5 in 2018. For this activity, based on its repeating regularity, mid-term prediction was tried and obtaied good result for a certain period.

Seismic Moments of Inland Small Earthquakes in Japan: Spectral Analyses Using the Hi-net

*Tomotake Ueno[1], Tatsuhiko Saito[1]

1. National Research Institute for Earth Science and Disaster Resilience

Seismic moments and moment magnitudes are one of the most important quantities in characterizing earthquakes. NIED reports moment magnitudes for moderate and large earthquakes (M_W > ~3.5) using the F-net or the KiK-net/K-NET. However, the moment magnitudes of small earthquakes (M_W < 3.5) aren't well determined because of sparse station distributions of the F-net and low sensitivity sensors of the KiK-net/K-NET. These earthquakes' magnitudes are determined using maximum amplitudes of the seismograms of the Hi-net, a dense seismic observations with high-sensitivity sensors. Such high sensitivity seismometers are also used to estimate seismic moments (e.g., Uchide and Imanishi, 2018). This study estimated seismic moments and moment magnitudes for inland earthquakes in Japan using the Hi-net.

We calculated seismic moment for inland earthquakes shallower than 20 km deep with magnitudes from 3 to 4 occurred in 2013 to 2017. Firstly, we calculated a source spectrum from waveform data during 1s before to 9s after the S-wave arrival time. Then, correcting path, site, and the instrumental response, we estimated source spectra. Comparing the observed source spectra with a theoretical one supposing the ω^2 model, we obtained the seismic moment.

The Hi-net detected 455 inland earthquakes with the magnitude from 3 to 4 in 2017. We successfully estimated the seismic moments more than 90 % of those earthquakes. We could estimate the moment magnitudes more than 90 % except 2016. Because the aftershocks of the Kumamoto earthquakes contaminated Hi-net records, we calculated the seismic moments only for 70 % of the 1730 earthquakes in 2016. We compared the moment magnitudes determined by the Hi-net with those by a moment tensor inversion of the F-net. The moment magnitude of Hi-net was smaller than those of the F-net by 0.13±0.11. On the other hand, the magnitude using the maximum amplitude of the Hi-net was larger than the F-net by 0.06±0.21.

Spatiotemporal variations of stress field in the 2016 Kumamoto earthquake (M 7.3) area

*Dapeng Zhao[1], Zhiteng Yu[2], Jiabiao Li[2], Zhouchuan Huang[3]

1. Department of Geophysics, Tohoku University, 2. State Oceanic Administration, 3. School of Earth Sciences and Engineering, Nanjing University

Focal mechanism solutions of 349 local crustal earthquakes and stress tensors in central-north Kyushu are determined using a large number of P-wave polarity data and a 3-D velocity model. The obtained tensional ($\sigma 3$) axis trends NNW-SSE or N-S horizontally, and the compressive ($\sigma 1$) axis trends WSW-ENE or E-W. The direction of the $\sigma 3$ axis is consistent with the spreading direction at the Okinawa Trough. The stress field in the 2016 Kumamoto earthquake area is attributed to rollback of the Philippine Sea plate and northward extension of the Okinawa Trough. The orientation of the $\sigma 3$ axis is quite stable, whereas the $\sigma 1$ and $\sigma 2$ axes are distributed in a wide range. With the 3-D velocity model, the principal stress axes can be better determined by inverting a large number of FMSs. Spatial and temporal variations of the stress field are well revealed in the Kumamoto source area. The $\sigma 3$ axis significantly rotated counterclockwise after the M 6.5 foreshock, and rotated clockwise after the M 7.3 mainshock on the Futagawa fault segment. The stress rotation suggests a small magnitude of deviatoric stress in the source area, which indicates a small friction coefficient on the seismogenic faults. In addition, a generally small value of friction (~0.4) on the faults is obtained by the stress inversions, indicating that the faults in the Kumamoto earthquake area are weak. The fault weakening may be caused by the arc magma and fluids ascending from the mantle wedge associated with the dehydration reactions of the subducting Philippine Sea slab.

Seismicity and crustal deformation following the 2016 Kumamoto earthquakes

*Kazuyoshi Nanjo[1], Jun Izutsu[2], Yoshiaki Orihara[3], Masashi Kamogawa[4], Toshiyasu Nagao[3]

1. University of Shizuoka, 2. Chubu University, 3. Tokai University, 4. Tokyo Gakugei University

The 2016 Kumamoto earthquakes include a magnitude *M*7.3 mainshock that struck April 16, 2016, as well as *M*6-class foreshocks (*M*6.5 and *M*6.4) and many *M*5-class aftershocks. This seismicity that fulfils sections along the Futagawa and Hinagu faults, is still being active. Seismicity and crustal deformation in the Kumamoto region were investigated to get implications of future seismic-activity trends.

We referred our previous work (Nanjo et al., 2016) that examined the spatial and temporal trend in *b* value of the Gutenberg-Richter's law, based on seismicity prior to the Kumamoto earthquakes. For the spatial distribution of *b* values, which shows data for a post-period (January 2017-January 2019), excluding the active aftershock period, we found a zone with low *b* values (130.6-130.8˚E, 32.5-32.6˚N), which lays further to the southwest of the *M*6.5 and *M*6.4 foreshocks along the Hinagu fault. A comparison with the spatial distribution of *b* values calculated for the seismicity from January 2000 to immediately before the Kumamoto earthquakes (Nanjo et al., 2016) reveals a zone where the *b* value decreased. This zone coincides with the low-*b*-value locations seen for seismicity after 2017. We compared the spatial distribution of earthquakes with *M*>5 in the Kumamoto sequence and the *b*-value distribution based on seismicity after 2017. Earthquakes with *M*> 5 have not occurred in the low-*b*-value zone.

While referring previous studies of crustal deformation associated with the Kumamoto earthquakes by GEONET (e.g., Hiyama et al., 2016), we investigated baseline changes of control stations near the Futagawa and Hinagu faults (the period from January 2013 until the end of 2018, with the "Misumi" (Shimane pref.) taken as a fixed station). A step-like change associated with the mainshock occurrence, followed by gradual changes associated with postseismic formation, is seen for all the baselines investigated. The same is true for the control station "Izumi" (130.79˚E, 32.58˚N), located in the low-*b* -value zone identified for seismicity after 2017, although the postseismic deformation is coming to an end. Therefore, active seismicity is expected to continue in the future.

Our method pinpointed the zone of low *b* values along the Hinagu fault, and this is the only one where the *b* value has decreased, compared to before the Kumamoto earthquakes. Nanjo et al. (2016) compared the *b*-value map with the sequence of foreshocks, mainshock, and aftershocks with *M*5 or greater, and showed that areas of low *b* values contained a high percentage (84%) of the sequence. If the *b* value is regarded, for the Kumamoto region, as an indicator for estimating the occurrence location of a relatively large earthquake in the future, the current low-*b*-value zone shows the high likelihood of "seismic gap", a segment considered to suffer a future *M*>5 earthquake.

The unique characters of intensity distribution of the 2018 Sep. 6 Mw6.6 Earthquake of Iburi region in Hokkaido, Japan

*Ritsuko S. Matsu'ura[1], Hiroto Tanaka[2], Mitsuko Furumura[1], Tsutomu Takahama[2]

1. Earthquake Research Center, Association for the Development of Earthquake Prediction, 2. Kozo Keikaku Engineering Inc.

On Sep. 6, 2018, the Mw6.6 (M_{JMA}6.7) earthquake of 35km depth (JMA depth 37km) occurred in the eastern part of Iburi region, Hokkaido, Japan. Waves from this event are characterized by the very high level in high frequency part. Although it is just an Mw6.6 earthquake, and the shortest distance to the land is larger than its depth, Japanese Instrumental Seismic Intensity (JISI) 7 was recorded at Shikanuma station, 43km away from the source. The comparison of observed waves with the various prediction equations of PGV or PGA for Japan, such as Si and Midorikawa(1999) shows that the observation was remarkably larger than most equations in distances less than 50km [e.g. Nishimura and Miyakoshi (2018)].

We applied the new prediction equation of JISI, which was classified by the physical source types, and in which the surface ground effect was removed by the term dependent on AVS30 of each station [Matsu'ura et al. (2018)], to this event. The equation for the PAC-intra type fits well to stations in distances less than 100km, while the equation for the PAC-inter type fits well to further stations in Iwate or southeastern part of Hokkaido (Fig.). It apparently shows the high stress-drop source feature like an event of intra slab, but the abnormal intensity effect due to the PAC is weaker than that of the PAC-intra type, and similar to that of the PAC-inter type. These features are well explained when this Mw6.6 event occurred within the rather cold shallow mantle overriding on the slab on the western foot of Hidaka Mountains. The high frequency waves were transferred very efficiently from the source to the PAC slab like those from interplate events, which suggests that the source lies in fairly homogeous area than the ordinary Japanese crust.

This study was done as a part of the Supporting Project for the Headquarters for Earthquake Research Promotion (HERP) sponsored by the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan.

Determination of Hypocenter Location in Sumani and Sianok Fault Segments, West Sumatra region Using Oct-Tree Importance Sampling Method

*Ade Surya Putra[1], Nanang Tyasbudi Puspito[2], Andri Dian Nugraha[2], Pepen Supendi[3,1]

1. Geophysical Engineering, Faculty of Mining and Petroleoum Engineering, Institute of Technology Bandung, 2. Global Geophysics Research Group, Faculty of Mining and Petroleoum Engineering, Institute of Technology Bandung, 3. Agency of Meteorology, Climatology and Geohysics (BMKG), Indonesia, Bandung, Indonesia

Sumani and Sianok segments are two of the many fault segments in Sumatra Fault Zone (SFZ) that have a considerable history of seismicity and cause significant impacts. An important effort to overcome this problem is the need to analyze tectonic structures in detail through one of them by elaborating an accurate hypocenter location. In this study, we conducted hypocenter determination by using a non-linear approach with the oct-tree importance sampling method through NonLinLoc software by using local velocity components for earthquakes in Sumani and Sianok Segments in the range of 2009-2017. The results of hypocenter determination in this study indicate an improvement in picking arrival time of P and S wave. The increment is denoted by the results of residual picking P and S wave arrival times using oct-tree sampling method that dominant at frequency of 0.1 seconds and there is a correlation between hypocenter location cluster in this study with a location of major earthquakes that have occurred in Sumani and Sianok Segments.

1D Seismic Velocity Modelling and Hypocenter Relocation around Central and East Java Region: Preliminary Result

*Faiz Muttaqy[1], Andri Dian Nugraha[2], Nanang Tyasbudi Puspito[2]

1. Geophysical Engineering Study Program, Faculty of Mining and Petroleum Engineering, Institut Teknologi Bandung,
2. Global Geophysics Research Group, Faculty of Mining and Petroleum Engineering, Institut Teknologi Bandung

Central and East Java are part of Sunda Arc which has relatively high seismicity and complex geological system as a result of Indo-Australian plate that subducted under the Eurasian plate. The early stage of seismic tomography study in order to obtain a reliable geometry about the velocity structure beneath the study area is to define the precise earthquake location and 1D seismic velocity model. In this study, we manually picked P- and S-wave arrival time recorded by BMKG network for the time period from January 2009 to September 2017. We determined the hypocenter location around Central and East Java region by using an NLLoc program. We also conducted a velocity inversion using the VELEST program to obtain an updated 1D velocity model in the study area. Afterward, the hypocenters were relocated using the double-difference algorithm and the updated 1D velocity model to improve the accuracy of the hypocenter locations. Our results indicate that the seismicity around Central and East Java is generally distributed in the southern part of the island, such as in the south of Kebumen, Yogyakarta, Pacitan, Malang, and Banyuwangi that associated with the subduction activity. Moreover, the shallow seismicity is probably controlled by the presence of active inland faults, such as Opak Fault and Kendeng Thrust. As further studies, we will determine the focal mechanism of selected events related to the active inland fault in this region and conduct 3D seismic tomography imaging beneath Central and East Java region.

Seismicity and Tectonics of the Bingöl Area: Eastern Anatolia

*Dogan Kalafat[1]

1. Bogazici University Kandilli Observatory and Earthquake Research Institute Cengelkoy, Istanbul Turkey

In this study, Bingöl Earthquakes which have occurred in recent years have been evaluated from seismological point of view. The Eastern Anatolia Region is the most seismologically deformed area of the Anatolian plate and is under compression due to the relative movement of the Arabian and Eurasian plates in general. The Anatolian plate bounded by the North Anatolian Fault Zone (NAFZ) and Eastern Anatolian Fault Zones (EAFZ) moves relatively westward. Bingöl Earthquakes are located within the Eastern Anatolian Fault Zone and this fault zone occurs due to the movement of the parts. Bingöl and the surrounding area is the most active regions in Turkey in terms of seismicity. The most important earthquakes in Bingöl during the instrumental period were the 1971 and 2003 earthquakes. Bingöl Fault starts from the south of Bingöl and extends along the Göynuk stream valley. This fault length is about 75 km. which is northern part of the Eastern Anatolian Fault Zone and joins the North Anatolian Fault Zone after passing through the villages of Serpmekaya and Sakaören. During the 1971 Bingöl Earthquake, about 38 km surface rupture occured which it started from Ormanardi to the southeast of Bingöl and extends to the N45ºE degree in the southwestern direction of Goynuk. The observed faults showed a strike-slip and a left lateral movement and the fault plane solutions supported the field observations.
The other important earthquake occurred on May 1, 2003. In this earthquake, 176 citizens were killed and 521 citizens were injured in various places. In particular, public buildings were severely damaged. The episantr area is between the Balikcay village plateau, Hanocayiri-Kurtulus and Sudugunu Plateau. Stepped fractures with NW-SE trending N20-30ºW trending were observed in Hanocayiri, which is one of the closest settlements of earthquake. As a result of earthquake, a great deal of collapses and mud currents were formed due to the effect of groundwater pressure. The fault traces in the region continued on the slopes of the NW-SE trending Kade mountains. Liquefaction, sitting, collapse and faulting samples were seen together in Hanocayiri hamlet. The earthquake caused severe damage, destruction and death in the buildings located on the alluvial terrace of Göynuk Creek in Bingöl province. During the earthquake, the Celtiksuyu Boarding School of Bingöl province was completely destroyed and 84 students died under the rubble. In addition, many public buildings were damaged. The macroseismic epicenter of the earthquake is approximately 12 km. distance between the district of Elcagini-Elmacayiri and Sudugunu plateaus. The area is mountainous and there are no frequent settlements. The nearest settlements are Balikcay, Hanocayiri Village, Elmacayiri village and Kurtulus village. It was observed that the epicenter of Bingöl Earthquake was highly compatible with the NW-SE trending faults. The fault of N-NW, which passes between Kurtulus-Elmacayiri-Hanocayiri and towards the Balikcay-Cimenli villages, was defined as the fault which was broken by the 2003 Bingöl Earthquake. In this study, 12 earthquakes fault plane solutions have given (magnitude Mw> 5.0) between 1971-2015 time period in Bingöl. The fault plane solution of 6 earthquakes was conducted within the scope of the study. The stress analysis shows that the dominant stress axes in the region are dominated by NW-SE directional compression and strike-slip faulting which are characterized by NE-SW extension axes.
The recent earthquakes showed that the ongoing deformation in the region continued with the strike-slip fault systems as the dominant. Structural heavy damages caused by earthquakes were mostly due to poor soil conditions, improper production, low quality and missing materials.

Seismicity along the North Anatolian Fault beneath the Marmara Sea, deduced from long-term ocean bottom seismographic observations

*Yojiro Yamamoto[1], Narumi Takahashi[2,1], Dogan Kalafat[3], Ali Pinar[3], Remzi Polat[3], Zeynep Coskun[3], Haluk Ozener[3], Yoshiyuki Kaneda[4]

1. Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 2. NIED, 3. KOERI, Bogaziti University, 4. Kagawa University

The North Anatolian Fault (NAF) beneath the Marmara Sea is recognized as a seismic gap for M >7 earthquake during more than 100 years. Earthquake hazard and disaster mitigation studies in Marmara region are sensitive to detailed information on fault geometry and its coupling status beneath the Marmara Sea. Although hypocenter distribution could help us to estimate them, it is difficult to obtain precise hypocenter location from only onshore permanent seismic stations. Thus, we have started a series of long-term ocean bottom seismographic (OBS) observations beneath the western and central Marmara Sea since 2014. We have installed 10~15 OBSs along the Main Marmara Fault(MMF) for each observation phases, and observation length is about 10 or 11 months. Based on the first phase observation, conducted from 2014 to 2015, Yamamoto et al. (2017) identified a segment boundary of the MMF beneath the central basin of the Marmara Sea (28.05˚E). Besides, they proposed that the zones of no seismicity within the upper crust appear to indicate locked sections of the MMF.
In this study, we analyze the second (from 2015 to 2016) and third phases (from 2016 to 2017) observation data. The OBS distribution of second phase is same as first phase,whereas that of third phase is about 20 km shifted to eastward relative to first and second phases. The tentative result shows that the feature of hypocenter distribution, including the location of no seismicity zones obtained by Yamamoto et al. (2017), is not changed for all phases, suggesting that the coupling status along the fault is almost same during at least three years. In the west of 28.05˚E, seismicity located not only the upper but also lower crust. On the other hand, the lower limit of the seismogenic zone in the east of 28.05˚E is about 15 km, shallower than the Conrad discontinuity. The largest no seismicity zone extended over the upper crust is located between 28.45˚E and 28.65˚E, where strong coupling is suggested from seafloor geodetic observation (Sakic et al., 2016).
According to the spatial relationship between the epicenter of microearthquakes and fault trace on the sea floor (Armijo et al., 2005) suggests that the MMF around 28.75˚E is near vertical to slightly northward dipping. Since previous study indicates that the east of 28.05˚E MMF is southward dipping (Yamamoto et al., 2017), there might be another segment boundary west of 28.75˚E. We also find an active seismic cluster around 40.8˚N, 28.7˚E, 14 km depth. There is a possibility that this cluster relates to the southern branch of NAF.

Microseismic Monitoring of the Sultandagi Fault Zone: Western Turkey

*Dogan Kalafat[1], Yavuz Gunes[1], Mehmet Kara[1], Kivanc Kekovali[1]

1. Bogazici University Kandilli Observatory and Earthquake Research Institute Cengelkoy, Istanbul Turkey

Western Turkey is one of the seismically active region in Turkey. The high seismic activity is a result of the complex tectonic deformation of the Anatolian plate which has been dominated by the N–S extensional tectonic regime in the western edge. In western Turkey, relatively 3 major earthquakes (Mw≧6.0) were identified on the Sultandagi Fault Zone (Afyon-Aksehir Graben) between years of 2000–2002. In this study, mentioned local earthquake activity, have been investigated to understand their nature and relation of the regional seismic activity and tectonic deformation on the Sultandagi Fault Zone (SFZ) in western Turkey. Due to these activities along the SFZ it is decided to monitor microseismic activity (M<2.5) by establishing low-magnitude threshold seismic network. For this purpose, 3 new broadband (BB) seismic stations were temporarily established to control the northern part of the Sultandagi Fault Zone, and the micro-seismicity of the fault zone was started to be observed in July 2017. Thus, the earthquake activity in the region started to be monitored sensitively. So we started to get 2 times more earthquakes than permanent stations in the region. The one of the biggest primary outcome by this study that there is a significant microseismic activity (M<2.5) at the SFZ which was not seen from prior studies and long-term seismicity catalogues from permanent network (M>2.5). At first, we started to analyze the distribution of micro-earthquakes in the region. During the data analysis, it was predicted that some intensive micro-earthquake activity in the project area could be caused by quary-blasting and some locations were visited during the field study. Relocation of common earthquakes recorded by KOERI and the study was carried out, and the earthquake epicenters were displaced approximately as ±0.8–6 km. There were also some positive changes in the depth distribution of earthquakes. Consequently, thanks to the stations established within the scope of the study, horizontal (distance) and vertical error (depth) margins of the events in the region have been reduced. As a result of the evaluation of the data obtained, it was observed that the Sultandagi Fault Zone has especially intense seismic activity in the middle and northwest part. In addition, a significant seismic activity was observed in NW-SE direction at the north of Isparta city .
This research is funded by Bogazici University Research Fund within the scope of Project Number 12280. We thank to Bogazici University Research Fund Commission and members.

Analysis of radiated seismic energy distributing in aftershock sequences at the Guerrero, Mexico subduction zone.

*Raymundo Omar Plata Martinez[1], Xyoli Pérez Campos[2], Krishna Shri Singh[2]

1. Kyoto University, 2. Geophysics Institute, UNAM

Radiated seismic energy is valuable parameter in seismic source studies, as it can be a good criterion to evaluate earthquakes size but also very useful to analyze the dynamics of the rupture process. Significant large thrust earthquakes have occurred over the last decades at the Mexican, subduction zone, however just a few researches have been done to understand the distribution of seismic energy release in the area. For this purpose, we calculated source spectra to estimate radiated seismic energy of three large earthquakes and their aftershocks (*M* larger than 4.0) in the Guerrero segment of the Mexican subductions zone; the 2012 Ometepec-Pinotepa Nacional (*Mw* 7.5), the 2014 Papanoa (*Mw* 7.2) and the 2018 Pinotepa Nacional (*Mw* 7.2) earthquakes. We found a mean value of the log of radiated seismic energy scaled with the seismic moment (Mo/Es) of -5.05 ±0.25, as well as, regional estimations tend to be higher than the teleseismic estimations by a factor of 1.3 to 6.3. A small dependence of scaled seismic energy with distance from the trench was seen, however distribution of seimsic energy seems to be spatially heterogeneous along the trench. We found four different regions with characteristic behaviors in energy release. One of the regions reveals recurrent low energies with possible slow rupturing close to the trench. Opposingly, high energy seismicity was present, adjacent to the Guerrero gap, which has not had a large earthquake in over 115 years. This suggests that radiated seismic energy can be highly influenced by complexities at the plate interphase, variations on the shear strength and/or coupling at the interface where seismic slip interacts over previous rupture patches.

Seasonal variations in crustal seismicity in San-in district, southwest Japan

*Taku Ueda[1], Aitaro Kato[1]

1. Earthquake Research Institute, the University of Tokyo

A growing body of evidence suggests that seismicity is seasonally modulated in a variety of tectonic environments (e.g., Gao et al., 2000; Heki, 2003; Bettinelli et al., 2008; Ben-Zion & Allam, 2013; Amos et al., 2014; Johnson et al., 2017). Identifying cyclic variations in seismicity leads to an improvement of our understanding about the physics of earthquake triggering.

San-in district, southwest Japan, is an active seismicity zone characterized as high shear strain rate by geodetic measurement (Nishimura and Takada, 2017). Moreover, Ogata (1983) has pointed out a possibility of seasonal variations in seismicity rate in the Inner Zone of southwest Japan. We here focus on seasonal variations in crustal seismicity in San-in district.

We used the JMA catalog (constructed by Japan Meteorological Agency) from 1975 through 2017 (magnitude M >= 3.0 and depth <= 20 km). We applied space-time Epidemic Type Aftershock Sequence (ETAS) model (e.g., Ogata, 1998; Zhuang et al., 2004) to the catalog and used a probability-based declustering procedure based on the work of Zhuang et al. (2002) to evaluate the significance of the seasonal variations, adopting uncertainties derived from the declustering scheme.

We demonstrated that semiannual variations in background seismicity rate, which increases in spring and autumn, are statistically significant from 1980 through 2017. The distribution of large historic and modern earthquakes (from 1850 through 2017, magnitude M >= 6.2, constructed by Chronological Scientific Tables) shows a similar pattern to recent background seismicity, suggesting that seismicity in San-in district has shown seasonal variations for over 150 years. There is some correlation between the monthly averaged background rate shifted backward 2 months and monthly averaged rain amount in the studied region. These results infer that seasonal variations in seismicity in San-in district can be explained by increasing pore pressure within fault zones, caused by infiltration of rainfall in autumn and decreasing surface mass due to snow melting in spring. Some correlation between seismicity and precipitation suggests that modulation of precipitation may be a key ingredient to produce time-dependence of background seismicity.

Source fault model of the 2018 M_w 5.6 northern Osaka earthquake, Japan, inferred from the aftershock sequence

*Aitaro Kato[1], Taku Ueda[1]

1. Earthquake Research Institute, the University of Tokyo

We reconstructed the spatiotemporal evolution of seismicity associated with the 2018 M_w 5.6 northern Osaka earthquake, Japan, to discuss the source fault model of the mainshock rupture, the possible link between this rupture and known active faults, and subsequent crustal deformation. We first relocated the hypocenters listed in the earthquake catalog determined by the Japan Meteorological Agency using a double-difference relocation algorithm. We then searched for the earthquake waveforms that closely resembled those of the relocated hypocenters by applying a matched filtering technique to the continuous waveform data. The relocated hypocenters revealed two distinct planar alignments with different fault geometries. A combination of the relocated hypocenters and focal mechanisms suggests that the mainshock rupture initiated on a NNW–SSE-striking thrust fault, dipping ~45° to the east, with the rupture propagating to an adjacent sub-vertical ENE–WSW-striking strike-slip fault ~0.3 s after the initial mainshock rupture, resulting in the simultaneous propagation of dynamic rupture along the two faults. The strike-slip fault is oblique to the strike of the Arima-Takatsuki Fault, indicating that blind strike-slip faulting occurred. While the east-dipping thrust fault is located deeper than the modeled extent of the Uemachi Fault, a simple extrapolation of the near-surface geometry of the Uemachi fault partially overlaps the mainshock rupture area. Although it is unclear as to whether a blind thrust fault or a deep portion of the Uemachi Fault ruptured during this mainshock–aftershock sequence, a mainshock rupture would have transferred a static stress change of >0.1 MPa to a portion of the east-dipping thrust fault system. Intensive aftershocks have persisted along the northern and southern edges of the source area, including moderate-magnitude events, whereas the seismicity in the central part of the source area has shown a rapid decay over time. Delayed triggered aftershocks were clearly identified along the northern extension of the rupture area. Because the background seismicity is predominant in this northern area, we interpret that aseismic deformation, such as cataclastic flow lubricated by crustal fluids, triggered this off-fault seismicity.

National Research Institute for Earth Science and Disaster Prevention

The Hokkaido Eastern Iburi earthquake (M_{JMA} = 6.7) occurred on 6 September 2018 in the Hokkaido-corner region where the Kurile and the northeastern Japan island arcs meet. We relocated aftershocks of this intraplate event immediately after the mainshock by using data from a permanent local seismic network and found that the aftershocks concentrated in depths from 20 to 40 km, which is extraordinarily deep when comparing with other shallow intraplate earthquakes in the inland area of Honshu and Kyushu, Japan. Moreover, we found that the aftershock area consists of three segments. The first one is located in the northern part of the aftershock area, the second one is located in the southern part, and the third one is located in a stepover segment between the first one and the second one. The hypocenter of the mainshock, which is a rupture initiation point, is located in the stepover segment. The centroid moment tensor solution for the mainshock indicates a reverse faulting, whereas the focal mechanism solution determined by using a first motion polarity of *P* wave indicates a strike-slip faulting. To explain this mismatch qualitatively, we present a model that the rupture started as a small strike-slip faulting in the stepover segment of the aftershock area and it is followed by the large rupture of two reverse faulting in the northern and the southern segments.

Layered structure of the upper mantle and the crust revealed in the time series analyses of the aftershocks of the 2018 Hokkaido Eastern Iburi Earthquake

*Takayuki Kawabe[1]

1. Faculty of Education, Arts and Sciences, Yamagata University

The 2018 Hokkaido Eastern Iburi Earthquake, occurred at September 6, 2018 03:07:57 am. Many aftershocks occurred along a plane which is striking north-northeastward and is dipping to the east at an inclination of 70 ˚. The depth of the upper limit at which aftershocks occurred has been becoming shallow over time.
According to time series analyses of the aftershocks, four depth zones are recognized. They are as follows;
Depth zone of 45 to 30 km deep: Many aftershocks occurred in the zone just after the main shock.
Depth zone of 30 to 20 km deep: Less aftershocks occur. However the magnitude of many of them are larger.
Depth zone of 20 to 10 km deep: Many small aftershocks were active. They distribute not uniformly but on multiple radial lines, and they occurred line by line.
Depth zone of 10 to 5 km deep: less aftershocks occur. However the dip of the plane on which aftershocks occurred is gentle as 45 ˚
These recognized zones seems to show the difference in physical properties of the underground geology. According to the slow development of aftershock and distribution form of epicenters suggest strongly the involvement of the deep hot water flow along the fault plane.

Aftershock sequence of the 1847 Zenkoji earthquake: Temporal decay presented in four historical materials and best fit values of paramaters for Omori-Utsu law

*Kentaro Hattori[1], Ichiro Nakanishi[1]

1. Kyoto Univ.

Seismic intensities estimated from damage caused by earthquakes have been most commonly used to locate earthquake epicentral area since Irish seismologist Mallet used degree of damage by the great Napoli earthquake of 1857 to locate earthquake source area. However, the scales of seismic intensity are different among countries. The seismic intensities are somewhat subjective and are affected by ground conditions.

Matsui and Oike (1997) proposed the use of the numbers of felt aftershocks right after large historical earthquakes to locate source area. A problem in their approach is that it is usually difficult to count the number of aftershocks in epicentral area or places close to the area.

We attempt to fit Omori-Utsu law (Utsu, 1961) to aftershock sequences of a historical large earthquake to overcome the above mentioned problem of the location of epicentral area. The value from counting aftershocks is integer, and seems to be more robust than the estimation of ground motion from the description in historical materials. The temporal decay of the number of aftershocks n(t) is described by the empirical Omori-Utsu law as $n(t) = K (t+c)^{-p}$, where t is the lapse time after the mainshock, p is an exponent showing the decay rate, c is a time scale, and K is a parameter showing aftershock activity.

We use aftershock sequence data of the 1847 Zenkoji earthquake presented in four historical materials owned in Matsushiro, Suwa, Fujinomiya, Gifu, in order of the distance from the epicentral area. We assume c=0.1 and p is common in four data, and obtain the best fitting p and four K. The result is shown in Fig.1. In the figure, it is clear that Omori-Utsu law does not fit the time range right after the earthquake occurrence for Matsushiro, Gifu, Suwa data, but fits Fujinomiya data. Another clear feature in Fig.1 is that the parameter K for Gifu data is 300. This value is much larger than those for Suwa (K=80) and Fujinomiya (K=6), both places are located closer to epicental area than Gifu. Fig.1 may suggest that the data preserved in Gifu were not written in Gifu, but in a place much closer to epicentral area.

The aseismic islands, Amakusa-Kamishima and Shimoshima, Kumamoto Prefecture, southwest Japan: What persistently shuts off regional seismicity

*Shinji Toda[1]

1. International Research Institute of Disaster Science, Tohoku University

Is there any inland region in Japan totally aseismic? This is a simple question against the frequently releasing comment by seismologists to the general public “none of the region in Japan can be avoided from strong ground motion.” To strictly check if this is true, we simply examined the Japan Meteorological Agency (JMA) earthquake catalog of 1923-January 2019, and then found one of the significantly aseismic regions in Kumamoto Prefecture, Amakusa-Kamishima and Shimoshima islands that extend about an area of 2,000 km^2 (hereinafter AAR). Neither historical destructive earthquake is documented in the AAR (Usami et al, 2013). Instead the AAR is surrounded by tectonically and seismically active zones of the Beppu-Shimabara graben to the north, Amakusa-nada graben to the west, the Futagawa-Hinagu fault system that caused the 2016 Kumamoto earthquake to the east, and highly seismic zone to the south. The AAR is characterized by high-Bouguer gravity anomaly possibly related to the underlying metamorphic rocks, while the most of the area exposes upper Cretaceous to Paleogene sedimentary rocks folded along NNE-trending axes (Takai and Sato, 1982). Numerous WNW-trending strike-slip faults, transverse these anticlines and synclines, are thought to have developed in the Miocene period but not been active during the late Quaternary period. Although the coastal geomorphologic features suggest uplifted marine terraces to the north and rias-type subsidence to the south formed during the late Quaternary, we infer long-term very gradual crustal uplift has been lasting since late Miocene due to the lack of sediments. Since the recent GNSS observation indicates a very low rate of strain in the AAR (GSI, 2018), we believe the AAR behaves as a rigid block enclosed by active tectonic zones mentioned above, those condition brings long-term stress shadow to bear such a persistent aseismic region.

Seismicity in the matle wedge around Ogasawara Islands and Lesser Antilles

*Akio Katsumata[1], Kenji Nakata[1], Akio Kobayashi[1], Fuyuki Hirose[1], Takahito Nishimiya[1]

1. Meteorological Research Institute, Japan Meteorological Agency

Nakata et al. (2018) deployed ocean bottom seismometers around Ogasawara Islands from July to October in 2015, and observed seismicity of the area. Double seismic zone and seismicity in the mantle wedge (green circles in the figure) were identified. Some hypocenters were distributed in the 20-50 km depth range inside the mantle wedge. These earthquakes are located beneath the Ogasawara Trough without forming any clusters. Ogasawara Trough is a forearc basin between the the current volcanic arc and the Ogasawara ridge.
Seismic activity is usually low in the mantle wedge in areas without complex plate interactions. However, seismicities in the mantle wedge have been reported for other regions. Uchida et al. (2010) found supraslab seismicity off Sanriku coast. Davey and Ristau (2011) reported seismicity observed in the mantle wedge beneath northeast New Zealand. Laigle et al. (2013) reported seismicity in the mantle wedge along the Lesser Antilles subduction zone. The seismicity in the mantle wedge beneath Lesser Antilles is distributed over trench-normal distance more than 50 km, which is wider than that seen in the figure.
Supraslab earthquakes offshore Sanriku (Uchida et al. 2010) are distributed mainly near the toe of the mantle wedge, and form clusters. Earthquakes in the mantle wedge beneath northeast New Zealand form clusters near the boundary of subducting slab. The seismicity around Ogasawara Islands looks like that of Lesser Antilles rather than those offshore Sanriku and beneath northeast New Zealand.
The tectonic features of the forearc basins in the Lesser Antilles and Ogasawara Island regions are similar. Ogasawara ridge was formed with volcanic activities in 41-48 Ma related to beginning of the Pacific plate subduction in this area (Ishizuka et al. 2006). The backarc and forearc basins of the Lesser Antilles were formed as a single structure, and the Lesser Antilles were formed by volcanic activities with dividing the single basin into the two (Aitken et al. 2011). The volcanic activity started at about 40 Ma (Briden et al. 1979) due to the rollback of the Atlantic oceanic slab subduction (Aitken et al. 2011). Both forearc basins around Ogasawara Islands and Lesser Antilles are related to beginning of oceanic slab subduction. The seismic activity in mantle wedge may be related to dehydration of minerals which were formed at the time of subduction onset.

Improvement of the accuracy of the unified Japan Earthquake Catalog using ocean bottom seismographs

*Hiroshi UENO[1], Mitsuharu Ueda[1], Hiromi Misu[1], Hirofumi Yokoyama[1], Yuriko Iwasaki[1], Iwakiri Kazuhiro[1]

1. Seismology and Volcanology Department, Japan Meteorological Agency

The Unified Earthquake catalog for Japan has already been made available to the public by the Japan Meteorological Agency (JMA). In this catalog, hypocenters are determined using high-density seismic data collected by Japanese institutes and universities.

Recently, many ocean bottom seismographs(OBS) were installed around Japan Trench and Nankai trough.

In order to utilize many OBS data, we will optimize the hypocenter determination method of JMA from the following viewpoints.
1. Applications of the correction travel times of OBS for sedimentary beneath OBS.
2. Applications of velocity structures for OBS stations estimated from some velocity structure investigations.
3. Applications of the correction values of OBS for calculating magnitude with velocity amplitudes.

Spatial distribution of seismic activity and stress field in the source region after the 2011 Tohoku-Oki earthquake

Tomoya Nishimori[1], *Ryota Hino[1], Masanao Shinohara[2]

1. Graduate School of Science, Tohoku University, 2. Earthquake Research Institute, The University of Tokyo

The 2011 Tohoku-Oki earthquake changed the stress field around its source region. Significant coseismic rotation of the principal stress axes was observed and it was suggested that almost all the accumulated shear stress was released on the ruptured plate boundary (e.g. Hasegawa et al. 2011). Therefore, it is important to study the spatial variation of the stress state after the Tohoku-Oki earthquake in detail to understand not only the coseismic stress change but also the stress state before the occurrence of the earthquake. Since previous studies used the focal mechanism solutions to estimate stress field inversion are based on the data of the onshore seismic networks, it has been difficult to discuss detailed features of the spatial variation of the stress state, especially of the depth variation, because accuracies of focal depths (centroid depths) of offshore earthquakes are not sufficient. In this study, we relocated the hypocenters by using arrival time data of ocean bottom seismic stations deployed in the central part of the Japan trench where the coseismic slip was large to improve three-dimensional distribution of the focal mechanism solutions of the earthquakes in the area occurred before and after the Tohoku-Oki earthquake. As a result of stress field estimation based on the improved focal mechanism catalogue, it was shown that the stress field after the Tohoku-Oki earthquake shows clear difference between the overring and the subducting plates in the west side of the coseismic slip region. This sharp change in the stress field across the plate boundary suggests that the shear stress along the plate interface is extremely small. The area corresponds to the region with extensive afterslip estimated from the postseismic deformation data. A remarkable intraplate seismicity extending upward from the plate interface by ~ 25 km was identified after the Tohoku-Oki earthquake at the western rim of the large coseismic slip area. By applying a moment tensor inversion to these earthquakes, we investigated the depth variation of the stress field in the upper plate above the large coseismic slip zone. As a result, the minimum principal stress axis was found to orient almost in the direction of the coseismic slip just above the plate boundary, whereas its direction changed to the along-strike direction in the shallow depth range. The change can be interpreted by the decrease of the tensional stress associated with the coseismic slip with the increasing distance from the rupture plane.

Assessment for a large earthquake occurrence on the northern side of the focal region of the 2011 off-Tohoku mega-thrust earthquake

*Kazuyoshi Nanjo[1], Kazuki Miyaoka[2], Akio Yoshida[3]

1. University of Shizuoka, 2. Japan Meteorological Agency, 3. Shizuoka University

Eight years have passed since the occurrence of the 2011 off-Tohoku mega-thrust earthquake (off-Tohoku earthquake). Seismic activity in the central part of the focal region has settled down. However, magnitude (*M*) 5 to 6 earthquakes occur occasionally along the coast and inland areas of Tohoku and Kanto. Therefore, it can be said that seismic activity in a wide area is still in a higher level than that before the off-Tohoku earthquake.

Soon after the off-Tohoku earthquake, it was worried that a large earthquake might occur in the northern or southern adjacent regions, for it is not rare that a mega-thrust earthquake was succeeded by an occurrence of another large shock within several years. Last year, Matsu’ura (2018) warned impendence of a large earthquake occurrence in east-off Hokkaido, based on analysis of seismicity changes as well as historical records about great earthquake occurrence in the concerned area. Here, we report results of a detailed investigation about changes in the seismicity and the *b* value in the sea area on the northern side of the focal region of the east-off Tohoku earthquake.

Based on a *b* value analysis using data in three years after the off-Tohoku earthquake, Tormann et al. (2015) inferred that stress level in the focal region had already returned to the state before the earthquake, and presented an idea that a large earthquake may not repeat at an interval of a characteristic period, but rather occur at random. On the other hand, Nanjo and Yoshida (2017) showed, by re-analyzing data of a longer time period, that such a feature of the notable lowering of the *b* value as was observed before the off-Tohoku earthquake in the large-slip area was not seen. However, it was found that the *b* value in the northern adjacent area, far-east off Aomori Prefecture, is notably low. The area covers the focal region of the 1994 far-off Sanriku earthquake partly and extends further north. Further, it was seen that seismicity there has been decreasing in recent years.

Based on seismicity in the study region covering from off Aomori Prefecture to east-off Hokkaido, we found, in this study, spatiotemporal variability in *b* value. In particular, the 2003 *M*8.0 Tokachi earthquake did not show a transition of *b* value to normal levels but further lowered *b* value and expanded zones of low *b* values. The result obtained here is consistent with that by our previous work (Nanjo and Yoshida, 2017). From these observations, we think that a large earthquake may occur in the northern adjacent area of the focal region of the off-Tohoku earthquake in the near future.

Seismicity along the coast of Tohoku on the down-dip side of the coupling region is still high. A seismic quiescence as well as lowering of the *b* value is often observed before occurrence of an *M*5~6-class earthquake in the area around their foci. Although effectiveness of the observation of seismic quiescence and lowering of the *b* value in the prediction of a large-earthquake occurrence is still a problem under debate, we would like to propose here that extent of the low-*b* value area and the *b* value at the center of the area may be useful indices in evaluating results of the *b* value analysis. This is an analogy of a typhoon where their magnitude and intensity are evaluated by an extent of the storm area and air pressure at the central point. We expect further that imminence of a large earthquake occurrence may be assessed by noting tendency of the lowering of the *b* value.

Spatial and temporal distributions of *b*-values related to long-term slow-slip and low-frequency earthquakes in the Bungo Channel and Hyuga-nada regions, Japan

*Keita Chiba[1]

1. Institute of Seismology and Volcanology, Faculty of Science, Kyushu University

Long-term slow-slip events (SSEs) and low-frequency earthquakes (LFEs) repeatedly occur in the area encompassing the Bungo Channel and Hyuga-nada region in Japan (e.g., Shelly et al., 2006; Ide et al., 2007; Ozawa et al., 2013; Ozawa, 2017). SSEs are slow earthquake events with a duration of months to years, characterized by a type of slip that is considered transitional between the fast rupture of regular earthquakes and stable sliding along a plate interface, and have characteristics sensitive to stress states near the plate interface (e.g., Obara and Kato, 2016). In addition, since LFEs are also thought to occur at the plate interface, it would be useful to infer the stress state in this region. This study focuses on the stress-dependent characteristics of the *b*-value of regular earthquakes, SSEs, and LFEs, as well as the spatio-temporal relationships between *b*-values and these events in this area, using the Japan Unified high-resolution relocated Catalog for Earthquakes (JUICE) (Yano et al., 2017). The *b*-value, which represents the relative proportion of large to small earthquakes (Gutenberg and Richter, 1944), is inversely related to differential stress or effective stress (e.g., Scholz, 1968, 2015; Wyss, 1973; Urbancic, 1992). As a result, the *b*-values are moderate to low (b = 0.6–1.1) in regions with a high incidence of long-term SSEs. This spatial anomaly in *b*-values is attributed to a partial release of the accumulated stress in regions with relatively high differential stress that are characterized by SSEs. In addition, the *b*-values in the Bungo Channel region are relatively higher than those in the Hyuga-nada region. It was also found that the difference of the *b*-values in the vertical direction within the plate for the Bungo Channel region is larger than that for the Hyuga-nada region. These findings support a generation model of LFEs by Nakajima and Hasegawa (2016), in which undrained conditions in the overlying plate are a key factor for generating LFEs. On the other hand, the *b*-values increase and decrease before and during periods of enhanced LFE activity in the Bungo Channel, respectively. The increase and following decrease in *b* -values are thought to reflect episodes of low and high shear strength along the plate interface, which were caused by the presence of abundant fluids supplied from the subducting slab under undrained conditions above the plate interface and the decreased pore pressure related to fluid consumptions by the generation of the LFEs, respectively.

4D b-Value Mapping for Japan

*Yasushi Harada[1], Yuichi Akamine[1], Masayoshi Anzai[1]

1. School of Marine Science and Technology, Tokai University

b-value is considered as an index for seismicity, and smaller b-value means relatively more earthquakes of large magnetude, larger b-value means relatively less earthquakes of large magnetude. We tied to produce 4D b-value map for Japan to examine the difference of seismicity before and after the M9-class 2011 Tohoku quake. Dr. Kazuki Nanjo kindly provided us his code for calculating b-value and the standard deviation(SD). We created not only 4D b-value maps of Japan but also maps of the SD of b-value. Since large SD may mean a failure of Gutenberg–Richter law. Also from the map of b-value around Japan, we noticed a tendency of smaller b-value at distant area from the coastline. The tendency can be explained by the fact that seismometers cannot detect small distant earthqukes. Therefore we constructed a correction formula for b-values. With this formula, the most of the effect of smaller b-value around the M9-class 2011 Tohoku quake are disappeared. However the current formula is not good enough and it have to be improved in future studies.

Fluid flows inferred from microseismic events associated with injection test in Okuaizu Geothermal Field

*Kyosuke Okamoto[1], Li Yi[2], Hiroshi Asanuma[1], Takashi Okabe[3], Yasuyuki Abe[4], Masatoshi Tsuzuki[5]

1. National Institute of Advanced Industrial Science and Technology, 2. Osaka University, 3. Geothermal Energy Research and Development Co., Ltd., 4. Okuaizu Geothermal Co., Ltd., 5. Japan Oil, Gas and Metals National Corporation

In the Okuaizu geothermal field (Yanaizu, Fukushima Prefecture), a recharge water injection test has been carried out to stabilize the steam production since 2015. In order to avoid cooling of the geothermal reservoir by the water injection and to obtain a larger recharge effect, it is important to grasp and anticipate the flows of the injected water. On the other hand, subsurface structures are generally complicated, especially within the brittle region. Therefore, it is difficult to predict the flows with a simple homogeneous model because the following phenomena are expected in real cases; selective flows passing through a highly permeable region such as a fracture zone as well as creation of a new flow path by shearing. In the shearing, the mechanism of its creation (e.g., reduction of effective stress due to in-flow into fractures, propagation of stress change, stress accumulation due to thermal change) is hard to identify, which is essential information to expect new flow paths.

In the Okuaizu geothermal field, a microseismic monitoring network has been established as part of the JOGMEC project named "Geothermal Reservoir Evaluation and Management Technology" since fiscal year 2015. In this study, we use the seismic record to estimate the subsurface fluid flows associated with the injection test. We investigate factors of the creation of microseismicity associated with the injection test by using elastic wave velocity changes in fractures estimated by seismic scattering analysis as well as pressure and temperature information.

3D distribution of intrinsic attenuation factors and random velocity fluctuations in southwestern Japan inferred from seismogram envelopes

*Masashi Ogiso[1]

1. Meteorological Research Institute, Japan Meteorological Agency

Hi-frequency (> 1 Hz) seismogram envelopes show various envelope shapes due to the influence of seismic scattering as well as intrinsic attenuation of the medium. Intrinsic and scattering attenuation structures inferred from seismogram envelopes are important for precise strong ground motion prediction as well as understanding the Earth structure. Ogiso (2019) have proposed a two-step approach to estimate the 3D distribution of intrinsic attenuation factors and scattering coefficients using envelope fitting method and sensitivity kernels proposed by Takeuchi (2016). In this study, we propose the method to estimate 3D distribution of intrinsic attenuation factors and random velocity fluctuations, which is the improved version of Ogiso (2019).

The same as Ogiso (2019), the proposed method consists of two steps. First, we estimate appropriate attenuation parameters (intrinsic attenuation factor and strength of random velocity fluctuation) for each observed envelope. Second, we map the estimated attenuation parameters in step 1 into 3D space using sensitivity kernels. Radiative transfer theory with non-isotropic scattering coefficients based on the Born approximation is used to model seismogram envelopes. The effect of depth-dependent velocity structure is also considered for modeling envelopes.

The proposed method is applied in southwestern Japan. The estimated structure has three main features: (1) both intrinsic attenuation factors and random velocity fluctuations are stronger in the Kyushu than the other regions, (2) both intrinsic attenuation factors and random velocity fluctuations are smaller in the lower crust than the upper crust, which is clearly found in the Chugoku region, and (3) horizontal heterogeneity in intrinsic attenuation factors at the depth of 10-50 km of the Shikoku region. These features, probably reflecting the tectonic settings of southwestern Japan, seem to be consistent with previous studies.

Acknowledgment

Regional to teleseismic strong ground motions from a 610 km deep 24 May 2013 Sea of Okhotsk earthquake

*Takashi Furumura[1], Brian LN Kennett[2]

1. Earthquake Research Institute The University of Tokyo, 2. Research School of Earth Sciences, The Australian National University

A very large deep earthquake (Mw8.3, 610 km depth) occurred in the Sea of Okhotsk near Kamchatka on 24 May 2013 producing a large shocks across the Japanese Islands. The maximum shaking intensity reached 3 on the JMA scale at Sarufutsu, Hokkaido and Akita, and the felt area spread to Kagoshima, 3000 km from the hypocenter. According to USGS, the shake was also reported in Northern India, California, and Dubai 6000 km away; also CNN reported that people in Moscow were evacuated from the buildings. Kuge (2015) analyzed teleseismic records and claimed that shaking at large distance is consistent with the radiation pattern of P wave, similar to the 1994 Bolivia Mw8.3 earthquake (Anderson et al., 2015). In this study we aim to understand the cause of large ground motion at regional to teleseismic distances from this very deep event using dense F-net, Hi-net, and IRIS DMC observations, complemented by 3D FDM simulation of seismic wave propagation.

Observed strong ground motion in Japanese Islands

The observed pattern of peak ground velocity (PGV) over Japan demonstrates large motions in Sea of Japan side, opposite to the large shake on the Pacific Ocean side as is usually seen in deep earthquakes. The PGV does not attenuate monotonically with distance, and a second PGV peak was seen at distance of about 2000 km.

At shorter distances (<2000 km) upward travelling waves arrive from the 610 km deep source, waves emitted downwards overlap somewhat and dominate beyond 2000 km. The large PGV is associated with successive arrivals of upgoing and downgoing S waves (near a caustic). S waves incident on the surface at the critical angle generates large sP conversions, which propagate in the crust and uppermost mantle to sustain PGV. Furthermore, a third PGV peak occurs at distances around 3000 km created by the SS wave traveling through deep mantle and reflected twice on the surface. Similar anomalous PGV attenuation is found for other deep earthquakes e.g. near Sakhalin in 2012 (Mw7.7; 600 km).

Strong motion simulation of deep earthquake

FDM simulations using ak135 model demonstrate the ways in which the S wave caustics and sP conversion create the second large PGV peak at regional distances, which moves from 1500 to 3000 km as the source depth increases from 200 to 610 km. The efficiency of sP and SS conversion and reflection is very sensitive to the thickness of the crust; SS is large and sP is weak by reflection from thick continental crust, and thin oceanic crust gives the reverse. The large SS observed over Japanese Island is due to the reflection of S wave at the thicker crust (20-30 km) in the Sea of Okhotsk, and large sP phase at Izu-Ogasawara Islands and the Northwest Pacific, corresponds well with the simulation results.

With a Pacific slab model (Yokota et al., 2017) in the 3D FDM simulation model, we find that S waves traveling through the High-V plate are refracted into the Low-V mantle, making large ground motions on the Sea of Japan side. This anti-waveguide effect differs from the stochastic waveguide effects in the plate at high-frequency (>1-2 Hz) waveguide effect, which is weak for the long-period wave of this distant earthquake with oblique transmission.

Shaking at thousands of kilometers due to long-period ground motion?

©2019. Japan Geoscience Union. All Right Reserved.

The IRIS DMC records show that the PGV has large peak at distance of about 3500 km due to the arrival of the SS wave. Then, PGV attenuate gently until the next large PGV peak around 7000 km with the arrival of the SSS phase. Shaking in the distance range 4000-6000 km from the Sea of Okhotsk earthquake comes from long-period SS and SSS waves. At Obinisk (OBN; 6050 km) near Moscow long-period S and SS produce 0.7 cm/s ground velocity at a period of 3.5 s. With amplification of long-period ground motions in sedimentary basins, the ground motion can grow to the JMA’s long-period intensity scale 1 (> 5 cm/s).

Trial estimation of eclogitization depths within subducting oceanic crust of the Philippine Sea slab inferred from head wave propagating along the oceanic Moho

*Shunsuke Takemura[1], Takashi Tonegawa[2], Junichi Nakajima[3], Katsuhiko Shiomi[1]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Japan Agency for Marine-Earth Science and Technology , 3. Tokyo Institute of Technology

To investigate structural properties within the subducting oceanic crust of the Philippine Sea slab, we analyzed head wave propagating along the oceanic Moho (P_{PHS}). In the case of offshore earthquakes occurred at depths shallower than oceanic Moho, P_{PHS} is first arrival at onshore seismic stations (e.g., Takemura et al., 2016 EPS). During southeast off Mie earthquake, observed Hi-net seismograms illustrated first arrivals with an apparent velocity of 7.2 km/s, which correspond to apparent velocity of P_{PHS}, at epicentral distances of 70-200 km. At distances greater than approximately 200 km, apparent velocity of first arrivals was increased. Such distance change of apparent velocities is related with velocity structure at depths below the continental Moho.

We conducted two-dimensional (2D) finite-difference method (FDM) simulations of seismic wave propagation using the realistic slab model (Hirose et al., 2008 JGR). Thickness of subducting oceanic crust was assumed to be 7 km. Crust and mantle structures were referred from the F-net 1D model (Kubo et al., 2002 Tectonophys.). Although P_{PHS} was clearly found in simulated seismograms, the simulation result with oceanic crust at deeper (> 70 km) depths did not reproduced observed first arrivals at greater (>200 km) distances. By replacing structural properties of the oceanic crust with ones of the oceanic mantle at depths of 40-60 km, simulated first arrivals were changed depending on structural change depth. A structural change depth of 52 km is the optimal model for explaining observed first arrivals. This depth well corresponds to an eclogitization depth of the subducting oceanic crust beneath the Kii Peninsula (Kato et al., 2014 EPS).

We consider that estimated structural change depth within the oceanic crust is linked with transformation to anhydrous eclogitic oceanic crust (Fukao et al., 1983 Nature; Abers et al., 2003 GRL; Hacker et al., 2003 JGR). Our analysis using head wave propagating along the oceanic Moho may provide depth of eclogitization within the oceanic crust.

Acknowledgement
NIED F-net MT catalog and Hi-net velocity seismograms were used. Finite-different method simulations were conducted on the Earth Simulator at the JAMSTEC.

Transient gravity perturbations due to a buried gravitational source in a homogeneous elastic half space

*Aditya Nitin Deshmukh[1], Pratik Laxman Borate[1], Abhishek Venkatesh Chitgopkar[1], Nobuki Kame[2], Ranjith Kunnath[1]

1. Mahindra Ecole Centrale, Hyderabad, India , 2. Division of Theoretical Geoscience, Earthquake Research Institute, University of Tokyo, Japan

Earthquake ruptures induce transient deformations which result in changes in the gravity field (Harms, *et. al* (2015)). Prompt elastogravity signals due to the earthquake source arrive before any seismic wave from the source and it has been proposed that these signals could be used for earthquake early warning systems. In this work, we study the model of a buried gravitational load in an isotropic, homogenous elastic half-plane or half-space. The response at the surface is determined for a suddenly applied gravitational line-load in an elastic half-plane. Also, the response at the surface is calculated for a suddenly applied gravitational point-load in an elastic half-space. Due to the gravitational field induced by a suddenly applied line-mass, every point in the half-plane acts as a source by itself. The elastic response due to each point in the half-plane is calculated using the solution of Garvin (1956) for a buried line blast load in an elastic half-plane. The total response at the receiver point on the surface of the half-plane is determined numerically by the convolution of Garvin’ s solution with the gravitational force. Similarly, the elastogravitational response to a suddenly applied point mass in a half-space is determined using the solution of Johnson (1974) to Lamb’ s problem of a source buried in a half-space. We show that in both these models, prompt gravity signals are obtained.Earlier, Kame and Kimura (2018) had considered the elastic response to a suddenly applied point mass in an unbounded medium. They showed that the ground acceleration at any receiver point is exactly cancelled by the gravity perturbation during the entire duration of the prompt period so that a gravimeter at the receiver will not detect any prompt signals. This appears to be a peculiarity of the model of an unbounded medium.

In the Kanto sedimentary basin, long-period ground motions have been frequently observed during shallow moderate-to-large earthquakes [e.g. Yoshimoto and Takemura (2014)]. Strong long-period ground motions, which are caused by surface waves, complicatedly propagate within the Kanto basin due to 3D structures of low-velocity sediments and bedrock topography [e.g., Furumura and Hayakawa (2007)]. For the precise prediction of long-period ground motions, we should investigate propagation characteristics of surface waves and subsurface structure within the Kanto basin. Array analysis using dense seismic stations in the Kanto basin may be useful to capture propagation characteristics of surface waves and structural properties. In this study, as a basic study for investigating a seismic velocity structure of the Kanto sedimentary basin, we applied a beamforming technique to the seismograms synthesized based on FDM simulations.

We selected shallow moderate earthquakes for our beamforming analysis, e.g. the northern Ibaraki prefecture earthquake on March 19, 2011 (Mw 5.8), the northern Tochigi prefecture earthquake on February 25, 2013 (Mw 5.8), and the northern Nagano prefecture earthquake on November 22, 2014 (Mw 6.3). We synthesized velocity seismograms based on the FDM simulations using a velocity structural model SBVSM [Masuda *et al.*(2014); Takemura *et al.* (2015)]. Virtual seismic stations were distributed at an interval of 750 m in the range of 35.5˚N to 35.9˚N and 139.4˚E to 139.9˚E. Our FDM simulations can evaluate ground motions for periods longer than 4 s. In our array analysis using a three-component beamforming [Riahi *et al.*(2013)], the size of the small local array was adjusted according to the analyzed period of Love waves. The analysis was conducted on the six periods: 5.9, 6.4, 7.3, 8.5, 10.2 and 12.8 s. We analyzed the seismograms for time window of 51.2 s, including the maximum amplitude of energy envelope for horizontal components.

By comparing the estimated phase velocities by our array analysis with theoretical ones from local 1D structure of SBVSM, we confirmed that the phase velocities of Love waves propagating in the large sedimentary basin are successfully obtained. Observed dispersion curves show clear normal dispersions. At the period of 5.9 s, the phase velocity was estimated stably for seismograms of all earthquakes. This period corresponds to the dominant period of long-period ground motions within the Kanto sedimentary basin [e.g. Yoshimoto and Takemura (2014)]. We also found that the phase velocity tends to be estimated stably in large PGV areas of long-period ground motions. These results imply that the propagation of surface waves may characterize the magnitude of long-period ground motions. The other results in detail will be exhibited in our presentation.

Similutanious estimation of amplitude and travel time variation in the transfer function with ACROSS

*Shuhei Tsuji[1], Koshun Yamaoka[1], Takahiro Kunitomo[1], Toshiki Watanabe[1], Ikuta Ryoya[2]

1. Graduate School of Environmental Studies, Nagoya University, 2. Faculty of Science, Shizuoka University

Summary

We developed a method for simultaneous estimation of deviation of the amplitude and the travel time of the transfer functions obtained by an artificial seismic source, ACROSS.

Background

Variation of the amplitude is important information for monitoring the strength of the fault plane (e.g. Nagata et al, 2008). However, studies on the variation of propagation properties were mainly discussing the deviation of the travel time (e.g. Ikuta et al., 2002; Hobiger et al., 2016). The conventional method using the signal envelope is affected by the noise level, which is the shortcoming of the method. Thus, we developed a new method to make a simultaneous estimation of the deviation of both the amplitude and travel time.

Method

The simultaneous estimation method is basically a maximum likelihood estimation using a least square method. We adopt the least square method for deviation functions which are obtained by dividing each transfer function by averaged transfer function on the complex plane in the frequency domain. This is incontrast to the cross-spectrum method which was commonly used for calculation of the deviation of the travel time. In our method, the amplitudes as well as the deviation of travel time is calculated similarly to the cross-spectrum method. We estimated the deviation of the amplitudes and travel times as a nonlinear model fitting problem. We made a model of the deviation function with an assumption that the deviation of the amplitude and travel time is independent of frequency. We searched for the best fitting parameters so that minimizing the sum of the square lengths on the complex plane by grid search. As a result, we could estimate the deviations for smaller SNR data. We also could estimate the errors of the obtained deviations.

Results

We applied the method to High Sensitivity Seismograph Network Japan (Hi-net) stations around an ACROSS seismic source which is deployed at Toki City, the middle part of Honshu Island, Japan. The estimated deviation of the travel time with this method generally coincides with the results with the conventional cross spectrum method. When the data has low SNR, the average of the deviation of the amplitude did not become one due to averaging in the complex domain. This is because the least square fitting is made on the complex plane which does not mathematically guarantee the averaging of amplitude.

Temporal variation in travel time of P and S-waves using ACROSS

*rina suzuki[1], Koshun Yamaoka[2]

1. Graduate School of Environmental Studies, Nagoya University, 2. Earthquake and Volcano Research Center,Graduate School of Environmental Studies,Nagoya University

We analyzed the temporal variation of travel time of P and S wave using observation data for one year by an artificial seismic source ACROSS which can generate controlled vibration repeatedly. In this study, we used a new type of ACROSS called ACR2014 that is installed in Toyohashi City, Aichi Prefecture. This ACROSS source can excite vertical vibration as well as horizontal vibration by rotation of the weight around the horizontal rotation axis to excite P wave efficiently. We used records at three observation stations called NU.MIK, N.THNH, and N.MKBH installed around ACR2014 and calculated transfer functions. From the components of transfer function, we chose the vertical component by vertical excitation and horizontal component by horizontal excitation for calculation of travel time of P and S wave, respectively. We calculated travel time variations from these components of transfer function using cross spectrum method. In this calculation, a window ranging 0.2 to 0.3 seconds was applied to the P and the S wave part, respectively. We compared the travel time variations with the precipitation data of nearby AMeDAS at Toyohashi and Mikkabi. In NU.MIK, short-term change with a step-like delay and following recovery occurred in both P and S waves at rains. The tendency of this recovery was different between the P and S wave. On the other hand, the long-term variation differs between the P and S waves at some observation stations. We interpreted the influence of rainfall on these short-term and long-term travel time variations, using a theoretical effect of the crack density and fluid saturation on the seismic velocity change. The observed difference in the P and S wave change can be explained with the difference in the response of crack density and fluid saturation between P and S waves. The long-term travel time variations in the P and S waves can be interpreted by assuming that the fluid saturation increases in the periods with high precipitation and decrease in the periods with low precipitation. The short-term change with the difference of the recovery between the P and S wave can be interpreted in similar way as the long-term variation.

Inversion analysis of S coda wave envelope based on radiation transfer theory - Estimation of heterogeneous structure of Izu Oshima volcano -

*Takahiro Ueda[1]

1. Department of Geophysics, Graduate School of Science, Tohoku University

It is well known that short period seismic waves are strongly influenced by heterogeneous structures in the crust or shallow structures. Analyses using seismic sources near the ground surface such as artificial sources and seismic wave interferometry have reported that strong heterogeneity appears remarkably due to shallow sediments of volcanoes. On the other hand, there are few studies in which volcano-tectonic earthquakes are used, and the characteristics of heterogeneous structure down to deep regions (10 km) of the volcanoes have not been well investigated. In this study, based on the Multiple Lapse Time Window method (Fehler et al. 1992) based on radiative transfer theory, we evaluate heterogeneity of the volcano structures, using an inversion method to obtain the intrinsic attenuation value, scattering attenuation value, the energy radiated from the source, and the site amplification factor, a of the Izu Oshima volcano. We use the seismic waveforms recorded at 4 V-net stations at Izu Oshima. From January 2014 to January 2018, events of M1.5 to M3.5, 150 earthquakes within 10 km deep are analyzed. Bandpass filters of 1-2 Hz, 2-4 Hz, 4-8 Hz, and 8-16 Hz bands are applied, and the envelope waveforms of the direct waves and coda waves of S waves are obtained in each frequency band. The Green’ s function is calculated based on the radiative transfer theory of the S wave multi isotropic scattering. The amplitude is expressed by the product of the site amplification factor, the energy radiated from the source, and Green’ s function. We fit the observation envelope with the theory and determine the internal attenuation and the scattering attenuation as well as site factors and source energy.
The results show that the scattering attenuations are 0.0393, 0.0210, 0.0027, 0.0001 in the 1-2 Hz, 2-4 Hz, 4-8 Hz, and 8-16 Hz bands, respectively, and the intrinsic attenuation was 0.0054, 0.0056, 0.0029, 0.0006. The average values of Japan's crustal structure (Calocoré and Sato, 2010) are almost same with intrinsic attenuation of this study, while the value of the scattering attenuation is larger by about 10 times in the low frequency region around 1.5 Hz. In addition, it is smaller than the results for very shallow part (Yamamoto and Sato., 2010, Hirose et al., 2019) by 1 to 2 orders of magnitude.
Based on the above results, the scattering attenuation parameter is dominant in Izu Oshima compared to the Japanese crust, compared to the internal damping, which is in harmony with the results of the previous study that the scattering damping is large around the active volcano , And it seems that the influence of the minute heterogeneous structure of the shallow part of the crust appeared strongly. In addition, theoretical envelope was well obtained by the envelope inversion method proposed in this research, and it was shown that it is effective as a method to evaluate the radiation energy and the radiation energy of the epicenter.

Strong motion characteristics at Nagomi-machi, Eta, during the northern Kumamoto pref. earthquake of Jan. 3rd, 2019

*Tomotaka Iwata[1], Kimiyuki Asano[1], Masayuki Yoshimi[2], Takeshi Sugiyama

1. Disaster Prevention Research Institute, Kyoto University, 2. Geological Survey of Japan, AIST

We estimate ground motion characteristics of Eta, Nagomi-machi, Kumamoto, during the 2019 Jan. 3rd northern Kumamoto earthquake (MJ5.5). The JMA seismic intensity of 6weak was observed at the site. Before this event, we have conducted the microtremor array measurement and obtained that the thin (about 20m) superficial layer with a S-wave velocity of less than 0.2km/s. We also estimated site amplification factor by the spectral inversion method (Somei et al., 2018). The site amplification factor shows the predominant period of about 0.4s for weak motion data. After the mainshock, we have conducted additional microtremor array measurement to give a more in-detail information in the area and single station H/V observations just beside of the seismic intensity meter and outside of the building for checking the effects of station setting of this site. In this moment, there is no significant effect of the station setting because of the similar H/V spectral ratio between the site and the one outside of the building in this period range. We also noticed that the predominant period of observed horizontal motions of the mainshock is about 0.5s, that is a little bit longer than that of the site effect for the weak motions. This would be caused by the non-linear behavior of the superficial layer during the strong shaking. Strong motion data are provided by JMA and Kumamoto prefecture. Microtremor observations and spectral inversion were conducted by the Comprehensive Research Project for the major active faults related to The 2016 Kumamoto Earthquake (2016FY-2018FY), Mext.

