Temperature of over 20 fumaroles has been measured repeatedly on Maruyama-sawa geothermal area, where small phreatic explosion occurred in 1940 (Toraishi and Tominaga, 1940; Anzai, 1941). The highest temperature exceeded 102 ˚C in 2012, but decreased over 7 ˚C within four months in 2013; fumarole temperature overall fell lower than 95 ˚C by 2014. After the first volcanic warning in 2015, the highest fumarole temperature reached nearly 100 ˚C temporarily, and then overall temperature rise occurred in 2016. In 2018, after volcanic warning was issued for the second time in January, the highest fumarole temperature exceeded 100 ˚C in June and reached 104 ˚C in July, which is the highest record in our survey since 2012.

We have paid attention to ruin of Niizeki hotspring, where high temperature and high concentration hotsprings gushed as a result of activization in the past, but no activity was recognized between 2012 and 2014. In September 2015, five months later from the first volcanic warning, we found that Niizeki hotspring resumed welling up with multiple hotsprings at around 32˚C. But in 2016 surveys, Niizeki hotspring had only a few weak cold-water springs, and no remarkable activity was recognized after the second volcanic warning in 2018.

In contrast with Maruyama-sawa and ruin of Niizeki hotspring, no thermal activity has been recognized on Okama crater lake thus far. The bottom temperature was around 4 ˚C in late May and early June (2014 and 2016), and around 7 ˚C in early September (2014, 2015, 2017 and 2018). We installed thermocouples in 2017 and 2018 on the bottom of Okama crater lake to record the temperature change one hour interval. We found that 3-4 ˚C temperature rise occurred in early October in 2017 and 2018, which is probably not be the results of thermal activity of Zao volcano but seasonal variation, because the degree of temperature change and the time of the year were identical. In 2018 other research group conducted topography survey of Okama crater lake bottom using a multiple-frequency sonar system and detected vertically extending reflection over a small mound on the center of the lake bottom, which may be caused by a chain of rising volcanic gas bubbles or hot water plume (Yamasaki et al., 2018). One of our

©2019. Japan Geoscience Union. All Right Reserved.

thermocouple is set within 10 m from the reflection source. Our thermocouple may catch the temperature change if thermal activity occurs there.

Inflation Event of Zao Volcano in 2015

*Satoshi Miura[1], Mare Yamamoto[1], Masahiro Ichiki[1], Tomotsugu Demachi[1]

1. Graduate School of Science, Tohoku University

Volcanic earthquakes and tremors have been occurring beneath Zao volcano located in the northern Honshu, Japan since 2013, following the increase in the number of deep low frequency earthquakes from around 2012. Tohoku University has deployed some new seismological, geodetic, and geomagnetic stations to enhance rather poor observation network prior to the activity. On account of a burst of volcanic earthquakes initiated in April 2015, the Japan Meteorological Agency announced a warning of eruption, however, the number of events gradually decreased for the next two months and the warning was canceled in June 2015. In the same time period, minor expansive deformation was observed by GNSS. Small-scale volcanic earthquakes and tremors are occasionally occurring, and long-period earthquakes have taken place sometimes accompanied by static tilt changes. In this talk, We report the outcome obtained from the five-year observational research to monitor the preparatory process going under the volcano for evaluation of the eruption potential.

Figure 1 demonstrate the horizontal and vertical movement around Zao, respectively, from Jan. to Jun. of 2015. The black arrows show the observed ground movement. The radial pattern of movement around the summit of the volcano is clearly seen and the upheaval indicated by the black bars also centered around the summit. These characteristics of deformation can be modeled by a infinitesimal pressure source underground (so called Mogi model). We tried inversion analyses to find its location and magnitude. It is located about 0.8 km east of the crater lake with depth of about 5.6 km, and the volumetric change equivalent to the pressure change is $3.8 \times 10^6 m^3$. The calculated displacements are shown in the figure by white arrows and bars.

Comparing the hypocenter map, the pressure source is located just above the deep low frequency earthquakes cluster. This suggests that the pressure source might be activated by geothermal heat supplied by magma or fluid. Ogawa et al. (2014) found a conductive zone beneath Zao volcano deeper than about 5km and this may support our result.

[S-VC38] Active Volcanism

convener:Yuta Maeda(Nagoya University), Takahiro Miwa(National research institute for earth science and disaster prevention), Takeshi Nishimura(Department of Geophysics, Graduate School of Science, Tohoku University), Chairperson:Mare Yamamoto, Yuta Maeda(Nagoya University)

This session discusses various aspects of active volcanisms including, but not limited to, recent and historical eruptions, various phenomena associated with the volcanic activities, underground structures of the volcanoes, and developments of new instruments based on geophysical, geochemical, geological, and multidiscipline approaches. We also welcome studies on understanding and predicting the transitions of the eruptive activities from observational, theoretical, and experimental approaches.

A machine-learning-based estimation of large amplitude regions for monitoring volcano seismicity

*Yuta Maeda[1]

1. Nagoya University

The seismic network of Mt. Ontake has improved after the 2014 eruption, producing one of the most dense observational networks in the world composed of 9 stations within 1 km of the summit, 17 within 4 km, and 29 within 10 km. This network has recorded long-period (LP) events and tremors which had been considered quite rare at Mt. Ontake (Maeda et al., 2018, JPGU). These signals are attributed to movements and volume changes of shallow volcanic fluids according to studies of similar signals at other volcanoes; thus they are important markers to understand the state and behavior of the fluids. However, despite finding several events, the entire activity of them are not known at Mt. Ontake; it is not easy to manually create an event catalog because of abundance of spurious events (i.e., local wind noise) and difficulty of distinguishing them from real volcano-seismic signals. This is partly related to a difficulty of comparing the records at many stations with a sufficient temporal resolution using a small number of figures. A new strategy to extract useful information from the large number of stations is thus needed.

In this study, we developed a method to investigate a spatiotemporal distribution of large amplitude regions to easily monitor the activities of earthquakes and tremors. The amplitudes could be a measure to monitor the seismicity including those without clear initial motions, but could be affected by local structures beneath the stations. To reduce this effect, we used information of whether the amplitudes are significantly larger than the normal level. We determined a threshold to distinguish significantly large and normal amplitudes from every 5-min-long window of each data trace, based on an idea that Gaussian and non-Gaussian portions of the frequency distribution of the amplitudes are normal and significantly large parts, respectively. This idea is implemented by creating a cumulative frequency distribution of absolute amplitudes in the 5-min-long window using only the smallest N data samples; calculating the fitting error between this distribution and an error function; and searching for an optimal N which minimizes the fitting error. The amplitude corresponding to this optimal N was regarded as the threshold. We then computed the ratio of large amplitude samples in every 1-sec-long window of each trace. We used the spatial distribution of this ratio as the input to a machine learning of a neural network model to investigate the large amplitude region for the 1-sec window. In this way, the spatial distribution of the large amplitude region is investigated for every 1-sec window, which could be used to distinguish true volcano-seismic signals from spurious ones.

We applied this method to the continuous records in November and December 2017 at Mt. Ontake. For most earthquakes occurred in the analysis domain, the large amplitude region distributed within a narrow area around the epicenter or spread with time from the epicentral area to a wider region. For distant earthquakes and local noise, the large amplitude region extended over the entire analysis domain with a small probability. These different patterns of the large amplitude regions were useful to distinguish the true volcano-seismic signals from spurious ones, although there were some missing detections of small earthquakes and tremors. Using the large amplitude region, only one figure is needed for each second, enabling a seismicity monitoring easier than detailed evaluations of continuous waveform records. We are now trying the 2nd stage of the machine learning to automatically detect earthquakes and tremors, which uses the spatiotemporal distribution of the large amplitude as the input, giving 93% success as a preliminary result.

Development of a technique for automatic determination of volcanic earthquakes with unclear onsets - Application to Mt. Asama -

*Takao Ohminato[1], Shigeki Horiuchi[2]

1. Earthquake Research Institute, Tokyo University, 2. Home Seismometer Corporation

Some of volcanic earthquakes have clear P and S-wave onsets, and other has unclear onsets. In the traditional classification of volcanic earthquakes, the former is called A-type, VT, or HF earthquakes, and the latter is called B-type, LP, or LF earthquakes. The source process of the former is thought to be the rock rupture due to the stress changes in the volcanic edifice. For the latter, various source processes involving volcanic fluids such as gas, hot water or magma, have been proposed.

Numerous B-type earthquakes are often detected by the seismic network near the active volcanic vent of a volcano even if the activity level of the volcano is not high. In addition, a sharp increase in the number of B-type earthquakes is often observed when volcanic activity increases. Because shallow B-type earthquakes reflect the state of the magma plumbing system or the shallow hydrothermal system, constant monitoring of their activity is important. However, since B-type earthquakes are numerous and it is difficult to read their onset by human eyes, manual processing is not easy. Therefore, it is necessary to develop a automatic method to detect the event and to determine the hypocenter location. For events with unclear onsets, various methods, such as obtaining travel time differences by using waveform correlation, using particle motion, using spatial distribution of amplitude, etc., have been proposed so far. In particular, methods using waveform amplitude are widely used for hypocenter determination of B-type earthquakes due to their excellent performance.

In this study, we first examine how effective the Horiuchi et al. (2010)'s method for hypocenter determination of volcanic earthquakes with unclear onset. This method has been used in hypocenter determination of non-volcanic earthquakes. The basic idea of this method is, first, to define an evaluation function that imitates the comprehensive judgment of experienced human beings, then, to optimize the parameters of the evaluation function automatically so that the results of automatic readings approach the human readings. Furthermore, the influence of noise is reduced by giving a higher score values to observation stations where the difference between the theoretical and the observed travel times is smaller and by choosing a solution with the sum of the score values of all observation stations is maximum. In order to further improve signal-to-noise ratio, S-waveforms are appropriately rotated before reading S-arrival.

When we applied the method in its original form to Mt. Asama data, the accuracy of the result was poor. Possible reasons would be, in addition to difficulty in onset reading itself, the influence of various factors such as poor human readings which are the basis of parameter optimization, and high noise level of the data. In order to improve the performance of the method, we have tried various remedy such as improving onset reading, utilizing amplitude, reducing noise, etc. and have finally reached the stage where automatic determination is satisfactory. The measures we have taken and their results are as follows.
1) If the conventional automatic reading method is applied as it is, the accuracy of S-reading is not good enough. We examined a method in which an approximate hypocenter location is determined first using the waveform amplitude, then the S-wave arrival is read using the correlation. In order for improving the accuracy of S-reading, we used the correlation of the S-waveform envelope. We then computed the hypocenter location by using both the amplitude and the travel time. But the high accuracy of the

©2019. Japan Geoscience Union. All Right Reserved.

S-reading was not reached. We abandoned this approach.
2) The hypocenters were determined by using both the automatic reading of S-arrival and amplitude, but accuracy was not satisfactory.
3) We performed following four remedy first: "To avoid reading noisy waveforms", "To discriminate between distant earthquakes and local volcanic earthquakes", "Not to use readings with low signal-to-noise ratio", "To remove amplitude data with inconsistent S-arrival". We then carried out hypocenter determination by using waveform amplitude alone. The results obtained by this procedure were most satisfactory.

When we apply above-mentioned improved method to the data for three months from November 2017 to January 2018, we could determine hypocenters of about 1900 events near the summit of Mt. Asama. The number of events that was determined manually during the same period was less than 100 events. Although we need to investigate more about the accuracy of the obtained hypocenter location, we believe that the improved version of this method is fairly promising.

Amplitude source location method with depth-dependent scattering and attenuation structures for volcano-seismic signals

*Hiroyuki Kumagai[1], John Makario Londono[2], Alvaro Esteban Acevedo Rivas[2], Yuta Maeda[1]

1. Graduate School of Environmental Studies, Nagoya University, 2. Colombian Geological Survey

The amplitude source location (ASL) method has been used to locate seismic events and tremor at various volcanoes. It has been indicated that the far-field and isotropic radiation equation for *S* waves used in the ASL method is valid in highly scattering wavefields. A constant *Q* value in the far-field and isotropic radiation equation has been commonly used in previous studies. This implicitly assumes homogenous distributions of scattering characteristics represented by the mean free path (l_0) and intrinsic attenuation (Q_i) beneath volcanoes. Wegler (JGR, 2004) and Kumagai et al. (JGR, 2018) showed that highly heterogeneous structures at volcanoes only exist in a surface thin layer with a thickness of about 1 km, below which less heterogeneous layers comparable to those in the normal crust exist. To evaluate the effects of such layered structures for ASL determinations, we performed synthetic tests using envelope waveforms simulated with the Monte Carlo method of Yoshimoto (JGR, 2000) for a two layer model based on the l_0 and Q_i structures at Nevado del Ruiz volcano (NRV) estimated by Kumagai et al. (2018). Our results indicated that the input source locations were estimated by the ASL method when appropriate values of *Q* values for the two layered model were used in the far-field and isotropic radiation equation. When a constant *Q* value was used, the estimated locations were largely deviated from the input locations especially in the depth direction. We then determined ASLs of volcano-tectonic (VT) earthquakes at NRV, which were compared with their hypocenters determined by the onset arrival times. Our results indicated that the differences between the ASLs and hypocenters of VT earthquakes became smaller when using a two layer *Q* model than those using a constant *Q* model. Our estimated ASLs of long-period (LP) events and tremor at NRV using the two layer *Q* model were more sharply clustered beneath the SW flank compared to those using the constant *Q* model. These locations corresponded to high *P*-wave to *S*-wave velocity ratio regions (Londono and Kumagai, JVGR, 2018), suggesting that the LP events and tremor were generated by fragmentation processes in a shallow magma storage region. These results indicate that use of appropriate *Q* values in the ASL method accommodating a thin surface heterogeneous layer is important to estimate precise source locations.

Seismic interferometry at active volcanoes in Japan: Analyses of seismic records of JMA for the period from 2012 to 2018

*Takeshi Nishimura[1], Tomoya Takano[1], Takashi Hirose[1], Hisashi Nakahara[1]

1. Department of Geophysics, Graduate School of Science, Tohoku University

We analyze the seismic records of JMA stations deployed at active volcanoes in Japan, to examine the basic characteristics of daily variations of seismic velocity changes in the shallow medium. About 20 active volcanoes are systematically analyzed at the frequency range of 0.5-4 Hz. Temporal changes of the seismic velocity changes calculated from comparison of 7 years averaged cross-correlations and 5-days ones show long-period changes with periods of a year and/or a few months. The frequency distributions of seismic velocity changes at each station pairs roughly follow the normal distributions with a standard deviation of about 0.2 to 1 percents. Several phreatic eruptions occurred at Kuchinoerabu-jima, Ontake, Hakone and Aso volcanoes during the observation period, but no significant change is observed in the seismic velocity changes. On the other hand, seismic velocity changes due to the strain changes by volcanic pressure sources, moderate and large earthquakes, and/or dike intrusion are observed at, for example, Sakurajima, Miyakejima, Izu-Ohshima, Azuma and Tarumae volcanoes.

Empirical relation for *Q* factors of crack resonances and its use to estimate source properties of volcanic LP events

*Kimiko Taguchi[1], Hiroyuki Kumagai[1], Yuta Maeda[1], Roberto Torres[2]

1. Nagoya University Environmental Studies, 2. Colombian Geological Survey

Long-period (LP) seismic events are thought to arise from the oscillations of a fluid-filled resonator. The resonator geometry and fluid properties of LP sources have been estimated by comparing observed frequencies and *Q* factors to those calculated from a crack model (Chouet, *J. Geophys. Res.*, 1986). Taguchi et al. (*J. Geophys. Res.*, 2018) developed a method based on an analytical formula for the crack resonance frequencies proposed by Maeda and Kumagai (*Geophys. J. Int.*, 2017). This method enables us to estimate all the parameters of crack geometry and fluid properties. But the comparison of *Q* factors was conducted by numerical simulations of the crack model, which took extensive computational time, especially for LP events with large *Q* factors. So we systematically investigated the relation between *Q* factors and the crack model parameters by numerical simulations. It is known that *Q* factors of the crack resonances are proportional to α/a, where α is the *P* wave velocity of the solid and *a* is the sound speed of the fluid in the crack (Kumagai and Chouet, *J. Geophys. Res.*, 2000). We additionally found an empirical relation, indicating that the proportional constant depends on $\log(W/L)$, where *L* and *W* are crack length and width, respectively. To test the applicability of this empirical relation, we used it to analyze LP events at Galeras volcano, Colombia, in January 1993. These LP events have been thought to be generated by resonances of the crack filled with dusty gas. Our estimates of the crack model parameters displayed decreasing trends in both crack volume (*V*) and gas-weight fraction of water vapor (*n*) in the crack. These trends are similar to those shown by Taguchi et al. (2018). We further analyzed LP events at Galeras in May 1993 and December 2006 with the empirical relation for *Q* factors assuming dusty gas as the fluid in the crack. Because of their large *Q* factors, the determinations of crack geometry and fluid properties for these LP events with numerical simulations of the crack model were computationally expensive. The empirical relation for *Q* factors enables us to estimate all the crack model parameters for these LP events easily, and we found similar decreasing trends in both *V* and *n* to those in January 1993. This similarity implies that these variations during the individual periods of LP events were caused by the similar processes at this volcano.

These results demonstrate that the empirical relation obtained in this study is applicable to estimate all the parameters of LP sources, and may contribute to improved monitoring of fluid states under volcanoes and better understanding of LP source processes.

A study on the radiation pattern for resonating fluid-filled crack

*Mare Yamamoto[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

Volcanic earthquakes observed around active volcanoes often exhibit harmonic characteristics having multiple spectral peaks, and thus the oscillation of fluid inclusions beneath volcanoes have been considered as one of the most plausible source models of these signals. As examples of such resonator model, the resonance of fluid inclusions whose shapes are sphere, cylinder, and crack have been proposed and successfully applied to the analyses of observed signals to explain the spectral characteristics of volcanic earthquakes. In recent years, it becomes more common that we have dense seismic observation close to the source of volcanic earthquakes, and we often observe varieties of spectral shapes showing different amplitude pattern between spectral peaks and between stations. To utilize the amplitude information of observed spectral peaks, in this study, I model the radiation pattern for a resonating fluid-filled crack, and discuss about the possibility to estimate the orientation and size of the fluid-filled crack.

In this study, the radiation of elastic waves from a resonating thin fluid-filled crack in 3-D infinite medium is considered. First, I compute the oscillation of fluid-filled crack, and compute the wave radiation from the crack by numerically integrating the elastic waves generated by the tensile dislocation on the crack surface. By computing the energy at each direction, the radiation pattern is then obtained as a function of distance from the crack. Because Yamamoto and Kawakatsu (2008) showed that the distribution of the tensile dislocation on the crack surface can be described by small numbers of Chebyshev polynomials as far as we consider the low-frequency oscillation of the crack, for the sake of comparison, I also calculate the wave propagation using this analytical expression. If we consider only far-field compressional wave, the model setting is same as that discussed in Chouet (1986). In contrast, in this study, I use analytical Green’s function including both near- and far-field terms for P and S waves to study the radiation pattern for the resonating fluid-filled crack.

In the case of the crack containing hydrothermal fluids, which have rather large acoustic velocity contrast between inside and outside of the crack, the radiation pattern of each resonant mode becomes almost comparable to that obtained only with far-field compressional term at distance larger than about 50 times of the crack size. On the other hand, the radiation pattern in short distance range is severely distorted due to the contribution of near-field term and the interference of waves emitted from different point of the crack. In addition, there exists the difference between even- and odd-modes of the resonant mode. These results can be explained by considering the following mainly two points: the wavelength of radiated elastic waves is same order of the crack size, and thus the distant range in which the contribution of near-field term dominates is proportional to the wavelength of each resonant mode; the distribution of tensile dislocation have different symmetry for odd/even modes, and thus the effect of the interference of waves emitted from different point of crack surface depends on the direction, as already pointed out by Kumagai et al. (2002). It also becomes clear that there exists the distant dependency of amplitude ratio between resonant modes.

These results indicate the possibility to estimate the orientation and size of fluid-filled crack beneath volcanoes by observing amplitude ratio between stations and between spectral peaks. Because the

©2019. Japan Geoscience Union. All Right Reserved.

spectral amplitude ignoring phase information is less affected by the wave scattering caused by small-scale heterogeneity in shallow volcanic edifice compared to the waveform itself, the methodology has an advantage in practical data analyses. These results also suggest the importance of near-field dense observation to understand the detailed source mechanism and source process of volcanic earthquakes.

[S-CG49] Hard-Rock Drilling Science: From Continental to Deep Sea Drilling, and Oman Project

convener:Katsuyoshi Michibayashi(Department of Earth and Planetary Sciences, Nagoya University), Eiichi TAKAZAWA(Department of Geology, Faculty of Science, Niigata University), Norikatsu Akizawa(Department of Ocean Floor Geoscience, Atmosphere and Ocean Research Institute, The University of Tokyo), Chairperson:Eiichi Takazawa(Niigata University), Norikatsu Akizawa(AORI The University of Tokyo)

The Oman Drilling Project (OmDP) has completed to drill numerous hard-rock cores within ancient oceanic lithosphere and the underlying subduction zone of the Samail ophiolite in Oman, with support from ICDP, IODP, Japan Society for the Promotion of Science, the Sloan Foundation's Deep Carbon Observatory, US, and European research agencies. Moreover, a number of IODP expeditions have focused on hard-rock drilling over the last several years including Expedition 352 in 2014, which drilled the volcanic sequence associated with subduction initiation in the Bonin fore-arc, Expedition 357, which drilled the Lost City hydrothermal field, Expedition 360, which drilled the lithosphere associated with ultraslow-spreading at the Southwest Indian Ridge in 2016, and Expedition 366, which drilled the serpentinite seamounts in the Mariana fore-arc. In this session, we invite presentations on the scientific results of hard-rock drilling at these and other sites. We also invite related presentations on oceanic lithosphere, island arc formation, and any other significant issue that could be addressed by future hard-rock drilling. This includes marine studies of oceanic lithosphere and on-land geological investigations of ophiolites, accreted arcs, and subduction complexes. The session is intended to be interdisciplinary, including the fields of geophysics, geochemistry, petrology, engineering, and biology.

Harzburgitic, dunitic, and wehrlitic rocks drilled at Atlantis Massif (Mid-Atlantic Ridge, 30˚N), where mantle-derived rocks were exhumed to the sea floor via detachment faulting, were investigated employing *in situ* geochemical analyses. Since dunitic and wehrlitic rocks are commonly interpreted as fossil melt channels, they likely represent transported parental melts of mid-ocean ridge basalt (MORB) beneath the paleo-ridge axis. Although the rocks are severely serpentinized, primary olivines, chromian spinels, orthopyroxenes, and clinopyroxenes were found in several samples. The Cr/(Cr + Al) ratios (Cr#) of the chromian spinel show a bimodal distribution, where one group records higher Cr# (0.35–0.5) and the other group is represented by lower Cr# (0.2–0.3). The extent of mantle melting is strongly correlated to the Cr# of the chromian spinel, thus the mantle-derived lithologies of the Atlantis Massif record at least two end-members with regards to the extent of melting: refractory mantle material with higher Cr#, and enriched mantle material with lower Cr#. To quantitatively evaluate mantle melting and melt transport mechanisms in the suboceanic mantle beneath this section of the Mid-Atlantic Ridge, a one-dimensional, steady-state decompositional mantle melting model was carried out based on rare-earth element concentrations of clinopyroxene. Our modelling results demonstrate that the melting region of the mantle extends unevenly across the ridge axis, with deeper melting occurring on-axis from the garnet-stability field, and shallower melting occurring off-axis from the spinel-stability field. We propose that depleted melts generated at depths in the absence of garnet within the off-axis region were possibly focused to the ridge axis via fracture-induced melt channels and produced wehrlite. It is likely that fracture-induced melt migration was dominantly a response to a decrease of temperature as the mantle was exhumed during detachment faulting.

Lower crustal accretion processes revealed from the study of gabbroic cores in Holes GT1A and GT2A, the ICDP Oman Drilling Project

*Sayantani Chatterjee[1], Eiichi TAKAZAWA[1], Katsuyoshi Michibayashi[2], Peter B Kelemen[3], Damon A.H. Teagle[4], Oman Drilling Project Phase I Science Party

1. Department of Geology, Faculty of Sciences, Niigata University, Japan, 2. Department of Earth and Environmental Sciences, Nagoya University, Japan, 3. Lamont Doherty Earth Observatory, Columbia University, USA, 4. Southampton Marine and Maritime Institute, University of Southampton, United Kingdom

Transition between middle crustal foliated and to lower crustal layered gabbros of Oman ophiolite was drilled at Hole GT2A and GT1A in Wadi Gideah of Wadi Tayin massif (22˚51.793'E/58˚31.198'N and 22˚53.535'/58˚30.904' respectively) during Phase 1 of Oman drilling project. With total depth of 406.77m long Hole GT2A core samples the middle foliated to layered gabbro. Hole GT1A drilled the lower crustal section in the southern Oman ophiolite and recovered 401.52 m of total cores (99.6% recovery). Petrographic observation of representative samples from GT2A and GT1A, we found two dominant rock types: gabbbro and olivine gabbro, where later dominates the lower part of the drill hole.

The layered structure is mainly controlled by the variable grain size and modal composition of minerals. Gabbros contain plagioclase and clinopyroxene (showing poikilitic texture) as primary minerals associated with few amounts of oxides. Clinopyroxenes are often replaced by brown amphibole along cleavages or at the rim. Olivine gabbros are constituted of plagioclase, clinopyroxene, olivine, some orthopyroxene and oxide minerals. Texturally, olivine grains are present as subhedral to skeletal in nature. Magmatic foliation is often demarcated by laths of plagioclase followed by elongated clinopyroxene. The contact between olivine and plagioclase frequently marked by presence of symplectitic intergrowth between spinel and orthopyroxenewhich suggests, olivine was reacting with late stage liquid and produce simultaneous coprecipitation of magnetite and orthopyroxene. Downhole evolution present from bottom to top for both in gabbro and olivine gabbro samples in terms of Mg#,TiO2, and Cr2O3 in clinopyroxene, olivine and plagioclase, particularly at 270mt and 130mt Mg# increase (influx of primitive melts at several intervals). TiO2 and Cr2O3 correspond with Mg#, and eventually follow fractionation trend. Data from rare earth elements implies that ol-gabbros are crystallized from different parent melts (at least two types) supported by the evidence from evolution with depth profile.

Gabbroic lithologies in GT1A represented by anhedral olivine with tabular to elongate shape. Plagioclase are partly or totally enclosed by large clinopyroxene. Clinopyroxenes are tabular to subequant in habit. Some thin films of orthopyroxene present as corona around olivine. Most of the samples have undergone alteration and obscured the igneous origin. In case of Hole GT2A, gabbros are much less affected by alteration compared to GT1A. Downhole variation in mineral composition (in-situ composition) can be correlated with several cycles of crystallization history. Detailed petrographic, microstructural and geochemical study of all the representative samples will be presented. We have also attempted to determine the oxygen fugacity, where (fO2 vs.T plot) oxide pairs are plotted within FMQ field (fO2 vs. T plot). Temperature estimation ranges from 600-800˚C (shallow level gabbro to deeper gabbro) cover total range of temperature from high to low and also have a clue to determine the thermal evolution by rate of cooling.

Listvenites obtained during the Phase 1 of the Oman Drilling Project can be generally divided into two main groups based on color: red series and green-white series. Although there is a clear color difference, the mineral assemblage is mainly composed of magnesite and quartz. Dolomite occurs as late veins and/or small patches. Opaque minerals are abundant in the red series which occur either as veins or disseminated grains which are commonly enveloped by carbonate minerals and quartz. The opaque minerals are hematite based on Raman spectrometry analysis. In the green-white listvenite series, opaque minerals are very scarce. Greenish portions in both listvenites were observed on a hand sample scale. In the green-white series, dark green and light green portions are present while only light green portions are observed in the red listvenites. These greenish features are interpreted as mainly polymineralic pseudomorphic replacement of orthopyroxene. In the same hole, pyroxene relics in serpentinites exhibit the same shape as with the previously described greenish pseudomorphs. The dark green portions in the green-white listevenites contain fuchsite (Cr-mica) around spinel relics. Silicified relic pyroxenes with fuchsite along relic cleavages are also present in the light green portions. On the other hand, the greenish portions in the red listvenite series are characterized by magnesite with intergranular fuchsite (?). Hematites in the red listvenites have similarities in form with the opaque minerals occurring as discontinuous veinlets in the serpentinite. The combined similarities in the petrographic features suggest that some listvenites were formed from serpentitnites. Quartz veins with Ni-bearing magnesite were observed in the red series and were formed in the last stage.

It is well known that oceanic crust covers almost 70 % of Earth’ s surface. It is formed at mid-ocean ridge and is subducted into mantle at convergent plate margin. This plate motion is pull many kinds of surface materials in inside the mantle and contributed to a global recycling system. However the details of the oceanic crusts and underlain upper mantle are still poor understanding. The construction of the oceanic crusts is defined by constructions of ophiolites which were the ancient oceanic plates exposed onto land.

To have better understandings of the oceanic crust, underlain upper-most mantle and related other things, the Oman Drilling Project by ICDP was done the drilling from 2016 to 2018 in Samail ophiolite, Oman. The Samail ophiolite in the northern part of Oman is the largest and having better exposed section of the oceanic lithosphere in the world.

We will report the preliminary results of the PGE abundances and Os isotope ratios in the whole-rock gabbros and mantle related peridotites from the drilling cores and compering to the data from the Oman surface data. These data will be help us to better understanding of the relationships between the oceanic crust and underlying upper mantle, mechanisms of making oceanic crust, and planning the future Mohole projects.

Overview of drilling of crust-mantle boundary at CM1&2 sites of Wadi Tayin massif of Oman ophiolite: the ICDP Oman Drilling Project

*Eiichi TAKAZAWA[1], Damon A H Teagle[2], Katsuyoshi Michibayashi[3], Yoshihiko Tamura[4], Jude Ann Coggon[2], Juerg Matter[2], Peter B Kelemen[5], Oman Drilling Project Phase 2 Science Party

At the boundary between the crustal section and the mantle section of the Oman ophiolite there are several tens to hundreds of meters thick, mainly composed of dunite called the crust-mantle transition zone (MTZ) [1]. Since it often accompanies thin veins or clots of plagioclase and clinopyroxene and several centimeters to meters thick gabbro sills, it leaves traces of magma activity right under the ridge. The origin of dunite in MTZ is still under debate: the accumulation of olivine crystallized from melt [2], or the reaction of harzburgite with pyroxene-undersatulated melt [3], or both [4]. Recently, the presence of water at the time of formation has also been pointed out [5]. To clarify the origin of MTZ, more detailed research by continuous core through MTZ is necessary.

From November 2017 to January 2018 MTZ of Wadi Zeeb (CM1&2 sites) in Wadi Tayin massif was drilled by the International Continental Scientific Drilling ProgramOman Drilling Project [6]. Geological mapping on ground associated with information from the recovered cores the thickness of the MTZ is estimated as about 150 m. The upper and lower boundaries of the MTZ has a strike in the east-west direction, and it is inclined about 30 degrees south. In the summer of 2018, the drilled cores were carefully described by scientists on the deep-sea drilling vessel "CHIKYU". The stratigraphy has been divided into four igneous sequences based on the abundance of different lithologies: Layered Gabbro Sequence, Dunite Sequence, Dunite with Gabbro Sequence, and Mantle Sequence. Dunite Sequence and Dunite with Gabbro Sequence are summarized as Crust - Mantle Transition.

Hole CM1A is inclined 60˚ northward. The upper 160 m of the core is the Layered Gabbro Sequence, mostly composed of olivine gabbro, interlayered with gabbro and a small amount of wehrlite, dunite, anorthosite and troctolite. From 160 to 310 m the Crust-Mantle Transition is divided into an upper 90 m Dunite Sequence and a lower 60 m Dunite with Gabbro Sequence containing small lenses of gabbro, troctolite and wehrlite. The dunites are highly serpentinized, and rodingite and diopsidite commonly replace minor gabbroic rocks in these sequences. The lower 80 m of the hole is the Mantle Sequence, with alternating layers of dunite and increasingly abundant, residual mantle harzburgite.

Hole CM2B is a vertical hole located 400 m north of CM1A, and samples the Crust-Mantle Transition and the Mantle Sequence. As in CM1A, the transition is divided into an upper Dunite Sequence and a lower Dunite with Gabbro Sequence. In contrast to Hole CM1A, a small amount of olivine has escaped complete serpentinization in the lower portions of the CM2B transition zone. In the Mantle Sequence, harzburgite is dominant. Dunite accounts for about 25% of this Sequence, less than in CM1A. The lowermost peridoties in Hole CM2B are strongly altered to talc+carbonate.

Petrological observation of core samples drilled from a mantle section of the Oman ophiolite: A preliminary report of the Oman Drilling Project Phase 2

*Yuji Ichiyama[1], Oman Drilling Project Phase 2 Scientific Party

1. Chiba University

The Oman ophiolite is the world’s largest ophiolite and will help us to understand the crustal formation, processes in the mantle, and evolution and modification of the oceanic lithosphere through the time. The drillings and investigations of the crust-mantle boundaries and mantle sections were operated in the Oman Drilling Project Phase 2. We report the preliminary results of the petrological observation of the drilling samples from the mantle sections in the Phase 2 Holes BA1B, BA3A, and BA4A.