Effects of the heterogeneous crustal structure on the amplitude fluctuation of high-frequency seismic waves

*Kazuo Yoshimoto[1], Shunsuke Takemura[2]

1. Graduate School of Nanobioscience, Yokohama City University, 2. National Research Institute for Earth Science and Disaster Resilience

It is considered in the seismic scattering analyses that crustal heterogeneity may be modeled by combining deterministic heterogeneity and stochastic heterogeneity. A simple technique of this modeling adopts a uniform averaged structure model (background structure model) for deterministic heterogeneity and a uniform random heterogeneity model for stochastic heterogeneity. Although this technique may be adequate for the seismic scattering analysis with a small target area, the simplification might lead erroneous results if the target area of the analysis becomes large. In this study, we investigated the effect of the deterministic crustal heterogeneity on the amplitude fluctuation of high-frequency (0.5-4 Hz) seismic waves on the basis of finite-difference method (FDM) simulations.
We conducted FDM simulations of shallow moderate earthquakes, including a target earthquake occurred on 25 November 2011 at a depth of 14 km beneath the Chugoku region, western Japan. Our simulation model covered a volume of 256×256×80 km^3, which was discretized by a uniform grid spacing of 0.05 km. Technical details are the same as those of Takemura et al. (2017). The background velocity structure was referred from the Japan Integrated Velocity Structure Model (JIVSM; Koketsu et al., 2012). Small-scale random velocity heterogeneity (Takemura et al., 2017) was superposed on the crust of the JIVSM. We adopted a double-couple point source with a focal mechanism reported by the F-net MT catalog. This model setting well reproduced observed high-frequency seismograms at the Hi-net borehole stations (Takemura et al., 2017). Because we employed a finer FDM grid compared to previous simulations (Takemura et al., 2017), our FDM simulation can evaluate seismic wave propagation for higher (~ 8 Hz) frequencies. To investigate fluctuation of seismic amplitudes, we evaluated peak ground velocity (PGV) from filtered synthetic seismograms.
Simulation results of a strike-slip source model showed that the cross-shaped (four-lobed) large PGV distribution in the epicentral area becomes unclear in the surrounding area as the hypocentral distance increases. Theoretical and empirical models of high-frequency seismic amplitudes also predicted a similar characteristic of apparent radiation pattern (Yoshimoto et al., 2015; Takemura et al., 2016). Although this phenomenon, which is mainly caused by the seismic scattering due to random heterogeneity, showed azimuthal symmetry, the symmetry was found to be broken for a certain focal depth condition. Our additional simulations using different properties of background structure model indicated that, at least in our target region, the reflection due to a small velocity contrast of the Conrad discontinuity (about 10% in JIVSM) may cause the large amplitude fluctuation of high-frequency seismic waves in the surrounding area of the epicenter (distance > 40 km).

Long-duration long-period ground motion in Hokkaido during off-Tohoku earthquakes (2) Roles of crust and Pacific slab

*Shinako Noguchi[1], Takuto Maeda[2], Takashi Furumura[3]

1. Association for the Development of Earthquake Prediction, 2. Faculty of Science and Technology, Hirosaki University, 3. Earthquake Research Institute, The University of Tokyo

Anomalously large, long-time-lasting long-period later phases were observed widely in Hokkaido, Japan during moderate to large (M>6.5) earthquakes occurred at off-Tohoku Pacific earthquakes. Such long-period signals spread widely over Hokkaido not only at deep Ishikari basin as reported by Noguchi et al. (2017; JpGU). In this study we discuss new mechanisms to generate this later phase in addition to well recognized deep sediment effect by means of 3D FDM simulations of seismic wave propagation using 3D heterogeneous subsurface structure model.

This long-period later phase caused by off Tohoku earthquakes appeared at most F-net stations in Hokkaido except for a few stations at southwestern Hokkaido. However, these later phases did not appear from inland earthquakes, outer-rise earthquakes and earthquakes occurred near Hokkaido. Dominant period of this later phases lay within the range between 15 s to 25 s, varying among earthquakes. The later phase in transverse component expected to be Love wave showed longer period and appeared earlier than that in radial and vertical components expected to be Rayleigh wave. Both waves showed normal dispersion.

The FDM simulations of seismic wave propagation in 3D heterogeneous crust and mantle structure was conducted using OpenSWPC (Maeda et al., 2017). This simulation model consists of sea water, topography, sediments and subducting plates based on Japan Integrated Velocity Structur Model (JIVSM; Koketsu et al., 2012) and the depth of Moho and Pacific slab is based on Matsubara et al. (2017) and Kita et al. (2010), respectively.

We confirmed two distinct phenomena from the FDM simulations as follows; Firstly, long tail of Rayleigh wave (< 3 km/s) propagating north and southward at western-side of Japan trench following the main packet of surface wave were generated. Then the long wavetrains spreading over Hokkaido were generated by conversion from the Rayleigh wave northward along trench at the edge of deep sediment at off Ishikari. Secondly, Love wave appearing at the junction of Japan trench and Kuril trench extended over Hokkaido in earlier time than the converted Rayleigh wave.

We investigated the phase and group velocities for Rayleigh wave and Love waves from off Tohoku to Hokkaido; we found a lower-wavespeed zone of group and phase velocities for Rayleigh wave at period around 20 s guiding Rayleigh wave along the west side of Japan trench, where was formed by the subsurface low-velocity layer covering over the Pacific slab. Such low-wavespeed zone was not appeared for Love wave. However, strong velocity contrast between the Pacific side and Japan side of trench due to different crustal thickness was confirmed which bended the ray of Love wave toward low-velocity side. Thus, Love waves traveling along low-velocity side released seismic energy toward Hokkaido at the junction of Japan trench and Kuril trench, producing anomalously large and long-time lasting long-period ground motions.

We conclude that the long period later phase observed over Hokkaido during off Tohoku earthquakes

were caused by the deep subsurface structure including crustal thickness and subducting slab in addition to deep sediments at off Ishikari.

Measuring the NCF dispersion without the long inter-station distance limitation –a new method based on hybrid peak time matching

*Ying-Nien Chen[1], Yuancheng Gung[2], Ling-Yun Chiao[3]

1. Institute of Seismology, National Chung Cheng University, Taiwan., 2. Department of Geosciences, National Taiwan University, Taipei, Taiwan., 3. Institute of Oceanography, National Taiwan University, Taipei, Taiwan.

Over the past decade, the probing of Earth structures using seismic ambient noises has been widely used by seismologists and is now a well-developed technique. Based on an implicit high-frequency approximation, the consensus is that the noise cross-correlation function (NCF) of continuous seismic records resembles the Green’ s Function (GF) of the far-field surface wave between sensors. This perspective leads to the application of the long interstation distance criterion in the dispersion measurements, and, accordingly, much of the low-frequency content in the NCF is rejected. Herein we show that, for a far-field source, the NCF used in most surface wave studies should not be considered as representative of the empirical Green’ s Function (EGF); instead, it is simply the interference product between sensors. We present a theoretical derivation of an explicit definition for a “high-frequency approximation” and clarify the relationship between the NCF and the EGF. Furthermore, we propose a new method to measure the NCF dispersion, in which the phase velocity is estimated by matching the peak delay time observed in the time domain NCF to the one predicted by the theoretical complex NCF signals. In this hybrid peak time matching technique, the long interstation distance is no longer a required condition and phase velocities can be determined more precisely at lower frequencies. Therefore, this permits the investigation of deeper structures using noise data.

Dynamic Triggering Earthquakes Exploration by Sonification of Seismograms

*Takahiko Uchide[1], Yota Morimoto[2], Masaki Matsubara[3]

1. Research Institute of Earthquake and Volcano Geology, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST), 2. Institute of Sonology, Royal Conservatory of the Hague, 3. University of Tsukuba

We have been proposing the sonification of seismograms for exploring dynamic triggering earthquakes (Uchide et al., JpGU, 2016, 2018; Matsubara et al., 2016). The seismic sonification for the 2011 Tohoku-oki earthquake successfully revealed a dynamic triggering event in the Hida area, Central Japan. For the ease of the seismic sonification for seismologists, we are developing the Sonification of Seismograms (SoS) system (Uchide et al., JpGU, 2018), which assigns sound whose amplitude and tone correspond to the maximum absolute value and the number of zero-crossings of seismograms in short time windows.

This study investigates dynamic triggering events by recent major earthquakes using the SoS software. In the case of the 2011 Tohoku-oki earthquake, the dynamic triggering event in the Hida area was M 4.2 (Ohmi et al., 2012) which is relatively large. Identification of smaller dynamic triggering events may be a challenge. Limiting areas of stations for the sonification help us identify where a dynamic triggering event may or may not occur.

In front of our poster, we will provide the opportunity to listen sonified sounds and demonstrate the interactive sonification process using the SoS.

The effect of P-wave velocity on the ellipticity of Rayleigh waves in a transversely isotropic medium

*Shun Fukushima[1], Kiyoshi Yomogida[1]

1. Hokkaido University,Graduate school of Science,Department of Natural History Sciences,Seismology Laboratory

The study of surface waves is one of effective approaches for the internal structure of the earth. Phase and group velocities data have ever been used, but the ellip- ticity of Rayleigh waves can be also used to infer it (e.g., Tsuboi & Saito, 1983) . The ellipticity of Rayleigh waves is defined as a V(vertical amplitude)/H(horizontal amplitude) ratio, which is more sensitive to shallow structures than the conventional phase or group dispersion data. Fundamentally, it is the same principle as strong ground motions with horizontal and vertical amplitudes of microtremors to evaluate near-surface structures easily. Tsuboi & Saito (1983) and Tanimoto & Tsuboi (2009) derived and calculated partial derivatives of ellipticity in an isotropic medium. In addition to the well-known anisotropy in the asthenosphere such as that included in PREM, the influence of a transversely isotropic medium may be important for shallow structures such as a sedimentary layer. A transversely isotropic medium has five elastic moduli (A, C , L, N .F) but propagations of surface waves can be formulated in a compact manner, similar to the isotropic case.
In this study, we first formulated partial derivatives of ellipticity in a transversely isotropic medium. In the same way as the isotropic medium, we determine the linear relationship using the variational principle and the reciprocal theorem. Then, we set an artificial eigenfunction for the boundary condition of non-zero normal stress at the surface in addition to the natural eigenfunction for the normal condition (i.e., zero stress at the surface). We then derived partial derivatives with the two kinds of eigenfuncitons combined. Several important features of PV-waves and PH-waves are revealed in comparison with those of P-waves in the isotropic case. P-waves have little effects on the ellipticity in an isotropic medium. In the transversely isotropic medium, partial derivatives of PV wave are quite different from those of PH wave with a relatively large amplitude in a shallow part. The reason of the small P-wave effect in the isotropic case comes from the sum of those of PV and PH waves of opposite signs. PH wave in a shallow part has a large positive effect on ellipticity while PV wave has a weak negative one. If there is a strongly laminated sedimentary layer near the surface, for example, the ellipticity does not vary so much, despite of small SV there. It is because the shallow PH velocity is not reduced in such a layer, in contrast with small SV and PV waves, and its partial derivatives is large and of the sign opposite to SV and PV waves. If we performed the inversion for the shallow structure with the data of ellipticity (i.e., only slightly anomalous), under the isotropic model with the dominance of SV wave velocity, the inversion result would lead to slightly small SV velocity near the surface with virtually no changes in P-wave velocity because partial derivatives in the isotropic case are large for SV but small for P wave.

Time series analyses of amplitude of the Earth’s background free oscillations

*Ryuichi Kunugi[1], Naoki Suda[1]

1. Hiroshima University

The Earth’s background free oscillations (BFO) are slightly and continuously excited free oscillations of the solid Earth persistent even in seismically quiet periods [Nawa et al. 1998; Suda et al. 1998; Kobayashi and Nishida 1998; Tanimoto et al. 1998]. The observed modes are fundamental modes, suggesting that the excitation sources are atmospheric and oceanic disturbances [e.g. Nishida 2013]. Amplitude of BFO exhibits seasonal variations [Nishida et al. 2000]. Along with such a periodic variation, there may exist transient variations correlated with atmospheric/oceanic phenomena.

The target modes are fundamental modes ${}_0S_{22}$-${}_0S_{43}$ at frequencies between 3 and 5 mHz because they are most clearly observed in the frequency domain. We used vertical records of STS-1 broadband seismometers at 65 quite seismic stations downloaded from IRIS DMC. The data periods are from 2000 to 2017. The analysis method is mainly the same as used in Nishida et al. (2000). Continuous records were divided into 3-days records with a step of 1 day. After applying the Hanning taper, each record was converted into power spectral density (PSD) with the correction of system response. To reject noisy data, we used the data whose mean PSD values at 3-5 mHz are between 10^{-19} and 10^{-18} m^2/s^3. The remained PSDs were then stacked over all the stations to create monthly averaged PSDs. To avoid the influence of temporally changing PSD baseline due to the random background noise, we averaged the PSD values in the mode and the noise frequency bands, and then the averaged noise PSD is subtracted from the averaged signal PSD.

We used two methods of time series analysis for the statistical analysis of long-term variations in amplitude of BFO: one is based on the state-space model and the other is on the regression model. In the state-space analysis we adopted the local level model with seasonal variations, which divide time series into random noise, seasonal variations and a long-term trend. In the regression analysis we adopted the model that consist of random noise, seasonal variations and a long-term trend. We used the R packages dlm and prophet for the state-space and the regression analyses, respectively.

The result obtained in the space-state analysis shows the long-term variation with a time scale of 10 years from 2002 to 2012: the minimum is in 2002 and 2012 and the maximum is in 2008. The long-term trend obtained in the regression analysis shows almost the same characteristics: the minimums in 2000 and 2012 and the maximum in 2008. Thus, we for the first time robustly obtained the nearly 10-year variation in amplitude of BFO from the two different time-series analyses. We can utilize data of infragravity waves at frequencies between 3-30 mHz from WAVEWATCH III. We will show the result of comparison between BFO and infragravity waves in the presentation.

Regional shear waves from an unusually deep earthquake beneath Ogasawara Islands: 660 km discontinuity and anisotropy

*Keiko Kuge[1]

1. Department of Geophysics, Graduate School of Science, Kyoto University

Following a large deep earthquake beneath Ogasawara Islands on 30 May, 2015, an aftershock (mb 4.9) took place at a depth of 678 km (USGS). P and S waves from the aftershock were recorded by F-net broadband stations in Japan at distances of 1 to 18 degrees. The aftershock is small enough to neglect source effect. Here I explore structure effect on the shear wave propagation. SH waves recorded by the transverse directions in western Japan were generally characterized by a single pulse. The peaks of the SH waves tend to arrive earlier than those of the SV waves in the radial directions. The dominance of a single pulse in the SH waves can be explained by the iasp91 model with the 660 km discontinuity shallower than the aftershock. When the 660 km discontinuity is assumed to be deeper than the aftershock, additional signals predicted in radial components can apparently cause different peak time arrivals between SH and SV waves. However, in these cases, the SV peaks arrive earlier than the SH peaks, which cannot fit the observations. It is thus more likely that the observed peak time difference is attributed to anisotropy. Because signals due to crustal reflection are predicted in the radial components ~6 sec after the direct S waves, shear wave splitting parameters were carefully estimated by using initial portions of S waves. The fast directions obtained in western Japan are nearly in the east-west, which looks different from the fast direction observed for a nearby deep earthquake in the Wadati-Benioff zone. We cannot see systematically early arrivals of SH peaks from Fiji earthquakes in a similar back azimuth. The anisotropic regions may be located deep.

On the estimation of G discontinuity in the oceanic upper mantle using ScS reverberations

*Jumpei Maruyama[1], Hitoshi Kawakatsu[1], Nozomu Takeuchi[1]

1. University of Tokyo, Earthquake Research Institute

On the upper mantle shear wave velocity structure in the northwestern Pacific, there is a disagreement between the estimations using ScS reverberations (Bagley et al. 2009) and Rayleigh waves (Isse et al., 2019). This may be ascribed to the difference between the sensitivities of these waves to η_κ, the new fifth parameter of VTI (Kawakatsu, 2016), and reflect a characteristic of anisotropy in the oceanic lithosphere-asthenosphere system (LAS).

The method used by previous work (Revenaugh & Jordan, 1991) employs two-step analysis: 0th order analysis for whole mantle parameters and 1st order analysis for the characteristics of mantle discontinuities. Since this method was introduced to investigate the land area of the western circum-Pacific, there has been no detailed verification if it is compatible for the oceanic area whose upper mantle structure significantly differs from that of the continental area. We applied a simplified analysis method to full wave synthetic waveforms generated for an oceanic model with G, and revealed that the conventional method might fail in estimating the upper mantle structure and the whole mantle quality factor Q because of a strong reflected wave from G.

We will attempt to improve ScS reverberation analysis method and to compare its result for the northwest Pacific area with the existing model.

Short-period body wave (1-3 Hz) extraction from ambient noise records observed at seafloor and borehole in the Nankai subduction zone

*Takashi Tonegawa[1], Toshinori Kimura[1]

1. Research and Development center for Earthquake and Tsunami, Japan Agency for Marine-Earth Science and Technology

In the Nankai subduction zone, a cabled-network, named DONET (Dense Oceanfloor Network system for Earthquakes and Tsunamis), and borehole stations connected to the DONET have been constructed. The station spacing of DONET is 15-20 km, but, corporating it with borehole sensors, some of station pairs have station spacing less than 15 km. We attempted to extract body waves by applying cross correlation analysis to ambient noise records observed at the southern part of those stations, because borehole sensors have constructed near the trough.
As a result, we found eight pairs showing P wave in the cross correlation functions (CCFs) at frequencies of 1–3 Hz, which emerged before T-wave. In the case of station spacing less than 5 km (2 pairs), P wave extraction required only one-day stacking of ambient noise records, but other pairs required 10–30 days. Although the reason for unstable retrieval on the pairs and time periods for stacking is still under debate, the retrieved P-wave was stable over the observation periods.

Characteristics of T-wave envelopes observed by S-net

*Kentaro Emoto[1], Hisashi Nakahara[1]

1. Graduate School of Science, Tohokuk University

S-net enables us to access continuous sea-floor network observation data. Different from observed data in the inland area, the strong signal of the T-wave appears following the P- and S-waves in the seismograms recorded by S-net stations. T-wave is the acoustic wave propagating in the ocean. The low-velocity layer called SOFAR channel efficiently delivers the T-wave to distant stations. Owing to this property, T-wave has been used to monitor nuclear tests and activities of submarine volcanoes [Okal, 2008]. The pulse width and the amplitude of the T-wave can be used as a proxy to distinguish the explosion source and the natural earthquake [Talandier & Okal, 2001]. The rise time of the T-wave and the amplitude ratio of the T-wave and the body wave is related to the focal depth [Yang & Forsyth, 2003; Dziak et al., 2005; Wech et al., 2018]. These features were derived from observations of the T-wave at distant stations. On the other hand, we now become able to investigate the detailed process of the conversion between seismic waves and T wave because we can analyze the T-wave generated by local earthquakes by using the S-net. In this study, we summarize the characteristics of envelopes of T-waves recorded by S-net stations.

We calculate envelopes of T-waves by summing squared three components velocity seismograms band-passed in the frequency range of 8-16 Hz. The duration of the envelope is characterized by $\tau_{1/3}$ or T_{rms} which do not depend on the onset, because the onset of the T-wave is gradual and sometimes buried in the S-wave coda. $\tau_{1/3}$ is the duration during which the amplitude is higher than the one-third of the peak. T_{rms} corresponds to the standard deviation of the envelope. The strength of the T-wave is defined by the TPEF (T-phase energy flux) [Okal et al., 2003].

The propagation velocity is about 1.5 km/s in general, but it is sometimes higher in deeper stations. The onset is not clear and the amplitude gradually increases to the peak. Different from the envelope of the seismic wave which shows the long coda compared to the rise time, the time scales of the increase and the decrease of the T-wave are almost the same. This indicates that the generation process is more dominant than the scattering effect in the propagation process. However, the scattering effect also exists, because the T_{rms} increases with the propagation distance. This result is different from the observation in the relatively flat bathymetry area [Yang & Forsyth, 2003]. $\tau_{1/3}$ in the shallow station is smaller than that in the deeper station, although it shows a large variation. Regarding the energy of the T-wave, TPEF is larger in the deeper stations. This is because the T-wave is reflected by the up-slope of the ocean trench and enough energy can't reach the shallower stations. T-waves generated by the earthquakes near the triple junction mainly propagates along the trench. The TPEF shows a power-law decay with distance. The power law exponent varies from -1 to -6 depending on the source location. Outer rise earthquakes generate strong T-wave compared to inter- and intra-plate earthquakes. This is because the T-waves converted at the down-slope of the trench enter the SOFAR channel with lower incident angles and are efficiently trapped. The conversion point for the case of the intra-plate earthquake whose focal depth is about 100 km is located around the trench. The seismic wave traveling along the slab is converted to the acoustic wave at the trench. This conversion shows strong directivity.

©2019. Japan Geoscience Union. All Right Reserved.

As we mentioned above, T-wave recorded by the S-net stations is strongly affected by the bathymetry and the Earth structure. The modeling of the T-wave by considering both the elastic and the seawater media is necessary to correctly model the T-wave envelopes. By modeling the characteristics observed in this study, we can understand the details of the conversion process between the elastic and acoustic waves.

Reverse time reflection imaging of active and passive seismic data with ocean-bottom seismographs

*Kazuya Shiraishi[1], Takao Nibe[2], Yasuhiro Yamada[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Japan Petroleum Exploration Co. Ltd.

Introduction

In most case of crustal seismic surveys or earthquake observations using ocean-bottom seismometers, however, because receiver spacing is generally large in the wide range survey/observation, technical improvements of imaging methods are required to interpolate the lack of subsurface imaging area. On the other hand, high-dense and continuous seismic (earthquake) observation using new and existing optic fiber cables have been advancing. Development of an efficient imaging method is also necessary to utilize the enormous data. Reverse time migration (RTM) in reflection seismic exploration is one of effective seismic imaging techniques for complex subsurface structures with reconstructing full wavefield. In this study, we developed reverse time reflection imaging method which is available in active seismic survey and passive seismic observation, and we conducted a field data application and a numerical feasibility study.

Method

A. basic RTM: source-to-receiver pairs

In case of active survey with artificial seismic sources or a passive observation with accurate source locating, basic imaging principle using primary reflections between the sources and receivers is available. In the basic reverse time reflection imaging, reflected waves are focused on subsurface imaging points by a temporal integration of product between forward-extrapolated wavefields from source and backward-extrapolated wavefields of the recorded seismic data from receiver points.

B. modified RTM: receiver-to-receiver (source-to-source) pairs

We propose a modified reverse time reflection imaging method in passive seismic survey without determining source information. Both forward and backward wavefield extrapolations are performed from all receiver locations with the recorded seismograms, and the surface-reflected multiple reflections are focused on the subsurface imaging points as pseudo-primary reflections. Based on source-receiver reciprocity, this method can be applied to source-to-source pairs to use multiple reflections in airgun-OBS surveys.

Case study

(1) Airgun-OBS survey data in the Nankai Trough

We applied the proposed method to a 2D wide-angle reflection survey data acquired along 170 km survey line (200 m spacing of airgun shots, and 1 - 10 km spacing of OBSs) in the Nankai Trough. In wavefield reconstruction in the imaging process, sources and receivers are exchanged based on source-receiver reciprocity. A final reflection profile can be obtained by stacking two results derived from the primary reflections from OBS to airgun locations with the basic RTM method and from the multiple reflections between different airgun locations with the modified RTM method. Deep structures including the subducting plate and its relationship with old and young accretionary prisms are imaged with long offset reflections. Shallow structures are also clearly shown including sea floor and topographic relief of the base surface of sedimentary basin without lack of imaging area.

(2) Numerical simulation of earthquake observation

We tested reflection imaging with the modified RTM method by using numerical simulation data of both on-land and ocean-bottom earthquake observation. There is a big difference on a boundary condition (i.e. presence of a water layer above receivers) between the ocean-bottom and on-land observation. Multiple

©2019. Japan Geoscience Union. All Right Reserved.

reflections due to the water layer is significant in the ocean-bottom observation. We confirmed that reflection imaging is possible from passive observations both of the on-land and ocean-bottom seismometers with the modified RTM method. The multiple reflections are helpful to illuminate subsurface reflectors more effectively in the ocean-bottom observation in case of spars receiver deployment.

[S-SS11] Seismic wave propagation: Theory and Application

convener:Kiwamu Nishida(Earthquake Research Institute, University of Tokyo), Kazuya Shiraishi(Japan Agency for Marine-Earth Science and Technology), Takao Nibe(JAPEX), Kaoru Sawazaki(National Research Institute for Earth Science and Disaster Resilience)

Seismic wave propagation provides rich information of earth's heterogeneities and the excitation sources. In order to extract the information, integrated studies are needed among mathematical/numerical studies based on the wave theory, miniature physical experiments using rock specimens, and practical data analyses. Furthermore, it is greatly beneficial to conduct comparative studies of various kinds of waves, such as elastic, acoustic, traveling ionospheric disturbances, and oceanic waves. This session widely invites presentations about the theories and applications related to seismic and other geophysical waves.

In the Kanto sedimentary basin, long-period ground motions have been frequently observed during shallow moderate-to-large earthquakes [e.g. Yoshimoto and Takemura (2014)]. Strong long-period ground motions, which are caused by surface waves, complicatedly propagate within the Kanto basin due to 3D structures of low-velocity sediments and bedrock topography [e.g., Furumura and Hayakawa (2007)]. For the precise prediction of long-period ground motions, we should investigate propagation characteristics of surface waves and subsurface structure within the Kanto basin. Array analysis using dense seismic stations in the Kanto basin may be useful to capture propagation characteristics of surface waves and structural properties. In this study, as a basic study for investigating a seismic velocity structure of the Kanto sedimentary basin, we applied a beamforming technique to the seismograms synthesized based on FDM simulations.

We selected shallow moderate earthquakes for our beamforming analysis, e.g. the northern Ibaraki prefecture earthquake on March 19, 2011 (Mw 5.8), the northern Tochigi prefecture earthquake on February 25, 2013 (Mw 5.8), and the northern Nagano prefecture earthquake on November 22, 2014 (Mw 6.3). We synthesized velocity seismograms based on the FDM simulations using a velocity structural model SBVSM [Masuda *et al.*(2014); Takemura *et al.* (2015)]. Virtual seismic stations were distributed at an interval of 750 m in the range of 35.5˚N to 35.9˚N and 139.4˚E to 139.9˚E. Our FDM simulations can evaluate ground motions for periods longer than 4 s. In our array analysis using a three-component beamforming [Riahi *et al.*(2013)], the size of the small local array was adjusted according to the analyzed period of Love waves. The analysis was conducted on the six periods: 5.9, 6.4, 7.3, 8.5, 10.2 and 12.8 s. We analyzed the seismograms for time window of 51.2 s, including the maximum amplitude of energy envelope for horizontal components.

By comparing the estimated phase velocities by our array analysis with theoretical ones from local 1D structure of SBVSM, we confirmed that the phase velocities of Love waves propagating in the large sedimentary basin are successfully obtained. Observed dispersion curves show clear normal dispersions. At the period of 5.9 s, the phase velocity was estimated stably for seismograms of all earthquakes. This period corresponds to the dominant period of long-period ground motions within the Kanto sedimentary basin [e.g. Yoshimoto and Takemura (2014)]. We also found that the phase velocity tends to be estimated stably in large PGV areas of long-period ground motions. These results imply that the propagation of surface waves may characterize the magnitude of long-period ground motions. The other results in detail will be exhibited in our presentation.

Similutanious estimation of amplitude and travel time variation in the transfer function with ACROSS

*Shuhei Tsuji[1], Koshun Yamaoka[1], Takahiro Kunitomo[1], Toshiki Watanabe[1], Ikuta Ryoya[2]

1. Graduate School of Environmental Studies, Nagoya University, 2. Faculty of Science, Shizuoka University

Summary

We developed a method for simultaneous estimation of deviation of the amplitude and the travel time of the transfer functions obtained by an artificial seismic source, ACROSS.

Background

Variation of the amplitude is important information for monitoring the strength of the fault plane (e.g. Nagata et al, 2008). However, studies on the variation of propagation properties were mainly discussing the deviation of the travel time (e.g. Ikuta et al., 2002; Hobiger et al., 2016). The conventional method using the signal envelope is affected by the noise level, which is the shortcoming of the method. Thus, we developed a new method to make a simultaneous estimation of the deviation of both the amplitude and travel time.

Method

The simultaneous estimation method is basically a maximum likelihood estimation using a least square method. We adopt the least square method for deviation functions which are obtained by dividing each transfer function by averaged transfer function on the complex plane in the frequency domain. This is incontrast to the cross-spectrum method which was commonly used for calculation of the deviation of the travel time. In our method, the amplitudes as well as the deviation of travel time is calculated similarly to the cross-spectrum method. We estimated the deviation of the amplitudes and travel times as a nonlinear model fitting problem. We made a model of the deviation function with an assumption that the deviation of the amplitude and travel time is independent of frequency. We searched for the best fitting parameters so that minimizing the sum of the square lengths on the complex plane by grid search. As a result, we could estimate the deviations for smaller SNR data. We also could estimate the errors of the obtained deviations.

Results

We applied the method to High Sensitivity Seismograph Network Japan (Hi-net) stations around an ACROSS seismic source which is deployed at Toki City, the middle part of Honshu Island, Japan. The estimated deviation of the travel time with this method generally coincides with the results with the conventional cross spectrum method. When the data has low SNR, the average of the deviation of the amplitude did not become one due to averaging in the complex domain. This is because the least square fitting is made on the complex plane which does not mathematically guarantee the averaging of amplitude.

Temporal variation in travel time of P and S-waves using ACROSS

*rina suzuki[1], Koshun Yamaoka[2]

1. Graduate School of Environmental Studies, Nagoya University, 2. Earthquake and Volcano Research Center,Graduate School of Environmental Studies,Nagoya University

We analyzed the temporal variation of travel time of P and S wave using observation data for one year by an artificial seismic source ACROSS which can generate controlled vibration repeatedly. In this study, we used a new type of ACROSS called ACR2014 that is installed in Toyohashi City, Aichi Prefecture. This ACROSS source can excite vertical vibration as well as horizontal vibration by rotation of the weight around the horizontal rotation axis to excite P wave efficiently. We used records at three observation stations called NU.MIK, N.THNH, and N.MKBH installed around ACR2014 and calculated transfer functions. From the components of transfer function, we chose the vertical component by vertical excitation and horizontal component by horizontal excitation for calculation of travel time of P and S wave, respectively. We calculated travel time variations from these components of transfer function using cross spectrum method. In this calculation, a window ranging 0.2 to 0.3 seconds was applied to the P and the S wave part, respectively. We compared the travel time variations with the precipitation data of nearby AMeDAS at Toyohashi and Mikkabi. In NU.MIK, short-term change with a step-like delay and following recovery occurred in both P and S waves at rains. The tendency of this recovery was different between the P and S wave. On the other hand, the long-term variation differs between the P and S waves at some observation stations. We interpreted the influence of rainfall on these short-term and long-term travel time variations, using a theoretical effect of the crack density and fluid saturation on the seismic velocity change. The observed difference in the P and S wave change can be explained with the difference in the response of crack density and fluid saturation between P and S waves. The long-term travel time variations in the P and S waves can be interpreted by assuming that the fluid saturation increases in the periods with high precipitation and decrease in the periods with low precipitation. The short-term change with the difference of the recovery between the P and S wave can be interpreted in similar way as the long-term variation.

Inversion analysis of S coda wave envelope based on radiation transfer theory - Estimation of heterogeneous structure of Izu Oshima volcano -

*Takahiro Ueda[1]

1. Department of Geophysics, Graduate School of Science, Tohoku University

It is well known that short period seismic waves are strongly influenced by heterogeneous structures in the crust or shallow structures. Analyses using seismic sources near the ground surface such as artificial sources and seismic wave interferometry have reported that strong heterogeneity appears remarkably due to shallow sediments of volcanoes. On the other hand, there are few studies in which volcano-tectonic earthquakes are used, and the characteristics of heterogeneous structure down to deep regions (10 km) of the volcanoes have not been well investigated. In this study, based on the Multiple Lapse Time Window method (Fehler et al. 1992) based on radiative transfer theory, we evaluate heterogeneity of the volcano structures, using an inversion method to obtain the intrinsic attenuation value, scattering attenuation value, the energy radiated from the source, and the site amplification factor, a of the Izu Oshima volcano. We use the seismic waveforms recorded at 4 V-net stations at Izu Oshima. From January 2014 to January 2018, events of M1.5 to M3.5, 150 earthquakes within 10 km deep are analyzed. Bandpass filters of 1-2 Hz, 2-4 Hz, 4-8 Hz, and 8-16 Hz bands are applied, and the envelope waveforms of the direct waves and coda waves of S waves are obtained in each frequency band. The Green’ s function is calculated based on the radiative transfer theory of the S wave multi isotropic scattering. The amplitude is expressed by the product of the site amplification factor, the energy radiated from the source, and Green’ s function. We fit the observation envelope with the theory and determine the internal attenuation and the scattering attenuation as well as site factors and source energy.
The results show that the scattering attenuations are 0.0393, 0.0210, 0.0027, 0.0001 in the 1-2 Hz, 2-4 Hz, 4-8 Hz, and 8-16 Hz bands, respectively, and the intrinsic attenuation was 0.0054, 0.0056, 0.0029, 0.0006. The average values of Japan's crustal structure (Calocoré and Sato, 2010) are almost same with intrinsic attenuation of this study, while the value of the scattering attenuation is larger by about 10 times in the low frequency region around 1.5 Hz. In addition, it is smaller than the results for very shallow part (Yamamoto and Sato., 2010, Hirose et al., 2019) by 1 to 2 orders of magnitude.
Based on the above results, the scattering attenuation parameter is dominant in Izu Oshima compared to the Japanese crust, compared to the internal damping, which is in harmony with the results of the previous study that the scattering damping is large around the active volcano , And it seems that the influence of the minute heterogeneous structure of the shallow part of the crust appeared strongly. In addition, theoretical envelope was well obtained by the envelope inversion method proposed in this research, and it was shown that it is effective as a method to evaluate the radiation energy and the radiation energy of the epicenter.

Strong motion characteristics at Nagomi-machi, Eta, during the northern Kumamoto pref. earthquake of Jan. 3rd, 2019

*Tomotaka Iwata[1], Kimiyuki Asano[1], Masayuki Yoshimi[2], Takeshi Sugiyama

1. Disaster Prevention Research Institute, Kyoto University, 2. Geological Survey of Japan, AIST

We estimate ground motion characteristics of Eta, Nagomi-machi, Kumamoto, during the 2019 Jan. 3rd northern Kumamoto earthquake (MJ5.5). The JMA seismic intensity of 6weak was observed at the site. Before this event, we have conducted the microtremor array measurement and obtained that the thin (about 20m) superficial layer with a S-wave velocity of less than 0.2km/s. We also estimated site amplification factor by the spectral inversion method (Somei et al., 2018). The site amplification factor shows the predominant period of about 0.4s for weak motion data. After the mainshock, we have conducted additional microtremor array measurement to give a more in-detail information in the area and single station H/V observations just beside of the seismic intensity meter and outside of the building for checking the effects of station setting of this site. In this moment, there is no significant effect of the station setting because of the similar H/V spectral ratio between the site and the one outside of the building in this period range. We also noticed that the predominant period of observed horizontal motions of the mainshock is about 0.5s, that is a little bit longer than that of the site effect for the weak motions. This would be caused by the non-linear behavior of the superficial layer during the strong shaking. Strong motion data are provided by JMA and Kumamoto prefecture. Microtremor observations and spectral inversion were conducted by the Comprehensive Research Project for the major active faults related to The 2016 Kumamoto Earthquake (2016FY-2018FY), Mext.

Effects of the heterogeneous crustal structure on the amplitude fluctuation of high-frequency seismic waves

*Kazuo Yoshimoto[1], Shunsuke Takemura[2]

1. Graduate School of Nanobioscience, Yokohama City University, 2. National Research Institute for Earth Science and Disaster Resilience

It is considered in the seismic scattering analyses that crustal heterogeneity may be modeled by combining deterministic heterogeneity and stochastic heterogeneity. A simple technique of this modeling adopts a uniform averaged structure model (background structure model) for deterministic heterogeneity and a uniform random heterogeneity model for stochastic heterogeneity. Although this technique may be adequate for the seismic scattering analysis with a small target area, the simplification might lead erroneous results if the target area of the analysis becomes large. In this study, we investigated the effect of the deterministic crustal heterogeneity on the amplitude fluctuation of high-frequency (0.5-4 Hz) seismic waves on the basis of finite-difference method (FDM) simulations.
We conducted FDM simulations of shallow moderate earthquakes, including a target earthquake occurred on 25 November 2011 at a depth of 14 km beneath the Chugoku region, western Japan. Our simulation model covered a volume of 256×256×80 km^3, which was discretized by a uniform grid spacing of 0.05 km. Technical details are the same as those of Takemura et al. (2017). The background velocity structure was referred from the Japan Integrated Velocity Structure Model (JIVSM; Koketsu et al., 2012). Small-scale random velocity heterogeneity (Takemura et al., 2017) was superposed on the crust of the JIVSM. We adopted a double-couple point source with a focal mechanism reported by the F-net MT catalog. This model setting well reproduced observed high-frequency seismograms at the Hi-net borehole stations (Takemura et al., 2017). Because we employed a finer FDM grid compared to previous simulations (Takemura et al., 2017), our FDM simulation can evaluate seismic wave propagation for higher (~ 8 Hz) frequencies. To investigate fluctuation of seismic amplitudes, we evaluated peak ground velocity (PGV) from filtered synthetic seismograms.
Simulation results of a strike-slip source model showed that the cross-shaped (four-lobed) large PGV distribution in the epicentral area becomes unclear in the surrounding area as the hypocentral distance increases. Theoretical and empirical models of high-frequency seismic amplitudes also predicted a similar characteristic of apparent radiation pattern (Yoshimoto et al., 2015; Takemura et al., 2016). Although this phenomenon, which is mainly caused by the seismic scattering due to random heterogeneity, showed azimuthal symmetry, the symmetry was found to be broken for a certain focal depth condition. Our additional simulations using different properties of background structure model indicated that, at least in our target region, the reflection due to a small velocity contrast of the Conrad discontinuity (about 10% in JIVSM) may cause the large amplitude fluctuation of high-frequency seismic waves in the surrounding area of the epicenter (distance > 40 km).

Long-duration long-period ground motion in Hokkaido during off-Tohoku earthquakes (2) Roles of crust and Pacific slab

*Shinako Noguchi[1], Takuto Maeda[2], Takashi Furumura[3]

1. Association for the Development of Earthquake Prediction, 2. Faculty of Science and Technology, Hirosaki University, 3. Earthquake Research Institute, The University of Tokyo

Anomalously large, long-time-lasting long-period later phases were observed widely in Hokkaido, Japan during moderate to large (M>6.5) earthquakes occurred at off-Tohoku Pacific earthquakes. Such long-period signals spread widely over Hokkaido not only at deep Ishikari basin as reported by Noguchi et al. (2017; JpGU). In this study we discuss new mechanisms to generate this later phase in addition to well recognized deep sediment effect by means of 3D FDM simulations of seismic wave propagation using 3D heterogeneous subsurface structure model.

This long-period later phase caused by off Tohoku earthquakes appeared at most F-net stations in Hokkaido except for a few stations at southwestern Hokkaido. However, these later phases did not appear from inland earthquakes, outer-rise earthquakes and earthquakes occurred near Hokkaido. Dominant period of this later phases lay within the range between 15 s to 25 s, varying among earthquakes. The later phase in transverse component expected to be Love wave showed longer period and appeared earlier than that in radial and vertical components expected to be Rayleigh wave. Both waves showed normal dispersion.

The FDM simulations of seismic wave propagation in 3D heterogeneous crust and mantle structure was conducted using OpenSWPC (Maeda et al., 2017). This simulation model consists of sea water, topography, sediments and subducting plates based on Japan Integrated Velocity Structur Model (JIVSM; Koketsu et al., 2012) and the depth of Moho and Pacific slab is based on Matsubara et al. (2017) and Kita et al. (2010), respectively.

We confirmed two distinct phenomena from the FDM simulations as follows; Firstly, long tail of Rayleigh wave (< 3 km/s) propagating north and southward at western-side of Japan trench following the main packet of surface wave were generated. Then the long wavetrains spreading over Hokkaido were generated by conversion from the Rayleigh wave northward along trench at the edge of deep sediment at off Ishikari. Secondly, Love wave appearing at the junction of Japan trench and Kuril trench extended over Hokkaido in earlier time than the converted Rayleigh wave.

We investigated the phase and group velocities for Rayleigh wave and Love waves from off Tohoku to Hokkaido; we found a lower-wavespeed zone of group and phase velocities for Rayleigh wave at period around 20 s guiding Rayleigh wave along the west side of Japan trench, where was formed by the subsurface low-velocity layer covering over the Pacific slab. Such low-wavespeed zone was not appeared for Love wave. However, strong velocity contrast between the Pacific side and Japan side of trench due to different crustal thickness was confirmed which bended the ray of Love wave toward low-velocity side. Thus, Love waves traveling along low-velocity side released seismic energy toward Hokkaido at the junction of Japan trench and Kuril trench, producing anomalously large and long-time lasting long-period ground motions.

We conclude that the long period later phase observed over Hokkaido during off Tohoku earthquakes

were caused by the deep subsurface structure including crustal thickness and subducting slab in addition to deep sediments at off Ishikari.

Measuring the NCF dispersion without the long inter-station distance limitation –a new method based on hybrid peak time matching

*Ying-Nien Chen[1], Yuancheng Gung[2], Ling-Yun Chiao[3]

1. Institute of Seismology, National Chung Cheng University, Taiwan., 2. Department of Geosciences, National Taiwan University, Taipei, Taiwan., 3. Institute of Oceanography, National Taiwan University, Taipei, Taiwan.

Over the past decade, the probing of Earth structures using seismic ambient noises has been widely used by seismologists and is now a well-developed technique. Based on an implicit high-frequency approximation, the consensus is that the noise cross-correlation function (NCF) of continuous seismic records resembles the Green’ s Function (GF) of the far-field surface wave between sensors. This perspective leads to the application of the long interstation distance criterion in the dispersion measurements, and, accordingly, much of the low-frequency content in the NCF is rejected. Herein we show that, for a far-field source, the NCF used in most surface wave studies should not be considered as representative of the empirical Green’ s Function (EGF); instead, it is simply the interference product between sensors. We present a theoretical derivation of an explicit definition for a “high-frequency approximation” and clarify the relationship between the NCF and the EGF. Furthermore, we propose a new method to measure the NCF dispersion, in which the phase velocity is estimated by matching the peak delay time observed in the time domain NCF to the one predicted by the theoretical complex NCF signals. In this hybrid peak time matching technique, the long interstation distance is no longer a required condition and phase velocities can be determined more precisely at lower frequencies. Therefore, this permits the investigation of deeper structures using noise data.

Keywords: phase velocity measurement, Empirical Green’ s Function, ambient noise

Dynamic Triggering Earthquakes Exploration by Sonification of Seismograms

*Takahiko Uchide[1], Yota Morimoto[2], Masaki Matsubara[3]

1. Research Institute of Earthquake and Volcano Geology, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST), 2. Institute of Sonology, Royal Conservatory of the Hague, 3. University of Tsukuba

We have been proposing the sonification of seismograms for exploring dynamic triggering earthquakes (Uchide et al., JpGU, 2016, 2018; Matsubara et al., 2016). The seismic sonification for the 2011 Tohoku-oki earthquake successfully revealed a dynamic triggering event in the Hida area, Central Japan. For the ease of the seismic sonification for seismologists, we are developing the Sonification of Seismograms (SoS) system (Uchide et al., JpGU, 2018), which assigns sound whose amplitude and tone correspond to the maximum absolute value and the number of zero-crossings of seismograms in short time windows.

This study investigates dynamic triggering events by recent major earthquakes using the SoS software. In the case of the 2011 Tohoku-oki earthquake, the dynamic triggering event in the Hida area was M 4.2 (Ohmi et al., 2012) which is relatively large. Identification of smaller dynamic triggering events may be a challenge. Limiting areas of stations for the sonification help us identify where a dynamic triggering event may or may not occur.

In front of our poster, we will provide the opportunity to listen sonified sounds and demonstrate the interactive sonification process using the SoS.

The effect of P-wave velocity on the ellipticity of Rayleigh waves in a transversely isotropic medium

*Shun Fukushima[1], Kiyoshi Yomogida[1]

1. Hokkaido University,Graduate school of Science,Department of Natural History Sciences,Seismology Laboratory

The study of surface waves is one of effective approaches for the internal structure of the earth. Phase and group velocities data have ever been used, but the ellip- ticity of Rayleigh waves can be also used to infer it (e.g., Tsuboi & Saito, 1983) . The ellipticity of Rayleigh waves is defined as a V(vertical amplitude)/H(horizontal amplitude) ratio, which is more sensitive to shallow structures than the conventional phase or group dispersion data. Fundamentally, it is the same principle as strong ground motions with horizontal and vertical amplitudes of microtremors to evaluate near-surface structures easily. Tsuboi & Saito (1983) and Tanimoto & Tsuboi (2009) derived and calculated partial derivatives of ellipticity in an isotropic medium. In addition to the well-known anisotropy in the asthenosphere such as that included in PREM, the influence of a transversely isotropic medium may be important for shallow structures such as a sedimentary layer. A transversely isotropic medium has five elastic moduli (A, C , L, N .F) but propagations of surface waves can be formulated in a compact manner, similar to the isotropic case.
In this study, we first formulated partial derivatives of ellipticity in a transversely isotropic medium. In the same way as the isotropic medium, we determine the linear relationship using the variational principle and the reciprocal theorem. Then, we set an artificial eigenfunction for the boundary condition of non-zero normal stress at the surface in addition to the natural eigenfunction for the normal condition (i.e., zero stress at the surface). We then derived partial derivatives with the two kinds of eigenfuncitons combined. Several important features of PV-waves and PH-waves are revealed in comparison with those of P-waves in the isotropic case. P-waves have little effects on the ellipticity in an isotropic medium. In the transversely isotropic medium, partial derivatives of PV wave are quite different from those of PH wave with a relatively large amplitude in a shallow part. The reason of the small P-wave effect in the isotropic case comes from the sum of those of PV and PH waves of opposite signs. PH wave in a shallow part has a large positive effect on ellipticity while PV wave has a weak negative one. If there is a strongly laminated sedimentary layer near the surface, for example, the ellipticity does not vary so much, despite of small SV there. It is because the shallow PH velocity is not reduced in such a layer, in contrast with small SV and PV waves, and its partial derivatives is large and of the sign opposite to SV and PV waves. If we performed the inversion for the shallow structure with the data of ellipticity (i.e., only slightly anomalous), under the isotropic model with the dominance of SV wave velocity, the inversion result would lead to slightly small SV velocity near the surface with virtually no changes in P-wave velocity because partial derivatives in the isotropic case are large for SV but small for P wave.

Time series analyses of amplitude of the Earth’s background free oscillations

*Ryuichi Kunugi[1], Naoki Suda[1]

1. Hiroshima University

The Earth’s background free oscillations (BFO) are slightly and continuously excited free oscillations of the solid Earth persistent even in seismically quiet periods [Nawa et al. 1998; Suda et al. 1998; Kobayashi and Nishida 1998; Tanimoto et al. 1998]. The observed modes are fundamental modes, suggesting that the excitation sources are atmospheric and oceanic disturbances [e.g. Nishida 2013]. Amplitude of BFO exhibits seasonal variations [Nishida et al. 2000]. Along with such a periodic variation, there may exist transient variations correlated with atmospheric/oceanic phenomena.

The target modes are fundamental modes ${}_0S_{22}$-${}_0S_{43}$ at frequencies between 3 and 5 mHz because they are most clearly observed in the frequency domain. We used vertical records of STS-1 broadband seismometers at 65 quite seismic stations downloaded from IRIS DMC. The data periods are from 2000 to 2017. The analysis method is mainly the same as used in Nishida et al. (2000). Continuous records were divided into 3-days records with a step of 1 day. After applying the Hanning taper, each record was converted into power spectral density (PSD) with the correction of system response. To reject noisy data, we used the data whose mean PSD values at 3-5 mHz are between 10^{-19} and 10^{-18} m^2/s^3. The remained PSDs were then stacked over all the stations to create monthly averaged PSDs. To avoid the influence of temporally changing PSD baseline due to the random background noise, we averaged the PSD values in the mode and the noise frequency bands, and then the averaged noise PSD is subtracted from the averaged signal PSD.

We used two methods of time series analysis for the statistical analysis of long-term variations in amplitude of BFO: one is based on the state-space model and the other is on the regression model. In the state-space analysis we adopted the local level model with seasonal variations, which divide time series into random noise, seasonal variations and a long-term trend. In the regression analysis we adopted the model that consist of random noise, seasonal variations and a long-term trend. We used the R packages dlm and prophet for the state-space and the regression analyses, respectively.

The result obtained in the space-state analysis shows the long-term variation with a time scale of 10 years from 2002 to 2012: the minimum is in 2002 and 2012 and the maximum is in 2008. The long-term trend obtained in the regression analysis shows almost the same characteristics: the minimums in 2000 and 2012 and the maximum in 2008. Thus, we for the first time robustly obtained the nearly 10-year variation in amplitude of BFO from the two different time-series analyses. We can utilize data of infragravity waves at frequencies between 3-30 mHz from WAVEWATCH III. We will show the result of comparison between BFO and infragravity waves in the presentation.

Regional shear waves from an unusually deep earthquake beneath Ogasawara Islands: 660 km discontinuity and anisotropy

*Keiko Kuge[1]

1. Department of Geophysics, Graduate School of Science, Kyoto University

Following a large deep earthquake beneath Ogasawara Islands on 30 May, 2015, an aftershock (mb 4.9) took place at a depth of 678 km (USGS). P and S waves from the aftershock were recorded by F-net broadband stations in Japan at distances of 1 to 18 degrees. The aftershock is small enough to neglect source effect. Here I explore structure effect on the shear wave propagation. SH waves recorded by the transverse directions in western Japan were generally characterized by a single pulse. The peaks of the SH waves tend to arrive earlier than those of the SV waves in the radial directions. The dominance of a single pulse in the SH waves can be explained by the iasp91 model with the 660 km discontinuity shallower than the aftershock. When the 660 km discontinuity is assumed to be deeper than the aftershock, additional signals predicted in radial components can apparently cause different peak time arrivals between SH and SV waves. However, in these cases, the SV peaks arrive earlier than the SH peaks, which cannot fit the observations. It is thus more likely that the observed peak time difference is attributed to anisotropy. Because signals due to crustal reflection are predicted in the radial components ~6 sec after the direct S waves, shear wave splitting parameters were carefully estimated by using initial portions of S waves. The fast directions obtained in western Japan are nearly in the east-west, which looks different from the fast direction observed for a nearby deep earthquake in the Wadati-Benioff zone. We cannot see systematically early arrivals of SH peaks from Fiji earthquakes in a similar back azimuth. The anisotropic regions may be located deep.

On the estimation of G discontinuity in the oceanic upper mantle using ScS reverberations

*Jumpei Maruyama[1], Hitoshi Kawakatsu[1], Nozomu Takeuchi[1]

1. University of Tokyo, Earthquake Research Institute

On the upper mantle shear wave velocity structure in the northwestern Pacific, there is a disagreement between the estimations using ScS reverberations (Bagley et al. 2009) and Rayleigh waves (Isse et al., 2019). This may be ascribed to the difference between the sensitivities of these waves to η_κ, the new fifth parameter of VTI (Kawakatsu, 2016), and reflect a characteristic of anisotropy in the oceanic lithosphere-asthenosphere system (LAS).

The method used by previous work (Revenaugh & Jordan, 1991) employs two-step analysis: 0th order analysis for whole mantle parameters and 1st order analysis for the characteristics of mantle discontinuities. Since this method was introduced to investigate the land area of the western circum-Pacific, there has been no detailed verification if it is compatible for the oceanic area whose upper mantle structure significantly differs from that of the continental area. We applied a simplified analysis method to full wave synthetic waveforms generated for an oceanic model with G, and revealed that the conventional method might fail in estimating the upper mantle structure and the whole mantle quality factor Q because of a strong reflected wave from G.

We will attempt to improve ScS reverberation analysis method and to compare its result for the northwest Pacific area with the existing model.

Short-period body wave (1-3 Hz) extraction from ambient noise records observed at seafloor and borehole in the Nankai subduction zone

*Takashi Tonegawa[1], Toshinori Kimura[1]

1. Research and Development center for Earthquake and Tsunami, Japan Agency for Marine-Earth Science and Technology

In the Nankai subduction zone, a cabled-network, named DONET (Dense Oceanfloor Network system for Earthquakes and Tsunamis), and borehole stations connected to the DONET have been constructed. The station spacing of DONET is 15-20 km, but, corporating it with borehole sensors, some of station pairs have station spacing less than 15 km. We attempted to extract body waves by applying cross correlation analysis to ambient noise records observed at the southern part of those stations, because borehole sensors have constructed near the trough.
As a result, we found eight pairs showing P wave in the cross correlation functions (CCFs) at frequencies of 1–3 Hz, which emerged before T-wave. In the case of station spacing less than 5 km (2 pairs), P wave extraction required only one-day stacking of ambient noise records, but other pairs required 10–30 days. Although the reason for unstable retrieval on the pairs and time periods for stacking is still under debate, the retrieved P-wave was stable over the observation periods.

Characteristics of T-wave envelopes observed by S-net

*Kentaro Emoto[1], Hisashi Nakahara[1]

1. Graduate School of Science, Tohokuk University

S-net enables us to access continuous sea-floor network observation data. Different from observed data in the inland area, the strong signal of the T-wave appears following the P- and S-waves in the seismograms recorded by S-net stations. T-wave is the acoustic wave propagating in the ocean. The low-velocity layer called SOFAR channel efficiently delivers the T-wave to distant stations. Owing to this property, T-wave has been used to monitor nuclear tests and activities of submarine volcanoes [Okal, 2008]. The pulse width and the amplitude of the T-wave can be used as a proxy to distinguish the explosion source and the natural earthquake [Talandier & Okal, 2001]. The rise time of the T-wave and the amplitude ratio of the T-wave and the body wave is related to the focal depth [Yang & Forsyth, 2003; Dziak et al., 2005; Wech et al., 2018]. These features were derived from observations of the T-wave at distant stations. On the other hand, we now become able to investigate the detailed process of the conversion between seismic waves and T wave because we can analyze the T-wave generated by local earthquakes by using the S-net. In this study, we summarize the characteristics of envelopes of T-waves recorded by S-net stations.

We calculate envelopes of T-waves by summing squared three components velocity seismograms band-passed in the frequency range of 8-16 Hz. The duration of the envelope is characterized by $\tau_{1/3}$ or T_{rms} which do not depend on the onset, because the onset of the T-wave is gradual and sometimes buried in the S-wave coda. $\tau_{1/3}$ is the duration during which the amplitude is higher than the one-third of the peak. T_{rms} corresponds to the standard deviation of the envelope. The strength of the T-wave is defined by the TPEF (T-phase energy flux) [Okal et al., 2003].

The propagation velocity is about 1.5 km/s in general, but it is sometimes higher in deeper stations. The onset is not clear and the amplitude gradually increases to the peak. Different from the envelope of the seismic wave which shows the long coda compared to the rise time, the time scales of the increase and the decrease of the T-wave are almost the same. This indicates that the generation process is more dominant than the scattering effect in the propagation process. However, the scattering effect also exists, because the T_{rms} increases with the propagation distance. This result is different from the observation in the relatively flat bathymetry area [Yang & Forsyth, 2003]. $\tau_{1/3}$ in the shallow station is smaller than that in the deeper station, although it shows a large variation. Regarding the energy of the T-wave, TPEF is larger in the deeper stations. This is because the T-wave is reflected by the up-slope of the ocean trench and enough energy can't reach the shallower stations. T-waves generated by the earthquakes near the triple junction mainly propagates along the trench. The TPEF shows a power-law decay with distance. The power law exponent varies from -1 to -6 depending on the source location. Outer rise earthquakes generate strong T-wave compared to inter- and intra-plate earthquakes. This is because the T-waves converted at the down-slope of the trench enter the SOFAR channel with lower incident angles and are efficiently trapped. The conversion point for the case of the intra-plate earthquake whose focal depth is about 100 km is located around the trench. The seismic wave traveling along the slab is converted to the acoustic wave at the trench. This conversion shows strong directivity.

©2019. Japan Geoscience Union. All Right Reserved.

As we mentioned above, T-wave recorded by the S-net stations is strongly affected by the bathymetry and the Earth structure. The modeling of the T-wave by considering both the elastic and the seawater media is necessary to correctly model the T-wave envelopes. By modeling the characteristics observed in this study, we can understand the details of the conversion process between the elastic and acoustic waves.

Reverse time reflection imaging of active and passive seismic data with ocean-bottom seismographs

*Kazuya Shiraishi[1], Takao Nibe[2], Yasuhiro Yamada[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Japan Petroleum Exploration Co. Ltd.

Introduction

In most case of crustal seismic surveys or earthquake observations using ocean-bottom seismometers, however, because receiver spacing is generally large in the wide range survey/observation, technical improvements of imaging methods are required to interpolate the lack of subsurface imaging area. On the other hand, high-dense and continuous seismic (earthquake) observation using new and existing optic fiber cables have been advancing. Development of an efficient imaging method is also necessary to utilize the enormous data. Reverse time migration (RTM) in reflection seismic exploration is one of effective seismic imaging techniques for complex subsurface structures with reconstructing full wavefield. In this study, we developed reverse time reflection imaging method which is available in active seismic survey and passive seismic observation, and we conducted a field data application and a numerical feasibility study.

Method

A. basic RTM: source-to-receiver pairs

In case of active survey with artificial seismic sources or a passive observation with accurate source locating, basic imaging principle using primary reflections between the sources and receivers is available. In the basic reverse time reflection imaging, reflected waves are focused on subsurface imaging points by a temporal integration of product between forward-extrapolated wavefields from source and backward-extrapolated wavefields of the recorded seismic data from receiver points.

B. modified RTM: receiver-to-receiver (source-to-source) pairs

We propose a modified reverse time reflection imaging method in passive seismic survey without determining source information. Both forward and backward wavefield extrapolations are performed from all receiver locations with the recorded seismograms, and the surface-reflected multiple reflections are focused on the subsurface imaging points as pseudo-primary reflections. Based on source-receiver reciprocity, this method can be applied to source-to-source pairs to use multiple reflections in airgun-OBS surveys.

Case study

(1) Airgun-OBS survey data in the Nankai Trough

We applied the proposed method to a 2D wide-angle reflection survey data acquired along 170 km survey line (200 m spacing of airgun shots, and 1 - 10 km spacing of OBSs) in the Nankai Trough. In wavefield reconstruction in the imaging process, sources and receivers are exchanged based on source-receiver reciprocity. A final reflection profile can be obtained by stacking two results derived from the primary reflections from OBS to airgun locations with the basic RTM method and from the multiple reflections between different airgun locations with the modified RTM method. Deep structures including the subducting plate and its relationship with old and young accretionary prisms are imaged with long offset reflections. Shallow structures are also clearly shown including sea floor and topographic relief of the base surface of sedimentary basin without lack of imaging area.

(2) Numerical simulation of earthquake observation

We tested reflection imaging with the modified RTM method by using numerical simulation data of both on-land and ocean-bottom earthquake observation. There is a big difference on a boundary condition (i.e. presence of a water layer above receivers) between the ocean-bottom and on-land observation. Multiple

©2019. Japan Geoscience Union. All Right Reserved.

reflections due to the water layer is significant in the ocean-bottom observation. We confirmed that reflection imaging is possible from passive observations both of the on-land and ocean-bottom seismometers with the modified RTM method. The multiple reflections are helpful to illuminate subsurface reflectors more effectively in the ocean-bottom observation in case of spars receiver deployment.

[S-SS14] Fault Rheology and Earthquake Physics

convener:Keishi Okazaki(Japan Agency for Marine-Earth Science and Technology), Hideki Mukoyoshi(Department of Geoscience Interdisciplinary Graduate School of Science and Engineering, Shimane University), Hiroyuki Noda(Kyoto University, Disaster Prevention Research Institute), Keisuke Yoshida(Tohoku University), Chairperson:Keisuke Yoshida(東北大学大学院理学研究科 地球物理学専攻), Keishi Okazaki(JAMSTEC)

The goal of this session is to integrate theoretical, experimental, observational, and numerical perspectives from various fields such as seismology, geodesy, geology, mineralogy, and so on, to define what is known about earthquake source processes and the physical and chemical elementary processes of faulting. This session welcomes studies that address such issues as pre-, co-, and post-seismic processes, the rheology of seismogenic faults and fault rocks, laboratory experiments on elementary processes, numerical models based on frictional laws, and estimates of the stress field in the seismogenic zones. We also welcome studies on fault-zone drilling projects and in situ stress measurements.

Spatio-temporal Evolution of Micro-Earthquakes illuminated by “0.1 manten” Hyper Dense Seismic Observation: Implication of Fault Growth

*Aitaro Kato[1], Shin'ichi Sakai[1], Satoshi Matsumoto[2], Yoshihisa Iio[3]

1. Earthquake Research Institute, the University of Tokyo, 2. Kyushu University, 3. Kyoto University

To deepen fundamental understanding of earthquake faulting, it is of crucial importance to image fine scale structure of fault zone. We installed a thousand of seismic stations in the source area, which covers an entire aftershock zone of the 2000 Western-Tottori earthquake (Mw 6.7) from March 2017 to March 2018. The spatial interval of each seismic station ranges from 1 to 2 km. We initially detected ~3000 earthquakes from the continuous waveforms, using automatic arrival time picking technique. Applying a double-difference algorithm to the arrival data-set, we relocated more precise hypocenters in the studied region. The completeness magnitude of the catalog is around -0.7.

From the center to the southeast part, the relocated hypocenters are aligned along sharp fault planes, which are dipping almost vertically. In contrast, at the northwest area, the hypocenter distributions are complex, including several fault planes which are conjugate to the main NW-SE aftershock trend.

We focus on a tiny seismic cluster associated with Mj 1.7 event (main event) in the aftershock zone, which took place on 24th Dec., 2017. Following this event, a total of ~80 micro-earthquakes were detected by automatic-processng and matched filter technique. We visually picked up P-wave arrival times for each micro-earthquake. Using differential travel times derived from waveform cross-correlation technique, we succeeded to relocate them very precicely. The relative hypocenter acuuray appears to be less than 5 m. The relocated micro-earthquakes are sharply aligned along vertically NNW-SSE-striking fault. The length and dip-width of the fault dimension is about 200 m, respectively. This hypoenter alignment is well consisten with a focal mechanism of the main event. Based on the distribution of the earthquakes, the fault zone width is estimated to be ~10 m. The ratio of the fault (process) zone width to the fault length is ~0.01, which fairly matches with that geological observation of fault exposure.

In addition, we identify spatial-temporal evolution of the micro-earthquakes after the main Mj 1.7 event. Interestingly, these migrating events occurred so that they did not overlap events that occurred earlier, like complementary manner. The migration speed is estimated to be < ~0.1 km/day, which is quite lower than that slow slip events observed typically along subduction. This slow migration is similar to fluid migration speeds inferred from seismic observation of induced seismicities following the 2011 Tohoku-Oki earthquake. These results indicate a growth of fault network on a scale of tens of meters.

Estimation of fault model of the 2017 Pohang, South Korea earthquake using seismic and geodetic analyses

*Sun-Cheon Park[1], Won-Jin Lee[2], Geunyoung Song[1], Duk Kee Lee[1]

1. Korea Meteorological Administration, 2. National Institute of Environmental Research

After the 2017 Pohang, South Korea earthquake with magnitude (ML) 5.4, surface deformation was observed using Interferometric Synthetic Aperture Radar (InSAR) technique. This observation of surface deformation can be a constraint to estimate the fault model in addition to aftershock distribution and other seismic information. As the result of InSAR processing using X-band Cosmo-Sky-Med and C-band Sentinel-1 data, we observed the maximum deformation of about 4 cm in Line-Of-Sight (LOS) direction. Considering this observation, we estimated the fault model of the 2017 Pohang earthquake. We determined hypocenters of the earthquake sequence and carried out moment tensor inversion. Then we estimated the dimension and depth of the fault plane using aftershock distribution and displacement on the fault using the seismic moment. Surface deformation was calculated using the formula of Okada (1985) and assuming several models of slip distribution on the fault and was compared with the surface deformation pattern in LOS direction. Larger surface deformation toward the satellite was observed to the northeast from the epicenter and this pattern was well explained by fault models having the slip on the shallow fault plane. During the presentation, we will discuss more about the fault model comparing surface deformation and the aftershock distribution.

Dominant frequency or duration of seismic waves is considered to reflect the fault size. Some studies used the dominant frequency for the estimation of fault size and stress drop for small earthquakes assuming simple fault models (e.g., Brune, 1970; Sato & Hirasawa, 1973; Madariaga, 1976) without estimating heterogeneous slip distribution on the fault. Some of the simple source models are based on a symmetrical circular fault model (Madariaga & Ruiz, 2016). The assumption of the isotropic rupture evolution on a symmetrical circular fault can lead to a large estimation error of the fault size and thus the stress drops if the real source process is asymmetrical or exhibits a significant directivity effect (e.g., Kaneko & Shearer, 2015). We should carefully check if we can assume a symmetrical source model when we apply it in analyzing seismograms of small earthquakes.

We investigated the rupture directivities of small and moderate-sized earthquakes (M_JMA>2) in the Yamagata-Fukushima border earthquake swarm which was estimated to be triggered by the upward fluid movement after the 2011 Tohoku-Oki earthquake. We utilized the dense nationwide seismic network in Japan to estimate the rupture directivity. Apparent source time functions were calculated at each station for 1,782 earthquakes based on the waveform deconvolution technique with nearby (< 300 m) small earthquakes to remove the propagation- and site-effects. We found clear directional dependences of the peak amplitude and the pulse width in the apparent source time functions, suggesting the earthquake rupture directivity, for 904 of 1,782 events.

Based on the unilateral rupture model, we estimated the direction, duration, and velocity of rupture for each earthquake. Rupture directions of most earthquakes tend to be different from those of the hypocenter migration. This difference between the microscopic and macroscopic propagations of rupture might be explained by the spatial variation of the frictional strength; ruptures of each earthquake are hindered to develop toward shallower part due to higher frictional strength ahead of the pore-pressure front (shallower part) than behind (deeper part). It suggests the importance of the knowledge of frictional strength on fault to understand fracture dynamics of small earthquakes.

Besides, we estimated fault planes of small and moderate-sized earthquakes based on focal mechanism and rupture directivity (Fig.). Most of fault planes are parallel to the macroscopic planar structures, which suggests that they were triggered by fluid intrusions along those common planar structures. By taking the limitation of the resolution of hypocenter relocation, information from the rupture directivity can be unique data to reliably determine the fault planes of small and moderate-sized earthquakes.

By considering the estimated fault planes and areas of small earthquakes, we confirmed the temporal increase in stress drop reported by Yoshida et al. (2017, JGR). The systematic temporal changes in frictional strength, stress drop, background seismicity rate, b-values, the upward hypocenter migration along the planar structures, and the rupture directivity rather opposite to the hypocenter migration can be explained in a consistent manner by the effects of the upward fluid flow along several pre-existing planes after the 2011 M9 Tohoku-Oki earthquake.

Possible aseismic phenomena causing the hypocenter migration in the precursory activity and aftershocks of the 2017 M 5.3 Kagoshima Bay earthquake, Kyusyu, SW Japan

*Yoshiaki Matsumoto[1], Keisuke Yoshida[1], Toru Matsuzawa[1], Akira Hasegawa[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Tohoku University

An earthquake occurs when the shear stress acting on the fault plane reaches the frictional strength. It has been suggested that an increase in pore pressure plays an important role in earthquake occurrence (e.g. Hasegawa, 2017; Hubbert & Rubey, 1959; Nur & Booker, 1972; Sibson, 1992). Migration behavior of earthquake hypocenters is considered to be caused by aseismic processes such as fluid movements or aseismic slip propagations. It is expected that information on aseismic processes in the crust can be obtained by examining the hypocenter migration in detail.

On 11 July 2017, an M 5.3 earthquake occurred at approximately 10 km depth in Kagoshima Bay, Kyusyu, SW Japan. Near the main shock hypocenter, seismicity had been activated since December 2016. In order to investigate the generation mechanism of this seismic sequence, we improved relative locations of hypocenters of the precursory activity and aftershocks by using waveform cross correlations.

First, precise differential arrival times were obtained by calculating cross correlations of a pair of waveforms out of the earthquakes that occurred after January 2010 in the Southern Kagoshima Bay region. We used waveform data observed at 20 stations located around the main shock hypocenter. Calculations of cross correlations of waveforms were performed in the same way as Yoshida & Hasegawa (2018). Then, we applied the double-difference relocation method (Waldhauser and Ellsworth, 2000) to the differential arrival time data thus obtained by cross correlations and those listed in the JMA (Japan Meteorological Agency) unified catalog. We used hypocenters listed in the JMA unified hypocenter catalog as the initial hypocenters in the relocation.

The relocated hypocenters are concentrated forming several thin “planes”. The dominant orientations of the planes agree with the eithers of nodal planes of focal mechanisms of the main shock and aftershocks.

Hypocenters of the precursory activity are neatly concentrated along one of the planes and exhibit distinct migration behavior. Hypocenter distribution of the precursory activity along that plane shows a clear seismic gap located adjacent to the main shock hypocenter. Most of aftershock hypocenters are distributed along the same plane but did not fill this seismic gap. We calculated the corner frequency of the mainshock source spectrum using the spectral ratio method and estimated the mainshock fault size. The estimated fault size is consistent with the size of the seismic gap. It suggests that the seismic gap reflects the main shock rupture area (e.g. Wetzler et al., 2018).

Aftershocks tend to move upward with time along several thin planes. This spatiotemporal feature of earthquake hypocenters is similar to those observed in the earthquake swarms in central Tohoku that were triggered by the 2011 M9 Tohoku-Oki earthquake probably due to the upward movement of fluids (Yoshida & Hasegawa, 2018)

©2019. Japan Geoscience Union. All Right Reserved.

We explain the characteristics of the precursory activity, main shock and aftershocks as follows. (1) Prior to the occurrence of the main shock, crustal fluids penetrated into an existing weak plane from below and reduced the frictional strength, which caused the precursory seismic activity along the plane and the migration of hypocenters. Aseismic slip might also contribute to the hypocenter migration. (2) Then the seismic gap, which had not been ruptured by the precursory activity, was finally ruptured by the main shock. (3) Due to the stress change associated with the main shock, aftershocks were triggered in the region surrounding the main shock hypocenter. Aftershock hypocenters moved upward due to the upward fluid movements after the main shock.

Stress and pore fluid pressure changes in fault zone preceding the earthquake occurrence

*Teruo Yamashita

I theoretically study stress and fluid pressure changes in fluid-saturated fault zone that deforms elasto-plastically. Such study will be useful to gain an insight into the process leading to the earthquake occurrence. I employ poro-elasto-plasticity theory (Coussy,2006) and assume a Capped Drucker-Prager model as the yield criterion (Figure 1). The line segment (A) is described by the equation $f= \tau_J + f_m \sigma_{eff} + \kappa = 0$, where f_m and κ are the internal friction coefficient and a function of the hardening variable; $(\tau_J)^2$ and σ_{eff} denote the second deviatoric stress invariant and the effective mean stress. The point I represents the initial state in the elastic region and the yield criterion is satisfied first at point P on A; relatively low effective normal stress is assumed. The stresses τ_J and σ_{eff} move in a direction indicated by the arrow along the line segment A with the increase in the remotely applied stresses. I assume a non-associated flow law; the plastic potential corresponding to the line segment A is given by the equation $g= \tau_J + f_d \sigma_{eff} + \kappa$, where f_d is the dilatancy factor. It is known that the plastic component of volumetric strain is positive on the line segment A, so that the fluid pressure change will be negative there. It is known that f_m is larger for larger values of porosity (Chang et al.,2006). It is also known for low porosity rocks that permeability is higher at locations closer to the fault core, so that it will be allowed to assume that f_m is smaller at locations closer to the fault core. I therefore assume a 1D model such that f_m takes a minimum value just outside the fault core ($|y|=c+0$) and it increases linearly with the distance and attains a constant value (Figure 2). The f_m-increase zone is defined as the fault damage zone. Since the porosity is sufficiently low in the fault core, the value of f_m in the fault core is assumed to be equal to that at $y=\infty$; the boundary at $|y|=c$ is assumed to be impermeable. I also assume the absolute values of the remotely applied principal stresses ($\sigma_1 < \sigma_2 < \sigma_3 < 0$) increase quasi-statically with time. Hence, the yield criterion is first satisfied at $|y|=c+0$; the plastic zone expands with further stress accumulation. The plastic deformation never occurs in the fault core during the calculation. In this model, the time scale is governed by the magnitude of permeability. I assume that the increase rate of the maximum principal stress σ_1 that is remotely applied is 0.2MPa/year. Figure 3 shows examples of fluid pressure change at $|y|=c+0$ for the permeability$10^{-18}m^2$. The curve A is the case of plastic hardening. While both B and C are the cases of perfect plasticity, the damage zone width for C is twice as large as that for B. The figure shows that the fluid pressure decrease is larger for smaller degree of plastic hardening or for larger damage zone width. However, the elastic component of fluid pressure change (elevation) is estimated to be about 10MPa at time t/dt=10,000. Hence, the plastic decrease of fluid pressure is almost negligible. The calculation also shows that the values of $|\sigma_1 - \sigma_3|$ and $|\sigma_1 + \sigma_3|$ in the plastic zone are, respectively, smaller and larger than those in the elastic zone; the difference grows with the expansion of plastic zone. This suggests that the fault damage zone become more stable with the expansion of plastic zone, while the sudden stress and fluid pressure changes formed at $|y|=c$ may damage the impermeable boundary there. However, such stable situation never lasts indefinitely. The yield criterion such as represented by the curve B in Figure 1 seems to be satisfied once stresses exceeds a critical threshold. The plastic component of volumetric strain turns negative on the curve B, so that the damage zone may become unstable. Hence, the stress point is required to move onto the curve B for the occurrence of earthquake. I will show numerical examples of the whole process leading to the earthquake occurrence in the presentation.

Micromechanical model of fluid-induced seismicity to reproduce observed spatiotemporal changes in source parameters and on-fault fluid diffusion

*Daisuke Sato[1], Keisuke Yoshida[2]

1. Disaster Prevention Research Institute, Kyoto University, 2. Tohoku University

Fluid and seisimicity are considered to be related, as suggested from earthquake swams of natural earthquakes and man-made earhtquakes induced by fluid injection. Some data analysis with relocation techniques of earthquake sources showed that the earthquake activities propagete facially (e.g., Yukutake et al., 2010), and that some source parameters (such as stres drops, strength, b-value, seismicity rate) are functions of elapsed time from fluid injection (Bachmann et al., 2012) or sudden increase of (possibly fluid-induced) seisimicity rate not following mainshocks (Yoshida et al., 2017). In this research, by considering strength heterogeneity of faults expected from experimentally verified physics, we provide the micromechanical model of such seismicity induced by on-fault fluid diffusion, and explain the results of the above data-driven analysis.

Presentation contains following four contents. First, the micromechanical model is proposed. In the model, many patches are distributed randomly on a fault so that the patches are sufficiently small (or distant) to interact with each other; those patches rupture when the effective strength becomes smaller than applied shear stress due to the fluid diffusion. Second, the spatiotemporal changes of the source parameters are obtained as the solutions of the model. Consequently, multiple source parameters are parametrized by injected pressure, diffusion raidus of fluid, normal stress on the fault, and the fluctuation of the exess strength; after the parametrization, those source parameters are shown to follow the common master curve. Third, the observed data is fitted, and the consistency between the theory and the observation is suggested. Fourth, the thoretical prediction for the temporal transience in the moment release rate is checked by the data of Yoshida et al. (2017), and the result strongly supports the theory.

[J] Poster | S (Solid Earth Sciences)：S-SS Seismology

Tue. May 28, 2019 1:45 PM - 3:15 PM JST | Tue. May 28, 2019 4:45 AM - 6:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_7

[S-SS15] Active faults and paleoseismology

convener:Mamoru Koarai(Earth Science course, College of Science, Ibaraki University), Takashi OGAMI(National Institute of Advanced Industrial Science and Technology), Ryosuke Doke(Hot Springs Research Institute of Kanagawa Prefecture), Hisao Kondo(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology)

Geologic and historic information on seismic cycles and on the magnitude and source faults of past earthquakes is essential information to understand future large earthquakes. The study of past faulting and seismicity is an important issue for an interdisciplinary community of seismologists, geologists, geomorphologists, archaeologists, and historians.

Paleoseismicity of Atsuma Town , Hokkaido: Evidence from landslide deposits

*Jun Tajika[1], Tetsuya Inui[2]

1. Docon Co.,Ltd., 2. Board of Education, Atsuma Town

Many landslides occurred by the 2018 Hokkaido Eastern Iburi Earthquake in Atsuma-cho. We reported about discovering of ancient landslide deposit from an archeological site of the Jomon period in Atsuma in 2004 and 2016. It was inferred that this landslide was caused by an earthquake and it probably occurred at activity event of the Ishikari teichi-toen active fault zone. The morphological characteristic of the landslide deposit resembles that of landslide caused by this earthquake. The archeological findings of the past remains excavation in Atsuma-cho area shows that the event of a lot of landslides caused by earth quake is only 2018 Hokkaido Eastern Iburi Earthquake and an earthquake of the Jomon period during last 9,000 years.

Gravity survey and subsurface structure across the Aomoriwan-Seigan Fault Zone, Northeast Japan(part 2; estimation of the subsurface structure using the density of rock samples)

*Shinsuke Okada[1], Hideki Kosaka[2], Kyoko Kagohara[3], Toshifumi Imaizumi[4], Kohei Abe[5], Susumu Sakashita[5], Atsushi Miwa[5], Kouta Koshika[5], Yusuke Oda[5], Yuki tsukamoto[6], Takahiro Miyauchi[7], Tomoo Echigo[8]

1. International Research Institute of Disaster Science, Tohoku University, 2. Kankyo Chishitsu, Co. Ltd., 3. Faculty of Education, Yamaguchi University, 4. Emeritus professor of Tohoku University, 5. OYO Corporation, 6. Graduate School of Science, Tohoku University, 7. Department of Earth Sciences, Graduate School and Faculty of Science, Chiba University, 8. Geo-Research Institute

The Aomoriwan-Seigan Fault Zone is a fault zone of NNW-SSE trending western dipping reverse faults, which is composed of Aomoriwan West Fault, Nogiwa Fault, and Nyunai Fault. The fault zone is distributed about 31-km long along the eastern foot of the Tsugaru Mountains from Yomogita village of Aomori prefecture to Aomori city (Headquarters of Earthquake Research Promotion, 2004). We carried out a seismic reflection survey and CSAMT (Controlled Source Audio-frequency Magnetic Telluric) survey across the Aomoriwan West Fault (Kagohara et al., 2017; Sakashita et al., 2017) in 2016-2017. The low angle thrust faults of Tsugaru Fault and inclined geological structure until the depth of 1.5 km were revealed in these results. In addition to these surveys, we conducted gravity survey along the seismic survey line, and obtained the Bouguer gravity anomaly (Okada et al., 2018).
In the previous our presentation in the 2018 JpGU (Okada et al., 2018), we use the Talwani method (Talwani et al., 1959) to calculated the Bouguer gravity anomaly, in which the subsurface density structure is determined from the interpretation of the seismic and CSAMT surveys (Kagohara et al., 2017; Sakashita et al., 2017). In a part of the western part of the profile, there were some discrepancies between calculated and observed gravity anomalies. And it was also difficult to estimate the density of each layers. To resolve these problems, we conducted additional field survey and obtained several rock samplings from outcrops around the survey line, which we measured the density of samplings based on the method of Murata et al. eds. (1991). The discrepancies between calculated and observed gravity anomaly were improved by take into the layer densities from samplings.

Was the 1611 Keicho earthquake a giant interplate event like the 2011 Tohoku earthquake?

*Tomoya Harada[1], Akihito Nishiyama[1], Kenji Satake[1], Takashi Furumura[1]

1. Earthquake Research Institute, The University of Tokyo

After the 2011 Tohoku earthquake (M9.0), the 1611 Keicho earthquake along the Japan trench has been regarded as a giant interplate event. In this study, from the examination of reliability of the historical records about the 1611 event and comparison between the impact on Kanto by the 2011 and 1611 events, we consider that the 1611 earthquake was not a giant interplate event but a tsunami/outer-rise earthquake.
From the historical documents, the Dec. 2nd, 1611 Keicho earthquake generated large tsunami on the Pacific Coasts of Tohoku and Hokkaido while this event caused no seismic damage in Tohoku and Kanto. Since the 1896 tsunami earthqauke (M8.1) and 1933 outer-rise earthquake (M8.1) had similar features, the 1611 event had been regarded as an M~8 tsunami/outer-rise earthquake (Hatori, 1975; Aida, 1977; Watanabe, 1998). After the 2011 Tohoku earthquake, however, some studies claimed that the 1611 earthquake was probably a giant event because the tsunami heights and inundation areas estimated from the historical documents (e.g. Hatori, 1975; Tsuji et al., 2011; Ebina and Imai, 2014) are comparable to (or larger than) those of the 2011 event (e.g. Ebina, 2014; Iwamoto, 2013). Following this claim, tsunami researchers attempted to make fault models to reproduce the 1611 tsunami by the tsunami numerical simulation. Imai et al. (2015) proposed two fault models. One is a giant interplate event (fault size: 400km*200km, Mw8.7), another is a model (Mw8.4) of simultaneous occurrence of a great interplate event (fault size: 400km*150km) and a great outer-rise event (fault size: 400km*50km). Fukuhara and Tanioka (2017) considered that the 1611 event was a giant tsunami earthquake (fault size: 250km*50km, the maximum slip: 80m, Mw9.0).
In this study, however, we considered that the 1611 Keicho earthquake was not a giant interplate event but a M~8 tsunami/outer-rise earthquake from the following reasons: (1) Reliability of the 1611 tsunami heights and inundation areas is not high because they are estimated from the historical records without examination of reliability. There are historians who dispute the 1611 giant earthquake based on the unreliable historical records (e.g. Kan’no, 2014; Sasaki, 2014; Saino, 2017); (2) Strong shaking by the 2011 mainshock caused severe damage in Kanto and aftershocks and induced events caused additional damage and successive shakings in this region for several weeks. Whereas, as for the 1611 earthquake, only two shakings in Edo (present Tokyo) are recorded in the court nobles' diaries and there is no record of the seismic damage in Kanto. From the primary historical documents, Ieyasu Tokugawa went hunting with hawks to the present Saitama Pref. and court nobles went sightseeing to environs of Edo on the next day of the 1611 event. Therefore, the 1611 earthquake was probably an event which didn’t impact on Kanto, i.e. not a giant interplate event like the 2011 earthquake. M~8 interplate event in 1793 offshore present Miyagi Pref. caused minor seismic damage in Edo and its 2-days aftershocks shocked Edo more than 50 times (Usami et al. 2013); (3) Even if the 1611 earthquake was an M~9 tsunami event, ~80m slip on the large fault (250km*50km) should cause many aftershocks and widely induce earthquakes including M7-8 events. As mentioned above, however, there is no record about the successive earthquakes after the 1611 event; (4) No tsunami deposit by the 1611 event is discovered at the ruins in Sendai Plain excepting Taka-ose Ruin in the present Iwanuma City (Saino, 2017), while they are discovered on the Sanriku Coasts (e.g. Takada et al., 2016). In addition, they are not discovered at the Idagawa marsh in the present Fukushima Pref. (Kusumoto, et al. 2018). Therefor, 1611 tsunami probably didn’t inundate deeply in the lowlands on the Pacific Coast in Miyagi and Fukushima Pref. Recently, Goto et al. (2019) reported that the

Neotectonic characteristics along both flanks of the Ou Backbone Range, Tohoku Region, Japan, from fluvial geomorphic analyses

*Jhih Hao Liao[1], J Bruce H Shyu[1], Yasufumi Iryu[2], Hiroyuki Tsutsumi[3], Chia-Yu Chen[1]

1. Department of Geosciences, National Taiwan University, Taipei, Taiwan, 2. Graduate School of Science, Tohoku University, Sendai, Japan, 3. Department of Environmental Systems Science, Doshisha University, Kyotanabe, Japan

The islands of Japan are located at the boundaries between the Eurasian, Philippine Sea, and Pacific plates, with frequent earthquakes and numerous active structures. In the Tohoku Region, for example, the Ou Backbone Range is bounded on its both sides by two major active structural systems: the Eastern Marginal Fault Zone of the Yokote Basin in the west and the Western Marginal Fault Zone of the Kitakami Lowland in the east. However, the relative activeness and characteristics of these two systems are still not clear. As fluvial systems are capable of recording variations of topography caused by tectonic, climatic, lithologic, and anthropogenic influences, we hope to further understand these two structural systems using fluvial geomorphology of the Ou Backbone Range area.
In this study, we analyzed river profiles to obtain the geomorphic index χ and the river steepness index (k_{sn}). The results show that the steepness index of river channels along the two flanks of the Ou Backbone Range are different, likely indicating different tectonic activities. However, we also found a number of knickpoints along several river networks. We investigated these knickpoints with satellite imagery and field surveys. Our results show that these knickpoints are mostly produced by local resistant rock layers or check dams, instead of reflecting different states of tectonic activity.
Therefore, we were able to exclude the influence of the knickpoints and to focus only on the results of river steepness index. The results show that rivers along the western flank of the Ou Backbone Range generally have steeper channels than those along the eastern flank. This suggests that the uplift rate of the range’s western flank is higher, and the structures in the west may have higher activity. The results are consistent with the vertical slip rate estimates of the faults; ~1 mm/yr for the western flank and 0.2-0.4 mm/yr for the eastern flank. Moreover, the northern segment of the range’s western flank has the steepest river channels. This result appears to correspond with the surface ruptures of the Senya fault, Ota fault, and other related faults during the 1896 Rikuu earthquake. As a result, we propose that the northern segment of the Eastern Marginal Fault Zone of the Yokote Basin may be the primary structural system in the region, producing the faster uplift of the range and rapid subsidence of the basin, and steeper channels along the western flank of the Ou Backbone Range.

Tsunami record of the last 700 years in bottom sediment of lake Kasumi-ga-ura, southeastern part of Ibaragi Prefecture

*Yoshio Inouchi[1]

1. Faculty of Human Sciences, Waseda University

Lake Kasumi-ga-ura connects the Pacific Ocean via Tone River. Sampling site in this lake lies more than 50km far from the river mouth of Tone. Maximum tidal height at March 11, 2011 was +2.5m at the river mouth of Tone and +1.6m at water gate located 18km from the river mouth. Based on these facts, we started studies on tsunamiites in bottom sediment of Lake Kasumi-ga-ura. Cored sediment of 77cm length was taken at the central part of the lake where water depth is 6m on August 21, 2018. CT scan photograph was taken and samples for grain size analysis at each 1cm thickness were taken. Tephra seams of Asama-A in 1873 A.D. and Fuji Hoei in 1707 A.D. were observed at depth 42cm and 50cm respectively. Shells of *Corbicula japonica* were observed at depth from 70 to 73cm. More than 10 event layers were observed having more than 10 micrometers in mean diameter and relatively less transparency in X-ray. Sand size particles are chiefly composed of minerals of quartz, feldspar, pyroxene etc. and fragments of pumices and scorias and sometimes minor plant fragments and shell fragments. Sedimentary ages of event layers estimated based on dry weight of sediment and ages and depths of tephras show good correlation to historical large tsunamis. As mentioned above, Lake Kasumi-ga-ura locates more than 50km far from the river mouth of Tone. Tidal height is supposed to decrease rapidly. But existence of event sediments in Lake Kasumi-ga-ura shows that large tsunamis could reach that lake. Those sediment can be correlated to tsunamis of Showa Sanriku in 1933, Chiba Boso in 1909, Meiji Sanriku in 1896, Chile in 1877 or 1837, Genroku in 1703, Enpou Boso in 1677, keichou in 1605 or Keichou Sanriku in 1611, Tenshou in 1586, Meiou in 1498 or Kyouroku in 1454 and Shouhei in 1361.

Detecting concealed fault by microtremor H/V study in Miura Peninsula

*Kazuzi Ogawa[1], Yasuyuki Iwase[1], Takumi Murakoshi[1], Toshihisa Itano[1]

1. National Defense Academy

The Miura Peninsula in the southern part of the Kanto region has many active faults. According to geologic map described by Geological Survey of Japan, there is a concealed fault that has about E-W strike in the center of Shonankokusaimura (Etoh et al., 1998). Therefore, in this study, we adopted a microtremor H/V study to detect this concealed fault. Microtremor is a vibration that is constantly shaking the ground even when there is no earthquake. It occurs from natural phenomena and human activities. It contains information on the ground which is the medium of propagation of tremor though it seems random noise. Currently, method of microtremor H/V spectral ratio is widely used such as site effects assessment (Nakamura et al., 1986), underground structure estimation (Gueguen et al., 2000) and detecting active fault (Shibuya, 2008; Sant et al., 2017).

In this study, we carried out microtremor measurements at 15 points across the fault using the JU410 seismometer. Sampling rate was 100 Hz and 15 minutes measurements were conducted for each observational point. In the analysis, the averaged H/V spectral ratio was calculated from the non-overlapped data sets in which the data window length and number were set to 20 seconds and 45, respectively, and noisy portions were removed. The calculation method of the H/V spectral ratio in this study is as follows. At first, Fourier spectra of N-S, E-W, and U-D wave components are calculated. Secondly, H/V spectral ratio is calculated from dividing the square root of the sum of N-S and E-W components by U-D components. Finally, NS/UD and EW/UD are obtained from dividing the N-S by the U-D components and dividing the E-W by the U-D components, respectively. Final process is performed separately from the second in order to take into account the anisotropy for the N-S and E-W directions.

As a result, change of the peak frequencies of the H/V spectral ratio in the direction perpendicular to the fault strike is confirmed and the peak frequencies of the H/V spectral ratio are about 5 Hz in the northern part and about 3 Hz in the southern part, respectively, and its boundary locates approximately 100 meters south of the concealed faults described in the geological map. This suggests the depth of the boundary between the basement rock and sedimentary layer is decreasing from the north to the south in the center of Shonankokusaimura. Focusing on the direction, EW/UD tends to be larger than NS/UD at the frequency that shows the peak in the H/V spectral ratio. These results may show the possibility of existence of the concealed fault in the center of Shonankokusaimura and imply the occurrence of anisotropy of the H/V spectral ratio near the fault. It is expected that the microtremor measurements and analysis considering anisotropy of wave components can lead to future fault research.

Distribution, geometry and slip rates of branch faults around the Kita-Izu fault zone

*Ryuhei Oda[1], Daisuke Ishimura[1], Takehiko Suzuki[1]

1. Tokyo Metropolitan University

In the northeastern part of the Izu Peninsula, there is the Kita-Izu fault zone which extends N-S direction. A branch fault group showing NW-SE strike (Earthquake Research Committee, 2005) is distributed in the east side of the Kita-Izu fault zone. However, slip rates of branch faults have not been estimated. Additionally, the distribution and formation ages of geomorphic surfaces around the Kita-Izu fault zone have not been revealed. Thus, we focus on branch faults (oblique, subparallel to the Tanna fault or Ukihashi central fault) and clarify the distribution, geometry and slip rates of them. Furthermore, we reveal the distribution of geomorphic surfaces around the Kita-Izu fault zone and consider formation ages of them.
In this study, we carried out geomorphic interpretation, field surveys, and measuring the amount of displacements of branch faults using DEM data. In field surveys, we observed fault topographies along active faults and deposits forming geomorphic surfaces around active faults.
From geomorphic interpretation, branch faults are located mainly on the east side of the Tanna fault and the Ukihashi central fault. They are composed of left-lateral slip faults striking N-S and right-lateral slip faults striking NW-SE or E-W. From field surveys, deposits that can estimate formation ages of geomorphic surfaces were not identified. Therefore, we used ages of geology (Oikawa et al., 2011) as lower limits of formation ages of geomorphic surfaces.
Lower limits of slip rates of branch faults were estimated using vertical and horizontal displacements and lower limits of formation ages of geomorphic surfaces. As a result, lower limits of horizontal and vertical slip rates of branch faults were estimated to be 0.10-1.0 mm/yr and 0.01-0.10 mm/yr, respectively. Similarly, we estimated horizontal slip rates of the Tanna and Ukihashi central faults and compared to those of branch faults. Then, we found that horizontal slip rates of Tanna and Ukihashi central faults are one order larger than those of branch faults. Thus, the activity of branch faults is considered to be lower than that of Tanna and Ukihashi central faults. In the north of the Tanna fault, left-lateral slip active faults striking N-S or NW-SE are located. These faults and the Tanna fault form right-stepping en echelon arrays and their slip rates are larger than those of branch faults. Furthermore, there is a possibility that they acted with the Tanna fault in Kita-Izu earthquake in 1930. Thus, some left-lateral slip active faults located in the north of the Tanna fault may constitute the northern end of the Tanna fault.

Geotectonic history of the Inadani fault zone in southern part of Nagano prefecture, central Japan

*Shuuhei Tsukui[1], Kenta Kobayashi[1]

1. Department of Geology, Faculty of Science, Niigata University

Central Japan is a region where many active faults are distributed, one of Japan's most active fault-dense areas (active fault study, 1991). Many of these active faults are characterized as high angle strike slip fault group with NE-SW strike and NW-SE strike. The Inadani fault zone, which is located in the southern part of Nagano Prefecture, is a unique fault zone characterized as a low-angle reverse fault, while the lateral slippage is dominant in this area.
The Inadani fault zone has been considered as a parallel reverse fault group of the conventional NE trending, but in recent years the evaluation of the activity to the fault group in the southern fault zone was revised, and the Inadani fault zone main part and the southeast part of the Inadani fault zone. The Inadani fault zone main part and the southeastern part were connected by the Shimojo sanroku fault which is the active fault of the NW strike, and it turned out that it is forming complicated fault geometry than conventionally thought. In this way, it is an important task to understand the tectonics of the Central Japan to elucidate how the Inadani fault zone, whose recognition for its motion image has been modified, has developed a unique form It is considered to be.
In order to elucidate the structural development history of the Inadani fault zone, a survey was conducted in the granitic distribution area expected to record longer deformation. Surface survey focused on the form of the fault, sense of movement, properties of the fault rock and so on. Stress analysis using multiple inverse method (Yamaji, 1999) was carried out in indoor work from the data obtained in the survey.In addition, XRD analysis was performed on the obtained fault rock samples to identify clay minerals contained.
From the cutting relationship between faults and the estimation of stress field, the deformation of the area was divided into three deformation stages. Stage: 1 ~ Stage: 2 is deformation with cataclasite with high angle N - S stroke, and Stage: 3 was deformation with fault gouge at low angle to medium angle. In Stage: 1, lateral shear stress solution of EW compression was detected, lateral stress stress solution of NW - SE compression in Stage: 2, and lateral shift to reverse tomographic stress solution of ENE - WSW compression in Stage: 3.
As a result of the XRD analysis, Illite and Smectite were included in all fault gouges, and the quantity ratio was changed depending on the sample.
This area is located in eastern south of southwestern Japan and is subject to clockwise rotation of the massive mass accompanying the enlargement of the Sea of Japan and counterclockwise rotation of the mass due to collision of the Izu arc. In order to discuss the stress direction , It is necessary to correct this influence. The corrected stress field is Stage: 1: E-W compressive stress field, Stage: 2: N-S compressive stress field, Stage: 3: E-W to NE-SW compressive stress field, and the Scaenzuyama fault detected by Katori (2016 MS) This is in good agreement with the stress direction in which the same correction is applied to the stress direction. Therefore, it can be said that the stress detected this time is stress acting widely on the Chubu region. If the cause of the wide area stress is required for the motion of the plate, it is possible that the cataclasite which is the oldest fault rock in this area was formed by driving the westward movement of the Pacific plate after 40 Ma.

Characteristics of the fault zone with only the recent slips in the Atera Fault

Atsushi Nishida[1], *Tomoyuki Ohtani[1], Takuya Niimi[1], Jun'ichi Tsubaki[1], Keiichi Ueta[2]

1. Department of Civil Engineering, Gifu University, 2. CRIEPI

The activity assessment of the active faults basically needs younger sediments. To understand the fault activity in the area with no younger sediments, it is desired to develop the new method which assesses the fault activity from the fault rocks in the basement rocks. As the recent slip zone in the active fault exposure is displaced not only in the recent slip event but also the other previous events, the recent slip zone may record many slip experiences. This suggests that the characteristics of the latest slip zone reflect not only the recent slips near surface but also the other older slips in the deeper part. The fault zone with only the recent slips should be studied to understand the phenomenon that occurred in the recent slips near surface. The purpose of this study is to clarify the characteristics of the fault zone with only the recent slips. For this purpose, the Atera Fault zone has studied to understand the above characteristics. The studied exposure of the Atera Fault is located at Tase, Tsukechi, Nakatsuawa in Gifu Prefecture. In this exposure, the fault is mainly a boundary between the Quaternary sedimentary layers and the Cretaceous granite. The fault is divided into two in the upper part of the exposure. The upper and lower faults are located in the granite and at the boundary of the sediments and granite, respectively. The upper fault contacts with the sand and gravel layer in the uppermost part. Toda *et al.* (1994) have clarified that the three seismic events are detected from the exposure and that the upper fault have displaced in recent several seismic events.

The detailed observation of the fault structure, thin section observation, the powder X-ray diffraction (XRD) and the X-ray fluorescence analysis (XRF) were performed using the samples collected along the upper fault. The detailed observation of the fault structure revealed that the upper fault consists of A1 and A2 fault zone and their branch point is consistent with that of the upper and lower faults. The brown fault gouges distributes in the recent slip zone from the branch point of A1 and A2 to 4 m away from the branch point, and the light gray fault gouge far from 4 m. The latest slip occurred in the A1 fault zone based on the radiocarbon dating (Toda et al., 1994), and the cumulative amount of A1 displacement is 2.5 m from the upper plane of the granite. These fault zones involve the fragments of the surrounding weathered granite. The XRD results show that smectite appears within 1 m from the branch point. The XRF results show that Mn-rich zones are within 4 m and 3 m, respectively.
The lower fault zone had been displaced before the upper fault zone was formed, and the brown fault gouge, smectite and Mn-rich zone are included in the lower fault zone. This indicates that some of them in the upper fault zone should be displaced from the lower zone. The distribution of brown fault gouge and Mn-rich zone in the upper zone, however, cannot be explained only the fault displacement. This suggests that the recent Mn concentration would be occurred in the upper fault zone within recent several thousand years.

Identification of active fault location using real-time ground measurements of atmospheric methane concentration by portable Cavity Ring-down Spectroscopy system: Case study at the Atera fault

*Michito Shimo[1], Masakazu Niwa[2], Kenji Amano[2], Tomochika Tokunaga[3], Kenichi Tonokura[3], Toshifumi Matsuoka[1], Sebastien Biraud[4]

1. Fukada Geological Institute, 2. Japan Atomic Energy Agency, 3. Department of Environment Systems, University of Tokyo, 4. Lawrence Berkeley National Laboratory, USA

Faults and associated fracture zones often provide pathways for the migration of gases, such as methane, hydrogen and helium, formed in the deep subsurface formations. It is expected that information on fault location and fault activity may be obtained by measuring trace gas concentration at the ground surface.

Development of atmospheric trace gas measurement technology using Cavity Ring-Down Spectroscopy (CRDS) enabled us to measure methane gas concentration with an accuracy and precision of a few ppb and a dynamic range of 0 to 5000 ppm.

In order to investigate the applicability of this technology to active fault survey, we conducted field measurements of methane gas concentration using two portable CRDS gas analyzers (Manufacturer: Picarro Inc, models G4301 and G4302) at the Atera fault area in Gifu prefecture. Both instruments have capability of measuring methane concentration with accuracy of 3 ppb and a response time of less than 1 second. Field measurements were carried out at two locations, a fault outcrop at Tase and a fault cliff at Tsukechi town both in the Nakatsugawa city.

For measurement at the fault outcrop, a soil chamber, connected to the G4301 instrument was placed on the ground surface. Concentration of methane released from the fault was measured to be between 20 to 30 ppm. Methane release was confirmed only at the vicinity of the fault gouge and concentration 1m away from the gouge was found to be close to atmospheric background level, 1.85 to 1.88 ppm. Kurosawa et al. (2010, JAEA - Data / Code 2010 - 36) reported that maximum methane concentration was 168 ppm from their measurement using shallow boreholes excavated at the six locations along the outcrop of the Atera fault.

In the vicinity of the fault cliff, two CRDS instruments were mounted in a car and methane gas concentration in the atmosphere along the road was measured continuously with a car speed of several km/h to 30 km/h. Location of the measurements were also recorded using a GPS system. The measurement results showed anomalies of methane concentration at the two locations, approximately 1 km apart from each other, where the road and the extension of the cliff crosses. The peak atmospheric concentration of the anomalies were 1.95 to 2.05 ppm. The nearly 100 ppb difference between the anomaly peaks and the background is significant compared to the measurement accuracy of 3 ppb of the instrument. The anomalies were detected repeatedly at each location when we crossed the fault cliff. Furthermore, the methane concentration obtained by the two instruments were almost identical, confirming that these anomalies were the real responses and not associated with instrument noise.

The anomaly of 100 ppb from background suggests the methane gas emitted from the fault is diluted to about 1/200 to 1/1000 of source gas concentration. Such a small concentration signal was hardly

©2019. Japan Geoscience Union. All Right Reserved.

detected by conventional technology and was successfully detected by using the CRDS technology we employed this time.

In summary, we have confirmed that methane is emitted at the very vicinity of the fault plane at the Atera fault. We also found that the location of the fault can be successfully detected using the CRDS instrument installed on a survey vehicle. From these results, we expect that trace gas measurement using a CRDS technology can be one of the promising approaches to delineate the locations of the active faults creating migration paths of the deep-seated fluids.

This report is part of the achievement in FY2018 by the "Research Committee on Application of High-Accuracy Trace Gas Measurement Technology to Geological Exploration (chairman: Professor Tomochika Tokunaga, the University of Tokyo)" that is operated by the Fukada Geological Institute.

Geomorphological evudence of a newly found active fault along the Shirakawa fault in western part Gifu Prefecture

*Yorihide Kohriya[1], Masashi Omata[1], Hiroshi Yokota[1]

1. PASCO CORPORATION

Recently, expression of micro topography was made possible by improvement of LiDER DEM technology.
The surface rupture in the southern part of Mt. Kunimi, Oshu City, Iwate Prefecture that occurred in the 2008 Iwate-Miyagi Nairiku earthquake was expressed using airborne LiDAR-derived 0.5-m-grid DEM (Maruyama et al. 2011).
It is difficult to detect fault traces in the forest zone using photographs, and it is effective to use LiDER DEM.
When 1 m grid DEM was prepared from LiDER data along Shougawa village of Shogawa village, Gifu prefecture, we confirmed new fault topography with possibility of sub fault of Shirakawa fault.
The LiDER data was measured by Jinzu River Sabo Office, Hokuriku Regional Development Bureau, MLIT in 2016.
The photograph taken at the same time as LiDER is difficult to recognize fault topography because it is a forest zone.

At the Kiya point along the Sho river, west side of study area, the trench of the Shirakawa fault was investigated (Sugiyama et al. 1993).
In the trench survey, at least one earthquake event has been certified since 2,500 y.B.P.
However, the last event and activity interval are unclear.
A new fault trace is found on the right bank slope of Nonomata Valley on the east side of Kiya, Shokawa village, Gifu Prefecture, and the length reaches 1.3 km.
The fault topography along the trace is a gentle slope and a reverse-facing fault scarplet which are linearly continuous on the slope of the mountain.
The vertical component is a western uplift similar to the Shirakawa fault, and is about 10 to 20 m from the topography section.
There is a weak left offset ridge across the fault topography.
In addition, a left offset ridge with a slope top of about 200 m is found on the northern side of the fault topography.
From these evidences we assume that this fault has repeated activity.
In the southern part of the fault topography there are reverse-facing fault scarplet and relatively wide gentle slopes, which are suitable for trench survey.
At this point there is no accumulation of coarse-grained sediments by rivers, and there is little loss of formation. Therefore it is possible to identify the last event of the Shirakawa fault.

Active faults around the Niu Mountains, northern part of Fukui Prefecture, Japan

*Masayoshi Tajikara[1], Takashi Nakata[2], Hiroyuki Tsutsumi[3], Hideaki Goto[2]

1. Association for the Development of Earthquake Prediction, 2. Hiroshima University, 3. Doshisha University

The Niu Mountains is located between Japan Sea and the Fukui Plain, northern Fukui Prefecture. Many active faults have already been reported around the Niu Mountains (e.g., Research Group for Active Faults, 1991). Along the eastern coastal area of the Niu Mountains, the Yanagase-Sekigahara Fault develops in submarine area, and the Ayukawa Faults develop in the land area, respectively. In the eastern side of the Niu Mountains, the Sarage Fault, the Asahi Fault, the Semiguchi Fault, the Sabae Fault, and the Ozowara Fault are mapped, but tectonic landforms of these active faults have not been described in detail. In this study, we mapped distribution of faults somewhat different from previous studies by interpretation of 1/10000 air photographs and stereoscopic image created from 5-10 m DEM of GSI. In this presentation, we report the precise distribution and characteristics of tectonic landforms of these active faults, and discuss their tectonic implications briefly.

This study was done as a part of the Supporting Project for the Headquarters for Earthquake Research Promotion sponsored by the Ministry of Education, Culture, Sports, Science and Technology, Japan.

Gifu-Ichinomiya Fault shown from the characteristics of the damage of the Nobi earthquake

*Nobuhisa Matsuta[1,2], Fumiaki KIMATA[2]

1. Okayama University Graduate School of Education, 2. Tono Research Institute of Earthquake Science

The record of the historical earthquake in Japan shows that the ratio of the number of victims to the number of completely destroyed houses increases in the case of the earthquake in which the surface rupture. Using this relationship, we discussed the question "Is there a surface rupture along the Gifu-Ichinomiya fault at the time of the Nobi earthquake?" The record used for the examination is the damaged data in the municipality at the time. As a result, it was found that the ratio of the number of victims to the number of completely destroyed houses is higher along the Gifu - Ichinomiya fault than in the surrounding area. Therefore, Gifu - Ichinomiya fault existed, we believe there was a displacement in the Nobi earthquake.

Electrical resistivity structure from the surface to the seismogenic zone below the Gomura fault zone, Kyoto, Southwest Japan

*Satoru Yamaguchi[1], Akira Mimura[1], Kazuki Fukue[1], Shigehiro Katoh[2], Hideki Murakami[3], Makoto Uyeshima[4]

1. Department of Geosciences, Graduate School of Science, Osaka City University, 2. The Museum of Nature and Human Activities, Hyogo, 3. Science and Technology Unit, Research and Education Faculty, Kochi University, 4. Earthquake Research Institute, The University of Tokyo

The Gomura Fault Zone in the Tango Peninsula, Kyoto, consists of three fault segments, the Go-seihou, Gomura, and Chuzenji Faults. They show different features in fault activity (average slip rates, the latest events etc.). The Go-seihou Fault is a very short in length (~2.8km long) with no clear displacement. Along the Gomura Fault, a clear surface rupture has appeared at the 1927 Kita-Tango earthquake. Cumulative geomorphological displacement is well recognized along the Chuzenji Fault, but no surface rupture appeared at the 1927 Kita-Tango earthquake. Conductivity structure can be one of the crucial elements to clarify subsurface structure of active faults. Furthermore, the Gomura fault zone is especially suitable for studying the relationships between conductivity structure and fault activity because three faults run nearly parallel within about 3km in simple geological setting.
We proposed the conductivity models of the Gomura Fault Zone combining the two conductivity models; one is the shallow model (0 –1.5 km in depth) and the deep model (0 -12 km in depth). The shallow model is determined based on the result obtained using an audio-frequency magnetotelluric (AMT) method which is excellent in shallow part resolution. While, the deep model is determined based on the result using a wide-band magnetotelluric (WBMT) method which is suitable for wide- and deep-range survey.
The final model is characterized and interpreted as follows.
(1) The final model covers from the surface to a depth of 12 km including the epicenter of the 1927 Kita-Tango earthquake and three faults (the Go-seihou, Gomura and Chuzenji Faults).
(2) The final model is characterized by six conductive zones and one resistive zone.
(3) The fault plane of the Gomura Fault starts the hypocenter of the 1927 Kita-Tango earthquake, goes through seismogenic and conductive region, and reaches to the Gomura Fault.
(4) The clear conductive zones were detected below both the Gomura and Chuzenji Faults in the shallow model. The conductive zone below the Gomura Fault is wider and more conductive than that below the Chuzenji Fault. We interpreted these differences reflect the latest faulting event age: that of the Gomura Fault (~90 yrs. ago) is much younger than that of the Chuzenji Fault. The conductive zones are formed by intruding groundwater into a damage zone around the faults.
(5) No conductive zone is recognized below the Go-seihou Fault and the result indicates that the fault is a secondary fault.
(6) The bottom of the resistive zone can be interpreted as that of the Miyazu granite.

Re-analysis and re-interpretation of the very shallow land seismic reflection survey data across the Naruto-South fault, north side of Tokushima Plain.

*Kobayashi Takayuki[1], Dai Nobuoka[2], Tomio Inazaki[1]

1. Public Works Research Institute Japan, 2. OYO Corporation

We conducted re-analysis and re-interpretation of the very shallow land seismic reflection survey data across the Naruto-South fault, north side of Tokushima Plain. In this study, we show that more detailed active fault structures are obtained by re-analysis and re-interpret old data to give useful information for urban disaster planning. The Naruto-south fault is located in Tokushima Prefecture, the eastern part of Shikoku island, Japan. It is the branch of the Median Tectonic Line (MTL) active fault system. The Naruto south fault is situated 500m to 1000m south of Naruto fault, and cut the Tokushima alluvial plain. The length of the it is expected about 8km (Tokushima Prefecture, 1998). The last faulting event is in 16th century or later. The probability of earthquake indicated the MTL active fault is very low, 0 to 0.4% within 30 years. In the other hand, the expected magnitude of earthquake is very high, 8, and, when the earthquake are occurred, its damage will be tremendous. From this fact, to minimize damages, the clarifying fault structure is required. So, we re-analyze and re-interpret the very shallow S-wave land seismic reflection survey data across the Naruto-South fault acquired in 1998 to obtain more detailed structure of the fault. Measurement length is 100m, receiver spacing is 0.5m and shot source interval is 1.0m. S-wave portable vibrator is utilized for seismic source. Sweep frequency is 40 to 300Hz and sweep length is 7s. As the result of re-analysis, we obtained more detailed active fault structure less than 50m depth. In this study, we can identify the position of the about 70 degrees dip fault, lied from 15m to 50m depth, with more resolution. Also, we achieved to show the continuous structure, not cut off by the active fault, more clearly than conventional. Also, by applying the dating method results, we could estimate the displacement of fault. Maximum displacement is 14.4m, 10.8kyBP to 12.2kyBP, and deformation rate is 1.77mm/yr.

Kochi Univerisity, Center for Advanced Marine Core Research , 4. Kochi Univerisity, 5. Japan Agency for Marine-Earth Science and Technology

In a coastal area of Nomi bay (Susaki city, Kochi Prefecture, Japan), a traditional tale about a village named Kuroda-gori (or Nomi sengen, Otani sengen), which was probably submerged during the Hakuho Nankai earthquake of AD 684, has been passed down orally. Local residents reported a well on the seabed at Nomi bay. However, evidence linking Kuroda-gori to these sites and to historical earthquake is lacking. Therefore, we investigated seabed at Nomi bay near Heshima Island and Otani area to find the artifacts that can be related to historical earthquakes.

Our data were obtained from a research boat “Neptune” of Kochi University. The detailed bathymetric maps and the acoustic reflection distribution maps were acquired by a side-scan sonar system. A sub-bottom profiler was also used to obtain a geological structure below the seabed. Underwater omnidirectional camera was used to observe seafloor carefully.

In a bathymetrical map, the small submarine plateaus (200m×300m in area) was found on the north-western part of Heshima Island, delimited by a steep slope. The plateau was located at the depth of around 10 m. Sediment sampling by gravity corers and underwater images from camera showed that the seafloor on the plateau was composed by hard sandy materials and large conglomerate blocks. On the contrary, the seafloors on the outside of the plateau was composed by soft clayey sediments. No artifact or artificial structure were observed from the sub-bottom profiling data. Several strange mosaic images were obtained from the side scan sonar, and then divers identified some of the strange images were artifacts (an octopus pot, a vinyl sheet). We did not discover a well on the seafloor from mosaic images, underwater camera, or sub-bottom images.
The submarine plateau was probably formed by wave-induced erosion, and Shimomura (1980) reported the similar submarine structures and concluded that the plateaus was formed by the subsidence during the Hakuho Nankai earthquake of AD 684. While any well-like structures were not found, gravels (boulder) arranged in a circle were observed. Therefore, the well that local residents suggested might be the gravels. We plan to perform dating analysis (e.g. radiocarbon dating) using subsea floor sediments at the plateau to assess the co-seismic subsidence. We present preliminary results obtained from a scientific cruise at Urano-uchi Bay on March 2019.

Tectonic geomorphological and paleoseismological study in the Anoriguchi Canyon: Foraminiferal analysis and ^{14}C dating

*Nobuhiko Sugito[1], Masao Iwai[2], Hitomi Wakaki-Uchimura[2], Hiroki Matsui[2], Yasuhiro Suzuki[3]

1. Faculty of Sustainability Studies, Hosei University, 2. Center for Advanced Marine Core Research, Kochi University, 3. Disaster Mitigation Research Center, Nagoya University

It is well known that there exist numerous submarine active faults in the Nankai Trough area. We have to reveal geometry and slip history of these faults, to reveal the origins of the past destructive earthquakes as well as to predict future large earthquakes in more detail. From this point of view, we have conducted a tectonic geomorphological and paleoseismological feasibility study on a submarine active fault of the Nankai Trough area in the Anoriguchi Canyon from FY2016 (Sugito et al., 2018). In this presentation, we report our result of a series of core analysis, including foraminiferal analysis and radiocarbon dating. Based on the data obtained, we infer that the submarine active fault across the Anoriguchi Canyon probably slipped one or more time(s) during this ~10,000 years to produce north-side-up vertical offset of ~10 m. This study illustrates the importance of the tectonic geomorphological and paleoseismological approaches in the studies of historical earthquakes and near-future earthquake potentials.

Subsurface survey around the Matoishi-bokujo 1 Fault in the northwest of the outer rim of the Aso caldera, southwestern Japan

*Takayuki Nakano[1], Hiroshi Une[1], Hiroshi, P. Sato[2], Keitaro Komura[3]

1. GSI of Japan, 2. Nihon Univ., 3. CRIEPI

1. Introduction

A lot of linear surface displacement derived by the 2016 Kumamoto Earthquake (Mj 7.3) were detected by InSAR analysis around the northwest of the outer rim of the Aso caldera, central Kyushu Island, southwestern Japan, and it is estimated that they were displaced passively. Many of them appeared along the known active faults. We have investigated the detail topography and geology to elucidate the mechanism around Matoishi-bokujo 1 Fault. In this presentation, we report the results of the subsurface structure survey found by using topographical/geological survey and ground-penetrating radar (GPR) survey.

2. Result & Discussion

The trenching survey at the foot of fault scarp of the Matoishi-bokujo 1 Fault showed that a white color pyroclastic layer presumed as Aso-4 pyroclastic flow deposit (89Ka) was observed around GL-3.5m (EL= ca. 917.4m) in deep case and GL-0.3m (EL= ca. 921.6m) in shallow case (Une et al., 2018). Also, the topographical and geological survey around the fault showed that the Aso-4 pyroclastic flow deposit was observed at the stream bed on the north side of the fault (EL= ca. 917.8m) and at the gully bed on the south side of the fault (EL= ca. 935.0m). Furthermore, on the east side of the site, the outcrop of stratum considered to be representative of the sedimentary structure in this area can be observed, and it was found that blackish soil layer and loam layer sandwiching multiple tephra layers above the Aso-4 pyroclastic flow deposit accumulated ca. 5m in thickness.

GPR profiles performed on the survey line crossing the fault showed clear echoes in GL-2m to -4m on the south side of the fault. It is presumed from the trenching survey and geological survey in the waterway on the south side of the fault so far that these clear echoes correspond to the upper surface of loam layer below the subsurface blackish soil or riverbed gravel layer covering the loam. On the north side of the fault, since GPR echoes are decayed drastically at deeper than GL-1 to -1.5m (EL= ca. 930.5 to 931.0m), it is suggested that there are a layer with a relative dielectric constant greater than that of the upper layer (blackish soil) at GL -1.5m or deeper. In addition, there is a weak echo around GL -4 to -5m (EL= ca. 927 to 928m). It is possible that this weak echo corresponds to the upper surface of the Aso-4 pyroclastic flow deposit from its continuity.

From these result, although the shape of the upper surface of the Aso-4 pyroclastic flow deposit is roughly similar to the present topography surface, it is located at GL-5m deeper on the south side of the fault and around GL-4 to -5m at the north side of the fault. Therefore, its relative height difference is estimated to be about 13 m or more, and this is considered to be the apparent vertical offset of the fault for ca. 90,000 years.

3. Summary and Challenges

As a result of topographical and geological investigation and the subsurface structure survey around the Matoishi-bokujo 1 Fault which was secondarily displaced associated with the Kumamoto Earthquake, we could presume the subsurface structure and the apparent vertical offset of the Aso-4 pyroclastic flow deposit surface. We plan to analyze and interpret the GPR profile in more detail with reference to the result of percussion boring in the future.

Past activity of 'triggered fault' in the northwest of outer rim of Aso caldera estimated from the results of excurvation survey and displacement topography

*Hiroshi Une[1], Takayuki Nakano[1], Hiroshi, P. Sato[2], Hiroshi YAGI[3], Keitaro Komura[4]

1. Geospatial Information Authority of Japan, 2. Nihon University, 3. Yamagata University, 4. Central Research Institute of Electric Power Industry

Matoishi Bokujo 1 Fault is one of the "triggered faults" in the northwest of outer rim of Aso caldera associated with the Kumamoto Earthquake in 2016 with clear tectonic geomorphology, significant phase discontinuity appeared in SAR interferometry and surface displacement in the field. We carried out a geomorphological and geological survey including a pit excavation, ground penetrating radar (GPR) survey and simple core samplings in a site on the fault, and discussed the history of past activities. We excavated a pit with 10 m long and 4 m deep at maximum at the bottom of the fault scarp and observed the both walls. A white Aso-4 pyroclastic flow deposit appeared at the bottom of the walls, directly covered by a river bed deposit composed of medium sand and granule and a debris flow deposit composed of rubble on the pit valley side, and the slope sediments of brown sand and mud with rubble on the pit mountain side. They are covered with slope sediments of black sand and mud that accompanies with rubble or that are scarce in rubble. At least two fault ruptures appeared with displacements of these strata and disorientation of gravel. We assume that the upper surface of Aso-4 at the bottom of the walls shows the unconformity of the deposition surface when the pyroclastic flow arrived in 90,000 year BP, for the low relief surface surrounds this area which is the deposition surface of Aso-4 pyroclastic flow, and outcrops of Aso-4 pyroclastic flow deposit are widely observed at a comparatively shallow position, i.e. several meters below the surface of the earth. From the pit survey and the simple core samplings, it is estimated that the upper layer of the white layer gradually lowers its altitude from the south to the north toward the fault scarp, and is raised about 10 m above the fault scarp, consistent with the topography and displacement pattern by SAR interferometry. Considering the results of the ^{14}C dating of the black soil of the slope sediments collected from the wall, a faulting event which brought the movement of slope deposits from the mountain side resulting the coverage of river deposit at the valley side occurred in between about 3,500 and about 3,400 years ago, followed by another faulting event that caused two fault ruptures in between about 3,500 and about 2,000 years ago or younger. It is suggested that the number of events experienced by lower slope sediments is larger than that of upper one (the amount of displacement of upper one is about 2 times). This suggests that the accumulation of displacements like this time formed fault scarp of Matoishi Bokujo I Fault.

ACKNOWLEDGMENT: This work was supported by JSPS KAKENHI Grant Number (JP17K01234) (Research Director: Hiroshi P. Sato). The ownership of Daichi 2 (ALOS-2) data is in the Japan Aerospace Exploration Agency (JAXA). In the field survey and analysis of the materials, we received great cooperation from the students of the Kaneda laboratory of the Graduate School of Science of Chiba University and the Department of Geography of the Nihon University School of Science and Engineering.

Visualization of three-dimensional SAR analysis data by stereo isogram map: Precise detection of surface ruptures of the 2016 Kumamoto earthquake sequence

*Yasuo Awata[1]

1. Institute of Earthquake and Volcano Geology, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

Advances in geodetic surveying technology make it possible to grasp the crustal deformation in a wide range from several cms to several meters. In particular, the observation by the spaceborne SAR enables high-resolution detection of crustal deformation using interferometric and three-dimensional analysis. These advances are bringing about a major change to the conventional field investigation method of surface ruptures associated with earthquakes. Here, I tried to visualize the 3D-SAR data of the 2016 Kumamoto earthquake sequence (Kobayashi, 2017) to detect the regional and local surficial deformations with high accuracy.

For visualization of 3D-SAR data to high-resolution and high-dynamic-range images, the stereo contour and relief mapping method is applied. The 3D data is divided into three components, the east-west, north-south, and vertical components, each consists of geographic coordinates and a single value. The isogram map having fine line interval up to the equivalent to the accuracy of data is generated from the data. For east-west and vertical components having the high accuracy, practically fine isogram at a line interval up to 1 cm are drown. Those isogram images are processed into anaglyph capable of stereoscopic viewing with a wide field of view.

In the visual interpretation using an anaglyph image at a line interval of 1 cm, both the main fault zones (Futagawa River, Idenokuchi and Takagi earthquake faults) accompanied by regional crustal deformation and numerous small ruptures scattered in a 50 km square area are observed in a single image. The interpretation results of small ruptures are generally consistent with that of Fijiwara et al. (2016) based on conventional InSAR images that spatial resolution is assumed to be one digit higher. It is easy to detect the ruptures with a displacement of east-west and north-south components of about 5 cm using the image. Furthermore, ruptures up to 2 cm in displacement are recognizable in the Kumamoto urban area where the gradient of regional deformation is small. In the field survey based on the 3D-image interpretation, I found those small ruptures and measured the displacements of guardrails, road curbs, and concrete structures.

Preliminary active fault mapping of Mongolia by interpretation of ALOS 30 DEM image

*Takashi Nakata[1], Yasuhiro Suzuki[2], Mitsuhisa Watanabe[3]

1. Hiroshima University, 2. Nagoya University, 3. Toyo University

Mongolia has experienced huge earthquakes generated from extensive active faults in the 20th Century, namely 1905 Tsetserleg (M7.9), 1905 Bulnai (M8.4), 1931 Fu-Yun (M8.0), 1857 Gobi-Altai (8.1) and 1967 Mogod (M7.1). These earthquakes were generated from pre-existing active faults that have been studied in detail. However most of the other extensive active faults were mapped mainly based by 2D satellite and Google Earth imageries, and they are commonly delineated along distinctive topographic boundaries sometimes without enough evidence for late Pleistocene activities. In order to map active faults throughout Mongolia, we employ stereoscopic interpretation of anaglyph images processed from ALOS 30 DSM images to obtain topographic evidence such as fault scarps across late Pleistocene and Holocene topography and lateral stream offset for late Quaternary activities, and we compiled a preliminary active fault map of Mongolia.

Ground penetrating radar profiling across the Sanchiao fault in northeast Taiwan

*Mamoru Nakamura[1], How-wei Chen[2]

1. Faculty of Science, University of the Ryukyus, 2. National Central University, Taiwan

Keelung earthquake (M 6.9-7.2) occurred on December 18, 1867, in northeast Taiwan. The seismic intensity distribution and tsunami runup height distribution for this earthquake were estimated from a review of relevant literature. The seismic intensity of the earthquake reached a maximum of VII at downtown Jinshan (northeast Taiwan) according to the scale of the Central Weather Bureau of Taiwan (Cheng et al., 2016 TAO), whilst the tsunami runup height reached 6-15 m along the northeast coast of Taiwan. From the seismic intensity distribution, the source fault of the Keelung earthquake is estimated to have been at the seaward extension of the Sanchiao fault (Cheng et al., 2016 TAO). The Sanchiao fault is a normal fault, approximately 53 km in length, and passes from the south of Taipei through to Jinshan (Shyu et al., 2015 TAO). From morphological surveys, borehole surveys, and seismic reflection surveys, the Sanchiao fault is estimated to pass along the foot of the mountain to the north of downtown Jinshan. However, it is unclear whether the land area of the Sanchiao fault moved in 1867. Therefore, we carried out a Ground Penetrating Radar (GPR) survey to detect the location of the Sanchiao fault.

The GPR survey was carried out on a coastal dune to the north of Jinshan. The coastal sand dune runs in a northwest-southeast direction along the shore, perpendicularly to the Sanchiao fault. The following two types of GPR survey lines were set up: a long range type (100-200 m) running parallel to the coastal dune, and a short range type (20 m) running perpendicularly to the coastal dune. Surveys were carried out from August 15-17, 2017 and from August 13-17, 2018. Three short lines were set up parallel to the dune and two lines perpendicularly to the dune. The pulseEKKO from Sensors & Software Inc. was used for the GPR survey, and the survey frequency of the radar was 50 MHz, 100 MHz, and 250 MHz.

A conspicuous radar reflector was found in the survey line running parallel to the coastal dune. The depth of this reflection changed near the fault trace of the Sanchiao fault, as estimated from boreholes. Furthermore, the depth of the reflection at the northwestern region of the fault was approximately 1 m deeper than that at the southeastern region. This is inconsistent with the vertical displacement of the normal faulting of the Sanchiao fault that dips southeastward, and suggests that the deformation could have been caused by the branching off of the splay fault from the main Sanchiao fault.

Paleo-earthquake records of the Hengchun offshore structure, southern Taiwan

*Sze-Chieh Liu[1], J Bruce H Shyu[1], Yuan-Lu Tsai[1], Chuan-Chou Shen[1]

1. National Taiwan University

In the southernmost part of Taiwan, the Western Hengchun Tableland is a prominent topographic feature, with several steps of late Pleistocene uplifted marine terraces forming the top of the tableland, and uplifted Holocene coral reefs along the coast. To interpret the formation of this tableland, an inferred Hengchun offshore structure has been proposed as an active structure located offshore to the tableland’ s west. The uplift and the eastward tilting of the tableland are therefore produced by neotectonic activities of this structure. However, the presence of this structure is still debated, and no record of paleo-earthquakes related to this structure has been identified. To solve this, we utilized fossil coral microatolls as paleo-sea-level indicators to identify possible paleo-earthquake records produced by this structure. The highest level of survival (HLS) of corals is limited by the low tide level. Once living corals grow to this level, the upward growth will stop and they will grow outward instead, forming microatoll morphology with a flat top surface. This makes microatolls great tools to record local sea level history. If microatolls were uplifted and killed by co-seismic uplift, the elevation difference between microatolls and the HLS would represent the amount of uplift, and the age of the coral would constrain the age of the earthquake event. In this study, we surveyed six sites along the coast surrounding the Western Hengchun Tableland. Based on our field survey data and U-Th dating results of uplifted corals, we reconstructed a coastal uplift history of the area, and proposed several paleo-earthquake events in the past 2,500 years. These results enabled us to further understand the seismogenic properties and the possible earthquake recurrence intervals of the Hengchun offshore structure.

LC-InSAR analysis of the Sulawesi earthquake in Indonesia

*Jun Sugimoto[1], Masashi Omata[1], Yoshiteru Akiyama[1], Yutaka Horaku[1]

1. PASCO CORPORATION

On 28 September 2018, a shallow, large earthquake struck in the neck of the Minahasa Peninsula, Indonesia, with its epicenter located in the mountainous area, Central Sulawesi. The magnitude was 7.5.The main active onshore structure in the western part of Central Sulawesi is the left-lateral NNW-SSE trending Palu-Koro strike-slip fault that forms the boundary between the North Sula and Makassar blocks. It was reported that the earthquake caused major soil liquefaction in and around Palu.
In this study, the authors conducted the interferometry analysis using ALOS-2 data and found out the followings:
1) A phase discontinuity lines found in the LC-InSAR diagram can be Palu-Koro fault and other small strike-slip faults around Palu-Koro.
2) In the LC-InSAR diagram, areas with low coherence are distributed in a wider range than the range where damage was caused by liquefaction. This shows the possibility that the ground change has occurred in a wider range than the extent of damage caused by liquefaction.

The authors confirmed that analysis using ALOS-2 data can identify places and scopes of disasters with extensive damages occurred not only in Japan but also in other countries.

Recent, many destructive earthquakes and tsunamis occurred around the plate boundary in the world, which are, 2004 Sumatra Earthquake/Tsunami, 2011 East Japan Earthquake/Tsunami in Japan, and so on. Along plate boundary in Turkey, the North Anatolian Fault (NAF) distributes and the large earthquakes has occurred there. The one of the events along NAF in Turkey is the 1999 Izmit Earthquake, and severe damages was brought to residents The NAF between the eastern end of Turkey and the Aegean Sea has been ruptured in turn from the both ends, and the part off Istanbul city still remains as unruptured zone. It is considered that future large event brings fatal damages not only Istanbul city but also the entire of Turkish economy.

To prepare future large earthquake there, Japan and Turkey made an agreement to start a multidisciplinary research project, MarDiM SATREPS in 2003. The Project has four research groups with the following goals. Group 1 is Marmara Earthquake Source region observational research group to clarify seismicity, crustal structures and crustal displacement, and to construct a possible fault model. Group 2 focuses on scenario researches of earthquake occurrence along NAF and precise tsunami simulation in the Marmara region. Group 3 aims improvements and constructions of seismic characterizations and damage predictions based on observation researches and precise simulations. Group 4 promotes disaster educations using research result visuals and construct strategies of disaster mitigation.

Group 1 constructed a fault model along NAF with some asperities and with variation on the dip. The segment boundary was also identified through the modeling and it is consistent with the past rupture pattern and fluid distribution. The NAF on the western region of Sea of Marmara has creep and the rate is nearly half of block motion based on direct seafloor observation for crustal displacement. Group 2 calculated cyclic rupture pattern along NAF using heterogeneous fault model and constructed monitoring system “SWIFT” for crustal stress field by mechanisms of many events estimated automatically. We developed tsunami calculation code to image inundation around the coastal area. Group 3 investigated ground structure through regular fine shake observation, and constructed city model of industrial region supporting Turkish economy. We simulated strong motion using ground structure, city model and fault model derived from Group 1 and made a new hazard map. Group 4 considered teaching materials for disaster prevention including Japanese animation technique based on above results of three groups. These materials are utilized for disaster mitigation in Marmara region and disaster education in Turkey.