The Hole BA1B is composed of upper dunite and lower harzburgite associated with mafic dikes. The Hole BA3A is dominated mainly by harzburgite and also contains a minor amount of thin dunitic layers and mafic dikes. The Hole BA4A consists of alternation of dunite and harzburgite with abundant mafic dikes. The mafic dikes observed in each hole are gabbro to olivine gabbro, and sometimes wehrlitic. Brown to pale brown hornblende is usually included in almost all lithology. Phlogopite is also present in association with hornblende. Chromian spinel in an olivine-gabbro sample from the BA4A is characterized by high $Fe^{3+}/(Cr + Al + Fe^{3+})$ ratio (>0.15) and intermediate TiO_2 content (1–2 wt.%), which are comparable with those in island arc basalts. In the contact between the mafic dikes and peridotite, orthopyroxene is formed as a reaction product between the mantle peridotite and mafic melt. The petrological characteristics of the mafic dikes indicate that they crystallized from hydrous, oxidized magmas, which imply that the intrusion event occurred in a convergent margin rather than a typical spreading axis.

[S-CG49] Hard-Rock Drilling Science: From Continental to Deep Sea Drilling, and Oman Project

convener:Katsuyoshi Michibayashi(Department of Earth and Planetary Sciences, Nagoya University), Eiichi TAKAZAWA(Department of Geology, Faculty of Science, Niigata University), Norikatsu Akizawa(Department of Ocean Floor Geoscience, Atmosphere and Ocean Research Institute, The University of Tokyo), Chairperson:Tomoaki Morishita(Kanazawa University), Katsuyoshi Michibayashi

The Oman Drilling Project (OmDP) has completed to drill numerous hard-rock cores within ancient oceanic lithosphere and the underlying subduction zone of the Samail ophiolite in Oman, with support from ICDP, IODP, Japan Society for the Promotion of Science, the Sloan Foundation's Deep Carbon Observatory, US, and European research agencies. Moreover, a number of IODP expeditions have focused on hard-rock drilling over the last several years including Expedition 352 in 2014, which drilled the volcanic sequence associated with subduction initiation in the Bonin fore-arc, Expedition 357, which drilled the Lost City hydrothermal field, Expedition 360, which drilled the lithosphere associated with ultraslow-spreading at the Southwest Indian Ridge in 2016, and Expedition 366, which drilled the serpentinite seamounts in the Mariana fore-arc. In this session, we invite presentations on the scientific results of hard-rock drilling at these and other sites. We also invite related presentations on oceanic lithosphere, island arc formation, and any other significant issue that could be addressed by future hard-rock drilling. This includes marine studies of oceanic lithosphere and on-land geological investigations of ophiolites, accreted arcs, and subduction complexes. The session is intended to be interdisciplinary, including the fields of geophysics, geochemistry, petrology, engineering, and biology.

Discussion

Structural analyses of ultramafic rocks used by X-ray CT core imaging (Oman Drilling Project Phase 2, D/V CHIKYU)

*Katsuyoshi Michibayashi[1], Yuki Kakihata[1], Ikuo Katayama[2], Atsushi Okamoto[3], Keishi Okazaki[4], Peter B Kelemen[5], Eiichi TAKAZAWA[6], Damon A H Teagle[7], Oman Drilling Project Phase 2 Science Party[8]

1. Department of Earth and Planetary Sciences, Graduate School of Environmental Studies, Nagoya University, 2. Hiroshima University, 3. Tohoku University, 4. KCC, JAMSTEC, 5. Columbia University of New York, 6. Niigata University, 7. Southampton University, 8. ICDP

X-ray computed tomography (X-ray CT) images were obtained on all cores drilled during Oman Drilling Project (OmanDP) Phase 2 (Holes CM1A, CM2B, BA1B, BA3A and BA4A) as a routine part of the IODP measurement protocol onboard D/V Chikyu. X-ray CT scanning enables the non-destructive observation of the internal structure of the core, providing information about chemical composition and density. The data are useful for assessing sample locations and quality. X-ray CT images can be used for 3D fabric analyses even after core has been cut in half and subsampled for other analyses.

The X-ray CT scanner (Discovery CT 750HD, GE Medical Systems) scans and reconstructs an image of a 1.4 m section in 10 minutes and produces a series of scan images, each 0.625 mm thick. The X-ray source and detector are installed inside of the gantry opposite each other. The excitation voltage and current for X-ray tube are 140kV and 100 mA, respectively.

Core samples are scanned in the gantry with a scanning rate of 20 mm/sec. The distribution of attenuation values mapped to an individual slice comprises the raw data that are used for subsequent image processing. Successive two-dimensional (2D) slices of 512 x 512 pixels yield a representation of attenuation values in three-dimensional (3D) voxels of 512 x 512 by ~1600 in length. Data generated for each core consist of core-axis-normal planes (XY planes) of X-ray attenuation values with dimensions of 512 ×512 pixels in 9 cm ×9 cm cross-section, with a resolution of 0.176 mm/pixel.

X-ray intensity varies as a function of X-ray path length and the linear attenuation coefficient (LAC) of the target material, which is a function of the chemical composition and density of the target material. The basic measure of attenuation, radiodensity, is the CT number given in Hounsfield units (HU). CT numbers of air and water are -1000 and 0, respectively.

CT numbers of OmanDP cores reveal structural features such as the attitude of foliation in primary peridotites, defined by spinel and orthopyroxene crystal shape. Combined with microstructural analyses such as EBSD mapping, we can study petrophysical properties of the uppermost mantle in the mantle section. Moreover, comparing with density profiles measured onboard, we can also estimate the degree of serpentinization in core from Holes BA1B, BA3A and BA4A, ranging from 80 to almost 100%. Profiles of

©2019. Japan Geoscience Union. All Right Reserved.

the degree of serpentinization with depth may provide insight into ongoing serpentinization processes.

Petrophysical characteristics of serpentinized peridotites of Hole BA1B, BA3A and BA4A

*Kakihata Yuki[1], Katsuyoshi Michibayashi[2], Laura Crispini[3], Bjorn Jamtveit[4], Samuel Barbier[5], Joe Aslin[6], Manuel Menzel[7], Marguerite Godard[8]

1. Graduate School of Science, Shizuoka University, 2. Graduate School of Environmental Studies, Nagoya University, 3. University of Genova, 4. University of Oslo, 5. Claude Bernard University Lyon 1, 6. University of Liverpool, 7. Andalusian Earth Science Institute, 8. Géosciences Montpellier, CNRS, Univ. Montpellier

Structural characteristics within peridotites of Hole BA1B, BA3A and BA4A have been described during the Oman Drilling Project Phase 2 from 5th August to 3rd September, 2018 on D/V Chikyu. The peridotites consisted of intensely serpentinized harzburgite and dunite, which exhibited foliations defined by elongation and alignment of constituent minerals. Crystal plastic fabrics in harzburgite were described prior to those in dunite because orthopyroxene grains are clearer than spinel grains in serpentinized peridotites at macro scale.

Harzburgites in BA1B show variously deformed textures ranging from pophyroclastic to protomylonitic textures in dependent on the depth. In BA3A, harzburgites with protogranular texture were observed in relatively shallow sections (10-90 m), whereas porphyroclastic to strongly foliated textures were dominant in deeper sections. Most of hartzburgites in BA4A show porphyroclastic texture, partly clear foliation and protomylonitic textures by strongly elongated orthopyroxene grains. Dip angles of measured foliations in BA1B are mostly 0-20˚, which are nearly horizontal. Most of dip angles in BA3A are at around 30˚, up to 50˚. In BA4A, dip angles of orthopyroxene grains take various values between 10-50˚. In BA3A and BA4A show similar dip angles, but significantly steeper than those in BA1B. In each hole, dip angles were nearly constant independent on the depth.

Pyroxene and spinel grains in strongly foliated to protomylonitic peridotites are intensely elongated and aligned, exhibiting clear foliation at thin section scale. In protogranular peridotites, pyroxene and spinel grains have rounded shapes and are not elongated and aligned, and foliations are unclear. Elongated pyroxene and olivine grains in protomylonitic peridotites show kink bands and wavy extinction, whereas few rounded pyroxene grains in protogranular peridotites show these features.

We report physical property measurements of core samples from the Samail ophiolite in Oman, drilled by the ICDP Oman Drilling Project. Onboard core logging was conducted on D/V Chikyu for 4 months in total in the summers of 2017 and 2018. We analyzed 4 holes (GT1A, GT2A, GT3A and BT1B) in 2017, and 5 holes (CM1A, CM2B, BA1B, BA3A and BA4A) in 2018. The total core length of those 9 holes is about 3200 m. Cores from Holes GT1A and GT2A in the lower crust section of the ophiolite are mainly composed of gabbros (gabbro and olivine gabbro), with small amounts of ultramafic rocks (wehrlite and dunite), whereas those from Hole GT3A at the boundary between the sheeted dikes and gabbro are mainly composed of basalt and diabase, followed by gabbros (gabbro, olivine gabbro and oxide gabbro). Minor felsic trondhjemite and tonalite dikes intrude the mafic rocks. In contrast, Hole BT1B penetrated from mantle section through the basal thrust and into the metamorphic sole. The CM holes were drilled through the crust-mantle transition, from gabbroic lower crust, through dunite with minor gabbros, and in to residual mantle harzburgite. BA holes were taken from the mantle section and are composed of dunite and harzburgite intruded by minor gabbroic and pyroxenite dikes. Ultramafic rocks at both sites were extensively serpentinized, but the names of igneous protoliths are used here.

Whole-round data, including X-ray CT images, natural gamma radiation (NGR), gamma ray attenuation (GRA) density, magnetic susceptibility (MS), P-wave velocity (Vp) and noncontact electrical resistivity were obtained. Split core color spectroscopy data were also collected. Magnetic susceptibility, electrical resistivity under both nominally dry and brine-saturated conditions, P-wave velocity, bulk/grain density, porosity and thermal conductivity were measured in discrete samples. Nearly 100% core recovery allowed us to take a large data set of petrophysical data on the cores from Oman ophiolite including fault zones and highly altered intervals.

Generally, gabbroic rock types have higher density, P-wave velocity, and electrical resistivity, and lower porosity than ultramafic lithologies. Serpentinized dunite have lower density, P-wave velocity and electrical resistivity, and higher porosity than serpentinized harzburgite, and these physical properties are correlated with magnetic susceptibility, probably due to crystallization of magnetite during alteration. Average X-ray CT values are also correlated with many other physical properties in most lithologies. Those physical property data and the lithological characteristics of the Moho transition zone in the Oman ophiolite revealed apparent difference and similarities with the oceanic data, especially in the seismic profiles from the oceanic plate. In this paper, we would like to compare the data from ocean drilling, Oman Drilling and seismic profiles.

Seismic anisotropy under high pressure conditions of harzburgite collected from Oman Drilling Project Phase II

*Kohei Hatakeyama[1], Ikuo Katayama[1], Natsue Abe[2], The Oman Drilling Project Phase II Science Party

1. Department of earth and planetary systems science, Hiroshima University , 2. JAMSTEC

The Oman ophiolite interpreted as ancient oceanic lithosphere has been drilled recently, and core samples of harzburgite were collected from mantle section (Oman Drilling Project). These compressional wave velocity of three orthogonal directions (X, Y and Z axis) was measured under ambient condition onboard D/V Chikyu. Velocity of Z axis was lower than that of orthogonal directions (X and Y axis), showing approximately 4% of anisotropy. Although anisotropy caused by preferred orientation of olivine was observed at oceanic mantle, olivine in harzburgite collected from ophiolite is almost transformed to serpentine, implying that anisotropy of core samples is caused by preferred orientation of pyroxene. In addition, the preferred orientation of cracks also causes anisotropy, which is sensitive to the type of pore fluid (Anderson et al., 1974). However, the dominant factor of anisotropy is unclear because both effects are included in the measurement under the ambient condition. In this study, we measured elastic wave velocity of harzburgite under high confining pressure where most pores are closed, and determine a dominant factor causing seismic anisotropy.
Harzburgite collected from Hole BA1B and BA3A were selected as the experimental samples. Density and porosity of these samples are 2.60 to 2.64 g/cm^{3}and 0.5% to 1.0%, respectively.Intra-vessel deformation and fluid flow apparatus at Hiroshima University were used to conduct the measurements under high confining pressure of up to 200 MPa. Two loading cycles were applied to each specimen to measure velocity successively under both dry and wet conditions. In wet condition, pore pressure was set at 10 MPa using a syringe pump.Both compressional and shear wave velocity ($V_P$andV_S) on two orthogonal directions (Y and Z axis) were measured from the pulse transmission method with the amplitude and the frequency of a trigger wave of 5 V and 2 MHz, respectively.
In the preliminary results at 200 MPa of confining pressure under dry conditions, harzburgite collected from Hole BA3A shows V_P = 5.86 km/s and V_S = 3.03 km/s on the direction of Y axis, and V_P = 5.49 km/s and V_S = 2.95 km/s on the direction of Z axis. Anisotropy under high confining pressure indicates 6.5% and 2.7% for compressional and shear wave velocity, respectively. Therefore, the preferred orientation of minerals is likely to be a dominant factor.

Understanding of the mode of seafloor spreading and the architecture of upper oceanic crust by oceanfloor drilling at off-Hawaii MoHole candidate site

*Susumu Umino[1], Tomoaki Morishita[1], Mikiya Yamashita[2], Osamu Ishizuka[3]

1. Department of Earth Sciences, Kanazawa University, 2. Japan Agency for Marine-Earth Science and Technology, 3. Geological Survey of Japan, AIST

Understanding how seafloor spreading and mantle melting are linked to ocean crust architecture is Challenge 9 of the IODP Science Plan for 2013-2023 and is one of the major goals of the mantle drilling project MoHole to Mantle (M2M). Deep basement drilling is skewed to young and slow-spread crust, with a wide gap of crust age between 20 and 110 Ma, including the world average of 62.5 Ma and spreading rate of 7.6 cm/a. Among the three candidate sites of M2M, only off-Hawaii site can provide the information of oceanic crust of the missing age and spreading rate. We propose a deep drilling off-Hawaii to penetrate through the upper crust and into the gabbros to understand the architecture and governing processes of the upper oceanic crust.

ODP Holes 504B and 1256D have brought invaluable information and fruitful insight into the architecture and formation processes of the upper oceanic crust.

Hole 504B is the deepest drill hole that penetrated 1815 m into 6.9-Ma basement formed at an intermediate rate of 6.6 cm/a at the Costa Rica Rift (Dick et al., 1992). The 504B upper crust, consisting of less dense extrusive rocks underlain by denser sheeted dikes than their source magmas, yields an apparent level of neutral buoyancy that traps accreted magma as dike intrusions. Thus, the 504B crust relaxes stress induced by plate movement and extends by both fault displacement and dike intrusions, which leads to development of rugged summit and axial troughs.

On the contrary, the 15-Ma 1256D crust, formed at the East Pacific Rise, has a distinctly high extrusive to intrusive ratio (814 m / 343 m) compared to that of the 504B crust (780 m / >1056 m). As is expected for the ultrafast spreading rate of 22 cm/a, the extrusive rocks are dominantly of massive and lobate sheet flows, which are as dense as the extruding magma (Umino et al., 2008). This results crust without an apparent level of neutral buoyancy and the persistently over pressurized axial magma chamber (AMC). Only a small increase in magmatic pressure or reduction in horizontal stress leads to dike intrusions followed by eruptions. Conversely, extension of the 1256D upper crust was primarily accomplished by dike intrusions without large faults.

These examples articulate how the density structures of upper crust partition magma into extrusive and intrusive rocks and form characteristic architectures.

Density structures are intimately correlated with magma budget, the amount of magma supplied and consumed to keep the same cross-sectional area of the ridge for a time scale of 100 ky.

The Galapagos Spreading Center (GSC) shows thickening on-axis and thinning total extrusive rocks with AMC depth, indicating axial valleys develop to trap thick on-axis flows with deepening AMC and decreasing magma budget (Blacic et al., 2004). For the GSC spreading rate of 4.5–5.5 cm/a, more than

©2019. Japan Geoscience Union. All Right Reserved.

50 % of flows in the axial valleys are pillows. Consequently, the GSC is underlain by less dense pillows interbedded with fault breccias. The density structure of this crust is essentially the same as the 504B crust.

Likewise, the magmatically robust East Pacific Rise (EPR) shows a negative correlation of total extrusive thickness and AMC depth, while on-axis flow thickness remains constant (Hooft et al., 1996, 1997). Accordingly, the axial troughs do not develop, and the upper crust extends mainly by dikes intrusions. This is facilitated by the presence of dense extrusive rocks comprising more than 80 % sheet flows, considering the spreading rates of 11–14 cm/a, primarily the same as the 1256D crust.

How two types of upper crust architecture change from one type to the other is yet to be understood. If any critical threshold that distinguishes two crust types exists, it would reside in the crust with a spread rate between 7 cm/a and 10 cm/a. The off-Hawaii crust spread at 7–8 cm/a will provide a missing link that connects the two crust architectures and brings us thorough understanding of the seafloor spreading.

[S-CG49] Hard-Rock Drilling Science: From Continental to Deep Sea Drilling, and Oman Project

convener:Katsuyoshi Michibayashi(Department of Earth and Planetary Sciences, Nagoya University), Eiichi TAKAZAWA(Department of Geology, Faculty of Science, Niigata University), Norikatsu Akizawa(Department of Ocean Floor Geoscience, Atmosphere and Ocean Research Institute, The University of Tokyo)

The Oman Drilling Project (OmDP) has completed to drill numerous hard-rock cores within ancient oceanic lithosphere and the underlying subduction zone of the Samail ophiolite in Oman, with support from ICDP, IODP, Japan Society for the Promotion of Science, the Sloan Foundation's Deep Carbon Observatory, US, and European research agencies. Moreover, a number of IODP expeditions have focused on hard-rock drilling over the last several years including Expedition 352 in 2014, which drilled the volcanic sequence associated with subduction initiation in the Bonin fore-arc, Expedition 357, which drilled the Lost City hydrothermal field, Expedition 360, which drilled the lithosphere associated with ultraslow-spreading at the Southwest Indian Ridge in 2016, and Expedition 366, which drilled the serpentinite seamounts in the Mariana fore-arc. In this session, we invite presentations on the scientific results of hard-rock drilling at these and other sites. We also invite related presentations on oceanic lithosphere, island arc formation, and any other significant issue that could be addressed by future hard-rock drilling. This includes marine studies of oceanic lithosphere and on-land geological investigations of ophiolites, accreted arcs, and subduction complexes. The session is intended to be interdisciplinary, including the fields of geophysics, geochemistry, petrology, engineering, and biology.

Permeability is a key property that controls heat and chemical exchange in the oceanic lithosphere as well as microbial activity in the sub-seafloor. Although direct measurements of permeability were not made on board D/V Chikyu during analysis of cores from the Oman Drilling Project, we estimated permeability profiles based on onboard measurements of electrical resistivity. For each core sample, we measure its resistivity at nominally dry conditions to obtain the dry resistivity. We then saturate the sample with NaCl solution (3.5g/L) and repeat the resistivity measurements at brine-saturated conditions to obtain the wet resistivity. Owing to the conductive brine in the pore space, the wet resistivity is systematically lower than dry resistivity. Because the difference between dry and wet resistivity is predominantly controlled by the movement of dissolved ions in the brine that occupied the pore space, we can use the resistivity data to infer the volume fraction of pores that contribute to electrical transport (termed “transport porosity”). We apply the Hashin-Shtrikman upper bound to estimate transport porosity. The estimated transport porosity shows a positive correlation with bulk porosity measured on board (MAD analysis), but is approximately one order of magnitude lower. Using an empirical cubic law between transport porosity and permeability, we produce estimated permeability profiles for the crust-mantle transition zone and the serpentinized mantle sections in the Hole CM1A, BA1B, BA3A and BA4A. The results indicate, (1) the gabbro sequence exhibits a markedly lower permeability than the underlying mantle sequence, (2) serpentinized dunites have higher permeability compared to serpentinized harzburgites, and (3) the general variation of discrete sample permeability is correlated with fault zone and intervals with abundant fractures. These permeability structures are most likely modified by alteration and juxtapositions, and do not represent the in-situ profile of the oceanic lithosphere; but this technique can be applicable to infer on-board permeability in future hard rock drilling.

Relationship between alteration intensity and elastic wave velocity of gabbroic rocks from ICDP Hole CM1A, Oman Drilling Project Phase II

*Kosuke Kimura[1], Ikuo Katayama[1], Kohei Hatakeyama[1], Yuya Akamatsu[1], Natsue Abe[2], Keishi Okazaki[2], The Oman Drilling Project Phase II Science Party

1. Hiroshima University, 2. JAMSTEC

The mafic to ultramafic rocks suffer metamorphism and metasomatism by the seafloor hydrothermal activities. These alterations can influence the elastic wave velocity due to the change of mineral assemblages during the ocean floor metamorphism. However, most previous studies have measured the elastic wave velocity of relatively unaltered samples. In this study, we measured elastic wave velocity of the altered gabbro from the Semail ophiolite collected from the Oman Drilling Project Phase II in order to estimate the effect of ocean floor metamorphism on the elastic wave velocity.

Gabbro samples were collected from CM1A site that is reported to be a layered gabbro sequence. Total seven samples those have different alteration intensity were measured. We use intra-vessel deformation and fluid flow apparatus at Hiroshima University to measure elastic wave velocity under confining pressure up to 200 MPa. Elastic wave velocity was measured by the pulse transmission method, with the amplitude and the frequency of a trigger wave of 5 V and 2 MHz, respectively. After measurements under dry condition, measurements under wet conditions injecting pore water were performed (P_P = 10 MPa). Alteration intensity is recognized by the relative abundances of the secondary minerals.

On the basis of the petrography, alteration group could be divided into four types. First type is almost fresh, olivine altered to serpentine and chlorite partially with less green minerals present. Second type has saussuritized plagioclase dominantly and also some sample shows alteration of clinopyroxene to amphibole. In the third type amphibolitization of clinopyroxene is dominant, and also saussuritization of plagioclase occur. Fourth type is the most altered sample showing alteration halo along the veins. Almost of the minerals are changed to prehnite except a few relict clinopyroxene. This type has higher porosity than other types.

Sample density ranges from 2.77-3.08 g/cm^3, and porosity ranges from 0.02-0.22% except ca. 1% from halo alteration sample. Data from these samples show a trend that elastic wave velocities (V_P and V_S) increase with increasing the confining pressure from 20 to 200 MPa. V_P increases from 5.68-6.80 to 6.16-6.91 km/s, V_S slightly increases from 3.65-3.97 to 3.69-3.99 km/s and V_P/V_S is almost constant ranging between 1.56-1.86 to 1.64-1.88 under dry condition, and on the other hand, V_P increases from 6.08-6.82 to 6.31-6.93 km/s, V_S slightly increases from 3.64-3.98 to 3.69-4.00 km/s and V_P/V_S is almost constant 1.67-1.86 to 1.68-1.87 under fluid-saturated condition, respectively. This result is mostly consistent with the layered gabbro occur in a normal oceanic crust (e.g. White et al., 1992; Shinohara et al., 2008).

At 200 MPa and under dry condition, V_P moderately decreases with increase in alteration intensity. About 0.75 km/s decreases in response to the increase in alteration intensity from 10 to 80 %. Comparing dV_P (difference in calculated and measured values) from the back-calculated original mineral assemblages of gabbro and peridotite reveled that the decrease in dV_P for the former is less than the latter. Moreover, both the curves of V_P and impedance change cross-over each other for gabbro and peridotite after nearly 50% of alteration.

©2019. Japan Geoscience Union. All Right Reserved.

From the above results, we suggest that if both gabbro and peridotite suffer more than 50% alteration, reversal of seismic velocity and impedance occurs, which effectively would affect the determination of geophysical Moho.

Physical property of the fossilized crust-mantle transition zone from ICDP Oman Drilling Project Hole CM1A and CM2B measured onboard D/V Chikyu

*Keishi Okazaki[1], Natsue Abe[1], Kohei Hatakeyama[2], Yuya Akamatsu[2], Ikuo Katayama[2], Eiichi TAKAZAWA[3], Damon A H Teagle[4], Peter B Kelemen[5], Jude Coggon[4], The Oman Drilling Project Phase 2 Science Party

1. Japan Agency for Marine-Earth Science and Technology, 2. Hiroshima University, 3. Niigata University, 4. University of Southampton, 5. Columbia University

To understand physical properties of the oceanic crust and the mantle is fundamentally important to reveal the dynamics of plate tectonics, and the global circulations of H_2O and CO_2 fluids. We report results on physical property measurements of core samples from Oman Drilling Project (OmanDP) Holes CM1A and CM2B, which drilled from the lower igneous crust into the upper mantle in the Samail Ophiolite, Sultanate of Oman.

X-ray CT, bulk/grain density, porosity, magnetic susceptibility, P-wave velocity, electrical resistivity and thermal conductivity were measured onboard D/V Chikyu using whole-round cores and discrete samples for core sections from CM1A and CM2B.

The paleo-Moho in CM1A may not preserve the original structure due to minor faulting, possibly during obduction. The gabbro-dunite transition (paleo-Moho) in Hole CM1A is characterized by a sharp change in physical property data. For example, P-wave velocity decreases from ~6.7 km/s in the layered gabbro sequence to ~4.9 km/s in the MTZ. Low P-wave velocity and density (~2.6 g/cm^3) in serpentinized dunites reflect the fact that olivine in the dunites is almost completely serpentinized. Serpentinization could have occurred during hydrothermal alteration near the spreading ridge axis, during subduction of 100’s of km of oceanic crust and sediment beneath the ophiolite, during obduction onto the Arabian continental margin, and/or during present-day weathering. In contrast to the paleo-Moho, the boundary between the Crust-Mantle Transition (CMT) sequences (i.e., dunites and dunites with gabbro lenses) and the underlying, residual mantle harzburgites is somewhat gradual. P-wave velocity gradually increases from ~4.9 km/s for dunite in the CMT to ~5.5 km/s for harzburgite in the mantle sequence. The thickness of the CMT is 50–70 m in Holes CM1A and CM2B. We also report on correlations between physical properties, especially electrical conductivity and magnetic susceptibility, and the fault intensity and alteration intensity from the core descriptions.

Microstructures of lower crust gabbros from the Oman Ophiolite: Analyses of the drilled cores of the Oman Drilling Project

*Koki Iida[1], Takahiro Fudai[1], Susumu Umino[1], Yuki Kusano[2]

1. Kanazawa University, 2. Geological Survey of Japan

Oman Drilling Project in 2016 to 2017 recovered 400 m long cores of layered gabbros at Site GT1 in the Wadi Tayin Massif of the Oman Ophiolilte. The purpose of this research is to describe microstructures of the layered gabbro core samples and to discuss the conditions of magmatic and hypersolidus deformation that operated in the lower crust beneath the Oman paleoridge.

Core samples were cut into slabs parallel to foliation and slabs normal to foliation and parallel to lineation, which were made into thin sections for microscopic observations. Structural fabrics and the relationships between crystal shapes and alliginment were described to identify magmatic and hypersolidus deformation structures.

Cored samples are predominantly olivine gabbros consisting of anhedral olivine, anhedral to subhedral clinopyroxene and subhedral to euhedral plagioclase. Grain size ranges from 0.5 mm to a few millimeters irrespective of mineral species.

The structures shown by the gabbros are classified into three regimes by temperature or the amount of melt present: Regime I, magmatic conditions without or minimal plastic deformation; regime Ⅱ, plastic deformation assisted by interstitial melt (Dunn, 2000); regime Ⅲ, near solidus deformation. Regime Ⅱ is identified by ameboid grain boundaries with no intracrystalline deformation and equigranular textures, resulted from decreasing internal strain energy by at high temperatures. The presence of melt is evidenced by the clear euhedral plagioclase rims with resorbed turbid cores as discussed below.

Regime I. Magmatic structures are identified as modal layering due to changes in mineral mode, no preferred orientation or shape-preferred orientation of clinopyroxene and plagioclase, poikilitic texture of olivine enclosing plagioclase laths and ophitic texture of clinopyroxene including plagioclase laths.

Regime II. The hypersolidus deformation structures overprint igneous structures: ameboid olivine with or without strain in the crystal, elongated olivine, and lenticular aggregates of olivine grains with an asymmetric quarter structure. Single clinopyroxene crystals show an asymmetric quarter structure like olivine aggregates. Ophitic clinopyroxenes consist of subgrains with slightly different orientations <10˚. Plagioclase shows deformation twin and undulose extinction. Equigranular fine-grained plagioclase with grain boundaries intersecting at 120˚ are common. Large plagioclases have a resorbed core with a wavy outline and are surrounded by euhedral rim.

Regime III. Subsolidus recrystallization includes buldging and grain boundary migration resulted in ameoboid grain boundaries of clinopyroxene. Undulose extinction and kinked twinning of plagioclase are observed.

It is well known that mid-ocean ridge basalt magma commonly crystallizes in the order of olivine, plagioclase and clinopyroxene, which is also true for the gabbros of the Oman Ophiolite (Adachi and Miyashita, 2003). Nevertheless, only plagioclase shows euhedral to subhedral shapes in the observed

©2019. Japan Geoscience Union. All Right Reserved.

layered gabbro core samples. Deformed olivine aggregates and clinopyroxene with quarter structures are embedded in plagioclase with equilibrium granoblastic textures and large euhedral plagioclases with resorbed turbid cores. Considering these textures combined with the mechanical strength of the three constituent minerals, these gabbros suffered deformation under the presence of melt, which assisted complete recovery of strain through recrystallization of fine-grained plagioclase and overgrowth of euhedral rims around magmatic plagioclase cores. Poikilitic olivine occurs through the hole, whereas ophitic Cpx occurs at 73 m and 220 m in depth. Most deformation structures of regime II are present irrespective to depth. The asymmetric structures of olivine and clinopyroxene were used to determine the relative sense of shear. Both dextral and sinistral sense of shear are observed within the same samples.

Olivine fabric and mineral compositions in the Maqsad area of the Samail massif, the southern Oman ophiolite

*Kaho Takahashi[1], Eiichi TAKAZAWA[2,3], Katsuyoshi Michibayashi[4], Kakihata Yuki[4], Ryoko Senda[5]

1. Graduate School of Science and Technology, Niigata University, 2. Department of Geology, Faculty of Science, Niigata University, 3. JAMSTEC, 4. Nagoya University, 5. Kyushu University

In this study, we conducted structural and chemical analysis of oriented samples of 17 harzburgites and 4 dunites collected from the Maqsad area of Samail massif in the southern Oman ophiolite. We investigated the degree of partial melting and the mantle-melt reaction with relation to mantle diapir structure.

The crystallographic preferred orientation (CPO) of olivine grains were measured in highly polished XZ thin sections using a scanning electron microscope equipped with an electron-back scatter diffraction system at Shizuoka University. After plotting the results in the Vp Flinn plot expanded for olivine fabric types [1,2], the fabric type of peridotites in this study are summarized as follows. The distribution of A type is limited in the southeastern part where the diapir structure has been identified [3], whereas D type is dominant in the peripheral part of the diapir. Minor amounts of AG type and E type are also observed in the peripheral part. From these, the olivine in the southeastern part (diapir area) of this study area is likely to have been deformed under high temperature whereas the peripheral part was deformed at slightly lower temperature. The CPOs of olivine in both areas do not show any influence from the presence of H2O except for only one sample with E type CPO. Moreover, strong alignment of [100] to the vertical orientation was observed in the southeastern part (diapir area) of this study area. Since vertical mantle flow has been estimated in this diapir area, our results are consistent with the previous study [3,4].

The Cr# (=Cr/[Cr+Al] atomic ratio) of spinel in the harzburgites and dunites are as high as 0.55-0.58 in the central part of the southeastern part (diapir area) and along the paleo-ridge axis running in the NW - SE direction [3,4]. On the other hand, the Cr# of spinel in the peripheral part is 0.41-0.55 indicating slightly less depleted than in the central part. In addition, the REE abundance of clinopyroxenes in the central part of the diapir area is lower than in the peripheral part being consistent with the distribution of spinel Cr#.

We consider that the upwelling rate in the southeastern part (diapir area) may have been greater than the peripheral part possibly due to higher temperature in the focused vertical mantle flow. This model is consistent with the distribution of the Cr# of spinel: the degree of melting was greater in the diapir area where Cr# of spinel are higher than the peripheral part. The strongly focused pipe-like model for axis location [3,5] is well fitted by our observations in this study.

The evolution of melt inclusions in podiform chromitite in Oman

*Yuan YAO[1], Eiichi TAKAZAWA[2,3], Oman Drilling Project Phase 2 Science Party

1. Graduate School of Sciences& Technology, Niigata University, Japan, 2. Department of Geology, Faculty of Science, Niigata University, Japan, 3. Research and Development Center for Ocean Drilling Science, JAMSTEC, Japan

Melt inclusions are tiny inclusions which trapped in the host magmatic minerals. After trapping, the host mineral can be considered as a closed and isolated system (Roedder, 1984). Thus, melt inclusions behave as time capsules, which record the liquid line of descent of magmatic systems (Frezzotti, 2001). Therefore, melt inclusions can provide important information of the primary melts (Kent, 2008).

We studied the melt inclusions in chromite from a chromitite deposit mine in the north of Maqsad and the core sample from the Oman drilling project phase 2. The silicate inclusions range in diameter from 5 μm to 200 μm, contain pargasite, tremolite, aspidolite, high Cr# (=Cr/[Cr+Al] atomic ratio) chromite, diopside, enstatite, forsterite, grossular, albite, titanite, pentlandite, apatite, chlorite, wollastonite and serpentine. We found the high Cr# chromite occurs as lining of the inclusion, moreover the daughter minerals precipitated in the high Cr# chromite lining. Those phenomenon can be explained by the crystallization of chromite on the wall of inclusion. In addition, this is the first report about the necking down of melt inclusion in chromitite. The necking down of inclusions is an originally large, liquid-filled inclusion divided into smaller inclusions. If the necking down happens after the phase change of inclusion, the compositions of smaller inclusions probably are inhomogeneity. Last year, we conducted the high temperature homogenized experiments, the result showed that the homogenized quenching glass are heterogeneous. We consider the inhomogeneity of inclusions perhaps caused by the necking down. Based above all, we suggest the composition of homogenized inclusion can not represent the parental melt.

To summarize, we suggest before analysis and experiment of inclusions in chromite, the origin and the evolution of inclusions should be carefully studied.

Melt/fluid - rock reaction inferred from the Wadi Tayin mantle section in the southern Oman ophiolite

*Keisuke ISHII[1], Eiichi TAKAZAWA[2], Akihiro kuriyama[2], Kyouka Someya[2], Yoshihiko Tamura[3]

1. Graduate School of Science and Technology, Niigata University, 2. Department of Geology, Faculty of Science, Niigata University , 3. R&D Center for Ocean Drilling Science, Japan Agency for Marine-Earth Science and Technology

We report the petrology and the mineral compositions of peridotites from the Wadi Tayin massif in the southern Oman ophiolite [1-3] to investigate the influence of arc related magmatism during oceanic thrusting of the ophiolite. Harzburgites, dunites and a small number of lherzolite were systematically corrected along wadis to cover the mantle section from the boundary between lower crust and uppermost mantle namely “Moho” to the basal thrust. Spinel Cr# [=Cr/(Cr+Al) atomic ratio] of harzburgite varies from 0.22 to 0.58 similar to the range in abyssal peridotites [4]. Moreover, it gradually increases from the basal part to the Moho indicating the compositional variation expected for the residual mantle column formed at a mid ocean ridge. On the other hand, the spinel Cr# of dunite often exceeds 0.6 in the NW-SE striking shear zone in the middle part of the study area. The chondrite-normalized rare earth element (REE) patterns of clinopyroxenes in peridotites from the shear zone show a linear pattern that monotonously decreases from heavy REE to light REE (LREE). Calculated melt compositions in equilibrium with these clinopyroxenes are equivalent with the V2 (Type2) lava reported in the northern Oman ophiolite [5-6].

The plots in Cr# of spinel versus Ce/Yb ratio of clinopyroxenes show a linear trend with a positive correlation. It indicates that the LREE enrichment of clinopyroxene is associated with an increase in the degree of melting. Clinopyroxenes in the dunite from the shear zone are most significantly enriched in LREE to middle REE and have REE abundances being in equilibrium with the V2 lava. We consider that harzburgites were suffered from a flux melting by infiltration of H2O-rich fluid producing V2 lava. Comparing to the results from the northern massifs the linear trend in the diagram of Cr# of spinel versus Ce/Yb ratio of clinopyroxenes in the southern massif is obviously shifted toward lower in Cr#. It suggests that the infiltration of H2O-rich fluid may have started at early stage of melting in the Wadi Tayin massif relative to the northern massifs.

Numerical simulations for reaction-induced fracture formation of layered gabbro during hydration process

*Kazuki Yoshida[1], Hiroyuki Shimizu[2], Noriyoshi Tsuchiya[1], Atsushi Okamoto[1], Phase 2 Science Party Oman Drilling Project[3]

1. Tohoku university, 2. Geotechnical Analysis Group, Advanced Analysis Department, Civil Engineering Design Division, Kajima Corporation, 3. Oman Drilling Project Phase 2 Science Party

Serpentinization of oceanic lithosphere is important for various geological processes, including magmatism and earthquake at subduction zone, and generation of hydrogen and hydrocarbon at seafloor. For understanding the extent of the water infiltration into mantle within the oceanic lithosphere, permeability of the lower crust is an important factor, since gabbro has low permeability at high confining pressure (Katayama et al., 2012). In natural olivine-bearing gabbro, serpentinization of olivine grains produced radial fractures within the plagioclase matrix, which can potentially enhance the permeability (Jamtveit et al., 2008). Based on the numerical simulations using discrete element method (DEM), Jamtveit et al. (2008) shows that fracture network is produced by the volume expansion of olivine grains during hydration. However, their model dos not treat the advective fluid flow explicitly, it is not clear how permeability evolves during such processes. In this study, inspired by the natural textures of olivine gabbro taken from CM1A-7A (Wazi Zeeb, Oman Drilling Project), we conducted the DEM simulation for understanding the feedback of the fluid flow –olivine hydration –fracturing to the layered gabbro, which consists of olivine-rich layer and olivine-poor layer alternately. In particular, we focus on the contrasting fracture patterns between olivine and plagioclase, the evolution and anisotropy of permeability produced by the reaction-induced fracturing within the layered gabbro.

We conducted the two-dimensional DEM model, and the details of the model follows Okamoto and Shimizu (2015) and Shimizu and Okamoto (2016). We consider a simple volume increasing hydration reaction ($A + H_2O \rightarrow B$; 50% volume increase), and the reaction rate is defined as a linear function of fluid pressure. In the model, advective fluid flow occurs through apertures between particles, in response to difference of fluid pressure of individual domains. The rock model is consist of reactive part (it can change from olivine to sperneitne) and non-reactive part (e.g., plagioclase and clnopyronene). The reaction rate constant and aperture width of matrix and fracture are defined based on the non-dimensional numbers based on Shimizu and Okamoto (2016).

Firstly, we conducted the simulations for the model in which a single olivine exists in non-reactive matrix. When fluid is supplied through matrix, hydration of olivine starts, which produces the mesh-like textures inside the olivine grain and radial cracks within the unreactive matrix, which is consistent with those observed in the gabbro sample from CM1A. Second, we conducted a case where several olivine grains exist in matrix. In this case, we found the formation of fracture network that connects among the olivine grains, and positive relationship between the reaction rate and permeability. Finally, we tested the case of the layered structure that consists of olivine-rich layer and olivine-absent layer, and that fluid flows in direction perpendicular to the layers. The results of the simulations reveals that the development of vertical fractures in both olivine-rich and non-reactive layers, whereas the horizontal fractures are only developed in the olivine-rich layers. These features of fracture orientation are consistent with the natural observations and indicate that he reaction-induced fracturing could significantly enhance the fluid infiltration through layered gabbro.

X-ray CT images of oceanic lithologies obtained on Oman Drilling Project drillcores during ChikyuOman 2017 and 2018

*Katsuyoshi Michibayashi[1], Peter B Kelemen[2], Margurette Godard[3], Eiichi TAKAZAWA[4], Damon A H Teagle[5], The Oman Drilling Project Science Party[6]

1. Department of Earth and Planetary Sciences, Nagoya University, 2. Columbia University, 3. Université Montpellier, 4. Niigata University, 5. Southampton University, 6. ICDP

The Oman Drilling Project (OmanDP) has drilled >3,200 meters of the Oman ophiolite during Phases 1 and 2 in Holes GT1A, GT2A, GT3A, BT1B, CM1A, CM2B, BA1B, BA3A and BA4A. All cores have been described on board D/V Chikyu during the summers of 2017 and 2018. X-ray computed tomography (X-ray CT) images were obtained on all cores as a routine part of the IODP measurement protocol onboard D/V Chikyu.

The X-ray CT scanner (Discovery CT 750HD, GE Medical Systems) scans and reconstructs an image of a 1.4 m section in 10 minutes and produces a series of scan images, each 0.625 mm thick. The X-ray source and detector are installed inside of the gantry opposite each other. The excitation voltage and current for X-ray tube are 140 kV and 100 mA, respectively. Core samples are scanned in the gantry with a scanning rate of 20 mm/sec. The distribution of attenuation values mapped to an individual slice comprises the raw data that are used for subsequent image processing. Successive two-dimensional (2D) slices of 512 x 512 pixels yield a representation of attenuation values in three-dimensional (3D) voxels of 512 x 512 by ~1600 in length. Data generated for each core consist of core-axis-normal planes (XY planes) of X-ray attenuation values with dimensions of 512 ×512 pixels in 9 cm ×9 cm cross-section, with a resolution of 0.176 mm/pixel.

As a consequence, we have >3,200 meters length of X-ray CT images from the dyke/gabbro transition zone to the gabbroic sequence to the mantle sequence to the basal thrust of the ophiolite. All X-ray CT images have been processed to match with individual photo images of the archive halves of the cores. The data are useful for assessing sample locations and quality. X-ray CT images can be used for 3D fabric analyses even after core has been cut in half and subsampled for other analyses.

Re-examination of the crystallization process of clinopyroxene oikocrysts in layered gabbros at Hess Deep Rift, EPR

*Akane Yasui[1], Takashi Hoshide[1]

1. Graduate School of International Resource Sciences, Akita University

In the Hess Deep Rift, located about 60km east of the East Pacific Rise, the lower crustal gabbros which have been formed at the fast-spreading ridge are exposed. In the IODP Exp. 345, primitive layered gabbros were collected from the lower crust as mainly three drill cores (U1415 I, J, P; Gillis et al., 2014). From the U1415J, unique gabbroic rocks (troctolites) with poikilitic clinopyroxenes (oikocrysts) including many small plagioclase laths have been found (Maeda and Kaise, 2015, Abstracts of the Geological Society of Japan).

Recently, on the origins of clinopyroxene-oikocryst-bearing gabbroic rocks, the different hypotheses have been proposed by Leuthold et al. (2018) and Maeda and Kaise (2015).
Leuthold et al. (2018) proposed that initial olivine gabbros had been partially molten by the intrusion of a primitive melt and then clinopyroxene oikocrysts had crystallized from clinopyroxene-rich basaltic melts formed by the mixing between the partial melt and the primitive magma.
On the other hands, Maeda and Kaise (2015) proposed that clinopyroxenes have first crystallized from a primitive magma and after molten by the encounter with another primitive magma they have continued to grow further and then, the clinopyroxene rim has simultaneously crystallized with matrix olivine and plagioclase. Several hypotheses other than those above (e.g.,Tegner et al., 1995; Nicolas and Boudier., 2011) have been also proposed for the origin of the clinopyroxene oikocrysts in gabbroic rocks. The question is still open to discussion.
Therefore, I re-examine the process of clinopyroxene-oikocryst formation through the textural observation and chemical analysis of the constituent minerals for 8 samples of clinopyroxene-oikocryst-bearing gabbros from 3R, 5R, 7G, 8R and 15G of the U1415J core collected at the IODP Exp. 345.

The matrix part is troctolite consisting mainly of olivine (about 0.5 mm - 2 mm in size, amoeboidal, Fo85~) and plagioclase (about 1 mm in size, An#77-82). Spherical to ellipsoidal clinopyroxene oikocrysts (5-10 mm in size, Mg#85 to 88) is distributed in the matrix troctolite. In addition, clinopyroxene oikocrysts exhibit the following characteristics:

(1) Clinopyroxene oikocrysts basically do not contain any olivine crystals. Rarely, they contain aggregates of plagioclase and olivine.
(2) Orthopyroxene rims (about 100 μm thick, film-like, Mg#85-87) are observed only in matrix olivines (Fo85~) near the rim of the clinopyroxene oikocryst. The olivine crystals rimmed by orthopyroxene are shrinked.
(3) The decreases in Al and Cr contents towards the plagioclase chadacrysts are observed in clinopyroxene oikocrysts.
(4) In the core of the clinopyroxene oikocrysts, we can find parts with Mg# higher than the values which can be in the Fe/Mg equilibrium with olivine in the matrix troctolite.

The facts of (1) and (2) indicate that the assemblage of olivine and plagioclase had already existed when the clinopyroxene oikocrysts crystallized from the melt. In additions, these facts suggest that the melt which formed clinopyroxene oikocryst was in a reaction relationship with olivine. These interpretations

©2019. Japan Geoscience Union. All Right Reserved.

are consistent with the hypothesis of Leuthold et al. (2018).

Structural petrology of peridotites from the Kalaymyo ophiolite

*Kouhei Asano[1,2], Katsuyoshi Michibayashi[1], Jung-Woo Park[3]

1. Graduate School of Environmental Studies, Nagoya University, 2. Shizuoka University, 3. Seoul National University

The Kalaymyo ophiolite is located at Myanmar. The Kalaymyo ophiolite includes large peridotite massifs, where peridotites are commonly well preserved. In recent years, petrologic and geochemical studies have been carried out on the Kalaymyo peridotites. These results suggest that the Kalaymyo peridotites have been undergone melt-rock interactions. In this study, we used fourteen samples from outcrops and drill cores, and carried out analyses of crystal preferred orientations (CPOs) of olivine and of major elements of olivine and spinel. The samples show coarse-grained equigranular textures. The mineral compositions in spinel Cr# and olivine Mg# plot in the field of OSMA (olivine-spinel mantle array) indicate that these samples represent residual upper mantle rocks after partial melting. Spinel grains with Cr# higher than 0.3 have relatively high TiO_2 contents (0.10-0.20 wt.%). Because Ti is incompatible element, high spinel TiO_2 content suggests that these peridotites have experienced melt-rock interaction. There is a positive correlation between J-index and spinel Cr# in the samples. The correlation also has two trends: high and low positive relationships between J-index and spinel Cr#, respectively. Samples experienced melt-rock interaction belong to the low positive trend. It suggests that melt percolation by melt-rock interaction could have an impact on deformation, in particular on CPO development. We propose that melt-rock interaction was synchronous with deformation. It is noted that peridotites experienced melt-rock interaction are intensely located on a narrow range with respect to the elevation, indicating that the occurrence of melt-rock interaction was localized within the Kalaymyo ophiolite.

Reevaluation of the origin of mafic layers in the Upper Zone of the Horoman Peridotite

*Yumeto KOGURE[1], Eiichi TAKAZAWA[1]

1. Department of Geology, Faculty of Science, Niigata University

Horoman peridotite is situated at the southern tip of the Hidaka mountain range, spreads 8 km east-west, 10 km north-south, and has a layer thickness of 3,000 m. We reevaluated the origin of the mafic layer in the Upper Zone of the Horoman Peridotite. We studied Fumo section in the Upper Zone. This section has total thickness of 263 m and consists of plagioclase lherzolite, harzburgite and mafic layer. In the Fumo section, the mafic layer is only interlayered in the plagioclase lherzolite. In the Al2O3, CaO, and Na2O vs. MgO diagrams of whole rock compositions, the mafic layer is plotted on the extension of the linear composition trend indicated by plagioclase lherzolite and harzburgite. There are two types of mafic layer, one plotted in the vicinity of N-MORB and the other plotted in the vicinity of plagioclase lherzolite. The plagioclase lherzolites which have higher Al2O3, CaO, and Na2O and lower MgO contents than the Depleted MORB Mantle (DMM) [1] contain amphiboles whereas the other plagioclase lherzolite which has lower Al2O3, CaO, and Na2O contents and higher MgO content than the DMM do not contain amphibole. Chondrite-normalized whole rock rare earth element (REE) patterns of plagioclase lherzolites are flat from heavy REE to middle REE and show convex upward pattern with depletion in light REE. The mafic layers also show the similar pattern although the abundances of REE is much lower than N-MORB.

From these results, the mafic layers in the Fumo section do not have the composition of primary melt and is considered to be cumulate [2,3]. Also, in the whole rock FeO, TiO2 vs. MgO diagrams, the compositional trends suddenly bend at the most fertile plagioclase lherzolite and becomes depleted in FeO, TiO2 toward the thin mafic layers. On the extension of this bent trends reach to the composition of Cpx and plagioclase. The mafic layer in the Fumo section suggests the possibility that Cpx and plagioclase were crystallized from a melt penetrated into plagioclase lherzolite in a relatively low pressure where the combination of Cpx and plagioclase was stable.

A structural and petrological study of "Shibukawa ultramafic body" in the Sanbagawa belt, western Shizuoka, Japan

*Hikaru Shioya[1,2], Katsuyoshi Michibayashi[1], Ken-ichi Hirauchi[2]

1. Graduate School of Environmental Studies, Nagoya University, 2. Institute of Geosciences, Shizuoka University

We studied an ultramafic body, which is named "Shibukawa ultramafic body" in this study, in the Sanbagawa belt located to the western Shizuoka, focusing on their primary mineral olivine to reveal its petrogenesis. Shibukawa ultramafic body is composed of dunites and wehlites, although the body was heavily weathered due to serpentinization. Yet, most of samples still contain olivine, spinel and a few amounts of clinopyroxene. The olivine crystal preferred orientations (CPOs) of this body were divided into two types: D type and single maxima type. The CPO intensities were relatively high in the north area, whereas those in the south area were relatively low. Considering the grain size distribution of olivine in the samples, the samples in the south area was weakly deformed as they preserve porphyroclastic olivine grains in the fine-grained matrix. In contrast, grain size reduction due to deformation has been completed in the north area. Olivine CPO patterns and major elements composition of both olivine and spinel indicate that the origin of this ultramafic body could be cumulate such as the Mikabu belt and is different from those of Shikoku mountains in the Sanbagawa belt.

[S-CG49] Hard-Rock Drilling Science: From Continental to Deep Sea Drilling, and Oman Project

convener:Katsuyoshi Michibayashi(Department of Earth and Planetary Sciences, Nagoya University), Eiichi TAKAZAWA(Department of Geology, Faculty of Science, Niigata University), Norikatsu Akizawa(Department of Ocean Floor Geoscience, Atmosphere and Ocean Research Institute, The University of Tokyo)

The Oman Drilling Project (OmDP) has completed to drill numerous hard-rock cores within ancient oceanic lithosphere and the underlying subduction zone of the Samail ophiolite in Oman, with support from ICDP, IODP, Japan Society for the Promotion of Science, the Sloan Foundation's Deep Carbon Observatory, US, and European research agencies. Moreover, a number of IODP expeditions have focused on hard-rock drilling over the last several years including Expedition 352 in 2014, which drilled the volcanic sequence associated with subduction initiation in the Bonin fore-arc, Expedition 357, which drilled the Lost City hydrothermal field, Expedition 360, which drilled the lithosphere associated with ultraslow-spreading at the Southwest Indian Ridge in 2016, and Expedition 366, which drilled the serpentinite seamounts in the Mariana fore-arc. In this session, we invite presentations on the scientific results of hard-rock drilling at these and other sites. We also invite related presentations on oceanic lithosphere, island arc formation, and any other significant issue that could be addressed by future hard-rock drilling. This includes marine studies of oceanic lithosphere and on-land geological investigations of ophiolites, accreted arcs, and subduction complexes. The session is intended to be interdisciplinary, including the fields of geophysics, geochemistry, petrology, engineering, and biology.

Permeability is a key property that controls heat and chemical exchange in the oceanic lithosphere as well as microbial activity in the sub-seafloor. Although direct measurements of permeability were not made on board D/V Chikyu during analysis of cores from the Oman Drilling Project, we estimated permeability profiles based on onboard measurements of electrical resistivity. For each core sample, we measure its resistivity at nominally dry conditions to obtain the dry resistivity. We then saturate the sample with NaCl solution (3.5g/L) and repeat the resistivity measurements at brine-saturated conditions to obtain the wet resistivity. Owing to the conductive brine in the pore space, the wet resistivity is systematically lower than dry resistivity. Because the difference between dry and wet resistivity is predominantly controlled by the movement of dissolved ions in the brine that occupied the pore space, we can use the resistivity data to infer the volume fraction of pores that contribute to electrical transport (termed “transport porosity”). We apply the Hashin-Shtrikman upper bound to estimate transport porosity. The estimated transport porosity shows a positive correlation with bulk porosity measured on board (MAD analysis), but is approximately one order of magnitude lower. Using an empirical cubic law between transport porosity and permeability, we produce estimated permeability profiles for the crust-mantle transition zone and the serpentinized mantle sections in the Hole CM1A, BA1B, BA3A and BA4A. The results indicate, (1) the gabbro sequence exhibits a markedly lower permeability than the underlying mantle sequence, (2) serpentinized dunites have higher permeability compared to serpentinized harzburgites, and (3) the general variation of discrete sample permeability is correlated with fault zone and intervals with abundant fractures. These permeability structures are most likely modified by alteration and juxtapositions, and do not represent the in-situ profile of the oceanic lithosphere; but this technique can be applicable to infer on-board permeability in future hard rock drilling.

Relationship between alteration intensity and elastic wave velocity of gabbroic rocks from ICDP Hole CM1A, Oman Drilling Project Phase II

*Kosuke Kimura[1], Ikuo Katayama[1], Kohei Hatakeyama[1], Yuya Akamatsu[1], Natsue Abe[2], Keishi Okazaki[2], The Oman Drilling Project Phase II Science Party

1. Hiroshima University, 2. JAMSTEC

The mafic to ultramafic rocks suffer metamorphism and metasomatism by the seafloor hydrothermal activities. These alterations can influence the elastic wave velocity due to the change of mineral assemblages during the ocean floor metamorphism. However, most previous studies have measured the elastic wave velocity of relatively unaltered samples. In this study, we measured elastic wave velocity of the altered gabbro from the Semail ophiolite collected from the Oman Drilling Project Phase II in order to estimate the effect of ocean floor metamorphism on the elastic wave velocity.

Gabbro samples were collected from CM1A site that is reported to be a layered gabbro sequence. Total seven samples those have different alteration intensity were measured. We use intra-vessel deformation and fluid flow apparatus at Hiroshima University to measure elastic wave velocity under confining pressure up to 200 MPa. Elastic wave velocity was measured by the pulse transmission method, with the amplitude and the frequency of a trigger wave of 5 V and 2 MHz, respectively. After measurements under dry condition, measurements under wet conditions injecting pore water were performed (P_P = 10 MPa). Alteration intensity is recognized by the relative abundances of the secondary minerals.

On the basis of the petrography, alteration group could be divided into four types. First type is almost fresh, olivine altered to serpentine and chlorite partially with less green minerals present. Second type has saussuritized plagioclase dominantly and also some sample shows alteration of clinopyroxene to amphibole. In the third type amphibolitization of clinopyroxene is dominant, and also saussuritization of plagioclase occur. Fourth type is the most altered sample showing alteration halo along the veins. Almost of the minerals are changed to prehnite except a few relict clinopyroxene. This type has higher porosity than other types.

Sample density ranges from 2.77-3.08 g/cm^3, and porosity ranges from 0.02-0.22% except ca. 1% from halo alteration sample. Data from these samples show a trend that elastic wave velocities (V_P and V_S) increase with increasing the confining pressure from 20 to 200 MPa. V_P increases from 5.68-6.80 to 6.16-6.91 km/s, V_S slightly increases from 3.65-3.97 to 3.69-3.99 km/s and V_P/V_S is almost constant ranging between 1.56-1.86 to 1.64-1.88 under dry condition, and on the other hand, V_P increases from 6.08-6.82 to 6.31-6.93 km/s, V_S slightly increases from 3.64-3.98 to 3.69-4.00 km/s and V_P/V_S is almost constant 1.67-1.86 to 1.68-1.87 under fluid-saturated condition, respectively. This result is mostly consistent with the layered gabbro occur in a normal oceanic crust (e.g. White et al., 1992; Shinohara et al., 2008).

At 200 MPa and under dry condition, V_P moderately decreases with increase in alteration intensity. About 0.75 km/s decreases in response to the increase in alteration intensity from 10 to 80 %. Comparing dV_P (difference in calculated and measured values) from the back-calculated original mineral assemblages of gabbro and peridotite reveled that the decrease in dV_P for the former is less than the latter. Moreover, both the curves of V_P and impedance change cross-over each other for gabbro and peridotite after nearly 50% of alteration.

©2019. Japan Geoscience Union. All Right Reserved.

From the above results, we suggest that if both gabbro and peridotite suffer more than 50% alteration, reversal of seismic velocity and impedance occurs, which effectively would affect the determination of geophysical Moho.

Physical property of the fossilized crust-mantle transition zone from ICDP Oman Drilling Project Hole CM1A and CM2B measured onboard D/V Chikyu

*Keishi Okazaki[1], Natsue Abe[1], Kohei Hatakeyama[2], Yuya Akamatsu[2], Ikuo Katayama[2], Eiichi TAKAZAWA[3], Damon A H Teagle[4], Peter B Kelemen[5], Jude Coggon[4], The Oman Drilling Project Phase 2 Science Party

1. Japan Agency for Marine-Earth Science and Technology, 2. Hiroshima University, 3. Niigata University, 4. University of Southampton, 5. Columbia University

To understand physical properties of the oceanic crust and the mantle is fundamentally important to reveal the dynamics of plate tectonics, and the global circulations of H_2O and CO_2 fluids. We report results on physical property measurements of core samples from Oman Drilling Project (OmanDP) Holes CM1A and CM2B, which drilled from the lower igneous crust into the upper mantle in the Samail Ophiolite, Sultanate of Oman.

X-ray CT, bulk/grain density, porosity, magnetic susceptibility, P-wave velocity, electrical resistivity and thermal conductivity were measured onboard D/V Chikyu using whole-round cores and discrete samples for core sections from CM1A and CM2B.

The paleo-Moho in CM1A may not preserve the original structure due to minor faulting, possibly during obduction. The gabbro-dunite transition (paleo-Moho) in Hole CM1A is characterized by a sharp change in physical property data. For example, P-wave velocity decreases from ~6.7 km/s in the layered gabbro sequence to ~4.9 km/s in the MTZ. Low P-wave velocity and density (~2.6 g/cm^3) in serpentinized dunites reflect the fact that olivine in the dunites is almost completely serpentinized. Serpentinization could have occurred during hydrothermal alteration near the spreading ridge axis, during subduction of 100’s of km of oceanic crust and sediment beneath the ophiolite, during obduction onto the Arabian continental margin, and/or during present-day weathering. In contrast to the paleo-Moho, the boundary between the Crust-Mantle Transition (CMT) sequences (i.e., dunites and dunites with gabbro lenses) and the underlying, residual mantle harzburgites is somewhat gradual. P-wave velocity gradually increases from ~4.9 km/s for dunite in the CMT to ~5.5 km/s for harzburgite in the mantle sequence. The thickness of the CMT is 50–70 m in Holes CM1A and CM2B. We also report on correlations between physical properties, especially electrical conductivity and magnetic susceptibility, and the fault intensity and alteration intensity from the core descriptions.

Microstructures of lower crust gabbros from the Oman Ophiolite: Analyses of the drilled cores of the Oman Drilling Project

*Koki Iida[1], Takahiro Fudai[1], Susumu Umino[1], Yuki Kusano[2]

1. Kanazawa University, 2. Geological Survey of Japan

Oman Drilling Project in 2016 to 2017 recovered 400 m long cores of layered gabbros at Site GT1 in the Wadi Tayin Massif of the Oman Ophiolilte. The purpose of this research is to describe microstructures of the layered gabbro core samples and to discuss the conditions of magmatic and hypersolidus deformation that operated in the lower crust beneath the Oman paleoridge.

Core samples were cut into slabs parallel to foliation and slabs normal to foliation and parallel to lineation, which were made into thin sections for microscopic observations. Structural fabrics and the relationships between crystal shapes and alliginment were described to identify magmatic and hypersolidus deformation structures.

Cored samples are predominantly olivine gabbros consisting of anhedral olivine, anhedral to subhedral clinopyroxene and subhedral to euhedral plagioclase. Grain size ranges from 0.5 mm to a few millimeters irrespective of mineral species.

The structures shown by the gabbros are classified into three regimes by temperature or the amount of melt present: Regime I, magmatic conditions without or minimal plastic deformation; regime Ⅱ, plastic deformation assisted by interstitial melt (Dunn, 2000); regime Ⅲ, near solidus deformation. Regime Ⅱ is identified by ameboid grain boundaries with no intracrystalline deformation and equigranular textures, resulted from decreasing internal strain energy by at high temperatures. The presence of melt is evidenced by the clear euhedral plagioclase rims with resorbed turbid cores as discussed below.

Regime I. Magmatic structures are identified as modal layering due to changes in mineral mode, no preferred orientation or shape-preferred orientation of clinopyroxene and plagioclase, poikilitic texture of olivine enclosing plagioclase laths and ophitic texture of clinopyroxene including plagioclase laths.

Regime II. The hypersolidus deformation structures overprint igneous structures: ameboid olivine with or without strain in the crystal, elongated olivine, and lenticular aggregates of olivine grains with an asymmetric quarter structure. Single clinopyroxene crystals show an asymmetric quarter structure like olivine aggregates. Ophitic clinopyroxenes consist of subgrains with slightly different orientations <10˚. Plagioclase shows deformation twin and undulose extinction. Equigranular fine-grained plagioclase with grain boundaries intersecting at 120˚ are common. Large plagioclases have a resorbed core with a wavy outline and are surrounded by euhedral rim.

Regime III. Subsolidus recrystallization includes buldging and grain boundary migration resulted in ameoboid grain boundaries of clinopyroxene. Undulose extinction and kinked twinning of plagioclase are observed.

It is well known that mid-ocean ridge basalt magma commonly crystallizes in the order of olivine, plagioclase and clinopyroxene, which is also true for the gabbros of the Oman Ophiolite (Adachi and Miyashita, 2003). Nevertheless, only plagioclase shows euhedral to subhedral shapes in the observed

©2019. Japan Geoscience Union. All Right Reserved.

layered gabbro core samples. Deformed olivine aggregates and clinopyroxene with quarter structures are embedded in plagioclase with equilibrium granoblastic textures and large euhedral plagioclases with resorbed turbid cores. Considering these textures combined with the mechanical strength of the three constituent minerals, these gabbros suffered deformation under the presence of melt, which assisted complete recovery of strain through recrystallization of fine-grained plagioclase and overgrowth of euhedral rims around magmatic plagioclase cores. Poikilitic olivine occurs through the hole, whereas ophitic Cpx occurs at 73 m and 220 m in depth. Most deformation structures of regime II are present irrespective to depth. The asymmetric structures of olivine and clinopyroxene were used to determine the relative sense of shear. Both dextral and sinistral sense of shear are observed within the same samples.

Olivine fabric and mineral compositions in the Maqsad area of the Samail massif, the southern Oman ophiolite

*Kaho Takahashi[1], Eiichi TAKAZAWA[2,3], Katsuyoshi Michibayashi[4], Kakihata Yuki[4], Ryoko Senda[5]

1. Graduate School of Science and Technology, Niigata University, 2. Department of Geology, Faculty of Science, Niigata University, 3. JAMSTEC, 4. Nagoya University, 5. Kyushu University

In this study, we conducted structural and chemical analysis of oriented samples of 17 harzburgites and 4 dunites collected from the Maqsad area of Samail massif in the southern Oman ophiolite. We investigated the degree of partial melting and the mantle-melt reaction with relation to mantle diapir structure.

The crystallographic preferred orientation (CPO) of olivine grains were measured in highly polished XZ thin sections using a scanning electron microscope equipped with an electron-back scatter diffraction system at Shizuoka University. After plotting the results in the Vp Flinn plot expanded for olivine fabric types [1,2], the fabric type of peridotites in this study are summarized as follows. The distribution of A type is limited in the southeastern part where the diapir structure has been identified [3], whereas D type is dominant in the peripheral part of the diapir. Minor amounts of AG type and E type are also observed in the peripheral part. From these, the olivine in the southeastern part (diapir area) of this study area is likely to have been deformed under high temperature whereas the peripheral part was deformed at slightly lower temperature. The CPOs of olivine in both areas do not show any influence from the presence of H2O except for only one sample with E type CPO. Moreover, strong alignment of [100] to the vertical orientation was observed in the southeastern part (diapir area) of this study area. Since vertical mantle flow has been estimated in this diapir area, our results are consistent with the previous study [3,4].

The Cr# (=Cr/[Cr+Al] atomic ratio) of spinel in the harzburgites and dunites are as high as 0.55-0.58 in the central part of the southeastern part (diapir area) and along the paleo-ridge axis running in the NW - SE direction [3,4]. On the other hand, the Cr# of spinel in the peripheral part is 0.41-0.55 indicating slightly less depleted than in the central part. In addition, the REE abundance of clinopyroxenes in the central part of the diapir area is lower than in the peripheral part being consistent with the distribution of spinel Cr#.

We consider that the upwelling rate in the southeastern part (diapir area) may have been greater than the peripheral part possibly due to higher temperature in the focused vertical mantle flow. This model is consistent with the distribution of the Cr# of spinel: the degree of melting was greater in the diapir area where Cr# of spinel are higher than the peripheral part. The strongly focused pipe-like model for axis location [3,5] is well fitted by our observations in this study.

The evolution of melt inclusions in podiform chromitite in Oman

*Yuan YAO[1], Eiichi TAKAZAWA[2,3], Oman Drilling Project Phase 2 Science Party

1. Graduate School of Sciences& Technology, Niigata University, Japan, 2. Department of Geology, Faculty of Science, Niigata University, Japan, 3. Research and Development Center for Ocean Drilling Science, JAMSTEC, Japan

Melt inclusions are tiny inclusions which trapped in the host magmatic minerals. After trapping, the host mineral can be considered as a closed and isolated system (Roedder, 1984). Thus, melt inclusions behave as time capsules, which record the liquid line of descent of magmatic systems (Frezzotti, 2001). Therefore, melt inclusions can provide important information of the primary melts (Kent, 2008).