Introduction: Active faults are recognized by displacement / deformation of current topography and the Quaternary strata. However, in the absence of them, it is very difficult to decide whether the fault there is an active fault or not. In this study, we tried multivariate analysis using chemical composition data of fault gouge of active faults and inactive faults in Japan, and tried to determine the presence or absence of fault activity.
Methods: This research was carried out in the following order; collection of papers, extraction of chemical composition data of fault gouge, addition of new chemical analysis data, formatting of input data, variable selection, linear discriminant analysis. First, chemical composition data of fault gouge of active faults and inactive faults in Japan was extracted from existing publications. In this case, the extraction condition clearly describes whether the analysis target is an active fault or an inactive fault and that the basement rock is diverse. In addition, a chemical analysis of the fault gouge sample possessed by the JAEA was carried out, and we created a database that integrates both of them. In this database, in addition to the sample name and analytical value of each sample, 2 categories of active fault and inactive fault were given. Then, we decided elements to be candidates for explanatory variables from this database and arranged them as input data. Since the chemical elements extracted from the literature are not all analyzed for the same element, common elements are chosen so that the number of samples can be taken as much as possible. In order to further extract elements suitable for discrimination between active fault and inactive fault from these elements, variables were selected by two methods of Akaike Information Criterion (AIC: Akaike, 1973) and principal component analysis. Finally, linear discriminant analysis was performed using as an explanatory variable a combination of an element selected by AIC and an element whose factor loading amount was considered to be high in the principal component analysis.
Results: As a result of collection of papers, chemical composition data of fault gouge was extracted from 7 existing papers and 5 reports of the JAEA. We extracted 17 elements as candidates for variables from the database, to which a chemical analysis result of 6 fault gouge samples possessed by the JAEA was added. The number of data was 41 samples for active fault and 16 samples for inactive fault, totaling 57 samples. From these 17 elements, 13 elements were extracted as optimum combination of elements in AIC. In the principal component analysis, synthesis expressions from the first principal component to the 17th principal component were obtained, and elements with high factor loading amounts were calculated for each synthesis formula. From these results, linear discriminant analysis was carried out with a following combination of elements; (a) 13 elements of AIC, combination of elements whose average value of factor load amounts falls in the top 10 of (b) Up to the 3rd principal component of principal component analysis (explain the scattering degree of chemical composition by 65%), (c) Up to the 5th principal component (also 80%), (d) Up to the 8th principal component (also 90%). As a result, a combination of (a), (c) and (d) gives a primary equation that accurately divides the 2 groups of active fault and inactive fault.
Consideration: The elements common to the combination of the above are 6 elements of TiO_2, Al_2O_3, MgO, Na_2O, P_2O_5, Ba. Linear discriminant analysis was carried out again with (e) the combination of these 6 elements, and it resulted in accurate division of the 2 groups. Since these elements are selected by different methods or filters, there is a possibility of elements representing the difference between active faults and inactive faults. Also, as a result of assigning data of 3 specimens of fault gouge of another active

©2019. Japan Geoscience Union. All Right Reserved.

fault to each primary equation, values which are judged to be active faults in all equations were obtained. However, these values were out of the distribution range of the population, and the tendency was more conspicuous as the number of elements was larger. From this, the primary equation consisting of 6 elements of (e) was considered to be the best formula to separate active fault and inactive fault.
This study was carried out under a contract with Ministry of Economy, Trade and Industry of Japan as part of its R&D supporting program for developing geological disposal technology.

Bayesian optimization of fault-shape parameters using finite element analysis: parameter sets for strong slip partitioning

*Hidetaka Saomoto[1]

1. National Institute of Advanced Industrial Science and Technology

The Bayesian optimization algorithm is now a key technique in various scientific and engineering fields that require the parameter optimization. The technique can reduce the number of simulation trials as compared with the grid-search because the algorithm can act as an artificial intelligence with a statistical decision-making. Because a three-dimensional finite element analysis (FEA) for seismic faulting consumes much CPU time, the use of the Bayesian optimization with the FEA is logical and is expected to accelerate the parameter detection process.

Here, I present the method of combining an open source library Optuna (1) based on a Bayesian optimization algorithm, Tree-Structured Parzen Estimator (TPE) with the seismic faulting FEA based on COMSOL Multiphysics and then demonstrate a Baysian optimization for the fault-shape parameters that activates strong slip partitioning.

The parameter sets obtained from the Bayesian optimization algorithm result in a stronger slip partitioning than that obtained from the grid-search. More specifically, the optimized parameter set was found as a dip angle for the reverse-slip fault of 54.5 degree, a dip angle for the strile-slip fault of 86.3 degree, and the principal stress direction of 56.1 degree clockwise from the strike direction.

The Bayesian optimization detected the parameter set after 50 trials, whereas the grid-search was composed of 784 trials. In summary, the use of the Bayesian optimization algorithm is an effective and efficient way of a parameter optimization for a seismic faulting simulation that requires long CPU time.

Tue. May 28, 2019 5:15 PM - 6:30 PM JST | Tue. May 28, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_31

[S-SS15] Active faults and paleoseismology

convener:Mamoru Koarai(Earth Science course, College of Science, Ibaraki University), Takashi OGAMI(National Institute of Advanced Industrial Science and Technology), Ryosuke Doke(Hot Springs Research Institute of Kanagawa Prefecture), Hisao Kondo(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology)

Geologic and historic information on seismic cycles and on the magnitude and source faults of past earthquakes is essential information to understand future large earthquakes. The study of past faulting and seismicity is an important issue for an interdisciplinary community of seismologists, geologists, geomorphologists, archaeologists, and historians.

Paleoseismicity of Atsuma Town , Hokkaido: Evidence from landslide deposits

*Jun Tajika[1], Tetsuya Inui[2]

1. Docon Co.,Ltd., 2. Board of Education, Atsuma Town

Many landslides occurred by the 2018 Hokkaido Eastern Iburi Earthquake in Atsuma-cho. We reported about discovering of ancient landslide deposit from an archeological site of the Jomon period in Atsuma in 2004 and 2016. It was inferred that this landslide was caused by an earthquake and it probably occurred at activity event of the Ishikari teichi-toen active fault zone. The morphological characteristic of the landslide deposit resembles that of landslide caused by this earthquake. The archeological findings of the past remains excavation in Atsuma-cho area shows that the event of a lot of landslides caused by earth quake is only 2018 Hokkaido Eastern Iburi Earthquake and an earthquake of the Jomon period during last 9,000 years.

Emeritus professor of Tohoku University, 5. OYO Corporation, 6. Graduate School of Science, Tohoku University, 7. Department of Earth Sciences, Graduate School and Faculty of Science, Chiba University, 8. Geo-Research Institute

The Aomoriwan-Seigan Fault Zone is a fault zone of NNW-SSE trending western dipping reverse faults, which is composed of Aomoriwan West Fault, Nogiwa Fault, and Nyunai Fault. The fault zone is distributed about 31-km long along the eastern foot of the Tsugaru Mountains from Yomogita village of Aomori prefecture to Aomori city (Headquarters of Earthquake Research Promotion, 2004). We carried out a seismic reflection survey and CSAMT (Controlled Source Audio-frequency Magnetic Telluric) survey across the Aomoriwan West Fault (Kagohara et al., 2017; Sakashita et al., 2017) in 2016-2017. The low angle thrust faults of Tsugaru Fault and inclined geological structure until the depth of 1.5 km were revealed in these results. In addition to these surveys, we conducted gravity survey along the seismic survey line, and obtained the Bouguer gravity anomaly (Okada et al., 2018).
In the previous our presentation in the 2018 JpGU (Okada et al., 2018), we use the Talwani method (Talwani et al., 1959) to calculated the Bouguer gravity anomaly, in which the subsurface density structure is determined from the interpretation of the seismic and CSAMT surveys (Kagohara et al., 2017; Sakashita et al., 2017). In a part of the western part of the profile, there were some discrepancies between calculated and observed gravity anomalies. And it was also difficult to estimate the density of each layers. To resolve these problems, we conducted additional field survey and obtained several rock samplings from outcrops around the survey line, which we measured the density of samplings based on the method of Murata et al. eds. (1991). The discrepancies between calculated and observed gravity anomaly were improved by take into the layer densities from samplings.

Was the 1611 Keicho earthquake a giant interplate event like the 2011 Tohoku earthquake?

*Tomoya Harada[1], Akihito Nishiyama[1], Kenji Satake[1], Takashi Furumura[1]

1. Earthquake Research Institute, The University of Tokyo

After the 2011 Tohoku earthquake (M9.0), the 1611 Keicho earthquake along the Japan trench has been regarded as a giant interplate event. In this study, from the examination of reliability of the historical records about the 1611 event and comparison between the impact on Kanto by the 2011 and 1611 events, we consider that the 1611 earthquake was not a giant interplate event but a tsunami/outer-rise earthquake.
From the historical documents, the Dec. 2nd, 1611 Keicho earthquake generated large tsunami on the Pacific Coasts of Tohoku and Hokkaido while this event caused no seismic damage in Tohoku and Kanto. Since the 1896 tsunami earthqauke (M8.1) and 1933 outer-rise earthquake (M8.1) had similar features, the 1611 event had been regarded as an M~8 tsunami/outer-rise earthquake (Hatori, 1975; Aida, 1977; Watanabe, 1998). After the 2011 Tohoku earthquake, however, some studies claimed that the 1611 earthquake was probably a giant event because the tsunami heights and inundation areas estimated from the historical documents (e.g. Hatori, 1975; Tsuji et al., 2011; Ebina and Imai, 2014) are comparable to (or larger than) those of the 2011 event (e.g. Ebina, 2014; Iwamoto, 2013). Following this claim, tsunami researchers attempted to make fault models to reproduce the 1611 tsunami by the tsunami numerical simulation. Imai et al. (2015) proposed two fault models. One is a giant interplate event (fault size: 400km*200km, Mw8.7), another is a model (Mw8.4) of simultaneous occurrence of a great interplate event (fault size: 400km*150km) and a great outer-rise event (fault size: 400km*50km). Fukuhara and Tanioka (2017) considered that the 1611 event was a giant tsunami earthquake (fault size: 250km*50km, the maximum slip: 80m, Mw9.0).
In this study, however, we considered that the 1611 Keicho earthquake was not a giant interplate event but a M~8 tsunami/outer-rise earthquake from the following reasons: (1) Reliability of the 1611 tsunami heights and inundation areas is not high because they are estimated from the historical records without examination of reliability. There are historians who dispute the 1611 giant earthquake based on the unreliable historical records (e.g. Kan’no, 2014; Sasaki, 2014; Saino, 2017); (2) Strong shaking by the 2011 mainshock caused severe damage in Kanto and aftershocks and induced events caused additional damage and successive shakings in this region for several weeks. Whereas, as for the 1611 earthquake, only two shakings in Edo (present Tokyo) are recorded in the court nobles' diaries and there is no record of the seismic damage in Kanto. From the primary historical documents, Ieyasu Tokugawa went hunting with hawks to the present Saitama Pref. and court nobles went sightseeing to environs of Edo on the next day of the 1611 event. Therefore, the 1611 earthquake was probably an event which didn’t impact on Kanto, i.e. not a giant interplate event like the 2011 earthquake. M~8 interplate event in 1793 offshore present Miyagi Pref. caused minor seismic damage in Edo and its 2-days aftershocks shocked Edo more than 50 times (Usami et al. 2013); (3) Even if the 1611 earthquake was an M~9 tsunami event, ~80m slip on the large fault (250km*50km) should cause many aftershocks and widely induce earthquakes including M7-8 events. As mentioned above, however, there is no record about the successive earthquakes after the 1611 event; (4) No tsunami deposit by the 1611 event is discovered at the ruins in Sendai Plain excepting Taka-ose Ruin in the present Iwanuma City (Saino, 2017), while they are discovered on the Sanriku Coasts (e.g. Takada et al., 2016). In addition, they are not discovered at the Idagawa marsh in the present Fukushima Pref. (Kusumoto, et al. 2018). Therefor, 1611 tsunami probably didn’t inundate deeply in the lowlands on the Pacific Coast in Miyagi and Fukushima Pref. Recently, Goto et al. (2019) reported that the

1611 tsunami deposits were not discovered at the Numano-hama of Sanriku Coast.

Neotectonic characteristics along both flanks of the Ou Backbone Range, Tohoku Region, Japan, from fluvial geomorphic analyses

*Jhih Hao Liao[1], J Bruce H Shyu[1], Yasufumi Iryu[2], Hiroyuki Tsutsumi[3], Chia-Yu Chen[1]

1. Department of Geosciences, National Taiwan University, Taipei, Taiwan, 2. Graduate School of Science, Tohoku University, Sendai, Japan, 3. Department of Environmental Systems Science, Doshisha University, Kyotanabe, Japan

The islands of Japan are located at the boundaries between the Eurasian, Philippine Sea, and Pacific plates, with frequent earthquakes and numerous active structures. In the Tohoku Region, for example, the Ou Backbone Range is bounded on its both sides by two major active structural systems: the Eastern Marginal Fault Zone of the Yokote Basin in the west and the Western Marginal Fault Zone of the Kitakami Lowland in the east. However, the relative activeness and characteristics of these two systems are still not clear. As fluvial systems are capable of recording variations of topography caused by tectonic, climatic, lithologic, and anthropogenic influences, we hope to further understand these two structural systems using fluvial geomorphology of the Ou Backbone Range area.
In this study, we analyzed river profiles to obtain the geomorphic index χ and the river steepness index (k_{sn}). The results show that the steepness index of river channels along the two flanks of the Ou Backbone Range are different, likely indicating different tectonic activities. However, we also found a number of knickpoints along several river networks. We investigated these knickpoints with satellite imagery and field surveys. Our results show that these knickpoints are mostly produced by local resistant rock layers or check dams, instead of reflecting different states of tectonic activity.
Therefore, we were able to exclude the influence of the knickpoints and to focus only on the results of river steepness index. The results show that rivers along the western flank of the Ou Backbone Range generally have steeper channels than those along the eastern flank. This suggests that the uplift rate of the range’s western flank is higher, and the structures in the west may have higher activity. The results are consistent with the vertical slip rate estimates of the faults; ~1 mm/yr for the western flank and 0.2-0.4 mm/yr for the eastern flank. Moreover, the northern segment of the range’s western flank has the steepest river channels. This result appears to correspond with the surface ruptures of the Senya fault, Ota fault, and other related faults during the 1896 Rikuu earthquake. As a result, we propose that the northern segment of the Eastern Marginal Fault Zone of the Yokote Basin may be the primary structural system in the region, producing the faster uplift of the range and rapid subsidence of the basin, and steeper channels along the western flank of the Ou Backbone Range.

Tsunami record of the last 700 years in bottom sediment of lake Kasumi-ga-ura, southeastern part of Ibaragi Prefecture

*Yoshio Inouchi[1]

1. Faculty of Human Sciences, Waseda University

Lake Kasumi-ga-ura connects the Pacific Ocean via Tone River. Sampling site in this lake lies more than 50km far from the river mouth of Tone. Maximum tidal height at March 11, 2011 was +2.5m at the river mouth of Tone and +1.6m at water gate located 18km from the river mouth. Based on these facts, we started studies on tsunamiites in bottom sediment of Lake Kasumi-ga-ura. Cored sediment of 77cm length was taken at the central part of the lake where water depth is 6m on August 21, 2018. CT scan photograph was taken and samples for grain size analysis at each 1cm thickness were taken. Tephra seams of Asama-A in 1873 A.D. and Fuji Hoei in 1707 A.D. were observed at depth 42cm and 50cm respectively. Shells of *Corbicula japonica* were observed at depth from 70 to 73cm. More than 10 event layers were observed having more than 10 micrometers in mean diameter and relatively less transparency in X-ray. Sand size particles are chiefly composed of minerals of quartz, feldspar, pyroxene etc. and fragments of pumices and scorias and sometimes minor plant fragments and shell fragments. Sedimentary ages of event layers estimated based on dry weight of sediment and ages and depths of tephras show good correlation to historical large tsunamis. As mentioned above, Lake Kasumi-ga-ura locates more than 50km far from the river mouth of Tone. Tidal height is supposed to decrease rapidly. But existence of event sediments in Lake Kasumi-ga-ura shows that large tsunamis could reach that lake. Those sediment can be correlated to tsunamis of Showa Sanriku in 1933, Chiba Boso in 1909, Meiji Sanriku in 1896, Chile in 1877 or 1837, Genroku in 1703, Enpou Boso in 1677, keichou in 1605 or Keichou Sanriku in 1611, Tenshou in 1586, Meiou in 1498 or Kyouroku in 1454 and Shouhei in 1361.

Detecting concealed fault by microtremor H/V study in Miura Peninsula

*Kazuzi Ogawa[1], Yasuyuki Iwase[1], Takumi Murakoshi[1], Toshihisa Itano[1]

1. National Defense Academy

The Miura Peninsula in the southern part of the Kanto region has many active faults. According to geologic map described by Geological Survey of Japan, there is a concealed fault that has about E-W strike in the center of Shonankokusaimura (Etoh et al., 1998). Therefore, in this study, we adopted a microtremor H/V study to detect this concealed fault. Microtremor is a vibration that is constantly shaking the ground even when there is no earthquake. It occurs from natural phenomena and human activities. It contains information on the ground which is the medium of propagation of tremor though it seems random noise. Currently, method of microtremor H/V spectral ratio is widely used such as site effects assessment (Nakamura et al., 1986), underground structure estimation (Gueguen et al., 2000) and detecting active fault (Shibuya, 2008; Sant et al., 2017).

In this study, we carried out microtremor measurements at 15 points across the fault using the JU410 seismometer. Sampling rate was 100 Hz and 15 minutes measurements were conducted for each observational point. In the analysis, the averaged H/V spectral ratio was calculated from the non-overlapped data sets in which the data window length and number were set to 20 seconds and 45, respectively, and noisy portions were removed. The calculation method of the H/V spectral ratio in this study is as follows. At first, Fourier spectra of N-S, E-W, and U-D wave components are calculated. Secondly, H/V spectral ratio is calculated from dividing the square root of the sum of N-S and E-W components by U-D components. Finally, NS/UD and EW/UD are obtained from dividing the N-S by the U-D components and dividing the E-W by the U-D components, respectively. Final process is performed separately from the second in order to take into account the anisotropy for the N-S and E-W directions.

As a result, change of the peak frequencies of the H/V spectral ratio in the direction perpendicular to the fault strike is confirmed and the peak frequencies of the H/V spectral ratio are about 5 Hz in the northern part and about 3 Hz in the southern part, respectively, and its boundary locates approximately 100 meters south of the concealed faults described in the geological map. This suggests the depth of the boundary between the basement rock and sedimentary layer is decreasing from the north to the south in the center of Shonankokusaimura. Focusing on the direction, EW/UD tends to be larger than NS/UD at the frequency that shows the peak in the H/V spectral ratio. These results may show the possibility of existence of the concealed fault in the center of Shonankokusaimura and imply the occurrence of anisotropy of the H/V spectral ratio near the fault. It is expected that the microtremor measurements and analysis considering anisotropy of wave components can lead to future fault research.

Distribution, geometry and slip rates of branch faults around the Kita-Izu fault zone

*Ryuhei Oda[1], Daisuke Ishimura[1], Takehiko Suzuki[1]

1. Tokyo Metropolitan University

In the northeastern part of the Izu Peninsula, there is the Kita-Izu fault zone which extends N-S direction. A branch fault group showing NW-SE strike (Earthquake Research Committee, 2005) is distributed in the east side of the Kita-Izu fault zone. However, slip rates of branch faults have not been estimated. Additionally, the distribution and formation ages of geomorphic surfaces around the Kita-Izu fault zone have not been revealed. Thus, we focus on branch faults (oblique, subparallel to the Tanna fault or Ukihashi central fault) and clarify the distribution, geometry and slip rates of them. Furthermore, we reveal the distribution of geomorphic surfaces around the Kita-Izu fault zone and consider formation ages of them.
In this study, we carried out geomorphic interpretation, field surveys, and measuring the amount of displacements of branch faults using DEM data. In field surveys, we observed fault topographies along active faults and deposits forming geomorphic surfaces around active faults.
From geomorphic interpretation, branch faults are located mainly on the east side of the Tanna fault and the Ukihashi central fault. They are composed of left-lateral slip faults striking N-S and right-lateral slip faults striking NW-SE or E-W. From field surveys, deposits that can estimate formation ages of geomorphic surfaces were not identified. Therefore, we used ages of geology (Oikawa et al., 2011) as lower limits of formation ages of geomorphic surfaces.
Lower limits of slip rates of branch faults were estimated using vertical and horizontal displacements and lower limits of formation ages of geomorphic surfaces. As a result, lower limits of horizontal and vertical slip rates of branch faults were estimated to be 0.10-1.0 mm/yr and 0.01-0.10 mm/yr, respectively. Similarly, we estimated horizontal slip rates of the Tanna and Ukihashi central faults and compared to those of branch faults. Then, we found that horizontal slip rates of Tanna and Ukihashi central faults are one order larger than those of branch faults. Thus, the activity of branch faults is considered to be lower than that of Tanna and Ukihashi central faults. In the north of the Tanna fault, left-lateral slip active faults striking N-S or NW-SE are located. These faults and the Tanna fault form right-stepping en echelon arrays and their slip rates are larger than those of branch faults. Furthermore, there is a possibility that they acted with the Tanna fault in Kita-Izu earthquake in 1930. Thus, some left-lateral slip active faults located in the north of the Tanna fault may constitute the northern end of the Tanna fault.

Geotectonic history of the Inadani fault zone in southern part of Nagano prefecture, central Japan

*Shuuhei Tsukui[1], Kenta Kobayashi[1]

1. Department of Geology, Faculty of Science, Niigata University

Central Japan is a region where many active faults are distributed, one of Japan's most active fault-dense areas (active fault study, 1991). Many of these active faults are characterized as high angle strike slip fault group with NE-SW strike and NW-SE strike. The Inadani fault zone, which is located in the southern part of Nagano Prefecture, is a unique fault zone characterized as a low-angle reverse fault, while the lateral slippage is dominant in this area.
The Inadani fault zone has been considered as a parallel reverse fault group of the conventional NE trending, but in recent years the evaluation of the activity to the fault group in the southern fault zone was revised, and the Inadani fault zone main part and the southeast part of the Inadani fault zone. The Inadani fault zone main part and the southeastern part were connected by the Shimojo sanroku fault which is the active fault of the NW strike, and it turned out that it is forming complicated fault geometry than conventionally thought. In this way, it is an important task to understand the tectonics of the Central Japan to elucidate how the Inadani fault zone, whose recognition for its motion image has been modified, has developed a unique form It is considered to be.
In order to elucidate the structural development history of the Inadani fault zone, a survey was conducted in the granitic distribution area expected to record longer deformation. Surface survey focused on the form of the fault, sense of movement, properties of the fault rock and so on. Stress analysis using multiple inverse method (Yamaji, 1999) was carried out in indoor work from the data obtained in the survey.In addition, XRD analysis was performed on the obtained fault rock samples to identify clay minerals contained.
From the cutting relationship between faults and the estimation of stress field, the deformation of the area was divided into three deformation stages. Stage: 1 ~ Stage: 2 is deformation with cataclasite with high angle N - S stroke, and Stage: 3 was deformation with fault gouge at low angle to medium angle. In Stage: 1, lateral shear stress solution of EW compression was detected, lateral stress stress solution of NW - SE compression in Stage: 2, and lateral shift to reverse tomographic stress solution of ENE - WSW compression in Stage: 3.
As a result of the XRD analysis, Illite and Smectite were included in all fault gouges, and the quantity ratio was changed depending on the sample.
This area is located in eastern south of southwestern Japan and is subject to clockwise rotation of the massive mass accompanying the enlargement of the Sea of Japan and counterclockwise rotation of the mass due to collision of the Izu arc. In order to discuss the stress direction , It is necessary to correct this influence. The corrected stress field is Stage: 1: E-W compressive stress field, Stage: 2: N-S compressive stress field, Stage: 3: E-W to NE-SW compressive stress field, and the Scaenzuyama fault detected by Katori (2016 MS) This is in good agreement with the stress direction in which the same correction is applied to the stress direction. Therefore, it can be said that the stress detected this time is stress acting widely on the Chubu region. If the cause of the wide area stress is required for the motion of the plate, it is possible that the cataclasite which is the oldest fault rock in this area was formed by driving the westward movement of the Pacific plate after 40 Ma.

Characteristics of the fault zone with only the recent slips in the Atera Fault

Atsushi Nishida[1], *Tomoyuki Ohtani[1], Takuya Niimi[1], Jun'ichi Tsubaki[1], Keiichi Ueta[2]

1. Department of Civil Engineering, Gifu University, 2. CRIEPI

The activity assessment of the active faults basically needs younger sediments. To understand the fault activity in the area with no younger sediments, it is desired to develop the new method which assesses the fault activity from the fault rocks in the basement rocks. As the recent slip zone in the active fault exposure is displaced not only in the recent slip event but also the other previous events, the recent slip zone may record many slip experiences. This suggests that the characteristics of the latest slip zone reflect not only the recent slips near surface but also the other older slips in the deeper part. The fault zone with only the recent slips should be studied to understand the phenomenon that occurred in the recent slips near surface. The purpose of this study is to clarify the characteristics of the fault zone with only the recent slips. For this purpose, the Atera Fault zone has studied to understand the above characteristics. The studied exposure of the Atera Fault is located at Tase, Tsukechi, Nakatsuawa in Gifu Prefecture. In this exposure, the fault is mainly a boundary between the Quaternary sedimentary layers and the Cretaceous granite. The fault is divided into two in the upper part of the exposure. The upper and lower faults are located in the granite and at the boundary of the sediments and granite, respectively. The upper fault contacts with the sand and gravel layer in the uppermost part. Toda *et al.* (1994) have clarified that the three seismic events are detected from the exposure and that the upper fault have displaced in recent several seismic events.

The detailed observation of the fault structure, thin section observation, the powder X-ray diffraction (XRD) and the X-ray fluorescence analysis (XRF) were performed using the samples collected along the upper fault. The detailed observation of the fault structure revealed that the upper fault consists of A1 and A2 fault zone and their branch point is consistent with that of the upper and lower faults. The brown fault gouges distributes in the recent slip zone from the branch point of A1 and A2 to 4 m away from the branch point, and the light gray fault gouge far from 4 m. The latest slip occurred in the A1 fault zone based on the radiocarbon dating (Toda et al., 1994), and the cumulative amount of A1 displacement is 2.5 m from the upper plane of the granite. These fault zones involve the fragments of the surrounding weathered granite. The XRD results show that smectite appears within 1 m from the branch point. The XRF results show that Mn-rich zones are within 4 m and 3 m, respectively.
The lower fault zone had been displaced before the upper fault zone was formed, and the brown fault gouge, smectite and Mn-rich zone are included in the lower fault zone. This indicates that some of them in the upper fault zone should be displaced from the lower zone. The distribution of brown fault gouge and Mn-rich zone in the upper zone, however, cannot be explained only the fault displacement. This suggests that the recent Mn concentration would be occurred in the upper fault zone within recent several thousand years.

Identification of active fault location using real-time ground measurements of atmospheric methane concentration by portable Cavity Ring-down Spectroscopy system: Case study at the Atera fault

*Michito Shimo[1], Masakazu Niwa[2], Kenji Amano[2], Tomochika Tokunaga[3], Kenichi Tonokura[3], Toshifumi Matsuoka[1], Sebastien Biraud[4]

1. Fukada Geological Institute, 2. Japan Atomic Energy Agency, 3. Department of Environment Systems, University of Tokyo, 4. Lawrence Berkeley National Laboratory, USA

Faults and associated fracture zones often provide pathways for the migration of gases, such as methane, hydrogen and helium, formed in the deep subsurface formations. It is expected that information on fault location and fault activity may be obtained by measuring trace gas concentration at the ground surface.

Development of atmospheric trace gas measurement technology using Cavity Ring-Down Spectroscopy (CRDS) enabled us to measure methane gas concentration with an accuracy and precision of a few ppb and a dynamic range of 0 to 5000 ppm.

In order to investigate the applicability of this technology to active fault survey, we conducted field measurements of methane gas concentration using two portable CRDS gas analyzers (Manufacturer: Picarro Inc, models G4301 and G4302) at the Atera fault area in Gifu prefecture. Both instruments have capability of measuring methane concentration with accuracy of 3 ppb and a response time of less than 1 second. Field measurements were carried out at two locations, a fault outcrop at Tase and a fault cliff at Tsukechi town both in the Nakatsugawa city.

For measurement at the fault outcrop, a soil chamber, connected to the G4301 instrument was placed on the ground surface. Concentration of methane released from the fault was measured to be between 20 to 30 ppm. Methane release was confirmed only at the vicinity of the fault gouge and concentration 1m away from the gouge was found to be close to atmospheric background level, 1.85 to 1.88 ppm. Kurosawa et al. (2010, JAEA - Data / Code 2010 - 36) reported that maximum methane concentration was 168 ppm from their measurement using shallow boreholes excavated at the six locations along the outcrop of the Atera fault.

In the vicinity of the fault cliff, two CRDS instruments were mounted in a car and methane gas concentration in the atmosphere along the road was measured continuously with a car speed of several km/h to 30 km/h. Location of the measurements were also recorded using a GPS system. The measurement results showed anomalies of methane concentration at the two locations, approximately 1 km apart from each other, where the road and the extension of the cliff crosses. The peak atmospheric concentration of the anomalies were 1.95 to 2.05 ppm. The nearly 100 ppb difference between the anomaly peaks and the background is significant compared to the measurement accuracy of 3 ppb of the instrument. The anomalies were detected repeatedly at each location when we crossed the fault cliff. Furthermore, the methane concentration obtained by the two instruments were almost identical, confirming that these anomalies were the real responses and not associated with instrument noise.

The anomaly of 100 ppb from background suggests the methane gas emitted from the fault is diluted to about 1/200 to 1/1000 of source gas concentration. Such a small concentration signal was hardly

©2019. Japan Geoscience Union. All Right Reserved.

detected by conventional technology and was successfully detected by using the CRDS technology we employed this time.

In summary, we have confirmed that methane is emitted at the very vicinity of the fault plane at the Atera fault. We also found that the location of the fault can be successfully detected using the CRDS instrument installed on a survey vehicle. From these results, we expect that trace gas measurement using a CRDS technology can be one of the promising approaches to delineate the locations of the active faults creating migration paths of the deep-seated fluids.

This report is part of the achievement in FY2018 by the "Research Committee on Application of High-Accuracy Trace Gas Measurement Technology to Geological Exploration (chairman: Professor Tomochika Tokunaga, the University of Tokyo)" that is operated by the Fukada Geological Institute.

Geomorphological evudence of a newly found active fault along the Shirakawa fault in western part Gifu Prefecture

*Yorihide Kohriya[1], Masashi Omata[1], Hiroshi Yokota[1]

1. PASCO CORPORATION

Recently, expression of micro topography was made possible by improvement of LiDER DEM technology.
The surface rupture in the southern part of Mt. Kunimi, Oshu City, Iwate Prefecture that occurred in the 2008 Iwate-Miyagi Nairiku earthquake was expressed using airborne LiDAR-derived 0.5-m-grid DEM (Maruyama et al. 2011).
It is difficult to detect fault traces in the forest zone using photographs, and it is effective to use LiDER DEM.
When 1 m grid DEM was prepared from LiDER data along Shougawa village of Shogawa village, Gifu prefecture, we confirmed new fault topography with possibility of sub fault of Shirakawa fault.
The LiDER data was measured by Jinzu River Sabo Office, Hokuriku Regional Development Bureau, MLIT in 2016.
The photograph taken at the same time as LiDER is difficult to recognize fault topography because it is a forest zone.

At the Kiya point along the Sho river, west side of study area, the trench of the Shirakawa fault was investigated (Sugiyama et al. 1993).
In the trench survey, at least one earthquake event has been certified since 2,500 y.B.P.
However, the last event and activity interval are unclear.
A new fault trace is found on the right bank slope of Nonomata Valley on the east side of Kiya, Shokawa village, Gifu Prefecture, and the length reaches 1.3 km.
The fault topography along the trace is a gentle slope and a reverse-facing fault scarplet which are linearly continuous on the slope of the mountain.
The vertical component is a western uplift similar to the Shirakawa fault, and is about 10 to 20 m from the topography section.
There is a weak left offset ridge across the fault topography.
In addition, a left offset ridge with a slope top of about 200 m is found on the northern side of the fault topography.
From these evidences we assume that this fault has repeated activity.
In the southern part of the fault topography there are reverse-facing fault scarplet and relatively wide gentle slopes, which are suitable for trench survey.
At this point there is no accumulation of coarse-grained sediments by rivers, and there is little loss of formation. Therefore it is possible to identify the last event of the Shirakawa fault.

Active faults around the Niu Mountains, northern part of Fukui Prefecture, Japan

*Masayoshi Tajikara[1], Takashi Nakata[2], Hiroyuki Tsutsumi[3], Hideaki Goto[2]

1. Association for the Development of Earthquake Prediction, 2. Hiroshima University, 3. Doshisha University

The Niu Mountains is located between Japan Sea and the Fukui Plain, northern Fukui Prefecture. Many active faults have already been reported around the Niu Mountains (e.g., Research Group for Active Faults, 1991). Along the eastern coastal area of the Niu Mountains, the Yanagase-Sekigahara Fault develops in submarine area, and the Ayukawa Faults develop in the land area, respectively. In the eastern side of the Niu Mountains, the Sarage Fault, the Asahi Fault, the Semiguchi Fault, the Sabae Fault, and the Ozowara Fault are mapped, but tectonic landforms of these active faults have not been described in detail. In this study, we mapped distribution of faults somewhat different from previous studies by interpretation of 1/10000 air photographs and stereoscopic image created from 5-10 m DEM of GSI. In this presentation, we report the precise distribution and characteristics of tectonic landforms of these active faults, and discuss their tectonic implications briefly.

This study was done as a part of the Supporting Project for the Headquarters for Earthquake Research Promotion sponsored by the Ministry of Education, Culture, Sports, Science and Technology, Japan.

Gifu-Ichinomiya Fault shown from the characteristics of the damage of the Nobi earthquake

*Nobuhisa Matsuta[1,2], Fumiaki KIMATA[2]

1. Okayama University Graduate School of Education, 2. Tono Research Institute of Earthquake Science

The record of the historical earthquake in Japan shows that the ratio of the number of victims to the number of completely destroyed houses increases in the case of the earthquake in which the surface rupture. Using this relationship, we discussed the question "Is there a surface rupture along the Gifu-Ichinomiya fault at the time of the Nobi earthquake?" The record used for the examination is the damaged data in the municipality at the time. As a result, it was found that the ratio of the number of victims to the number of completely destroyed houses is higher along the Gifu - Ichinomiya fault than in the surrounding area. Therefore, Gifu - Ichinomiya fault existed, we believe there was a displacement in the Nobi earthquake.

Electrical resistivity structure from the surface to the seismogenic zone below the Gomura fault zone, Kyoto, Southwest Japan

*Satoru Yamaguchi[1], Akira Mimura[1], Kazuki Fukue[1], Shigehiro Katoh[2], Hideki Murakami[3], Makoto Uyeshima[4]

1. Department of Geosciences, Graduate School of Science, Osaka City University, 2. The Museum of Nature and Human Activities, Hyogo, 3. Science and Technology Unit, Research and Education Faculty, Kochi University, 4. Earthquake Research Institute, The University of Tokyo

The Gomura Fault Zone in the Tango Peninsula, Kyoto, consists of three fault segments, the Go-seihou, Gomura, and Chuzenji Faults. They show different features in fault activity (average slip rates, the latest events etc.). The Go-seihou Fault is a very short in length (~2.8km long) with no clear displacement. Along the Gomura Fault, a clear surface rupture has appeared at the 1927 Kita-Tango earthquake. Cumulative geomorphological displacement is well recognized along the Chuzenji Fault, but no surface rupture appeared at the 1927 Kita-Tango earthquake. Conductivity structure can be one of the crucial elements to clarify subsurface structure of active faults. Furthermore, the Gomura fault zone is especially suitable for studying the relationships between conductivity structure and fault activity because three faults run nearly parallel within about 3km in simple geological setting.
We proposed the conductivity models of the Gomura Fault Zone combining the two conductivity models; one is the shallow model (0 –1.5 km in depth) and the deep model (0 -12 km in depth). The shallow model is determined based on the result obtained using an audio-frequency magnetotelluric (AMT) method which is excellent in shallow part resolution. While, the deep model is determined based on the result using a wide-band magnetotelluric (WBMT) method which is suitable for wide- and deep-range survey.
The final model is characterized and interpreted as follows.
(1) The final model covers from the surface to a depth of 12 km including the epicenter of the 1927 Kita-Tango earthquake and three faults (the Go-seihou, Gomura and Chuzenji Faults).
(2) The final model is characterized by six conductive zones and one resistive zone.
(3) The fault plane of the Gomura Fault starts the hypocenter of the 1927 Kita-Tango earthquake, goes through seismogenic and conductive region, and reaches to the Gomura Fault.
(4) The clear conductive zones were detected below both the Gomura and Chuzenji Faults in the shallow model. The conductive zone below the Gomura Fault is wider and more conductive than that below the Chuzenji Fault. We interpreted these differences reflect the latest faulting event age: that of the Gomura Fault (~90 yrs. ago) is much younger than that of the Chuzenji Fault. The conductive zones are formed by intruding groundwater into a damage zone around the faults.
(5) No conductive zone is recognized below the Go-seihou Fault and the result indicates that the fault is a secondary fault.
(6) The bottom of the resistive zone can be interpreted as that of the Miyazu granite.

Re-analysis and re-interpretation of the very shallow land seismic reflection survey data across the Naruto-South fault, north side of Tokushima Plain.

*Kobayashi Takayuki[1], Dai Nobuoka[2], Tomio Inazaki[1]

1. Public Works Research Institute Japan, 2. OYO Corporation

We conducted re-analysis and re-interpretation of the very shallow land seismic reflection survey data across the Naruto-South fault, north side of Tokushima Plain. In this study, we show that more detailed active fault structures are obtained by re-analysis and re-interpret old data to give useful information for urban disaster planning. The Naruto-south fault is located in Tokushima Prefecture, the eastern part of Shikoku island, Japan. It is the branch of the Median Tectonic Line (MTL) active fault system. The Naruto south fault is situated 500m to 1000m south of Naruto fault, and cut the Tokushima alluvial plain. The length of the it is expected about 8km (Tokushima Prefecture, 1998). The last faulting event is in 16th century or later. The probability of earthquake indicated the MTL active fault is very low, 0 to 0.4% within 30 years. In the other hand, the expected magnitude of earthquake is very high, 8, and, when the earthquake are occurred, its damage will be tremendous. From this fact, to minimize damages, the clarifying fault structure is required. So, we re-analyze and re-interpret the very shallow S-wave land seismic reflection survey data across the Naruto-South fault acquired in 1998 to obtain more detailed structure of the fault. Measurement length is 100m, receiver spacing is 0.5m and shot source interval is 1.0m. S-wave portable vibrator is utilized for seismic source. Sweep frequency is 40 to 300Hz and sweep length is 7s. As the result of re-analysis, we obtained more detailed active fault structure less than 50m depth. In this study, we can identify the position of the about 70 degrees dip fault, lied from 15m to 50m depth, with more resolution. Also, we achieved to show the continuous structure, not cut off by the active fault, more clearly than conventional. Also, by applying the dating method results, we could estimate the displacement of fault. Maximum displacement is 14.4m, 10.8kyBP to 12.2kyBP, and deformation rate is 1.77mm/yr.

Keywords: Active fault, seismic reflection survey

In a coastal area of Nomi bay (Susaki city, Kochi Prefecture, Japan), a traditional tale about a village named Kuroda-gori (or Nomi sengen, Otani sengen), which was probably submerged during the Hakuho Nankai earthquake of AD 684, has been passed down orally. Local residents reported a well on the seabed at Nomi bay. However, evidence linking Kuroda-gori to these sites and to historical earthquake is lacking. Therefore, we investigated seabed at Nomi bay near Heshima Island and Otani area to find the artifacts that can be related to historical earthquakes.

Our data were obtained from a research boat “Neptune” of Kochi University. The detailed bathymetric maps and the acoustic reflection distribution maps were acquired by a side-scan sonar system. A sub-bottom profiler was also used to obtain a geological structure below the seabed. Underwater omnidirectional camera was used to observe seafloor carefully.

In a bathymetrical map, the small submarine plateaus (200m×300m in area) was found on the north-western part of Heshima Island, delimited by a steep slope. The plateau was located at the depth of around 10 m. Sediment sampling by gravity corers and underwater images from camera showed that the seafloor on the plateau was composed by hard sandy materials and large conglomerate blocks. On the contrary, the seafloors on the outside of the plateau was composed by soft clayey sediments. No artifact or artificial structure were observed from the sub-bottom profiling data. Several strange mosaic images were obtained from the side scan sonar, and then divers identified some of the strange images were artifacts (an octopus pot, a vinyl sheet). We did not discover a well on the seafloor from mosaic images, underwater camera, or sub-bottom images.
The submarine plateau was probably formed by wave-induced erosion, and Shimomura (1980) reported the similar submarine structures and concluded that the plateaus was formed by the subsidence during the Hakuho Nankai earthquake of AD 684. While any well-like structures were not found, gravels (boulder) arranged in a circle were observed. Therefore, the well that local residents suggested might be the gravels. We plan to perform dating analysis (e.g. radiocarbon dating) using subsea floor sediments at the plateau to assess the co-seismic subsidence. We present preliminary results obtained from a scientific cruise at Urano-uchi Bay on March 2019.

It is well known that there exist numerous submarine active faults in the Nankai Trough area. We have to reveal geometry and slip history of these faults, to reveal the origins of the past destructive earthquakes as well as to predict future large earthquakes in more detail. From this point of view, we have conducted a tectonic geomorphological and paleoseismological feasibility study on a submarine active fault of the Nankai Trough area in the Anoriguchi Canyon from FY2016 (Sugito et al., 2018). In this presentation, we report our result of a series of core analysis, including foraminiferal analysis and radiocarbon dating. Based on the data obtained, we infer that the submarine active fault across the Anoriguchi Canyon probably slipped one or more time(s) during this ~10,000 years to produce north-side-up vertical offset of ~10 m. This study illustrates the importance of the tectonic geomorphological and paleoseismological approaches in the studies of historical earthquakes and near-future earthquake potentials.

Subsurface survey around the Matoishi-bokujo 1 Fault in the northwest of the outer rim of the Aso caldera, southwestern Japan

*Takayuki Nakano[1], Hiroshi Une[1], Hiroshi, P. Sato[2], Keitaro Komura[3]

1. GSI of Japan, 2. Nihon Univ., 3. CRIEPI

1. Introduction

A lot of linear surface displacement derived by the 2016 Kumamoto Earthquake (Mj 7.3) were detected by InSAR analysis around the northwest of the outer rim of the Aso caldera, central Kyushu Island, southwestern Japan, and it is estimated that they were displaced passively. Many of them appeared along the known active faults. We have investigated the detail topography and geology to elucidate the mechanism around Matoishi-bokujo 1 Fault. In this presentation, we report the results of the subsurface structure survey found by using topographical/geological survey and ground-penetrating radar (GPR) survey.

2. Result & Discussion

The trenching survey at the foot of fault scarp of the Matoishi-bokujo 1 Fault showed that a white color pyroclastic layer presumed as Aso-4 pyroclastic flow deposit (89Ka) was observed around GL-3.5m (EL= ca. 917.4m) in deep case and GL-0.3m (EL= ca. 921.6m) in shallow case (Une et al., 2018). Also, the topographical and geological survey around the fault showed that the Aso-4 pyroclastic flow deposit was observed at the stream bed on the north side of the fault (EL= ca. 917.8m) and at the gully bed on the south side of the fault (EL= ca. 935.0m). Furthermore, on the east side of the site, the outcrop of stratum considered to be representative of the sedimentary structure in this area can be observed, and it was found that blackish soil layer and loam layer sandwiching multiple tephra layers above the Aso-4 pyroclastic flow deposit accumulated ca. 5m in thickness.

GPR profiles performed on the survey line crossing the fault showed clear echoes in GL-2m to -4m on the south side of the fault. It is presumed from the trenching survey and geological survey in the waterway on the south side of the fault so far that these clear echoes correspond to the upper surface of loam layer below the subsurface blackish soil or riverbed gravel layer covering the loam. On the north side of the fault, since GPR echoes are decayed drastically at deeper than GL-1 to -1.5m (EL= ca. 930.5 to 931.0m), it is suggested that there are a layer with a relative dielectric constant greater than that of the upper layer (blackish soil) at GL -1.5m or deeper. In addition, there is a weak echo around GL -4 to -5m (EL= ca. 927 to 928m). It is possible that this weak echo corresponds to the upper surface of the Aso-4 pyroclastic flow deposit from its continuity.

From these result, although the shape of the upper surface of the Aso-4 pyroclastic flow deposit is roughly similar to the present topography surface, it is located at GL-5m deeper on the south side of the fault and around GL-4 to -5m at the north side of the fault. Therefore, its relative height difference is estimated to be about 13 m or more, and this is considered to be the apparent vertical offset of the fault for ca. 90,000 years.

3. Summary and Challenges

As a result of topographical and geological investigation and the subsurface structure survey around the Matoishi-bokujo 1 Fault which was secondarily displaced associated with the Kumamoto Earthquake, we could presume the subsurface structure and the apparent vertical offset of the Aso-4 pyroclastic flow deposit surface. We plan to analyze and interpret the GPR profile in more detail with reference to the result of percussion boring in the future.

Past activity of 'triggered fault' in the northwest of outer rim of Aso caldera estimated from the results of excurvation survey and displacement topography

*Hiroshi Une[1], Takayuki Nakano[1], Hiroshi, P. Sato[2], Hiroshi YAGI[3], Keitaro Komura[4]

1. Geospatial Information Authority of Japan, 2. Nihon University, 3. Yamagata University, 4. Central Research Institute of Electric Power Industry

Matoishi Bokujo 1 Fault is one of the "triggered faults" in the northwest of outer rim of Aso caldera associated with the Kumamoto Earthquake in 2016 with clear tectonic geomorphology, significant phase discontinuity appeared in SAR interferometry and surface displacement in the field. We carried out a geomorphological and geological survey including a pit excavation, ground penetrating radar (GPR) survey and simple core samplings in a site on the fault, and discussed the history of past activities. We excavated a pit with 10 m long and 4 m deep at maximum at the bottom of the fault scarp and observed the both walls. A white Aso-4 pyroclastic flow deposit appeared at the bottom of the walls, directly covered by a river bed deposit composed of medium sand and granule and a debris flow deposit composed of rubble on the pit valley side, and the slope sediments of brown sand and mud with rubble on the pit mountain side. They are covered with slope sediments of black sand and mud that accompanies with rubble or that are scarce in rubble. At least two fault ruptures appeared with displacements of these strata and disorientation of gravel. We assume that the upper surface of Aso-4 at the bottom of the walls shows the unconformity of the deposition surface when the pyroclastic flow arrived in 90,000 year BP, for the low relief surface surrounds this area which is the deposition surface of Aso-4 pyroclastic flow, and outcrops of Aso-4 pyroclastic flow deposit are widely observed at a comparatively shallow position, i.e. several meters below the surface of the earth. From the pit survey and the simple core samplings, it is estimated that the upper layer of the white layer gradually lowers its altitude from the south to the north toward the fault scarp, and is raised about 10 m above the fault scarp, consistent with the topography and displacement pattern by SAR interferometry. Considering the results of the ^{14}C dating of the black soil of the slope sediments collected from the wall, a faulting event which brought the movement of slope deposits from the mountain side resulting the coverage of river deposit at the valley side occurred in between about 3,500 and about 3,400 years ago, followed by another faulting event that caused two fault ruptures in between about 3,500 and about 2,000 years ago or younger. It is suggested that the number of events experienced by lower slope sediments is larger than that of upper one (the amount of displacement of upper one is about 2 times). This suggests that the accumulation of displacements like this time formed fault scarp of Matoishi Bokujo I Fault.

Visualization of three-dimensional SAR analysis data by stereo isogram map: Precise detection of surface ruptures of the 2016 Kumamoto earthquake sequence

*Yasuo Awata[1]

1. Institute of Earthquake and Volcano Geology, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

Advances in geodetic surveying technology make it possible to grasp the crustal deformation in a wide range from several cms to several meters. In particular, the observation by the spaceborne SAR enables high-resolution detection of crustal deformation using interferometric and three-dimensional analysis. These advances are bringing about a major change to the conventional field investigation method of surface ruptures associated with earthquakes. Here, I tried to visualize the 3D-SAR data of the 2016 Kumamoto earthquake sequence (Kobayashi, 2017) to detect the regional and local surficial deformations with high accuracy.

For visualization of 3D-SAR data to high-resolution and high-dynamic-range images, the stereo contour and relief mapping method is applied. The 3D data is divided into three components, the east-west, north-south, and vertical components, each consists of geographic coordinates and a single value. The isogram map having fine line interval up to the equivalent to the accuracy of data is generated from the data. For east-west and vertical components having the high accuracy, practically fine isogram at a line interval up to 1 cm are drown. Those isogram images are processed into anaglyph capable of stereoscopic viewing with a wide field of view.

In the visual interpretation using an anaglyph image at a line interval of 1 cm, both the main fault zones (Futagawa River, Idenokuchi and Takagi earthquake faults) accompanied by regional crustal deformation and numerous small ruptures scattered in a 50 km square area are observed in a single image. The interpretation results of small ruptures are generally consistent with that of Fijiwara et al. (2016) based on conventional InSAR images that spatial resolution is assumed to be one digit higher. It is easy to detect the ruptures with a displacement of east-west and north-south components of about 5 cm using the image. Furthermore, ruptures up to 2 cm in displacement are recognizable in the Kumamoto urban area where the gradient of regional deformation is small. In the field survey based on the 3D-image interpretation, I found those small ruptures and measured the displacements of guardrails, road curbs, and concrete structures.

Preliminary active fault mapping of Mongolia by interpretation of ALOS 30 DEM image

*Takashi Nakata[1], Yasuhiro Suzuki[2], Mitsuhisa Watanabe[3]

1. Hiroshima University, 2. Nagoya University, 3. Toyo University

Mongolia has experienced huge earthquakes generated from extensive active faults in the 20th Century, namely 1905 Tsetserleg (M7.9), 1905 Bulnai (M8.4), 1931 Fu-Yun (M8.0), 1857 Gobi-Altai (8.1) and 1967 Mogod (M7.1). These earthquakes were generated from pre-existing active faults that have been studied in detail. However most of the other extensive active faults were mapped mainly based by 2D satellite and Google Earth imageries, and they are commonly delineated along distinctive topographic boundaries sometimes without enough evidence for late Pleistocene activities. In order to map active faults throughout Mongolia, we employ stereoscopic interpretation of anaglyph images processed from ALOS 30 DSM images to obtain topographic evidence such as fault scarps across late Pleistocene and Holocene topography and lateral stream offset for late Quaternary activities, and we compiled a preliminary active fault map of Mongolia.

Ground penetrating radar profiling across the Sanchiao fault in northeast Taiwan

*Mamoru Nakamura[1], How-wei Chen[2]

1. Faculty of Science, University of the Ryukyus, 2. National Central University, Taiwan

Keelung earthquake (M 6.9-7.2) occurred on December 18, 1867, in northeast Taiwan. The seismic intensity distribution and tsunami runup height distribution for this earthquake were estimated from a review of relevant literature. The seismic intensity of the earthquake reached a maximum of VII at downtown Jinshan (northeast Taiwan) according to the scale of the Central Weather Bureau of Taiwan (Cheng et al., 2016 TAO), whilst the tsunami runup height reached 6-15 m along the northeast coast of Taiwan. From the seismic intensity distribution, the source fault of the Keelung earthquake is estimated to have been at the seaward extension of the Sanchiao fault (Cheng et al., 2016 TAO). The Sanchiao fault is a normal fault, approximately 53 km in length, and passes from the south of Taipei through to Jinshan (Shyu et al., 2015 TAO). From morphological surveys, borehole surveys, and seismic reflection surveys, the Sanchiao fault is estimated to pass along the foot of the mountain to the north of downtown Jinshan. However, it is unclear whether the land area of the Sanchiao fault moved in 1867. Therefore, we carried out a Ground Penetrating Radar (GPR) survey to detect the location of the Sanchiao fault.

The GPR survey was carried out on a coastal dune to the north of Jinshan. The coastal sand dune runs in a northwest-southeast direction along the shore, perpendicularly to the Sanchiao fault. The following two types of GPR survey lines were set up: a long range type (100-200 m) running parallel to the coastal dune, and a short range type (20 m) running perpendicularly to the coastal dune. Surveys were carried out from August 15-17, 2017 and from August 13-17, 2018. Three short lines were set up parallel to the dune and two lines perpendicularly to the dune. The pulseEKKO from Sensors & Software Inc. was used for the GPR survey, and the survey frequency of the radar was 50 MHz, 100 MHz, and 250 MHz.

A conspicuous radar reflector was found in the survey line running parallel to the coastal dune. The depth of this reflection changed near the fault trace of the Sanchiao fault, as estimated from boreholes. Furthermore, the depth of the reflection at the northwestern region of the fault was approximately 1 m deeper than that at the southeastern region. This is inconsistent with the vertical displacement of the normal faulting of the Sanchiao fault that dips southeastward, and suggests that the deformation could have been caused by the branching off of the splay fault from the main Sanchiao fault.

Paleo-earthquake records of the Hengchun offshore structure, southern Taiwan

*Sze-Chieh Liu[1], J Bruce H Shyu[1], Yuan-Lu Tsai[1], Chuan-Chou Shen[1]

1. National Taiwan University

In the southernmost part of Taiwan, the Western Hengchun Tableland is a prominent topographic feature, with several steps of late Pleistocene uplifted marine terraces forming the top of the tableland, and uplifted Holocene coral reefs along the coast. To interpret the formation of this tableland, an inferred Hengchun offshore structure has been proposed as an active structure located offshore to the tableland’ s west. The uplift and the eastward tilting of the tableland are therefore produced by neotectonic activities of this structure. However, the presence of this structure is still debated, and no record of paleo-earthquakes related to this structure has been identified. To solve this, we utilized fossil coral microatolls as paleo-sea-level indicators to identify possible paleo-earthquake records produced by this structure. The highest level of survival (HLS) of corals is limited by the low tide level. Once living corals grow to this level, the upward growth will stop and they will grow outward instead, forming microatoll morphology with a flat top surface. This makes microatolls great tools to record local sea level history. If microatolls were uplifted and killed by co-seismic uplift, the elevation difference between microatolls and the HLS would represent the amount of uplift, and the age of the coral would constrain the age of the earthquake event. In this study, we surveyed six sites along the coast surrounding the Western Hengchun Tableland. Based on our field survey data and U-Th dating results of uplifted corals, we reconstructed a coastal uplift history of the area, and proposed several paleo-earthquake events in the past 2,500 years. These results enabled us to further understand the seismogenic properties and the possible earthquake recurrence intervals of the Hengchun offshore structure.

LC-InSAR analysis of the Sulawesi earthquake in Indonesia

*Jun Sugimoto[1], Masashi Omata[1], Yoshiteru Akiyama[1], Yutaka Horaku[1]

1. PASCO CORPORATION

On 28 September 2018, a shallow, large earthquake struck in the neck of the Minahasa Peninsula, Indonesia, with its epicenter located in the mountainous area, Central Sulawesi. The magnitude was 7.5.The main active onshore structure in the western part of Central Sulawesi is the left-lateral NNW-SSE trending Palu-Koro strike-slip fault that forms the boundary between the North Sula and Makassar blocks. It was reported that the earthquake caused major soil liquefaction in and around Palu.
In this study, the authors conducted the interferometry analysis using ALOS-2 data and found out the followings:
1) A phase discontinuity lines found in the LC-InSAR diagram can be Palu-Koro fault and other small strike-slip faults around Palu-Koro.
2) In the LC-InSAR diagram, areas with low coherence are distributed in a wider range than the range where damage was caused by liquefaction. This shows the possibility that the ground change has occurred in a wider range than the extent of damage caused by liquefaction.

The authors confirmed that analysis using ALOS-2 data can identify places and scopes of disasters with extensive damages occurred not only in Japan but also in other countries.

Recent, many destructive earthquakes and tsunamis occurred around the plate boundary in the world, which are, 2004 Sumatra Earthquake/Tsunami, 2011 East Japan Earthquake/Tsunami in Japan, and so on. Along plate boundary in Turkey, the North Anatolian Fault (NAF) distributes and the large earthquakes has occurred there. The one of the events along NAF in Turkey is the 1999 Izmit Earthquake, and severe damages was brought to residents The NAF between the eastern end of Turkey and the Aegean Sea has been ruptured in turn from the both ends, and the part off Istanbul city still remains as unruptured zone. It is considered that future large event brings fatal damages not only Istanbul city but also the entire of Turkish economy.

To prepare future large earthquake there, Japan and Turkey made an agreement to start a multidisciplinary research project, MarDiM SATREPS in 2003. The Project has four research groups with the following goals. Group 1 is Marmara Earthquake Source region observational research group to clarify seismicity, crustal structures and crustal displacement, and to construct a possible fault model. Group 2 focuses on scenario researches of earthquake occurrence along NAF and precise tsunami simulation in the Marmara region. Group 3 aims improvements and constructions of seismic characterizations and damage predictions based on observation researches and precise simulations. Group 4 promotes disaster educations using research result visuals and construct strategies of disaster mitigation.

Group 1 constructed a fault model along NAF with some asperities and with variation on the dip. The segment boundary was also identified through the modeling and it is consistent with the past rupture pattern and fluid distribution. The NAF on the western region of Sea of Marmara has creep and the rate is nearly half of block motion based on direct seafloor observation for crustal displacement. Group 2 calculated cyclic rupture pattern along NAF using heterogeneous fault model and constructed monitoring system “SWIFT” for crustal stress field by mechanisms of many events estimated automatically. We developed tsunami calculation code to image inundation around the coastal area. Group 3 investigated ground structure through regular fine shake observation, and constructed city model of industrial region supporting Turkish economy. We simulated strong motion using ground structure, city model and fault model derived from Group 1 and made a new hazard map. Group 4 considered teaching materials for disaster prevention including Japanese animation technique based on above results of three groups. These materials are utilized for disaster mitigation in Marmara region and disaster education in Turkey.

Estimation of fault activity by multivariate analysis using chemical composition of fault gouge

*Ryo Tateishi[1], Koji Shimada[2], Tadamasa Ueki[2], Mayuko Shimizu[2], Tetsuya Komatsu[2], Shigeru Sueoka[2], Masakazu Niwa[2], Ken-ichi Yasue[1], Tsuneari Ishimaru[2]

1. University of Toyama, 2. Japan Atomic Energy Agency

Introduction: Active faults are recognized by displacement / deformation of current topography and the Quaternary strata. However, in the absence of them, it is very difficult to decide whether the fault there is an active fault or not. In this study, we tried multivariate analysis using chemical composition data of fault gouge of active faults and inactive faults in Japan, and tried to determine the presence or absence of fault activity.
Methods: This research was carried out in the following order; collection of papers, extraction of chemical composition data of fault gouge, addition of new chemical analysis data, formatting of input data, variable selection, linear discriminant analysis. First, chemical composition data of fault gouge of active faults and inactive faults in Japan was extracted from existing publications. In this case, the extraction condition clearly describes whether the analysis target is an active fault or an inactive fault and that the basement rock is diverse. In addition, a chemical analysis of the fault gouge sample possessed by the JAEA was carried out, and we created a database that integrates both of them. In this database, in addition to the sample name and analytical value of each sample, 2 categories of active fault and inactive fault were given. Then, we decided elements to be candidates for explanatory variables from this database and arranged them as input data. Since the chemical elements extracted from the literature are not all analyzed for the same element, common elements are chosen so that the number of samples can be taken as much as possible. In order to further extract elements suitable for discrimination between active fault and inactive fault from these elements, variables were selected by two methods of Akaike Information Criterion (AIC: Akaike, 1973) and principal component analysis. Finally, linear discriminant analysis was performed using as an explanatory variable a combination of an element selected by AIC and an element whose factor loading amount was considered to be high in the principal component analysis.
Results: As a result of collection of papers, chemical composition data of fault gouge was extracted from 7 existing papers and 5 reports of the JAEA. We extracted 17 elements as candidates for variables from the database, to which a chemical analysis result of 6 fault gouge samples possessed by the JAEA was added. The number of data was 41 samples for active fault and 16 samples for inactive fault, totaling 57 samples. From these 17 elements, 13 elements were extracted as optimum combination of elements in AIC. In the principal component analysis, synthesis expressions from the first principal component to the 17th principal component were obtained, and elements with high factor loading amounts were calculated for each synthesis formula. From these results, linear discriminant analysis was carried out with a following combination of elements; (a) 13 elements of AIC, combination of elements whose average value of factor load amounts falls in the top 10 of (b) Up to the 3rd principal component of principal component analysis (explain the scattering degree of chemical composition by 65%), (c) Up to the 5th principal component (also 80%), (d) Up to the 8th principal component (also 90%). As a result, a combination of (a), (c) and (d) gives a primary equation that accurately divides the 2 groups of active fault and inactive fault.
Consideration: The elements common to the combination of the above are 6 elements of TiO_2, Al_2O_3, MgO, Na_2O, P_2O_5, Ba. Linear discriminant analysis was carried out again with (e) the combination of these 6 elements, and it resulted in accurate division of the 2 groups. Since these elements are selected by different methods or filters, there is a possibility of elements representing the difference between active faults and inactive faults. Also, as a result of assigning data of 3 specimens of fault gouge of another active

©2019. Japan Geoscience Union. All Right Reserved.

fault to each primary equation, values which are judged to be active faults in all equations were obtained. However, these values were out of the distribution range of the population, and the tendency was more conspicuous as the number of elements was larger. From this, the primary equation consisting of 6 elements of (e) was considered to be the best formula to separate active fault and inactive fault.
This study was carried out under a contract with Ministry of Economy, Trade and Industry of Japan as part of its R&D supporting program for developing geological disposal technology.

Bayesian optimization of fault-shape parameters using finite element analysis: parameter sets for strong slip partitioning

*Hidetaka Saomoto[1]

1. National Institute of Advanced Industrial Science and Technology

The Bayesian optimization algorithm is now a key technique in various scientific and engineering fields that require the parameter optimization. The technique can reduce the number of simulation trials as compared with the grid-search because the algorithm can act as an artificial intelligence with a statistical decision-making. Because a three-dimensional finite element analysis (FEA) for seismic faulting consumes much CPU time, the use of the Bayesian optimization with the FEA is logical and is expected to accelerate the parameter detection process.

Here, I present the method of combining an open source library Optuna (1) based on a Bayesian optimization algorithm, Tree-Structured Parzen Estimator (TPE) with the seismic faulting FEA based on COMSOL Multiphysics and then demonstrate a Baysian optimization for the fault-shape parameters that activates strong slip partitioning.

The parameter sets obtained from the Bayesian optimization algorithm result in a stronger slip partitioning than that obtained from the grid-search. More specifically, the optimized parameter set was found as a dip angle for the reverse-slip fault of 54.5 degree, a dip angle for the strile-slip fault of 86.3 degree, and the principal stress direction of 56.1 degree clockwise from the strike direction.

The Bayesian optimization detected the parameter set after 50 trials, whereas the grid-search was composed of 784 trials. In summary, the use of the Bayesian optimization algorithm is an effective and efficient way of a parameter optimization for a seismic faulting simulation that requires long CPU time.

[S-SS15] Active faults and paleoseismology

convener:Mamoru Koarai(Earth Science course, College of Science, Ibaraki University), Takashi OGAMI(National Institute of Advanced Industrial Science and Technology), Ryosuke Doke(Hot Springs Research Institute of Kanagawa Prefecture), Hisao Kondo(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology), Chairperson:Mamoru KOARAI(Ibaraki University), Taku Komatsubara(産業技術総合研究所)

Geologic and historic information on seismic cycles and on the magnitude and source faults of past earthquakes is essential information to understand future large earthquakes. The study of past faulting and seismicity is an important issue for an interdisciplinary community of seismologists, geologists, geomorphologists, archaeologists, and historians.

Discussion

Historical documents and oral transmissions on historical tsunamis in the Paciffic coast of Tohoku

*ebina yuichi[1]

1. International Research Institute of Disaster Science

I analyzed historical tsunamis which attacked the Pacific coast of Tohoku, especially on the AD 1611 Keicho Oshu earthquake and tsunami (commonly called as the Keicho Sanriku earthquake and tsunami), based on historical documents, oral transmissions, and formation process of them.

After the AD 2011 Great East Japan Earthquake, huge historical tsunamis which damaged in the Pacific coast of Tohoku district have received attention. Some people consider the AD 869 Jogan earthquake as the precursor of AD 2011 earthquake and believe huge tsunamis occur once a thousand years. People also recognize the importance of oral transmission and the place name comes from past disasters. Previous studies pointed out the underestimation of the AD 1611 Keicho Oshu earthquake and tsunami but reinvestigated the earthquake and tsunami based on historical documents (Ebina and Imai 2014). Recently, some studies considered the AD 1454 Kyotoku earthquake as a similar event to AD 1611 Keicho oshu earthquake (Namegaya and Yata 2014; Sawai et al., 2015). Furthermore, the tsunami deposit can be correlated with this event have been found in Miyagi and Iwate Prefectures (e.g., Sawai et al., 2012; Takada et al., 2016).

According to “Sunpu Seiji Roku” and “Sunpu Ki", a vassal of the Date family said that another vassal of that encountered the tsunami on the boat during fishing and the boat was driven to the top of the mountain “Senganmatsu”. This event was estimated to occur near the mouth of Abukumagawa River in Iwanuma City. Watanabe (1998) considered this story was not true because Senganmatsu area is too high to be inundated. However, the pictorial map around Iwanuma created in Edo period indicates that Abukumagawa River was located inland from the present position of the river in that time, where a fishing village has been located since the middle ages (Ebina, 2014). Therefore, it is likely that the tsunami actually attacked the area although the story has a little exaggeration.
It is important to restore old geographical features for constraining the sizes of earthquakes and tsunamis. For instance, Fukuhara and Tanioka (2018) estimated that the magnitude of the Keicho earthquake is similar to or large than that of AD 2011 earthquake based on the data of tsunami height inferred from historical documents and oral transmissions in Miyako City, Iwate Prefecture compiled by Ebina and Imai (2014). However, the restored geographical features show that places inundated by the Keicho tsunami were located near the old channel. Therefore, the inundation in Miyako can be interpreted as the result of river run-up.

The knowledge of historical earthquakes and tsunamis along the Pacific coast of Tohoku have not been known by local residents before AD 2011 earthquake and tsunami. According to “Zishigaku Oyobi Chirigaku Kenkyu Zairyo Hokoku”, when the Imperial Science University of Tokyo (present the University of Tokyo) carried out a questionnaire about the existence of "Kaisyo" to municipal corporations all over the country in the 1890s, those in the coastal regions of Iwate answered that there are no historical records and oral transmissions on the historical earthquakes and tsunamis before AD 1856 Ansei Hachinohe-oki earthquake tsunami (Ebina and Satake 2018). This report shows that the coastal residents did not recognize that tsunamis frequently attack the Pacific coast of Tohoku in those days. Shoshin Yamana reevaluated the historical records and oral transmissions still remained in the coastal area. He

©2019. Japan Geoscience Union. All Right Reserved.

carried out the survey after the AD 1896 Meiji Sanriku earthquake tsunami and wrote “Sanriku Engan Daikaisyo Torisirabe Syo”. This book includes that the description of the damage in many areas and Keicho Oshu earthquake tsunami hand-copied from the reference books of "Muto Rokuemon Syozo Komonzyo" and “Miyako Yurai Ki. These materials are obtained by the survey for influential local persons in various places. Yamana also studied the place name may be coming from driftage by past tsunamis through the interview survey to the local residents and compiled those as “Iwate Engan Kochimei Ko”. Among those 40 place names, half of them still exist (Muranaka et al., 2017). However, it is difficult to consider that many of those places were inundated by tsunamis. The possibility that some oral transmissions of those place names newly generated under the confusion by the Meiji Sanriku earthquake and tsunami.
Considering the historical viewpoint on formation processes of historical documents and oral transmissions will be useful for studies on paleo earthquakes and tsunamis.