We studied the melt inclusions in chromite from a chromitite deposit mine in the north of Maqsad and the core sample from the Oman drilling project phase 2. The silicate inclusions range in diameter from 5 μm to 200 μm, contain pargasite, tremolite, aspidolite, high Cr# (=Cr/[Cr+Al] atomic ratio) chromite, diopside, enstatite, forsterite, grossular, albite, titanite, pentlandite, apatite, chlorite, wollastonite and serpentine. We found the high Cr# chromite occurs as lining of the inclusion, moreover the daughter minerals precipitated in the high Cr# chromite lining. Those phenomenon can be explained by the crystallization of chromite on the wall of inclusion. In addition, this is the first report about the necking down of melt inclusion in chromitite. The necking down of inclusions is an originally large, liquid-filled inclusion divided into smaller inclusions. If the necking down happens after the phase change of inclusion, the compositions of smaller inclusions probably are inhomogeneity. Last year, we conducted the high temperature homogenized experiments, the result showed that the homogenized quenching glass are heterogeneous. We consider the inhomogeneity of inclusions perhaps caused by the necking down. Based above all, we suggest the composition of homogenized inclusion can not represent the parental melt.

To summarize, we suggest before analysis and experiment of inclusions in chromite, the origin and the evolution of inclusions should be carefully studied.

Melt/fluid - rock reaction inferred from the Wadi Tayin mantle section in the southern Oman ophiolite

*Keisuke ISHII[1], Eiichi TAKAZAWA[2], Akihiro kuriyama[2], Kyouka Someya[2], Yoshihiko Tamura[3]

1. Graduate School of Science and Technology, Niigata University, 2. Department of Geology, Faculty of Science, Niigata University , 3. R&D Center for Ocean Drilling Science, Japan Agency for Marine-Earth Science and Technology

We report the petrology and the mineral compositions of peridotites from the Wadi Tayin massif in the southern Oman ophiolite [1-3] to investigate the influence of arc related magmatism during oceanic thrusting of the ophiolite. Harzburgites, dunites and a small number of lherzolite were systematically corrected along wadis to cover the mantle section from the boundary between lower crust and uppermost mantle namely “Moho” to the basal thrust. Spinel Cr# [=Cr/(Cr+Al) atomic ratio] of harzburgite varies from 0.22 to 0.58 similar to the range in abyssal peridotites [4]. Moreover, it gradually increases from the basal part to the Moho indicating the compositional variation expected for the residual mantle column formed at a mid ocean ridge. On the other hand, the spinel Cr# of dunite often exceeds 0.6 in the NW-SE striking shear zone in the middle part of the study area. The chondrite-normalized rare earth element (REE) patterns of clinopyroxenes in peridotites from the shear zone show a linear pattern that monotonously decreases from heavy REE to light REE (LREE). Calculated melt compositions in equilibrium with these clinopyroxenes are equivalent with the V2 (Type2) lava reported in the northern Oman ophiolite [5-6].

The plots in Cr# of spinel versus Ce/Yb ratio of clinopyroxenes show a linear trend with a positive correlation. It indicates that the LREE enrichment of clinopyroxene is associated with an increase in the degree of melting. Clinopyroxenes in the dunite from the shear zone are most significantly enriched in LREE to middle REE and have REE abundances being in equilibrium with the V2 lava. We consider that harzburgites were suffered from a flux melting by infiltration of H2O-rich fluid producing V2 lava. Comparing to the results from the northern massifs the linear trend in the diagram of Cr# of spinel versus Ce/Yb ratio of clinopyroxenes in the southern massif is obviously shifted toward lower in Cr#. It suggests that the infiltration of H2O-rich fluid may have started at early stage of melting in the Wadi Tayin massif relative to the northern massifs.

Numerical simulations for reaction-induced fracture formation of layered gabbro during hydration process

*Kazuki Yoshida[1], Hiroyuki Shimizu[2], Noriyoshi Tsuchiya[1], Atsushi Okamoto[1], Phase 2 Science Party Oman Drilling Project[3]

1. Tohoku university, 2. Geotechnical Analysis Group, Advanced Analysis Department, Civil Engineering Design Division, Kajima Corporation, 3. Oman Drilling Project Phase 2 Science Party

Serpentinization of oceanic lithosphere is important for various geological processes, including magmatism and earthquake at subduction zone, and generation of hydrogen and hydrocarbon at seafloor. For understanding the extent of the water infiltration into mantle within the oceanic lithosphere, permeability of the lower crust is an important factor, since gabbro has low permeability at high confining pressure (Katayama et al., 2012). In natural olivine-bearing gabbro, serpentinization of olivine grains produced radial fractures within the plagioclase matrix, which can potentially enhance the permeability (Jamtveit et al., 2008). Based on the numerical simulations using discrete element method (DEM), Jamtveit et al. (2008) shows that fracture network is produced by the volume expansion of olivine grains during hydration. However, their model dos not treat the advective fluid flow explicitly, it is not clear how permeability evolves during such processes. In this study, inspired by the natural textures of olivine gabbro taken from CM1A-7A (Wazi Zeeb, Oman Drilling Project), we conducted the DEM simulation for understanding the feedback of the fluid flow –olivine hydration –fracturing to the layered gabbro, which consists of olivine-rich layer and olivine-poor layer alternately. In particular, we focus on the contrasting fracture patterns between olivine and plagioclase, the evolution and anisotropy of permeability produced by the reaction-induced fracturing within the layered gabbro.

We conducted the two-dimensional DEM model, and the details of the model follows Okamoto and Shimizu (2015) and Shimizu and Okamoto (2016). We consider a simple volume increasing hydration reaction ($A + H_2O \rightarrow B$; 50% volume increase), and the reaction rate is defined as a linear function of fluid pressure. In the model, advective fluid flow occurs through apertures between particles, in response to difference of fluid pressure of individual domains. The rock model is consist of reactive part (it can change from olivine to sperneitne) and non-reactive part (e.g., plagioclase and clnopyronene). The reaction rate constant and aperture width of matrix and fracture are defined based on the non-dimensional numbers based on Shimizu and Okamoto (2016).

Firstly, we conducted the simulations for the model in which a single olivine exists in non-reactive matrix. When fluid is supplied through matrix, hydration of olivine starts, which produces the mesh-like textures inside the olivine grain and radial cracks within the unreactive matrix, which is consistent with those observed in the gabbro sample from CM1A. Second, we conducted a case where several olivine grains exist in matrix. In this case, we found the formation of fracture network that connects among the olivine grains, and positive relationship between the reaction rate and permeability. Finally, we tested the case of the layered structure that consists of olivine-rich layer and olivine-absent layer, and that fluid flows in direction perpendicular to the layers. The results of the simulations reveals that the development of vertical fractures in both olivine-rich and non-reactive layers, whereas the horizontal fractures are only developed in the olivine-rich layers. These features of fracture orientation are consistent with the natural observations and indicate that he reaction-induced fracturing could significantly enhance the fluid infiltration through layered gabbro.

X-ray CT images of oceanic lithologies obtained on Oman Drilling Project drillcores during ChikyuOman 2017 and 2018

*Katsuyoshi Michibayashi[1], Peter B Kelemen[2], Margurette Godard[3], Eiichi TAKAZAWA[4], Damon A H Teagle[5], The Oman Drilling Project Science Party[6]

1. Department of Earth and Planetary Sciences, Nagoya University, 2. Columbia University, 3. Université Montpellier, 4. Niigata University, 5. Southampton University, 6. ICDP

The Oman Drilling Project (OmanDP) has drilled >3,200 meters of the Oman ophiolite during Phases 1 and 2 in Holes GT1A, GT2A, GT3A, BT1B, CM1A, CM2B, BA1B, BA3A and BA4A. All cores have been described on board D/V Chikyu during the summers of 2017 and 2018. X-ray computed tomography (X-ray CT) images were obtained on all cores as a routine part of the IODP measurement protocol onboard D/V Chikyu.

The X-ray CT scanner (Discovery CT 750HD, GE Medical Systems) scans and reconstructs an image of a 1.4 m section in 10 minutes and produces a series of scan images, each 0.625 mm thick. The X-ray source and detector are installed inside of the gantry opposite each other. The excitation voltage and current for X-ray tube are 140 kV and 100 mA, respectively. Core samples are scanned in the gantry with a scanning rate of 20 mm/sec. The distribution of attenuation values mapped to an individual slice comprises the raw data that are used for subsequent image processing. Successive two-dimensional (2D) slices of 512 x 512 pixels yield a representation of attenuation values in three-dimensional (3D) voxels of 512 x 512 by ~1600 in length. Data generated for each core consist of core-axis-normal planes (XY planes) of X-ray attenuation values with dimensions of 512 ×512 pixels in 9 cm ×9 cm cross-section, with a resolution of 0.176 mm/pixel.

As a consequence, we have >3,200 meters length of X-ray CT images from the dyke/gabbro transition zone to the gabbroic sequence to the mantle sequence to the basal thrust of the ophiolite. All X-ray CT images have been processed to match with individual photo images of the archive halves of the cores. The data are useful for assessing sample locations and quality. X-ray CT images can be used for 3D fabric analyses even after core has been cut in half and subsampled for other analyses.

In the Hess Deep Rift, located about 60km east of the East Pacific Rise, the lower crustal gabbros which have been formed at the fast-spreading ridge are exposed. In the IODP Exp. 345, primitive layered gabbros were collected from the lower crust as mainly three drill cores (U1415 I, J, P; Gillis et al., 2014). From the U1415J, unique gabbroic rocks (troctolites) with poikilitic clinopyroxenes (oikocrysts) including many small plagioclase laths have been found (Maeda and Kaise, 2015, Abstracts of the Geological Society of Japan).

Recently, on the origins of clinopyroxene-oikocryst-bearing gabbroic rocks, the different hypotheses have been proposed by Leuthold et al. (2018) and Maeda and Kaise (2015).
Leuthold et al. (2018) proposed that initial olivine gabbros had been partially molten by the intrusion of a primitive melt and then clinopyroxene oikocrysts had crystallized from clinopyroxene-rich basaltic melts formed by the mixing between the partial melt and the primitive magma.
On the other hands, Maeda and Kaise (2015) proposed that clinopyroxenes have first crystallized from a primitive magma and after molten by the encounter with another primitive magma they have continued to grow further and then, the clinopyroxene rim has simultaneously crystallized with matrix olivine and plagioclase. Several hypotheses other than those above (e.g.,Tegner et al., 1995; Nicolas and Boudier., 2011) have been also proposed for the origin of the clinopyroxene oikocrysts in gabbroic rocks. The question is still open to discussion.
Therefore, I re-examine the process of clinopyroxene-oikocryst formation through the textural observation and chemical analysis of the constituent minerals for 8 samples of clinopyroxene-oikocryst-bearing gabbros from 3R, 5R, 7G, 8R and 15G of the U1415J core collected at the IODP Exp. 345.

The matrix part is troctolite consisting mainly of olivine (about 0.5 mm - 2 mm in size, amoeboidal, Fo85~) and plagioclase (about 1 mm in size, An#77-82). Spherical to ellipsoidal clinopyroxene oikocrysts (5-10 mm in size, Mg#85 to 88) is distributed in the matrix troctolite. In addition, clinopyroxene oikocrysts exhibit the following characteristics:

(1) Clinopyroxene oikocrysts basically do not contain any olivine crystals. Rarely, they contain aggregates of plagioclase and olivine.
(2) Orthopyroxene rims (about 100 μm thick, film-like, Mg#85-87) are observed only in matrix olivines (Fo85~) near the rim of the clinopyroxene oikocryst. The olivine crystals rimmed by orthopyroxene are shrinked.
(3) The decreases in Al and Cr contents towards the plagioclase chadacrysts are observed in clinopyroxene oikocrysts.
(4) In the core of the clinopyroxene oikocrysts, we can find parts with Mg# higher than the values which can be in the Fe/Mg equilibrium with olivine in the matrix troctolite.

The facts of (1) and (2) indicate that the assemblage of olivine and plagioclase had already existed when the clinopyroxene oikocrysts crystallized from the melt. In additions, these facts suggest that the melt which formed clinopyroxene oikocryst was in a reaction relationship with olivine. These interpretations

are consistent with the hypothesis of Leuthold et al. (2018).

Structural petrology of peridotites from the Kalaymyo ophiolite

*Kouhei Asano[1,2], Katsuyoshi Michibayashi[1], Jung-Woo Park[3]

1. Graduate School of Environmental Studies, Nagoya University, 2. Shizuoka University, 3. Seoul National University

The Kalaymyo ophiolite is located at Myanmar. The Kalaymyo ophiolite includes large peridotite massifs, where peridotites are commonly well preserved. In recent years, petrologic and geochemical studies have been carried out on the Kalaymyo peridotites. These results suggest that the Kalaymyo peridotites have been undergone melt-rock interactions. In this study, we used fourteen samples from outcrops and drill cores, and carried out analyses of crystal preferred orientations (CPOs) of olivine and of major elements of olivine and spinel. The samples show coarse-grained equigranular textures. The mineral compositions in spinel Cr# and olivine Mg# plot in the field of OSMA (olivine-spinel mantle array) indicate that these samples represent residual upper mantle rocks after partial melting. Spinel grains with Cr# higher than 0.3 have relatively high TiO_2 contents (0.10-0.20 wt.%). Because Ti is incompatible element, high spinel TiO_2 content suggests that these peridotites have experienced melt-rock interaction. There is a positive correlation between J-index and spinel Cr# in the samples. The correlation also has two trends: high and low positive relationships between J-index and spinel Cr#, respectively. Samples experienced melt-rock interaction belong to the low positive trend. It suggests that melt percolation by melt-rock interaction could have an impact on deformation, in particular on CPO development. We propose that melt-rock interaction was synchronous with deformation. It is noted that peridotites experienced melt-rock interaction are intensely located on a narrow range with respect to the elevation, indicating that the occurrence of melt-rock interaction was localized within the Kalaymyo ophiolite.

Keywords: Kalaymyo ophiolite, peridotite, melt-rock interaction, J-index

Reevaluation of the origin of mafic layers in the Upper Zone of the Horoman Peridotite

*Yumeto KOGURE[1], Eiichi TAKAZAWA[1]

1. Department of Geology, Faculty of Science, Niigata University

Horoman peridotite is situated at the southern tip of the Hidaka mountain range, spreads 8 km east-west, 10 km north-south, and has a layer thickness of 3,000 m. We reevaluated the origin of the mafic layer in the Upper Zone of the Horoman Peridotite. We studied Fumo section in the Upper Zone. This section has total thickness of 263 m and consists of plagioclase lherzolite, harzburgite and mafic layer. In the Fumo section, the mafic layer is only interlayered in the plagioclase lherzolite. In the Al2O3, CaO, and Na2O vs. MgO diagrams of whole rock compositions, the mafic layer is plotted on the extension of the linear composition trend indicated by plagioclase lherzolite and harzburgite. There are two types of mafic layer, one plotted in the vicinity of N-MORB and the other plotted in the vicinity of plagioclase lherzolite. The plagioclase lherzolites which have higher Al2O3, CaO, and Na2O and lower MgO contents than the Depleted MORB Mantle (DMM) [1] contain amphiboles whereas the other plagioclase lherzolite which has lower Al2O3, CaO, and Na2O contents and higher MgO content than the DMM do not contain amphibole. Chondrite-normalized whole rock rare earth element (REE) patterns of plagioclase lherzolites are flat from heavy REE to middle REE and show convex upward pattern with depletion in light REE. The mafic layers also show the similar pattern although the abundances of REE is much lower than N-MORB.

From these results, the mafic layers in the Fumo section do not have the composition of primary melt and is considered to be cumulate [2,3]. Also, in the whole rock FeO, TiO2 vs. MgO diagrams, the compositional trends suddenly bend at the most fertile plagioclase lherzolite and becomes depleted in FeO, TiO2 toward the thin mafic layers. On the extension of this bent trends reach to the composition of Cpx and plagioclase. The mafic layer in the Fumo section suggests the possibility that Cpx and plagioclase were crystallized from a melt penetrated into plagioclase lherzolite in a relatively low pressure where the combination of Cpx and plagioclase was stable.

A structural and petrological study of "Shibukawa ultramafic body" in the Sanbagawa belt, western Shizuoka, Japan

*Hikaru Shioya[1,2], Katsuyoshi Michibayashi[1], Ken-ichi Hirauchi[2]

1. Graduate School of Environmental Studies, Nagoya University, 2. Institute of Geosciences, Shizuoka University

We studied an ultramafic body, which is named "Shibukawa ultramafic body" in this study, in the Sanbagawa belt located to the western Shizuoka, focusing on their primary mineral olivine to reveal its petrogenesis. Shibukawa ultramafic body is composed of dunites and wehlites, although the body was heavily weathered due to serpentinization. Yet, most of samples still contain olivine, spinel and a few amounts of clinopyroxene. The olivine crystal preferred orientations (CPOs) of this body were divided into two types: D type and single maxima type. The CPO intensities were relatively high in the north area, whereas those in the south area were relatively low. Considering the grain size distribution of olivine in the samples, the samples in the south area was weakly deformed as they preserve porphyroclastic olivine grains in the fine-grained matrix. In contrast, grain size reduction due to deformation has been completed in the north area. Olivine CPO patterns and major elements composition of both olivine and spinel indicate that the origin of this ultramafic body could be cumulate such as the Mikabu belt and is different from those of Shikoku mountains in the Sanbagawa belt.

Rheology of granular materials near the jamming transition under oscillatory shear

*Michio Otsuki[1], Hisao Hayakawa[2]

1. Graduate School of Engineering Science, Osaka University, 2. Yukawa Institute for Theoretical Physics, Kyoto University

Amorphous materials consisting of repulsive and dissipative particles such as granular materials, colloidal suspensions, foams, and emulsions behave like liquids below a critical value of the packing fraction, while they behave like solids above that value. This sudden change is known as a jamming transition [1]. In this talk, we present our recent numerical results on the rheological properties of granular materials near the jamming transition under oscillatory shear. It is confirmed that the shear modulus depends on the amplitude of the initial oscillatory shear before the measurement [2]. Even at densities below the transition point, where isotropic jamming occurs without shear, the initial oscillatory shear can induce the finite shear modulus. This behavior is consistent with a transition known as shear jamming. We also discuss the yielding transition above the jamming point under sufficiently large strain.

The real-scale numerical sandbox experiments for understanding stress state in accretionary prisms

*Mikito Furuichi[1], Arthur Bauville[1], Daisuke Nishiura[1], Takane Hori[1], Osamu Kuwano[1]

1. Japan Agency for Marine-Earth Science and Technology

The sandbox experiment is known as a scaled physical analog model of accretionary prisms. Thus, understanding the stress state inside the sand layer is the interesting challenge of the geology. However, measuring stress states in laboratory sandbox experiments is still practically infeasible. Here we performed real-scale numerical sandbox experiments using the Discrete Element Method (DEM) to understand the 3D stress state in the accretionary prism. The critical bottleneck of DEM was the limited number of particles acceptable for practical computation time and it was difficult to simulate a system with a huge number of particles required by such as our target sandbox test with realistic particle size. We had overcome this issue by developing the dynamic load balancing technique for the DEM codes and run the real-scale numerical sandbox simulation using up to 2.4 billion particles [Furuichi et.al. 2017]. We also performed the large-scale stress chain analysis. One of the interesting findings was that the simulation of the horizontal shortening of the granular layer showed undulated margins similar to those observed in accretionary prism, despite the nearly uniform initial conditions. The 3D stress chain analysis that is practically infeasible for the laboratory experiment studies, revealed that arcuate faults emerge from micro-scale perturbations owing to the formation of the stress arch [Furuichi et.al. 2018]. Furthermore, analyses demonstrate that the in-situ stress orientation from borehole data can be a signal of either the regional direction of plate convergence or the local stress orientation associated with such a stress arch. The results may greatly enhance the outcome of long-term monitoring in areas, such as the Nankai Trough. In this contribution, we also investigated the stress state associated with a seamount (indenter) entering the accretionary prisms. The role of indenter was significant as a frictional heterogeneity to control the tomography (taper angle), material transport and stress chain distribution. Especially, amount of sediment covering the indenter was transported inward without deformation. This mechanism potentially constructs the thick low-velocity zone into the plate boundary, the subduction channel. In this presentation, we discuss the detail mechanism of these observed compressional events inside the sand layers.

Numerical analysis on the fracture of Maxwell fluid by phase field models

*Masaharu Kameda[1], Keita Yamanishi[1], Akinori Yamanaka[1], Mie Ichihara[2]

1. Department of Mechanical Systems Engineering, Tokyo University of Agriculture and Technology, 2. Earthquake Research Institute, The University of Tokyo

Brittle fragmentation of vesicular magma is a key process in explosive eruption. Recent estimation on the decompression time in real explosive events indicates that the style of fragmentation is to be “brittle-like fragmentation” (Kameda et al. JVGR 2013). The solid-like fracture of the material occurs even if the bulk rheological properties is close to fluid state. We also found the fact that the spatial inhomogeneity of bubble distribution is a major source of crack development that lead to brittle-like fragmentation (Kameda et al. Sci. Rep. 2017).

In order to model our findings by numerical approach, we propose a continuum description of fracture in viscoelastic fluid using the phase field fracture model developed by Kuhn et al. (Comput. Mat. Sci. 2015). The phase-field modes with sharp interfaces consist in incorporating a continuous field variable so-called “order parameter,” by which the magma and the bubbles (or the cracks) are distinguished. The evolution of fracture is obtained implicitly by solving the coupled mathematical models formed by the phase field fracture model and the dynamics of the material. A commercial multiphysics solver (COMSOL) is used as the platform of numerical simulation. The phase field fracture model is solved using PDE solver of COMSOL. The dynamics of the material is calculated using conventional finite element analysis (FEM) prepared in the solver, in which the rheology of unbroken magma is assumed to be a linear Maxwell fluid.

First, we simulated crack propagation in a two-dimensional notched plate in a tensile test at a constant extension rate. We obtained the extension of crack with a sharp tip in pure elastic body (Fig. 1(a)) or viscoelastic body with sufficiently high viscosity (Fig. 1(b)). On the contrary, in the viscoelastic liquid with moderate viscosity the blunted tip occurs after the crack extension starts (Fig. 1(c)). Subsequently, the crack propagates again due to further extension.

Second, we simulated crack initiation and propagation in a porous material, which is a sphere including a large bubble at the center. Additionally, we placed two satellite bubbles nearby the large bubble. The pressure at the outer surface of the material was reduced to generate the non-uniform stress field in the material. As a result, the plane crack was generated between the satellite bubbles. The crack reached outer boundary, then a sharp crack was opened. The computed time scale in the crack propagation was equivalent to the scale observed in the experiment (Kameda et al. Sci. Rep. 2017). This time scale is much smaller than the scale simulated with another phase field fracture model proposed by Karma et al. (Phys. Rev. Lett. 2001).

Diagenesis- and earthquake-driven transformations of carbonaceous materials and their implication for frictional strength and earthquake rupture dynamics in carbon-bearing plate-subduction faults

*Shunya Kaneki[1], Tetsuro Hirono[1]

1. Graduate School of Science, Osaka University

Various physicochemical reactions on fault-forming materials, such as illitization of smectite and crystallization of amorphous silica, have been suggested as possible controls on frictional strength of rocks and thus on earthquake dynamics in plate-subduction zones. Carbonaceous material is one of the universal materials that exist in and around both active plate-boundary and inland faults, and previous studies suggest that transformation of carbonaceous material may affect its frictional strength during frictional slip. However, there is currently no systematic study attempting to investigate the relationship of maturity of carbonaceous material to its frictional strength, and thus how diagenesis- and earthquake-driven transformations of carbonaceous material can affect frictional strength and rupture dynamics of carbon-bearing faults, still remains unknown. We conducted high-velocity friction experiments together with elemental analysis, transmission electron microscope observation, X-ray diffraction analysis, and infrared and Raman spectroscopies, on four grades of carbonaceous material in the form of lignite, bituminous coal, anthracite, and graphite. Our experimental results clearly show that an increase in maturity and crystallinity of carbonaceous material results in a decrease in the peak friction coefficient at the initial stage of slip, from 0.5 (lignite) to 0.2 (graphite). We also infer from our results of spectroscopic analyses that low- (lignite and bituminous coal) and intermediate-grade carbonaceous material (anthracite) increases its maturity by high-velocity frictional slip, but friction applied to high-grade carbonaceous material (graphite) induces an opposite trend. Furthermore, by considering systematic decrease and increase in fracture energy and stress ratio with increasing maturity of carbonaceous material, both of which strongly affect rupture propagation process during earthquake, both diagenesis- and earthquake-driven transformations of carbonaceous material can strongly affect the frictional strength of carbon-bearing faults, potentially affecting the depth-dependences of not only frictional strength but also rupture dynamics on plate-subduction faults.

Viscous behavior of chert during frictional melting

*Ginta Motohashi[1], Kiyokazu Oohashi[2], Kohtaro Ujiie[1]

1. University of Tsukuba, 2. Yamaguchi University

Pelagic chert is one of the major lithology in accretionary complexes. Thus, frictional properties of chert at seismic slip rates are important for understanding of earthquake faulting in subduction zones. Here, we conducted high-velocity friction experiments on chert collected from the Jurassic accretionary complex in central Japan at a slip rate of 1.3 m/s and normal stresses of 5–13 MPa under room humidity conditions. The results show that initial slip weakening was followed by slip strengthening and subsequent second slip weakening toward a steady-state shear strength. Slip strengthening resulted from the formation of a silica-rich melt layer (experimentally generated pseudotachylyte) at lower melting temperatures than expected. The chemical composition of the pseudotachylyte matrix suggests the frictional melting of quartz with a small amount of illite, which may contribute to reduce melting temperatures. The second slip weakening occurred despite an increasing shear strain rate because of the thinning of the melt layer, implying that the viscosity of the melt layer decreased with slip. The estimated temperatures before and after the second slip weakening and microstructural and chemical features of experimentally generated pseudotachylytes suggest that the viscosity decrease during the second slip weakening is not due to a change in the chemical composition of melt layer, but rather a temperature increase in the melt layer.

Effect of friction and comminution on the optically-stimulated luminescence of quartz grains

*Kiyokazu Oohashi[1], Koji Akasegawa[2], Yuki Minomo[1], Noriko Hasebe[3], Kazumasa Miura[4]

1. Graduate School of Sciences and Technology for Innovation, Yamaguchi University, 2. Daiwa Exploration & Consulting Co., Ltd., 3. Institute of Nature and Environmental Technology, Kanazawa University, 4. Graduate School of Natural Science & Technology, Kanazawa University

Optically-stimulated luminescence(OSL) dating is considered to be applicable for fault dating owing to its instability even for short-time heating such as frictional heating. However, fault zone material may experience not only heat but also friction and comminution with coseismic faulting. If the OSL signal becomes small or disappear due to friction and comminution that is also accompanied by stable sliding (fault creep), OSL signal zeroing in natural fault zone can not be simply attributed to earthquake event. Here we report an increment of OSL signal of quartz during a low- to intermediate-velocity frictional sliding. The increments of OSL signal intensities were found from finely ground recovered sample (<75 μm). We also recognized an increment of fast to medium component of OSL with increasing sliding velocity. These results can be explained by (1) trapping of electron on newly-formed mineral surface, (2) rate-dependent emission of electron, such as triboemission, at asperity contact.

Frictional behaviors of smectite clay: constraints for the mobility of slow-moving landslides in the cold season

*Tatsuya Shibasaki[1], Sumio Matsuura[2]

1. Japan Conservation Engineers and Co., Ltd, 2. DPRI, Kyoto University

In Japan, reactivated landslides are distributed on gentle clayey slopes in specific geological settings, such as Neogene soft sedimentary rock areas and hydrothermally altered rock areas around active and inactive volcanoes. These strata are typically composed of smectite-bearing high-plasticity soils. Of all the clay minerals, smectite shows an extremely low residual friction angle. Therefore, landslides consisting of these soils can easily become unstable and be reactivated on very gentle slopes. In many cases, such landslides are likely to be reactivated during certain seasons every year, moving slowly with typical velocities ranging from 0.01 to 0.1 mm/min. According to behavioral data of landslides in the Niigata Prefecture, a well-known landslide-prone area in Japan, some landslides begin to move during the early cold season (late autumn or early winter). Some landslides are activated during the winter, and display continuous movement, while others are activated predominantly during the snow-melting period. These various behaviors cannot be explained solely by fluctuations in pore-water pressure (ground water levels), and this therefore raises the question of what the key controlling mechanisms are. Shallow landslides, less than 10 m deep, are sometimes activated in the early cold season. We inferred that the change in ground temperature may play a key role in activating landslides. In order to verify this, we investigated the effect of temperature on residual shear strength of various clayey soils. Reversal box shear experiments and ring shear experiments were performed on undisturbed slip-surface soils and reconstituted soil samples, respectively. The test results revealed that the shear strength of smectite-rich soils decreases with decreasing temperatures under slow shearing rates of lower than 0.1 mm/min. This finding implies that seasonal fluctuation in ground temperature can influence slope instability, especially for shallow, slow-moving landslides. It is also evident that the effect of temperature on residual strength changes with the shearing rate. We infer that the velocity-dependent characteristic is strongly regulated by the fabric of smectite particles along the shearing plane.

Strength of a deep fault zone along the Median Tectonic Line: Influence of chrolite friction

*Ichiko Shimizu[1], Ayumi S. Okamoto, Andre R. Niemeijer[2], Christopher J. Spiers[2], Shun Arai[3], Toru Takeshita[4]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, 2. Faculty of Geosciences, Utrecht University, 3. Tohoku University, 4. Hokkaido University

To explore the fault strength at the middle crustal levels, we conducted high-pressure hydrothermal experiments using natural fault rocks exposed along the Median Tectonic Line (MTL), focusing on the role of chlorite in fault weakening. Chlorite is a hydrous mineral commonly observed in basic metamorphic rocks and fault zones, and is known to have low friction coefficients around 0.3–0.4 at room temperature water saturated conditions (Behnsen and Faulkner, 2012), and about 0.3 at hydrothermal conditions (Okamoto et al., *in review*).

The experiments were performed on powdered samples of cataclasite and protomylonite, which are originated from tonalite or basic rocks in the Ryoke belt on the northern side of MTL. Cataclasites contain ~30 wt.% mica and clay minerals. Among them, chlorite-rich cataclasite (Chl-cataclasite) contains ~14 wt.% chlorite, and mica-rich cataclasite (Ms-cataclasite) contains ~14 wt.% white mica. Chlorite geothermometer (Bourdelle *et al*., 2013, CMP) yields a bimodal distribution (230–240˚C and 290–340˚C) for the protomylonite sample. The low-temperature chlorite occurs as blobs with the diameter of ~1–2 mm, which contain lamella of white mica. These chlorite grains are considered as pseudomorphs of biotite. The high-temperature chlorite filled fractures and interstice of grains. We therefore interpreted that brittle deformation first occurred at a temperature around 300˚C and subsequent hydrothermal alteration occurred at 230–240˚C. Chl-cataclasite also shows a bimodal temperature distribution (180–220˚C and 240–300˚C), although no clear relationships between temperatures and microstructures were found.

To simulate the deformation conditions at depth, friction experiments were conducted at temperature of 300˚C, normal stress of 300 MPa, and pore fluid pressures of 120 MPa and 240 MPa, using the hydrothermal ring shear apparatus at Utrecht University. Sliding velocities were varied from 0.001 mm/s to 0.1 mm/s. The steady-state friction coefficients obtained for protomylonite were ~0.68, whereas those for Ms- and Chl-cataclasites were ~0.65 and ~0.56 at 120 MPa, and ~0.87 and ~0.66 at 240 MPa, respectively. Velocity stepping tests yielded velocity-weakening or neutral behaviours, although existing laboratory data for pure chlorite gouges mostly show velocity-strengthening behaviours. Our results indicate that fault strengths and sliding behaviours in the middle crusts are not drastically changed by the presence of phyllosilicates even if chlorite contents in fault zones are relatively high (<14 wt.%).

Changes in seismic wave velocity during brittle deformation of gabbro and peridotite

*Yuya Akamatsu[1], Ikuo Katayama[1]

1. Hiroshima University

The Moho is defined as a discontinuity of seismic wave velocity and often interpreted to be the crust-mantle boundary. The oceanic crust is continuously created by magma system at the mid ocean ridge; consequently, the discontinuity of seismic wave velocity and/or sharp seismic reflection at the Moho is expected to be laterally uniform. However, recent seismic observations reported regional variations of the Moho reflectivity (e.g., Mutter and Carton, 2013; Ohira et al., 2018). As seismic wave velocity is greatly influenced by nucleation and growth of microcracks, such seismic anomaly at the Moho can be influenced by microcracks. We found that minor amounts of dilatancy in peridotite relative to mafic rocks based on strain measurements during triaxial deformation tests using these rocks (Akamatsu et al., 2019). This contrasting dilatant behaviors possibly lead to different evolution of seismic wave velocity between crust and mantle, and potentially cause the regional seismic anomaly in the oceanic plate. In this study, we measured elastic wave velocities of gabbro and peridotite during triaxial deformation experiments, and discussed how brittle deformation influences on the seismic velocity and reflectivity.

We used gabbro collected from the Oman ophiolite, and peridotite collected from the Horoman Complex. Triaxial deformation experiments were performed with intra-vessel deformation and fluid flow apparatus at room temperature, a constant strain rate of ~10^{-6} s^{-1}, and a constant confining pressure of 20 MPa. Compressional and shear waves traveling in a direction normal to the loading axis were measured during deformation, where shear waves were polarized normal and parallel to the loading axis. Seismic wave velocities were determined by a pulse transmission method, in which travel times of seismic waves through the sample were measured.

In gabbros, both Vp and Vs markedly decreased (Vp: ~40%, Vs: ~30%) as the samples approache failure. Crack density inverted from the velocities showed anisotropic crack orientation, where microcracks parallel to the loading axis (axial microcracks) were dominantly created. These results correspond to strain data and microstructural observation of recovered samples after deformation (Akamatsu et al., 2019). On the other hand, in peridotites, a small decrease in Vp and Vs (<20%) were observed up to the maximum stress, and inverted crack density showed no significant increase in axial microcracks. This indicates that microcracks developed in peridotites were mainly “mode II” shear microcracks, corresponding to strain data and microstructural observation. These contrasting evolutions of seismic wave velocity and crack density between gabbro and peridotite during brittle deformation can modify the seismic discontinuity and reflectivity at the Moho, and contribute to the variation of the Moho in the oceanic plate.

Dislocation textures in shock-compressed MgO and their formation mechanisms

*Kiyoshi Fujino[1], Xun Liu[2], Tsutomu Mashimo[2]

1. Geodynamics Research Center, Ehime University, 2. Institute of Pulsed Power Science, Kumamoto University

Deformation phenomena under high-pressure in Earth and planetary science occur under the shock compression as well as under the static or quasi-static compression. However, the studies on dislocation textures of materials under the shock compression are very limited, compared to those under the static or quasi-static compression. To fill such gap, the shock compression experiments on MgO were carried out and the dislocation textures of the recovered samples were examined under TEM to consider the formation mechanisms of those dislocation textures.

The shock compression experiments of single-crystal MgO were performed with a powder gun at the Institute of Pulsed Power Science, Kumamoto Univ. The shock compression experiments were done along the <100> and <110> directions. The recovered MgO samples were examined under 200 kV TEM at the Geodynamics Research Center, Ehime University.

In the previous studies, the Burgers vector of MgO is always $(\boldsymbol{a}_1 + \boldsymbol{a}_2)/2$ and the slip planes are mostly {110} and {100}. The present TEM examination showed that the sample under the <100> compression has dislocations of only the {110} slip plane, while under the <110> compression the sample has dislocations of only the {110} slip plane at low pressure but has dislocations of both {110} and {100} slip planes at higher pressure, indicating that the slip plane changes from {110} to {100} with increasing pressure. In addition to these results the dislocation textures which are usually not observed in the static or quasi-static compression, were also observed. In the presentation, the formation mechanisms of the observed dislocation textures are also discussed.

Development of rotational diamond anvil cell and large strain deformation experiments of lower-mantle materials

*Shintaro Azuma[1,2], Ryuichi Nomura[3,4], Kentaro Uesugi[5], Yu Nishihara[4], Doi Shunta[4], Takeshi Arimoto[4], Tetsuo Irifune[4]

1. Tokyo Tech., 2. Kyushu Univ., 3. Kyoto Univ., 4. Ehime Univ., 5. Japan Synchrotron Radiation Research Institute (JASRI)

The rheological properties of lower-mantle materials are key to understanding the dynamics and evolution in the Earth’ s interior. However, the pressure range of deformation apparatuses which can achieve large strain is limited to ~30–40 GPa due to a technical reason. We developed the rotational diamond anvil cell (rDAC) which can conduct deformation experiments with large strain under ultra-high pressure conditions, corresponding to those of core-mantle boundary [Nomura et al., 2017]. The rDAC can apply the torsional deformation to sample with constant strain rate by a gearbox and diamond anvils with grooves [Azuma et al., 2018]. However, the stress measurement and high temperature conditions has not been achieved in rDAC. To solve these problems, the vacuum chamber newly designed for rDAC was installed and the stress measurements using X-ray Diffraction (XRD) were applied to deformation experiments in rDAC at SPring-8 (Japan). In this presentation, we will present the preliminary results of stress measurements, high temperature techniques in rDAC, and the results of deformation experiments of lower-mantle materials.

In this study, the mixture of bridgmanite $(Mg,Fe)SiO_3$ and ferropericlase (Mg,Fe)O, which was synthesized from San Carlos olivine, was deformed under torsion geometry using the rDAC. The experimental conditions are ranging 26–130 GPa, 300–673 K. Starting material was grooved by FIB and the groove was deposited by Pt as a strain-marker. Recovered samples were cut by FIB to observe the deformation microstructures in each cross-section. Deformation experiments were conducted at BL47XU, SPring-8 (Japan) and 3D visualization of strain marker within samples was performed every rotation angle of upper anvil of 5–30 degree using X-ray laminography technique [Nomura and Uesugi, 2016]. Stress was measured by collecting X-ray diffraction pattern at twelve different azimuthal angles, Ψ= 0º, ±30º, ±60º, ± 90º, ±120º, ±150º, and 180º. Testing of the new vacuum chamber was also performed at SPring-8. The vacuum chamber has a removable Kapton window for incident and diffracted X-ray, and can keep the vacuum state (<~10 Pa) to prevent the diamond anvils from oxidation during high-temperature deformation experiments. Platinum wires were used as a resistance heater surrounding the sample and Rhenium gasket.

The geometry of strain-marker in cross-section of deformed samples show nearly simple shear (or general shear). Deformed microstructure of recovered samples was observed using FE-SEM and we determined the 2D surface area of ferropericlase and aspect ratio of bridgmanite. The deformation microstructures of the recovered samples showed that ferropericlase highly deformed and formed an interconnected weak layer. On the other hand, the aspect ratio of bridgmanite did not change with the strain, indicating that bridgmanite has high viscosity compared with ferropericlase. These results imply that ferropericlase dominates the deformation in the regions where large shear strain occurs under relatively low-temperature conditions in the lower mantle (e.g., mantle portion in subducted slabs).

Stress in bridgmanite was estimated by using diffraction peaks (110) and (112) at P = 50 GPa and T= 673 K. Shear stress in bridgmanite was relatively constant values, whereas uniaxial stress changed during

©2019. Japan Geoscience Union. All Right Reserved.

deformation experiments. This preliminary experiment was performed under low-temperature and high-pressure conditions, thus the equivalent stress in bridgmanite was about three times higher than that in previous studies [Girard et al., 2016].

In heating experiments using new vacuum chamber, temperature was monitored by Pt/Rh thermocouple placed close to the sample and and we succeeded in increasing temperature up to ~1000 K. However, the resistance heater (Pt) was unstable in vacuum. In the future, high-temperature deformation experiments using rDAC will be conducted in reducing atmosphere produced by inactive gas or internal heating system should be developed for rDAC.

Rheology of hcp-iron

*Yu Nishihara[1], Doi Shunta[1], Noriyoshi Tsujino[2], Daisuke Yamazaki[2], Yuji Higo[3]

1. Geodynamics Research Center, Ehime University, 2. Institute of Planetary Materials, Okayama University, 3. Japan Synchrotron Radiation Research Institute

Seismic observations have revealed presence of axi-symmetric anisotropy with respect to polar direction in the Earth’ s inner core which consists of solid metal, where a P- wave propagating along the polar direction is ~3% faster than that along the equatorial direction. Although many hypotheses have been proposed for origin of seismic anisotropy in the inner core, there is no general consensus for its origin. Lasbleis and Deguen (2015) discussed that dominant mechanism of the inner core dynamics depends on the inner core age and viscosity, and there are several candidate mechanisms which includes anisotropic growth model (Yoshida et al., 1996) and thermal convection model (Jeanloz and Wenk, 1988). Since the inner core is considered to consist of hexagonal close-packed iron(hcp-iron), information of viscosity of hcp-iron is a key for the understanding of the inner core dynamics. In this study, we have studied rheology of hcp-iron based on high-pressure and high-temperature deformation experiments.
Uniaxial deformation experiments were carried out using a D111-type apparatus installed on a beamline NE7A at PF-AR, KEK and a deformation-DIA apparatus installed on a beamline BL04B1 at SPring-8. Using polycrystalline bcc-iron as a starting material, deformation experiments were carried out at pressure of 16.9-22.6 GPa, temperature of 423-873 K, and strain rate of $0.2–5.2\times10^{-5}$ s^{-1}. Stress and strain during deformation were determined based on two-dimensional X-ray diffraction and X-radiography, respectively, using monochromatized synchrotron X-ray with energy of 60 keV.
A preliminary analysis of the observed data suggests that power-law dislocation creep with stress exponent of ~5 is dominant at >700 K whereas power-law breakdown occurs at lower temperatures. Extrapolation of the data based on homologous temperature scaling suggests that viscosity of hcp-iron at the inner core conditions is ~10^{21} Pa s or higher.

[J] Poster | S (Solid Earth Sciences)：S-CG Complex & General

Tue. May 28, 2019 3:30 PM - 5:00 PM JST | Tue. May 28, 2019 6:30 AM - 8:00 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_20

[S-CG54] Rheology, fracture and friction in Earth and planetary sciences

convener:Miki Tasaka(Shimane University), Osamu Kuwano(Japan Agency for Marine-Earth Science and Technology), Ichiko Shimizu(Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University), Hidemi Ishibashi(Faculty of Science, Shizuoka University)

The aim of this session is to join people from various research area in the earth and planetary sciences and to stimulate discussion beyond the boundaries of each research area. Our goal is to deepen our understanding of dynamics in geosciences by looking over whole areas in the earth and planetary sciences from the viewpoint of PHYSICS OF DEFORMATION, FLOW, AND FRACTURE. We welcome any field (e.g., earthquake, volcano, earth surface, crust, mantle and the core, and other planets and satellites) and any approach (e.g., laboratory experiments, numerical simulations, field observations, and theories).

First-principles study on frictional characteristics of gibbsite

*Hanaya Okuda[1], Kenji Kawai[1], Hiroshi Sakuma[2]

1. Department of Earth and Planetary Science, School of Science, University of Tokyo, 2. Research Center for Functional Materials, National Institute for Materials Science

Sheet-structure minerals, which have layered crystal structures, are known to be observed in natural faults (e.g. Chester et al., 2013). The fault slip behaviors are considered to be controlled by the frictional characteristics of sheet-structure minerals because they have lower and diverse friction coefficients than general minerals (Byerlee, 1978; Moore & Lockner, 2004). Recent studies suggested that the low and diverse frictional characteristics of sheet-structure minerals can be estimated by the variation of the potential energy between layers while being sheared (Sakuma et al., 2018; Okuda et al., submitted).

In this study, we focus on the frictional characteristics of two sheet-structure minerals, brucite (magnesium hydroxides) and gibbsite (aluminum hydroxides). Brucite has the friction coefficient of 0.42 and shows stick-slip behavior, whereas gibbsite has the friction coefficient of 0.75 and shows stable sliding (Moore & Lockner, 2004). These two minerals were composed by MgO_6 and AlO_6 octahedral sheets, respectively (Fig. 1). The difference between them was brucite has no vacant site within the octahedral sheet, whereas gibbsite has 1/3 vacancy with in the sheet (Fig. 2). These two octahedral sheets were the main component of phyllosilicates and their influence of crystal structures on frictional characteristics is important for understanding the frictional characteristics of sheet-structure minerals. We theoretically examined the frictional characteristics of brucite in our previous study (Okuda et al., submitted). Here we calculate atomic-scale frictional characteristics of gibbsite using first-principles calculations based on the density functional theory and compare the results of gibbsite with those of brucite.

Preliminary results showed that gibbsite has lower atomic-scale shear stress than brucite. This is because the hydroxyls of gibbsite can be easily moved due to the vacancy within the octahedral sheet of gibbsite and that makes the potential energy low and increases the structural stability while being sheared. On the other hand, the yield strength of gibbsite is 1~2 GPa estimated by Mohs hardness (Mehrotra et al., 2015; Broz et al., 2006). This yield strength is lower then that of brucite (4.0 GPa (Okuda et al., submitted)) and this low yield strength increases the macroscopic friction coefficient when considering the adhesion theory of friction. We will quantitatively discuss the atomic-scale shear stress and yield strength of gibbsite and investigate what controls the difference of frictional characteristics between brucite and gibbsite.

Feasibility Study of Morphological Characterization to Comminuted Particles by A Particle Characterization Approach (4)

*Daisuke Sasakura[1], Osamu Kuwano[2]

1. MalvernPanalytical Japan ,Div of Spectris Co.Ltd,., 2. JAMSTEC

A faults zone contains fine rock powders called gouge that have been ground up by past fault motions. Particle size distribution and particle shape of gouge particles may affect the frictional properties of the fault and reflect the comminution process by the past fault motions. It is well known that particle size distribution (PSD) of fault gouge show power-law distributions. Exponent of this power law is considered to reflect the style and degree of deformation. In this report, we will discuss about the relationship between the PSD and the degree of comminution of model particles by automated particle image analysis and laser diffraction as a particle characterization method.

We did several shear experiments using a rotary shear apparatus with the shear displacement ranges between10mm to 1m. As an automated particle image analysis, Morphologi G3-SE (Malvern Instruments) was used for evaluation of particle size and shape. The observation mode was diascopic mode (Transmittance mode) and a magnification was choose to sufficient to cover 1 to 10,000um. The sample was dispersed with SDU (Sample Dispersion Unit) which attached Morphologi G3-SE. Number of measured particles was over than ten thousand and a parameter filter function on software was used based on shape and pixel number of particle image.

Rheological property of basaltic lava at rigid-deformable transition

*Akio Goto[1]

1. Center for Northeast Asian Studies, Tohoku University

The viscosity of Izu Oshima basaltic lava flows, effused from summit crater in 1950-1951 and 1986 eruptions, were estimated from slope angle, thickness and surface velocity with supposed density of the flowing lava (Murauchi, 1950; Minakami, 1951; Shirao, 1986). They seem to be curious in that the viscosity of 1950 lava changed over two orders within 15 ˚C (1.7×10^4 Pa s at 1063 ˚C and 3.3×10^6 Pa s at 1048 ˚C), and 1950 lava at 1048 ˚C had over two orders higher viscosity than 1951 lava at 1038 ˚C (2.3×10^4 Pa s). Minakami (1951) also pointed out that the viscosity from field observation were several tens times higher than the measured viscosity in laboratory by Kani (1934). To solve these paradoxical observation results uniaxial compression viscometry was performed for 1986 LC lava cored cylindrically with 15 mm diameter and 30 mm high (Goto, 2017, JpGU meeting). Contrary to the expectation before the experiment that the viscosity decreases continuously with increasing temperature, the lava became deformable drastically at around 1100 ˚C, which did not seem to be by fluidization but by brittle failure; the middle of the cylindrical core was crushed and their surface skin was pushed out brittly. Below this temperature viscosity changed continuously with temperature, although they were almost at solid state range and much higher than the observed viscosity. These rheological properties were common for other Izu Oshima lavas: 1777 pahoehoe, 1950 aa and two types of 1951 pahoehoe (Goto, 2018, VSJ Fall meeting). A new question arose whether these properties were also common for other basaltic lavas. To confirm it Miyake-jima 1983 lava and Mt. Fuji Kemnarubi 1 (porphyritic) and 2 (aphyric) lavas were newly used for uniaxial compressional viscometry.

Similar deformation was seen for Miyake-jima and Mt. Fuji basaltic lavas, indicating that brittle behavior is common for most, if not all, basaltic lava when the drastic deformation occurs. As was also seen for Izu Oshima lavas the highly deformed sample had enough strength not to separate into pieces after the experiments, indicating melt phase surely existed. Melt composition analysis was impossible for Izu Oshima samples after the uniaxial compression experiments due to dendrite crystallization during cooling (10 ˚C/min); alternatively samples quenched after annealing was used for melt composition analysis to calculate the viscosity using the model by Giordano et al. (2008). The melt phase viscosity scattered within few orders even in each sample, i.e., at the same annealed temperature, due to the variation of the melt composition, and was almost similar with or within few orders higher than the viscosity observed by Murauchi (1950) and Minakami (1951) at the same temperature range. If 1 wt% water was supposed 2 orders viscosity decrease was expected, but high crystallinity (e.g., 50 vol% at 1105 ˚C and 78 vol% at 1095 ˚C in annealed sample) might compensate the viscosity decrease by water or rather heighten the bulk viscosity than observed lava flow viscosity. The mechanism of brittle deformation is not interpreted yet, but high mobility after the brittle deformation may sustain the low bulk viscosity of lava flow, and variation of melt composition at the same temperature may be the source of the above mentioned curious observed viscosity.

Cataclasitic texture in gabbroic xenoliths of the Fuji 1707 eruption, Japan

*Hidemi Ishibashi[1], Yumiko Harigane[2], ATSUSHI YASUDA[3], Natsumi Hokanishi[3]

1. Faculty of Science, Shizuoka University, 2. Geological Survey of Japan, AIST, 3. Earthquake Research Institute, University of Tokyo

Gabbroic xenoliths are often found in the volcanic products of the 1707 eruption at Fuji volcano, Japan. These xenoliths offer an opportunity to investigate processes occurred in an active magma reservoir. We observed ~300 samples of the gabbroic xenoliths and found several samples which show cataclasitic textures. Cataclasite is typically formed by brittle fracturing associated with a fault. Therefore, the gabbroic xenolths with cataclastic textures may imply interaction between fault and magma plumbing system. In this study, we performed textural observations and chemical analyses of minerals and glasses for the gabbro cataclaseite xenolths to clarify the formation process of the cataclasitic textures.

The gabbro cataclaseite xenolth samples mainly consists of clast and fine-grained matrix, that we also observed a foliated cataclasite at several samples. Mineral assemblage is plagioclase + olivine + pyroxenes + FeTi oxides and interstitial glass is often observed; this is similar to the xenoliths without cataclaseite-like textures. Fine-grained fragmented plagioclase grains sometimes show undulatory extinction whereas less-fragmented coarse plagioclase grains do not show it. Cracks in less-fragmented parts are filled by rhyolitic melt of ~75 wt.% SiO_2. The melt is chemically different from the melt erupted during the 1707 eruption, indicating that the melt is not derived from host magma. In addition, pyroxene reaction rims are found between the melt and olivine, suggesting that the melt was not the product of deformation-induced melting. Plagioclase-hosted melt inclusions in the gabbroic rocks have similar composition with the crack-filling melt. Therefore, the melt was derived from interstitial melt in crystal mush and infiltrated into cracks during formation of cataclastic textures. Compositional relation of FeTi oxide-plagioclase-melt constrains the temperature-water content condition of the crack-filling melt to be ~800 degree C and ~8 wt.%, which is similar to those of melts in the xenoliths without cataclastic textures. Saturation pressure of the water content is calculated to be ~290 MPa, which corresponds to the depth of ~11 km, indicating that the cataclastic textures were formed at the depth.
One of possible causes of the cataclastic textures is the fault at the depth of 5-15 km beneath the SW flank of Fuji volcano. The fault is recognized by Shizuoka-Tobu earthquake occurred at March 15, 2011; the NE edge of the fault is located beneath the vent of the 1707 eruption, implying interaction between the fault and the magma plumbing system of the 1707 eruption. However, the estimated temperature for the gabbro is higher than that at which a tectonic earthquake occurs. Alternatively, deformation of magma reservoir, associated with magma supply and/or compaction of crystal mush, may induce strain localization and local fault movement, resulting in the formation of the cataclastic textures in gabbros.

Heterogeneous deformation and intragranular recrystallization in experimentally deformed fossil-bearing limestone

*Nahyeon Kim[1], Miki Takahashi[2], Jin-Han Ree[1], Haemyeong Jung[3]

1. Korea University, 2. Geological Survey of Japan, AIST, 3. Seoul National University

Deformation of rocks is heterogeneous particularly when constituent minerals have significant difference in crystallography and/or grain size. Recrystallized grains usually develop from the intragranular region of calcite porphyroclasts in natural shear zones, leading to grain-size reduction and thereby causing rheological change of deforming. However, detailed processes of the intragranular recrystallization and microfabric evolution still remain unclear. To investigate the intragranular recrystallization processes we performed experimental deformation on fossil-bearing limestone using triaxial testing machine. The fossils in the limestone are mainly crinoids and trilobites. The crinoids mostly occur as monocrystalline calcites with larger grain size (700 μm) than that of the matrix (tens μm). In contrast, the trilobites occur as polycrystalline calcites with their grain size (7 μm) much finer than that of matrix. The experiments were performed at temperatures of 500 ~700 ℃, strain rate of 10^{-4}~10^{-5} s^{-1}, confining pressure of 200 MPa and axial strain of up to 30 %. Our strain analyses show that bulk strain is more accommodated in the fine-grained calcites with increase in temperature. In deformed fine-grained calcites of trilobites, fabric strength becomes much weaker with increasing temperature and some grain growth occurs forming equant shape of grains with straight boundaries. These suggest that intergranular process is important in fine-grained calcites of trilobites. In contrast, dynamic recrystallization occurs within the monocrystalline fossil domain of deformed crinoids. The recrystallized grains develop along or near e-twin boundaries and have similar grain size to that of the subgrains (30 μm) formed adjacent to e-twin boundaries. There is a strong correlation of misorientation distribution between the recrystallized grains and e-twin boundaries, suggesting that the intragranular recrystallization in the crinoid fossil is dominated by rotation recrystallization along e-twin boundaries, resulting in misorientation inheritance from the e-twin boundaries. Thus, e-twin boundaries play an important role in intragranular recrystallization processes and grain-size reduction of deforming calcites.

Development of the geobarometer using size and mineral species dependence of residual pressure of fluid inclusions

*Yuuki Hagiwara[1], Junji Yamamoto[1]

1. Hokkaido University

Accurate measurements of the residual pressure of the fluid inclusions at given temperature has a potential to guess the depth provenance and *P–T–t* path of the rocks from the equilibrium temperature of the rocks and the equation of state of the fluid (Levresse et al. 2016; Oglialoro et al. 2017). Since this method does not depend on mineral species, it can also be applied to rocks which cannot use conventional geobarometer based on the mineral composition. Furthermore, since fluid density quickly responds to ambient temperature and pressure change, it is possible to trace a phenomenon on a short time scale. Although the existence of mineral species and size dependence of residual pressure (Yamamoto et al. 2008; Campione 2018) has been pointed out, but its geological significance is not well understood. Therefore, in this study, we measured the residual pressure of the fluid inclusions in the various mineral species by Raman spectroscopy, and discussed the possibilities of fluid density variations as the geothermometer, geobarometer, and geospeedmeter.

However, in order to assess re-equilibration processes of the fluid inclusions, it is necessary to obtain physicochemical information of fluid inclusions of various sizes including very small ones since the fluid retentivity depends on the sizes of the fluid inclusions (Bodnar et al., 1989; Doppler et al., 2013; Campione, 2018). Particularly with respect to the residual pressure, the most reliable size range of fluid inclusions for density calculation is close to the submicrometer level since the smaller the fluid inclusions are, the higher the pressure retentivity is (Bodnar et al., 1989; Wanamaker et al., 1990; Campione et al., 2015; Campione, 2018). Although microthermometry is available to determine the residual pressure of H_2O–CO_2 fluid inclusions (Bakker and Diamond, 2000), for fluid inclusion smaller than ~5 μm and/or those in which the CO_2 liquid and vapor homogenize to the vapor phase upon heating, it is difficult to estimate the internal pressure of the fluid accurately (Rosso and Bodnar, 1995; Kobayashi et al., 2012).

Alternatively, in order to measure the residual pressure of the smaller fluid inclusions, several previous studies have described the application of Raman spectroscopy for quantitative analysis of the residual pressure for various fluid composition. Several groups have improved CO_2 barometers (densimeters) and shown the pressure (density) dependence of the wave number difference (Δ) between the two large peaks of the Raman spectrum of CO_2 (e.g. Hagiwara et al. 2018). In case of H_2O–CO_2 mixture, relationship between Δ and pressure (density) can be altered since some H_2O will be dissolved in the CO_2 depending on fluid pressure even at ambient temperature. However, how the H_2O affects the CO_2 peak positions is still unknown. Practically, some studies have shown that other fluids in a gas mixture affect the Raman spectral features of Δ (Seitz et al. 1996; Lamadrid et al. 2018). Therefore, we experimentally confirmed that the Raman based CO_2 barometer can extend to high pressure H_2O–CO_2 system that may be encountered in natural systems, which is common in fluid inclusions in mantle xenoliths (Roedder, 1984; Frezzotti et al., 2012). By using this method, we measured the residual pressure of fluid inclusions in submicron to 10 μm in mantle xenoliths.

Raman spectra were acquired using excitation by a diode pumped solid-state laser (532 nm, Gem 532; Laser Quantum), and using a spectrometer with 75 cm focal length (Acton SP-2750; Princeton Instruments, Inc.) and a CCD camera (1650 ×200 pixels, 16 μm width, iVac; Andor Technology). The

©2019. Japan Geoscience Union. All Right Reserved.

laser power was ~10 mW at the sample. The respective sizes and depths of the fluid inclusions were measured using a 2000× objective (VH-ZST; Keyence Co.) with a digital microscope (VHX-5000; Keyence Co.). The fluid inclusion size was measured automatically by identifying the outline of a fluid inclusion using the brightness contrast.
The results show that the residual pressure of the fluid inclusion systematically changes depending on the diameter of the fluid inclusion, and the smaller the fluid inclusions are, the higher the pressure retentivity is. Furthermore, the absolute value of the residual pressure retained by the mineral species are also different. Based on these data, we discuss the cause of the variation of the residual pressure of the fluid inclusions from the viewpoint of the brittleness, elasticity and plasticity characteristics of the fluid inclusion-host mineral system.

Microstructures and misorientation analysis of quartz in the Sanbagawa metamorphic belt, Shikoku, Japan

*Tadamasa Ueda[1], Ichiko Shimizu[1]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University

It was previously revealed that quartz grains in the Sanbagawa metamorphic belt show microstructures of subgrain rotation and strain-driven grain migration irrespective of metamorphic grades along Asemi river route (Ueda and Shimizu, 2018 JpGU). This study scrutinized intracrystalline misorientation of quartz to investigate the subgrain rotation process in the schists, using electron back-scattered diffraction (EBSD) maps obtained by the previous study.

To extract boundaries in single grains from the total data set, the misorientation analysis was conducted by making data sets of grains that are larger than about 9 times the mapping step sizes and are not in contact with each other. The grain detection before this procedure was conducted with 12˚ threshold excluding dauphine-twin boundaries. Such extraction of grains was conducted for a few times for each thin section so that the sum of the data sets covers most (>~80% in area) of indexed quartz grains and no quartz grain is duplicated in the data sets. To eliminate boundaries arising from dauphine-twin-type misindexed grains, the grains smaller than 5 times the mapping step sizes that occur in grain detection without excluding dauphine-twin boundaries were excluded from the data set.

Samples showed the following features irrespective of metamorphic grades. Misorientation angle distributions show two peaks; one is at low angles (<10˚) and the other is at 60˚. Boundaries with 30-40˚ misorientation are nearly absent and those with >65˚ misorientation are absent. The frequency of misorientation gradually decreases from low angle to ~30˚, gradually increases from ~45˚ to 60˚, and rapidly decreases above 60˚. In the crystal coordinate system, misorientation axis distributions of <~12˚ misorientation show weak concentration about c-axis and do not show concentration about the pole to the m planes, even though most samples show c-axis concentration subnormal to the foliation. Compared to the concentration of low-angle misorientation axis about c-axis, misorientation axis distributions of ~15-40˚ generally show concentration off the c-axis direction. Misorientation axis distributions of 45-65˚ show strong concentration at the direction of c-axis. Grains with c-axis nearly normal to the foliation show weaker concentration of misorientation axis of low-angle boundaries about c-axis than grains with c-axis parallel to the foliation and perpendicular to the lineation, but general characteristics of misorientation in crystal coordinate system are similar. In the sample coordinate system, misorientation axis distribution of <~12˚ show weak concentration about the direction parallel to the foliation and perpendicular to the lineation for samples in which flattened planes of quartz grains are subparallel to the foliation. For samples in which flattened planes of quartz are at high angle (>~45˚) to the foliation, misorientation axes of <~12˚ are weakly concentrated about the direction subparallel to the quartz flattening plane and perpendicular to the lineation.

©2019. Japan Geoscience Union. All Right Reserved.

The misorientation angle distributions and misorientation axis distributions indicate that the misorientation of boundaries formed solely by subgrain rotation is less than ~40° and high angle boundaries of ~45-60° are formed by the combination of dauphine twinning and subgrain rotation. The weak concentration of misorientation axes about c-axis for low angle boundaries, which implies prism-a slip, is enigmatic, considering most samples show c-axis concentration nearly perpendicular to the foliation, which is generally interpreted as basal-a slip. However, the coexistence of the misorientation feature and c-axis fabric may be justified, considering that subgrain boundaries are annealed dislocation structures and that most dislocations in crystals suffering steady-state deformation are generally supposed to be forest dislocations. Misorientation axis of subgrain boundaries may indicate rather subsidiary slip systems than main ones.

Microstructural & petrological analysis of peridotite xenolith in Noyama-dake, Shimane prefecture ~ implication of plastic deformation during Japan sea opening

*Miki Tasaka[1], Shunsuke Inagawa[1]

1. Shimane University

A number of Cenozoic ultramafic xenoliths are located on the southwest Japan arc. In this study, we conducted microstructural and petrological analyses using peridotite xenoliths in Noyama-dake, Shimane prefecture. These microstructural and petrological results imply that these textures are formed by plastic deformation during Japan Sea opening (=15 Ma) with various stress conditions before Noramadake eruption (~7 Ma).

The microstructure of peridotites is classified into three types, including (1) coarse-grained equigranular texture (~ 1mm), (2) fine-grained texture (~50 um), and (3) large- and fine-grained fractured texture. Based on electron backscattered diffraction (EBSD) analysis, the olivine crystals in (1) coarse-grained equigranular texture and (2) fine-grained texture have a crystallographic preferred orientation (CPO), indicating plastic deformation with various stress condition. Straight cracks are observed in large olivine grains in (3) large- and fine-grained fractured texture. Basaltic melt and fine-grained olivine aggregates with CPO intrude in these cracks. These features indicate that large- and fine-grained fractured texture results from brittle-ductile deformation during volcanic eruption.

Based on electron probe micro analyzer (EPMA), (1) coarse-grained equigranular texture has origin of residual mantle, whereas (2) fine-grained texture and (3) large- and fine-grained fractured textures are originated from cumulus mantle. Two pyroxene geothermometer indicates that the rock has equilibrium temperature T ~ 1200C, resulting from high temperature at the pressure of spinel stability field (P ~ 1 to 2 GPa).

Thermodynamic approach to grain boundary premelting in a binary eutectic system

*Akihiro Tsunoda[1], Yasuko Takei[1], Hatsuki Yamauchi[1]

1. Earthquake Research Institute, The University of Tokyo

The structure of a weak asthenosphere and a rigid lithosphere constitutes the essential element of plate tectonics. The weakness of asthenosphere has been attributed to the partial melting of rocks. However, in the recent experimental study by using a rock analogue (borneol + diphenylamine binary eutectic system), anelastic relaxation and viscous creep were significantly enhanced from just below the eutectic temperature, where melt does not exist (Yamauchi and Takei, 2016). The mechanisms of anelasticity and viscosity are related to grain boundary sliding and grain boundary diffusion respectively, which implies that thesechanges in the mechanical properties resulted from the changes in grain boundary properties. That means that the “weak asthenosphere” can be explained by “weak grain boundaries” at near solidus temperatures without invoking melt. However, the mechanism causing the change in grain boundary properties is unclear.

In the areas of material science and physics, it is known that the grain boundary is disordered just below the melting temperature or solidus, which is called grain boundary premelting. The results of experiment are expected to be explained by grain boundary premelting. In this study, we investigate the possible occurrence of grain boundary premelting in the upper mantle and its effects on the mechanical properties of rock by using a theoretical model developed in these areas.

In this study, we use a thermodynamic model called phase-field model. We consider a two component bicrystal containing a single grain boundary at x=0. Tang et al. (2006) modeled this system by using three field parameters, composition c(x), crystal orientation θ(x), and crystallinity η(x).(η is sometimes called order parameter or phase-field parameter.) Using the theory of Cahn and Hilliard (1958), they phenomenologically derived the free energy of this nonuniform system as a function of c(x), θ(x), and η(x). By calculating the condition which minimize the free energy, we can predict the equilibrium composition and crystallinity of the grain boundary as functions of temperature. Occurrence of grain boundary premelting can be predicted as an increase in grain boundary disorder (decrease in η at x=0) near the eutectic temperature. We investigate the effects of various model parameters, such as melting temperature, melting enthalpy, and grain boundary misorientation, on the grain boundary crystallinity.

Size effects on hardness and fracture toughness of olivine

*Sanae Koizumi[1], Tohru S Suzuki[2], Takehiko Hiraga[1]

1. Earthquake Research Institute,The University of Tokyo, 2. National Institute for Materials Science

We conducted Vickers indentation tests on Fe-free (Mg_2SiO_4) and Fe-bearing ($Mg_{1.8}Fe_{0.2}SiO_4$) olivine. Their single crystals and highly-dense polycrystalline materials with various average grain sizes (d) from 170 to 890 nm were tested. The largest Vickers microhardness (H_v) of 18 GPa at the lowest load of 0.1 N, which corresponds an indentation depth (h) of 0.6 μm was measured from the polycrystalline material with the finest grain size. The H_v decreases with increasing d and h, both of which are represented by $H_v \propto l^x$ where l corresponds to both sizes with a common x value of ~0.09. The relationship no longer holds at of > 4 μm and of > 1 μm where H_v take constant values of ~9.5 and ~8 GPa for Fe-free and Fe-bearing olivine, respectively. Fracture toughness (K_{IC}) measured from indentation diagonal size and length of cracks radiated outward from the indentation corners is ~0.8 MPa・$m^{1/2}$ for the polycrystalline materials, whose value does not change with the applied load, and olivine chemistry and grain size. The single crystals exhibit lower and orientation dependent toughness from 0.4 to 0.7 MPa・$m^{1/2}$.