Co-seismic crustal movements along reverse faults which subsidence component is larger than uplifting component

*Taku Komatsubara[1]

1. Institute of Geology and Geoinformation, Advanced Industrial Science and Technology

Introduction

Reverse faulting should cause crustal movement which uplifting component is larger than subsidence component. There are many reverse faults which subsidence component is larger than uplifting one in the Niigata-Kobe and eastern margin of Japan Sea tectonic zones during geological era, Presenter gathered examples of historical co-seismic crustal movement along such faults.

Example 1. Kuwana fault and AD 1586 Tensho Earthquake, Mie Pref., central Japan

Height of the MIS5e shoreline in the uplift area of the Kuwana fault is +63m, it of the upper surface of MIS5e marine deposits in the subsidence area is -92 to -72m.

This fault is one of the source of the 1586 Tensho Earthquake, however a house built on AD 1576 is existing in the subsidence area near the coast at that time. Almost all medieval structural remain surfaces in the subsidence area are less than 1m beneath ground in depth.

Example 2. Hyuuga fault and AD 1662 Kambun Ohmi-Wakasa Earthquake, Fukui Pref., central Japan

Height of the MIS5e shoreline in the uplift area of the Hyuuga fault is +15 to +16m, and it of the upper surface of the MIS5 lacustrine sediments in the subsidence area is -90 to -80 m.

Ahistorical document reported 2.4 m uplift on the north eastern side of Lake Mikata (Suga) and 1.5 m subsidence on the south western side of it occurred during the 1662 Kambun Ohmi-Wakasa Earthquake.

Example 3. Noshiro fault zone and AD1694 Genroku Noshiro Earthquake, Akita Pref., north eastern Japan

Height of the MIS5e shoreline in the uplift area of the Noshiro fault is +30 to 60m, it of the upper surface of the MIS5e marine deposits in the subsidence area is -85m. The 1694 Genroku Noshiro Earthquake induced uplifting of northern bank of the Hachiro-gata lagoon, but no reports describes subsidence in the footwall side of it.

Conclusion

These three historical co-seismic crustal movement along the subsidence prevailing reverse fault did not go with distinct subsidence. This suggests aseismic subsidence in the footwall side of these faults have occurred in the geological era.

The Iyo-Bungo, southwest Japan, earthquake on September 1st, 1596 as deduced from contemporary historical records

*Katsuhiko Ishibashi[1]

1. Emeritus Professor, Kobe University

In leap July of the 5th year of the Bunroku era (in the old Japanese lunar calendar; September, 1596 in the Gregorian calendar) Bungo province (present-day Oita Prefecture) in Kyushu, southwest Japan, suffered from severe earthquake and tsunami disasters. Concerning the occurrence date of the causative earthquake, currently prevailing idea is that a large earthquake took place on leap July 9 in Iyo province (present-day Ehime Prefecture) in Shikoku, on the eastward opposite shore of Bungo, and another large earthquake occurred on leap July 12 around Bungo. Against this idea I claim that a single event which could be called "the Iyo-Bungo earthquake" occurred around seven p.m. on leap July 9 in the Iyo-Bungo region based on reliable contemporary historical records.

There are more than 70 documents on this (these) earthquake(s) printed in the existing collections of historical earthquake materials, but their values as historical records vary considerably. Since the essential principle of historiographical seismology is to utilize only reliable first-grade documents, I performed historical source criticism to select 16 contemporary materials. I referred to their original or best texts, not using texts printed in the collections.

According to the contemporary records, in Bungo, violent earthquake ground motion collapsed shrines around seven to nine p.m. on leap July 9 and a large tsunami hit Fuchu (Oita) in the twilight (*"Yusuhara-no-miya Nendai Ryakki"*). *"Kodo-ji Daihan'nyakyo Okugaki"* and *"Shibayama Kanbei Ki"* also describe strong earthquake shaking and large tsunami around Fuchu on that day. In Kyoto, roughly 430 km east-northeast of Bungo, earthquake ground motion was felt around seven to nine p.m. on leap July 9 (*"Kotokuni-kyo Ki"*), or around seven p.m. on the same day rather strongly (*"Ozuki-Takasuke-Sukune Ki"*). In Hiroshima Prefecture, at Hatsuka-ichi and Itsukushima strong ground motions were felt at night on leap July 9 without damages (*"Hoida Motokiyo's letter"*), and at Mihara strong earthquake tremors continued from leap July 9 till 12 (*"Buttsu-zenji Juji Ki"*). In Iyo, *"Yakushi-ji Daihan'nyakyo Okugaki"* says a severe earthquake tremor occurred on leap July 9 and the whole Iyo province had trouble, suggesting earthquake disaster in a wide area. In Satsuma and Osumi provinces (present-day Kagoshima Prefecture), *"Kabayama Shoken Jiki"* writes a strong earthquake on leap July 9, and *"Nanko Nikki Zankan"* also writes an earthquake on the same day. *"Chosa Yachi's letter"* written on leap July 29 describes that since leap July 8 earthquake tremors had continued.

As a fundamental methodology of historiographical seismology, these tremors and tsunami in Bungo, Iyo, Kyoto, Hiroshima and Kagoshima on leap July 9 are considered to have been produced by an identical earthquake unless there is any counter-evidence. Leap July 12, the other proposed date of the Bungo earthquake, comes from historical materials written after 1698, which probably mistook the great Kyoto earthquake in the midnight of leap July 12 for the Bungo event. The seismic intensities are evaluated to be stronger 6 in some places in Bungo and Iyo, 4 in Hiroshima, stronger 3 in Kyoto, and about 3 in Kagoshima on the JMA scale. The most simple and reasonable interpretation is that a large earthquake with the source region from around Oita to the midst of Iyo took place around seven p.m. on leap July 9, whose magnitude being around 7.5, and the tsunami on the Bungo coast followed. The rupture of the Kawakami fault in the MTL fault zone during this earthquake suggested by Tsutsumi *et al.* (2000) may have

Geologically recorded historical and prehistoric tsunamis in the Tonankai region

*Shigehiro Fujino[1], Haruo Kimura[2], Junko Komatsubara[3], Dan Matsumoto[3], Yuichi Namegaya[3], Yuki Sawai[3], Masanobu Shishikura[3]

1. Faculty of Life and Environmental Sciences, University of Tsukuba, 2. Civil Engineering Research Laboratory, Central Research Institute of Electric Power Industry, 3. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST)

A coring survey at a coastal lowland in Mie Prefecture exposed 10 sand layers deposited from about 4500 to 500 years ago. The layers are interpreted as tsunami deposits because of the presence of abundant bioclasts of marine organisms such as foraminifers and gastropods, and sedimentary structures common in modern tsunami deposits. At the study site, no substantial seawater inundations and sand depositions have been recorded even for the largest typhoons to ever hit the region. On the other hand, written document tells that the Ansei-Tokai earthquake tsunami (1854 CE) inundated the study site and deposited substantial sand layer. Estimated ages of the youngest three sand layers overlap well with tsunamis in 1498, 1096, and 684 CE. Our results support the hypothesis suggested by archaeological studies that the 684 CE rupture extended farther eastward than the historical record indicates or that another tsunami occurred at some time close to 684 CE. We did not find any sand layers that were definitely correlated with the tsunamis of 1361 and 887 CE, which are thought to have occurred by multi-segment ruptures of the Nankai Trough that includes the segment directly offshore from the study site. If the sand layers found at the study site were deposited by the tsunamis of 1498, 1096, and 684 CE, and if the tsunamis of 1361 and 887 CE did not inundate the study site, the tsunami recurrence interval during the relevant time period was about 400 years. This finding does not support the widely believed hypothesis that earthquakes and tsunamis occur at regular intervals of approximately 100 years in this area. In addition, similar to the historical tsunamis, intervals of geologically recorded prehistoric tsunamis at the study site vary from about 100 to 600 years. The hypothesis of variable recurrence of earthquakes and tsunamis along the Nankai Trough should be tested by future geological and historical studies in unbiased way.

[S-IT21] Interaction and Coevolution of the Core and Mantle in the Earth and Planets

convener:Kenji Kawai(Department of Earth and Planetary Science, School of Science, University of Tokyo), Tsuyoshi Iizuka(University of Tokyo), Kenji Ohta(Department of Earth and Planetary Sciences, Tokyo Institute of Technology), Taku Tsuchiya(Geodynamics Research Center, Ehime University), Chairperson:Kenji Kawai, Sebastian Ritterbex

Recent observational and experimental investigations have significantly advanced our understanding of the structure and constituent materials of the deep Earth. Yet, even fundamental properties intimately linked with formation and evolution of the planet, such as details of the chemical heterogeneity in the mantle and light elements dissolved in the core, remained unclear. Seismological evidence has suggested a vigorous convection in the lower mantle, whereas geochemistry has suggested the presence of stable regions there that hold ancient chemical signatures. The amounts of radioactive isotopes that act as heat sources and drive dynamic behaviors of the deep Earth are also still largely unknown. We provide an opportunity to exchange the achievements and ideas, and encourage persons who try to elucidate these unsolved issues of the core-mantle evolution using various methods, including high-pressure and high-temperature experiments, high-precision geochemical and paleomagnetic analyses, high-resolution geophysical observations, geo-neutrino observations, and large-scale numerical simulations. Papers stimulating an interdisciplinary collaboration relating to establishment of the Japan-SEDI community are also welcomed.

Seismological Explorations of Earth's Outer Core: Normal Mode and Body Wave Analyses

*Jessica C E Irving[1], Sanne Cottaar[2], Vedran Lekic[3], Wenbo Wu[4]

1. Princeton University, 2. University of Cambridge, 3. University of Maryland, College Park, 4. California Institute of Technology

Earth's outer core is a source of both the geodynamo and heat for mantle convection. However, we still do not fully understand its chemical composition, and there is debate about whether the uppermost outer core may contain a stratified layer enriched in light elements. We present low frequency normal mode and high frequency body wave investigations of the outer core's properties.

Normal mode oscillations of the whole Earth, excited by large earthquakes, are sensitive to the large-scale variations in velocity and density. We use reported centre frequencies of hundreds of normal mode oscillations to investigate the bulk properties of the outer core. We carry out a Bayesian inversion using a mineralogical Equation-of-State framework to infer the outer core's velocity, density and mineralogical properties, under the assumption that the outer core is well mixed and adiabatic. The model we produce, EPOC, describes the Elastic Parameters of the Outer Core. EPOC predicts seismic velocities at the top of the outer core which are closer to some existing body-wave models than to PREM, resolving a long-standing discrepancy. EPOC also fits normal-mode data better than the Preliminary Reference Earth Model. We also consider the effects of relaxing our assumptions that (i) there is no stratified layer at the top of the outer core, and (ii) that PREM is correct outside the outer core.

To better assess the uppermost outer core, often referred to as the E' layer, we use a novel, iterative technique to measure SmKS differential travel times. SmKS waves are particularly sensitive to the E' layer, and reflect (m-1) times from the underside of the core-mantle boundary. We find that the SmKS differential travel times are better described by models with seismic velocities in the E' layer slower than PREM, such as EPOC or body-wave derived KHOMC (Kaneshima and Helffrich, 2013).

On the 1-D radial convective structure of the Earth’s core inferred from a coupled core-mantle evolution model

*Takashi Nakagawa[1]

1. Department of Earth Sciences, The University of Hong Kong

A coupled core-mantle evolution model in the global heat and mass balance of the Earth’s mantle and core is to reveal the 1-D radial convective structure of the Earth’s core over the geologic time-scale. Since tracking the convective structure of the Earth’s core over the geologic time-scale is not still available for numerical geodynamo simulations, the assessment with the global heat and mass balance model of Earth’s core and mantle is quite powerful. Regarding the global heat balance of the Earth’s mantle, the global heat balance approach incorporating with the heat transport by the partial melting is assumed, which is the parameterized mantle convection based on the modified version of Driscoll and Bercovici (2014). The heat flow across the core-mantle boundary computed from this parameterized convection model is used to compute the thermal and chemical structure of the Earth’s core based on the global heat balance of the Earth’s core with the realistic material properties of the Earth’s core provided from Labrosse (2003; 2015) However, on the assessment of convective structure, the effects of compositional convection caused by releasing the light elements associated with inner core growth and/or the metal-silicate partitioning are included (e.g. Takehiro and Sasaki, 2018). As indicated in Takehiro and Sasaki (2018), the effects of compositional convection are essential for understanding the convective structure of the Earth’s core even if the realistic density structure of the Earth’s core is included in the energy flux computations. On the magnetic field generation caused by geodynamo actions, again, the compositional convection plays a significant role under the high thermal conductivity expected from the high-pressure physics. In the presentation, I will indicate the evolution of the convective structure described as the entropy flux of the Earth’s outer core over 4 billion years as a function of the evolution of the heat flows across the core-mantle boundary and oceanic lithosphere.

Structural and transport properties of liquid iron-light-element mixtures under outer core conditions

*Satoshi Ohmura[1], Taku Tsuchiya[2]

1. Hiroshima Inst. of Tech., 2. Ehime Univ.

It is widely believed that Earth’ s outer core consists of liquid iron (or liquid-nickel alloy) with light element (LE) impurities. For understanding magnetic and thermal behaviors of the Earth, it is required to explore electrical and thermal conductivities of liquid iron and influence of the light elements on these properties.

For this reason, we have investigated influences of light elements on transport properties of liquid iron under high pressure by using ab initio molecular dynamics simulations. We reported the structural and transport properties of liquid Fe-LE binary systems in connection with a microscopic structural properties. This times, in addition to binary systems, we have investigated transport properties of Fe-LE ternary systems. To provide further details of the effects of light-element, we discuss structural and transport properties of liquid Fe alloys in terms of the type and amount of light elements.

Development of New Technology for Geoneutrino Directional Measurement

*Hiroko Watanabe[1]

1. Research Center for Neutrino Science, Tohoku University

Neutrino is an elusive particle and it can penetrate even astronomical objects. While neutrino experiments continue to explore the neutrino propertied, e.g. oscillation nature of neutrino flavor transformation, mass-square differences and mixing angles, we have began to utilize neutrino as a tool to look into the Earth. Anti-neutrinos emitted from radioactive isotopes, geo-neutrinos, bring unique and direct information of the Earth's interior and thermal dynamics.

KamLAND, Kamioka Liquid-scintillator Anti-neutrino Detector, has 1 kton ultra pure liquid scintillator. They reported the first experimental study of geo-neutrino in 2005. Later the geo-neutrino signals were used to estimate the Earth's radiogenic heat production and constrain the composition models of the bulk silicate Earth. Following the Fukusima reactor accident in March 2011, the entire Japanese nuclear reactor industry has been subjected to a protected shutdown. This unexpected situation allows us to improve the sensitivity for geo-neutrinos.

The liquid scintillator detectors have the sensitivity for measuring total amount of geo-neutrinos from the Earth's crust and mantle. However, we do not have the technology to track the direction of incoming geo-neutrinos at present due to the high miss-identification in a neutrino's track reconstruction. The direction-sensitive detector can map out the U and Th distribution inside the Earth and this technic is also applicable to resolving crust versus mantle contributions. Recent progress in studying this this new technology confirmed that a signify improvement is possible in neutrino tracking identification with a combination of ^{6}Li-loaded liquid scintillator and imaging detector. We developed prototype detector to measure 3D image of scintillation light and study the methodology for the image reconstruction. We will present recent status of our prototype detector and achievement of dark noise reduction of pixelated detector.

Investigation of multi light elements in iron-silicate-water system using high pressure and temperature neutron experiments: Implications for the Earth's evolution

*Riko Iizuka-Oku[1], Hirotada Gotou[2], Ko Fukuyama[1], Hiroyuki Kagi[1]

1. Geochemical Research Center, Graduate School of Science, The University of Tokyo, 2. The Institute for Solid State Physics, The University of Tokyo

Introduction:

The Earth’s core is considered to consist of Fe alloy and some light elements (O, S, Si, H, C). Hydrogen (H) is the most abundant element in the universe and one of the promising candidates existing in the Earth’s core. However, its amount dissolved in the core and its process are still unknown because H cannot be detected by X-ray diffraction (XRD) and it easily escapes from iron by the release of pressure. Recently, H content in *fcc*-Fe at high pressure and high temperature (high-PT) has been determined using in-situ neutron diffraction measurements at J-PARC [1], suggesting that H had preferentially dissolved into iron before any other light elements have dissolved in the very early stage of Earth’s evolution. It is important to further study the partitioning of the other light elements between iron hydride (not pure iron) and silicates. To clarify the effects of multi light elements on the core-mantle segregation in the Earth’s formation, we have focused on sulfur (S) and investigated its effect on hydrogenation of iron.

Experimental:

Iron fine powder was pelletized with/without S powder and placed at the center of the graphite sample capsule. Powder mixture of quartz (SiO_2), brucite $Mg(OD)_2$ (or MgO for comparison of the water existence) surrounds the Fe pellet. Sample composition of Fe:$Mg(OD)_2$:SiO_2=2:1:1 of molar ratio with 5wt.% of S simulates an ideal condition of the primitive Earth.

In-situ high-PT neutron experiments were carried out using a six-axis multi-anvil press “Atsuhime” installed at MLF, PLANET (BL11), J-PARC. An originally improved multi-anvil 6-6 type assembly was applied. Three samples were pressurized up to 6–7 GPa and then heated up to 700 ˚C step by step. The reaction processes (dehydration of $Mg(OD)_2$, phase transformations of Fe (*bcc*-*fcc*) and FeS, formation of silicates) were carefully checked in real time. The diffraction patterns of *fcc*-Fe were measured at 550 ˚C and 700 ˚C for long time and analyzed using the Rietveld refinement method to determine structural and atomic parameters of *fcc*-Fe and sub-products. The recovered samples were examined by XRD and SEM-EDS to more precisely identify the products, their compositions, and the elements partition.

Results and Discussion:

The cell volume changes in *fcc*-Fe and sub-phase of FeS-V were investigated for every hour during the long-time measurements at 700 ˚C. For the sample including water, the volume of *fcc*-Fe was significantly increased with time, while the sample without water showed no change regardless of temperatures. The cell volume of FeS-V did not increase, suggesting that the formation of FeS was promoted in the existence of water, but its hydrogenation was negligible. Fe gradually incorporated D in the existence of water and FeD_x formed (x~0.10 at a maximum). From the results of SEM, the inhibition of deuterization might be due to the formation of FeS layer surrounding Fe pellet, whereas such a thick layer was not observed when using the Fe+S pellet. The sample without water did not include FeS layer nor Fe-bearing silicates.

It is suggested that both S and Fe were not mobile and could not react with each other without the existence of water. H and S can be preferentially incorporated into solid Fe at lower-T (~700 ˚C) before melting. The other light elements (C, O, Si) could have dissolved into molten iron hydride and/or FeS in the later process of Earth’s core-mantle differentiation at much higher-PT condition.

[S-IT21] Interaction and Coevolution of the Core and Mantle in the Earth and Planets

convener:Kenji Kawai(Department of Earth and Planetary Science, School of Science, University of Tokyo), Tsuyoshi Iizuka(University of Tokyo), Kenji Ohta(Department of Earth and Planetary Sciences, Tokyo Institute of Technology), Taku Tsuchiya(Geodynamics Research Center, Ehime University), Chairperson:Noriyoshi Tsujino, Kenta Ueki

Recent observational and experimental investigations have significantly advanced our understanding of the structure and constituent materials of the deep Earth. Yet, even fundamental properties intimately linked with formation and evolution of the planet, such as details of the chemical heterogeneity in the mantle and light elements dissolved in the core, remained unclear. Seismological evidence has suggested a vigorous convection in the lower mantle, whereas geochemistry has suggested the presence of stable regions there that hold ancient chemical signatures. The amounts of radioactive isotopes that act as heat sources and drive dynamic behaviors of the deep Earth are also still largely unknown. We provide an opportunity to exchange the achievements and ideas, and encourage persons who try to elucidate these unsolved issues of the core-mantle evolution using various methods, including high-pressure and high-temperature experiments, high-precision geochemical and paleomagnetic analyses, high-resolution geophysical observations, geo-neutrino observations, and large-scale numerical simulations. Papers stimulating an interdisciplinary collaboration relating to establishment of the Japan-SEDI community are also welcomed.

The accretion of planets from primordial materials and their subsequent differentiation to form a core and a mantle are fundamental questions in terrestrial and solar system. Many of the questions about the processes are still open and much debated. For example, could the presenceof water during the metallic phase segregation affect the planet-accretion models? The existing studies on the elemental metal-silicate partitioning under hydrous conditions were extended recently to a range of P, T, f_{O2} and water content (5 - 20 GPa, 2000 - 2500 K, from 1 to 5 log units below the iron-wüstite buffer, and for X_{H2O} varying from 500 ppm to 1.5 wt%) [1]. These experimental results show that except for Fe, there is no effect of water on the partitioning of moderately siderophile elements. It allowed us to build consistent models of planetary accretion from reducing to oxidized conditions. Furthermore, for the range of water concentrations studied, there is no evidence of important hydrogen incorporation into planetary cores, thus making unlikely for hydrogen to be a major light element of the core as previsously assumed [2]. We report H metal-silicate partition coefficients of about 0.2, up to two orders of magnitude lower than reported previously, and indicative of lithophile behavior. Our results imply H content of ~60 ppm in the Earth and Martian cores [3].

Fe_2S: the most iron-rich Fe-S compound at pressures of the inner core

*Shigehiko Tateno[1,2], Haruka Ozawa[2,3], Kei Hirose[1,4], Toshihiro Suzuki[5]

Sulfur is considered to be one of the light elements in the Earth’ s core as iron sulfides are universally found in iron meteorites. The phase diagram of the Fe–FeS system at the high-pressure and high-temperature (P-T) conditions of the core has particular importance to understand the composition and state of the Earth’ s core. Because Fe3S is known as the most iron-rich Fe–S compound at > 20 GPa, the iron–sulfur core model has been discussed considering Fe and Fe_3S in the solid core. However, our previous experiment reveals that Fe_3S decomposes into S-bearing hcp-Fe and CsCl (B2)-type phase above ~250 GPa from X-ray diffraction measurements (XRD) (Ozawa et al., 2013 GRL). Furthermore, TEM analysis on the recovered sample exhibits that S-poor phase, likely to be a former hcp-Fe, coexisted with S-rich phase with >33.5 atm% S. Hence, the S-rich end-member compound has not been constrained under pressure more than 250 GPa. In order to re-investigated the phase relations in Fe-FeS system, we studied phase relations in Fe_2S at multi-megabar pressure range.

High P-T conditions were generated in a laser-heated diamond-anvil cell (DAC) using double-beveled diamond anvils with 40 or 60 μm culets. We used the Fe_2S phase as the starting material, which was synthesized beforehand at high pressures in a multianvil apparatus and confirmed by microprobe analysis. SiO_2 glass and MgO were used for thermal insulation and pressure calibration. We loaded such sample assembly as MgO/SiO_2-glass/Fe_2S/SiO_2-glass so that MgO was detached from an iron sample, in order to avoid possible chemical reaction at high temperature. Angle-dispersive XRD measurements were conducted at BL10XU, SPring-8. Heating was performed from both sides of the sample by employing a pair of 100 W Yb fiber lasers.

We performed three separate sets of experiments at pressures between from 120-310 GPa and temperature up to 3000 K. When we heated the Fe_2S sample being mostly amorphous by compression to 300 GPa at 300 K, the 20 new peaks appeared in a few minutes and became spotty with further heating. All peaks are assigned to the orthorhombic structure, which agrees well with Pnma symmetry phase proposed by the theoretical prediction (Bazhanova et al., 2017). This observation indicates that Fe_2S composition crystallizes as a single phase. In the following decompression and re-heating the sample, its stability was confirmed to be 150-310 GPa.

Our previous study (Mori et al., 2017 EPSL) reported that hcp-Fe and B2 phase crystallizes in Fe-6wt% S bulk composition at 270 GPa and 2400 K. Then, the peaks from the B2 phase become weak at further hearting. We re-analyzed the series of XRD datum, and found that such apparent weakening was caused due to the appearance of Fe_2S phase. Indeed, in the XRD patten collected at 3500 K, we confirmed that additional weak peaks from Pnma-Fe_2S were clearly visible and the reflection from the coexisting hcp-Fe phase became intense simultaneously. This indicates that stable phase assemblage in Fe-6wt% S bulk composition changes from hcp-Fe + B2-FeS into hcp-Fe + Pnma-Fe_2S. Hence, Fe_2S is the sulfur-rich end-member compound after the decomposition of Fe_3S at 250 GPa. The slope of eutectic melting curve should have kink at the decomposition of Fe_3S. Also, pressure evolution of the eutectic composition should change as well. Since the extrapolation from lower pressure data <250 GPa is not available, higher P-T experiments are necessary to establish the phase diagram at the pressure of inner core boundary.

First-principles Investigation of Iron Diffusion Properties with Implications to Inner Core Plasticity

*Sebastian Ritterbex[1], Taku Tsuchiya[1]

1. GRC Ehime University

The mechanical properties of Earth’ s inner core are key for understanding the evolution and dynamics of the core. However, little is known about the mechanical properties of iron (alloys) at inner core conditions. Therefore, long-standing questions remain open about the viscous strength of the inner core (Yoshida et al., 1996; Karato, 1999), about the origin of its seismic anisotropy (Deuss, 2014) and about its rotational dynamics (Buffett, 1997). All these issues rely on plastic deformation of the inner core, which is barely constrained.

Under extreme conditions of the Earth’ s deep interior, plasticity is expected to be rate limited by atomic diffusion. Experimental studies of diffusion in iron-nickel alloys at elevated P,T conditions finally rely on extrapolation to inner core conditions (Yunker and Van Orman, 2007; Reaman et al., 2012). Here, we investigate vacancy diffusion in iron at the appropriate inner core conditions. We use a density functional approach to calculate all quantities entering the diffusion coefficient, including the role of pressure and temperature, and quantify the self-diffusion coefficient of hcp iron according to transition state theory (TST).

Vacancy diffusion controls many deformation mechanisms such as dislocation creep, an effective strain producing mechanism in metals. We derived a creep model (based on Weertman, 1955 and Nabarro, 1967) to quantify the rate limiting bounds of climb-controlled dislocation creep in hcp iron to provide the first theoretical estimates of the inner core viscosity. Our results suggest an inner core viscosity that is significantly lower than that of Earth’ s mantle.

Dependence of the dipole component dominancy on the Rayleigh number and inner core size in geodynamo simulations

*Yuki Nishida[1], Yuto Katoh[1], Hiroaki Matsui[2], Masaki Matsushima[3], Atsushi Kumamoto[1]

1. Department of Geophysics, Graduate School of Science, Tohoku University, 2. Dept. of Earth and Planetary Sciences, University of California, Davis, 3. Department of Earth and Planetary Sciences, School of Science, Tokyo Institute of Technology

Geomagnetic field is generated by a dynamo action in the fluid outer core. Studies of the thermochemical evolutions of the Earth's core suggest that the solid inner core has been growing up for approximately one billion years [e.g., O'Rourke and Stevenson, 2016]. Results of numerical dynamo simulations with various aspect ratios (ratios of inner to outer core radii) indicates that the sustained magnetic field is categorized into dipolar-dominated or non-dipolar-dominated regime [e.g., Hori et al., 2010; Driscoll, 2016]. However, any dominant factors controlling the regime have not been fully understood. In the present study, we perform dynamo simulations with various inner core radii using a geodynamo code Calypso to investigate the characteristics of the generated magnetic field. We fix the Ekman, Prandtl, and magnetic Prandtl numbers to be $E = 10^{-3}$, $Pr = 1$, and $Pm = 5$, respectively, and change the Rayleigh number and the aspect ratio to be $r_i/r_o = 0.15$, 0.25, and 0.35. Then we examine the dominancy of the dipole component in two approaches; one is calculating the dipolarity, f_{dip}, which is the ratio of the amplitude of the axial dipole magnetic field to the total amplitude, and the other is comparing magnetic energy for the dipole component with extrapolated magnetic energy for $l = 1$ using an exponential function for odd degree components from $l = 3$ to $l = 19$. The magnetic energy for the dipole component is compared with that extrapolated from the fitting curve.

In $r_i/r_o = 0.25$ and 0.35 cases, f_{dip} is approximately 0.8 at $Ra/Ra_{crit} \fallingdotseq 2.0$ and gradually decreases to approximately 0.45 with increase of Ra/Ra_{crit} up to around 6.0, where Ra_{crit} is the critical Rayleigh number. By referring to the obtained fitting curve, we find that the magnetic energy for the dipole component is more than 5 times larger than the extrapolated value for $l = 1$ at $Ra/Ra_{crit} \fallingdotseq 2.0$ and decreases with increase of Ra/Ra_{crit} in both aspect ratios. The dependency of the dipole component dominancy on the Rayleigh number is similar in both aspect ratio cases. However, in the $r_i/r_o = 0.15$ case, f_{dip} is approximately 0.4 at $Ra/Ra_{crit} \fallingdotseq 8.0$ and decreases to approximately 0.1 with increase of Ra/Ra_{crit} up to around 15.6. At $Ra/Ra_{crit} = 8.1$ and 9.0, the amplitude of the dipole component is comparable to extrapolated value from the fitting curves. At $Ra/Ra_{crit} > 10.1$, the magnetic energy for $l = 1$ component is smaller than that for the $l = 2$ component. Consequently, the magnetic field obtained in the simulation results is non-dipolar. To summarize above, we categorize the present dynamo simulations as shown in Figure 1. Here we define strong/weak dipolar dynamo by a condition that the magnetic energy is larger/smaller than the kinetic energy. The axial dipolar component becomes small in all three ratio cases for larger Rayleigh numbers. Non-dipolar components become larger for the smaller inner core. In other words, for $r_i/r_o < 0.35$, it is likely that the dipolar magnetic field is dominant for larger inner core.

Elasticity of Fe-Si Alloy

*Taku Tsuchiya[1], Yu Fukunaga[1]

1. Geodynamics Research Center, Ehime University

Earth’ s inner core (329~364 GPa and 5000~6000 K) is thought to be composed of solid Fe-Ni alloy with some unknown light elements (e.g., Mao et al., 1998). Thermoelasticity of iron alloys is therefore a key to interpreting seismological information of the inner core: density, seismic wave velocities, and their anisotropy. So far, several studies reported that pure hcp iron has a shear modulus distinctly larger than that of the inner core and a small P-wave anisotropy (e.g., Mao et al., 1998; Vocadlo et al., 2009). This large V_P/V_S ratio of the inner core is one of the remaining inexplicable features of the deep Earth, and it suggests the presence of mechanisms to lower the S-wave velocity in the inner core, such as a low-velocity component (Prescher et al., 2015), pre-melting effect (Martorell et al., 2013), anelasticity, and so on.

In this study, we perform ab initio molecular dynamics simulations on the thermoelasticity of alloy compositions including potential light element candidate of Si. Computations are conducted at the inner core P,T conditions. The obtained velocities, density and aggregate anisotropies are compared against seismological constraints, and we show the first evidential result on the suitable compositions to the inner core constituents, which can reproduce all of V_P, V_S, V_Φ, and ρ of the inner core simultaneously. We also report why Fe-Si alloy can have a large V_P/V_S ratio.

[E] Poster | S (Solid Earth Sciences)：S-MP Mineralogy & Petrology

Tue. May 28, 2019 10:45 AM - 12:15 PM JST | Tue. May 28, 2019 1:45 AM - 3:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_7

[S-MP29] Oceanic and Continental Subduction Processes

convener:REHMAN Ur Hafiz(Department of Earth and Environmental Sciences, Graduate School of Science and Engineering, Kagoshima University), Tatsuki Tsujimori(Tohoku University), Chin-Ho Tsai(Department of Natural Resources and Environmental Studies, National Dong Hwa University), Kazuaki Okamoto(Faculty of Education, Saitama University)

This JpGU-AGU joint session aims at bringing earth scientists from Japan and overseas to present their research related to the processes of oceanic and continent subduction, continent-continent collisions, metamorphism of crustal rocks, formation of the oceanic/continental arcs, and accretion/ tectonic erosion of material along subduction boundaries.

Topics such as role of the fore- and back-arcs in the subduction zones, process of accretion of volcaniclastic and terrigenous sediments along the subduction/collision boundaries, deformation and metamorphism of subducted crust, and exhumation will be the main focus of the session.

In addition to the above mentioned topics, our focus for the10th anniversary of this international session will be towards our understanding and progress on the ultrahigh-pressure/temperature metamorphic terranes in the world.

Exchange of ideas among geoscientists applying different approaches on problems related to the theme of the session are most welcome.

Combined chronological study using detrital zircon U-Pb dating and phengite K-Ar dating enables to understand the tectonic evolution of the high *P/T* metamorphic belt. The youngest age of detrital zircon U-Pb ages of psamites in the Hida marginal metamorphic rocks (HMMR = Renge belt) approximate its depositional ages (Tsutsumi et al., 2009). The closure temperature of the phengite K-Ar ages are controlled by deformation and recrystallization during exhumation of the metamorphic rocks(Itaya and Tsujimori, 2015). Therefore, the gap between the youngest age of detrital zircons and phengite K-Ar ages are the age difference between subuduction and uplift of metamorphics.
The Hakogase (Nigure-gawa, Kuzuryu, Fukui Prefecture) metamorphic rocks belong to HMMR member as the olistolith in the Cretaceous Tedori Group. It consists mainly pelites with small amount of basites and mables. The main index mineral assemblage of metasediments are garnet + chlorite, and the phenigite K-Ar ages are 287.8 - 283.6 Ma (Kunugiza et al., 2004). Relic Lawsonite was also found in the basaites and psamites (Miyakawa, 1982).
The detrital Zircons U-Pb ages in the two pelites are obtained by the SHRIMP II of KBSI. The youngest U-Pb ages of detrital zircons are 307Ma. The gap of the sedimentation between uplift of the Hakogase metamorphics is estimated 20 Ma. This value means the migration speed of the HMMR metamorphic rocks are 1/10 of plate motion. This rapid migration speed is common for the high *P/T* metamorphic rocks.

Late Permian to Early Triassic back-arc type volcanism in the southern Mongolia volcano-plutonic belt of the Central Asian Orogenic Belt: Implication for timing of the final closure of the Palaeo-Asian Ocean

*Takeshi Imayama[1], Yoichiro Koh[2], Kazumasa Aoki[3], Mototaka Saneyoshi[4], Koshi Yagi[5], Shogo Aoki[4], Yoshihiro Sawada[6], Chiaki Ikawa[5], Tomoya Terada[4], Shinobu Ishigaki[4], Shin Toyoda[3], Khishigjav Tsogtbaatar[7], Buuvei Mainbayar[7]

Faculty of Biosphere - Geosphere Science, Okayama University of Science, 5. Hiruzen Institute for Geology and Chronology, 6. Emeritus Professor of Shimane University, 7. Institute of Paleontology and Geology, Mongolian Academy of Sciences

The timing of final subduction and closure of the Palaeo-Asian Ocean is still controversial in the eastern segments of the Central Asian Orogenic Belt (CAOB). A more detailed understanding is needed with respect to the formation of volcanic rocks and sediments associated with the final closure of the Palaeo-Asian Ocean in southern Mongolia. We investigated alkali series volcanic rocks newly discovered in the southern Mongolia volcano-plutonic belt of the CAOB and classified as basalt, basaltic trachyandesite, andesite, trachyandesite, and trachyte, mainly showing andesitic-dacitic compositions. In Harker diagrams, the TiO_2, FeO, MnO, Al_2O_3, CaO, and MgO contents generally decrease with increasing SiO_2, representing a series of differentiated volcanic rocks. The primitive mantle-normalized trace element spider diagram is characterized by incompatible element-rich patterns and negative Nb anomalies. The tectonic discrimination diagrams show that the volcanic rocks were formed by arc-related volcanism rather than within-plate volcanism. K-Ar dating of feldspars from six volcanic rocks yields ages ranging from 270 to 239 Ma, indicating that andesitic and dacitic magmatism occurred during this period. These geochemical and geochronological data indicate that the differentiated volcanic rocks intruding middle to late Palaeozoic volcanic sediments were formed by back-arc type subduction ca. 270–240 Ma. Based on detrital zircon U-Pb ages, the terrigenous sandstones underlain by the volcanic sediments record a maximum depositional age of Late Triassic (ca. 220–200 Ma) and include a main cluster of Early Devonian ages (ca. 410–390 Ma), possibly derived from the Devonian-Carboniferous arc complex observed surrounding this study area. These results from the volcanic and sedimentary rocks in this study, combined with investigations in previous studies, imply that subduction beneath the eastern segments of the CAOB to consume the Palaeo-Asian Ocean continued until Late Permian to Early Triassic.

Mantle dynamics of slab breakoff constrained from the temporal change of the melting depth estimated from the Cumulate Member of the Ordovician Hayachine-Miyamori Ophiolite

*Takafumi Kimura[1], Kazuhito Ozawa[1]

1. Department of Earth and Planetary Science, The University of Tokyo

Slab breakoff, detachment of oceanic lithosphere highly expected during arc-continent collision, is one of the important mechanisms inducing passive upwelling of the asthenosphere and magma generation in arc environments [1]. In order to better understand the mantle dynamics of slab breakoff, we need to use continuous geological record with high time resolution. In this study, we have extracted a record of temporal change of the magma generation depth from cumulates in an Ordovician arc ophiolite at a time resolution of several tens of million years.
The Hayachine-Miyamori Ophiolite, northern Japan, is one of the Ordovician ophiolite formed in an arc environment [2]. The ultramafic member was built up by three main magmatic stages, which are recorded in three rock units: Tectonite Member, Cumulate Member, and ultramafic dikes, in the order of formation ages. The last two units in the entire evolution of the ophiolite is explained by decompressional melting of sub-slab mantle triggered by slab breakoff [2][3]. The melting depth of an ultramafic magma solidified as dikes in the Cumulate Member is estimated to be ~170km [3]. Our recent field study clarified a large-scale stratification characterized by alternation of wehrlite-dominant and dunite-dominant layers in the Cumulate Member. Each layer has a thickness from several meters to ~1 km and, the total thickness attains ~3km. Moreover, we succeeded in specifying the strike and plunge of the gravity field to be ~N48°E and ~20°NE during the cumulate formation from field information and westward stratigraphic younging [4].
We estimated the temporal change of generation depth of parent magmas of the Cumulate Member by garnet signature in heavy rare earth elements (HREEs) as depth proxy. The information may constrain the mantle dynamics during the slab breakoff. We examined stratigraphic variation of HREE ratio at the core of clinopyroxenes over the thickness of ~2km in the Cumulate Member. The obtained variation of the Dy/Lu increases from ~12.9 to ~16.5 with increasing the stratigraphic height. We estimated the extent of melting in the garnet stability field increasing from ~50 to ~90% of the total melting by applying an open-system fractional melting model to reproduce the Dy/Lu variation.
We also estimated the time scale of formation of the Cumulate Member by using cm –10cm scale heterogeneity recorded in contact zone of intruded magma and the host. The profile of Mg# of olivine in xenoliths of the Tectonite Member occurring at the bottom of the Cumulate Member shows that the cooling time is less than several tens of million years [5]. The dunite of the Cumulate Member contacting the ultramafic dike shows a systematic decrease of Mg# from 90 to 86.8 over the distance of 54 mm towards the contact. We calculated the time scale of subsolidus diffusional exchange between the dunite and dike and obtained several tens of million years at ~1000℃. The host was kept at a high temperature when the dikes intruded because of the absence of chilled margin. We thus estimated time scale of formation of the Cumulate Member to be < several tens of million years.
We propose the following tectonic model in the Ordovician northern Japan on the basis of the above result. The slab breakoff took place at the depth slightly deeper than the boundary of spinel and garnet stability fields (~80 km) and induced counter flow and adiabatic melting of the sub-slab mantle. The melting depth deepened down to ~170 km on the time scale of several tens of million years, which corresponds to the time scale to complete the slab breakoff. The sinking velocity of the slab is more than

Evidence of HIMU seamount on the Farallon Plate: Application of *in-situ* Sr-Pb isotope analysis to Franciscan lawsonite-bearing metagreywacke

*Tomomi Hara[1], Tatsuki Tsujimori[1], Jun-Ichi Kimura[2]

1. Tohoku University, 2. Japan Agency for Marine-Earth Science and Technology

Since bulk isotopic composition of oceanic basalt is susceptible to element remobilization during alteration process, there is a risk of causing misread of geochemical signatures from bulk metabasaltic rocks in subduction complex. As Hara et al. (2018) demonstrated, however, *in-situ* Sr-Pb isotope analysis of lawsonite in high-pressure metabasaltic rocks has a great potential for tracing the geochemical signatures reflecting the igneous protolith. In this study, we have applied the method to lawsonite in metasedimentary rocks to explore clastic components of a trench-fill sediment. A jadeite-bearing Franciscan metagreywacke from Pacheco Pass area, east-central Diablo Range, California Coast Ranges was selected for geochemical reconnaissance.

Lawsonites in the Franciscan metagreywacke record a high initial Pb isotope ratios ($^{206}Pb/^{204}Pb$ = 18.74–19.66, $^{207}Pb/^{204}Pb$ = 15.58–15.70 and $^{208}Pb/^{204}Pb$ = 38.41–39.34). This Pb-isotope signature suggests that a protolith of the metagreywacke have contained a debris derived from a HIMU-type basalt. Considering the maximum depositional age of the metagreywacke at ~102 Ma, the underflow of the Farallon Plate beneath continental crust of the North American Plate would have carried a HIMU seamount to a Franciscan trench.

Our study has demonstrated the potential application of 'lawsonitology' as sedimentary provenance analyses for metamorphosed accretionary complex. Moreover, the results would manifest that Pb isotopic signature of ancient oceanic basalt can be detectable from Ca-Al silicate mineral, such as lawsonite, epidote and pumpellyite, in metamorphic rocks.

Boron isotope variations of antigorite serpentinites associated with high-pressure metamorphic rocks: A case study in the Itoigawa–Omi area of the Hida-Gaien Belt, Japan

*Chinatsu Yamada[1], Tatsuki Tsujimori[1], King Chang[2], Jun-Ichi Kimura[2]

1. Tohoku University, 2. Japan Aegency for Marine-Earth Science and Technology

Boron isotope study of serpentinites in the Franciscan Complex using an ablation volume correction (AVC) LA-MC-ICPMS discriminates two groups (Yamada et al., 2018 JpGU abstr.; Yamada et al. 2019, in press). Serpentinites associated with blueschists are characterized by lighter boron isotope than serpentinites without blueschist-facies rocks. The lighter boron isotope signature (< ~10 ‰) of blueschist-bearing serpentinites results from interaction with forearc slab fluids with low δ^{11}B in deeper depth. In order to evaluate the versatility of B isotopes and composition of high-pressure metamorphosed serpentinites, we investigated antigorite serpentinites associated with three different type of high-pressure metamorphic rocks in the Itoigawa–Omi area.

The investigated serpentinites can be grouped into two types based on the B isotopes. Antigorite serpentinite with blueschist- and eclogite-facies metamorphic rocks in the Yunotani Valley is characterized by moderate boron (12.5–48.4 $\mu g \cdot g^{-1}$) and lower δ^{11}B (+6.6 to +12.3‰ [mostly smaller than +8‰]; n= 10); Brucite-bearing antigorite serpentinite with barroisite-bearing mafic schist in the Kotaki-gawa River is characterized by very high boron (37.5 –302 $\mu g \cdot g^{-1}$) and lower δ^{11}B (+5.8 to +10.7‰ [mostly smaller than +8‰]; n= 10). In contrast, antigorite serpentinite with garnet amphibolite in the Omi-gawa River is characterized by a wide range of boron (9.1–145 $\mu g \cdot g^{-1}$) and relatively high δ^{11}B (+11.5 to + 14.8 ‰; n= 10).

Our preliminary reconnaissance shows significantly lower δ^{11}B (smaller than +8‰) in antigorite serpentinites of the 'Eclogite Unit' proposed by Tsujimori (2002). This trend is consistent with our earlier study in the Franciscan Complex. The antigorite serpentinites in the 'Eclogite Unit' might have been affected by a deep forearc slab fluids.

Study of zircons structures from the Miocene Shibi-san Granodiorite, Kagoshima Prefecture, Japan

*Nakabayashi Marimo[1], REHMAN Ur Hafiz[1]

1. Kagoshima University

The Miocene granodiorite body (zircon fission track age by Miyachi, 1985) of the Mount Shibi, Kagoshima prefecture is a lenticular stock that intrudes the Cretaceous sedimentary rocks of the Shimanto belt. Previous studies subdivided the granodiorite body into the Kusu-bae (core facies) and Hira-bae (marginal facies) types based on the changes in litho-facies and distinct chemical composition of biotite and amphibole (Yamamoto et al., 1988). We conducted field survey in the study area and found no clear contrasts to sub-divide the body, instead it represents a single pluton with local chemical variation along the marginal portions. Based on detailed petrography, the entire body appears as homogeneous stock exhibiting identical mineral assemblage with no clear evidence that can mark the boundary between Kusu-bae and Hira-bae types. Moreover, to understand the processes of magmatic crystallization we investigated more than 600 zircon grains from about 8 samples for external (applying the zircon morphology method of Pupin, 1980) and internal morphology using the Cathodoluminescence imaging. Based on the Pupin’ s method, the deduced temperature range for the zircon crystallization was between 750 and 850℃. In addition, internal structures of zircon (CL images) showed oscillatory zoning with continuous growth domains and abundant apatite inclusions, suggesting the magma was fluid-rich and have been crystallized under relatively higher temperature. We also investigated zircons from the surrounding hornfels (Shimanto belt rocks) that were affected thermally due to the contact metamorphism. Zircons from the hornfels are completely different and rounded with different internal structures. Zircons from the so-called Kusu-bae and Hira-bae types are identical and suggest their crystallization from a single parental magma hence the pluton cannot be sub divisible.

Experimental modeling of eclogite and C-O-H fluid interaction in the subduction zones

*Nadezda Chertkova[1], Shigeru Yamashita[2], Hiroaki Ohfuji[1], Tetsuo Irifune[1], Hirokazu Kadobayashi[1], Yoshitaka Yamamoto[3]

1. Ehime University, Geodynamics Research Center, 2. Okayama University, Institute for Planetary Materials, 3. National Institute of Advanced Industrial Science and Technology

The presence of volatile components controls melting relationships in the subducting oceanic plate and the overlying mantle wedge, affecting their physical properties and seismic observables. The major volatile species in the mantle low oxygen fugacity environment are considered to be H_2O and CH_4, as estimated for mantle xenoliths and C-O-H fluid speciation in equilibrium with diamond [1,2]. Experimental studies with the direct monitoring of phase assemblages and melting relationships in the silicate systems with C-O-H components can shed light on the processes, which take place in the subduction zones, and provide important data for interpretation of observed physical parameters.
In this study, we employed *in situ* spectroscopic methods in combination with the diamond anvil cell (DAC) technique for investigation of C-O-H fluid behavior and its influence on phase relationships in the eclogite–5.75H_2O–CH_4 system at temperatures up to 1000 degree C and pressures exceeding 5 GPa. We designed a new cell assembly for Mao-type symmetric diamond anvil cell with large optical access to the sample in order to make it suitable for infrared and Raman measurements directly at high-pressure and high-temperature conditions. Mineral phase assemblages, observed during experiments, are consistent with those described in the dry system of the similar basaltic composition [3]. At the same time, miscibility between aqueous and carbonaceous components in the fluid phase coexisting with silicate minerals was confirmed at temperatures above 800 degree C and pressures above 3.2 GPa.

Microfabrics of omphacite and garnet in eclogite from the Lanterman Range, northern Victoria Land, Antarctica

*Daeyeong Kim[1], Taehwan Kim[2], Jungmin Kim[3]

1. Division of Polar-Earth Sciences, Korea Polar Research Institute, 2. School of Earth and Environmental Sciences, Seoul National University, 3. Earth and Environmental Sciences, Korea University

Layered structures in metamorphic rocks are sometimes crucial to occur strain localization then affect to seismic properties. We conducted microstructural analyses omphacite and garnet in foliated eclogite from the Lanterman Range, northern Victoria Land, Antarctica, to determine the influence of the layered structure on seismic observations in subduction zone. The analyzed eclogite, composed of layered garnet-rich and omphacite-rich layers, shows the low aspect ratios, similar angular distribution of long axes relative to the foliation, uniform grain size distribution, near-random crystallographic preferred orientations (CPOs), and misorientation angle distributions of garnet and opposite characteristics of omphacite in both layers. The results of fabric analyses are consistent with strain localization into omphacite or omphacite-rich layers rather than garnet or garnet-rich layers. Our results therefore demonstrate the importance of the layered structure in strain localization and in the development of the seismic anisotropies of subducting oceanic crust.

Primordial Apatite from Ophiolite in Taiwan

*Nobuaki Niitsuma[1], Reishi Takashima[2], Yuan Hsi Lee[3]

1. Institute of Geosciences,Shizuoka University, 2. Tohoku University Museum, 3. National Chung-Cheng University, Taiwan

Apatite is a common accessory mineral in igneous rocks. Because apatite has a wide range of trace element compositions as well as strong resistance to diagenetic alteration, the trace element composition of apatite has been used for tracing petrogenetic processes of plutonic bodies as well as the tephrochronology of Paleozoic tephras and Quaternary volcaniclastic deposits.

We studied trace element compositions of apatites from Ophiolite in Taiwan. The Ophiolite with mafic-ulatramafic rocks (150811-14) expose along the anticlinal axes of the metamorphic belts in Backbone Range of Taiwan, and exotic gabbro block (MA-15B) in chaotic deposits of Lichi Melange, in the southern end of Longitudinal Valley, in East Taiwan.

Lee (2015 JpGU; Chen et al., 2017 Tectonics) reported that zircon ages of Ophiolites in Taiwan are concentrated to 15 Ma, which should relate with termination of spreading in South China Sea and Shikoku & Parece Vela Basin just before Japan Sea Opening, and large scale igneous activities in the Outer Zone of Southwest Japan just after Japan Sea Opening (Niitsuma & Lee, 2018 JpGU).

Fifteen and twelve apatite phenocrysts from samples of MA-15B and 150811-14 were analyzed for major and minor elements using a JEOL 8530F wavelength dispersive Electron Probe Micro Analyzer (Takashima et al., 2017 Quaternary Geochronology) in weight % as follow;
__major elements: P=17.956 +/-0.100, 17.926 +/-0.129
_____Ca=38.362 +/-0.329, 38.128 +/-0.273
_____F=1.082+/-0.151, 0.445+/-0.046
__trace elements: Cl<0.01, 0.04 Mg<0.01, 0.01 Mn<0.04, 0.05
_____Fe<0.03, 0.17 Ce<0.09, 0.05 Y<0.13, 0.04

The contents of trace elements are extremely low and we concluded the apatite might be primordial without any contaminations and petrogenetic effect, and crystallized directly in the magma above rifted mantle along the northwestern margin of West Philippine Basin just before Japan Sea Opening.

The evolution of the Cretaceous Jinan Basin in South Korea and the age and tectonic setting for the volcanic rocks in it

*Seung Hwan LEE[1], Chang Whan Oh[1]

1. Department of earth and environmental sciences Chonbuk national university

The Jinan Basin is one of the Cretaceous pull-apart basins in the South Korea. It locates along the Yongdong-Gwangju fault system and consists of non-marine sediments with volcanic and pyroclastic rocks. The sinistral strike slip movement which formed the Cretaceous pull apart basins was occurred by the collision between Siberian and Manchuria blocks at ca. 130~100Ma. LA-MC-ICPMS age dating on the zircons from sedimentary and igneous rocks indicates followings. The sedimentation in the Jinan Basin had started at least from 97.7Ma and continued until 89.47Ma. During the sedimentation, basaltic andesite extruded at 90-92 Ma and later rhyolitc and andesitic magma intruded the Jinan Basin at 90-89 Ma and 85-84 Ma respectively. Later the Jinan Basin uplifted to form Noryeong mountain range due to the compression which was related with dextral strike slip fault movement. This fault movement is expected to be caused by the collision between Indian plate and Eurasian plate at ca. 55~25Ma. AFT(Apatite Fission Track) age from sediments in the Jinan Basin is approximately 68Ma. Due to the formation of Noryeong mountain range, the *Coreoleuciscus splendidus* was differentiated into two species, these two species of *Coreoleuciscus splendidus* have the same ancestors at around 38Ma. These data indicate that the Noryeong mountain range including the Jinan Basin are expected to have uplifted at around 68-38Ma. Rhyolitic volcanic rocks in and around the Jinan Basin are plotted on the VAG (Volcanic Arc Granite) field and basaltic to intermediated volcanic rocks are plotted on the CAB (Calc-Alkaline Basalt) and WPB (WIthin Plate Basalt) fields in the tectonic discrimination diagrams. There was a roll back of subduction zone toward Pacific ocean at ca. 100 Ma. These data suggest that the igneous rocks in the Jinan Basin formed by the mantle upwelling due to extension caused by the roll back of subduction zone. The upwelling asthenospheric mantle supplied heat which caused the felsic magma by the melting of the lithospheric mantle and crust which had been contaminated by crustal material supplied from subducting sediment or ocean before roll back of the subduction zone. The upwelling asthenospheric mantle was also melted to form basaltic magma. The deep faults formed by sinistral strike slip movement around the Jinan Basin at the Cretaceous, gave the path toward surface for the magma at deep depth.

GEOCHORONOLOGY AND PETROCHEMISTREY OF LATE PALEOZOIC MAGMATIC ROCKS OF THE MANDAKH AREA, SOUTHEAST MONGOLIA

*Undarmaa Batsaikhan[1], Noriyoshi Tsuchiya[1], Masaoki Uno[1], Yukio Isozaki[2], Uyanga Bold[2], Hikaru Sawada[2]

1. Graduate School of Environmental Studies, Tohoku University, 2. Graduate School of Arts and Sciences The University of Tokyo

The southeast Mongolia has become a major survey area for unraveling the Paleozoic tectonic evolution because Mongolia occupies the central part of the CAOB which is enormous and composed of a multiplicity of terranes including ancient island and continental arcs, ophiolites, passive continental margins, Precambrian continental blocks and high-T/low-P metamorphic zones and where porphyry Cu deposits occur. The late Paleozoic magmatic rocks are widely distributed in the Mandakh area which is located in the Curvansaikhan and Manlai terrains, in the southeast Mongolia. We will discuss petrochemical features, mineral assemblage and new geochronological constrain of magmatic rocks in the Mandakh area. Furthermore, we compared petrochemical characteristics of the Mandakh area with Tampakan deposit (Philippines), Cerro Colorado deposit (Chili) and negative criteria of Cu deposits (Japan) in order to characterize potential of the porphyry copper deposit in Mandakh area.

The Mandakh area’ s igneous rocks the geochemical features are calc-alkaline, magnetite-series, I type and similar to adakite type. The Devonian intrusive rocks comprised of syenite and syenogranite, while the Carboniferous intrusive rocks consist of granodiorite, monzodiorite, quartz-monzonite and hornblende granite. Devonian magmatic rocks are more alkali in composition. Although Devonian and Carboniferous igneous rocks in the Mandakh area are a little different each other, these igneous rocks are possibility copper deposits as suggested by petrochemical comparisions with bonanza copper deposits in the world.

Feedbacks Offshore the Cascadia Margin

*Joan S Gomberg[1]

1. USGS Earthquake Science Center

A growing body of evidence from the Cascadia subduction zone in the U.S. Pacific Northwest suggests that there are significant feedbacks among the offshore upper-plate material properties, geologic and geomorphic structures, seismic shaking, sediment redistribution, and mega-thrust slip behaviors. Analyses of seafloor seismic data show that the thick accretionary wedge sediments amplify and prolong shaking by low-frequency seismic waves and attenuate high frequencies (Gomberg, 2018). This strong contrast in shaking feeds back into reshaping the sediments, by controlling where they are likely to be destabilized and redistributed by shaking. Analyses of submarine landslide morphology and numerical modeling of slope strength suggest that different feedbacks, perhaps related to shaking-induced sediment compaction, may actually make sediments stronger (ten Brink et al., 2016; Scholz et al., 2016). Understanding of these contrasting influences in turn feeds into interpretations of turbidites as proxies for paleo-earthquakes, and hazard assessments based on earthquake recurrence models derived from them; for example, regions with greater numbers of turbidites may reflect permanent features of the shaking that are more suitable to trigger failure, but may be interpreted as indicative of a greater rate of earthquakes. Abrupt strike-perpendicular changes in shaking characteristics, apparent along most of the length of the margin, coincide with sharp gradients in topography and structure along the edge of the continental shelf. This same apparent boundary along the shelf-edge also coincides with concentrations of methane bubble plumes, with gas characteristics indicative of origins within the accretionary prism. One explanation is that the shelf is bounded by faults that connect with the megathrust and act as conduits for gas extrusion, some of which may connect with the megathrust directly or indirectly. This suggests another feedback, as structural changes promote or are caused by faulting, which itself permits pore pressure changes that modify the potential for additional faulting. Taken together, the aforementioned correlations and others observed between areas of non-volcanic tremor with gravity lows, crustal faulting patterns, and marginal basins, imply feedbacks between processes along the megathrust and upper plate structure (Wells et al., 2017). To reduce the degree of speculation about some of these feedbacks, several major experiments are planned and underway. These experiments, to be summarized in this presentation, will image the margin structure with sufficient resolution to identify and characterize faults, map changes in material properties, and more, along nearly the entire length of the Cascadia margin.

[E] Poster | S (Solid Earth Sciences)：S-MP Mineralogy & Petrology

Tue. May 28, 2019 5:15 PM - 6:30 PM JST | Tue. May 28, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_32

[S-MP29] Oceanic and Continental Subduction Processes

convener:REHMAN Ur Hafiz(Department of Earth and Environmental Sciences, Graduate School of Science and Engineering, Kagoshima University), Tatsuki Tsujimori(Tohoku University), Chin-Ho Tsai(Department of Natural Resources and Environmental Studies, National Dong Hwa University), Kazuaki Okamoto(Faculty of Education, Saitama University)

This JpGU-AGU joint session aims at bringing earth scientists from Japan and overseas to present their research related to the processes of oceanic and continent subduction, continent-continent collisions, metamorphism of crustal rocks, formation of the oceanic/continental arcs, and accretion/ tectonic erosion of material along subduction boundaries.

Topics such as role of the fore- and back-arcs in the subduction zones, process of accretion of volcaniclastic and terrigenous sediments along the subduction/collision boundaries, deformation and metamorphism of subducted crust, and exhumation will be the main focus of the session.

In addition to the above mentioned topics, our focus for the10th anniversary of this international session will be towards our understanding and progress on the ultrahigh-pressure/temperature metamorphic terranes in the world.

Exchange of ideas among geoscientists applying different approaches on problems related to the theme of the session are most welcome.

Zircon U-Pb ages of metasedimentary rocks in the Hakogase (Hida Marginal) area, Fukui Prefecture.

*Atsushi MIYASHITA[1], Tatsuki Tsujimori[2], Daniel Pastor-Galán[3], Yi Keewook[4]

1. Seikei University, 2. Tohoku University, 3. Salamanca University, 4. Korea Basic Science Institue

Combined chronological study using detrital zircon U-Pb dating and phengite K-Ar dating enables to understand the tectonic evolution of the high *P/T* metamorphic belt. The youngest age of detrital zircon U-Pb ages of psamites in the Hida marginal metamorphic rocks (HMMR = Renge belt) approximate its depositional ages (Tsutsumi et al., 2009). The closure temperature of the phengite K-Ar ages are controlled by deformation and recrystallization during exhumation of the metamorphic rocks(Itaya and Tsujimori, 2015). Therefore, the gap between the youngest age of detrital zircons and phengite K-Ar ages are the age difference between subuduction and uplift of metamorphics.
The Hakogase (Nigure-gawa, Kuzuryu, Fukui Prefecture) metamorphic rocks belong to HMMR member as the olistolith in the Cretaceous Tedori Group. It consists mainly pelites with small amount of basites and mables. The main index mineral assemblage of metasediments are garnet + chlorite, and the phenigite K-Ar ages are 287.8 - 283.6 Ma (Kunugiza et al., 2004). Relic Lawsonite was also found in the basaites and psamites (Miyakawa, 1982).
The detrital Zircons U-Pb ages in the two pelites are obtained by the SHRIMP II of KBSI. The youngest U-Pb ages of detrital zircons are 307Ma. The gap of the sedimentation between uplift of the Hakogase metamorphics is estimated 20 Ma. This value means the migration speed of the HMMR metamorphic rocks are 1/10 of plate motion. This rapid migration speed is common for the high *P/T* metamorphic rocks.

Late Permian to Early Triassic back-arc type volcanism in the southern Mongolia volcano-plutonic belt of the Central Asian Orogenic Belt: Implication for timing of the final closure of the Palaeo-Asian Ocean

*Takeshi Imayama[1], Yoichiro Koh[2], Kazumasa Aoki[3], Mototaka Saneyoshi[4], Koshi Yagi[5], Shogo Aoki[4], Yoshihiro Sawada[6], Chiaki Ikawa[5], Tomoya Terada[4], Shinobu Ishigaki[4], Shin Toyoda[3], Khishigjav Tsogtbaatar[7], Buuvei Mainbayar[7]

Faculty of Biosphere - Geosphere Science, Okayama University of Science, 5. Hiruzen Institute for Geology and Chronology, 6. Emeritus Professor of Shimane University, 7. Institute of Paleontology and Geology, Mongolian Academy of Sciences

The timing of final subduction and closure of the Palaeo-Asian Ocean is still controversial in the eastern segments of the Central Asian Orogenic Belt (CAOB). A more detailed understanding is needed with respect to the formation of volcanic rocks and sediments associated with the final closure of the Palaeo-Asian Ocean in southern Mongolia. We investigated alkali series volcanic rocks newly discovered in the southern Mongolia volcano-plutonic belt of the CAOB and classified as basalt, basaltic trachyandesite, andesite, trachyandesite, and trachyte, mainly showing andesitic-dacitic compositions. In Harker diagrams, the TiO_2, FeO, MnO, Al_2O_3, CaO, and MgO contents generally decrease with increasing SiO_2, representing a series of differentiated volcanic rocks. The primitive mantle-normalized trace element spider diagram is characterized by incompatible element-rich patterns and negative Nb anomalies. The tectonic discrimination diagrams show that the volcanic rocks were formed by arc-related volcanism rather than within-plate volcanism. K-Ar dating of feldspars from six volcanic rocks yields ages ranging from 270 to 239 Ma, indicating that andesitic and dacitic magmatism occurred during this period. These geochemical and geochronological data indicate that the differentiated volcanic rocks intruding middle to late Palaeozoic volcanic sediments were formed by back-arc type subduction ca. 270–240 Ma. Based on detrital zircon U-Pb ages, the terrigenous sandstones underlain by the volcanic sediments record a maximum depositional age of Late Triassic (ca. 220–200 Ma) and include a main cluster of Early Devonian ages (ca. 410–390 Ma), possibly derived from the Devonian-Carboniferous arc complex observed surrounding this study area. These results from the volcanic and sedimentary rocks in this study, combined with investigations in previous studies, imply that subduction beneath the eastern segments of the CAOB to consume the Palaeo-Asian Ocean continued until Late Permian to Early Triassic.

Mantle dynamics of slab breakoff constrained from the temporal change of the melting depth estimated from the Cumulate Member of the Ordovician Hayachine-Miyamori Ophiolite

*Takafumi Kimura[1], Kazuhito Ozawa[1]

1. Department of Earth and Planetary Science, The University of Tokyo

Slab breakoff, detachment of oceanic lithosphere highly expected during arc-continent collision, is one of the important mechanisms inducing passive upwelling of the asthenosphere and magma generation in arc environments [1]. In order to better understand the mantle dynamics of slab breakoff, we need to use continuous geological record with high time resolution. In this study, we have extracted a record of temporal change of the magma generation depth from cumulates in an Ordovician arc ophiolite at a time resolution of several tens of million years.
The Hayachine-Miyamori Ophiolite, northern Japan, is one of the Ordovician ophiolite formed in an arc environment [2]. The ultramafic member was built up by three main magmatic stages, which are recorded in three rock units: Tectonite Member, Cumulate Member, and ultramafic dikes, in the order of formation ages. The last two units in the entire evolution of the ophiolite is explained by decompressional melting of sub-slab mantle triggered by slab breakoff [2][3]. The melting depth of an ultramafic magma solidified as dikes in the Cumulate Member is estimated to be ~170km [3]. Our recent field study clarified a large-scale stratification characterized by alternation of wehrlite-dominant and dunite-dominant layers in the Cumulate Member. Each layer has a thickness from several meters to ~1 km and, the total thickness attains ~3km. Moreover, we succeeded in specifying the strike and plunge of the gravity field to be ~N48°E and ~20°NE during the cumulate formation from field information and westward stratigraphic younging [4].
We estimated the temporal change of generation depth of parent magmas of the Cumulate Member by garnet signature in heavy rare earth elements (HREEs) as depth proxy. The information may constrain the mantle dynamics during the slab breakoff. We examined stratigraphic variation of HREE ratio at the core of clinopyroxenes over the thickness of ~2km in the Cumulate Member. The obtained variation of the Dy/Lu increases from ~12.9 to ~16.5 with increasing the stratigraphic height. We estimated the extent of melting in the garnet stability field increasing from ~50 to ~90% of the total melting by applying an open-system fractional melting model to reproduce the Dy/Lu variation.
We also estimated the time scale of formation of the Cumulate Member by using cm –10cm scale heterogeneity recorded in contact zone of intruded magma and the host. The profile of Mg# of olivine in xenoliths of the Tectonite Member occurring at the bottom of the Cumulate Member shows that the cooling time is less than several tens of million years [5]. The dunite of the Cumulate Member contacting the ultramafic dike shows a systematic decrease of Mg# from 90 to 86.8 over the distance of 54 mm towards the contact. We calculated the time scale of subsolidus diffusional exchange between the dunite and dike and obtained several tens of million years at ~1000℃. The host was kept at a high temperature when the dikes intruded because of the absence of chilled margin. We thus estimated time scale of formation of the Cumulate Member to be < several tens of million years.
We propose the following tectonic model in the Ordovician northern Japan on the basis of the above result. The slab breakoff took place at the depth slightly deeper than the boundary of spinel and garnet stability fields (~80 km) and induced counter flow and adiabatic melting of the sub-slab mantle. The melting depth deepened down to ~170 km on the time scale of several tens of million years, which corresponds to the time scale to complete the slab breakoff. The sinking velocity of the slab is more than

Evidence of HIMU seamount on the Farallon Plate: Application of *in-situ* Sr-Pb isotope analysis to Franciscan lawsonite-bearing metagreywacke

*Tomomi Hara[1], Tatsuki Tsujimori[1], Jun-Ichi Kimura[2]

1. Tohoku University, 2. Japan Agency for Marine-Earth Science and Technology

Since bulk isotopic composition of oceanic basalt is susceptible to element remobilization during alteration process, there is a risk of causing misread of geochemical signatures from bulk metabasaltic rocks in subduction complex. As Hara et al. (2018) demonstrated, however, *in-situ* Sr-Pb isotope analysis of lawsonite in high-pressure metabasaltic rocks has a great potential for tracing the geochemical signatures reflecting the igneous protolith. In this study, we have applied the method to lawsonite in metasedimentary rocks to explore clastic components of a trench-fill sediment. A jadeite-bearing Franciscan metagreywacke from Pacheco Pass area, east-central Diablo Range, California Coast Ranges was selected for geochemical reconnaissance.