Dislocation creep of dry orthoenstatite aggregates under high *P-T* conditions

*Yumiko Tsubokawa[1], Tomohiro Ohuchi[1], Yuji Higo[2], Yoshinori Tange[2], Tetsuo Irifune[1]

1. Ehime University Geodynamics Research Center, 2. Japan Synchrotron Radiation Research Institute

Large-scale tectonic processes such as subduction of slabs depend critically on the rheological behaviour of major mantle minerals. Because olivine is the most dominant mineral under the lithospheric conditions, viscosity of dry olivine have been considered to control the strength of the oceanic lithosphere. However, this assumption needs to be reconsidered because olivine is too strong to allow the operation of plate tectonics (Kohlstedt et al., 1995). Ohuchi et al. (2011) showed that orthoenstatite, the second most abundant mineral, could be much weaker than olivine at lithospheric temperatures. Creep strength of polycrystalline orthoenstatite needs to be considered when we discuss the strength of lithosphere because mechanical data on single crystals give the upper/lower limits of the strength of orthoenstatite.

In order to determine the flow-law parameters for dislocation creep of orthoenstatite under the lithospheric conditions, deformation experiments of dry orthoenstatite aggregates were conducted at high temperatures (up to 1473 K) and high pressures (1.8-4.7 GPa) using a deformation DIA (D-DIA) apparatus combined with synchrotron X-ray radiation. Orthoenstatite aggregates, fabricated from powdered natural single crystals, were fired under controlled oxygen fugacity conditions near the FMQ-buffer to remove dissolved water in the samples. Applied differential stress and axial strain were measured using monochromatic X-ray diffraction patterns of orthoenstatite and radiograph images, respectively.

At a constant strain rate ranging from 7.7×10^{-6} to 5.2×10^{-5} s^{-1} , a steady-state creep strength (200-1200 MPa) was achieved at a strain higher than 4% during the uniaxial compression. The water content of samples was mostly less than 50 ppm (H/Si) through a sample deformation. Steady-state creep strength at each experimental conditions followed the power-law dislocation creep with the stress exponent n~3. TEM observations showed development of dislocations with the Burgers vector of either [001] or [0kl] in the recovered samples. The n and the activation energy (Q^* ~170 kJ/mol) , and Burgers vector determined in this study are comparable to those for the [001](010) slip system of dry orthoenstatite (Ohuchi et al., 2011). Viscosity of dry orthoenstatite is ~10 times lower than that of dry olivine (calculated from the flow law by Karato and Jung, 2003) under our experimental conditions (in the case of uniform stress at lithospheric conditions), suggesting that operation of plate tectonics is possible if the strength of a subducting slab is controlled by orthoenstatite.

[J] Poster | S (Solid Earth Sciences)：S-CG Complex & General

Tue. May 28, 2019 5:15 PM - 6:30 PM JST | Tue. May 28, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_36

[S-CG54] Rheology, fracture and friction in Earth and planetary sciences

convener:Miki Tasaka(Shimane University), Osamu Kuwano(Japan Agency for Marine-Earth Science and Technology), Ichiko Shimizu(Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University), Hidemi Ishibashi(Faculty of Science, Shizuoka University)

The aim of this session is to join people from various research area in the earth and planetary sciences and to stimulate discussion beyond the boundaries of each research area. Our goal is to deepen our understanding of dynamics in geosciences by looking over whole areas in the earth and planetary sciences from the viewpoint of PHYSICS OF DEFORMATION, FLOW, AND FRACTURE. We welcome any field (e.g., earthquake, volcano, earth surface, crust, mantle and the core, and other planets and satellites) and any approach (e.g., laboratory experiments, numerical simulations, field observations, and theories).

First-principles study on frictional characteristics of gibbsite

*Hanaya Okuda[1], Kenji Kawai[1], Hiroshi Sakuma[2]

1. Department of Earth and Planetary Science, School of Science, University of Tokyo, 2. Research Center for Functional Materials, National Institute for Materials Science

Sheet-structure minerals, which have layered crystal structures, are known to be observed in natural faults (e.g. Chester et al., 2013). The fault slip behaviors are considered to be controlled by the frictional characteristics of sheet-structure minerals because they have lower and diverse friction coefficients than general minerals (Byerlee, 1978; Moore & Lockner, 2004). Recent studies suggested that the low and diverse frictional characteristics of sheet-structure minerals can be estimated by the variation of the potential energy between layers while being sheared (Sakuma et al., 2018; Okuda et al., submitted).

In this study, we focus on the frictional characteristics of two sheet-structure minerals, brucite (magnesium hydroxides) and gibbsite (aluminum hydroxides). Brucite has the friction coefficient of 0.42 and shows stick-slip behavior, whereas gibbsite has the friction coefficient of 0.75 and shows stable sliding (Moore & Lockner, 2004). These two minerals were composed by MgO_6 and AlO_6 octahedral sheets, respectively (Fig. 1). The difference between them was brucite has no vacant site within the octahedral sheet, whereas gibbsite has 1/3 vacancy with in the sheet (Fig. 2). These two octahedral sheets were the main component of phyllosilicates and their influence of crystal structures on frictional characteristics is important for understanding the frictional characteristics of sheet-structure minerals. We theoretically examined the frictional characteristics of brucite in our previous study (Okuda et al., submitted). Here we calculate atomic-scale frictional characteristics of gibbsite using first-principles calculations based on the density functional theory and compare the results of gibbsite with those of brucite.

Preliminary results showed that gibbsite has lower atomic-scale shear stress than brucite. This is because the hydroxyls of gibbsite can be easily moved due to the vacancy within the octahedral sheet of gibbsite and that makes the potential energy low and increases the structural stability while being sheared. On the other hand, the yield strength of gibbsite is 1~2 GPa estimated by Mohs hardness (Mehrotra et al., 2015; Broz et al., 2006). This yield strength is lower then that of brucite (4.0 GPa (Okuda et al., submitted)) and this low yield strength increases the macroscopic friction coefficient when considering the adhesion theory of friction. We will quantitatively discuss the atomic-scale shear stress and yield strength of gibbsite and investigate what controls the difference of frictional characteristics between brucite and gibbsite.

Feasibility Study of Morphological Characterization to Comminuted Particles by A Particle Characterization Approach (4)

*Daisuke Sasakura[1], Osamu Kuwano[2]

1. MalvernPanalytical Japan ,Div of Spectris Co.Ltd,., 2. JAMSTEC

A faults zone contains fine rock powders called gouge that have been ground up by past fault motions. Particle size distribution and particle shape of gouge particles may affect the frictional properties of the fault and reflect the comminution process by the past fault motions. It is well known that particle size distribution (PSD) of fault gouge show power-law distributions. Exponent of this power law is considered to reflect the style and degree of deformation. In this report, we will discuss about the relationship between the PSD and the degree of comminution of model particles by automated particle image analysis and laser diffraction as a particle characterization method.

We did several shear experiments using a rotary shear apparatus with the shear displacement ranges between10mm to 1m. As an automated particle image analysis, Morphologi G3-SE (Malvern Instruments) was used for evaluation of particle size and shape. The observation mode was diascopic mode (Transmittance mode) and a magnification was choose to sufficient to cover 1 to 10,000um. The sample was dispersed with SDU (Sample Dispersion Unit) which attached Morphologi G3-SE. Number of measured particles was over than ten thousand and a parameter filter function on software was used based on shape and pixel number of particle image.

Rheological property of basaltic lava at rigid-deformable transition

*Akio Goto[1]

1. Center for Northeast Asian Studies, Tohoku University

The viscosity of Izu Oshima basaltic lava flows, effused from summit crater in 1950-1951 and 1986 eruptions, were estimated from slope angle, thickness and surface velocity with supposed density of the flowing lava (Murauchi, 1950; Minakami, 1951; Shirao, 1986). They seem to be curious in that the viscosity of 1950 lava changed over two orders within 15 ˚C (1.7×10^4 Pa s at 1063 ˚C and 3.3×10^6 Pa s at 1048 ˚C), and 1950 lava at 1048 ˚C had over two orders higher viscosity than 1951 lava at 1038 ˚C (2.3×10^4 Pa s). Minakami (1951) also pointed out that the viscosity from field observation were several tens times higher than the measured viscosity in laboratory by Kani (1934). To solve these paradoxical observation results uniaxial compression viscometry was performed for 1986 LC lava cored cylindrically with 15 mm diameter and 30 mm high (Goto, 2017, JpGU meeting). Contrary to the expectation before the experiment that the viscosity decreases continuously with increasing temperature, the lava became deformable drastically at around 1100 ˚C, which did not seem to be by fluidization but by brittle failure; the middle of the cylindrical core was crushed and their surface skin was pushed out brittly. Below this temperature viscosity changed continuously with temperature, although they were almost at solid state range and much higher than the observed viscosity. These rheological properties were common for other Izu Oshima lavas: 1777 pahoehoe, 1950 aa and two types of 1951 pahoehoe (Goto, 2018, VSJ Fall meeting). A new question arose whether these properties were also common for other basaltic lavas. To confirm it Miyake-jima 1983 lava and Mt. Fuji Kemnarubi 1 (porphyritic) and 2 (aphyric) lavas were newly used for uniaxial compressional viscometry.

Similar deformation was seen for Miyake-jima and Mt. Fuji basaltic lavas, indicating that brittle behavior is common for most, if not all, basaltic lava when the drastic deformation occurs. As was also seen for Izu Oshima lavas the highly deformed sample had enough strength not to separate into pieces after the experiments, indicating melt phase surely existed. Melt composition analysis was impossible for Izu Oshima samples after the uniaxial compression experiments due to dendrite crystallization during cooling (10 ˚C/min); alternatively samples quenched after annealing was used for melt composition analysis to calculate the viscosity using the model by Giordano et al. (2008). The melt phase viscosity scattered within few orders even in each sample, i.e., at the same annealed temperature, due to the variation of the melt composition, and was almost similar with or within few orders higher than the viscosity observed by Murauchi (1950) and Minakami (1951) at the same temperature range. If 1 wt% water was supposed 2 orders viscosity decrease was expected, but high crystallinity (e.g., 50 vol% at 1105 ˚C and 78 vol% at 1095 ˚C in annealed sample) might compensate the viscosity decrease by water or rather heighten the bulk viscosity than observed lava flow viscosity. The mechanism of brittle deformation is not interpreted yet, but high mobility after the brittle deformation may sustain the low bulk viscosity of lava flow, and variation of melt composition at the same temperature may be the source of the above mentioned curious observed viscosity.

Cataclasitic texture in gabbroic xenoliths of the Fuji 1707 eruption, Japan

*Hidemi Ishibashi[1], Yumiko Harigane[2], ATSUSHI YASUDA[3], Natsumi Hokanishi[3]

1. Faculty of Science, Shizuoka University, 2. Geological Survey of Japan, AIST, 3. Earthquake Research Institute, University of Tokyo

Gabbroic xenoliths are often found in the volcanic products of the 1707 eruption at Fuji volcano, Japan. These xenoliths offer an opportunity to investigate processes occurred in an active magma reservoir. We observed ~300 samples of the gabbroic xenoliths and found several samples which show cataclasitic textures. Cataclasite is typically formed by brittle fracturing associated with a fault. Therefore, the gabbroic xenolths with cataclastic textures may imply interaction between fault and magma plumbing system. In this study, we performed textural observations and chemical analyses of minerals and glasses for the gabbro cataclaseite xenolths to clarify the formation process of the cataclasitic textures.

The gabbro cataclaseite xenolth samples mainly consists of clast and fine-grained matrix, that we also observed a foliated cataclasite at several samples. Mineral assemblage is plagioclase + olivine + pyroxenes + FeTi oxides and interstitial glass is often observed; this is similar to the xenoliths without cataclaseite-like textures. Fine-grained fragmented plagioclase grains sometimes show undulatory extinction whereas less-fragmented coarse plagioclase grains do not show it. Cracks in less-fragmented parts are filled by rhyolitic melt of ~75 wt.% SiO_2. The melt is chemically different from the melt erupted during the 1707 eruption, indicating that the melt is not derived from host magma. In addition, pyroxene reaction rims are found between the melt and olivine, suggesting that the melt was not the product of deformation-induced melting. Plagioclase-hosted melt inclusions in the gabbroic rocks have similar composition with the crack-filling melt. Therefore, the melt was derived from interstitial melt in crystal mush and infiltrated into cracks during formation of cataclastic textures. Compositional relation of FeTi oxide-plagioclase-melt constrains the temperature-water content condition of the crack-filling melt to be ~800 degree C and ~8 wt.%, which is similar to those of melts in the xenoliths without cataclastic textures. Saturation pressure of the water content is calculated to be ~290 MPa, which corresponds to the depth of ~11 km, indicating that the cataclastic textures were formed at the depth.
One of possible causes of the cataclastic textures is the fault at the depth of 5-15 km beneath the SW flank of Fuji volcano. The fault is recognized by Shizuoka-Tobu earthquake occurred at March 15, 2011; the NE edge of the fault is located beneath the vent of the 1707 eruption, implying interaction between the fault and the magma plumbing system of the 1707 eruption. However, the estimated temperature for the gabbro is higher than that at which a tectonic earthquake occurs. Alternatively, deformation of magma reservoir, associated with magma supply and/or compaction of crystal mush, may induce strain localization and local fault movement, resulting in the formation of the cataclastic textures in gabbros.

Heterogeneous deformation and intragranular recrystallization in experimentally deformed fossil-bearing limestone

*Nahyeon Kim[1], Miki Takahashi[2], Jin-Han Ree[1], Haemyeong Jung[3]

1. Korea University, 2. Geological Survey of Japan, AIST, 3. Seoul National University

Deformation of rocks is heterogeneous particularly when constituent minerals have significant difference in crystallography and/or grain size. Recrystallized grains usually develop from the intragranular region of calcite porphyroclasts in natural shear zones, leading to grain-size reduction and thereby causing rheological change of deforming. However, detailed processes of the intragranular recrystallization and microfabric evolution still remain unclear. To investigate the intragranular recrystallization processes we performed experimental deformation on fossil-bearing limestone using triaxial testing machine. The fossils in the limestone are mainly crinoids and trilobites. The crinoids mostly occur as monocrystalline calcites with larger grain size (700 μm) than that of the matrix (tens μm). In contrast, the trilobites occur as polycrystalline calcites with their grain size (7 μm) much finer than that of matrix. The experiments were performed at temperatures of 500 ~700 ℃, strain rate of 10^{-4}~10^{-5} s^{-1}, confining pressure of 200 MPa and axial strain of up to 30 %. Our strain analyses show that bulk strain is more accommodated in the fine-grained calcites with increase in temperature. In deformed fine-grained calcites of trilobites, fabric strength becomes much weaker with increasing temperature and some grain growth occurs forming equant shape of grains with straight boundaries. These suggest that intergranular process is important in fine-grained calcites of trilobites. In contrast, dynamic recrystallization occurs within the monocrystalline fossil domain of deformed crinoids. The recrystallized grains develop along or near e-twin boundaries and have similar grain size to that of the subgrains (30 μm) formed adjacent to e-twin boundaries. There is a strong correlation of misorientation distribution between the recrystallized grains and e-twin boundaries, suggesting that the intragranular recrystallization in the crinoid fossil is dominated by rotation recrystallization along e-twin boundaries, resulting in misorientation inheritance from the e-twin boundaries. Thus, e-twin boundaries play an important role in intragranular recrystallization processes and grain-size reduction of deforming calcites.

Development of the geobarometer using size and mineral species dependence of residual pressure of fluid inclusions

*Yuuki Hagiwara[1], Junji Yamamoto[1]

1. Hokkaido University

Accurate measurements of the residual pressure of the fluid inclusions at given temperature has a potential to guess the depth provenance and *P–T–t* path of the rocks from the equilibrium temperature of the rocks and the equation of state of the fluid (Levresse et al. 2016; Oglialoro et al. 2017). Since this method does not depend on mineral species, it can also be applied to rocks which cannot use conventional geobarometer based on the mineral composition. Furthermore, since fluid density quickly responds to ambient temperature and pressure change, it is possible to trace a phenomenon on a short time scale. Although the existence of mineral species and size dependence of residual pressure (Yamamoto et al. 2008; Campione 2018) has been pointed out, but its geological significance is not well understood. Therefore, in this study, we measured the residual pressure of the fluid inclusions in the various mineral species by Raman spectroscopy, and discussed the possibilities of fluid density variations as the geothermometer, geobarometer, and geospeedmeter.

However, in order to assess re-equilibration processes of the fluid inclusions, it is necessary to obtain physicochemical information of fluid inclusions of various sizes including very small ones since the fluid retentivity depends on the sizes of the fluid inclusions (Bodnar et al., 1989; Doppler et al., 2013; Campione, 2018). Particularly with respect to the residual pressure, the most reliable size range of fluid inclusions for density calculation is close to the submicrometer level since the smaller the fluid inclusions are, the higher the pressure retentivity is (Bodnar et al., 1989; Wanamaker et al., 1990; Campione et al., 2015; Campione, 2018). Although microthermometry is available to determine the residual pressure of H_2O–CO_2 fluid inclusions (Bakker and Diamond, 2000), for fluid inclusion smaller than ~5 μm and/or those in which the CO_2 liquid and vapor homogenize to the vapor phase upon heating, it is difficult to estimate the internal pressure of the fluid accurately (Rosso and Bodnar, 1995; Kobayashi et al., 2012).

Alternatively, in order to measure the residual pressure of the smaller fluid inclusions, several previous studies have described the application of Raman spectroscopy for quantitative analysis of the residual pressure for various fluid composition. Several groups have improved CO_2 barometers (densimeters) and shown the pressure (density) dependence of the wave number difference (Δ) between the two large peaks of the Raman spectrum of CO_2 (e.g. Hagiwara et al. 2018). In case of H_2O–CO_2 mixture, relationship between Δ and pressure (density) can be altered since some H_2O will be dissolved in the CO_2 depending on fluid pressure even at ambient temperature. However, how the H_2O affects the CO_2 peak positions is still unknown. Practically, some studies have shown that other fluids in a gas mixture affect the Raman spectral features of Δ (Seitz et al. 1996; Lamadrid et al. 2018). Therefore, we experimentally confirmed that the Raman based CO_2 barometer can extend to high pressure H_2O–CO_2 system that may be encountered in natural systems, which is common in fluid inclusions in mantle xenoliths (Roedder, 1984; Frezzotti et al., 2012). By using this method, we measured the residual pressure of fluid inclusions in submicron to 10 μm in mantle xenoliths.

Raman spectra were acquired using excitation by a diode pumped solid-state laser (532 nm, Gem 532; Laser Quantum), and using a spectrometer with 75 cm focal length (Acton SP-2750; Princeton Instruments, Inc.) and a CCD camera (1650 ×200 pixels, 16 μm width, iVac; Andor Technology). The

©2019. Japan Geoscience Union. All Right Reserved.

laser power was ~10 mW at the sample. The respective sizes and depths of the fluid inclusions were measured using a 2000× objective (VH-ZST; Keyence Co.) with a digital microscope (VHX-5000; Keyence Co.). The fluid inclusion size was measured automatically by identifying the outline of a fluid inclusion using the brightness contrast.
The results show that the residual pressure of the fluid inclusion systematically changes depending on the diameter of the fluid inclusion, and the smaller the fluid inclusions are, the higher the pressure retentivity is. Furthermore, the absolute value of the residual pressure retained by the mineral species are also different. Based on these data, we discuss the cause of the variation of the residual pressure of the fluid inclusions from the viewpoint of the brittleness, elasticity and plasticity characteristics of the fluid inclusion-host mineral system.

Microstructures and misorientation analysis of quartz in the Sanbagawa metamorphic belt, Shikoku, Japan

*Tadamasa Ueda[1], Ichiko Shimizu[1]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University

It was previously revealed that quartz grains in the Sanbagawa metamorphic belt show microstructures of subgrain rotation and strain-driven grain migration irrespective of metamorphic grades along Asemi river route (Ueda and Shimizu, 2018 JpGU). This study scrutinized intracrystalline misorientation of quartz to investigate the subgrain rotation process in the schists, using electron back-scattered diffraction (EBSD) maps obtained by the previous study.

To extract boundaries in single grains from the total data set, the misorientation analysis was conducted by making data sets of grains that are larger than about 9 times the mapping step sizes and are not in contact with each other. The grain detection before this procedure was conducted with 12˚ threshold excluding dauphine-twin boundaries. Such extraction of grains was conducted for a few times for each thin section so that the sum of the data sets covers most (>~80% in area) of indexed quartz grains and no quartz grain is duplicated in the data sets. To eliminate boundaries arising from dauphine-twin-type misindexed grains, the grains smaller than 5 times the mapping step sizes that occur in grain detection without excluding dauphine-twin boundaries were excluded from the data set.

Samples showed the following features irrespective of metamorphic grades. Misorientation angle distributions show two peaks; one is at low angles (<10˚) and the other is at 60˚. Boundaries with 30-40˚ misorientation are nearly absent and those with >65˚ misorientation are absent. The frequency of misorientation gradually decreases from low angle to ~30˚, gradually increases from ~45˚ to 60˚, and rapidly decreases above 60˚. In the crystal coordinate system, misorientation axis distributions of <~12˚ misorientation show weak concentration about c-axis and do not show concentration about the pole to the m planes, even though most samples show c-axis concentration subnormal to the foliation. Compared to the concentration of low-angle misorientation axis about c-axis, misorientation axis distributions of ~15-40˚ generally show concentration off the c-axis direction. Misorientation axis distributions of 45-65˚ show strong concentration at the direction of c-axis. Grains with c-axis nearly normal to the foliation show weaker concentration of misorientation axis of low-angle boundaries about c-axis than grains with c-axis parallel to the foliation and perpendicular to the lineation, but general characteristics of misorientation in crystal coordinate system are similar. In the sample coordinate system, misorientation axis distribution of <~12˚ show weak concentration about the direction parallel to the foliation and perpendicular to the lineation for samples in which flattened planes of quartz grains are subparallel to the foliation. For samples in which flattened planes of quartz are at high angle (>~45˚) to the foliation, misorientation axes of <~12˚ are weakly concentrated about the direction subparallel to the quartz flattening plane and perpendicular to the lineation.

©2019. Japan Geoscience Union. All Right Reserved.

The misorientation angle distributions and misorientation axis distributions indicate that the misorientation of boundaries formed solely by subgrain rotation is less than ~40° and high angle boundaries of ~45-60° are formed by the combination of dauphine twinning and subgrain rotation. The weak concentration of misorientation axes about c-axis for low angle boundaries, which implies prism-a slip, is enigmatic, considering most samples show c-axis concentration nearly perpendicular to the foliation, which is generally interpreted as basal-a slip. However, the coexistence of the misorientation feature and c-axis fabric may be justified, considering that subgrain boundaries are annealed dislocation structures and that most dislocations in crystals suffering steady-state deformation are generally supposed to be forest dislocations. Misorientation axis of subgrain boundaries may indicate rather subsidiary slip systems than main ones.

Microstructural & petrological analysis of peridotite xenolith in Noyama-dake, Shimane prefecture ~ implication of plastic deformation during Japan sea opening

*Miki Tasaka[1], Shunsuke Inagawa[1]

1. Shimane University

A number of Cenozoic ultramafic xenoliths are located on the southwest Japan arc. In this study, we conducted microstructural and petrological analyses using peridotite xenoliths in Noyama-dake, Shimane prefecture. These microstructural and petrological results imply that these textures are formed by plastic deformation during Japan Sea opening (=15 Ma) with various stress conditions before Noramadake eruption (~7 Ma).

The microstructure of peridotites is classified into three types, including (1) coarse-grained equigranular texture (~ 1mm), (2) fine-grained texture (~50 um), and (3) large- and fine-grained fractured texture. Based on electron backscattered diffraction (EBSD) analysis, the olivine crystals in (1) coarse-grained equigranular texture and (2) fine-grained texture have a crystallographic preferred orientation (CPO), indicating plastic deformation with various stress condition. Straight cracks are observed in large olivine grains in (3) large- and fine-grained fractured texture. Basaltic melt and fine-grained olivine aggregates with CPO intrude in these cracks. These features indicate that large- and fine-grained fractured texture results from brittle-ductile deformation during volcanic eruption.

Based on electron probe micro analyzer (EPMA), (1) coarse-grained equigranular texture has origin of residual mantle, whereas (2) fine-grained texture and (3) large- and fine-grained fractured textures are originated from cumulus mantle. Two pyroxene geothermometer indicates that the rock has equilibrium temperature T ~ 1200C, resulting from high temperature at the pressure of spinel stability field (P ~ 1 to 2 GPa).

Thermodynamic approach to grain boundary premelting in a binary eutectic system

*Akihiro Tsunoda[1], Yasuko Takei[1], Hatsuki Yamauchi[1]

1. Earthquake Research Institute, The University of Tokyo

The structure of a weak asthenosphere and a rigid lithosphere constitutes the essential element of plate tectonics. The weakness of asthenosphere has been attributed to the partial melting of rocks. However, in the recent experimental study by using a rock analogue (borneol + diphenylamine binary eutectic system), anelastic relaxation and viscous creep were significantly enhanced from just below the eutectic temperature, where melt does not exist (Yamauchi and Takei, 2016). The mechanisms of anelasticity and viscosity are related to grain boundary sliding and grain boundary diffusion respectively, which implies that thesechanges in the mechanical properties resulted from the changes in grain boundary properties. That means that the “weak asthenosphere” can be explained by “weak grain boundaries” at near solidus temperatures without invoking melt. However, the mechanism causing the change in grain boundary properties is unclear.

In the areas of material science and physics, it is known that the grain boundary is disordered just below the melting temperature or solidus, which is called grain boundary premelting. The results of experiment are expected to be explained by grain boundary premelting. In this study, we investigate the possible occurrence of grain boundary premelting in the upper mantle and its effects on the mechanical properties of rock by using a theoretical model developed in these areas.

In this study, we use a thermodynamic model called phase-field model. We consider a two component bicrystal containing a single grain boundary at x=0. Tang et al. (2006) modeled this system by using three field parameters, composition c(x), crystal orientation θ(x), and crystallinity η(x).(η is sometimes called order parameter or phase-field parameter.) Using the theory of Cahn and Hilliard (1958), they phenomenologically derived the free energy of this nonuniform system as a function of c(x), θ(x), and η(x). By calculating the condition which minimize the free energy, we can predict the equilibrium composition and crystallinity of the grain boundary as functions of temperature. Occurrence of grain boundary premelting can be predicted as an increase in grain boundary disorder (decrease in η at x=0) near the eutectic temperature. We investigate the effects of various model parameters, such as melting temperature, melting enthalpy, and grain boundary misorientation, on the grain boundary crystallinity.

Size effects on hardness and fracture toughness of olivine

*Sanae Koizumi[1], Tohru S Suzuki[2], Takehiko Hiraga[1]

1. Earthquake Research Institute,The University of Tokyo, 2. National Institute for Materials Science

We conducted Vickers indentation tests on Fe-free (Mg_2SiO_4) and Fe-bearing ($Mg_{1.8}Fe_{0.2}SiO_4$) olivine. Their single crystals and highly-dense polycrystalline materials with various average grain sizes (d) from 170 to 890 nm were tested. The largest Vickers microhardness (H_v) of 18 GPa at the lowest load of 0.1 N, which corresponds an indentation depth (h) of 0.6 μm was measured from the polycrystalline material with the finest grain size. The H_v decreases with increasing d and h, both of which are represented by $H_v \propto l^x$ where l corresponds to both sizes with a common x value of ~0.09. The relationship no longer holds at of > 4 μm and of > 1 μm where H_v take constant values of ~9.5 and ~8 GPa for Fe-free and Fe-bearing olivine, respectively. Fracture toughness (K_{IC}) measured from indentation diagonal size and length of cracks radiated outward from the indentation corners is ~0.8 MPa・$m^{1/2}$ for the polycrystalline materials, whose value does not change with the applied load, and olivine chemistry and grain size. The single crystals exhibit lower and orientation dependent toughness from 0.4 to 0.7 MPa・$m^{1/2}$.

Dislocation creep of dry orthoenstatite aggregates under high *P-T* conditions

*Yumiko Tsubokawa[1], Tomohiro Ohuchi[1], Yuji Higo[2], Yoshinori Tange[2], Tetsuo Irifune[1]

1. Ehime University Geodynamics Research Center, 2. Japan Synchrotron Radiation Research Institute

Large-scale tectonic processes such as subduction of slabs depend critically on the rheological behaviour of major mantle minerals. Because olivine is the most dominant mineral under the lithospheric conditions, viscosity of dry olivine have been considered to control the strength of the oceanic lithosphere. However, this assumption needs to be reconsidered because olivine is too strong to allow the operation of plate tectonics (Kohlstedt et al., 1995). Ohuchi et al. (2011) showed that orthoenstatite, the second most abundant mineral, could be much weaker than olivine at lithospheric temperatures. Creep strength of polycrystalline orthoenstatite needs to be considered when we discuss the strength of lithosphere because mechanical data on single crystals give the upper/lower limits of the strength of orthoenstatite.

In order to determine the flow-law parameters for dislocation creep of orthoenstatite under the lithospheric conditions, deformation experiments of dry orthoenstatite aggregates were conducted at high temperatures (up to 1473 K) and high pressures (1.8-4.7 GPa) using a deformation DIA (D-DIA) apparatus combined with synchrotron X-ray radiation. Orthoenstatite aggregates, fabricated from powdered natural single crystals, were fired under controlled oxygen fugacity conditions near the FMQ-buffer to remove dissolved water in the samples. Applied differential stress and axial strain were measured using monochromatic X-ray diffraction patterns of orthoenstatite and radiograph images, respectively.

At a constant strain rate ranging from 7.7×10^{-6} to 5.2×10^{-5} s^{-1} , a steady-state creep strength (200-1200 MPa) was achieved at a strain higher than 4% during the uniaxial compression. The water content of samples was mostly less than 50 ppm (H/Si) through a sample deformation. Steady-state creep strength at each experimental conditions followed the power-law dislocation creep with the stress exponent n~3. TEM observations showed development of dislocations with the Burgers vector of either [001] or [0kl] in the recovered samples. The n and the activation energy (Q^* ~170 kJ/mol) , and Burgers vector determined in this study are comparable to those for the [001](010) slip system of dry orthoenstatite (Ohuchi et al., 2011). Viscosity of dry orthoenstatite is ~10 times lower than that of dry olivine (calculated from the flow law by Karato and Jung, 2003) under our experimental conditions (in the case of uniform stress at lithospheric conditions), suggesting that operation of plate tectonics is possible if the strength of a subducting slab is controlled by orthoenstatite.

[S-CG61] Dynamics in mobile belts

convener:Yukitoshi Fukahata(Disaster Prevention Research Institute, Kyoto University), Toru Takeshita(Department of Natural History Sciences, Graduate School of Science, Hokkaido University), Hikaru Iwamori(Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology), Chairperson:Keisuke Yoshida(東北大学大学院理学研究科 地球物理学専攻), Masaoki Uno(東北大学)

The dynamic behaviours of mobile belts are expressed across a wide range of time scales, from the seismic and volcanic events that impact society during our lifetimes, to orogeny and the formation of large-scale fault systems which can take place over millions of years. Deformation occurs on length scales from microscopic fracture and flow to macroscopic deformation to plate-scale tectonics. To gain a physical understanding of the dynamics of mobile belts, we must determine the relationships between deformation and the driving stresses due to plate motion and other causes, which are connected through the rheological properties of the materials. To understand the full physical system, an integration of geophysics, geomorphology, and geology is necessary, as is the integration of observational, theoretical and experimental approaches. In addition, because rheological properties are greatly affected by fluids in the crust and fluid chemical reactions, petrological and geochemical approaches are also important. After the 2011 great Tohoku-oki earthquake, large-scale changes in seismic activity and regional scale crustal deformation were observed, making present-day Japan a unique natural laboratory for the study of the dynamics of mobile belts. This session welcomes presentations from different disciplines, such as seismology, geodesy, tectonic geomorphology, structural geology, petrology, and hydrology, as well as interdisciplinary studies, that relate to the dynamic behaviours of mobile belts.

Deciphering dynamics of thermal events at lithosphere-asthenosphere boundary from peridotite xenoliths of Ichinomegata maar, NE Japan

*Yuto Sato[1], Kazuhito Ozawa[1]

1. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo

Mantle xenoliths are fragments of mantle materials almost instantaneously transported to the surface by alkali basalt or kimberlite magmas (Nixon, 1987). They are unique in that they record temporal changes of mantle processes in chemical zonings and microstructures of constituent minerals. Thus, such information can potentially constrain time-dependent dynamic processes occurring in the lithosphere-asthenosphere boundary (LAB) zone, where mechanisms of heat and material transfer drastically change (Sleep, 2005, 2006). In this regard, Takahashi (1980) and Koyaguchi (1986) achieved key contributions. They examined chemical zonings of olivine and pyroxenes in spinel peridotite xenoliths from Ichinomegata, a latest Pleistocene andesitic-dacitic maar located in the back-arc side of NE Japan arc (Katsui et al., 1979). They clarified a variety of thermal history that the xenoliths underwent, but processes responsible for the diversity is not resolved yet because the derivation depth was not constrained. We have conducted very careful geothermobarometry of spinel peridotite xenoliths from Ichinomegata maar and successfully reconstructed the thermal, chemical, and rheological structures of the LAB zone beneath NE Japan arc at the time of Ichinomegata maar formation (80-60 ka) (Sato and Ozawa, 2017, 2018, JpGU meeting; Sato and Ozawa, 2016, 2017, AGU fall meeting; see our companion presentation in this meeting). We examined temporal changes of the structures through analyses of chemical zonings of pyroxenes in 9 plagioclase and spinel peridotite xenoliths from Ichinomegata.

In our previous study, the depths and temperatures of 8 of the 9 xenoliths just before the xenolith extraction are estimated to range 28-55 km and 828-1081 ˚C. The mantle beneath Ichinomegata consists of shallow (28-32 km), low temperature, granular (less strained), and amphibole-bearing zone and deep (41-55 km), high temperature, porphyroclastic (strained), and amphibole-free and melt-bearing zone. We identified the shallower zone as lithospheric mantle, the deeper zone as LAB zone, and that their boundary was controlled by wet solidus.

We obtained Ca, Al, Cr, and Ti zonings of large clinopyroxene and orthopyroxene using EPMA at the University of Tokyo and analyzed them with a diffusion model. The zoning patterns of Ca, Al, and Cr of pyroxenes allow us to identify 4 different thermal histories from 4 types of chemical zonings for orthopyroxene (O1-O4) and 3 types for clinopyroxene (C1-C3) as summarized in Table 1. They are (1) continuous cooling at a cooling rate of ~$1x10^{-4}$ ˚C/y over the time scale of ~1-10 million years from ~1000 to ~830 ˚C (constrained from O1 and C1), (2) cooling followed by weak heating at ~900 ˚C over the time scale of ~10-100 thousand years (from O2 and C1), (3) cooling followed by strong heating at ~1050 ˚C over the time scale of ~1-100 thousand years (from O3 and C2), and (4) prolonged cooling and heating at ~1000 ˚C (from O4 and C3). There is a systematic depth variation of thermal histories as summarized in Table 2. It is notable that the shallow lithospheric mantle is characterized by simple cooling or cooling followed by weak heating and the deep LAB zone by cooling followed by strong heating. This systematic depth variation requires a thermal perturbation of asthenospheric mantle beneath the deeper LAB zone, most plausibly asthenospheric upwelling.

The age of the Japan Sea opening is comparable to the time scale of cooling estimated from O1 and C1, and the continuous cooling at the shallow lithospheric mantle is attributable to the cooling of the

©2019. Japan Geoscience Union. All Right Reserved.

back-arc basin lithosphere, The timescale of the heating event in the deep LAB zone is too short to be explained by LAB-fixed heat conduction model. Effective heat transportation mechanisms are necessary, either partial crystallization of melt generated in the asthenosphere that passed through the LAB zone as advocated by Takahashi (1980) or extensive lithosphere thinning.

Experimental investigation of reaction-induced stress and permeability evolution in MgO–H_2O system

*Masaoki Uno[1], Hisamu Kasahara[1], Atsushi Okamoto[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies, Tohoku University

Crustal and mantle hydration reactions at subduction zones accompany large solid volume change as much as several vol.% to several tens of vol.%. Such large solid volume change can generate stress and fractures, accelerate reactions and fluid migrations (e.g., Kelemen and Hirth, 2012), and potentially influence the fluid transport in the crust and mantle (e.g., Jamtveit et al., 2000). Field observations of serpentinization and peridotite carbonation suggest fracture generation and permeability enhancement by such “reaction-induced stress” (e.g., Jamtveit et al., 2008; Plumer et al., 2012). However, the permeability enhancement during hydration reaction have not been reproduced by experiments, and the mechanisms and conditions of permeability enhancement by volume-increasing reactions remain largely unknown.

To understand the controlling mechanisms of fluid flow during hydration reactions, we show one of the first experimental trial to measure the permeability evolution during hydration reactions. We use MgO–H_2O system, where periclase (MgO) react with H_2O to produce brucite ($Mg(OH)_2$). The reaction involves solid volume increase of as much as +119%. Our earlier experiments have revealed that the reaction-induced stress in this system are controlled by the competition of reaction rate and stress-dependent deformation rate, and exceeds 40 MPa in this system which well exceeds the tensile strength of crustal rocks.

In this presentation, we have conducted flow thorough experiments to reveal the permeability evolution during hydration reactions. Experiments were conducted with sintered MgO with 4–14 vol.% porosity, under 100–300˚C with 5–50 MPa confining pressure and 5–15 fluid pressures. Preliminary experiments showed rapid permeability decrease in 2–3 orders, and finally the stainless sleeve broke by the reaction-induced expansion. The rate of permeability decrease is a function of the confining pressure, suggesting that the deformation of the reactant (brucite) has significant control over the permeability evolution during hydration reactions. We will present further experiments with various reaction rate/deformation rate ratios, and discuss the controlling factors of permeability enhancement/reduction during hydration reactions.

Fluid-Flow, Resistivity and Elastic Wave Velocity Simulation of Digital Rock Fracture and Comparison with Experimental Data

*Kazuki Sawayama[1], Fei Jiang[2], Takuya ISHIBASHI[3], Takeshi Tsuji[4], Yasuhiro Fujimitsu[4]

1. Department of Earth Resources Engineering, Graduate school of engineering, Kyushu University, 2. Department of Mechanical Engineering, Faculty of Engineering, Yamaguchi University, 3. Fukushima Renewable Energy Institute, National Institute of Advanced Industrial Science and Technology, 4. Department of Earth Resources Engineering, Faculty of engineering, Kyushu University

Fluid-flow in the fracture plays a key role to evaluate the mechanism of earthquake and fractured reservoirs (e.g., geothermal and shale) since fracture flow constrains the fluid-flow behavior and rock strength under the ground. To predict the fluid-flow and its distribution under the ground, geophysical explorations (seismic and electromagnetic methods) have been broadly applied. However, there is no established rock physical model to estimate the fluid-flow properties (e.g., permeability) in the fracture from resistivity or elastic wave velocity, and thereby fluid-flow behavior in the fracture are difficult to be precisely interpreted by geophysical explorations. For the better interpretation of these exploration data, more detailed investigation about the effect of fluid-flow behavior on resistivity and elastic wave velocity of fractured rocks is required. In this study, in order to discuss this effect, we measured and calculated them by using fractured rock samples which have different apertures.

We conducted laboratory fluid-flow testby using fractured Inada granite (50 mm in a diameter, 80 mm in a length) which have single tensile fracture with different aperture. For the numerical model, we digitalized this real rock fracture (0.1 mm grid resolution) to calculate fluid-flow, resistivity and elastic wave velocity under the same condition with experiment. Three dimensional fracture flow was simulated by using Lattice Boltzmann Method and we applied Finite Element Analysis to calculate resistivity and elastic wave velocity after this fluid-flow simulation.

As a result, permeability decreases with pressure increase under laboratory experiment and calculated permeability also shows the decrease as the aperture increases. This agreement suggests that fracture permeability is constrained by aperture closure due to the pressure effect. From the permeability matching approach, we found that permeability dramatically decreases after the fracture contact area exceeds ~80%. At this threshold value, fluid-flow path, resistivity and elastic wave velocity show inflections. Our results suggest that permeability change caused by aperture closure could be estimated by seismic and electromagnetic explorations.

Fluid distribution in the crust –inference from seismic velocity and electrical conductivity

*Tohru Watanabe[1], Kenta Yoshida[2]

1. Gradudate School of Science and Engineering, University of Toyama, 2. Research and Development Center for Ocean Drilling Science, Japan Agency for Marine-earth Science and Technology

Aqueous fluids must play important roles in crustal dynamics including seismicity. Geophysical mapping of fluids will thus give us insights into crustal dynamics. Electrical conductivity profiles have suggested that fluids exist pervasively in the crust. However, the fluid distribution has not been quantitatively constrained. It must be due to our poor understanding of pores that govern seismic velocity and electrical conductivity under high pressures.

In order to understand pores governing physical properties under pressures, simultaneous measurements of elastic wave velocities and electrical conductivity were conducted on a brine saturated granitic rock (Aji granite) under pressures up to 150 MPa and microstructure of pores was observed by X-ray micro CT and SEM with ion-milling and FIB. X-ray micro CT images show that many grain boundaries are open at atmospheric pressure. Elastic wave velocity increases and electrical conductivity decreases with increasing confining pressure. Most of grain bouundary cracks are closed under high pressures (>100 MPa). The electrical conductivity is, however, still much higher than that of the solid phase. The brine must be interconnected under high pressures. SEM images suggest that wide aperture parts in grain boundaries are open even at high pressures and form conduction paths.

There should be cracks with various sizes in the crust: from grain boundaries to large faults. Though cracks are closed under pressure, there must be a variation in the aperture. Wide aperture parts may form conduction paths even under high pressures. The influence of wide aperture parts on physical properties can be evaluated by tube model. Electrical conductivity is proportional to the fluid volume fraction. A change in conductivity by 4 orders of magnitude requires a change in fluid volume fraction by 4 orders of magnitude. However, seismic velocity for tube model is insenstive to fluid volume fraction. Seismic velocity will thus show relatively small decrease for a large change in fluid fraction. Observed large variation in conductivity and relatively small variation in seismic velocity (e.g., Ogawa et al., 2001; Matsubara et al., 2004) are consistent with tube model. The variation in fluid fraction must reflect that in the amount of wide aperture parts, which is attributed to the variation the amount of cracks.

The seismological structure about fault zone extending to the lower crust in the northern Kinki district, southwestern Japan

*Shinya Kato[1], Yoshihisa Iio[1], Takuo Shibutani[1], Hiroshi Katao[1], Masayo Sawada[1], Kazuhide Tomisaka[1]

1. Disater Prevention Research Institute, Kyoto University

The “water-weakened lower crust model” has been proposed to explain the mechanism of stress concentration on faults of inland earthquakes (Iio et al. 2002). According to this model, it is necessary that heterogeneous structure caused by the fluid exists locally in the deeper part of fault zones in the lower crust, but it has not been clearly confirmed in previous researches. This is because we do not resolve the heterogeneous structure due to fluid in the deeper part of fault zones in the lower crust. In order to solve this problem, in this study, we tried to image the heterogeneous structure in the lower crust in detail.

We conducted S-wave reflection analysis to detect the horizontal distribution of the heterogeneous structure (reflector), and receiver function analysis to estimate the structure beneath the reflector, in the northern Kinki district, southwestern Japan. As a result of the S-wave reflection analysis, it is found that the reflector exists on the north side of the Arima-Takatsuki fault zone and does not exist on the south side of it. We consider that the distribution of the reflector is related to the Arima-Takatsuki fault zone. From a result of the receiver function analysis, it is found that reflector is a thin layer with low S-wave velocity.

It is concluded that the thin layer with low S-wave velocity exists in the lower crust of the northern Kinki region. As the origin of it, it is possible to consider fluid dehydrated from the Philippine Sea slab subducting beneath the Arima-Takatsuki fault zone. In the vicinity of the Arima-Takatsuki fault zone, it is known that fluid that seems to originate in the mantle springs out (Kazahaya et al. (2014)). In the lower crust, pores between minerals exist independently (Yoshino et al. 2002), and fractures caused by faulting is thought to be necessary for fluid movement (Mibe et al. (2000)). Furthermore, since the spatial distribution of the reflector is related to the Arima-Takatsuki fault zone, we consider that the reflector in the lower crust indicates that fluid exists in fractures caused by faulting. This result supports the water-weakened lower crust model.

Inland repeating earthquakes in the vicinity of low frequency earthquakes around Hakodate, Hokkaido

*Keisuke Yoshida[1], Akira Hasegawa[1], Shinako Noguchi[2], Keiji Kasahara[2]

1. Tohoku University, 2. Association for the Development of Earthquake Prediction

Strength reduction due to pore pressure increase plays an important role for the generation of earthquakes. Earthquake swarms in central Tohoku activated after the 2011 Tohoku-Oki earthquake are examples of this; they are estimated to be caused by the upward fluid migration due to the decrease of WNW-ESE compressional stress after the earthquake (Yoshida & Hasegawa, 2018a and b). Inland deep low frequency earthquakes are also considered to be closely related to the fluids (e.g., Hasegawa & Yamamoto, 1994), but their detailed mechanism is poorly understood. In this presentation, we introduce our recent study on earthquakes occurring in Hakodate, Hokkdaido, which are covered by a dense seismic network installed by the Association for the Development of Earthquake Prediction (ADEP) (Noguchi et al., 2017). In this area many low frequency earthquakes are occurring, shallow ones of which occur in the immediate vicinity of ordinary earthquakes. This provides a unique opportunity to investigate the relationship between the diversity of fault motions and the fluid behavior.

We start by relocating hypocenters of ordinary earthquakes and low frequency earthquakes by applying the double-difference location method (Waldhauser & Ellsworth, 2002). We used precise differential arrival time data of P- and S-waves obtained by the waveform cross-correlation following Yoshida & Hasegawa (2018), which largely improved the accuracy of relative hypocenter locations. We relocated hypocenters of 198 earthquakes for the period from 2003 to Oct. 2018, which are listed in the JMA unified catalog or in the ADEP catalog; 22 of them are ordinary earthquakes and 176 are low frequency earthquakes. Relative locations of ordinary earthquakes are very precisely determined due to the similarity of waveform, but those of low frequency earthquakes are almost controlled by the manually picked arrival time data because of the diversity of their waveforms.

Relocated hypocenters show that low frequency earthquakes are distributed in a plate shape dipping eastward with focal depths from 5 to 35 km, which are confirmed by the S-P times obtained at the stations just above their epicenters. Low frequency earthquakes occurring in the shallow part of the crust are located in the immediate vicinity of ordinary earthquakes. We found that the initial parts of P- and S-waves of these low frequency earthquakes have similar waveform characteristics with those of the nearby ordinary earthquakes. Furthermore, ordinary earthquakes occurring near the low frequency earthquakes have very similar waveforms themselves. They turned out to be inland repeating earthquakes based on the hypocenter relocations using precise differential arrival times obtained by the waveform cross-correlation. Other repeating earthquake sequences were also found based on the template matching method (Shelly et al., 2013). Some earthquakes in one of those repeating earthquake sequences occur with a time interval of about ten minutes or so. Similar repeating earthquake occurrences with such a short time interval have been found in an induced seismicity of a recent fluid-injection experiment (Lengline et al., 2014), which suggests that natural repeating earthquakes are also caused by a similar mechanism to the fluid injection induced seismicity; slips are repeatedly caused in the same locations due to successive reduction in frictional strength by the pore pressure increase.

[S-CG61] Dynamics in mobile belts

convener:Yukitoshi Fukahata(Disaster Prevention Research Institute, Kyoto University), Toru Takeshita(Department of Natural History Sciences, Graduate School of Science, Hokkaido University), Hikaru Iwamori(Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology), Chairperson:Bunichiro Shibazaki, Daisuke Sato

The dynamic behaviours of mobile belts are expressed across a wide range of time scales, from the seismic and volcanic events that impact society during our lifetimes, to orogeny and the formation of large-scale fault systems which can take place over millions of years. Deformation occurs on length scales from microscopic fracture and flow to macroscopic deformation to plate-scale tectonics. To gain a physical understanding of the dynamics of mobile belts, we must determine the relationships between deformation and the driving stresses due to plate motion and other causes, which are connected through the rheological properties of the materials. To understand the full physical system, an integration of geophysics, geomorphology, and geology is necessary, as is the integration of observational, theoretical and experimental approaches. In addition, because rheological properties are greatly affected by fluids in the crust and fluid chemical reactions, petrological and geochemical approaches are also important. After the 2011 great Tohoku-oki earthquake, large-scale changes in seismic activity and regional scale crustal deformation were observed, making present-day Japan a unique natural laboratory for the study of the dynamics of mobile belts. This session welcomes presentations from different disciplines, such as seismology, geodesy, tectonic geomorphology, structural geology, petrology, and hydrology, as well as interdisciplinary studies, that relate to the dynamic behaviours of mobile belts.

Modeling strain concentration and mountain building processes in central Japan considering heterogeneous rheological structure

*Bunichiro Shibazaki[1]

1. International Institute of Seismology and Earthquake Engineering, Building Research Institute

Recent analysis of crustal deformation using GEONET data has revealed the existence of several strain concentration zones in the Niigata–Kobe Tectonic Zone (Sagiya, et al., 2000), in the Ou backbone range (Miura et al., 2004), in Kyushu, and San-in (Nishimura et al., 2018), etc. Many large inland earthquakes have occurred in the strain concentration zones. Elucidating the mechanism of strain concentration leads to understanding generation processes of large inland earthquakes. We develop a model of strain concentration and mountain building in the island-arc crust of central Japan, where several high mountain ranges have been formed by active crustal deformation. We use the finite element code with nonlinear viscoelasticity and plasticity based on Mohr-Coulomb criterion (e.g. Shibazaki et al., 2016). We consider gravitational force as a body force because the plasticity and the flow law depend on absolute stress.

Based on dense geothermal gradient data from Hi-net (Matsumoto et al., 2007) and the Geological Survey of Japan (Tanaka et al., 2004), we develop a thermal structure. We also consider a thick sedimentary layer where the friction coefficient is low based on the J-SHIS deep subsurface structure (NIED). Numerical results show that under the compressional tectonic setting, mountains are reproduced along high geothermal gradient regions. We can reproduce the Hida mountain range, Chikuma mountain, Echigo mountain range, and others, where a geothermal anomaly exists. Our model can also reproduce strain concentration in the Hida region. Furthermore, we can reproduce a strain concentration zone by setting the frictional coefficient to be low in the basement of the Niigata region.

However, the model cannot reproduce the strain concentration zone in the Atotsugawa and Kinki regions where strike slip faulting is dominant; therefore, we consider the boundary condition that yields the stress state of the strike-slip faulting and the effect of water distribution or rheology of partial melting based on seismic velocity anomalies (Nakajima and Hasegawa, 2007). We can reproduce strain concentration along the seismic velocity anomalies. Our results suggest that the Niigata-Kobe strain concentration zone is developed by several factors: thermal anomaly, pre-existing rift structure, and the presence of fluid and partial melting in the crust and the upper mantle.

Inelastic strain rate and deviatoric stress field of the seismic gap in west part of Kyushu, Japan, estimated from seismic and geodetic data

*Yuhei Yuasa[1], Satoshi Matsumoto[2], Shigeru Nakao[3], Takeshi Matsushima[2], Takahiro Ohkura[4]

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University, 2. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, 3. Department of Earth and Environmental Sciences, Graduate School of Science and Engineering, Kagoshima University, 4. Aso Volcanological Laboratory, Institute for Geothermal Sciences, Graduate School of Science, Kyoto University

An earthquake is a phenomenon that differential stress loading on the Earth’ s crust is released. Thus, we need to know state of stress in the crust to understand the earthquake generation mechanism. The state in the crust has been investigated in many studies, based on data of the focal mechanisms and seismic moment tensors (e.g., Michael 1984; Horiuchi et al. 1995; Terakawa & Matsu’ ura 2008). However, information on the stress fields in non-active seismic areas is insufficient because accurate stress estimation requires the data from a number of earthquakes. A key factor for acquiring knowledge of the stress field in an aseismic zone is the inelastic strain, which is related to the deviatoric stress based on the flow rule in plasticity theory (Matsumoto 2016). Thus, the strain rate due to inelastic deformation source needs to be separated from the total strain rate measured via geodetic observation. Here, we propose a new method for estimation of the deviatoric stress field through inelastic strain analysis that combines the seismic moment tensor and geodetic data. In this method, the deformation source of inelastic strain in the upper crust is estimated from short wavelength component of the observed total strain rate field, and the inelastic source tensor yields tensor shape of deviatoric stress field based on the flow rule. This method is applied to data for a region in and around the aseismic zone of Amakusa located at west part of Kyushu Island, Japan. It was found that the inelastic deformation in the seismic gap exhibits either normal-fault or strike-slip type. Furthermore, the deviatoric stress field estimated from the inelastic deformation has same trend as the surroundings. In addition, the estimated stress explained slip vectors of event rarely occurring there. These results might provide us with important information regarding the origin of the seismic gap and stress concentration on the surrounding fault.

Persistent and time-dependent crustal deformation in northern Fossa Magna and its tectonic implications

*Takeshi Sagiya[1], Koki Kumagai[2], Angela Meneses-Gutierrez[3], Nobuhisa Matsuta[4], Daisuke Hirouchi[5], Kenjiro Matsuhiro[2], Takashi OKUDA[2]

1. Disaster Mitigation Research Center, Nagoya University, 2. Graduate School of Environmental Studies, Nagoya University, 3. Disaster Prevention Research Institute, Kyoto University, 4. Graduate School of Education, Okayama University, 5. Faculty of Education, Shinshu University

In the northern Fossa Magna of the northern Nagano Prefecture, GNSS observations over last two decades identified a rapid E-W contraction around the northern Itoigawa-Shizuoka Tectonic Line (ISTL) and the Western Nagano Basin Fault (WNBF). After the 2011 Tohoku-oki earthquake, postseismic deformation with a large E-W extension occurred throughout northeast Japan. However, the northern Nagano area has been still under contraction, implying that the local contraction is a persistent deformation feature. Similar persistent deformation was identified in the Niigata area by Meneses-Gutierrez and Sagiya (2016) and around other active faults in central Japan. These observations illustrate that there exists persistent localized deformation in the lower crust beneath active faults, driven by the regional stress field. This localized deformation in the lower crust is the driving force for faults in the upper crust. The persistent local crustal deformation around active faults suggests that the long-term inland deformation and resultant inland seismic activity are steady over a longer time scale than that of an earthquake cycle at subduction zones. On the other hand, after the 2014 Northern Nagano Earthquake (Mw6.3) along the northern ISTL, an acceleration of contraction along the WNBF was identified. This observation implies that the northern ISTL and WNBF are not independent but mechanically interact each other, forming an active deformation system that accommodates regional deformation. Such a complicated behavior of the fault system implies that the long-term activity of each fault in the system is not steady but time-dependent. Such a time-dependence may be a cause of irregular activity of inland faults and such a possibility should be considered for evaluation of seismic hazard.

Unexpected relationship between ΔCFF and the strain-rate paradox: separation of plastic strain from inelastic strain

*Yukitoshi Fukahata[1], Angela Meneses-Gutierrez[1], Takeshi Sagiya[2]

1. Disaster Prevention Research Institute, Kyoto University, 2. Disaster Mitigation Research Center, Nagoya University

In the field of seismic activity, the phenomena of stress shadow is well known, that is to say, the area with negative ΔCFF after an large earthquake tends to have fewer aftershocks (e.g., Toda et al. 2011, GRL). The concept of ΔCFF is also usful to understand earthquake activity for longer time scales as exemplified by Shikakura et al. (2014, JGR), which shows that large inland earthquakes that happened in western Japan recent 500 years can be very well exlpained by the change history of ΔCFF, which is mainly controled by the repeated occurrences of the Nankai earthquakes and secular increase of east-west compression.

Meneses-Gutierrez and Sagiya (2016, EPSL) have successfully separated the component of inelastic strain from the analysis of pre- and post-seismic GNSS data of the 2011 Tohoku-oki earthquake in the area around the Niigata prefecture. However, when we examine the observed GNSS data in detail, the separated inelastic strain rate is slightly but clearly faster before the Tohoku-oki earthquake. If the inelastic strain is due to viscous flow that depends only on the absolute stress, it is difficult to explain the observed GNSS data, because the stress change due to the 2011 Tohoku-oki earthquake in this area is less than 1 MPa, which is likely to be much smaller than the absolute stress.

Therefore, we consider that the concept of ΔCFF could be applicable not only to seismic activity but also to crustal deformation. In other words, we consider that the change of the inelastic strain rate is caused by plastic strain, which was active before the 2011 Tohoku-oki earthquake but ceased after the earthquake, because the stress level is dropped due to the occurrence of the 2011 Tohoku-oki earthquake, although inelastic strain due to viscous flow occurs essentially in the same manner before and after the 2011 Tohoku-oki earthquake.

If we accept this concept, the strain rate paradox of Japan is viewed differently, that is, the strain rate was exceptionally faster before the 2011 Tohoku-oki earthquake. It might also be possible to issue more effective warnings of large inland earthquakes in western Japan from detailed analyses of crustal deformation data.

Active period of inland earthquakes based on numerical simulation of megathrust earthquake cycle incorporating viscoelasticity

*Tsukasa MITOGAWA[1], Takuya NISHIMURA[2]

1. Graduate School of Science, Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University

In the subduction zone, megathrust earthquakes may modulate shallow crustal seismicity in the overriding plate. Historical documents demonstrate that large inland earthquakes frequently occurred for 50 years before and 10 years after megathrust earthquakes along the Nankai trough, southwest Japan. Previous studies suggest that inland earthquakes cannot occur until recovering the stress reduced by a megathrust earthquake on the fault. In this study, we modeled megathrust earthquake cycle in a simple oblique subduction zone and calculated temporal evolution of the Coulomb’ s Failure Stress changes (ΔCFS) on inland right-lateral strike-slip faults. And we examined the influence of megathrust earthquake cycle on the activity tune of inland earthquake.

Sources for loading inland faults are assumed to be interseismic locking and coseismic slip on the megathrust fault, stress changes due to inland earthquake and interaction between inland earthquake, and creep on a deeper extension of the inland faults. The stress change due to the megathrust fault was computed with numerical code by Fukahata and Matsu'ura (2006), assuming a medium composed of an elastic layer overlying a Maxwell viscoelastic half-space. We focus on ΔCFS depending on the distance from the megathrust fault, not its along-strike variation. In other words, only two-dimensional stress change at the center of a sufficiently long thrust fault plane (length 2000 km) is calculated. The megathrust fault is represented by a single rectangular fault whose depth, width, strike, dip, and rake are 11 km, 108 km, 270˚, 10˚, and 117˚, respectively. We assigned 6 m of coseismic slip at an interval of 100 years and 6 cm/year of back-slip during the interseismic period on the megathrust fault.The inland faults are located at 150 km (hereafter fault A) and 300 km (hereafter fault B) away from the upper edge of the megathrust fault and their depth, length, width, strike, dip, and rake are 4 km, 30 km, 6 km, 110˚, 90˚, and 180˚, respectively. Coseismic slip of 2 m was assigned when ΔCFS at the center of the inland faults exceeded 4.4 MPa.Becuase the code of Fukahata and Matsu'ura (2006) approximates a rectangular fault by numbers of point sources, a stress change on the fault plane can’ t be calculated. Therefore, we calculated a coseismic stress change on the fault plane assuming a semi-infinite elastic medium (Okada, 1992). In addition, stress loading by creep on a deeper extension of the inland faults was given to each inland fault at a constant rate.

ΔCFS on both inland faults is negative at the megathrust earthquake. When the stress loading rate is 5 kPa/year, the inland earthquake does not occur for 42 years on fault A and 15 years on fault B after the megathrust earthquake. Our interpretation is that viscoelastic effects of megathrust earthquakes makes these quiescence periods shorter and longer for faults A and B, respectively. Also, when the stress loading rate is 0.5 kPa/year, the quiescence period is 83 and 71 years for faults A and B. It is interesting that the quiescence period is not much dependent on the distance from the megathrust fault if the stress loading rate is small, though ΔCFS on both inland faults is highly dependent on the distance at the megathrust earthquake.

Influence of viscoelastic relaxation on estimated interplate coupling along the Nankai Trough, southwest Japan

*Takuya NISHIMURA[1], Fred F Pollitz[2]

1. Disaster Prevention Research Institute, Kyoto University, 2. U.S. Geological Survey

Viscoelastic relaxation in asthenosphere is an important factor for understanding crustal deformation in the subduction zone. Although interplate coupling on subduction interface has often been estimated from geodetic data using a purely elastic dislocation model, several recent studies (e.g., Li et al., 2015) pointed out that ignoring viscoelasticity in the medium made estimated coupling distribution biased. Pollitz and Evans (2017) developed viscoelastic block models introducing a viscoelastic correction term for earthquake cycles to estimate both interplate coupling and rigid rotation of microplates in western US. Once you subtracted the viscoelastic correction velocities from observed ones, the corrected velocities can be inverted by conventional elastic block models. The viscoelastic correction term consists of two components. One (hereafter, 1st component) is viscoelastic velocities due to interplate locking in the past, which is constant over the interseismic period. The other (hereafter, 2nd component) is total postseismic velocities of past earthquakes repeated with a certain recurrence interval, which is dependent on a time from the last earthquake. Here we examine these viscoelastic correction components for megathrust earthquake cycles along the Nankai trough.

We calculated viscoelastic deformation using VISCO1D (Pollitz, 1997) and assumed a 35 km thick elastic plate overriding a Maxwell viscoelastic half-space with a viscosity of 10^{19} Pa s. Coseismic fault model for the 1944 Tonankai and 1946 Nankai earthquakes estimated by Sagiya and Thatcher (1999) is used for viscoelastic calculation. A recurrence interval of megathrust earthquakes is 117 years and slip deficit accumulated for the interseismic period is completely released by the megathrust earthquakes. Figs. A-C show 1st and 2nd components as well as the sum of them as of 2007. 1st component represent a difference between elastic and viscoelastic responses of locking that has continued since the infinite past. It reaches 2 cm/yr along the Pacific coast and several mm/yr even along the coast of Sea of Japan (Fig. A). 2nd component is generally reverse to 1st component and decays with time from the last earthquake. Amplitude of 2nd component is roughly equal to that of 1st component 30 years after the last earthquake. Therefore, total viscoelastic correction is minimized 30 years after the last earthquakes during the interseismic period. Even after 61 years of the last earthquakes, velocities of 2nd component is still comparable to those of 1st component (Fig. B). Total correction velocities, therefore, exceed 2 mm/yr only near peninsulas along the Pacific Ocean (Fig. C). 2nd component reaches several mm/yr in the last years of the interseismic period for the Nankai subduction zone and cannot be ignored for better viscoelastic correction.

We present a result of applying viscoelastic correction to the block model of Nishimura et al.(2018) which models onshore GNSS and offshore GNSS-Acoustic velocities in southwest Japan.

[S-CG61] Dynamics in mobile belts

convener:Yukitoshi Fukahata(Disaster Prevention Research Institute, Kyoto University), Toru Takeshita(Department of Natural History Sciences, Graduate School of Science, Hokkaido University), Hikaru Iwamori(Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology), Chairperson:Naoki Uchida, Takeshi Iinuma

The dynamic behaviours of mobile belts are expressed across a wide range of time scales, from the seismic and volcanic events that impact society during our lifetimes, to orogeny and the formation of large-scale fault systems which can take place over millions of years. Deformation occurs on length scales from microscopic fracture and flow to macroscopic deformation to plate-scale tectonics. To gain a physical understanding of the dynamics of mobile belts, we must determine the relationships between deformation and the driving stresses due to plate motion and other causes, which are connected through the rheological properties of the materials. To understand the full physical system, an integration of geophysics, geomorphology, and geology is necessary, as is the integration of observational, theoretical and experimental approaches. In addition, because rheological properties are greatly affected by fluids in the crust and fluid chemical reactions, petrological and geochemical approaches are also important. After the 2011 great Tohoku-oki earthquake, large-scale changes in seismic activity and regional scale crustal deformation were observed, making present-day Japan a unique natural laboratory for the study of the dynamics of mobile belts. This session welcomes presentations from different disciplines, such as seismology, geodesy, tectonic geomorphology, structural geology, petrology, and hydrology, as well as interdisciplinary studies, that relate to the dynamic behaviours of mobile belts.

Revisiting the Forearc Sliver Scenario Along the Southern Kurile Trench to Reconcile Interdisciplinary Observations

*Yuji ITOH[1], Kelin WANG[2], Takuya NISHIMURA[3]

1. Graduate School of Science, Kyoto University, 2. Pacific Geoscience Centre, Geological Survey of Canada, 3. Disaster Prevention Research Institute, Kyoto University

Forearc sliver has been proposed as a mechanism to accommodate margin-parallel component of oblique plate convergence along the southern Kurile trench. The sliver scenario was established based mostly on the presence of the margin-perpendicular Hidaka Mountain Range (HMR), graben at Bussol Strait, en echelon Kurile Islands and high temperature metamorphic and intrusive rocks exposed at HMR. Along the volcanic front, geological faults including Kamishi-Yubetsu tectonic zone with 50 km right-lateral displacement was reported. Seismic velocity tomography and refraction/reflection experiments beneath HMR show the heterogeneous crustal structure relating to collision of the Kurile forearc and Northeast Japan arc, indicating upwelling of upper mantle, sinking of crustal material and delamination of upper mantle beneath HMR, and shortening in the foreland of HMR. Anomalous deep crustal earthquakes beneath HMR such as the 1970 M6.7 Hidaka and 1982 M7.1 Urakawa-oki earthquakes show active margin-parallel compression. However, other observations cast doubt on the forearc sliver being presently active. Although some active faults are reported along the volcanic front, they are not right-lateral faults. Interseismic GNSS velocities do not show localized right-lateral shear deformation along the volcanic front, although they show active margin-normal shortening in the foreland of HMR consistent with active collision. In this study, we propose a new scenario of forearc kinematics and strain partitioning along the southern Kurile trench to reconcile these seemingly discordant observations.

A mountain like HMR pushes sideways because of gravity and acts as a buttress of the forearc sliver to impede its migration. We compared the stress field inferred from CMT solution with that predicted from a buttressed sliver model. The comparison suggests that (1) the forearc sliver is buttressed at HMR and (2) resistance to right-lateral shear along the volcanic front is very large. Therefore, we propose a scenario as follows. The forearc sliver had been increasingly buttressed as HMR rose, so that the rate of strain partitioning diminished with time. Eventually, the forearc migration became too slow to cause recurring large earthquakes and to maintain a mature active fault zone along the volcanic front. As a result, the fault zone healed with time. At present, the forearc and backarc deform together without active faulting and localized shear along the volcanic front.