Lawsonites in the Franciscan metagreywacke record a high initial Pb isotope ratios ($^{206}Pb/^{204}Pb$ = 18.74–19.66, $^{207}Pb/^{204}Pb$ = 15.58–15.70 and $^{208}Pb/^{204}Pb$ = 38.41–39.34). This Pb-isotope signature suggests that a protolith of the metagreywacke have contained a debris derived from a HIMU-type basalt. Considering the maximum depositional age of the metagreywacke at ~102 Ma, the underflow of the Farallon Plate beneath continental crust of the North American Plate would have carried a HIMU seamount to a Franciscan trench.

Our study has demonstrated the potential application of 'lawsonitology' as sedimentary provenance analyses for metamorphosed accretionary complex. Moreover, the results would manifest that Pb isotopic signature of ancient oceanic basalt can be detectable from Ca-Al silicate mineral, such as lawsonite, epidote and pumpellyite, in metamorphic rocks.

Boron isotope variations of antigorite serpentinites associated with high-pressure metamorphic rocks: A case study in the Itoigawa–Omi area of the Hida-Gaien Belt, Japan

*Chinatsu Yamada[1], Tatsuki Tsujimori[1], King Chang[2], Jun-Ichi Kimura[2]

1. Tohoku University, 2. Japan Aegency for Marine-Earth Science and Technology

Boron isotope study of serpentinites in the Franciscan Complex using an ablation volume correction (AVC) LA-MC-ICPMS discriminates two groups (Yamada et al., 2018 JpGU abstr.; Yamada et al. 2019, in press). Serpentinites associated with blueschists are characterized by lighter boron isotope than serpentinites without blueschist-facies rocks. The lighter boron isotope signature (< ~10 ‰) of blueschist-bearing serpentinites results from interaction with forearc slab fluids with low δ^{11}B in deeper depth. In order to evaluate the versatility of B isotopes and composition of high-pressure metamorphosed serpentinites, we investigated antigorite serpentinites associated with three different type of high-pressure metamorphic rocks in the Itoigawa–Omi area.

The investigated serpentinites can be grouped into two types based on the B isotopes. Antigorite serpentinite with blueschist- and eclogite-facies metamorphic rocks in the Yunotani Valley is characterized by moderate boron (12.5–48.4 $\mu g \cdot g^{-1}$) and lower δ^{11}B (+6.6 to +12.3‰ [mostly smaller than +8‰]; n= 10); Brucite-bearing antigorite serpentinite with barroisite-bearing mafic schist in the Kotaki-gawa River is characterized by very high boron (37.5 –302 $\mu g \cdot g^{-1}$) and lower δ^{11}B (+5.8 to +10.7‰ [mostly smaller than +8‰]; n= 10). In contrast, antigorite serpentinite with garnet amphibolite in the Omi-gawa River is characterized by a wide range of boron (9.1–145 $\mu g \cdot g^{-1}$) and relatively high δ^{11}B (+11.5 to + 14.8 ‰; n= 10).

Our preliminary reconnaissance shows significantly lower δ^{11}B (smaller than +8‰) in antigorite serpentinites of the 'Eclogite Unit' proposed by Tsujimori (2002). This trend is consistent with our earlier study in the Franciscan Complex. The antigorite serpentinites in the 'Eclogite Unit' might have been affected by a deep forearc slab fluids.

Study of zircons structures from the Miocene Shibi-san Granodiorite, Kagoshima Prefecture, Japan

*Nakabayashi Marimo[1], REHMAN Ur Hafiz[1]

1. Kagoshima University

The Miocene granodiorite body (zircon fission track age by Miyachi, 1985) of the Mount Shibi, Kagoshima prefecture is a lenticular stock that intrudes the Cretaceous sedimentary rocks of the Shimanto belt. Previous studies subdivided the granodiorite body into the Kusu-bae (core facies) and Hira-bae (marginal facies) types based on the changes in litho-facies and distinct chemical composition of biotite and amphibole (Yamamoto et al., 1988). We conducted field survey in the study area and found no clear contrasts to sub-divide the body, instead it represents a single pluton with local chemical variation along the marginal portions. Based on detailed petrography, the entire body appears as homogeneous stock exhibiting identical mineral assemblage with no clear evidence that can mark the boundary between Kusu-bae and Hira-bae types. Moreover, to understand the processes of magmatic crystallization we investigated more than 600 zircon grains from about 8 samples for external (applying the zircon morphology method of Pupin, 1980) and internal morphology using the Cathodoluminescence imaging. Based on the Pupin’ s method, the deduced temperature range for the zircon crystallization was between 750 and 850℃. In addition, internal structures of zircon (CL images) showed oscillatory zoning with continuous growth domains and abundant apatite inclusions, suggesting the magma was fluid-rich and have been crystallized under relatively higher temperature. We also investigated zircons from the surrounding hornfels (Shimanto belt rocks) that were affected thermally due to the contact metamorphism. Zircons from the hornfels are completely different and rounded with different internal structures. Zircons from the so-called Kusu-bae and Hira-bae types are identical and suggest their crystallization from a single parental magma hence the pluton cannot be sub divisible.

Experimental modeling of eclogite and C-O-H fluid interaction in the subduction zones

*Nadezda Chertkova[1], Shigeru Yamashita[2], Hiroaki Ohfuji[1], Tetsuo Irifune[1], Hirokazu Kadobayashi[1], Yoshitaka Yamamoto[3]

1. Ehime University, Geodynamics Research Center, 2. Okayama University, Institute for Planetary Materials, 3. National Institute of Advanced Industrial Science and Technology

The presence of volatile components controls melting relationships in the subducting oceanic plate and the overlying mantle wedge, affecting their physical properties and seismic observables. The major volatile species in the mantle low oxygen fugacity environment are considered to be H_2O and CH_4, as estimated for mantle xenoliths and C-O-H fluid speciation in equilibrium with diamond [1,2]. Experimental studies with the direct monitoring of phase assemblages and melting relationships in the silicate systems with C-O-H components can shed light on the processes, which take place in the subduction zones, and provide important data for interpretation of observed physical parameters.
In this study, we employed *in situ* spectroscopic methods in combination with the diamond anvil cell (DAC) technique for investigation of C-O-H fluid behavior and its influence on phase relationships in the eclogite–5.75H_2O–CH_4 system at temperatures up to 1000 degree C and pressures exceeding 5 GPa. We designed a new cell assembly for Mao-type symmetric diamond anvil cell with large optical access to the sample in order to make it suitable for infrared and Raman measurements directly at high-pressure and high-temperature conditions. Mineral phase assemblages, observed during experiments, are consistent with those described in the dry system of the similar basaltic composition [3]. At the same time, miscibility between aqueous and carbonaceous components in the fluid phase coexisting with silicate minerals was confirmed at temperatures above 800 degree C and pressures above 3.2 GPa.

Microfabrics of omphacite and garnet in eclogite from the Lanterman Range, northern Victoria Land, Antarctica

*Daeyeong Kim[1], Taehwan Kim[2], Jungmin Kim[3]

1. Division of Polar-Earth Sciences, Korea Polar Research Institute, 2. School of Earth and Environmental Sciences, Seoul National University, 3. Earth and Environmental Sciences, Korea University

Layered structures in metamorphic rocks are sometimes crucial to occur strain localization then affect to seismic properties. We conducted microstructural analyses omphacite and garnet in foliated eclogite from the Lanterman Range, northern Victoria Land, Antarctica, to determine the influence of the layered structure on seismic observations in subduction zone. The analyzed eclogite, composed of layered garnet-rich and omphacite-rich layers, shows the low aspect ratios, similar angular distribution of long axes relative to the foliation, uniform grain size distribution, near-random crystallographic preferred orientations (CPOs), and misorientation angle distributions of garnet and opposite characteristics of omphacite in both layers. The results of fabric analyses are consistent with strain localization into omphacite or omphacite-rich layers rather than garnet or garnet-rich layers. Our results therefore demonstrate the importance of the layered structure in strain localization and in the development of the seismic anisotropies of subducting oceanic crust.

Primordial Apatite from Ophiolite in Taiwan

*Nobuaki Niitsuma[1], Reishi Takashima[2], Yuan Hsi Lee[3]

1. Institute of Geosciences,Shizuoka University, 2. Tohoku University Museum, 3. National Chung-Cheng University, Taiwan

Apatite is a common accessory mineral in igneous rocks. Because apatite has a wide range of trace element compositions as well as strong resistance to diagenetic alteration, the trace element composition of apatite has been used for tracing petrogenetic processes of plutonic bodies as well as the tephrochronology of Paleozoic tephras and Quaternary volcaniclastic deposits.

We studied trace element compositions of apatites from Ophiolite in Taiwan. The Ophiolite with mafic-ulatramafic rocks (150811-14) expose along the anticlinal axes of the metamorphic belts in Backbone Range of Taiwan, and exotic gabbro block (MA-15B) in chaotic deposits of Lichi Melange, in the southern end of Longitudinal Valley, in East Taiwan.

Lee (2015 JpGU; Chen et al., 2017 Tectonics) reported that zircon ages of Ophiolites in Taiwan are concentrated to 15 Ma, which should relate with termination of spreading in South China Sea and Shikoku & Parece Vela Basin just before Japan Sea Opening, and large scale igneous activities in the Outer Zone of Southwest Japan just after Japan Sea Opening (Niitsuma & Lee, 2018 JpGU).

Fifteen and twelve apatite phenocrysts from samples of MA-15B and 150811-14 were analyzed for major and minor elements using a JEOL 8530F wavelength dispersive Electron Probe Micro Analyzer (Takashima et al., 2017 Quaternary Geochronology) in weight % as follow;
__major elements: P=17.956 +/-0.100, 17.926 +/-0.129
_____Ca=38.362 +/-0.329, 38.128 +/-0.273
_____F=1.082+/-0.151, 0.445+/-0.046
__trace elements: Cl<0.01, 0.04 Mg<0.01, 0.01 Mn<0.04, 0.05
_____Fe<0.03, 0.17 Ce<0.09, 0.05 Y<0.13, 0.04

The contents of trace elements are extremely low and we concluded the apatite might be primordial without any contaminations and petrogenetic effect, and crystallized directly in the magma above rifted mantle along the northwestern margin of West Philippine Basin just before Japan Sea Opening.

The evolution of the Cretaceous Jinan Basin in South Korea and the age and tectonic setting for the volcanic rocks in it

*Seung Hwan LEE[1], Chang Whan Oh[1]

1. Department of earth and environmental sciences Chonbuk national university

The Jinan Basin is one of the Cretaceous pull-apart basins in the South Korea. It locates along the Yongdong-Gwangju fault system and consists of non-marine sediments with volcanic and pyroclastic rocks. The sinistral strike slip movement which formed the Cretaceous pull apart basins was occurred by the collision between Siberian and Manchuria blocks at ca. 130~100Ma. LA-MC-ICPMS age dating on the zircons from sedimentary and igneous rocks indicates followings. The sedimentation in the Jinan Basin had started at least from 97.7Ma and continued until 89.47Ma. During the sedimentation, basaltic andesite extruded at 90-92 Ma and later rhyolitc and andesitic magma intruded the Jinan Basin at 90-89 Ma and 85-84 Ma respectively. Later the Jinan Basin uplifted to form Noryeong mountain range due to the compression which was related with dextral strike slip fault movement. This fault movement is expected to be caused by the collision between Indian plate and Eurasian plate at ca. 55~25Ma. AFT(Apatite Fission Track) age from sediments in the Jinan Basin is approximately 68Ma. Due to the formation of Noryeong mountain range, the *Coreoleuciscus splendidus* was differentiated into two species, these two species of *Coreoleuciscus splendidus* have the same ancestors at around 38Ma. These data indicate that the Noryeong mountain range including the Jinan Basin are expected to have uplifted at around 68-38Ma. Rhyolitic volcanic rocks in and around the Jinan Basin are plotted on the VAG (Volcanic Arc Granite) field and basaltic to intermediated volcanic rocks are plotted on the CAB (Calc-Alkaline Basalt) and WPB (WIthin Plate Basalt) fields in the tectonic discrimination diagrams. There was a roll back of subduction zone toward Pacific ocean at ca. 100 Ma. These data suggest that the igneous rocks in the Jinan Basin formed by the mantle upwelling due to extension caused by the roll back of subduction zone. The upwelling asthenospheric mantle supplied heat which caused the felsic magma by the melting of the lithospheric mantle and crust which had been contaminated by crustal material supplied from subducting sediment or ocean before roll back of the subduction zone. The upwelling asthenospheric mantle was also melted to form basaltic magma. The deep faults formed by sinistral strike slip movement around the Jinan Basin at the Cretaceous, gave the path toward surface for the magma at deep depth.

GEOCHORONOLOGY AND PETROCHEMISTREY OF LATE PALEOZOIC MAGMATIC ROCKS OF THE MANDAKH AREA, SOUTHEAST MONGOLIA

*Undarmaa Batsaikhan[1], Noriyoshi Tsuchiya[1], Masaoki Uno[1], Yukio Isozaki[2], Uyanga Bold[2], Hikaru Sawada[2]

1. Graduate School of Environmental Studies, Tohoku University, 2. Graduate School of Arts and Sciences The University of Tokyo

The southeast Mongolia has become a major survey area for unraveling the Paleozoic tectonic evolution because Mongolia occupies the central part of the CAOB which is enormous and composed of a multiplicity of terranes including ancient island and continental arcs, ophiolites, passive continental margins, Precambrian continental blocks and high-T/low-P metamorphic zones and where porphyry Cu deposits occur. The late Paleozoic magmatic rocks are widely distributed in the Mandakh area which is located in the Curvansaikhan and Manlai terrains, in the southeast Mongolia. We will discuss petrochemical features, mineral assemblage and new geochronological constrain of magmatic rocks in the Mandakh area. Furthermore, we compared petrochemical characteristics of the Mandakh area with Tampakan deposit (Philippines), Cerro Colorado deposit (Chili) and negative criteria of Cu deposits (Japan) in order to characterize potential of the porphyry copper deposit in Mandakh area.

The Mandakh area’ s igneous rocks the geochemical features are calc-alkaline, magnetite-series, I type and similar to adakite type. The Devonian intrusive rocks comprised of syenite and syenogranite, while the Carboniferous intrusive rocks consist of granodiorite, monzodiorite, quartz-monzonite and hornblende granite. Devonian magmatic rocks are more alkali in composition. Although Devonian and Carboniferous igneous rocks in the Mandakh area are a little different each other, these igneous rocks are possibility copper deposits as suggested by petrochemical comparisions with bonanza copper deposits in the world.

Feedbacks Offshore the Cascadia Margin

*Joan S Gomberg[1]

1. USGS Earthquake Science Center

A growing body of evidence from the Cascadia subduction zone in the U.S. Pacific Northwest suggests that there are significant feedbacks among the offshore upper-plate material properties, geologic and geomorphic structures, seismic shaking, sediment redistribution, and mega-thrust slip behaviors. Analyses of seafloor seismic data show that the thick accretionary wedge sediments amplify and prolong shaking by low-frequency seismic waves and attenuate high frequencies (Gomberg, 2018). This strong contrast in shaking feeds back into reshaping the sediments, by controlling where they are likely to be destabilized and redistributed by shaking. Analyses of submarine landslide morphology and numerical modeling of slope strength suggest that different feedbacks, perhaps related to shaking-induced sediment compaction, may actually make sediments stronger (ten Brink et al., 2016; Scholz et al., 2016). Understanding of these contrasting influences in turn feeds into interpretations of turbidites as proxies for paleo-earthquakes, and hazard assessments based on earthquake recurrence models derived from them; for example, regions with greater numbers of turbidites may reflect permanent features of the shaking that are more suitable to trigger failure, but may be interpreted as indicative of a greater rate of earthquakes. Abrupt strike-perpendicular changes in shaking characteristics, apparent along most of the length of the margin, coincide with sharp gradients in topography and structure along the edge of the continental shelf. This same apparent boundary along the shelf-edge also coincides with concentrations of methane bubble plumes, with gas characteristics indicative of origins within the accretionary prism. One explanation is that the shelf is bounded by faults that connect with the megathrust and act as conduits for gas extrusion, some of which may connect with the megathrust directly or indirectly. This suggests another feedback, as structural changes promote or are caused by faulting, which itself permits pore pressure changes that modify the potential for additional faulting. Taken together, the aforementioned correlations and others observed between areas of non-volcanic tremor with gravity lows, crustal faulting patterns, and marginal basins, imply feedbacks between processes along the megathrust and upper plate structure (Wells et al., 2017). To reduce the degree of speculation about some of these feedbacks, several major experiments are planned and underway. These experiments, to be summarized in this presentation, will image the margin structure with sufficient resolution to identify and characterize faults, map changes in material properties, and more, along nearly the entire length of the Cascadia margin.

Tue. May 28, 2019 1:45 PM - 3:15 PM JST | Tue. May 28, 2019 4:45 AM - 6:15 AM UTC | A08 TOKYO BAY MAKUHARI HALL

[S-MP29] Oceanic and Continental Subduction Processes

convener:REHMAN Ur Hafiz(Department of Earth and Environmental Sciences, Graduate School of Science and Engineering, Kagoshima University), Tatsuki Tsujimori(Tohoku University), Chin-Ho Tsai(Department of Natural Resources and Environmental Studies, National Dong Hwa University), Kazuaki Okamoto(Faculty of Education, Saitama University), Chairperson:Hafiz REHMAN(Kagoshima University), Tatsuki Tsujimori

This JpGU-AGU joint session aims at bringing earth scientists from Japan and overseas to present their research related to the processes of oceanic and continent subduction, continent-continent collisions, metamorphism of crustal rocks, formation of the oceanic/continental arcs, and accretion/ tectonic erosion of material along subduction boundaries.

Topics such as role of the fore- and back-arcs in the subduction zones, process of accretion of volcaniclastic and terrigenous sediments along the subduction/collision boundaries, deformation and metamorphism of subducted crust, and exhumation will be the main focus of the session.

In addition to the above mentioned topics, our focus for the10th anniversary of this international session will be towards our understanding and progress on the ultrahigh-pressure/temperature metamorphic terranes in the world.

Exchange of ideas among geoscientists applying different approaches on problems related to the theme of the session are most welcome.

Pb-isotope of Fe-Ni alloy associated with serpentinite: Geochemical constraints on the fluid-mediated hyper-reducing environment in mantle wedge

*Mayu Kakefuda[1], Tatsuki Tsujimori[1], Katsuyuki Yamashita[2], Yoshiyuki Iizuka[3]

Although the occurrence of Fe-Ni alloy is very limited in the vicinity of modern Earth’s surface due to the highly oxidized state, serpentinization in the forearc mantle wedge can rarely provide extraordinary reducing environments that stabilizes the Fe-Ni alloy.

In order to understand those fluid-mediated hyper-reducing environments in serpentinizing mantle wedge of an active convergent plate margin, we revisited so-called ‘josephinite' —an unusual ‘metallic rock' composed mainly of Fe-Ni alloy (awaruite)— found in the Josephine Ophiolite, by engaging in microtextural and geochemical analyses.

Microtextural analyses using high-resolution FE-SEM and FE-EPMA found the presence of Ni-As mineral within aggregates of Fe-Ni alloy; the Ni-As mineral also occurs as discrete grains in ‘josephinite'-hosting serpentinite, suggesting that Ni-As mineral acted as a precursor seed before the crystallization of Fe-Ni alloy.

Since each leachate obtained by stepwise leaching of a ‘josephinite' pebble confirmed compositional homogeneity, this allows to calculate weighted mean values that give much precise Pb isotope compositions of aliquots of seventeen leaching steps determined by ID-TIMS; the values yielded $^{207}Pb/^{204}Pb$ = 18.3378 ±0.0016, $^{206}Pb/^{204}Pb$ = 15.5693 ±0.0015, and $^{208}Pb/^{204}Pb$ = 38.0879 ± 0.0044. These newly obtained high precision Pb isotope compositions revealed that the ‘josephinite'-forming fluids have a minor GLOSS-like sedimentary component. The presence of Ni arsenide also supports the infiltration of arsenic-bearing external fluids derived from sedimentary rocks.

Considering the geological context of the Josephine Ophiolite, the ‘josephinite’-forming fluids might have been derived from the top layer of subducting sediments. The lack of high-pressure metamorphic rocks such as blueschist in ‘josephinite'-hosted serpentinite implies that the ‘josephinite' formation might have occurred at a relatively shallow level of serpentinizing mantle wedge.
The absence of carbonate minerals further postulates that redox agent of the ‘josephinite' forming hyper-reducing environment was H_2 evolved by the serpentinization rather than CH_4 that is commonly preserved in blueschist and eclogites. This fact would speculate a widespread hyper-reducing environment caused by H_2 fluids in a shallow level of serpentinizing mantle wedge.

PETROCHEMISTRY AND AGE DETERMINATION OF THE NEWLY DISCOVERED ECLOGITE IN THE WESTERN MONGOLIA

*Kosuke Naemura[1], Erdenjargal Choindonjamts[4], Takenori Kato[5], Otgonkhuu Javkhlan[3], Katsuyoshi Michibayashi[2]

This study report on newly discovered eclogite from the Western Mongolia in the Central Asian Orogenic Belt. Lenticular eclogite bodies with several meters in length are enclosed in quartzite of the Shubun/Urgamal formation in the southernmost part of the Zavkhan block which forms a part of the Neoproterozoic Tuva-Mongolian arc. Trace element patterns of eclogites are like those of OIB. We used relatively fresh eclogite sample and amphibolite sample to reconstruct the pressure-temperature history. Fresh eclogite preserves omphacite (with jadeite 38 mole%) coexisting with garnet ($Alm_{56}Gros_{35}Pyr_{8}$), barroisite, phengite (Si=3.36 apfu, O=11), quartz, epidote, rutile with accessory apatite, calcite, and hematite (assemblage 1). Garnet-core includes paragonite and kyanite coexisting with titanite, quartz, barroisite, which represents prograde stage mineral assemblage (Stage 0). The eclogite assemblages are variably retrogressed into amphibolite assemblage of hornblende, plagioclase, quartz, biotite, Mg-rich garnet-rim ($Alm_{61}Gros_{29}Pyr_{9}$), epidote and titanite (assemblage-2). In amphibolite sample, atoll-shaped garnet is ubiquitously observed. The atoll-shaped garnet consists of the eclogite facies core, Ca-rich mantle ($Alm_{53}Gros_{44}Pyr_{3}$) probably formed during the amphibolite facies stage 2, and a Ca-poor Mg-rich rim (or shell) ($Alm_{64}Gros_{25}Pyr_{10}$). The last Ca-poor garnet rim coexists with plagioclase, hornblende, epidote, quartz, titanite (assemblage-3). The earliest stage of metamorphism might happen in the "lawsonite stability field" if we interpret kyanite formed from paragonite. Subsequent Stage 1 P-T condition was determined at about 2 GPa and 480 ºC by garnet-clinopyroxene-phengite geothermobarometry. The eclogite once experienced decompression to the epidote-amphibolite assembalge equilibrated at ca. 0.8 GPa and 400 ºC during the Stage 2, determined by garnet-hornblende-plagioclase geothermobarometry. After the initial exhumation, the eclogite experienced heating to the high-pressure amphibolite stage 3 formed at ca. 600 ºC and 1.2 GPa. Such multiple P-T paths have been reported from eclogites from collision zones such as Sesia Alps and W.Tianshan. Additionally, we determined U-Pb age of zircon by CHIME method. Zircon typically exhibit oscillatory zoning and are sometimes included at the garnet core. Most zircons are severely altered, with rare fresh core only in large zircon grains (>0.1 mm). We obtained three populations of age at 1170 Ma, 680 Ma and 340 Ma for such zircon fresh cores. If we interpret these ages as igeneous protolith ages, the eclogite-facies metamorphism should have taken place after 340 Ma. Combining the metamorphic history and U-Pb zircon ages, we speculated that the eclogite primarily formed at the ocean island on the Mongol-Okhotsk (MO) ocean. If so, eclogite-facies metamorphism (assemblage 0→1) should have taken place when the MO plate subducted beneath the Siberian craton. Subsequently the eclogite probably separated from the subducting plate and come up to the crustal depth through the subduction channel, and was transformed into epidote-amphibolite assemblage (assemblage 2). Finally, continental collision took place when the N. China craton collide with the Siberian craton to close the MO ocean at 140 Ma, which transformed the rock to high-pressure amphibolite (assemblage 3).

Continental subduction, “*Intraslab UHP Metasomatism*”, and the formation of metamorphic diamond

*Yoshihide Ogasawara[1]

1. Department of Earth Sciences, Waseda University

Deep continental subduction is the process carrying supracrustal materials into deep mantle, and UHP metamorphic rocks are the direct evidence for this process as the materials having the information of P-T and the chemical environments during subduction, escaped from the homogenization with mantle rocks. Usually, UHPM silicate rocks have been strongly retrograded during exhumation, and the preservation of UHPM information is limited excepting inclusions in refractory minerals; decoding the chemical processes in subducted materials is difficult. In carbonate and calc-silicate rocks, UHPM information has been well preserved and can be decoded even in the matrix because the chemical reactions in these rocks make distinct changes from the protolith chemistries, not erased during exhumation.

Carbonate-bearing assemblages have large P-T stabilities at HP/UHP and low H_2O activity, and this indicates high possibility of survival of carbonates and transportation of carbon into deep mantle. H_2O-fluid supply is necessary for metamorphic reactions in these rocks because H_2O-fluid lowers temperatures of decarbonations. As a model showing the processes in deeply subducting continental materials, *Intraslab UHP Metasomatism* (metasomatism within subducting continental materials at UHP mantle depths) will be introduced on the basis of our last 20 years research on the Kokchetav UHPM rocks. In this model, key materials are H_2O and CO_2 in the subducting continental slab, and a key process is H_2O-fluid infiltration within the slab. The outline of this model is as follows. 1) In the subducting slab, silicate rocks (gneisses and eclogite) were a H_2O reservoir, and carbonate and calc-silicate rocks were a CO_2 reservoir. 2) During subduction, H_2O-fluid with several components (e.g. C, K, Ti) occurred by dehydrations of silicate rocks. 3) Dehydrations in silicate rocks preceded decarbonation reactions in carbonate and calc-silicate rocks. 4) Infiltration of H_2O-fluid into carbonate and calc-silicate rocks was a trigger for decarbonations. 5) H_2O-fluid infiltration was controlled by the timing of dehydrations in silicate rocks and vaired in mm to cm scales to form or to characterize the mineral assemblages in carbonate and calc-silicate rocks. 6) H_2O-fluid (with C-bearing species) contributed to the formation of diamond in some carbonate calc-silicate rocks. 7) Modal compositions of carbonates in the protoliths controlled the survival of carbonate depending on the intensity of fluid infiltration.

The following subjects from the Kokchetav UHPM rocks support this model. A) Dolomite marble contains abundant diamond formed at two stages; 2nd stage diamond ($\delta^{13}C$: -17 to -27 ‰) from H_2O-fluid. Dol + Di is not the highest-T assemblage and was controlled by fluid composition, XCO_2 as 0.1, which was suitable for diamond formation. B) Dolomitic marble has the highest-T assemblages, Arg-Fo, Arg-Ti-Chum, but diamond was unstable because of low XCO_2 as 0.01. C) Calcite (after Arg) marble with Coe exsolution in Ttn contains diamond only in Di layer, and other parts do not; this indicates short-term stability of diamond in this rock depending on changing XCO_2. The later fluid was low XCO_2 as 0.02; too low for diamond formation. D) Two types of Grt-Cpx rocks occur; diamond-bearing and diamond-free. Their protoliths are a mixture of silicates and carbonates. Minor diamond occurs as two modes in diamond-bearing Grt-Cpx rock; one is fine-grained (several μm) and the other is cubic (max. 200 μm). A cubic diamond has fine core and crystallized slowly from H_2O-fluid on a fine grain as a seed crystal. E) In gneisses, diamond occurrence is diverse; several morphologies with different colors were observed. Two-stage growth was not confirmed. Dissolution of carbon from diamond in gneisses could be possible,

©2019. Japan Geoscience Union. All Right Reserved.

and carbon was carried into dolomite marble by H_2O-fluid to crystallize 2^{nd} stage diamond.

Many of the subjects being still unclear will be mentioned as the targets of future research.

Ultrahigh-pressure pseudotachylyte in a marble

*Tadao Nishiyama[1], Tomoya Fujimoto[1]

1. Department of Earth and Environmental Sciences, School of Science, Graduate School of Science and Technology, Kumamoto University

A black vein in a marble from the Higo metamorphic rock in central Kyushu, Japan, represents a signature of dolomite growth from a carbonate melt and also evidence of liquid immiscibility between carbonate and silicate melts. The formation condition is estimated to be 3.5 GPa and 1280 C by the dolomite composition based on the phase diagram in the system CaCO3– MgCO3. This is a peculiar example of pseudotachylyte formed under ultrahigh-pressure condition.

The Higo metamorphic rock is Cretaceous low P/T metamorphic rock, however, some authors have suggested the existence of high to ultrahigh-pressure metamorphism prior to the low P/T metamorphism. In the south of Mt. Kousadake, Tomochi Town, Kumamoto Prefecture, marble occurs as several layers intercalated with pelitic and siliceous gneisses. The thickness of the marble layer is variable from several meters to several tens of meters. In one of the marble layers, near the contact with the surrounding pelitic gneiss, we found a black vein 10 cm thick and 1 m long, of which strike crosscuts that of the boundary between the marble and gneiss. It shows a branching texture, extending perpendicular to the vein strike from the vein towards the country rock (marble). The branching is a signature typical to the pseudotachylyte.
The marble consists of pure calcite, whereas the black vein consists of dolomite domain and silicate domain. The dolomite domain is composed of aggregates of anhedral to subhedral dolomite grains of 10 micrometers in size with oscillatory or complex zoning in terms of Ca, Mg and Fe. The dolomite grains do not show any deformation texture. The dolomite domain occasionally includes fractured quartz clasts, of which fractures are filled with dolomite. The silicate domain occurs as rounded or irregular-shaped aggregates of several hundred micrometres in size. It consists of rounded quartz grains, fibrous aggregates of hydrous alumino-silicate (unknown clay mineral) and minor dolomite grains. The silicate domains occur sporadically in the dolomite domains, and some silicate domains are connected with each other by network veins of silicates of the same material as the silicate domain. Rounded zircon rarely occurs in the silicate domain. In some parts of the vein, thin marble layers several millimeters thick occur, showing a flow folding.
Subhedral shape, oscillatory zoning and non-deformed texture of dolomite in the dolomite domain indicates the origin of dolomite either as precipitates from the fluid or as growth in the melt. If dolomite precipitated from the C-O-H fluid, the assemblage of dolomite + quartz, which occurs both in the dolomite and silicate domains, is stable at relatively low T, high P and high XCO2 region. Outside the stability field, it will react to form diopside. Diopside is common in calc-silicate gneisses in this region, therefore, the assemblage of dolomite + quartz + C-O-H fluid would imply temperature condition lower than that of the regional metamorphic condition. This observation leads to a conclusion that the dolomite grew from the melt, because fault rocks should show temperature condition higher than that of the country rock owing to frictional heating. The silicate domain may represent recrystallized silicate melt, and the coexistence of carbonate and silicate domains implies the liquid immiscibility between carbonate and silicate melts. In such a case, dolomite should represent a minimum melt composition in the system CaCO3 –MgCO3. The minimum melt composition and its temperature depends strongly on pressure (Irvine and Wyllie, 1975 and Buob et al., 2006), therefore, we can estimate the melting temperature and pressure from the dolomite composition. The effect of FeCO3 component is evaluated to be small based

©2019. Japan Geoscience Union. All Right Reserved.

on the experiment of Shatsky et al. (2014). The estimated pressure and temperature conditions are 3.5 GPa and 1280 C. Thus, we interpret that the black vein is a pseudotachylyte formed under ultrahigh-pressure condition, indicating that the Higo metamorphic rock has experienced the ultrahigh-pressure.

Dehydration and Deformation process of subducted large Oceanic Pleateau -case study of the Mikabu blueschist-

*Kazuaki Okamoto[1]

1. Faculty of Education, Saitama University

In order to know an origin of mega-earthquake related to subducted large seamount, observation of deformation process recorded in the blueschist (high P/T metamorphic rock) is the best method. Mikabu blueschist is considered as accreted large oceanic plateau and suffered blueschist facies metamorphism at Jurassic time. It extends approximately 1000 km in EW direction from the Kanto Mountain to Kyushu Island. In north-south direction, succession of ocean plateau stratigraphy can be reconstructed although accretion thrusts duplicate them. We have done detailed field observation along the N-S route and collected the rock sample systematically. In the outcrop, the Mikabu blueschist is well foliated with mineral lineation. However, we have identified massive, cataclastic samples in the structural middle in the NS section. Under the microscope, glassy parts suffered brittle and ductile deformation. Origin of the most glass part can be ascribed as igneous product. However, some glass layers along the deformation band in stilpnomelane aggregates might be formed as melt due to shear heating. If this zone is related to earthquake fault zone, it indicates that a huge earthquake has occurred. Metamorphic petrology based on mineral assemblage devides the Mikabu belt as three zones; the North, Mid, and the South zone, respectively. Psseudo-section analysis concludes that the North zone suffered relatively higher T metamorphism compated to the South zone. In the Mid zone, local temperature increase stabilized stilpnomelane after chlorite.

Unusually high Nb/Ta ratio of fluid-precipitated jadeites from New Idria serpentinite body, California: Implications for extreme fractionation in slab fluids

*Naoko Takahashi[1], Tatsuki Tsujimori[2], Qing Chang[3], Jun-Ichi Kimura[3]

1. Graduate School of Science, Tohoku Univ., 2. CNEAS, Tohoku Univ., 3. Department of Solid Earth Geochemistry, JAMSTEC

Fractionation of Nb and Ta, which are conventionally thought as geochemical twins, is a key to understanding the evolution of the silicate Earth. The subchondritic Nb/Ta ratio of the continental crust (12-13; Barth et al., 2000), which is a long-standing problem, has been explained by Nb/Ta fractionation during subduction processes such as slab melting and/or dehydration. However, recent studies have revealed that extreme Nb/Ta fractionation of subduction-zone fluids from minerals in eclogite (up to 87; Xiao et al., 2006; Liang et al., 2009) and metagranite (up to 239; Chen and Zheng, 2015). In order to decipher Nb-Ta (and Zr-Hf) behavior of slab-derived fluids in shallower levels, we investigated a veined jadeitite from the New Idria serpentinite body, which is regarded as direct precipitates from slab-derived fluids at forearc depth. We applied *in-situ* measurements of trace element abundance of jadeites using a LA-ICP-QMS. The New Idria jadeites is characterized by remarkably high Nb concentration but depleted in Ta. Consequently Nb/Ta ratio varies from 10 to 115; Zr/Hf ratio also shows a wide range of 38–164. Nb–Ta and Zr–Hf correlations suggest coupling behaviors of those elemental pairs in fluids during the jadeitite vein formation. A simple Rayleigh fractional crystallization model for jadeite growth using partitioning coefficient D_{Nb} and D_{Ta} between clinopyroxene-aqueous fluid (Stalder et al., 1998) is also unlikely to explain the data. Although the extreme Nb/Ta and Zr/Hf fractionation can occur in seawater (Firdaus et al., 2011), oxygen isotope composition of New Idria jadeites ($\delta^{18}O$ = +8.4 to +9.9‰; Sorensen et al., 2006) eliminates a possibility that jadeitite-forming fluid source was originated from pore fluids derived from seawater. Alternatively, the Nb-Ta behavior might be explained by breakdown of hydrous minerals with high Nb/Ta ratio such as phengitic mica and/or consequences of high degree of fluid-rock interaction in a case of $D_{Nb}/D_{Ta} > \sim 10$ for fluid-rock system. New Idria jadeitite veins would provide an evidence for the presence of highly Nb/Ta fractionated fluids in serpentinized mantle wedge beneath forearc, supporting the idea that Nb and Ta are highly mobile and fractionate during the early stage of oceanic plate subduction before the appearance of rutile.

Along the Qinling–Dabie–Odesan collisional belt between the North Korea-China and South Korea-China Cratons, the peak metamorphic conditions reflect systematically changing metamorphic regimes from east to west: ultra-high temperature (UHT) granulite-facies metamorphism in the Odesan area (905–1160˚C, 9-10.6 kbar) at 247-245 Ma; high pressure (HP) eclogite-facies metamorphism in the Hongseong area (819–835˚C, 23-25 kbar) at 250 Ma; ultra-high pressure (UHP) eclogite-facies metamorphism in the Sulu, Dabie and Hong’an areas (620–880˚C, 26–43 kbar) at 220-240 Ma; HP eclogite facies metamorphism in the Tonbai area (530–610˚C, 17–20 kbar) at 216 Ma; epidote–amphibolite and blueschist facies metamorphism in the Wudang area (505–550˚C, 10–13 kbar) at 216 Ma ; and HP granulite-facies metamorphism in the western Qinling area (657–772˚C, 9.7–13.2 kbar) at 214 Ma. Additionally, the Triassic post-collisional igneous rocks regionally intruded at both ends of the collision belt, in the Hongseong–Odesan areas at 230 Ma and in the west Qinling at 210 Ma. These observations indicate that the following collisional processes occurred along the Qinling–Dabie–Odesan collisional belt. The collision between the North Korea-China Craton and South Korea-China Craton first occurred in the eastern margin of the collision belt (the Odesan area) with an angle of approximately 60˚ between their long axes of two Cratons and propagated towards west. The amount of oceanic slab subducted before the collision increased from the Odesan area to the Sulu area due to westwards increase in the width of the ocean between the North Korea-China and South Korea-China Cratons, resulting an increase in the depth of slab break-off. After slab break-off occurred in the Sulu area, the lateral tearing force strengthened, resulting a decrease in the depth of slab break-off from the Sulu area to the western Qinling area as collision propagated westward. At both ends of the collision belt, post collisional igneous activities occurred with metamorphism higher than granulite facies relating to high heat supply from upwelling mantle due to shallow depth of slab break-off.

Contrasting collision processes between northwest and central Himalaya: examination from the "Lesser Himalayan granites" in Pakistan

*Masatsugu Ogasawara[1], Mayuko Fukuyama[2], Rehanul H Siddiqui[3]

1. Institute of Geology and Geoinformation, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, 2. Graduate School of Engineering Science, Akita University, 3. Balochistan University of Information Technology, Engineering and Management Sciences

The Himalayan orogenic belt was formed by the Cenozoic collision of Indian and Eurasian plates. In the eastern and central part of the Himalaya, four main tectonostratigraphic zones have been recognized, such as from south to north, Sub-Himalaya, Lesser Himalaya, Greater Himalaya and Tethys Himalaya. However, the northwest Himalaya in Pakistan and northwest India shows some distinct features differ from the main part of the Himalaya, i.e., (1) Presence of the Cretaceous island arc blocks between the Indian and the Eurasian blocks: (2) Boundary between the Lesser Himalaya and Greater Himalaya is not well defined: (3) Presence of UHP eclogites: (4) Extensive exposure of "Lesser Himalayan granites" represented by the Mansehra granite in Pakistan. As granite and granitic gneiss are major components of the Himalayan orogenic belt, we have examined geochemical and isotopic characteristics of the Mansehra granite and compared those with "Lesser Himalaya granites" and granite gneisses of the Greater Himalaya in the central part of the Himalaya. Before the collision of the India to the Eurasian, granites similar to the Mansehra granite were present along the northern margin of the India continent. The collision of India continent with the Tibet of the Eurasia plate formed two separate zones of granites, the "Lesser Himalayan granites" and extensively deformed granite gneiss in the Greater Himalaya. In the collision of India to the Cretaceous island arc blocks in northwest Himalaya did not disturbed distribution of the granite, resulting large exposure of the Mansehra granite. The southern extension of the Karakoram Fault which is a dextral strike-slip fault separating the Tibet and the Karakoram/Pamir block, approximates a boundary between the northwest Himalaya and the eastern and central Himalaya.

New petrologic indications of subduction metamorphism in the Yuli belt, eastern Taiwan

*Chin-Ho Tsai[1], Chih-Ying Yeh[1], Dominikus Deka Dewangga[1], Yui Kouketsu[2], Masaki Enami[3]

1. Department of Natural Resources & Environmental Studies, National Dong Hwa Univ., 2. Department of Earth & Planetary Sciences, Nagoya Univ., 3. Institute for Space-Earth Environmental Research, Nagoya Univ.

Previous reports of high-pressure (HP) metamorphism in the Yuli belt are mainly from meta-igneous and meta-volcaniclastic rocks, which are minor constituents within allochthonous metabasite-serpentinite blocks embedded in the dominant metasedimentary schists. By contrast, no HP minerals have yet been found in the metasedimentary rocks, whereas serpentinite is not suitable for pressure constraint. Thus skepticism on whether the Yuli belt is truly a HP metamorphic belt still exists. To solve this problem, we have investigated garnet-bearing pelitic schists using quartz-inclusion Raman spectroscopy barometry and surveyed the metasomatic zones around the Tsunkuanshan serpentinite body. Our Raman spectroscopic analyses on quartz inclusions in garnet from three metapelitic samples yielded residual (entrapment) pressures of 11-15 kbar at temperatures of 420-620˚C (constrained by Raman spectra of carbonaceous material thermometry). These results are essentially consistent with those of HP metabasites, glaucophane schists, and metaplagiogranites in the Yuli belt by recent pseudosection modeling. In the Tsunkuanshan area, meter-scale metasomatic zones crop out at the contact between serpentinite and surrounding pelitic schists. We discovered rare early-stage glaucophane (crossite) in an intermediate amphibole-albite rich rock in the metasomatic zones. This new occurrence indicates that serpentinite bodies might have been incorporated into a (paleo) subduction channel and subsequently recrystallized together with the host metasediments in HP conditions. Both the new pressure-temperature constraints from metasedimentary rocks and the finding of blue amphibole in metasomatic zones around serpentinite bodies indicate that the Yuli belt was subject to ‘warm’ subduction metamorphism.

The importance of Mn-nodules on the sea floor during subduction for the formation of ophiolitic diamond

*Richard Wirth[1]

1. Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences 3.5 Surface Geochemistry

Diamonds, native elements and unusual metal alloys from chromitites in ophiolites have been reported already almost 20 years ago (Bai et al., 2000). However, the genesis of these diamonds enclosed in chromite is still challenged. A major question is the origin of all the unusual elements and alloys recorded so far such as W, Co, Ta, CrFe, NiCu, AgAu, CoFeNi and most important Mn-Ni-Co alloys. Meanwhile, diamonds in chromite in ophiolites have been reported from several different locations on the planet (Tibet, Mongolia, Polar Urals, Turkey, Albania), which are separated from each other by long distances (Yang et al., 2014). There is one common feature observed in these diamonds, they usually contain small inclusions (from nanometre up to a few micrometre in size) of a Mn-Ni-Co alloy. The composition of the alloy is varying in diamond from different locations. These diamonds are natural diamonds that is demonstrated by the presence or coexistence of several additional nanoinclusions in diamond such as oxides, silicates and sulphides and selenides. Thinking about the genesis of these ophiolitic diamonds the question arises where all these strange elements and alloys come from? They are not typical Upper Mantle components. However, it is well known that Mn-nodules from the sea floor contain all these rare and unusual elements (Wegorzweski et al., 2015 and ref. therein). Subduction of the sea floor transports the nodules to a depth where melting of the nodules finally occurs. Depending on the Co-concentration melting of a Mn-Ni-Co ally will start at temperatures < 900˚C with increasing Co-concentration at much lower temperature. Under local reducing conditions such Mn-Ni-Co alloy melt pools might exist in the subducted slab. The sea floor also contains plenty of organic material that could potentially supply the carbon necessary for the formation of diamond. Carbon rich fluids might react with the Mn-Ni-Co alloy melt, the melt acting as a catalyst to reduce the C-rich fluid to C. Carbon is dissolved in the alloy melt to a high amount depending on pressure and temperature. A change in PT during uplift then will result in the precipitation of solid carbon from the melt. If that happens in the diamond stability field diamond will precipitate. That process would explain the presence of such kind of Mn-Ni-Co alloy inclusions in diamond. Mn-nodules with their content of a wide variety of elements from the periodic system cannot only explain the unusual occurrence of diamond in chromitite in ophiolites but also the presence of other unusual elements and compounds. The details of the processes involved are not fully understood and they are subject of future investigations.

Along-strike variability of primitive magmas inferred from olivine-hosted melt inclusions, southernmost Andean Southern Volcanic Zone, Chile

*Derek Weller[1,2], Charles R Stern[2]

1. Earthquake Research Institute, 2. University of Colorado

Glass compositions of melt inclusions in olivine phenocrysts found in tephras derived from explosive eruptions of the four volcanoes along the volcanic front of the southernmost Andean Southern Volcanic Zone (SSVZ) are used to constrain primitive magma compositions and melt generation parameters. Primitive magmas from Hudson, Macá, and Melimoyu have similar compositions and are formed by low degrees (8-18 %) of partial melting. Compared to these other three centers, primitive magmas from Mentolat have higher Al_2O_3 and lower MgO, TiO_2 and other incompatible minor elements, and are generated by somewhat higher degrees (12-20%) of partial melting. The differences in the estimated primitive parental magma compositions between Mentolat and the other three volcanic centers are consistent with difference in the more evolved magmas erupted from these centers, Mentolat magmas having higher Al_2O_3 and lower MgO, TiO_2 and other incompatible minor element contents, suggesting that these differences are controlled by melting processes in the mantle source region above the subducted oceanic plate. The observed along-arc changes in parental magma chemistry may be due to the close proximity below Mentolat of the subducted Guamblin Fracture Zone that could efficiently transport hydrous mineral phases, seawater, and sediment into the mantle, driving enhanced volatile fluxed melting beneath this center compared to the others.

[S-MP30] Crust-Mantle Connections

convener:Yoshihiko Tamura(Research Institute for Marine Geodynamics, Japan Agency for Maine-Earth Science and Technology), Osamu Ishizuka(Geological Survey of Japan, AIST), Chris Conway(Geological Survey of Japan)

A paradigm of the solid Earth geochemical cycles is that the Earth's crust forms by melting of the Earth's upper peridotitic mantle. How divers is the spectrum of primary melts and which factors may contribute to its variations? What is the influence of crustal processing vs. primary magma diversity in creating the diversity of the Earth's crust? The session seeks to explore the crust-mantle connections at divergent and convergent plate boundaries, and oceanic island settings based on volcanology, petrology, geochemistry, geophysics, geochronology, and geodynamics studies.

International Ocean Discovery Program (IODP) Expedition 351 'Izu–Bonin–Mariana (IBM) Arc Origins' drilled Site U1438, situated in the north-western margin of the Philippine Sea, into volcaniclastic sediments of the proto-IBM arc. Brandl *et al.* (2017, *Earth and Planetary Science Letters*) have analysed the major, trace and volatile elements of 304 melt inclusions hosted in fresh silicate minerals to unveil the magmatic evolution of the proto-IBM arc between 30 and 40 Ma, when the arc volcanism matured following subduction initiation at 52 Ma. Brandl *et al.* (2017) concluded that: (1) volcanism of the proto-IBM arc shifted from calc-alkaline affinity to tholeiitic affinity over time; and (2) such compositional shift is linked to both the volcanic productivity and the maturation of an evolving island arc. To better integrate the composition of melt inclusions with the magmatic evolution of the proto-IBM arc, this study extends the dataset of Brandl *et al.* (2017) by: (1) additional analysis of volatiles (H_2O, S, F and Cl) and P_2O_5 for 47 carefully selected melt inclusions by Secondary Ion Mass Spectrometry (SIMS); and (2) statistical analysis on the composition of 237 representative melt inclusions covering the full time range (30–40 Ma) of the dataset. Based on statistical analysis of the melt inclusion compositions and by considering trace element compositions and volatile concentrations, we can confidently distinguish five main clusters of melt inclusion compositions which can be further separated into a total of nine sub-clusters. Among the nine sub-clusters, we identified three major magma types: (1) medium-K enriched magmas which form a tholeiitic trend (30–38 Ma); (2) less-depleted medium-K melts which form a calc-alkaline trend (35–39 Ma); and (3) low-K depleted magmas which form a calc-alkaline trend (35–40 Ma). We demonstrate that: (1) volcanism of calc-alkaline depleted magmas lasted until 35 Ma; (2) the volcanism of calc-alkaline depleted magmas and that of more enriched normal arc magmas (tholeiitic and calc-alkaline affinities) overlap between 35 and 38–39 Ma and; (iii) the volcanism of normal arc magmas became predominant thereafter at the proto-IBM arc. Such identification of three major magma types is distinct from that of Brandl *et al.* (2017), in which less-depleted medium-K calc-alkaline magmas amd depleted low-K calc-alkaline gammas were not distinguished. We infer that depleted source mantle had been replaced by enriched mantle due to mantle convection beneath the proto-IBM arc from >40 Ma to 35 Ma. Statistical analysis is a useful tool to partition a mixture of multivariable dataset, such as datasets of melt inclusion compositions, into several distinct groups and potentially reconstruct their geological evolution.

The Jurassic magmatism of protoliths of Mikabu greenstones in SW Japan: zircon U-Pb dating and trace element analysis

*Hikaru Sawada[1], Yukio Isozaki[1], Shogo Aoki[3], Shuhei Sakata[2], Ryo Hasegawa[1], Yasuo Nakamura[1]

1. Department of General Systems Studies, the University of Tokyo, 2. Department of Chemistry, Gakushuin Universtiy, 3. Department of Applied Science, Okayama University of Science

The Mikabu greenstones, incorporated with the Cretaceous high P/T-type Sanbagawa metamorphic belt in SW Japan, are accreted fragments of an oceanic plateau. We identified a Late Jurassic igneous age for the protoliths of the Mikabu greenstones in the eastern Kii Peninsula, by measuring U-Pb age and trace element composition (REE, Y, Sc, Nb, Ta, Hf, U, Th) of zircon grains with an Agilent 8800 single-collector triple quadrupole ICPMS coupled to a NWR-213 laser-ablation system. The U-Pb ages have a weighted average of 154.6 ±1.6 Ma (the Kimmeridgian, Late Jurassic) with an overlap within 2-sigma error. The igneous age is slightly younger than the previously reported radiolarian ages (Middle Jurassic) of deep-sea pelagic chert associated with the Mikabu greenstones. The age difference between them suggests that mafic magmas intruded pelagic deep-sea sediments on the pre-existing oceanic lithosphere. Trace element composition further indicates that the dated zircon grains are more similar to those in oceanic crusts than in granitic continental crusts, and the host mafic magma of the zircon grains was derived from depleted mantle like the mid-oceanic ridge-type source, rather than fertile mantle sources like Hawaii and Iceland. As rocks from the Shatsky Rise in the modern NW Pacific Ocean have similar age and compositional characteristics, this study concluded that the protoliths of the Mikabu greenstones had formed a part of an oceanic plateau, which was generated by the Late Jurassic intra-oceanic plate mafic magmatism in the ancient Pacific Ocean.

Origin of variable CaO/Al_2O_3 in olivine-hosted melt inclusions from Kibblewhite Volcano, Kermadec Arc

*Yasuhiro Hirai[1], Yoshihiko Tamura[2], Kaj Hoernle[3], Christian Timm[4], Folkmar Hauff[3], Reinhard Werner[3], Takeshi Hanyu[2], Bogdan Vaglarov[2], Qing Chang[2], Takashi Miyazaki[2], Jun-Ichi Kimura[2]

During R/V SONNE expedition SO-255 mafic basaltic to magnesian andesitic lavas containing melt inclusion hosting forsteritic olivines ($Fo_{90.3–92.4}$) were recovered from Kibblewhite Volcano, southern Kermadec Arc. The re-homogenized melt inclusions have compositions similar to primitive basalt (49.6–52.0 wt.% SiO_2; 12.7–15.9 wt.% MgO). Their CaO/Al_2O_3 values, however, range from 0.9 to 1.6, which cannot be explained by melting of lherzolite. Moreover, CaO/Al_2O_3 values in the melt inclusions correlate negatively with Ni contents of their host olivines suggesting that the high CaO/Al_2O_3 values result from interaction between mafic melts and subarc lithospheric mantle. Prior to the interaction the mafic magma must have had high Ni contents and low CaO/Al_2O_3 values, thus they crystallized high Ni olivines trapping low CaO/Al_2O_3 melt inclusions. During the interaction the olivines crystallized from the mafic magmas and its latent heat assimilated pyroxenes from the surrounding lithospheric mantle. This assimilation of pyroxenes allowed the Ni content of the melt to decrease and CaO/Al_2O_3 to increase while buffering the the Mg-number of the mafic magmas during the ascent. Thus, magmas during and after the interaction could crystallize low Ni olivines bearing high CaO/Al_2O_3 melt inclusions.

Ankaramite from Doyo seamount in the Izu-Ogasawara arc: A precursor of continents?

*Yoshihiko Tamura[1], Tomoki Sato[1], Osamu Ishizuka[1,2], Takashi Miyazaki[1], Yasuhiro Hirai[1,3], Mami Takehara[4], Eri Sakamoto[5]

1. JAMSTEC, 2. AIST, 3. Kanazawa Univ., 4. NIPR, 5. NME

Izu-Ogasawara-Mariana (IOM) system of arcs (also known as the Izu-Bonin-Mariana arc system) is a typical oceanic arc produced by subduction of the Pacific Plate beneath the Philippine Sea Plate. Volcanoes along the southern segment of the Izu-Ogasawara arc are underlain by thin crust (10-20 km). According to the hypothesis presented by Tamura *et al.* (2016), rising mantle diapirs stall near the base of the oceanic crust at depths controlled by the thickness of the overlying crust. Where the crust is thin, melting occurs at relatively low pressures in the mantle wedge producing andesitic magmas. Andesites erupted from Nishinoshima that were produced in the recent history of the volcano have been generated by olivine fractionation of primary andesitic magmas (Tamura *et al.*, 2019).

To further examine this hypothesis, we have dived Doyo Seamount by using manned submersible SHINKAI 6500 to sample primitive magmas from the volcano, which is located about 50 km north of Nishinoshima and is underlain by thinner curst (15 km) compared to Nishinoshima. Doyo Seamount is located approximately 900 km south of Tokyo at 27˚41’ N, 140˚48’ E in the Ogasawara Arc. The seamount attained an elevation of ~400 m below sea level (mbsl) and its submarine flanks extend to the depth of 3,200 mbsl. The basal dimeter of the volcano is about 30 km. The deeper parts of this large submarine edifice have yet to be explored. Primitive lavas tend to erupt in the deeper parts of submarine volcanoes at the depth of ~2,000 m. Deeper satellite vents are expected to erupt more primitive magmas compared to the main summit vents because primitive magmas could bypass the shallow magma chambers where crystal fractionation and magma mixing happen.

There is a small satellite cone about 11 km east of the summit of Doyo Seamount at the depth of ~3,000 m. A ridge extends on the flank of the volcano from the summit in the ENE direction to the depth of ~2,400 m. Thus, we tried to sample this satellite cone and the deeper part of the ridge. Interestingly, 13 samples out of all 21 samples, which we have recovered during this dive 6K#1519, are olivine-clinopyroxene basalts containing 20-40 % of very coarse clinopyroxene phenocrysts, which could be called ankaramite (Figure 1). Ankaramites are strongly vesiculated and their blocks have rough and rugged surface, which are different from smooth surface of basaltic pillow lavas. Some of ankaramite magmas might have had explosive eruptions at the depth of 2,000~3,000 m, which have resulted in volcaniclastic cones or brecciated lava flows.

Similar primitive and phenocryst-rich ankaramitic basalts were recovered from the old submarine knolls near Nishinoshima (Tamura et al., 2019). We suggested that lithospheric mantle was thicker before the development of Nishinoshima volcano (Figure 2). Primary basaltic magmas could have been generated at depth beneath the thicker lithospheric lid, and these magmas might have interacted with the lithospheric uppermost mantle during their ascent and have resulted in the unique ankaramite magmas (Figure 1). The temperature of the upper part of the mantle wedge increases with frequent passage of magmas through it, and continuous subduction beneath it will drench the whole mantle wedge, thus, the thickness of the lithosphere will decrease and approach the thickness of the curst in mature arcs. Doyo Seamount could represent the early stage of Nishinoshima volcano, and thus, ankaramite magma is deemed to be a

Different Moho reflections adjacent to Minami-Tori Shima and their petrologic origins

*Yoshihiko Tamura[1], Kentaro Kaneda[2], Gou Fujie[1], Akane Ohira[1], Eiichi TAKAZAWA[3], Georges Ceuleneer[4], Katsuyoshi Michibayashi[5], Tomoki Sato[1], Shuichi Kodaira[1], Seiichi Miura[1]

It is the common knowledge that Moho is the boundary between the crust and mantle, which was discovered by and named after Croatian seismologist Mohorovičić. We have shown that Moho is not the crust-mantle boundary and presented a new hypothesis about the origin of Moho based on seismological and petrological observations (Tamura et al., EGU2018-11069-2; JpGU2018 SMP36-05; AGCC2018 abstract volume590; Tamura et al., in preparation). Direct drilling and sampling of Moho could be the best scenario to examine the hypothesis. However, IODP drillings of basaltic crust could estimate the petrologic origins of the crust-mantle boundary far below the seafloor, which could be useful to examine the hypothesis of formation of Moho.

Kaneda et al. (2010) conducted seismic surveys across the Marcus-Wake seamount chain near Minami-Tori Shima, which is the Japanese easternmost and one and only island on the Pacific Plate. They found contrasting seafloor in the north and south of the seamount chain, which were referred to the northern and southern basins (Figure 1). Average water depths in the northern and southern basins are about 5900 m and 5700 m, respectively. Magnetic anomalies suggest Jurassic ages of M32 (159 Ma) and M42 (167 Ma) for the northern and southern basins, respectively. The southern basin has the clear Moho reflections, which are characteristically sharp, single, flat, and continuous, and of large amplitude, but in the northern basin, Moho reflections are extremely weak or even absent. Interestingly, the crust of the southern basin has a constant thickness of 7.5-8.0 km, but the crust of the northern basin shows a constant thickness of 6 km, 1.5-2 km thinner than that of the northern basin.The correlation between Moho reflections and crustal thicknesses have been generally observed in other seismic profiles (e.g. Ohira et al., 2017).

The boundary between mantle peridotite and layered gabbro from the lower oceanic crust in the Oman ophiolite consists of a dunitic transition zone (DTZ), mostly made of olivine + scattered Cr-spinel. The thickness of DTZ ranges from a few meters to a few hundred meters. When mantle melts under hydrous conditions, the liquidus field of forsterite expands relative to that of enstatite and enstatite melts incongruently to produce dunites and andesitic melts.

We present here a new hypothesis that (1) accidental influx of seawater at the mid-ocean ridges results in hydrous melting of mantle peridotite just beneath the crust and produces thick dunite at the crust-mantle boundaries, (2) the thick dunite represents reflective Moho, and (3) this additional hydrous melting of shallowest mantle increases the thickness of oceanic crust.

Although the andesitic melts, which are the outgrowth of dunites, would be mixed with dominant basaltic melts extracted from the deeper parts of melting column of MORB, there must be systematic and significant differences between crustal materials with Moho and those without Moho. Comparative drillings of oceanic crust in the northern and southern basins for future IODP expeditions will reveal the differences of basalts and examine the models for Moho.

Melt-rock interaction in plagioclase peridotites from the southern Palawan Ophiolite, Philippines

*FLORENCE ANNETTE CRUSPERO LABIS[1], BETCHAIDA D PAYOT[1], GABRIEL THEOPHILUS V VALERA[1], JULIUS A PASCO[1], JESLEY MEI A DYCOCO[1]

1. UNIVERSITY OF THE PHILIPPINES

This work presents new petrographic and geochemical data on the plagioclase peridotites and the spinel harzburgites of the mantle section of the southern Palawan Ophiolite. The plagioclase peridotites show peculiar textures evident of melt-rock interaction as indicated by: (1) interstitial clinopyroxene and subhedral orthopyroxene around plagioclase, and (2) plagioclase blebs within the peridotite matrix. The spinel harzburgites display protogranular to porphyroclastic textures and dominantly composed of olivine, orthopyroxene, and small amounts of clinopyroxene and spinel. These minerals show kink banding and bent lamellae which are indicative of plastic deformation. Major element geochemistry of the spinel harzburgites reveals high Cr# (0.53-0.78) and Mg# (0.40-0.51) in spinel, and high NiO wt.% (0.40-0.43) and Fo contents (89.9-90.5) in olivine reflecting residual origin. Their geochemical composition is comparable to the residual peridotites in arc settings. Consequently, the plagioclase peridotites have lower Mg# (0.23-0.34) and relatively high Cr# (0.60-0.61) in spinel, as well as lower Fo (83.3-85.9) contents in olivine. Spinel and clinopyroxene in the plagioclase peridotites have higher TiO_2 contents compared with those of the spinel harzburgites. Clinopyroxene in plagioclase peridotites are marked by strong depletion in LREE and flat MREE to HREE with significant negative Eu and Sr anomalies. In contrast, the spinel harzburgites have lower REE abundances which suggest higher degrees of partial melting. We propose that the spinel harzburgites of the southern Palawan Ophiolite are residual peridotites formed by high degrees of partial melting above a subduction zone and were subsequently infiltrated by melts leading to the formation of the plagioclase peridotites.

Intra-oceanic arc magma genesis: a case study from Havre volcano, Kermadec arc

*Chris Conway[1], Kenichiro Tani[2]

1. Geological Survey of Japan, 2. National Museum of Nature and Science

The Kermadec intra-oceanic arc comprises 33 active arc front volcanoes along its ~1200 km length, which represent key targets for studying the formation of Earth’ s crust. The discovery of numerous submarine caldera volcanoes and dacitic to rhyolitic pumice deposits from this setting has prompted new models for the genesis of intra-oceanic silicic arc magmas. A detailed investigation of the 2012 eruption of rhyolite pumice and lava at Havre volcano has provided a valuable opportunity to test these models. Moreover, the retrieval of older volcanic deposits from the edifice has given critical context for studying magma genesis throughout the lifetime of the volcano. Here we present whole-rock, mineral and glass major and trace element data for volcanic rock samples collected from Havre volcano. The samples, which span a compositional range from basalt to rhyolite, display several key features that support arguments against the derivation of silicic magmas primarily through crustal anatexis: (1) the range of sample compositions fit along coherent crystal fractionation trends; (2) low-MgO aphyric andesites fill the gap within the general bimodality of eruptive products from the Kermadec arc; and (3) there is a scarcity of tonalitic xenoliths. These features favour crystal fractionation over crustal anatexis as the dominant process for generating the compositional diversity seen at Havre volcano.

[S-MP30] Crust-Mantle Connections

convener:Yoshihiko Tamura(Research Institute for Marine Geodynamics, Japan Agency for Maine-Earth Science and Technology), Osamu Ishizuka(Geological Survey of Japan, AIST), Chris Conway(Geological Survey of Japan)

A paradigm of the solid Earth geochemical cycles is that the Earth's crust forms by melting of the Earth's upper peridotitic mantle. How divers is the spectrum of primary melts and which factors may contribute to its variations? What is the influence of crustal processing vs. primary magma diversity in creating the diversity of the Earth's crust? The session seeks to explore the crust-mantle connections at divergent and convergent plate boundaries, and oceanic island settings based on volcanology, petrology, geochemistry, geophysics, geochronology, and geodynamics studies.

International Ocean Discovery Program (IODP) Expedition 351 'Izu–Bonin–Mariana (IBM) Arc Origins' drilled Site U1438, situated in the north-western margin of the Philippine Sea, into volcaniclastic sediments of the proto-IBM arc. Brandl *et al.* (2017, *Earth and Planetary Science Letters*) have analysed the major, trace and volatile elements of 304 melt inclusions hosted in fresh silicate minerals to unveil the magmatic evolution of the proto-IBM arc between 30 and 40 Ma, when the arc volcanism matured following subduction initiation at 52 Ma. Brandl *et al.* (2017) concluded that: (1) volcanism of the proto-IBM arc shifted from calc-alkaline affinity to tholeiitic affinity over time; and (2) such compositional shift is linked to both the volcanic productivity and the maturation of an evolving island arc. To better integrate the composition of melt inclusions with the magmatic evolution of the proto-IBM arc, this study extends the dataset of Brandl *et al.* (2017) by: (1) additional analysis of volatiles (H_2O, S, F and Cl) and P_2O_5 for 47 carefully selected melt inclusions by Secondary Ion Mass Spectrometry (SIMS); and (2) statistical analysis on the composition of 237 representative melt inclusions covering the full time range (30–40 Ma) of the dataset. Based on statistical analysis of the melt inclusion compositions and by considering trace element compositions and volatile concentrations, we can confidently distinguish five main clusters of melt inclusion compositions which can be further separated into a total of nine sub-clusters. Among the nine sub-clusters, we identified three major magma types: (1) medium-K enriched magmas which form a tholeiitic trend (30–38 Ma); (2) less-depleted medium-K melts which form a calc-alkaline trend (35–39 Ma); and (3) low-K depleted magmas which form a calc-alkaline trend (35–40 Ma). We demonstrate that: (1) volcanism of calc-alkaline depleted magmas lasted until 35 Ma; (2) the volcanism of calc-alkaline depleted magmas and that of more enriched normal arc magmas (tholeiitic and calc-alkaline affinities) overlap between 35 and 38–39 Ma and; (iii) the volcanism of normal arc magmas became predominant thereafter at the proto-IBM arc. Such identification of three major magma types is distinct from that of Brandl *et al.* (2017), in which less-depleted medium-K calc-alkaline magmas amd depleted low-K calc-alkaline gammas were not distinguished. We infer that depleted source mantle had been replaced by enriched mantle due to mantle convection beneath the proto-IBM arc from >40 Ma to 35 Ma. Statistical analysis is a useful tool to partition a mixture of multivariable dataset, such as datasets of melt inclusion compositions, into several distinct groups and potentially reconstruct their geological evolution.

The Jurassic magmatism of protoliths of Mikabu greenstones in SW Japan: zircon U-Pb dating and trace element analysis

*Hikaru Sawada[1], Yukio Isozaki[1], Shogo Aoki[3], Shuhei Sakata[2], Ryo Hasegawa[1], Yasuo Nakamura[1]

The Mikabu greenstones, incorporated with the Cretaceous high P/T-type Sanbagawa metamorphic belt in SW Japan, are accreted fragments of an oceanic plateau. We identified a Late Jurassic igneous age for the protoliths of the Mikabu greenstones in the eastern Kii Peninsula, by measuring U-Pb age and trace element composition (REE, Y, Sc, Nb, Ta, Hf, U, Th) of zircon grains with an Agilent 8800 single-collector triple quadrupole ICPMS coupled to a NWR-213 laser-ablation system. The U-Pb ages have a weighted average of 154.6 ±1.6 Ma (the Kimmeridgian, Late Jurassic) with an overlap within 2-sigma error. The igneous age is slightly younger than the previously reported radiolarian ages (Middle Jurassic) of deep-sea pelagic chert associated with the Mikabu greenstones. The age difference between them suggests that mafic magmas intruded pelagic deep-sea sediments on the pre-existing oceanic lithosphere. Trace element composition further indicates that the dated zircon grains are more similar to those in oceanic crusts than in granitic continental crusts, and the host mafic magma of the zircon grains was derived from depleted mantle like the mid-oceanic ridge-type source, rather than fertile mantle sources like Hawaii and Iceland. As rocks from the Shatsky Rise in the modern NW Pacific Ocean have similar age and compositional characteristics, this study concluded that the protoliths of the Mikabu greenstones had formed a part of an oceanic plateau, which was generated by the Late Jurassic intra-oceanic plate mafic magmatism in the ancient Pacific Ocean.

Origin of variable CaO/Al_2O_3 in olivine-hosted melt inclusions from Kibblewhite Volcano, Kermadec Arc

*Yasuhiro Hirai[1], Yoshihiko Tamura[2], Kaj Hoernle[3], Christian Timm[4], Folkmar Hauff[3], Reinhard Werner[3], Takeshi Hanyu[2], Bogdan Vaglarov[2], Qing Chang[2], Takashi Miyazaki[2], Jun-Ichi Kimura[2]

During R/V SONNE expedition SO-255 mafic basaltic to magnesian andesitic lavas containing melt inclusion hosting forsteritic olivines ($Fo_{90.3–92.4}$) were recovered from Kibblewhite Volcano, southern Kermadec Arc. The re-homogenized melt inclusions have compositions similar to primitive basalt (49.6–52.0 wt.% SiO_2; 12.7–15.9 wt.% MgO). Their CaO/Al_2O_3 values, however, range from 0.9 to 1.6, which cannot be explained by melting of lherzolite. Moreover, CaO/Al_2O_3 values in the melt inclusions correlate negatively with Ni contents of their host olivines suggesting that the high CaO/Al_2O_3 values result from interaction between mafic melts and subarc lithospheric mantle. Prior to the interaction the mafic magma must have had high Ni contents and low CaO/Al_2O_3 values, thus they crystallized high Ni olivines trapping low CaO/Al_2O_3 melt inclusions. During the interaction the olivines crystallized from the mafic magmas and its latent heat assimilated pyroxenes from the surrounding lithospheric mantle. This assimilation of pyroxenes allowed the Ni content of the melt to decrease and CaO/Al_2O_3 to increase while buffering the the Mg-number of the mafic magmas during the ascent. Thus, magmas during and after the interaction could crystallize low Ni olivines bearing high CaO/Al_2O_3 melt inclusions.

Ankaramite from Doyo seamount in the Izu-Ogasawara arc: A precursor of continents?

*Yoshihiko Tamura[1], Tomoki Sato[1], Osamu Ishizuka[1,2], Takashi Miyazaki[1], Yasuhiro Hirai[1,3], Mami Takehara[4], Eri Sakamoto[5]

1. JAMSTEC, 2. AIST, 3. Kanazawa Univ., 4. NIPR, 5. NME

Izu-Ogasawara-Mariana (IOM) system of arcs (also known as the Izu-Bonin-Mariana arc system) is a typical oceanic arc produced by subduction of the Pacific Plate beneath the Philippine Sea Plate. Volcanoes along the southern segment of the Izu-Ogasawara arc are underlain by thin crust (10-20 km). According to the hypothesis presented by Tamura *et al.* (2016), rising mantle diapirs stall near the base of the oceanic crust at depths controlled by the thickness of the overlying crust. Where the crust is thin, melting occurs at relatively low pressures in the mantle wedge producing andesitic magmas. Andesites erupted from Nishinoshima that were produced in the recent history of the volcano have been generated by olivine fractionation of primary andesitic magmas (Tamura *et al.*, 2019).

To further examine this hypothesis, we have dived Doyo Seamount by using manned submersible SHINKAI 6500 to sample primitive magmas from the volcano, which is located about 50 km north of Nishinoshima and is underlain by thinner curst (15 km) compared to Nishinoshima. Doyo Seamount is located approximately 900 km south of Tokyo at 27˚41’ N, 140˚48’ E in the Ogasawara Arc. The seamount attained an elevation of ~400 m below sea level (mbsl) and its submarine flanks extend to the depth of 3,200 mbsl. The basal dimeter of the volcano is about 30 km. The deeper parts of this large submarine edifice have yet to be explored. Primitive lavas tend to erupt in the deeper parts of submarine volcanoes at the depth of ~2,000 m. Deeper satellite vents are expected to erupt more primitive magmas compared to the main summit vents because primitive magmas could bypass the shallow magma chambers where crystal fractionation and magma mixing happen.

There is a small satellite cone about 11 km east of the summit of Doyo Seamount at the depth of ~3,000 m. A ridge extends on the flank of the volcano from the summit in the ENE direction to the depth of ~2,400 m. Thus, we tried to sample this satellite cone and the deeper part of the ridge. Interestingly, 13 samples out of all 21 samples, which we have recovered during this dive 6K#1519, are olivine-clinopyroxene basalts containing 20-40 % of very coarse clinopyroxene phenocrysts, which could be called ankaramite (Figure 1). Ankaramites are strongly vesiculated and their blocks have rough and rugged surface, which are different from smooth surface of basaltic pillow lavas. Some of ankaramite magmas might have had explosive eruptions at the depth of 2,000~3,000 m, which have resulted in volcaniclastic cones or brecciated lava flows.

Similar primitive and phenocryst-rich ankaramitic basalts were recovered from the old submarine knolls near Nishinoshima (Tamura et al., 2019). We suggested that lithospheric mantle was thicker before the development of Nishinoshima volcano (Figure 2). Primary basaltic magmas could have been generated at depth beneath the thicker lithospheric lid, and these magmas might have interacted with the lithospheric uppermost mantle during their ascent and have resulted in the unique ankaramite magmas (Figure 1). The temperature of the upper part of the mantle wedge increases with frequent passage of magmas through it, and continuous subduction beneath it will drench the whole mantle wedge, thus, the thickness of the lithosphere will decrease and approach the thickness of the curst in mature arcs. Doyo Seamount could represent the early stage of Nishinoshima volcano, and thus, ankaramite magma is deemed to be a

precursor of andesitic magmas.

It is the common knowledge that Moho is the boundary between the crust and mantle, which was discovered by and named after Croatian seismologist Mohorovičić. We have shown that Moho is not the crust-mantle boundary and presented a new hypothesis about the origin of Moho based on seismological and petrological observations (Tamura et al., EGU2018-11069-2; JpGU2018 SMP36-05; AGCC2018 abstract volume590; Tamura et al., in preparation). Direct drilling and sampling of Moho could be the best scenario to examine the hypothesis. However, IODP drillings of basaltic crust could estimate the petrologic origins of the crust-mantle boundary far below the seafloor, which could be useful to examine the hypothesis of formation of Moho.

Kaneda et al. (2010) conducted seismic surveys across the Marcus-Wake seamount chain near Minami-Tori Shima, which is the Japanese easternmost and one and only island on the Pacific Plate. They found contrasting seafloor in the north and south of the seamount chain, which were referred to the northern and southern basins (Figure 1). Average water depths in the northern and southern basins are about 5900 m and 5700 m, respectively. Magnetic anomalies suggest Jurassic ages of M32 (159 Ma) and M42 (167 Ma) for the northern and southern basins, respectively. The southern basin has the clear Moho reflections, which are characteristically sharp, single, flat, and continuous, and of large amplitude, but in the northern basin, Moho reflections are extremely weak or even absent. Interestingly, the crust of the southern basin has a constant thickness of 7.5-8.0 km, but the crust of the northern basin shows a constant thickness of 6 km, 1.5-2 km thinner than that of the northern basin.The correlation between Moho reflections and crustal thicknesses have been generally observed in other seismic profiles (e.g. Ohira et al., 2017).

The boundary between mantle peridotite and layered gabbro from the lower oceanic crust in the Oman ophiolite consists of a dunitic transition zone (DTZ), mostly made of olivine + scattered Cr-spinel. The thickness of DTZ ranges from a few meters to a few hundred meters. When mantle melts under hydrous conditions, the liquidus field of forsterite expands relative to that of enstatite and enstatite melts incongruently to produce dunites and andesitic melts.

We present here a new hypothesis that (1) accidental influx of seawater at the mid-ocean ridges results in hydrous melting of mantle peridotite just beneath the crust and produces thick dunite at the crust-mantle boundaries, (2) the thick dunite represents reflective Moho, and (3) this additional hydrous melting of shallowest mantle increases the thickness of oceanic crust.

Although the andesitic melts, which are the outgrowth of dunites, would be mixed with dominant basaltic melts extracted from the deeper parts of melting column of MORB, there must be systematic and significant differences between crustal materials with Moho and those without Moho. Comparative drillings of oceanic crust in the northern and southern basins for future IODP expeditions will reveal the differences of basalts and examine the models for Moho.

We measured noble gas isotopic compositions of quenched lavas sampled from seamounts, so-called petit-spot volcanoes, on the 160-million-year-old northwestern Pacific Plate. The samples $^{3}He/^{4}He$ and $^{40}Ar/^{36}Ar$ ratios were, respectively, 2.5–8.3 Ra and up to 1735, where Ra stands for atmospheric $^{3}He/^{4}He$, which are analogous to or lower than those of MORB. Considering narrow sampling regions, a secondary effect might be responsible for variation of the data.
During ascent and subsequent cooling of magma in the oceanic lithosphere, chemical components in the magma will be assimilated with those in the lithosphere. Correlation between $CO_2/^{3}He$ ratios and carbon isotopic ratios suggests that carbon was affected by the incorporation of seafloor carbonate. The same would be true of noble gases. The mixing of noble gases among a mantle source, an atmospheric component dissolved in seawater and a radiogenic component can explain the data distribution. There is no $^{3}He/^{4}He$ ratio exceeding MORB-like value. The mantle source of the petit-spot magma was likely to have had a MORB-like $^{3}He/^{4}He$ ratio originally. The eruption of petit-spot magma shows a close relation with the bending of subducting oceanic plates. The MORB-like $^{3}He/^{4}He$ ratio supports the hypothesis that the petit-spot magma is derived from the lithosphere–asthenosphere boundary.

A series of cummingtonite-bearing rhyolites in Niijima, Izu-Bonin arc, Japan: petrological and geochemical constraints

*Yoji Arakawa[1], Daisuke Endo[2], Junya Oshika[3], Taro Shinmura[4], Kei Ikehata[1]

1. Earth Evolution Sciences, Faculty of Life and Environmental Sciences, University of Tsukuba, 2. Shimane Prefectural Sanbe Nature Museum Sahimeru (Shimane) , 3. Earth Resoueces Faculty, China University of Geosciences, 4. Faculty of Economics, Kumanoto-Gakuen University

Niijima volcano in the northern part of the Quaternary Izu–Bonin volcanic arc, Japan, consists predominantly of rhyolitic volcanic units and minor basaltic and andesitic units. Most of the rhyolites are characterized by a phenocryst assemblage of orthopyroxene (Opx), cummingtonite (Cum), biotite (Bt), and hornblende, and a lack of clinopyroxene (Cpx). These rocks can be classified into four types: Opx–Cum, Cum, Cum–Bt, and Bt according to their eruption sequence (e.g., Isshiki, 1987; Endo et al., 2010). Cummingtonite is a common phenocryst phase and is present in most of the rhyolitic units. This sequence of cummingtonite-bearing rhyolites is a unique feature amongst the silicic volcanoes of the northern Izu–Bonin volcanic arc, most of which have an Opx–Cpx phenocryst assemblage (Shukono et al., 2006; Tamura et al., 2009; Haraguchi et al., 2017).

The decreasing anorthite contents (An mol.%) of plagioclase and Mg values (Mg#) of cummingtonite and biotite with time possibly indicate a gradual decrease in the temperature (and pressure) of the magmas. The rhyolites have high whole-rock SiO_2 (73–78 wt.%) and K_2O (1.5–3.3 wt.%) contents, and their trace element contents and patterns differ slightly amongst and within the four types. Highly differentiated rare earth element (REE) patterns characterize most of the rhyolites from Niijima volcano. All rock types from Niijima volcano have limited ranges of isotope values ($^{87}Sr/^{86}Sr$ = 0.70317–0.70339; $^{143}Nd/^{144}Nd$ = 0.51303–0.51308). The phenocryst assemblages and mineral chemistries of the rhyolitic volcanic rocks suggest that these magmas were produced under low temperatures (<800˚C) and low pressures (<3 kbar), and possibly water-saturated conditions, which is consistent with the experimental results for similar dacites and rhyolites from other volcanic arcs (Geschwind and Rutherford, 1992; Nicholls et al., 1992). Major and trace element variations indicate that fractionation of mostly plagioclase and amphibole was the dominant process during evolution of the rhyolitic magma, as supported by the presence of tonalite–granite xenoliths with cumulate textures and chemistries.

The coeval basaltic and andesitic volcanic units and mafic–intermediate inclusions (or enclaves) indicate that these magmas played an important role in the generation and evolution of the dominant rhyolitic magmas. The parental rhyolitic magmas are likely to have been generated by partial melting of lower to middle crust as a result of basaltic underplating, after which the magmas ascended and fractionated into more silicic magmas, producing more than 13 magma units at shallow crustal levels. At deeper crustal levels, basaltic and rhyolitic (or dacitic) parental magmas were mixed to produce andesitic to dacitic magmas, and these magmas ascended and mingled with the shallow rhyolitic magmas before eruption. The complex magmatic system beneath Niijima volcano was developed within a relatively thick crustal sequence on the rear-arc side of the Izu–Bonin volcanic arc.

Generation of primary andesitic magma in oceanic arcs: Evidence from Kibblewhite Volcano, Kermadec Arc

*Yasuhiro Hirai[1,2], Yoshihiko Tamura[2], Kaj Hoernle[3], Christian Timm[4], Folkmar Hauff[3], Reinhard Werner[3], Bogdan Vaglarov[2], Qing Chang[2], Takashi Miyazaki[2], Jun-Ichi Kimura[2]

Melting of hydrous subarc mantle at low pressure (<1 GPa) may produce primary andesitic melts, suggesting that primary andesitic lavas can be expected in oceanic arcs where the crust is thin (Tamura et al., 2016). Beneath thick crust, melting of hydrous mantle at higher pressures will occur at higher pressures below the thick crust, generating basaltic primary melts. Recently, Tamura et al. (2018) discovered olivine-bearing andesites derived from primary andesitic melts at the Nishinoshima volcano in the Ogasawara Arc, Japan, where the crustal thickness is 21 km. Here, we will present another example for generation of primary andesitic melts in the southern Kermadec arc.

During R/V SONNE expedition in 2017 (SO-255), phenocryst-poor andesites (57.5–57.6 wt.% SiO_2) were recovered from Kibblewhite volcanic complex, southern Kermadec Arc. These andesites contain skeletal olivine and clinopyroxene microphenocrysts with similar and restricted Mg-numbers (Mg/[Mg+Fe] = 0.84–0.85) and a few euhedral olivine xenocrysts with a magnesian cores (Mg/[Mg+Fe] = ~0.92). The magnesian andesites (5.5–5.6 wt.% MgO; Mg# = 56.8–57.3) have relatively high Ni (~50 ppm) and Cr (~180 ppm) contents. These lavas have depleted high-field strength element and enriched large-ion lithophile element compositions (e.g., Nb/Yb = 0.75–0.80; Ba/Nb = 148–175), similar to the coeval Kibblewhite basalts and typical for other southern Kermadec Arc lavas. Sr-Nd-Hf-Pb isotope compositions for the andesites and basalts of the Kibblewhite Volcano also cannot be distinguished from each other and are consistent with the range of published data for the southern Kermadec Arc (Todd et al., 2011; Timm et al., 2014).

Calculation of equilibrium olivine compositions and olivine fractionation trends (Tamura et al., 2000) indicate that olivine microphenocrysts in the andesites are in equilibrium with host rocks and that the andesites have experienced 10% olivine fractionation from mantle-derived primary melts. Primary melt compositions for the andesites (estimated by addition of 10 wt.% equilibrium olivines) are still andesitic (55.9–56.0 wt.% SiO_2; 9.58–9.68 wt.% MgO) in composition and similar to the estimated primary andesite melt of the Nishinoshima volcano. According to thermo-barometric modelling of Lee et al. (2009) the primary melts for the andesites are segregated from mantle peridotite at temperatures of 1190–1220℃ and pressures of 0.45–0.55 GPa assuming primary H_2O contents to be 1.0–3.0 wt.%. The low primary magma segregation pressures, corresponding to 15–18 km depths, are consistent with thin (9–12 km; Bassett et al., 2016) crust beneath the southern Kermadec Arc.

Petrogenesis of high-Mg# andesite lavas from Ruapehu volcano, New Zealand

*Chris Conway[1], Katy Chamberlain[2], Yumiko Harigane[1], Daniel Morgan[3]

1. Geological Survey of Japan, 2. Univ. Derby, 3. Univ. Leeds

The eruption of high-magnesium andesites (HMA) with Mg# values >60 at continental arc volcanoes conflicts with the expectation that mantle-equilibrated primitive magmas produced at subduction zones are basaltic. Studies of the origins of HMA lavas provide details on how primitive magmas transit through arc lithosphere, which has implications for constraints on crust-mantle connections as well as volcanic hazards.

Here we report on the occurrence and origin of a sequence of HMA lavas erupted at ~45 ka from Ruapehu volcano, which is a frequently active andesite-dacite stratovolcano in the Taupo Volcanic Zone (TVZ). The suite of lavas forms linear trends on bivariate whole-rock major and trace element plots that are distinctly elevated for MgO, Ni and Cr compared with all other lavas of Ruapehu and most other calk-alkaline andesites of the TVZ. The relatively primitive whole-rock geochemical characteristics are attributed to the involvement of mafic sources during magma genesis, as revealed by the presence of sharply reverse-zoned pyroxene phenocrysts with rims of $Mg\#_{85-89}$ and olivine xenocrysts with cores of Fo_{88-93} and Cr-spinel inclusions. The contribution of felsic end-members to the genesis of Ruapehu HMA magmas is recorded by the presence of rhyolitic glass within partially fused metasedimentary xenoliths and the low Mg# cores for pyroxenes within crystal clots that also preserve rhyolitic interstitial glass and melt inclusions.

The petrological and geochemical features of the samples indicate that the assembly of HMA magmas involved influxes of mafic magmas from the mantle that entrained olivine xenocrysts into mush zones of bulk (rhyo-) dacitic composition, which had evolved via preceding assimilation, fractionation and mixing processes in the crust. Timescale results from Fe-Mg interdiffusion modelling of orthopyroxene indicate that eruptions occurred within days to weeks of magma mixing events. Ruapehu HMA lavas are valuable samples of high-Mg# magmas collected from the global subduction zone system that were formed by crustal level magma hybridization processes (cf. Streck and Leeman, 2018) rather than directly by mantle melting processes (cf. Mitchell and Grove et al. 2016).

Hydrous felsic magma generated by unmixing of slab-derived supercritical liquid: evidence from Rishiri Volcano, Kuril Arc

*Hajime Taniuchi[1], Takeshi Kuritani[2,3], Tetsuya Yokoyama[4,3], Eizo Nakamura[3], Mitsuhiro Nakagawa[2]

Institute for Planetary Materials, Okayama University, 4. Department of Earth and Planetary Sciences, Tokyo Institute of Technology

Introduction

Water-rich components released from the subducting slab play important roles in the generation of subduction-zone magmas in the mantle wedge (e.g. Elliott, 2003). With increasing fluid releasing depths, the slab-derived water-rich materials would become supercritical liquid (e.g. Bureau and Keppler, 1999).Experimental studies have suggested that slab-derived supercritical liquid is separated into hydrous silicate melt and aqueous fluid during the ascent in the mantle wedge (e.g. Kawamoto et al., 2012). However, the occurrence of magmas corresponding to this hydrous melt has not been reported so far. In this context, we have carried out a detailed petrological, geochemical, and chronological study on calc-alkaline andesite and dacite at Rishiri Volcano.

Results

Rishiri Volcano is a Quaternary stratovolcano in southern Kuril arc, and is 300 km above the Wadati-Benioff Zone. The volcanic activity started at ~0.2 Ma, which is characterized by coexistence of alkali basalt, tholeiitic andesite to dacite, and calc-alkaline andesite to dacite. The calc-alkaline andesitic products and the following dacitic lavas, investigated in this study, comprise Middle stage of the volcanic activity (Ishizuka, 1999). Our new $^{40}Ar/^{39}Ar$ age data for the dacitic and andesitic lavas are 35.5 ±1.4 ka and 34.6 ±3.0 ka, respectively.

The phenocryst assemblage of the dacitic lavas is Cpx + Opx + Pl, and that of the andesitic lavas is Ol + Cpx + Opx + Pl. All phenocrysts in the dacite have homogeneous compositions or show normal zonation with limited variations. In contrast, those in the andesite occasionally show reverse zonation. Some olivine and plagioclase phenocrysts have core compositions with up to Mg#89 and An#88, respectively. The dacitic lavas are characterized by high Sr/Y and La/Yb ratios (adakitic signature), no Eu anomaly, homogeneous Sr, Nd, and Pb isotopic ratios, and ^{230}Th-excesses. On the other hand, the andesitic lavas are heterogeneous in whole-rock major, trace, and isotopic compositions.

Discussion

The petrological and geochemical features of the andesitic products suggest that they were produced by mixing between felsic magma and primitive mafic magma. On the other hand, the dacitic lavas do not show any evidence of magma mixing. The absence of Eu anomaly negates a primary role of fractional crystallization in the magma genesis. In addition, the adakitic signature cannot be produced by crustal melting, because the underlying crust is too thin (Niu et al., 2016) for garnet to be stable (e.g. Rapp and Watson, 1995). Therefore, it is suggested that the dacitic magma was derived from the upper mantle, most plausibly, from the subducting slab. The slab origin of the magma is consistent with the ^{230}Th-excess

©2019. Japan Geoscience Union. All Right Reserved.

signature and the Pb isotopic compositions, which can be explained by mixing of a sediment component and an altered oceanic crust component of the slab.

One possible origin of the dacitic magma would be direct partial melting of the subducted slab (e.g. Defant and Drummont, 1990). However, extremely high temperatures with >1300ºC (Mibe et al., 2011) is required to melt the slab at ~300 km depth, which is highly unlikely. The andesitic and dacitic lavas erupted almost contemporaneously (~35 ka), with the former preceding the latter. The primitive mafic magma, involved in the generation of the andesitic magma, is considered to have been generated through fluid-fluxed melting of the mantle. These observations suggest that slab-derived aqueous fluid and slab-derived hydrous melt, corresponding to the dacitic magma, were almost simultaneously present in the upper mantle beneath the Rishiri Volcano at ~35 ka. Therefore, it is suggested that the dacitic magma may represent hydrous melt, which was separated from the ascending slab-derived supercritical liquid at the depth corresponding to the critical end point, leaving behind aqueous fluid (e.g. Kawamoto et al., 2012) that induced the generation of the primitive basaltic magma.

Genesis of recent mafic volcanism in the Taupo Volcanic Zone, New Zealand: insights into the birth and death of cataclysmic caldera-forming systems?

*Georg F Zellmer[1], Jun-Ichi Kimura[2], Claudine Stirling[3], Gert Lube[1], Phil A Shane[4]

1. Volcanic Risk Solutions, Massey University, Tennent Drive, Palmerston North 4410, New Zealand, 2. Department of Solid Earth Geochemistry, Japan Agency for Marine-Earth Science and Technology [JAMSTEC], Natsushima-cho 2-15, Yokosuka 237-0061, Japan, 3. Department of Chemistry, University of Otago, Dunedin 9054, New Zealand, 4. School of Environment, University of Auckland, Auckland 1142, New Zealand

Mafic magmatism of the actively extending Taupo Volcanic Zone (TVZ) of the North Island, New Zealand, is volumetrically minor, but thought to tap the material that provides the heat source for voluminous rhyolite production through partial melting of the crust, which ultimately results in cataclysmic caldera-forming eruptions. We have studied the major and trace element chemistry 14 mafic samples from across the entire TVZ, and the uranium isotopic composition of whole rocks, groundmasses and separates of mafic mineral phases from a selection of 9 samples (with the remaining 5 too sparsely phyric for mineral separation). Some minerals yield significant ^{234}U enrichments despite groundmass and whole rock close to ^{238}U-^{234}U secular equilibrium, pointing to uptake of variably hydrothermally altered antecrystic minerals prior to the eruption of originally sparsely pyric to aphyric mafic magmas. However, incompatible trace element pattern indicate that there are three chemically distinct groups of samples, and that all but one sample may be used to derive primary melt compositions. We employ the latest version of the Arc Basalt Simulator (ABS5) to forward model these compositions, deriving mantle source parameters including mantle fertility, slab liquid flux, mantle volatile content, degree of melting, and P-T conditions of melt segregation. We show that mafic rocks erupted in areas of old, now inactive calderas constitute low-degree, deep melts, while those in areas of active caldera-volcanism are high-degree partial melts segregated from a less depleted source at an intermediate depth. Finally high-Mg basaltic andesites erupted in the southwest and the northeast of the TVZ point to a fertile, shallow mantle source. Our data are consistent with a petrogenetic model where mantle melting is dominated by decompression, rather than fluid fluxing, and progresses from shallow to deeper levels with time. Melt volumes initially increase to a tipping point, at which large scale crustal melting and caldera volcanism become prominent, and then decrease due to progressive depletion of the mantle wedge by melting, resulting in the dearth of heat provided and eventual cessation of rhyolitic cataclysim. For the first time, a direct link becomes apparent between the chemistry of recently erupted mafic magmas and the long-term activity and evolution of caldera volcanism in the TVZ.

Tue. May 28, 2019 3:30 PM - 5:00 PM JST | Tue. May 28, 2019 6:30 AM - 8:00 AM UTC | A07 TOKYO BAY MAKUHARI HALL

[S-MP30] Crust-Mantle Connections

convener:Yoshihiko Tamura(Research Institute for Marine Geodynamics, Japan Agency for Maine-Earth Science and Technology), Osamu Ishizuka(Geological Survey of Japan, AIST), Chris Conway(Geological Survey of Japan), Chairperson:Chris Conway, Yoshihiko Tamura(JAMSTEC)

A paradigm of the solid Earth geochemical cycles is that the Earth's crust forms by melting of the Earth's upper peridotitic mantle. How divers is the spectrum of primary melts and which factors may contribute to its variations? What is the influence of crustal processing vs. primary magma diversity in creating the diversity of the Earth's crust? The session seeks to explore the crust-mantle connections at divergent and convergent plate boundaries, and oceanic island settings based on volcanology, petrology, geochemistry, geophysics, geochronology, and geodynamics studies.

Oceanic core complexes (OCCs) are domal bathymetric highs with axis-normal corrugations, and with exposure of serpentinized peridotite and gabbroic rocks, interpreted as exhumed footwalls of low-angle detachment faults. OCCs provide a valuable opportunity to directly study the architecture of oceanic lithosphere, together with the tectono-magmatic processes associated with its formation and evolution.

A significant fraction of the ocean floor is created in backarc basins where water plays a major role in generating backarc basin basalts, strikingly contrasting to magmatic process at mid-ocean ridges. The opportunity to explore the recent formation of backarc basin lower crust and upper mantle is, therefore, an important contribution to understanding the ocean basins. The extensive multi-beam bathymetric mapping by Japan’ s continental shelf survey has revealed the presence of potential OCCs in the multiple portions of the Philippine Sea Plate, such as in the Parece Vela Basin, Shikoku Basin, Kita-Daito Basin and West Philippine Basin. Among these, Godzilla Megamullion in the Parece Vela Basin is the largest known OCC on the Earth, and is one of the well-studied OCCs in the world.

In order to advance our understanding of the lithospheric composition of the Philippine Sea Plate, we need to utilize the potential Philippine Sea OCCs as tectonic windows to sample the lower crust and upper mantle materials. However, these potential OCCs have been remained largely unsampled and unstudied except only a few locations. We thus have started a new project focusing on the Shikoku Basin OCCs. Two cruises in the 2018 summer (YK18-07 and KH-18-2) collected peridotites and gabbros from the main Shikoku Basin OCC, here we named “Mado Megamullion”. The scheduled YK19-04S cruise in 2019 April will collect more datasets on this OCC.

In this contribution, we will show the general tectono-magmatic characteristics of Mado Megamullion. The OCC provides the information on the Shikoku Basin lower crust and upper mantle for the first time. Mado Megamullion is an ~20 km square OCC, the areal size is comparable to Kane Magamullion in the Mid-Atlantic Ridge. Thus it should be easier for us to make a comparative study between the two OCCs, providing useful information to understand the difference of the lithospheric characteristics between the two major ocean environments.

Spatial variation of petrological and geochemical characteristics of mantle peridotites in Mado Megamullion, Shikoku Basin

*Norikatsu Akizawa[1], Shiki Machida[2], Kyoko Okino[1], Yasuhiko Ohara[3]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology, 3. Hydrographic and Oceanographic Department of Japan

Oceanic core complex is one of the tectonic windows, where mantle peridotites are exposed directly to the ocean floor. The mantle peridotites can provide petrological and geochemical information of the inaccessible oceanic mantle. However, the mantle peridotites from the oceanic core complex bear a possibility that their petrological and geochemical characteristics were modified during exhumation to the ocean floor via detachment faulting. Thus, formation process of the oceanic core complex must be elucidated in order to better presume the pristine oceanic mantle materials therein. Here, we present petrological and geochemical characteristics of mantle peridotites collected from a newly termed backarc oceanic core complex, “Mado (window in Japanese)” Megamullion in the Shikoku Basin, Philippine Sea. The samples were collected through a series of scientific cruises, YK18-07 by R/V Yokosuka with DSV Shinkai 6500, and KH-18-2 by R/V Hakuho. A total of 16 samples is used here: 13 peridotites and 3 dunites. Vein-like oxide gabbros are included in some peridotite samples from a region close to the ridge axis (proximal region), whereas none of the peridotites showing such lithological characteristics were found from a region far from the ridge axis (distal region). In contrast, the dunite samples were found only from the distal region. Since dunites are commonly interpreted as fossil channels for primitive (silica-depleted) melts beneath mid-ocean ridges, they likely transported parental melts of mid-ocean ridge basalt (MORB) beneath paleo-ridge axis. With regards to the spatial variation of petrological and geochemical characteristics of the mantle peridotites, we delineate a scenario of Mado Megamullion formation, where the exhumed mantle materials were getting modified by evolved magmas with time proceeding, indicating magma stagnation due probably to time-dependent cooling of the ridge spreading system. Therefore, the mantle peridotites in the distal region might show relatively pristine geochemical compositions in comparison with those in the proximal region.

Magmatism-hydrothermalism interaction along the crust-mantle transition below oceanic spreading centres

*Mathieu Rospabe[1,2], Mathieu Benoit[1], Georges Ceuleneer[1]

1. GET, OMP, Univ. of Toulouse, CNRS, IRD, F-31400 Toulouse, France, 2. JAMSTEC, Yokosuka 237-0061, Japan.

Beneath oceanic spreading centres, the transition from the upwelling and partially molten peridotitic mantle and the accreting gabbroic lower crust appears as a major chemical, thermal and rheological interface. In most ophiolites worldwide, it is underlined by a dunitic horizon whatever the paleo-tectonic setting (mid-ocean ridges vs. supra-subduction zone). Since dunite is observed in present-day oceans in different geodynamic environments, in association with mantle harzburgite and with troctolitic-gabbroic veins and sills, it is reasonable to suppose that ophiolitic dunitic transition zone (DTZ) formed prior to the intra-oceanic thrusting leading to obduction.

As a matter of fact, the understanding of the petrological processes occurring in the mantle-crust transition zone beneath oceanic ridges can be studied in the Oman ophiolite. Particularly, the Maqsad area (Sumail massif) evolved in a MORB-like magmatic environment and presently exposes a >300 m thick DTZ above a paleo-mantle diapiric structure. It has been attributed to peridotite reactional melting or to the accumulation of olivine from Mg-rich melts, whether a combined origin is more likely. Following the reactional origin, a partially molten harzburgite reacts with interstitial melts, enhancing the orthopyroxene dissolution and the crystallization of secondary olivine, resulting in a rock essentially made of olivine. Interstitial mineral fractionation during melt migration between olivine grains (or melt-rock reaction) is partly responsible of the extensive petrological and geochemical variability observed at Moho level.

Recent studies evidenced a large interstitial mineral variety in dunites from the DTZ with, in addition to plagioclase and clinopyroxene expected in a MORB magmatic environment, the presence of orthopyroxene and amphibole among others. These minerals are also observed, together with mica, as silicate inclusions in chromite grains scattered in the dunite. This calls for the early involvement of hydrated, Si- and alkali-rich melts in the formation of dunite and chromitite ore bodies at Moho level beneath oceanic ridges. Since the presence of this peculiar mineralogy is ubiquitous within the DTZ and absent in mantle harzburgite, this distribution supports that the hydrated component originated from above, probably seawater in origin. These fluids interacted with surrounding rocks and with the variably evolved MORB issued from the Maqsad diapir, allowing to generate the hybrid melts, i.e. a blend between supercritical hydrothermal fluids rich in silica or trondhjemitic melts issued from hydrous melting of the country rocks.

The chemical variations observed along the Maqsad DTZ define trends with a characteristic vertical scale of few tens of meters. The chemical variation patterns are spatially correlated to the distribution of ridge-related faults or fracture zones (i.e. active at an early, high temperature magmatic stage), not only for fluid-mobile elements but also for immobile elements (e.g. REE, HFSE). These faults seem to have

©2019. Japan Geoscience Union. All Right Reserved.

enhanced (i) melt migration and extraction, from the mantle to the crust, and (ii) deep hydrothermal fluids introduction down to the Moho level. In other words, they are the main vectors for upwelling melt modification by hybridization, with hydrothermal fluids and/or silicic hydrous melts, and crystallization. In this context, the DTZ appears as a reactive interface that developed by the combination of three primary processes: tectonics, magmatism and deep, high temperature hydrothermal circulations. Fluid-melt-rocks reactions occurring at Moho level may have a significant impact on the MORB variability surveyed along present-day mid-ocean ridges and may contribute to part of the signatures observed at hydrothermal vents.

Serpentinization and carbonation of dunites in the western part of the Isua Supracrustal Belt, Southwestern Greenland

*Juan Miguel Ramirez Guotana[1], Tomoaki Morishita[1], Akihiro Tamura[1], Ikuya Nishio[1], Kenichiro Tani[2], Yumiko Harigane[3], Kristoffer Szilas[4], D. Graham Pearson[5]

1. Kanazawa University, 2. National Museum of Nature and Science, Japan, 3. Institute of Geology and Geoinformation Geological Survey of Japan/AIST, 4. University of Copenhagen, 5. University of Alberta

The 3.7 Ga Isua supracrustal belt (ISB) hosted in Itsaq Gneiss Complex in southwestern Greenland preserves one of the oldest metamorphosed mafic-ultramafic complex in the world which provides opportunity to study early petrological processes on Earth. Ultramafic bodies are common throughout the Isua supracrustal belt. These ultramafic rocks are interpreted to be possible mantle residues while other studies consider a cumulate origin. In the western limb of the ISB, less altered dunitic bodies enveloped by metasomatized dunites and amphibolites are exposed. The studied dunite lens is also referred as Lens B by previous studies. The northern part of Lens B dunites are highly deformed, highly serpentinized and carbonatized. The central and lower Lens B are less deformed and composed of olivine, serpentine, magnesite, magnetite, stichtite and Ti-rich humites. Ti-chondrodite (Ti-Chn) and Ti-clinohumite (Ti-Chu) are present in the central and southern part of Lens B. Ti-Chn and Ti-Chu occur commonly as irregular patches in olivine. In some portions, intergrowths of Ti-Chn and Ti-Chu are present. The F contents of the the Ti-Chn and Ti-Chu are also very low. Olivine grains are highly forsteritic and are comparable to those derived by deserpentinization process. The major serpentine phase is antigorite which occur as platy grains and minor amounts as inclusion in olivine. Stichtite, a magnesium-chromium hydroxycarbonate mineral, also includes clinohumite minerals. The clinohumite intergrowth in ISB dunites can be associated to the breakdown of Ti-Chn to Ti-Chu (Ti-Chn+Atg+Ol=Ti-Chu+H2O). The clinohumites are also almost F-free which suggests a lower temperature within the antigorite stability field compared to F-bearing clinohumites. Petrographic and geochemical results suggest that the dunites reached P-T conditions within the Ti-Ch and Atg stability field and retrogressed and carbonated (stichtite and magnesite) at lower pressure and temperature where Ti-Chu is stable.

Petrogenesis of fertile abyssal peridotites of the Pujada Ophiolite, SE Mindanao, Philippines

*Valerie Shayne Vargas Olfindo[1], Betchaida Duetes Payot[1], Gabriel Theophilus Valera[1], Shoji Arai[2], Tomoyuki Shibata[4], Masako Yoshikawa[3]

1. Rushurgent Working Group, National Institute of Geological Sciences, University of the Philippines, 2. Department of Earth Sciences, Kanazawa University, Kakuma, Kanazawa, Ishikawa 920-1192, Japan, 3. Institute for Geothermal Sciences, Graduate School of Science, Kyoto University, Beppu 874-0903, Japan, 4. Department of Earth and Planetary Systems Science, Hiroshima University, Hiroshima 739-8526, Japan

Fresh mantle peridotites of the Pujada Ophiolite are extensively exposed in southeast Mindanao, Philippines. Despite its good preservation, its origin and formation is not constrained due to lacking geologic data. In this study, petrographic and geochemical characteristics of the mantle section of the Pujada Ophiolite are investigated to determine its tectonic setting and the magmatic processes operating during its formation.

The mantle section of the Pujada Ophiolite is composed of massive and pyroxene-rich lherzolites and harzburgites and interlayers of variably serpentinized lherzolites, harzburgites and dunites. Mineral chemistry of the spinel peridotites reveal spinel Cr# =0.10-0.50 and olivine Fo =89-91 typical of abyssal peridotites. The mantle peridotites are classified into three based on their field occurrence and spinel Cr#: Group I - massive lherzolites and harzburgites with Cr# =0.10-0.40, Group II - interlayered lherzolites and harzburgites with Cr# =0.10-0.40, and Group III - interlayered harzburgites and dunites with Cr# >0.4. The Group I peridotites are protogranular with minor vermicular spinel. The Group II peridotites are highly serpentinized. Preserved portions show porphyroclastic texture with vermicular to subhedral spinel. The Group III peridotites are also highly serpentinized but porphyroclastic texture in the harzburgites can be observed. Clinopyroxene and orthopyroxene compositions of the peridotites reveal an increasing depletion in Al_2O_3 from Group I to Group II and III with increasing Mg#. Groups I and II show lower Mg# =0.90-0.93 and 0.92-0.93, respectively. The Group III peridotites have the highest Mg# =0.925-0.935. The clinopyroxene Na_2O and TiO_2 of the three groups are within the same range of 0.10-0.40 and 0.10-0.25, respectively. The orthopyroxenes also show the same range of Na_2O and TiO_2 of 0.01-0.10 and 0.01-0.20, respectively. In general, rare earth element composition shows depletion of light rare earth element (LREE) and relatively flat heavy rare earth element (HREE) which further suggest an abyssal origin. Trace element compositions of the peridotites are indicative of low degrees of partial melting within 6%-14%. A few peridotite samples also show LREE enrichment suggesting that metasomatism may have affected these rocks.

Ultramafic rock in the Hida metamorphic belt: an example of arc plutons

Yohei Ogusu[1], *Tomoaki Morishita[1], Akihiro Tamura[1]

1. Kanazawa University

We report petrology and mineral compositions of ultramafic rocks in the Hida metamorphic belt, which was metamorphosed at around 235-250 Ma (Takahashi et al., 2018, Island Arc). It was pointed out in a graduation thesis of Kanazawa University that a small ultramafic body exists in the Hida metamorphic blet of Ozoe area, Hakusan City (Nagaoka, 1970). A preliminary result revealed that this ultramafic rock of the Hakusan City is mainly composed of large poikilitic amphibole grains enclosing many olivine grains, which are traditionally called as cortlandite (Williams, 1893 Jour. Geol.). These amphibole-rich plutonic rocks are expected in deeper part of island arc (e.g., Davidson et al., 2007 Geology). In fact, cortlandite and/or amphibole-rich plutonic rocks in granitic rocks/felsic metamorphic rocks were reported from all over the world (e.g., Tiepolo et al., 2011 Jour. Petrol.). Although these formation ages are different, it is noticed that they formed at convergent plate boundaries (Tiepolo et al., 2011). Cortlandite is minor but is reported from the Ryoke metamorphic belt, Japan (e.g., Kutsukake, 1978, Memoir. Kyoto Univ. Ser. Geol. Mineral.). Cortlandite and related amphibole-rich rocks would shed light on magmatic processes occurred beneath island arcs.

Ultramafic rocks of the Hakusan city (simply call Hakusan Ultramafic rock hereafter) is mainly composed of large poikilitic amphibole and orthopyroxene enclosing olivine grains. These olivine grains contain chromian spinels. Olivine with spinel existed phases before amphibole and orthopyroxene were crystallized. Orthopyroxene are sometimes included in amphibole and amphibole shows euhedral shape against the next orthopyroxene grain indicating amphibole is an early crystallization phase. The Fo content of olivine is around 84 and XMg of amphibole is around 90. High XMg of mafic minerals indicate that the Hakusan Ultramafic rock was formed from a relatively primitive melt. Poikilitic amphibole is pargasitic in composition. Calculated melt compositions from trace element compositions of the poikilitic amphibole are characterized by high in LILEs with negative anomalies of HFSEs, and are similar to arc magmas. We concluded that the Hokuriku Ultramafic rocks are formed from arc-related magma. It is important to study the origin of cortlandite and related amphibole-rich plutons from other metamorphic belts with different ages to understand the differences in mode and conditions of arc formation.

[S-MP31] Supercontinents and Crustal Evolution

convener:Madhusoodhan Satish-Kumar(Department of Geology, Faculty of Science, Niigata University), Tomokazu Hokada(National Institute of Polar Research), Krishnan Sajeev(Centre for Earth Sciences, Indian Institute of Science), Yasuhito Osanai(Division of Evolution of Earth Environments, Faculty of Social and Cultural Studies, Kyushu University), Chairperson:M. Satish-Kumar(Niigata University), Tomokazu Hokada(National Institute of Polar Research)

Supercontinent formation and dispersion has been enigmatic in the Earth's history. Eurasia is one such current supercontinent and incredible progress in the understanding of its geological evolution has been achieved in the past decade. Earlier supercontinents in the Earth's history such as Gondwana (0.5 Ga), Rodinia (1.0 Ga), Columbia/Nuna (2.0 Ga), Kenorland (2.5 Ga) and Vaalbara (3.1 Ga), have been the focus of several studies, however limited information on older supercontinents has restricted an understanding of their tectonic evolution. In this session, we invite authors around the world to present new data as well as review existing results on the continental scale crustal processes and tectonic evolution that are associated with supercontinent formation and breakup events in the Earth's history. The well-studied Eurasia and Gondwana supercontinents are of particular focus. Topics of interest include, but not restricted to, extremes in metamorphism, P-T-d-t evolution, magmatism, and the role of fluids. We hope to provide a platform for scientific discussions that will enlighten our understanding of the physical and chemical processes in the continental crust that records episodes of orogenesis that contributed to the formation and evolution of supercontinents.

Tectonic development of the East Indian cratonic margin and its status in Columbia Supercontinent

*Kaushik Das[1]

1. Hiroshima University

The East Indian cratonic margin is an important geological area towards understanding the tectonic development of the Precambrian India co-evolving with its erstwhile continental neighbors, including Antarctica. It, at present spreads out several linearly arranged Mesoproterozoic sedimentary basins (Chhattisgarh Basin and its satelite basins) unconformably lying on the Archean Bastar cratonic basement rocks and also juxtaposed on its east by a Proterozoic orogenic belt (Eastern Ghats Belt, EGB). While the basement rocks reveal the origin and evolution of the Archean craton and later tectonics affecting it, the sedimentary basins preserve the history of basin tectonics and fluctuation of different geological and geochemical proxies indicating the fluctuation of paleoenvironment, and also the tectonics of surrounding areas. The adjacent orogenic belt also has a variegated history of its developement and final cratonization, at least the tectonic history of the southern part was older while major part of the northern part was younger than the formation of those sedimenatry basins.
Our group in recent years have carried out detailed sedimentological, geochemical, and geochronological studies of the early sediment fills of these Mesoproterozoic basins (Chakraborty et al., 2012, Precam. Res., 200-203, 129-148; Das et al., 2015, Geol. Soc. London, Memoirs, 43, 207–221; Saha et al., 2016, Precam. Res., 281, 363-383) In this presentation, the collated data on the paleo-environmental facies analysis, variation in Nd-isotope geochemistry and U-Pb detrital zircon geochronology will be presented for the sediments of Singhora Basin, Khariar Basin and Ampani Basin, and also the geochemical character with tectonic affinity of the ca. 1450 Ma felsic porcellanitic tuff layer in all these basins. This will help to have an integrated understanding of the evolution of deep- to shallow continental crust in the East Indian Craton margin, as well as the connection between its neighbors in the supercontinent, "Columbia".

Continental crust formation and metamorphism during the Neoarchean–Paleoproterozoic: an example from the Nilgiri Block, southern India

*VINOD O SAMUEL[1]

1. Yonsei University

Earth is a unique planetary body with an evolved felsic continental crust on its surface. Had this continental crust not evolved, Earth’ s crust would have been basaltic/gabbroic in composition, and covered almost completely by water. It is important to understand how the mafic crust, which formed after the differentiation of Planet Earth transformed to one that is felsic in composition. Presently active processes capable of transforming crust from mafic to felsic composition, on a large scale, are subduction and subsequent arc magmatism. However, whether such processes were active during the Hadean–Archean eon is highly debated. Field evidence from major cratons show that partial melting of the earlier formed mafic crust (e.g., processes like sagduction) formed felsic continental crust. Thus, understanding when subduction-related process started on the planet is important. Here we present evidence from metamorphosed magmatic rocks such as pyroxenite, metagabbro, two-pyroxene granulite, charnockite, hornblende-biotite gneiss and rhyolite from the Nilgiri Block, southern India. U-Pb zircon age data shows that all these rocks formed during the late Neoarchean (core ages between 2600–2500Ma) and that they underwent subsequent metamorphism during the early Paleoproterozoic (rim ages between 2500–2450Ma). If felsic rocks formed from the partial melting of earlier formed mafic rocks, the mafic rocks should be older. Since all these rocks were formed and metamorphosed simultaneously, it is possible that protoliths of these rocks formed through melt differentiation followed by partial melting in the mantle wedge during the subduction-related arc magmatic process. An enrichment in light field strength elements and REE compared to heavy ones, and Nb-Ta depletion are common signatures in rocks formed through the arc magmatic process, where fluids or melts formed from subducted basaltic crust and the overlying sediments enrich the mantle wedge in lighter elements. Further, during metamorphism, these rocks could partially melt and form granitic melts. However there is no field evidence that suggests partial melting during metamorphism in these rocks. Textural relations and vein networks of silicate-oxide-sulfide-phosphate minerals in these rocks suggest that they could have possibly metasomatized in the presence of saline fluids during the early Paleoproterozoic. Such saline fluids could have been released during the waning stages of the magmatic process, probably due to the collapse and mixing of the accretionary wedge to the mantle wedge.

Preliminary paleomagnetic studies on the mafic dykes in Western Dharwar craton, South India.

*Silpa Ammini Sasidharan[1], Madhusoodhan Satish-Kumar[2], Naoto Ishikawa[3], Krishnan Sajeev[4]

1. Graduate School of Science and Technology, Niigata University, 2. Department of Geology, Faculty of Science, Niigata University, 3. Graduate School of Human and Environmental Studies, Kyoto University, Kyoto, Japan, 4. Centre for Earth Sciences, Indian Institute of Science, Bangalore, India

Mafic dykes of varying dimensions and ages are well exposed all along the Archean Dharwar craton of south India. The mafic dykes in the Eastern Dharwar craton (EDC) have been studied in detail by several researchers previously (French and Heaman, 2010; Kumar et al., 2012, Srivastava et al., 2014). However, limited information is available for the dyke in Western Dharwar craton (WDC) and is considered in the present study. Representative samples were collected from dykes in the WDC and detailed petrography and geochemistry were carried out. The thin section observation revealed two different types of dykes based on the mineral assemblage, texture and the degree of alteration. First category of dykes is dolerites with typical ophitic texture and lath-shaped plagioclase. The other group of dyke samples showed high degree of alteration and remnant ophitic textures with the preservation of very less plagioclase laths as well as original mineralogy. This group termed as meta-dolerites, because of the prominent metamorphism. The dolerites and meta-dolerites are found to exhibit different distribution of major oxides as well as distinct trace and rare-earth element concentrations (Silpa and Satish-Kumar, 2018). The difference in petrography and geochemistry between the dolerites and meta-dolerites can lead to a preliminary inference that these two suits of rocks might not be co-genetic.

Understanding paleo- positions in which the dykes were emplaced is key while correlating the present, spatially distant cratons. Paleomagnetic studies will help to understand the paleo-position of the cratons and mafic dykes are expected to provide excellent records of the earth’s magnetic field as they cool rapidly when emplaced (Belica et al., 2014). For the preliminary paleomagnetic analyses, 86 core specimens were prepared from 33 sites including both dolerite and meta-dolerites and progressive demagnetization experiment has been conducted to assess the stability of natural remanent magnetization (NRM). Pilot specimens were subjected to alternating-field or thermal demagnetization and the NRMs were measured with a spinner magnetometer. Dolerite specimens yielded better magnetic behaviors with stable magnetic components. On the other hand, meta-dolerites show magnetic components probably carried by pyrrhotite and the magnetic behaviors were very unstable. Fig. 1 shows demagnetization behaviors of dolerite sample plotted on orthogonal vector-endpoint diagrams and equal area stereonets.

Studying the dykes in the Dharwar craton is key to understanding the evolution of the mantle during the Precambrian, especially in the Archean to Proterozoic transitional period. Dykes are emplaced after the period of major continental crust formation at around 2.7 Ga and hence the variation in mantle composition through time can be constrained. The dykes can be a result of a plume activity or an indicator of large igneous province and hence the study of which will give valuable information about the mantle source, the degree of melting and the source regions where melting occurred. Dyke swarms and LIPs are the products of major magmatic events in the Earth’s history that probably was the driving force in the breaking up of supercontinents, and they provide clues regarding the cratonic evolution through time. Due to their wide distribution, geochemically coherent dykes can be found in many cratons, thus providing key information on the close proximity of now separated supercontinents.

Syn-metamorphic boron-bearing fluid infiltrations deduced from tourmaline in the Main Central Thrust zone, eastern Nepal Himalayas

*Tetsuo Kawakami[1], Harutaka Sakai[1], Katsushi Sato[1]

1. Graduate School of Science, Kyoto University

Mode of occurrence and chemical composition of tourmaline in pelitic schists from the Main Central Thrust (MCT) zone of the Lesser Himalayan Sequences (LHS) are described in detail to deduce the chemical characteristics of tourmaline formed through boron-bearing fluid infiltration, and to estimate the syn-metamorphic fluid compositions.

Metasomatic tourmaline from the tourmalinized wall rocks of tourmaline-quartz veins and a plagioclase-quartz vein shows significant increase in X_{Ca} [=Ca/(Ca+Na)] at almost constant X_{Mg} [=Mg/(Mg+Fe_{total})]. Plagioclase present in such veins are anorthite-rich, and is not in equilibrium with tourmaline. These chemical characteristics of tourmaline are also confirmed in some of the tourmaline-rich pelitic schists that contain more than 1.0 vol% tourmaline. The tourmaline-rich pelitic schists, therefore, are considered to have formed through boron-bearing fluid infiltration. Ca-metasomatism observed in the pelitic schists adjacent to the metadolostone layers points to Ca-enrichment of the fluid composition when passing through the metadolostone layers. Episodic infiltration of such fluids into pelitic schists resulted in production of abundant tourmaline with increasing X_{Ca} trend at almost constant X_{Mg}. Most of the tourmaline in tourmaline-rich pelitic schists are in equilibrium with plagioclase, suggesting rock-buffered environment during the fluid infiltration. The pelitic schists without tourmaline enrichment mostly show increase in X_{Ca} at broad X_{Mg} values, reflecting its growth during longer range of metamorphism.

The fluid compositions that coexisted with tourmaline were estimated by applying experimentally-determined fluid/tourmaline chemical relationships to the vein, tourmaline-rich pelitic schist and tourmaline-poor pelitic schist samples. Assuming coexisting anion to be Cl, they all gave salinity similar to the sea water (~0.6 mol/l NaCl) and slightly above it (~0.4-0.9 mol/l NaCl+$CaCl_2$). The tourmaline-bearing veins and tourmaline-rich pelitic schists indicative of syn-metamorphic boron-bearing fluid infiltrations are widely distributed in the MCT zone of the LHS.

This observation supports that such fluid infiltrations into the High Himalayan Crystallines (HHC), contemporaneous with the inverted metamorphism of the MCT zone, caused vapor-saturated partial melting of the HHC and formed tourmaline leucogranite melts.

Geochemical characteristics of mafic and felsic igneous rocks (1.9-1.75 Ga) in the Lesser Himalaya: Regional variation and its implications for tectonic setting

*Ryuichi Shinjo[1], Tomoki Amuro[1], Kohei Oura[1], Kazuya Oshiro[1], Shiro Tahara[1], Harutaka Sakai[2]

1. Department of Physics and Earth Sciences, University of the Ryukyus, 2. Faculty of Science, Kyoto University

We present geochemical characteristics of mafic and felsic intrusive rocks (1.9-1.75 Ga) in the Lesser Himalaya and discuss about its tectonic setting. Rocks are taken from wide range of the Lesser Himalaya.

Models of tectonic setting for these rocks are controversial, which include subduction-zone setting (Kohn et al., 2010) and continental rift setting (Sakai et al., 2013).

Analyses of immobile trace element compositions suggest that mafic rocks (metagabbro) from the eastern Nepal have within-plate (or OIB) type composition, while the rocks from central and western Nepal have chemical compositions similar to subduction-related (active continental margin) basalt. It is noted that both types occur in the western Nepal. Based on these results, we suggest that plume-related rift system is more likely tectonic setting for these mafic magmatism than arc setting. Arc-like signature in western Nepal rocks may be derived from sub-continental lithospheric mantle.

Similar regional variation in trace element compositions for felsic rocks was observed. Initial 143Nd/144Nd and 176Hf/177Hf of felsic rocks are lower than those of mafic rocks; thus crustal component might involved significantly in generation of felsic magmas.

Keywords: Nepal, Lesser Himalaya, tectonic setting

Petrogenesis and tectonic implications of orbicular granodiorite from Yangtze cratonic nucleus

*Yihe Li[1]

1. China University of Geosciences Wuhan

Orbicular granodiorite outcropped in the Yangtze cratonic nucleus (Huangling Dome), where at least six Precambrian (3.4-0.8 Ga) tectonic events have been recorded. Hence, Huangling Orbicluar Granodiorite (HOG) could help us to investigate both petrogenesis and tectonic implications.

The HOG exposed in the northern margin of Neoproterozoic (~0.8 Ga) Huangling batholith, merely 30 meters long and 5 meters wide. They are composed of obicules (5-12 centimeters in diameter) and matrix. The obicules have different structure as no shell, one-layer shell and multiple-layer shells. In detail, one-layer shell are formed by dark color minerals such as amphibole and biotite; multiple-layer shells are made up of dark layers (dominated by amphibole) and light layers (dominated by plagioclase) at random intervals (0.2-4.3 millimeters). Their inner parts (core) are major plagioclase with minor amphiboles.

Mineral chemistry data are obtained by Electron Probe Micro Analyzer (EPMA) from two profiles crossing obicules. The An (An=100 Ca/(Ca+Na+K)) of plagioclase in matrix, shell and core from one-layer obicule are 26-30, 30-35 and 35-40, indicating the crystallization sequence is from core to shell and then matrix. The An of plagioclase in matrix, shell and core from multiple-layer obicule are more complicate, as 33, 36-46 and 42-45. The data suggest that the obicule crystallized before matrix, without distinct sequence between core and shells.

P-T conditions are calculated by Hb-Pl thermobarometry (Holland and Blundy, 1994; Bhadra and Bhattacharya, 2007). 0.63 GPa and 728℃ are obtained from core of one-layer obicule, while 0.49 GPa and 706℃ are gained from core of multiple-layer obicule. Moreover, P-T condition of multiple-layer shells vary from 0.50-0.80 Gpa and 669-713 ℃, showing pressure decrease towards core with few sharp increasing. The average P-T condition of shells are 0.60 Gpa and 700 ℃, whose pressure is higher than the core. As a result, the multiple-layer obicules may form during decompression. Besides, the sharp increase of An and P-T condition suggest that more basic (Ca-rich) composition may be added into shells during formation.

Chemical distribution patterns of shells and *in-situ* zircon structure have been examined by field emission scanning electron microscopy (FESEM). Energy-dispersive X-ray spectrometers (EDS) mapping shows that no obvious chemical differentiation have been observed in the rhythm shells. Core-mantle-rim structure zircons have been found in the matrix near the shells of obicules. Short columnar zircons with oscillatory bands have been found in amphiboles, while long columnar zircons with wide bands and overgrowth rims/patches have been found in plagioclase.

Zircons with Core-mantle-rim structure present concordant U-Pb ages as 1.95 Ga, 1.85 Ga and 0.88 Ga, with corresponding Epsilon Hf(t) values of -17.2 to -4.6, -10.8 to 0.36 and -23.6 to -21.5. Both short and long columnar zircons present concordant U-Pb ages of 0.88 Ga with Epsilon Hf(t) values of -23.7 to -19.85.

Based on new data and geological background, a model for generation of the HOG has been proposed as:

©2019. Japan Geoscience Union. All Right Reserved.

1) sediments metamorphosed at 1.95 Ga during continent-continent collision (Yin et al., 2013); 2) A-type granitic magma intruded the metasediments at 1.85 Ga (Xiong et al., 2009); 3) dioritic magma intruded the metasediments via the A-type granitic channel at 0.88 Ga; 4) water-rich superheating caused by dehydration of metasediments; 5) rapid crystallzation caused by undercooling while pressure decreasing.

[S-MP31] Supercontinents and Crustal Evolution

convener:Madhusoodhan Satish-Kumar(Department of Geology, Faculty of Science, Niigata University), Tomokazu Hokada(National Institute of Polar Research), Krishnan Sajeev(Centre for Earth Sciences, Indian Institute of Science), Yasuhito Osanai(Division of Evolution of Earth Environments, Faculty of Social and Cultural Studies, Kyushu University)

Supercontinent formation and dispersion has been enigmatic in the Earth's history. Eurasia is one such current supercontinent and incredible progress in the understanding of its geological evolution has been achieved in the past decade. Earlier supercontinents in the Earth's history such as Gondwana (0.5 Ga), Rodinia (1.0 Ga), Columbia/Nuna (2.0 Ga), Kenorland (2.5 Ga) and Vaalbara (3.1 Ga), have been the focus of several studies, however limited information on older supercontinents has restricted an understanding of their tectonic evolution. In this session, we invite authors around the world to present new data as well as review existing results on the continental scale crustal processes and tectonic evolution that are associated with supercontinent formation and breakup events in the Earth's history. The well-studied Eurasia and Gondwana supercontinents are of particular focus. Topics of interest include, but not restricted to, extremes in metamorphism, P-T-d-t evolution, magmatism, and the role of fluids. We hope to provide a platform for scientific discussions that will enlighten our understanding of the physical and chemical processes in the continental crust that records episodes of orogenesis that contributed to the formation and evolution of supercontinents.

Enderby Land in Antarctica comprises of Neoproterozoic-Cambrian (c.650-500 Ma) high-grade metamorphic terranes that constituting Gondwana supercontinent (e.g., Shiraishi et al., 2008). Easternmost part is “Western Rayner Complex” of which granulite-facies and partly UHT metamorphism (Motoyoshi et al., 1994, 1995) and 2400-1000 Ma protolith and 540-520 Ma metamorphic ages were reported (Shiraishi et al., 1997). Neighboring “Rayner Complex” is characterized by >2500-1000 Ma protolith and 980-910 Ma granulite-facies metamorphic ages. Boundary between the Rayner and the Western Rayner Complex has been not clearly defined until when Horie et al. (2016) obtained 934-894 Ma SHIRMP zircon U-Pb ages from Mt. Lira, Condon Hills and Mt. Yuzhnaya regions with minor 590-570 Ma zircons from Mt. Yuzhnaya. Hiroi (unpublished data) also demonstrated contrasting metamorphic P-T evolution among the Mt. Lira, Condon Hills and Mt. Yuzhnaya regions.

JARE-58 (2016-2017) geology team made a short visit and sampling at a small nunatak of west of Mt. Yuzhnaya, a small nunatak of east of Forefinger Point, and Point Widdows in order to assess the relationship between the Rayner and the Western Rayner Complexes. We will report and discuss the update of the characteristic features of the Rayner and the Western Rayner Complexes.

Composition of constituent minerals in corona-bearing and -free mafic gneisses from the Lützow-Holm Complex at Skallen, East Antarctica

*Yuki Mori[1], Takeshi Ikeda[2]

1. Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, 2. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

Corona is one of the non-equilibrium microstructures and has been employed to infer pressure-temperature path of the metamorphic rocks. The corona around garnet is common in mafic to ultramafic gneisses in the Lützow-Holm Complex (LHC) of East Antarctica (e.g., Hiroi et al., 1991). However, not every garnet in mafic to ultramafic gneisses accompanies the corona. In our ongoing study to reveal the controlling factors of presence and absence of the corona, we compare the composition of garnet and hornblende of the corona-bearing (no. I-223) and -free (no. I-232) mafic gneisses from Skallen.

The metamorphic grade of the complex increases progressively from the upper amphibolite facies to granulite facies toward the southwest, and the LHC is divided into three zones referred to as the amphibolite-facies zone, transitional zone, and granulite-facies zone (Hiroi et al., 1991). Recent studies have revealed that both transitional and granulite-facies zones had undergone high temperatures that exceed 800 ˚C (e.g., Iwamura et al, 2013; Kawakami et al., 2016). Skallen is an exposure located in the granulite-facies zone.

The constituent minerals in the matrix of the studied samples are almost same (garnet, hornblende, plagioclase with minor amounts of clinopyroxene and orthopyroxene), but I-223 further contains biotite. The microstructure and chemical composition of I-223 is as follows. The garnet grain is coarse (15 mm in diameter) and surrounded by a symplectitic corona composed of orthopyroxene and plagioclase. Garnet is clearly divided into two domains of Ca-rich core (Xgrs=0.23) and Ca-poor rim (Xgrs=0.18). X_{Mg} [=Mg/(Mg+Fe)] increases toward rim from 0.22 to 0.27, and that in the outer part of the rim decreases toward the boundary between the garnet and the corona from 0.27 to 0.22. The Ca-poor rim of the garnet includes irregular-shaped nanogranite composed of quartz, biotite, plagioclase, and K-feldspar. Hornblende is brown to brownish-green and polygonal. The X_{Mg} of the hornblende is 0.46-0.50. Matrix plagioclase often shows antiperthite intergrowing An50 plagioclase with Or96 K-feldspar. The coronal plagioclase has higher anorthite content (An80) than that in the matrix (An50). The microstructure and chemical composition of I-232 is as follows. The garnet grain is coarse (10 mm long) and elongated. The garnet and the hornblende define foliation of the rock. The hornblende is brown to pale brown. The composition of garnet gradually changes from core (Alm52Prp31Grs14Sps3) to rim (Alm52Prp28Grs17Sps3). The X_{Mg} in the hornblende varies from 0.60-0.70, and the composition is heterogeneous even in one grain. Most part of plagioclase is An45, and some parts of rim of the plagioclase have higher anorthite content of 70.

The garnet and hornblende in the corona-bearing gneiss have lower X_{Mg} than those in the corona-free gneiss. In addition, calcium content of the garnet and matrix plagioclase in the corona-bearing gneiss is higher than that in the corona-free gneiss. Therefore, we consider that bulk composition is one of the factors controlling the corona formation. The presence of nanogranite in the garnet surrounded by the corona suggests that partial melting and transport of the melt would cause the change of bulk composition in part.

“Pseudo-concordance” of U-Pb system in zircon at Harvey Nunatak, Napier Complex, East Antarctica

*Mami Takehara[1]

1. National Institute of Polar Research

U-Pb zircon dating has played a pivotal role in geochronology due to zircon’s high durability and high closure temperature. In addition, the paired decay scheme of two U isotopes allows us to verify the determined U-Pb zircon age. The Napier Complex in East Antarctica is well known because it preserves both of evidence of ultrahigh-temperature (UHT) metamorphism (e.g., Sheraton et al., 1987; Harley & Hensen 1990) and long Archaean crustal history from 3800 Ma to 2500 Ma (e.g., Harley & Black 1997). Previous researchers also reported the possibilities of the early Archean crust in the Napier Complex (e.g., Compston and Williams, 1982). Some previous researchers pointed out discordant U-Pb data including reverse discordance which was derived from the redistribution of radiogenic Pb isotopes in zircon in the Napier Complex samples (e.g., Kusiak et al., 2013). The some discordant U-Pb data looks concordant but actually reflect the Pb redistribution, namely “pseudo-concordance.” They suggest the redistribution of the radiogenic Pb isotopes in zircons was associated with the UHT metamorphism based on the Pb isotope mapping of the zircons. This report is critical for accurate U-Pb zircon geochronology in the UHT metamorphic region, such as the Napier Complex. Therefore, in this study, the zircons from the rock sample of the Napier Complex were characterized on the basis of the observation and trace-element contents, and the information was utilized for interpretation of the U-Pb data.
Zircons collected from a tonalitic gneiss (170223-2A-09) were first analyzed using sensitive high resolution ion-microprobes (SHRIMP IIe and SHRIMP IIe/AMC) at the National Institute of Polar Research, Japan. The sample was collected at the Harvey Nunatak, which is located close to Mt. Sones. The geochronological data from the Harvey Nunatak had never been reported. The sample was crushed by a high-voltage pulse power fragmentation device (Selfrag Lab) to preserve the external morphology of zircons and prevent contamination (Takehara et al., 2018). After pulverizing, the zircon grains were concentrated using conventional mineral separation techniques, including heavy liquid separation with methylene iodide and magnetic separation.
The zircon grains include fractures and slightly mineral inclusion based on the observation of transmitted light images by an optical microscope. BSE images show that some zircon grains have darker BSE-response domains, which suggests depletion of contents of Zr and Si during hydrothermal alteration of zircon. The zircons show typically high U contents (average is ~2500 ppm), and the U-Pb age from the high U zircons was corrected for the matrix effect derived from the high U contents according to the method by Williams & Hergt (2000) and White & Ireland (2012). It seems that the unaltered zircons show concordant data from about 2450 Ma to 2540 Ma with discordance (Disc.(%) = 1 −(206Pb/238U age)/(207Pb/206Pb age)} ×100 (e.g, Song et al., 1996)) ranges from -5 to +9%. On the other hand, trace element geochemistry of zircons does not support detritus protolith. In this presentation, the information of trace-element contents in zircons was utilized for the interpretation of U-Pb data and “pseudo-concordance.”

Rapid UHT metamorphism and exhumation of the Lützow-Holm Complex in Antarctica

*Yoshikuni Hiroi[1], Tomokazu Hokada[2], Tatsuro Adachi[3], Yasuhito Osanai[3], Yoichi Motoyoshi[2], Kazuyuki Shiraishi[2]

1. Chiba Univ, 2. National Institute of Polar Research, 3. Kyushu University

The Lützow-Holm Complex in Antarctica is a part of Neoproterozoic-Cambrian (c.650-500 Ma) collisional orogen to form Gondwana supercontinent. It is characterized by progressive metamorphism from upper amphibolite facies in the eastern part of the Prince Olav Coast to upper granulite facies in the southern Sôya Coast (e.g., Hiroi et al., 1991). UHT metamorphism is evidenced by such diagnostic mineral assemblages as Opx + Sil + Grt + Rt + Qz and Spr + Qz in Mg-Al-rich pelitic granulites in Rundvågshetta. Intimate intergrowths of Ky + Spr + Grt and Sil + Spr + Grt as well as andalusite-bearing falsite-nanogranite inclusions are included in the same porphyroblastic garnet, which is compositionally zoned, with Mg-rich core, Fe–Mn-rich rim, and core-to-rim oscillation of Ca. Integration of these new data with those previously documented leads to the inference of a rapid change in pressure–temperature conditions during regional UHT metamorphism in this part of the late Neoproterozoic to early Paleozoic ‘large and hot orogen’. Several lines of evidence indicate that partial melting and melt extraction took place even in mafic granulites of fragmented gabbro origin.

Tectonic History of Hiroo Complex and its implication inpaleo-Kuril Arc evolution

*Sreehari Lakshmanan[1], Tsuyoshi Toyoshima[2], Futoshi Nanayama[3]

1. Graduate School of Science and Technology, Niigata University, Niigata, Japan, 2. Department of Geology, Faculty of Science, Niigata Univ. , 3. Geological Survey of Japan, AIST

Melanges records information about deformation history and tectonic events in plate margins and orogens and hence they are important in evolution of accretionary complexes [1]. Mélange facies rocks and brocken formations distributed in Nakanogawa Group of Hidaak Belt in Central Hokkaido is known as Hiroo Complex. We carried out detailed field mapping and structural studies on melange facies rocks distributed around Tachiiwa, Kamitoyoni and Daimaruyama region of Hiroo Complex. Four different deformation processes (D1,D2,D3 and D4) are identified from field to micro-scale observations. D1 event shear zones are wide and considerd as penitrative but D2, D3 and D4 shear zones observed in narrow deformation zones and considerd as less penitrative local events. D1 shearzones are identified as scaly fabric in mudstone and asymmetrically sheared sandstone clast distributed in it. This is similar to 'block in matrix' structure, typical of tectonic melange devoloped in accretionary complexes. D1 foliation trends in N-NNW direction. Tectonic evolution of theses rocks confirmed by pressure solution cleavage, composite planar fabrics (P-Y-R shear), asymmetrical folds and dip-parallel streching lineation. P-Y-R shear relation and other asymmetrical structures in both field and microscale observation shows east-side-up sense of movement. This shear sense suggest that major penetrative deformatoin phase in melange was connected to accretionary complex devolopment in paleo-Kuril-Arc region, where initial subduction was directed in N-S direction and later it rotated clockwise and attained its present position. D2, D3 and D4 events were recognized as dextral strike-slip movement, sinistral-strike-slip to oblique-slip movement and west-side-down movement sense respectively . Mega-micro scale observation of D2 and D3 events show the properties of cataclastic deformation and D4 event is that of fault gouge. Based on this D2, D3 and D4 events are considered as upper crustal or local deformation processes. We consider these are linked to post-melange deformation processes and related to final stages of devolopment of Hidaka Metamorphic Belt (HMB). Recent geochemical studies from Daimaruyama region and geochronological studies from Nakanogawa Group region points that Hiroo Complex was part of initiallly northward subducting Paleo-Kuril Arc region [2]. Through detailed strucural analysis, this study also confirms that Hiroo Complex was devoloped in accretionary complex of paleo- Kuril-Arc by an offscrapping mode of evolution. Later Hiroo Complex became part of Nakanogawa Group through a series of deformation processes asocciated with arc-arc colission between paleo-Kuril Arc and paleo-Japan Arc.

Behaviour of C, O, Sr, Nd and Pb isotopes in high-grade metacarbonate rocks

*Madhusoodhan Satish-Kumar[1], Akari Imura[1], Momoko Shirakawa[2], Gen Shimoda[3], Kosuke T. Goto[3], M A Sanjeewa P K Malaviarachchi[4]

1. Department of Geology, Faculty of Science, Niigata University, 2. Graduate School of Science and Technology, Niigata University, 3. Geological Survey of Japan, 4. University of Peradeniya, Sri Lanka

Tectonic environment of metasedimentary sequences deposit in orogenic belts is of importance in understanding the formation and evolution of supercontinents. In particular, chemically deposited carbonate rocks are supposed to hold key information of extinct paleo-oceans, since they are directly precipitated from seawater. In this study, we carried out a comprehensive trace and rare earth element analysis, carbon, oxygen, strontium, neodymium and lead isotope measurements in metacarbonate rocks from the Highland Complex, Sri Lanka. The isotopic systems studied have distinct residence and mixing time in seawater, and are also controlled by the input from surrounding continents. We present here the behaviour of each isotopic system with respect to different processes right from the deposition of carbonate from the seawater through diagenesis and then prograde and retrograde metamorphism. TheProterozoic basement of Sri Lanka is subdivided into four lithotectonic units, namely, the Highland Complex (HC), the Wanni Complex (WC), the Vijayan Complex (VC), and the Kadugannawa Complex (KC), based on Nd isotope model ages. The HC is mainly composed of metasedimentary rocks (granulite facies metaquartzites, metapelitic gneisses and metacarbonate rocks), whereas exposures of the WC and the VC are mainly metaigneous rocks. The metacarbonate rocks in the HC generally occur as layers parallel with other metasedimentary lithological units, and show a NE trend.

We measured oxygen and carbon isotope ratios to understand the effect of diagenetic to metamorphic alterations, which can be recognized in negative isotope shifts. In general, the metacarbonate rocks have positive oxygen isotopic composition comparable with the Proterozoic unmetamorphosed carbonates, suggesting that these rocks were not affected by external fluids during digenesis, dolomitization or metamorphism. However, some of the rock units have been affected by later fluid infiltration as seen in major shifts in oxygen isotopic composition. Negative shifts in both carbon and oxygen isotopes correspond to the metamorphic decarbonation reactions being prominent. Strontium isotope chemostratigraphy was applied for the selected samples with least signatures of alteration. The depositional ages show a younging direction of sedimentation from the Wanni-side to the Vijayan-side. In the case of Nd isotopes, the values correspond to variable mixing of continent derived and oceanic crust derived components during carbonate deposition. This is clearly depicted in the ε Sr vs. ε Nd cross-plots where typical seawater-rock mixing relationship in metacarbonate rocks associated with continents and oceanic crusts can be deduced.Pb isotopic composition of the metacarbonate rocks in Sri Lanka indicated significant differences within the HC; the Vijayan side is more radiogenic than that of Wanni side. This might be due to the difference of initial composition, as well as the relationship to depositional basin and seawater composition. We also observed very low U/Pb ratios, which are considered to have occurred due to the U-loss during metamorphic recrystallization.Thus, the Sr-Nd-Pb isotopic composition in metacarbonate rocks suggests interaction between the oceanic crust and carbonate rocks on the Wanni side whereas on the Vijayan side, carbonate sedimentation was accompanied by interaction with cratonic continental crust.Thus, by applying a multi-element isotope geochemical approach on metacarbonate rocks collected from continental collisional zones, and by comparing the data with basement rocks from various neighbouring Gondwana continents, regional affinities could be established.

©2019. Japan Geoscience Union. All Right Reserved.

Sr, Nd and Pb isotopic compositions provide important information about the depositional settings of sedimentary rocks and provide key information about the surrounding terrains of oceanic and continental affinities during the time of deposition. This can lead to a better understanding of paleo-tectonic settings of crustal fragments that assemble to form supercontinents.

Enderby Land in Antarctica comprises of Neoproterozoic-Cambrian (c.650-500 Ma) high-grade metamorphic terranes that constituting Gondwana supercontinent (e.g., Shiraishi et al., 2008). Easternmost part is “Western Rayner Complex” of which granulite-facies and partly UHT metamorphism (Motoyoshi et al., 1994, 1995) and 2400-1000 Ma protolith and 540-520 Ma metamorphic ages were reported (Shiraishi et al., 1997). Neighboring “Rayner Complex” is characterized by >2500-1000 Ma protolith and 980-910 Ma granulite-facies metamorphic ages. Boundary between the Rayner and the Western Rayner Complex has been not clearly defined until when Horie et al. (2016) obtained 934-894 Ma SHIRMP zircon U-Pb ages from Mt. Lira, Condon Hills and Mt. Yuzhnaya regions with minor 590-570 Ma zircons from Mt. Yuzhnaya. Hiroi (unpublished data) also demonstrated contrasting metamorphic P-T evolution among the Mt. Lira, Condon Hills and Mt. Yuzhnaya regions.

JARE-58 (2016-2017) geology team made a short visit and sampling at a small nunatak of west of Mt. Yuzhnaya, a small nunatak of east of Forefinger Point, and Point Widdows in order to assess the relationship between the Rayner and the Western Rayner Complexes. We will report and discuss the update of the characteristic features of the Rayner and the Western Rayner Complexes.

Composition of constituent minerals in corona-bearing and -free mafic gneisses from the Lützow-Holm Complex at Skallen, East Antarctica

*Yuki Mori[1], Takeshi Ikeda[2]

1. Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, 2. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

Corona is one of the non-equilibrium microstructures and has been employed to infer pressure-temperature path of the metamorphic rocks. The corona around garnet is common in mafic to ultramafic gneisses in the Lützow-Holm Complex (LHC) of East Antarctica (e.g., Hiroi et al., 1991). However, not every garnet in mafic to ultramafic gneisses accompanies the corona. In our ongoing study to reveal the controlling factors of presence and absence of the corona, we compare the composition of garnet and hornblende of the corona-bearing (no. I-223) and -free (no. I-232) mafic gneisses from Skallen.

The metamorphic grade of the complex increases progressively from the upper amphibolite facies to granulite facies toward the southwest, and the LHC is divided into three zones referred to as the amphibolite-facies zone, transitional zone, and granulite-facies zone (Hiroi et al., 1991). Recent studies have revealed that both transitional and granulite-facies zones had undergone high temperatures that exceed 800 ˚C (e.g., Iwamura et al, 2013; Kawakami et al., 2016). Skallen is an exposure located in the granulite-facies zone.

The constituent minerals in the matrix of the studied samples are almost same (garnet, hornblende, plagioclase with minor amounts of clinopyroxene and orthopyroxene), but I-223 further contains biotite. The microstructure and chemical composition of I-223 is as follows. The garnet grain is coarse (15 mm in diameter) and surrounded by a symplectitic corona composed of orthopyroxene and plagioclase. Garnet is clearly divided into two domains of Ca-rich core (Xgrs=0.23) and Ca-poor rim (Xgrs=0.18). X_{Mg} [=Mg/(Mg+Fe)] increases toward rim from 0.22 to 0.27, and that in the outer part of the rim decreases toward the boundary between the garnet and the corona from 0.27 to 0.22. The Ca-poor rim of the garnet includes irregular-shaped nanogranite composed of quartz, biotite, plagioclase, and K-feldspar. Hornblende is brown to brownish-green and polygonal. The X_{Mg} of the hornblende is 0.46-0.50. Matrix plagioclase often shows antiperthite intergrowing An50 plagioclase with Or96 K-feldspar. The coronal plagioclase has higher anorthite content (An80) than that in the matrix (An50). The microstructure and chemical composition of I-232 is as follows. The garnet grain is coarse (10 mm long) and elongated. The garnet and the hornblende define foliation of the rock. The hornblende is brown to pale brown. The composition of garnet gradually changes from core (Alm52Prp31Grs14Sps3) to rim (Alm52Prp28Grs17Sps3). The X_{Mg} in the hornblende varies from 0.60-0.70, and the composition is heterogeneous even in one grain. Most part of plagioclase is An45, and some parts of rim of the plagioclase have higher anorthite content of 70.

The garnet and hornblende in the corona-bearing gneiss have lower X_{Mg} than those in the corona-free gneiss. In addition, calcium content of the garnet and matrix plagioclase in the corona-bearing gneiss is higher than that in the corona-free gneiss. Therefore, we consider that bulk composition is one of the factors controlling the corona formation. The presence of nanogranite in the garnet surrounded by the corona suggests that partial melting and transport of the melt would cause the change of bulk composition in part.

“Pseudo-concordance” of U-Pb system in zircon at Harvey Nunatak, Napier Complex, East Antarctica

*Mami Takehara[1]

1. National Institute of Polar Research

U-Pb zircon dating has played a pivotal role in geochronology due to zircon’s high durability and high closure temperature. In addition, the paired decay scheme of two U isotopes allows us to verify the determined U-Pb zircon age. The Napier Complex in East Antarctica is well known because it preserves both of evidence of ultrahigh-temperature (UHT) metamorphism (e.g., Sheraton et al., 1987; Harley & Hensen 1990) and long Archaean crustal history from 3800 Ma to 2500 Ma (e.g., Harley & Black 1997). Previous researchers also reported the possibilities of the early Archean crust in the Napier Complex (e.g., Compston and Williams, 1982). Some previous researchers pointed out discordant U-Pb data including reverse discordance which was derived from the redistribution of radiogenic Pb isotopes in zircon in the Napier Complex samples (e.g., Kusiak et al., 2013). The some discordant U-Pb data looks concordant but actually reflect the Pb redistribution, namely “pseudo-concordance.” They suggest the redistribution of the radiogenic Pb isotopes in zircons was associated with the UHT metamorphism based on the Pb isotope mapping of the zircons. This report is critical for accurate U-Pb zircon geochronology in the UHT metamorphic region, such as the Napier Complex. Therefore, in this study, the zircons from the rock sample of the Napier Complex were characterized on the basis of the observation and trace-element contents, and the information was utilized for interpretation of the U-Pb data.
Zircons collected from a tonalitic gneiss (170223-2A-09) were first analyzed using sensitive high resolution ion-microprobes (SHRIMP IIe and SHRIMP IIe/AMC) at the National Institute of Polar Research, Japan. The sample was collected at the Harvey Nunatak, which is located close to Mt. Sones. The geochronological data from the Harvey Nunatak had never been reported. The sample was crushed by a high-voltage pulse power fragmentation device (Selfrag Lab) to preserve the external morphology of zircons and prevent contamination (Takehara et al., 2018). After pulverizing, the zircon grains were concentrated using conventional mineral separation techniques, including heavy liquid separation with methylene iodide and magnetic separation.
The zircon grains include fractures and slightly mineral inclusion based on the observation of transmitted light images by an optical microscope. BSE images show that some zircon grains have darker BSE-response domains, which suggests depletion of contents of Zr and Si during hydrothermal alteration of zircon. The zircons show typically high U contents (average is ~2500 ppm), and the U-Pb age from the high U zircons was corrected for the matrix effect derived from the high U contents according to the method by Williams & Hergt (2000) and White & Ireland (2012). It seems that the unaltered zircons show concordant data from about 2450 Ma to 2540 Ma with discordance (Disc.(%) = 1 −(206Pb/238U age)/(207Pb/206Pb age)} ×100 (e.g, Song et al., 1996)) ranges from -5 to +9%. On the other hand, trace element geochemistry of zircons does not support detritus protolith. In this presentation, the information of trace-element contents in zircons was utilized for the interpretation of U-Pb data and “pseudo-concordance.”

Rapid UHT metamorphism and exhumation of the Lützow-Holm Complex in Antarctica

*Yoshikuni Hiroi[1], Tomokazu Hokada[2], Tatsuro Adachi[3], Yasuhito Osanai[3], Yoichi Motoyoshi[2], Kazuyuki Shiraishi[2]

1. Chiba Univ, 2. National Institute of Polar Research, 3. Kyushu University

The Lützow-Holm Complex in Antarctica is a part of Neoproterozoic-Cambrian (c.650-500 Ma) collisional orogen to form Gondwana supercontinent. It is characterized by progressive metamorphism from upper amphibolite facies in the eastern part of the Prince Olav Coast to upper granulite facies in the southern Sôya Coast (e.g., Hiroi et al., 1991). UHT metamorphism is evidenced by such diagnostic mineral assemblages as Opx + Sil + Grt + Rt + Qz and Spr + Qz in Mg-Al-rich pelitic granulites in Rundvågshetta. Intimate intergrowths of Ky + Spr + Grt and Sil + Spr + Grt as well as andalusite-bearing falsite-nanogranite inclusions are included in the same porphyroblastic garnet, which is compositionally zoned, with Mg-rich core, Fe–Mn-rich rim, and core-to-rim oscillation of Ca. Integration of these new data with those previously documented leads to the inference of a rapid change in pressure–temperature conditions during regional UHT metamorphism in this part of the late Neoproterozoic to early Paleozoic ‘large and hot orogen’. Several lines of evidence indicate that partial melting and melt extraction took place even in mafic granulites of fragmented gabbro origin.

Tectonic History of Hiroo Complex and its implication inpaleo-Kuril Arc evolution

*Sreehari Lakshmanan[1], Tsuyoshi Toyoshima[2], Futoshi Nanayama[3]

1. Graduate School of Science and Technology, Niigata University, Niigata, Japan, 2. Department of Geology, Faculty of Science, Niigata Univ. , 3. Geological Survey of Japan, AIST

Melanges records information about deformation history and tectonic events in plate margins and orogens and hence they are important in evolution of accretionary complexes [1]. Mélange facies rocks and brocken formations distributed in Nakanogawa Group of Hidaak Belt in Central Hokkaido is known as Hiroo Complex. We carried out detailed field mapping and structural studies on melange facies rocks distributed around Tachiiwa, Kamitoyoni and Daimaruyama region of Hiroo Complex. Four different deformation processes (D1,D2,D3 and D4) are identified from field to micro-scale observations. D1 event shear zones are wide and considerd as penitrative but D2, D3 and D4 shear zones observed in narrow deformation zones and considerd as less penitrative local events. D1 shearzones are identified as scaly fabric in mudstone and asymmetrically sheared sandstone clast distributed in it. This is similar to 'block in matrix' structure, typical of tectonic melange devoloped in accretionary complexes. D1 foliation trends in N-NNW direction. Tectonic evolution of theses rocks confirmed by pressure solution cleavage, composite planar fabrics (P-Y-R shear), asymmetrical folds and dip-parallel streching lineation. P-Y-R shear relation and other asymmetrical structures in both field and microscale observation shows east-side-up sense of movement. This shear sense suggest that major penetrative deformatoin phase in melange was connected to accretionary complex devolopment in paleo-Kuril-Arc region, where initial subduction was directed in N-S direction and later it rotated clockwise and attained its present position. D2, D3 and D4 events were recognized as dextral strike-slip movement, sinistral-strike-slip to oblique-slip movement and west-side-down movement sense respectively . Mega-micro scale observation of D2 and D3 events show the properties of cataclastic deformation and D4 event is that of fault gouge. Based on this D2, D3 and D4 events are considered as upper crustal or local deformation processes. We consider these are linked to post-melange deformation processes and related to final stages of devolopment of Hidaka Metamorphic Belt (HMB). Recent geochemical studies from Daimaruyama region and geochronological studies from Nakanogawa Group region points that Hiroo Complex was part of initiallly northward subducting Paleo-Kuril Arc region [2]. Through detailed strucural analysis, this study also confirms that Hiroo Complex was devoloped in accretionary complex of paleo- Kuril-Arc by an offscrapping mode of evolution. Later Hiroo Complex became part of Nakanogawa Group through a series of deformation processes asocciated with arc-arc colission between paleo-Kuril Arc and paleo-Japan Arc.

Behaviour of C, O, Sr, Nd and Pb isotopes in high-grade metacarbonate rocks

*Madhusoodhan Satish-Kumar[1], Akari Imura[1], Momoko Shirakawa[2], Gen Shimoda[3], Kosuke T. Goto[3], M A Sanjeewa P K Malaviarachchi[4]

1. Department of Geology, Faculty of Science, Niigata University, 2. Graduate School of Science and Technology, Niigata University, 3. Geological Survey of Japan, 4. University of Peradeniya, Sri Lanka

Tectonic environment of metasedimentary sequences deposit in orogenic belts is of importance in understanding the formation and evolution of supercontinents. In particular, chemically deposited carbonate rocks are supposed to hold key information of extinct paleo-oceans, since they are directly precipitated from seawater. In this study, we carried out a comprehensive trace and rare earth element analysis, carbon, oxygen, strontium, neodymium and lead isotope measurements in metacarbonate rocks from the Highland Complex, Sri Lanka. The isotopic systems studied have distinct residence and mixing time in seawater, and are also controlled by the input from surrounding continents. We present here the behaviour of each isotopic system with respect to different processes right from the deposition of carbonate from the seawater through diagenesis and then prograde and retrograde metamorphism. TheProterozoic basement of Sri Lanka is subdivided into four lithotectonic units, namely, the Highland Complex (HC), the Wanni Complex (WC), the Vijayan Complex (VC), and the Kadugannawa Complex (KC), based on Nd isotope model ages. The HC is mainly composed of metasedimentary rocks (granulite facies metaquartzites, metapelitic gneisses and metacarbonate rocks), whereas exposures of the WC and the VC are mainly metaigneous rocks. The metacarbonate rocks in the HC generally occur as layers parallel with other metasedimentary lithological units, and show a NE trend.

We measured oxygen and carbon isotope ratios to understand the effect of diagenetic to metamorphic alterations, which can be recognized in negative isotope shifts. In general, the metacarbonate rocks have positive oxygen isotopic composition comparable with the Proterozoic unmetamorphosed carbonates, suggesting that these rocks were not affected by external fluids during digenesis, dolomitization or metamorphism. However, some of the rock units have been affected by later fluid infiltration as seen in major shifts in oxygen isotopic composition. Negative shifts in both carbon and oxygen isotopes correspond to the metamorphic decarbonation reactions being prominent. Strontium isotope chemostratigraphy was applied for the selected samples with least signatures of alteration. The depositional ages show a younging direction of sedimentation from the Wanni-side to the Vijayan-side. In the case of Nd isotopes, the values correspond to variable mixing of continent derived and oceanic crust derived components during carbonate deposition. This is clearly depicted in the ε Sr vs. ε Nd cross-plots where typical seawater-rock mixing relationship in metacarbonate rocks associated with continents and oceanic crusts can be deduced.Pb isotopic composition of the metacarbonate rocks in Sri Lanka indicated significant differences within the HC; the Vijayan side is more radiogenic than that of Wanni side. This might be due to the difference of initial composition, as well as the relationship to depositional basin and seawater composition. We also observed very low U/Pb ratios, which are considered to have occurred due to the U-loss during metamorphic recrystallization.Thus, the Sr-Nd-Pb isotopic composition in metacarbonate rocks suggests interaction between the oceanic crust and carbonate rocks on the Wanni side whereas on the Vijayan side, carbonate sedimentation was accompanied by interaction with cratonic continental crust.Thus, by applying a multi-element isotope geochemical approach on metacarbonate rocks collected from continental collisional zones, and by comparing the data with basement rocks from various neighbouring Gondwana continents, regional affinities could be established.

©2019. Japan Geoscience Union. All Right Reserved.

Sr, Nd and Pb isotopic compositions provide important information about the depositional settings of sedimentary rocks and provide key information about the surrounding terrains of oceanic and continental affinities during the time of deposition. This can lead to a better understanding of paleo-tectonic settings of crustal fragments that assemble to form supercontinents.

A sequence of volcanic flank collapse and tsunami event on 22 December 2018 at Anak Krakatau volcano, Indonesia

*Fukashi Maeno[1], Takayuki Kaneko[1]

1. Earthquake Research Institute, University of Tokyo

Tsunamis were generated at the Sunda Strait, Indonesia, on 22 December 2018 (~21:00 local time), and a disaster (>430 victims) occurred along the coastal area close to Krakatau. As it became clear that the southwest side of Anak Krakatau Island that has continued eruptive activity in recent years had collapsed, the tsunamis are thought to have occurred with the edifice collapse of this volcanic island (PVMBG, 2018). The volume of collapsed material, the process of the collapse event, the tsunami generation and propagation processes, and the relationship between these and the eruption activity are still unclear. Therefore we investigated the sequence of the eruption and tsunami event at Anak Krakatau on 22 Dec 2018 based on satellite images and tsunami numerical simulation. Infrared data of Himawari-8 showed that thermal anomaly has continued since the middle of June 2018 but no specific anomaly signals were detected before the collapse-tsunami event. Then the data showed that the eruptive plume occurred from ~13:50 UTC on 22 December 2018. This time was 40-70 min before tsunami arrival at the coastal areas around Sunda Strait (~14:30-15:00 UTC). The first eruptive plume developed after ~13:50 but soon declined within an hour, then the second eruptive plume developed from ~15:20. It became much higher than the first one and sustained in the next couple of days. Numerical simulation of tsunami and volcanic flank collapse was carried out with the two-layer shallow water model based on non-linear long wave theory that has been developed for the tsunamis generated by gravity flows (pyroclastic flows, debris avalanche, etc.) flowing into the water. It was solved with a finite difference method. Bathymetry data is the same as that used in Maeno and Imamura (2011). The bottom friction coefficient of the gravity current was set to be 0.01 for subaerial condition and 0.06-0.12 for submarine condition. The interfacial drag coefficients between the gravity current and seawater were set to be 0.2. The four cases with different collapsed volumes (0.16, 0.21, 0.26, 0.31 km^3) were examined. The computed tsunami waveforms were compared with tide gauge records (PVMBG, 2018) at representative locations. The most likely initial condition to explain the tide gauge records was the initial collapse volume of 0.21-0.26 km^3. Other parameters don't significantly affect the results. Numerical results also showed that, for all cases, the maximum wave height (>3 m) in the SW coast of Java became higher than other areas. This tendency is consistent with the observational records that the SW coast of Java was more heavily damaged by tsunamis. This is probably because the direction of the collapse was southwestward but the direction of tsunami propagation was gradually changed from SW to S-SE by the effect of bathymetry. We also calculated tsunami travel times and estimated the occurrence time at the source, comparing with tsunami arrival times recorded in the tide gauges. As a result it seems that the tsunamis were caused by 13:54±2 min. We conclude that the collapse occurred almost simultaneously with the small eruption from ~13:50 UTC then followed by the main sustained eruption from ~15:20. In order to determine the timing and mechanism of the collapse event more precisely, it is necessary to further evaluate initial conditions and models as well as to compare with other geological and geophysical data.

The 2018 eddifice collapse event of Anak Krakatau, Indonesia: Telseismic waveform analysis and tsunami simulation

*Shingo Watada[1], Iyan E. Mulia[1], Masumi Yamada[2], Dimas Sianipar[3]

1. Earthquake Research Institute, University of Tokyo, 2. Disaster Prevention Research Institute, Kyoto University, 3. TIGP-ESS Academia Sinica, National Central University, Taiwan

On December 22, 2018 at around 14:30 UT, a tsunami hit the coast of Java and Sumatra islands near the Sunda Strait, Indonesia and claimed more than 400 lives. The Anak Krakatau volcano island in the Sunda Strait erupted coeval with the tsunami and the summit elevation decreased from 300 m before the eruption to 100 m after the eruption, suggesting that the tsunami was generated by the subaerial or submarine edifice collapse of Anak Krakatau. SAR images show that the edifice including the summit collapsed toward southwest and disappeared into the sea. Tide gauge records around the strait suggest that the tsunami was generated at around 13:58. There were no report of a strong seismic event in Indonesia before the tsunami event, although broadband seismic networks in and around Indonesia clearly recorded unusual seismic waves (S-waves and Rayleigh waves) dominated by the long-period (50-100 sec) components. S-waves arrived at the Ryukyu islands at 14:11 and Hokkaido at 14:16. Rayleigh waves arrived at Hokkaido at 14:27. All seismic waveforms indicate occurrence of a long-period seismic event at around 13:56 near Anak Krakatau. Teleseismic body waves hint that the source duration is less than 100 sec (about 1min). Three-component broadband seismic records from four stations near the Sunda Strait can be explained by a near horizontal slightly upward force of $5x10^{11}$ N acting toward northeast for the first 20 sec followed by a near horizontal slightly dipping force of the similar magnitude acting toward southwest for about 50 sec. The force direction and angle is consistent with a collapse model predicted by Giachetti et al. (2012, Geol. Soc. London) in which a resurgent volcano Anak Krakatau collapses into the bottom of submarine Krakatau caldera at 250 m deep along a sliding slope with a dip of 8 deg. The estimated total mass of the edifice collapse is $3x10^{11}$ kg based on the empirical formula between the maximum force and the total mass of landslides (Ekström and Stark 2013, Science). Assuming the soil density 2 g/cm^3 the volume is about 0.15 km^3, roughly consistent with the submarine landslide volume 0.2 km^3 estimated from our numerical tsunami simulation for tide gauge records. Based on the routine seismic monitoring no large earthquake enough to cause tsunami was registered. On the other hand, long-period seismic waves from the seismic event at Anak Krakatau coeval with the tsunamis arrived at Jakarta 40 sec after the event. If long-period seismic events were routinely monitored in Indonesia, we could have detect the edifice collapse of the Anak Krakatau volcano and were aware of the possibility of tsunami generation prior to the arrivals of disastrous tsunamis to the coasts.

The 2018 edifice collapse event of Anak Krakatau, Indonesia: Landslide movement history estimated from seismic waveforms

*Masumi Yamada[1], Shingo Watada[2], Haruhisa Nakamichi[1], Iyan Mulia[2], Karyono Dr.[3]

1. Disaster Prevention Research Institute, Kyoto University, 2. Earthquake Research Institute, University of Tokyo, 3. Center for Earthquake and Tsunami, BMKG

On December 22, 2018, a huge Tsunami occurred at the Sunda strait in Indonesia, and more than 400 people were killed. There was no large earthquake at that time and the tsunami was associated with the volcanic eruption and edifice collapse in Anak Krakatau island.

The seismic signals due to this event are recorded by the broadband seismic network in Indonesia. There are about 170 broadband stations all over Indonesia, with a spacing 50-100 km. We performed the seismic waveform inversion using long-period component (20-100 s) at the near-field distance (60-200 km), assuming a single force mechanism. We also performed a grid search with 10 km spacing to estimate the location of the source.

Our result shows that the onset of the event was about 14:55:50 (UTC), December 22, 2018. The duration of the source time function is about 1 min with a large amplitude, followed by a smaller signal about a few min. The particle motion of the source time function suggests the event was occurred from northeast to southwest direction with very low dipping angle (about 10 degree). The location of the event was estimated at the Anak Krakatau.

This seismic event was most likely caused by the edifice collapse of the Anak Krakatau. The satellite image shows that the southwest half of the island was subsided after the collapse, and there is a oceanic basin at the depth of 200 m in the southwest of the island, which was the old crater created by the eruption in 1883. These geometries are consistent with the movement history estimated by the seismic waveform inversion.

Based on the scaling relationship between single force amplitude vs mass of the landslide (Ekström and Sterk, 2013), the mass was estimated as 0.2-0.4 * 10^12 kg. This number is consistent with the volume estimated by the tsunami waveform simulation (Maeno and Kaneko 2019; Watada et al., 2019). We think that the edifice collapse was very low-dipping and moved like a landslide, and the mass sliding into the ocean caused the huge tsunami.

The relationship between this landslide and volcanic eruption is still debating, but Center for Volcanology and Geological Disaster Mitigation in Indonesia officially reported the timing of the eruption was 15:03 (UTC). Since the occurrence of the landslide was estimated as 14:55:50, the eruption may be triggered by the landslide, such as the 1980 eruption of Mount St. Helens triggered by the massive landslide.

Intense Swarm Activity in the Vicinity of Yake-dake Volcano, Central Japan, Started in November 2018

*Shiro Ohmi[1]

1. Earthquake Hazards Division, Disaster Prevention Research Institute, Kyoto University

An intense seismic swarm activity started in November, 2018 in the vicinity of the Yakedake volcano, Hida mountain range, central Japan. It started on November 22 and lasted for about 10 days (hereafter sited as Series A) . Hypocenters are located at the western flank of the Yakedake volcano in the depth range from 3 km to 4 km below sea level. On December 4, a small swarm activity occurred in the Kamikochi area, where is the eastern flank of Yake-dake volvano, that lasted for two days (Series B). Other small activities took place at the end of January 2019 (Series C) to the western area of the activity of Series A, as well as an activity just beneath the ridge of Hida mountain range where is several kilometers south to the summit of the Yake-dake volcano in the beginning of February 2019 (Series D).

Earthquakes in Series A exhibit ordinary characteristics of tectonic earthquakes with NW-SE compressional stress field and neither significant hypocenter migration nor change in source mechanism were observed during the activity. Earthquakes in Series B, however, some exhibit normal fault type stress field which is not coincide with the regional stress field.

The maximum intensity reported by JMA was less or equal to level 2 for all the events during the activity, however, instrumental seismic intensity observed nearby hypocentral area by DPRI recorded as large as level 4 for some earthquakes. Monitoring data of Yakedake volcano, that include crustal movement by GNSS and tiltmeter, geomagnetic total intensity by proton magnetometer, and ground temperature nearby summit, did not show the anomalous behavior during the swarm activity.

Change of the volcanic activity at Kuju volcano.

*Mori Takehiko[1], Muga Yaguchi[1], Yasushi Kawamura[2], Hideyuki Hiramatsu[3], Keiji Ikeda[2], Sugai Akira[2], Michitomo Sugahara[2], Kenichi Takata[2], Kyo Matsumoto[2], Fukuoka Regional Headquarters Japan Meteorological Agency, Oita Meteorological Office Japan Meteorological Agency

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Fukuoka Regional Headquarters, Japan Meteorological Agency, 3. Oita Meteorological Office, Japan Meteorological Agency

In Kuju volcano, after an eruption occurs at the east-hillside of Mt. Hossyo (near Mt. Iwo) in October 1995 and January 1996, the eruption has not occurred. The continuous volcanological observation by a research institution and Japan Meteorological Agency started after the eruption in 1995. Although the active seismicity which has the hypocenter in the shallow zone under Mt. Iwo was observed, the activity became calm after 2005. Moreover, after 1995, continued cooling in the shallow zone under Mt. Iwo was obtained by the geomagnetic observation, and the trend for fumarolic activity to decline gradually was seen. In this way, the declining volcanic activity was captured by various observation data.
Changes in volcanic activity of Kuju volcano began to appear around 2012. First, the GNSS observation showed that the length of the base line between the two points crossing Kuju volcano began to grow slightly. Next, the geomagnetic observation began showing the heat-reserve trend in the shallow region of Mt. Iwo from 2014. The gradual increase in fumarolic activity starts around 2015, and the slight increase in seismic activity also started around 2016.
Before the 1995 eruption, continuous volcano observation at Kuju volcano was not done, so the change of various phenomena preceding the eruption was not sufficiently obtained. We have not been able to judge whether the current volcanic activity change is an activity suggesting future eruptive activity. However, we believe that accumulation of observational data will help predict future volcanic activity. Then, by continuous observation of multiple items not only including geophysical observations but a volcano chemistry observation, the character of the volcanic activity in Kuju Volcano is grasped, and change of volcanic activity is monitored.

Posteruptive Thermoelastic Deflation of Intruded Magma in Usu Volcano, Japan, 1992–2017

*Yosuke Aoki[1], Xiaowen Wang[1]

1. Earthquake Research Institute, University of Tokyo

Secular ground subsidence at Usu volcano (Japan) has been reported around the eruption vents following the four eruptions in 1910, 1943, 1977, and 2000. However, the mechanisms accounting for the subsidence have not been well understood. In this study, we systematically investigated the posteruptive deformation at Usu volcano using interferometric synthetic aperture radar based on 111 JERS, ALOS-1, and ALOS-2 images acquired from 1992 to 2017. We also calculated quasi east-west and vertical ground displacements between 2006 and 2017. Our results show three localized deformation regions from west to east of Usu volcano with their locations corresponding to the 2000, 1977, and 1943 eruption vents, respectively. All the deformation sites show patterns of east-west contraction and subsidence. The extent and rate of posteruptive subsidence declined dramatically at the vent of the 2000 eruption site from 2006 to 2017, decreased gradually at the 1977 vent, and show a steady pattern for the 1943 site during 1992-2017. We ascribed the observed posteruptive subsidence to thermoelastic contraction of a sphere intruded at the time of the eruptions to constrain locations, depths, and volumes of heat sources with the assumption of the spherical source shapes. Thermoelastic modeling reveals that the heat sources are embedded at shallow depths not deeper than 400 m below sea level with volumes of about (8.72 ±0.19) $\times 10^6$, (132.18 ±5.21) $\times 10^6$, and (49.51 ±2.02) $\times 10^6$ m^3 for the 2000, 1977, and 1943 eruption sites, respectively. The modeling also highlights the importance of underground water in assessing the thermal diffusion process and the associated posteruptive deformation.

[S-VC38] Active Volcanism

convener:Yuta Maeda(Nagoya University), Takahiro Miwa(National research institute for earth science and disaster prevention), Takeshi Nishimura(Department of Geophysics, Graduate School of Science, Tohoku University), Chairperson:Jun Oikawa, Takeshi Tameguri

This session discusses various aspects of active volcanisms including, but not limited to, recent and historical eruptions, various phenomena associated with the volcanic activities, underground structures of the volcanoes, and developments of new instruments based on geophysical, geochemical, geological, and multidiscipline approaches. We also welcome studies on understanding and predicting the transitions of the eruptive activities from observational, theoretical, and experimental approaches.

Volcanic tremors and ash fall volumes associated with the 2018 vulcanian eruptions of Shinmoe-dake

*Jun Oikawa[1], Yasuhisa Tajima[2]

1. Earthquake Research Institute, University of Tokyo, 2. NIPPON KOEI CO.,LTD.

Kirishima volcanic chain is one of the active volcanoes in southern Kyushu, Japan and is categorized into a composite volcano whose active vents are Shinmoe-dake and Ohachi. The latest eruptive activity of Shinmoe-dake started on August 22, 2008. Subsequently, it erupted on March 30, April 17, May 27, June 27 and 28, and July 5 and 10, 2010. In 2011, the eruption started on January 19 included subplinian and vulcanian explosions. and was followed by sub-Pulinian eruption on 27 January. Eruptive activity gradually ceased since February 2, and moved to Vulcanian activities. It erupted on October in 2017 and on March in 2018. Eruptions continued until June 27. Tajima et. al (JpGU 2019) show volcanic ashfall volumes for each eruption in 2018 and we discuss the relation of ashfall volumes and durations of eruptions that is characterized by the power law: ashfall volume is proportional to durations to the second power.

Crustal deformation around the Kirishima Volcano Group detected by GNSS and SAR observation after 2018 eruption.

*Hiroshi Yarai[1], Tomokazu Kobayashi[1], Satoshi Fujiwara[1], Tomokazu Kobayashi[1], Hiroshi Munekane[1], Masaki Honda[1], Kyonosuke Hayahsi[1], Satoshi Kawamoto[1], Atsuko Oowaki[1]

1. GSI of Japan

Since July 2017, GNSS Earth Observation Network (GEONET) maintained by Geospatial Information Authority of Japan (GSI) has observed elongation at the baseline surrounding the Kirishima volcano group. Sharp shortening occurred at the eruption of Shinmoedake volcano in March, 2018, after which elongation was observed again. Similar crustal deformations are also observed during the Shinmoedake eruption in 2011, and at that time expansion and contraction of magma reservoir of about 6 to 7 km northwest of Shinmoedake is presumed (for example, Kobayashi et al., 2012) . In addition, in the Iwo-yama located in the northwest of Kirishima-yama, expansive crustal deformation centered the Iwo-yama was captured by analysis of Daichi 2 (ALOS-2) SAR data. In April 2018, an eruption took place in Iwooyama for the first time in 250 years.

Detailed investigation of crustal deformation of the Kirishima volcano group is important in grasping the situation of volcanic activity. In this research, we investigated the crustal deformation of the Kirishima volcano group including Shinmoe-dake and Iwo-yama after the eruption of Shinmoedake and Iwozan in 2018, using GNSS observation and ALOS-2 (Daichi 2) SAR data analysis.

Harmonic tremor during 2011 eruption at Shinmoedake, Japan

*Minoru Takeo[1]

1. Earthquake Research Institute, University of Tokyo

Volcanic tremor is a continuous seismic signal that is observed near active volcanoes and is often accompanied by evidence of subterranean movement or pressure fluctuation due to a physical or chemical process inside the volcano. However, the source of volcanic tremor is still poorly understood. Most existing tremor’ s models, except for Julian’ s nonlinear channel flow model (Julian, 1994), consider an acoustic resonance in the magma channels, but mechanism to excite this resonance has not been identified until now.

During 2011 eruption at Shinmoedake, Japan, we observed a series of volcanic tremors including harmonic tremor which exhibits a set of narrow, evenly spaced frequency peaks. Natsume *et al.*(2018) perform non-linear time-series analysis on a harmonic tremor recorded near the crater. They found that the stable oscillation of the harmonic tremor is predominantly a limit cycle, implying that the harmonic tremor is generated by self-sustained oscillation. In this paper, I propose a new model of harmonic tremor and reproduce the topological characteristics of observed harmonic tremor using the new model. I formulate a lumped-parameter model of incompressible viscous fluid flow through a partially constrictive path, which seems to be realistic modeling in a shallow part of conduit. I consider inertias and resistances in the upstream and in downstream pipes. The upstream pipe is connected to a large chamber with pressure of Po. Lengths and radiuses of the pipes and the constrictive path could be set flexibly in this model. This model leads to a third-order system of nonlinear ordinary differential equations with functions of area of throat, fluid velocities in upper stream and in downstream. The equations of the model are as follows:
Mass conservations in upstream and in downstream of the constricting path; Conservation of momentum in upstream and in downstream of the constricting path; Equations of motion in upstream pipe and in downstream pipe; Elastic law of the constrictive path;
Typical frequency of the harmonic tremor is 1~2Hz and the wavelength seems to be hundreds meter, so these signals were recorded within a distance of one wavelength, being little affected by wave propagation. Therefore, assuming that these observed signals represent only linear transformations of one parametric function of the nonlinear tremor model, we can compare topological characteristics of observed and simulated signals to evaluate validity of the new model. When the resistance of downstream is larger than that of upstream, a self-sustained oscillation starts in a suitable parameter range. For different driving pressure (Po), numerical solutions exhibit steady flow, simple limit-cycle oscillation, limit-cycle oscillation with double-loops or with quadruple-loops, and a chaotic oscillation. Changing Po in time, I succeed in simulating a harmonic tremor which has same topological characteristics with the observed harmonic tremor in several portions of time series (see Figure 1).

Forecasting Volcanic Eruption of Sakurajima Volcano Based on Magma Intrusion Rate

*Masato Iguchi[1], Takeshi Tameguri[1], Jun-ichi Hirabayashi, Haruhisa Nakamichi[1]

1. Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University

In order to find an empirical event branch logic from abnormal phenomena to following volcanic activity for forecasting scale and type of eruption, the magma intrusion rate prior to eruptions of Sakurajima volcano is examined using ground deformation mostly from observation data and partially based on legends, for eruptions after the 20th century: the 1914 eruption starting with plinian eruption followed by effusion of lava, the 1946 eruptions with lava effusion, eruptions at the summit crater of Minamidake during the period from 1955 to 2005, and vulcanian eruptions at Showa crater east of the summit from 2006 to 2017. Prior to the 1914 eruption, it is estimated that the magma intrusion rate attained a level of approximately 10^8 m^3/day and was on the order of 10^6 m^3/day during the effusion of lava in the 1946 eruption. During the eruptive period of Minamidake summit crater, three types of eruption occurred: vulcanian eruption, strombolian/lava fountain and continuous emission of volcanic ash. In cases of intrusion of magma forming a new conduit, the intrusion rate immediately before the 1914 eruption exceeded 10^8 m^3/day, but only 10^6m^3/day in the dyke-forming event of August 15, 2015. Magma intrusion rate into a pre-existing conduit prior to eruptions at Minamidake summit crater are ordered as follows: vulcanian eruption ($1x10^5$ to $8x10^5$ m^3/day) > continuous emission of volcanic ash (approximately $1x10^5$m^3/day) > strombolian/lava fountain ($0.2x10^5$ to $2x10^5$ m^3/day). The magma intrusion rate prior to vulcanian eruptions at Showa crater is smaller (approximately 10^4m^3/day) than for eruptions at Minamidake summit crater. However, the rate reached an order of 10^5m^3/day prior to lava fountain on August 22, 2017. Magma intrusion rates well correspond to the scale and type of eruption. In the case of magma intrusion under detection, the change of volcanic gas and increase in the heat discharge rate are available for the empirical event branch logic.

Keywords: magma intrusion rate, Sakurajima, volcanic earthquake, vulcanian eruption, strombolian eruption, plinian eruption

Tilt and strain change before and after the explosion at Minami-dake, Sakurajima, in 2017

*Kohei Hotta[1], Masato Iguchi[2]

1. University of Toyama, 2. Disaster Prevention Research Institute, Kyoto University

A deformation source associated with each eruption at Sakurajima have been estimated beneath Minami-dake [Ishihara, 1990; Iguchi et al., 2013]. Deformation sources for mid-long-term magma intrusion event were estimated beneath Aira caldera, Kita-dake and Minami-dake; and the deformation source beneath Kita-dake was found to act as a buffer of mid-long eruptive activity at Sakurajima [Hotta et al., 2016].

On November 13, 2017, an explosion with an infrasound occurred at Minami-dake at 22:07. Ground deformation was accompanied and kept for approximately five hours. For the period of 22:07–22:10 (period I), a large strain change at Arimura observation tunnel, which is the nearest tilt/strain station from Minami-dake crater and operated by Ministry of Land Infrastructure, Transport and Tourism, was detected whereas no significant change in tilt/strain was detected at other tilt/strain stations. For the period of 22:10–22:50 (period II), tilt/strain change was detected at all tilt/strain stations associated with violent eruptive activity. At around 23:00, style of eruption shifted from Vulcanian to Strombolian. For the period of 22:50–3:00 of the next day (period III), a pattern of tilt change at Japan Meteoritical Agency (JMA)-A station, which located on western area of Sakurajima, and tilt/strain gradually stopped.

We modeled the detected tilt/strain change using a finite spherical source model [McTigue, 1987]. Because of the poor constraint of the radius of the source, we assumed the radius of the source as 20 m for period I and 200 m for periods II and III. A shallow deflation source was located at a depth of 0.1 km above sea level beneath Minami-dake for period I. A deeper deflation source was located at a depth of 5.9 km below sea level beneath Minami-dake for period II. Then, a deflation source was located at a depth of 5.9 km below sea level beneath Kita-dake for period III. Deformation sources beneath Minami-dake for periods I and II are corresponding to the deformation sources previously found for each eruption at Sakurajima. Meanwhile, the deformation source beneath Kita-dake for period III is corresponding to the deformation source beneath Kita-dake which was found during mid-long eruptive activity. Each eruption at Sakurajima revealed to cause deflation of not only Minami-dake source but also Kita-dake one, which considered to repeat inflation/deflation during mid-long eruptive activity at Sakurajima. Temporal development of deflation accompanied by the eruption on November 13, 2017, will be revealed in our future study.

Pyroclastic Flow Accompanied with an Eruption on June 16, 2018 at Sakurajima Volcano

*Takeshi Tameguri[1], Masato Iguchi[1], Masayuki Maki[2], Haruhisa Nakamichi[1], Daisuke Miki[1]

1. Sakurajima Volcano Research Center,Disaster Prevention Research Institute, Kyoto University, 2. Research Field in Integrated Studies,Kagoshima University

At Sakurajima volcano, the explosive eruption has repeated at the summit crater since 1955. The eruption resumed for the first time in 58 years in the Showa crater on the eastern flank of the mountain, and the eruption activity was particularly active from 2009. The eruption activity has been transitioning again from the Showa crater to Minamidake summit crater since 2018. Characteristics of the explosive eruption include ejection of volcanic bombs, generation of shock waves, the release of sudden volcanic ash and gases. Besides, although the frequency is small, the explosive eruption of the Minamidake summit crater and Showa crater produces small pyroclastic flows. The pyroclastic flow is one of the most dangerous phenomena of volcanic eruption, with pyroclastic flow of high temperature and volcanic gas flowing down the flank at high speed, prediction of the pyroclastic flow occurrence is important for volcanic disaster prevention.
Seven pyroclastic flows have been confirmed with the eruption at Minamidake summit crater between 1967 and 1985 (Kamo and Ishihara, 1986). Furthermore, 37 pyroclastic flows have been reported to occur in the Showa crater from 2006 to 2014 with the eruption by the Japan Meteorological Agency. Travel distance of the pyroclastic flows from the Minamidake and Showa craters were less than 2 km. Although it is Sakurajima which continues active eruption activity, pyroclastic flow is minor phenomenon and the mechanism of pyroclastic flow generation in Sakurajima has not been elucidated. In the future, when the eruption activity becomes active, it is necessary to consider the occurrence of a large pyroclastic flow, and it is important to understand the occurrence mechanism of the pyroclastic flow. In this study, we will clarify the characteristics of precursory seismic activity and ground deformation data on the pyroclastic flow occurred in the Mimamidake and Showa craters between 2012 and 2018. In addition, we investigate whether it is possible to predict the scale and travel distance of the pyroclastic flow from the data of the precursory earthquakes and ground deformation.
In the explosive eruption at Minamidake summit crater that occurred on June 16, the volcanic ash reached to 4700 m and the pyroclastic flow went down 1.3 km from the crater in the southwest direction. The expansion of the ground deformation was observed about 18 hours before the occurrence of the eruption. The precursory earthquake sporadically occurred about 1 hour before the eruption, but it was not a clear activity compared to the eruption of the Showa crater. The pictures of the pyroclastic flow shows that the ejected material dropped from the plume flowed down the slope about 1 minute after the eruption started to rise. The pyroclastic flow does not occur simultaneously with the eruption, which has the same characteristics as the pyroclastic flow that occurred during the Minamidake activity period (Kamo and Ishihara, 1986). Amount of ejecta by the eruption is estimated to be 280,000 m3 from the ground deformation data. Not all of the ejecta will be pyroclastic flow. It is necessary to estimate the amount of pyroclastic flow out of the ejecta in order to predict the flow down distance. Estimate the amount of ejecta that became a pyroclastic flow from the calculation of fall volcanic ash using weather radar.

Tokachidake is an active volcano that repeated magmatic eruptions in 1926, 1962 and 1988. Prior to these eruptions, phreatic eruptions had been confirmed from several years ago. Although there has been no magmatic eruption in the last 30 years, long-term expansion centered around the 62-2 crater has been observed since around 2006. One of the GNSS stations near the crater moved more than 50 cm in total till the end of 2017. Coinciding with this expansive crustal deformation, long-term demagnetization under the 62-2 crater has also been observed.

Repetitive GNSS observations around the crater for more than 10 years suggested the fluctuation of deformation area centered around 62-2 crater and Taisho crater. Analysis of the temporal change of the motion vector assuming an isotropic deformation source at these two places revealed that the two inflation sources expanded at a substantially constant rate as a whole while changing the rate complementarily. Since the assumed fluctuation source is extremely shallow and flowing out of hot muddy water at the bottom of the 62-2 crater has occasionally been observed, we consider that this long-term deformation reflects the mechanical response of the shallow hydrothermal system.

Geodetic observation revealed that the long-term expansive deformation turned into stagnation in the period from the end of 2017 to the beginning of 2018. Almost at the same time, the total magnetic force data showed change in its trend of demagnetization. Also, in the Furikozawa fumaroles, an expansion of the geothermal area and an increase in fumarolic activity have been reported since around 2017.

Under such circumstances, number of volcanic earthquakes and tremors temporarily increased from late May 2018. A volcanic tremor on May 29th which activated seismicity was accompanied by a tilt motion showing a stepwise subsidence in the crater direction. Therefore, we visually examined the tiltmeter record from January 2018 which were obtained at the station MTKW (about 650 m west of the crater). Although there were few tilt events until around the end of March, occurrence frequency of such event increased thereafter, and it further increased on May 29th. A total of 117 events were identified by the end of August, 10 events by the end of March, 30 events in April and May and 77 events by August. Tilt events generally show a stepwise subsidence in the crater direction, but careful examination of each event revealed that there are various types of events: tilt change following a small preceding phase, inflation –deflation pattern, gradual change more than a few minutes, and events associated with VLP-like seismic signals, etc. Examining the direction of the tilt motion vector at MTKW about these 117 events, almost 90 % shows subsidence in the crater direction of N120 –135°E. For the event on May 29th, a preliminary analysis using tilt data around the crater showed that the tilt motion can be roughly explained by an isotropic deflation source of 130 m^3 located at 1300 m above sea level slightly south of the 62-2 crater.

Summarizing the shallow activities of Tokachidake volcano, expansion of the geothermal area and increase in fumarolic activity appeared almost at the same time with the latest stagnation of long-term expansive deformation and demagnetization for over 10 years. Volcanic earthquakes and tremors

accompanying stepwise subsidence in the crater direction increased around the same time with the deflation of the crater area. We can roughly consider two hypotheses for the latest deflation: one is a decrease in the amount of hot water supplied from the deep part, and the other is a change in supply / release balance due to an increase in discharge amount from fumaroles. Expansion of the fumarolic area, increase of the fumarolic activity, and increase of the tilt event strongly suggest the possibility of the latter hypothesis, although it is difficult to discuss the amount supplied from the deep part.

In recent decades, moment tensor inversion of very-long-period (VLP, 2-100 s) earthquakes associated with explosive/non-explosive activities has been applied to estimate the optimal source location and mechanism. Source mechanism of VLP associated with explosions at Stromboli volcano has been interpreted as the pressure source of opening/closing cracks embedded in the volcanic medium (Chouet et al., 2003). However, the nearest temporal station is 300 m away from the craters so that the source mechanism might have not been constrained well to discuss the detail processes of the magma motion in the conduit. In this study, we analyze broadband seismic data observed in the very-near-field condition, only 100-300 m away from the active craters, to obtain a more precise source mechanism solution.

We use the seismic data recorded at eight broadband seismic stations including temporary and permanent networks. Infrasonic array analyses show that the explosive eruptions mostly occurred at the north-east (NE) crater during the observation period in the end of September 2016. We apply a moment tensor inversion method to VLP (0.05-0.2 Hz) signals associated with the largest explosion occurring at the NE crater. The result shows that the optimal centroid is located at 200 m southwest of, 160 m beneath the NE crater. The source mechanism is greatly dominated by the vertical component of the moment tensor (Mzz), although the polarity inverts with other two diagonal components (Mxx, Myy). The squared error between the observed and synthetic waves (Ohminato et al. 1998) is only 11%.

We note that the squared errors less than 20 % are widely distributed around the optimal location: 300 m ×300 m in horizontal distances and 250 m in the vertical direction. For example, the solution obtained at a depth of 160 m beneath the NE crater shows the error of 18 %, which is within the confidence interval 95 % range of the residual at the optimal location. At this location, the inverted source mechanism is dominated by three diagonal components with a same polarity. This is much different from the best solution.

To examine why such different source mechanisms are obtained for nearby source locations, we calculate a model resolution matrix using the Green’ s functions computed from a point source at the optimal location and investigate how well the moment tensors can be resolved. The minimum singular value in the model resolution matrix is assumed to be 2.1 % of the maximum. We replace this value with zero and consider the pseudoinverse. The model resolution matrix for the pseudoinverse shows that the resolution of the diagonal components of moment tensors is lower than deviatoric ones. This suggests that the amplitudes of diagonal components are not well constrained from the moment tensor inversion even using near-by stations in our temporal observations. These results will be indispensable for discussing the spatial distribution of the volumetric change in the conduit or magma chamber accompanying the explosions.

Pressure source estimation of tilt changes associated with small explosions at Stromboli volcano

*Ayumu Ishikawa[1], Takeshi Nishimura[1], Hiroshi Aoyama[2], Ryohei Kawaguchi[3], Eisuke Fujita[4], Takahiro Miwa[4], Taishi Yamada[4], Maurizio Ripepe[5], Riccardo Genco[5]

Stromboli volcano is characterized by continuous activities of Strombolian explosions (small explosions) at summit craters. A lot of studies have investigated volcanic processes by multi-parameter observations. However, pressure source determination by geodetic measurements, which is indispensable to understand shallow magma reservoir which is a key for understanding magma dynamics, have not yet been well conducted because of insufficient geodetic observation network. In the present study, we analyze tilt records at 3 temporal and 2 permanent stations located closely to the summit craters to determine the locations and size of pressure source by comparing the observed tilt vectors with the theoretical ones that are calculated by using finite element method.

Temporal stations CPL, PZZ, RFR were equipped with Applied Geomechanics 701-2A, and installed at a distance of <500 m from the active craters. Continuous stations LFS, OHO, LSC, operated by University of Florence, were equipped with Pinnacle 5000T. We analyze continuous tilt records of 5 stations during July 1 to July 15 when small explosion activity was high. We extract uplift and subsidence tilt signals associated with each of small explosion and classify them in 4 stages: (A) Gradual uplift prior to small explosions, (B) Rapid uplift just before small explosions, (C) Rapid subsidence after small explosions, (D) Small uplift after (C). Tilt azimuths and amplitudes are almost same for the stages of (A) –(C), although LFS show about 30 degrees difference. We use the tilt vectors averaged for 680 events in the following analyses. We suppose that the pressure source is represented by an ellipsoidal cavity at (1) beneath the summit craters or (2) VLP source (Chouet et al., 2003; 200 m NW from the summit craters). We searched optimal source model which could explain the observed tilt vectors by changing the size and shape of the ellipsoidal cavity. The results show that simple shape sources such as a sphere cannot explain the observed tilts both for the locations of (1) and (2). A spheroidal source that is modeled from the VLP source mechanism do not explain the observed tilts, either. By changing the size and directions of ellipsoidal cavity, we find that the ellipsoidal cavity with a size of 300×150×600 m at 400 m depth beneath the summit craters can well explain the observed tilts. The pressure applied during the episode (A) is estimated to be about 1 kPa.

The size and position of the estimated ellipsoid is basically consistent with the picture of shallow magma reservoir inferred from an analysis of temporal evolution of flank lava effusion in 2007(Ripepe et al., 2015). The mass and volume of magma supplied for conduit during a small explosion that are estimated from the obtained pressure change, appropriate conduit radius and magma density is comparable to the ejected mass and volume of one small explosion estimated from the observations of surface phenomena.

Seismic and acoustic waves excited by volcanic explosion: analyses of energy ratio and source spectra

*Mohammad Hasib[1], Takeshi Nishimura[1], Hisashi Nakahara[1]

1. Department of Geophysics, Graduate School of Science, Tohoku University

Volcanic eruptions generally accompany both seismic and acoustic signals, and these signals are used to understand volcanic fluid motions in the conduit and/or its effusion process from active vents. In the present study, we compare these two kinds of signals observed at three volcanoes in Japan, systematically examining the temporal changes of radiated energy. We further examine the basic spectral characteristics of seismic and acoustic signal radiations during large and small Vulcanian explosions at Sakurajima volcano. We use seismic and acoustic records at seismic-acoustic stations operated by Japan Meteorological Agency (JMA).

We first examine the energy ratio between seismic and acoustic signals of volcanic explosions at Sakurajima, Kirishima, and Kuchinoerabu-jima volcanoes. We calculate the time series of energy ratio of acoustic signals to three-component seismic signals by calculating their envelopes at the frequency band of 1-5 Hz. To obtain averaged characteristics, we stack the energy ratios of seismic and acoustic signals of about 900 explosions at Sakurajima and 8 explosions Shinmoe-dake (Kirishima) volcanoes, respectively. We analyze only one eruption at Kuchinoerabu-jima. The results at Sakurajima and Shinmoedake (Kirishima) show the following characteristics in the temporal changes: the ratio of seismic energies to acoustic energies rapidly decreases at the beginning and reaches the minimum in about 10 s -20 s; then the ratio gradually increases for 20 s - 40 s; the seismic signals continue after the acoustic energy decreases down to the noise level. Although we can analyze one eruption data for Kuchinoerabu-jima volcano (18 December 2018), similar characteristics are recognized. These results suggest that the volcanic fluid motions are strong in the shallow parts in the beginning, and the active zone gradually becomes deep.

Next, we investigate the source spectra of acoustic signals of volcanic explosions. Applying the spectral ratio method that has been often used for seismic signals, we clarify the difference of source spectra between large and small acoustic signals. We stack the spectral ratios of acoustic signals according to their maximum amplitudes, and classify them into Classes IV, III, II, and I from the largest to the smallest. The maximum amplitude of the largest event is about 10 Pa, while the smallest is about 2.5 Pa. Since the wind around the volcano may disturb the wave propagations, we only select the acoustic signals excited by volcanic explosions occurring during a low wind speed (< 3.3 m/s) condition, using the assimilation wind data recorded by ECMWF (European Centre for Medium-Range Weather Forecasts). We observe that the spectral ratios of acoustic signals are similar among different stations both for direct and coda waves. This means that the spectral ratio method is applicable for the acoustic signals of volcanic explosions during low wind speeds. All pair of the observed source spectral ratios of acoustic signals (Class IV/I, III/I, II/I) are characterized by almost flat amplitudes at the frequency range of about 0.2 -10 Hz. The difference between the classes is the amplitude. This characteristic is much different from the seismic signals excited by Vulcanian explosions (Hasib et al., 2018), in which a flat amplitude at low frequency range (about 0.5 - 2 Hz), a gradual decrease with frequency at an intermediate frequency range (about 2–3.5 Hz), and a flat amplitude at high frequency range (about 3.5 –10 Hz). These differences suggest the differences in the generation mechanisms between seismic and acoustic signals, which may reflect the difference of excitation region: the seismic waves are in the volcanic conduit beneath the vent, while the

acoustic waves are at the orifice of the conduit.

Field survey report on Zao Volcano (2012–2018)

*Akio Goto[1], Noriyoshi Tsuchiya[2], Nobuo Hirano[2], Miwa Kuri[3], Tetsuya Matsunaka[4], Kengo Sawayama[2]

1. Center for Northeast Asian Studies, Tohoku University, 2. Graduate School of Environmental Studies, Tohoku University, 3. International Research Institute of Disaster Science, Tohoku University, 4. Institute of Nature and Environmental Technology, Kanazawa University

We have been conducting field surveys on Zao volcano since 2012, such as temperature monitoring and water sampling on Maruyama-sawa geothermal area, ruin of Niizeki hotspring and Okama crater lake, based on the expectation that Zao volcano may be activated by 2011 Great East Japan Earthquake. Geophysical observation network by Japan Meteorological Agency, which has started 24-hour monitoring in September 2010, detected volcanic tremor in January 2013 for the first time, and a tremor and preceding tilting occurred in April (JMA, 2013). Since then Zao volcano sustains its higher activity than usual. Volcanic warning, Level 2: Do not approach the crater, were issued in April 2015 due to the increase in volcanic earthquake and in January 2018 due to the occurrence of volcanic tremor with largest-ever amplitude and continuous tilt motion. In harmony with these activities our field surveys also detect some changes in surface activities. Here we review our field survey results since 2012, especially focusing on the 2017-2018 results which has not reported yet.