We also compared Kurile with other oblique subduction zones and found that margin (trench) curvature appears to principal control forearc kinematics. At Cascadia and Nankai where the margin is concave seaward, interseismic GNSS velocities do not show discernable localized shear to define the forearc sliver but strong margin-parallel shortening towards the area of maximum margin curvature. In contrast, in southernmost Chile where the trench is approximately straight, there is little margin-parallel shortening but significant forearc sliver migration. However, at Kamchatka, although the margin is concave off-Kamchatka Peninsula, significant margin-parallel migration of Aleutian Islands is still occurring, which we speculate is due to the extreme obliquity of plate convergence here. Even in this case, significant shortening is observed at the leading edge of the forearc sliver. The concave margin has buttressed the forearc sliver and caused shortening in the area of maximum curvature in the geological time scale as well because the tectonic setting itself, such as the margin curvature and the obliquity of plate convergence, is the controlling factor of the forearc kinematics.

Segmentation of crustal deformation area within the Sanriku coast, northeast Japan, on the basis of spatial distribution of millennial-scale crustal movements

*Yuichi Niwa[1]

1. Faculty of Science and Engineering, Chuo University

Along the Sanriku coast, northeast Japan, discrepancies in crustal movement have been reported between uplift on a timescale of 10^5 years (Koike and Machida, 2001) and subsidence on a timescale of 10^1 –10^2 years (Kato, 1983; Ozawa et al., 2011). Some hypothetical models, which explain these discrepancies, are proposed in relation to megathrust earthquake cycle (e.g., Ikeda et al., 2012; Nishimura, 2014). These models assume that crustal movement style is same within whole part of the Sanriku coast, and show that amount of accumulation of uplift exceeds that of subsidence during one earthquake cycle. However, because of lack of age data of marine terrace except for Hachinohe to Kuji (Miyazaki and Ishimura, 2018) and of putative marine terrace along the southern part of the Sanriku coast (Koike and Machida, 2001), spatial distribution of crustal movement cannot be estimated on the basis of only feature of Pleistocene marine terrace. On the other hand, sedimentary successions in alluvial plains distributed along the Sanriku coast may offer records of millennial-scale crustal movements during the Holocene.

Recent sediment core analyses and radiocarbon dating shows sedimentary succession influenced by sea-level changes during the past 10,000 years. In the Rikuzen-takata plain, Kesennuma Okawa plain, and Onuma, on the southern Sanriku coast, a millennial-scale subsidence is inferred on the basis of height distribution of intertidal sediments which is lower than non-tectonic relative sea-level (Niwa et al., 2014, 2015; Ishimura and Miyauchi, 2017). Depositional environment estimated from a sediment core of the Tsuya plain, between Kesennuma plain and Onuma, also support a millennial-scale subsidence (Niwa et al., 2016). In the Tsugaruishi plain, on the central coast, height distribution of intertidal sediments and aggradation of delta sediments since ca. 7500 cal BP indicates subsidence on a millennial-scale (Niwa et al., 2017). On the other hand, sedimentary feature typical of subsidence area is not identified in sediment cores obtained from Omoto plain, northern Sanriku coast, suggesting no noticeable subsidence on a millennial-scale (Niwa et al., in press).

Inferred millennial-scale crustal movements shows subsidence trend on central to southern Sanriku coast and relatively uplifting trend on northern part of the coast. This spatial distribution of millennial-scale crustal movements is consistent with geodetically estimated subsidence rate on a timescale of 10^1 –10^2 years (Kato, 1983) and the amount of subsidence at 2011 Tohoku-oki earthquake (Ozawa et al., 2011), indicating that the Sanriku coast presents a variety of crustal movement styles. These results suggest that the northern and the central to southern parts of the Sanriku coast should be considered separately when assessing crustal deformation related to subduction.

Shear wave splitting east off NE Japan based on the S-net data

*Naoki Uchida[1], Junichi Nakajima[2], Ryota Takagi[1], Keisuke Yoshida[1], Takashi NAKAYAMA[1], Ryota Hino[1], Tomomi Okada[1], Youichi Asano[3], Sachiko Tanaka[3]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions Graduate School of Science, Tohoku University, 2. Department of Earth and Planetary Sciences, Graduate School of Science and Engineering, Tokyo Institute of Technology, Tokyo, 3. National Research Institute for Earth Science and Disaster Resilience

We estimated the anisotropy of seismic wave speed by using shear wave splitting data in the offshore area of NE Japan. The analysis was made possible by the deployment of the Seafloor Observation Network for Earthquakes and Tsunamis along the Japan Trench (S-net) by National Research Institute for Earth Science and Disaster Resilience (NIED). We used the waveforms of 421 interplate earthquakes from August 2016 to October 2018 which are selected based on the focal mechanisms of Full Range Seismograph Network of Japan (F-net) operated by NIED and located under the S-net stations (within 35 degree from the vertical). We determined the fast polarization directions and delay times between fast- and slow-shear waves by the cross-correlation method.

The results show that the shear wave splitting tends to have trench parallel fast polarization direction for the region east off Chiba to Hokkaido which is the same with the observations in the land area of the forearc. Since we used earthquakes on the plate boundary, the anisotropy must be located in mantle wedge or forearc crust. The interpretation of the polarization includes the flow-normal fast direction of B-type olivine fabric in the forearc mantle-wedge and cracks aligned in the trench parallel direction due to the present forearc stress-field or fossil structures developed during the formation of the forearc.

Acknowledgements: We used S-net data which is deployed and maintained by NIED.

Gravity anomaly due to active faults and crustal rheology in the northeastern Japan arc inferred by fault dislocation model

*Mitsuhiro Hirano[1], Hiroyuki Nagahama[1], Jun Muto[1]

1. tohoku university

Short-wavelength Bouguer gravity anomaly reflects crustal structures including effective elastic thickness distribution in the northeastern (NE) Japan arc [1-3]. Moreover, earthquake epicenters and active faults tend to be located in the region of the negative gravity anomaly or high gradient in the anomaly in the NE Japan arc [1-3]. Following the relationship between gravity anomaly and active fault distributions, Yamazaki and Nagahama [4] derive an equation of static gravity change by volumetric strain due to fault dislocation, and argue that active faults contribute to Bouguer gravity anomaly in the NE Japan arc. On the other hand, seismicity and active fault distribution tend to be located in the region with high gradient of thermal gradients or along the boundary between high and low seismic wave velocity [5-7]. Thermal gradient and seismic wave velocity reflect mechanical behaviors (viscosity and elasticity) and they are indices of crustal rheology. However, relationship between gravity anomaly and the influence of the inhomogeneity in crustal rheological structures including active fault distributions have been not unknown yet. In addition, although large positive gravity anomaly is expected along the Ou-backbone Range by its pop-up structure, negative or small positive gravity anomaly zone exists along the Ou-backbone Range. So, we study relationship between gravity anomaly and rheological properties in the NE Japan arc. First, we calculated gravity anomaly due to volumetric strain by fault dislocation model in a homogeneous elastic half space. In this case, considering compressive stress field that has continued since 3 Ma in the NE Japan arc, we give total fault displacements in the 3 million years to active faults. This model calculation generates negative gravity anomaly less than 15 mGal around active faults and these generally agree with some negative areas of short-wavelength Bouguer gravity anomaly (such as the Ou-backbone Range, Yamagata Basin and the Niigata Plain). Next, we compare short-wavelength Bouguer gravity anomaly with three available datasets in the NE Japan (thermal gradient, crustal strain rate and P-wave velocity) along the two transects created normal to the arc. This comparison reveals the correlation between negative peak in the gravity anomaly and the peaks of thermal gradient and contraction, and negative peak of P-wave velocity around the Ou-backbone Range. The comparisons suggest the relationship between gravity anomaly and crustal rheology, and that contraction along the Ou Backbone Range produces negative gravity anomaly. The result also explains the relationship between gravity anomaly and seismicity and active fault distributions since both of them distribute to transitional areas of crustal rheological structures. Hasegawa et al. [8] pointed out that reverse faults and large contraction along the Ou Backbone Range reflects the heterogeneity in rheological properties in the NE Japan arc. Therefore, those comparisons imply that reverse faults and anelastic contraction produce continuous negative gravity anomaly along the Ou-backbone Range. Finally, we propose that the gravity anomaly can be an index of the heterogeneity in crustal rheology.

On the temporal decay of the localized strain rate in the Tohoku region after the Tohoku-Oki earthquake

*Youichiro Takada[1], Tomomi Inamatsu[2]

1. Faculty of Science, Hokkaido University, 2. Dept. Natural History Sciences, Hokkaido University

The 2011 Tohoku-Oki earthquake (Mw9.0) provides us the first opportunity to examine the responses of strain concentration zones and active faults to megathrust earthquakes with dense permanent GNSS network. Along the Backbone range in the Tohoku region, strain rate localization has been found before and after the Tohoku-Oki earthquake (e.g., Miura et al., 2004; Takada and Inamatsu, 2018). In this study, we focused on the post-seismic strain rate localization along the Backbone range, and examined its driving mechanism with GNSS data and simple FEM simulation.
We used daily coordinates obtained at GEONET stations operated by GSI. We estimated surface velocity field before and after the earthquake by removing annual and semi-annual perturbations. For post-seismic period, we estimated the velocity field for every two years to use linear approximation. From the velocities thus obtained, we calculated the strain rates following the method of Shen et al (1996). Next, we approximated the long wavelength components, which reflects the afterslip and/or the viscoelastic relaxation of Asthenosphere following the Tohoku-Oki earthquake, by polynomial function for each component, and removed it to extract the short wavelength component. Then, we found patchy distribution of localized contraction (negative dilatation rate) areas along the Backbone range with these amplitudes rapidly decreasing with time.
To examine the mechanism of rapidly decreasing strain rate, we conducted a simple numerical simulation with a finite element software COMSOL Multiphysics. There are thermally active regions with many calderas along the Backbone range (e.g., Yoshida, 2001; Takada and Fukushima, 2013). On the other hand, the thermal activity of surrounding area is not very high. Considering these points, we set a rectangular elastic body and located several ellipsoids in north-south direction that consist of low viscosity Maxwell viscoelastic medium. Then we applied gravitational body force to all the model region, and supported it from a lateral boundary. In addition, we also applied a step-wise 1 MPa stress change which represents coseismic stress perturbation due to the Tohoku-Oki earthquake. From the calculated results, we removed the long wave-length component. Then, we successfully extracted the short wave-length dilatation rate around the viscoelastic ellipsoids. Just after the step-wise stress change, whole medium responded as an elastic body. Soon after that, viscous flow starts in the ellipsoids. As differential stress decreases with time in the ellipsoids due to viscous relaxation, the surrounding elastic region becomes important to support the differential stress. Thus, the localized strain rates can be large only during the viscous relaxation in the ellipsoid. After the completion of viscous relaxation, all the differential stress is supported solely by elastic region, and the localized strain rates vanish. Thus, three dimensional connectivity of low viscosity regions play an important role when considering crustal response to an externally applied stress change.

Revisiting the Coseismic Slip Distribution of the 2011 Tohoku-oki Earthquake Considering Early Postseismic Deformation, Non-linear Viscoelasticity, and Heterogeneous Structure

*Takeshi Iinuma[1], Ryoichiro Agata[1], Yusaku Ohta[2], Ryota Hino[2], Takane Hori[1]

1. Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 2. Graduate School of Science, Tohoku University

The 2011 Tohoku-oki earthquake produced large coseismic displacements that were detected by terrestrial and seafloor geodetic observations, namely, global navigation satellite systems (GNSS), GNSS-Acoustic (GNSS-A), and ocean bottom pressure (OBP) measurements. Previous studies constructed coseismic slip distribution models of the Tohoku-oki earthquake using the daily GNSS site coordinate time series, seafloor GNSS-A, and/or OBP data to estimate the coseismic displacements [e.g., Ito et al., 2011; Koketsu et al., 2011; Ozawa et al., 2011; Iinuma et al., 2012]. However, studies for these several years suggested that the coseismic displacements must include early postseismic deformation due to a low-viscosity zone beneath the Pacific plate that is necessary to explain terrestrial and seafloor postseismic crustal deformations [Sun et al., 2014; Freed et al., 2017; Suito, 2017]. This low-viscosity zone may not be persistent but could result in huge changes in stress resulting from the coseismic slip with reflecting non-linear rheology [Muto et al., 2018; Agata et al., 2019]. The effect of non-linear rheology is great immediately after a main shock. Therefore, coseismic displacements based on the daily site coordinate time series and GNSS-A measurements inevitably must include early postseismic deformation.

Thus, we derived “pure” coseismic displacements based on 1-Hz site coordinate time series at GNSS sites of the Geospatial Information Authority of Japan estimated by utilizing kinematic PPP (precise point positioning) analysis and based on 1-min average seafloor level time series at OBP sites. The residual displacements were obtained by subtracting the pure coseismic displacement from that based on the daily site coordinate time series. The data showed subsidence and trenchward motions in the entire Tohoku district. These broad deformations could not be explained solely by aftershocks nor by afterslip on the plate interface. Viscoelastic deformation that occurs immediately after the main shock is required to explain the displacement field. We present the results of our investigations into coseismic slip distribution and early postseismic deformation by applying Green’s function, which is calculated by considering the shapes of surface terrain and subducting slabs as well as heterogeneous thermal structures and power-law rheology.

[S-CG61] Dynamics in mobile belts

convener:Yukitoshi Fukahata(Disaster Prevention Research Institute, Kyoto University), Toru Takeshita(Department of Natural History Sciences, Graduate School of Science, Hokkaido University), Hikaru Iwamori(Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology)

The dynamic behaviours of mobile belts are expressed across a wide range of time scales, from the seismic and volcanic events that impact society during our lifetimes, to orogeny and the formation of large-scale fault systems which can take place over millions of years. Deformation occurs on length scales from microscopic fracture and flow to macroscopic deformation to plate-scale tectonics. To gain a physical understanding of the dynamics of mobile belts, we must determine the relationships between deformation and the driving stresses due to plate motion and other causes, which are connected through the rheological properties of the materials. To understand the full physical system, an integration of geophysics, geomorphology, and geology is necessary, as is the integration of observational, theoretical and experimental approaches. In addition, because rheological properties are greatly affected by fluids in the crust and fluid chemical reactions, petrological and geochemical approaches are also important. After the 2011 great Tohoku-oki earthquake, large-scale changes in seismic activity and regional scale crustal deformation were observed, making present-day Japan a unique natural laboratory for the study of the dynamics of mobile belts. This session welcomes presentations from different disciplines, such as seismology, geodesy, tectonic geomorphology, structural geology, petrology, and hydrology, as well as interdisciplinary studies, that relate to the dynamic behaviours of mobile belts.

In Tohoku Japan, the Pacific plate that subducts under the Eurasian plate is old, thick, and cold. The basalt - eclogite phase transition is expected to occur at a depth of 100 km. The water released in the dehydration reaction forms serpentinite, which is transported to the deeper part. Serpentinite decomposes at a depth of about 150 km and water rises in the mantle due to buoyancy. Therefore, it is believed that there is no rise in water caused by slab mineral dehydration in the Northeast Japan forearc (Kazahaya et al., 2014). In contrast, the seismic tomography in NE Japan fore arc (Zhao et al., 2014) imaged low velocity regions in the forarc which suggests rising fluids from slabs which is called as "Water wall". In this research, we aimed to constrain the rising fluid distribution in the forearc from the 3d electric conductivity structure by magnetotelluric observations in Kitakami Mountains.
In our model, distribution of low resistivity indicating rising fluids from the deep part was not analyzed corresponding to the P wave low velocity region of Zhao et al.(2014). However, vertical low resistivity was analyzed from the volcanic front toward forarc. The conductors spread 30 km east of the volcanic front at depths of 10-40 km. This low resistivity is in good agreement with the low velocity distribution (Zhao et al., 2014; Okada et al., 2015). The low resistivity east of volcanic front is almost vertically continuous from the uppermost mantle to the middle crust. Therefore, this may indicate that the fluid on the mantle flow reaches the uppermost mantle of the forearc and releases fluids in the forearc crust.

Elastic wave velocity and electrical conductivity in brine-saturated rocks and microstructure of pores

*Arina Tomioka[1], Tohru Watanabe[1]

1. University of Toyama

Geophysical mapping of fluids is critical for understanding crustal processes. Seismic velocity and electrical resistivity structures have been studied to reveal the fluid distribution. However, the fluid distribution has been still poorly constrained. Observed velocity and resistivity should be combined to make a quantitative inference on fluid distribution. The combined interpretation requires a thorough understanding of velocity and resistivity in fluid-saturated rocks. We have made measurements of elastic wave velocities and electrical conductivity in brine-saturated rocks under confining pressures, and examined pore structures with SEM.

Measurements and microstructural observations were made on granites (Aji, Kagawa Pref., Ohshima, Ehime Pref.), granodiorite (Enzan, Yamanashi, Pref.) and tonalite (Kadohara, Fukui Pref.). Cylindrical rock samples (D=26 mm, L=30 mm) were filled with 0.1 M KCl aqueous solution, and velocity and conductivity were simultaneously measured by using a 200 MPa hydrostatic pressure vessel. The pore-fluid was electrically insulated from the metal work by using plastic devices. The confining pressure was incrementaly increased up to 150 MPa, while the pore-fluid pressure was kept at 0.1 MPa. It took 3 days or longer for the electrical conductivity to become stationary after increasing the confining pressure.

Rock samples showed moderate increase in velocity and large decrease in conductivity under confining pressures. Electrical conductivity steeply decreased at low pressures (<20 MPa) and then showed gradual decreases. Grain boundary cracks are pervasive in rock samples. The increase in velocity and decrease in conductivity at low pressures must be caused by the closure of grain boundary cracks with small aspect ratios ($<10^{-3}$). SEM images show that the aperture of a grain boundary crack varies along its width. Large aperture parts can be open even under high pressures to be conduction paths. The difference in conductivity at high pressures must reflect the difference in the amount of large aperture parts.

Influence of grain shape and grain size distribution on connectivity of pores in granular materials.

*Katazakai Haruka[1], Tohru Watanabe[1]

1. Toyama University

Transport properties such as electrical conductivity and permeability are sensitive to the connectivity of pores. Pore structure in granular materials varies with the shape and size distribution of grains. In order to understand the influence of the shape and size distribution of grains, electrical conductivity and permeability were measured on granular materials saturated with 0.1 mol/L KCl aqueous solution. Spherical glass beads and oblate quartz sand of various sizes were employed. The ratio of conductivity to porosity was significantly higher in glass beads than in quartz sand. This observation suggests that a higher connectivity of pore is established in glass beads than in quartz sand. The influence of the size distribution of grains was studied on mixtures of small (D=0.2 mm) and large (D=1 mm) glass beads. The porosity deceases from 36% to 22% as the fraction of large grains increases 0% to 60%. Electrical conductivity decreases with decreasing porosity, while permeability shows a small decrease. As the fraction of large grains increases from 60% to 100%, the porosity increases from 22% to 36% and permeability increases by around 2 orders of magnitude. This change suggests that the pore size steeply increases as the fraction of large grains increases from 60%, since permeability strongly depends on the size of pores. X-ray micro CT observation was conducted to examine pore structure.

Change of pore connectivity in granular materials under axial compression

*MAREMICHI ABE[1], Tohru Watanabe[1]

1. Toyama University

The influence of axial compression on the connectivity of pores in granular materials was studied. Electrical conductivity and compressional wave velocity were simultaneously measured on brine-saturated granular materials under uniaxial compression. Spherical glass beads and oblate quartz sand were employed. X-ray micro CT was conducted on granular materials impregnated with epoxy resin to examine microstructure of pores. Compressional wave velocity increases and electrical conductivity decreases with increasing axial stress. When the axial stress was increased from 0 to 5 MPa, compressional wave velocity increased by around 12% in both materials and electrical conductivity decreased by 0.7 and 1.7% in glass beads and quartz sand, respectively. The increase in compressional wave velocity must reflect the increase in contact area between grains, which was observed with X-ray micro CT. The decrease in conductivity must be caused by the decrease in connectivity of pores. X-ray micro CT images show that the connectivity of pores is easily lost under axial compression in quartz sand owing to its oblate shape.

Estimation of crustal strength using residual strain of quartz in deformed conglomerate and inhomogenous strain of conglomerate layer -As an example of multiple collision zone of Izu-Bonin arc, Fujikawa valley, Central Japan-

*Shun Suzuki[1], Kenta Kobayashi[1]

1. Graduate School of Science and Technology, Niigata University

South Fossa Magna is understood as a site where the Izu-Bonin arc on the Philippine Sea plate collides with Honshu arc, and it is the only arc-arc multiple collision zone in the world. Maruyama (2008) reported deformed conglomerate outcrop accompanied by cataclastic flow in the Hamaishidake Formation (late Miocene to Pliocene). Report of them in the collision zone is not limited to the Fujikawa area, but from the Ashigara Group and from the Erimo Formation in the Hidaka collision zone of Hokkaido (Uda, 1976), have been reported. In this study, various analyzes were performed on deformed conglomerates found in the Fujikawa area, and the cause (temperature / pressure condition) and the position in the collision zone were clarified, it aimed to restrict the multiple collision phenomenon and the deformation environment of trench fill sediments.

[Outcrop outline]
It is revealed that the deformed conglomerate outcrops occurred in the geologic body (Fujikawa Shear Zone) which makes a high dip zone in the direction of NW-SE, and they are modifying the initial NS system folding. The long axis direction of the gravel showing N40W trend and the shear fabric of the gravel showing sinistral sense.

[Paleo stress analysis by multiple inverse method]
The result of the MIM analysis (Yamaji et al., 2011) using the slip data of the gravel fault plane with the flow deformation mode shows ENE-WSW compression, which is not consistent with the current Philippine Sea plate motion.

[Restrictions on forming environmental condition of deformed conglomerate]
We tried to guess the maximum heat temperature of the geological body using the carbonaceous material Raman spectrum (Kouketsu et al., 2014), and examination of the differential stress level using the internal strain of the quartz (Takagi et al., 1988). As a result, it is revealed that deformed conglomerate outcrops heated only 150℃ or less, and the maximum heated temperature is rising toward the lower formation of Hamaishidake Formation. When the geothermal gradient is estimated by layer thickness conversion, the value such as 4~5℃ / 100 m is restored, and the depth at which the 150℃ heating can be recorded is about 3~4 km. That is, the deformed conglomerate is found to be a product under shallow and low temperature conditions. On the other hand, the estimated differential stress value is 50-100 MPa, which is strongly deformed despite being a shallow deformation.

[Discussion]
As for the ENE-WSW compression obtained from cataclastic flow slip data, it can not be explained with only the motion of the Philippine Sea plate. If these as deformation events after the deposition age limit (about 5 Ma) of the Hamaishidake Formation, it is necessary to consider the influence of E-W compression from around 3 Ma (Takahashi, 2006) or the ENE movement of Amur Plate (Komatsubara, 2015), and it

©2019. Japan Geoscience Union. All Right Reserved.

means that the tectonics are not only dominated by the Philippine Sea plate. Considering trench fill sediment objects in the Fujikawa Valley as accretionary bodies, since deformed conglomerate occurs near the boundary fault of the middle and upper strata of the Fujikawa Group, it may be a deformation near the Mega Splay Fault branching from the plate boundary fault at the Tanzawa block collision stage. In addition, considering the usual crustal strength (Byerlee, 1978), theoretically it is not possible to record a differential stress value of 100 MPa at 4 km underground. However, according to the data of drilling at the plate boundary Nankai Trough (Hamada et al., 2018), it is pointed out that the differential stress value rises in the Accretionary prism and reaches nearly 100 MPa. In other words, in the geological body near the plate boundary, it is predicted that the crustal strength is large and it is placed in the high differential stress state also in the subsurface shallow part, and the deformed conglomerate is considered to be a product in such a place.

An Introduction to Ryoke Cataclastic Rocks in Tsukide, Mie Prefecture, Japan: An Approach Using 3D Reconstructions From Thin Sections

*Thomas Jing Yi Yeo[1], Toru Takeshita[1]

1. Department of Natural History Sciences, Graduate School of Science, Hokkaido University

The Japan Median Tectonic Line (MTL) is the longest fault system in Japan where it spans from Kyushu Island and extends towards the north east direction up until Ibaraki Prefecture. It has been an active strike slip fault since the Mid-Cretaceous period, which was originally formed as the southern marginal shear zone in the Ryoke belt (e.g. Hara et al., 1980) leading to the formation of mylonite and superposed by cataclasite at the core region.

This study aims to identify the kinematic history of the fault plane and its effect on the cataclastic rocks from a 3D viewpoint. The fieldwork was conducted in the hanging wall section of the MTL in Mie Prefecture, Japan. The hanging wall of the MTL in the study area is characterized by Creataceous Ryoke granitic rocks which was deformed into mylonitic rocks and was later overprinted by cataclasite at the proximal region. The main objective of this project is to identify and relate the kinematics of the MTL and physical conditions during the formation of the cataclasite.

From the thin sections observations, the grain size reduction of the mylonitic clasts was observed and was related with cataclasis. The cataclasite formed at the brittle fault zone enables chemically rich fluids to penetrate. This promotes the growth of foliated phyllosilicate minerals mainly muscovite from the alteration of presumably feldspars. Microstructural features such as riedel shears with C’ -type shear band fabric assist in indicating the sense of motion. Fracture densities and distributions are also quantified in all of the three sides of the sample in order to obtain a clearer view on the brittle properties.

Also, based on the crossed cutting relationship seen in the microstructures of the sample, a schematic deformation history of the sample was constructed. The MTL begins with a sinistral shear sense which causes the mylonitisation of the Ryoke granitoids. Upon the cooling of temperature, cataclasite was formed and transpression of the shear zone causing pressure solution seams to be precipitated which resulted in the formation of phyllonite. Lastly, a late stage reactivation of the pressure solution seams caused faulting to occur.

Furthermore, using the rake angle of the C’ and S fabrics of the Riedel shears, measured from the thin sections representing the different sides of the sample, the orientations of both the C’ and S planes could be reconstructed and plotted as a stereographic projection with values of [278/ 48N] and [124/ 82SW] respectively. The XZ plane which is 90° away from the intersection point of C’ and S planes has an orientation of [031/ 67SE]. By assuming plane strain and with the assistant of the software StrainSim v3, the simple shear strain, γ=0.73, the angular shear, Ψ=36° and material internal friction angle, Φ= 56°. Similarly, the principle stress orientations are found to be at [62°→158], [23°→301] and [15°→037] for σ_1, σ_2 and σ_3 respectively. By combining all the relationships mention above, the motion sense of the fault was identified as the NE block moving NW and downwards with a more dominant dip slip component. This dominant dip slip movement of the fault could be potentially related to the normal faulting movement of the MTL during the Ichinokawa Phase at 63-58Ma.

Moreover, the electron backscatter diffraction (EBSD) analysis of the sample is currently being conducted

Relationships between spacing and growth or linkage of normal faults in the Miyako Island, South Ryukyu arc, Japan

*Sumire Maeda[1], Makoto Otsubo[1], Daisuke Asahina[1], Yuki Furuno [1]

1. Research Institute of Earthquake and Volcano Geology, Geological Survey of Japan/AIST

Estimating interaction and linkage of faults is one of the most important issues to evaluate the long-term activity of future earthquakes. For the long-term evaluation of the major active fault zones, Headquarters for Earthquake Research Promotion (e.g., HERP, 2010) uses so-called 5-km gap threshold (Matsuda,1990) to group and segment the fault traces. However, the fault size may change in the future, so it is necessary to introduce a multilateral index that can evaluate temporal and spatial evolution of faults.
Fault spacing, the horizontal distance between neighboring faults, has been related to stress reduction around faults (e.g., Soliva et al., 2006; Fossen and Rotevatn, 2016). Soliva et al. (2006) investigated the relationship between the fault spacing and the stress reduction area for a series of faults. Their studies show that the fault spacing is linearly related to the mechanical layer thickness. In the evolution process of normal fault, it is assumed that randomly distributed faults start to propagate and couple at the beginning, and the fault spacing becomes regularly distributed. Therefore, it may be possible to estimate the thickness of the mechanical layer in which the faults exist from the regular spacing of the saturated faults.
In this study, we investigated the normal faults in the Miyako Island, South Ryukyu arc, Japan in order to examine the possibility of fault linkage based on the fault spacing and the Coulomb shear stress perturbation. We found that the Miyako Island has three fault groups with different types of strikes, and these fault spacings are almost regularly distributed. The layer thickness of the NW-SE strike fault group can be estimated about 3,500 m based on the faults spacing. This results imply that the fault group extends only to the upper end of the seismogenic zone (3-17 km; HERP, 2012). In addition, the thickness of this fault group is close to the thickness of the Ryukyu Group and Shimajiri Group of the Miyako Island. Large-scale faults beneath the Miyako Island may be branched in the shallow soft-sedimentary rocks.

3D fault architecture along the Median Tectonic Line, eastern Kii Peninsula, SW Japan

*Norio Shigematsu[1], Takuma Katori[1,2], Jun Kameda[3], Ayumu Miyakawa[4]

1. Research Institute of Earthquake and Volcano Geology, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, 2. Graduate School of Science and Technology, Niigata University, 3. Department of Natural History and Sciences, Hokkaido University, 4. Research Institute of Geology and Geoinformation, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

The heterogeneous fault deformation around the brittle-plastic transition possibly affects the fault behavior significantly including the generation of earthquakes (e.g., Scholtz, 2001). To understand the effect, a detailed fault zone architecture is essential. In this study we have tried to construct a 3D fault zone architecture model based on the geological study of an exhumed fault zone, the Median Tectonic Line (MTL) in the western Kii peninsula SW Japan.

Accurate positions were determiend by applying SfM (structure from motion) and MVS (multi-view stereo) calculation (e.g., Furukawa and Hernández, 2013) to photos taken by an UAV (Unmanned Aerial Vehicles), and GNSS (Global Navigation Satellite system) surveying (e.g., Bemis et al., 2014) to reveal the 3D structures. The microstructures, chemical composition of minerals and crystallographic orientations of quartz using an electron back-scatter diffraction (EBSD) (Prior, et al., 1998) were analyzed to characterize the defomation of fault rocks. Based on these deformation features, the 3D fault zone architcture were constructed using a 3D-CAD software.

In the 3D fault zone architecture model, the fault plane of the MTL (lithological boundary) is an almost perfect plane dipping to the North. The structures can be divided into two main structures. One includes mylonite and cataclasite showing sinistral sense of shear. The other structures consist of scaly cataclasite showing dextral sense of shear and further younger structures including the lithological bonadry. The later structures cut the former structures indicating the sequence of deformation within the fault zone.

Scaly cataclasite only apper in the vicinity of the MTL, and is characterized by the strong foliation defined by the alignment of chlorite. Modal fraction chlorite is much larger than that in the surrounding Ryoke drived rocks, and pressure-solution seam is well developed. The estimated temperature based on the chlorite geothermometry is about 300 ºC (Bourdelle et al., 2013).
The deformation of the structures showing sinistral sense of shear varies from mylonite deformed at temperature of about 450 ºC (Higher-T mylonite), that deformed at about 300 ºC (Lower-T mylonite) to cataclasite deformed at about 300 ºC, suggesnting these structures record the brittle-plastic transition. One conspicuous feature in these structures is an altanation zone of black cataclasite and ultramylonite. This zone is a narrow and planar zone with width of 10 m. The cataclasite in this zone is black colored and strongly foliated. The ultramylonite in this zone show almost ramdom CPO (crstallographic preffered orientation) of quartz. We consider that this zone was the fault core when the present exhumed level experienced the brittle-plastic transiton.

Significant of thrust zone at Fuji river basin in the South Fossa Magna, Southern Yamanashi Prefecture, Central Japan
-Study of Structural geology of Minobu and Neguma fault-

*Minami Madoka[1], Kenta Kobayashi[1]

1. Niigata university department of geology science

There are Minobu fault that was certified as major active fault, Itoigawa shizuoka Tectonic Line (ISTL) and Fujikawa Kako Fault Zone (FKFZ) in the South Fossa Magna. The region is very precious to reveal formation of Japan island because the area is collision and accretion zone to Southwest Japan of Izu-Ogasawara arc. Mainly, Fujikawa group is distributed that filled trough made by past collisional block in this study area.
Minobu Fault is high probability to connect ISTL and FKFZ in the blank range of active fault. In recent years, it was shown sinistral fault sense from geomorophological point of view.(Mizumoto,2016) Howevere, nortern Minobu Fault is estimated reverse fault sense because of stratigraphy difference.
We discover and described new Minobu fault outcrops and divide Minobu fault into Segment Ⅰ and Ⅱ. We are obtained datas from stress analysis and XRD analysis in the area.
We will discuss the formation mechanism and history of geological structure deveropment of Minobu and Neguma fault in South Fossa Magna from kinematics of the faults and geological structure.

Mineralogical characteristics of fault rocks in the aftershock regions of the 2000 Western Tottori earthquake and its spatial distribution

*Shunya Kaneki[1], Tetsuro Hirono[1], Hideki Mukoyoshi[2], Kenta Kobayashi[3], Toru Takeshita[4]

1. Graduate School of Science, Osaka University, 2. Graduate School of Science and Engineering, Shimane University, 3. Graduate School of Science and Technology, Niigata University, 4. Graduate School of Science, Hokkaido University

A large earthquake (*Mw*6.6) occurred on 6 October 2000 in the western part of Tottori Prefecture, southwestern Japan. The main shock was considered as an almost left-lateral strike-slip event with the hypocenter located at 35.269 ˚N and 133.357 ˚E. The rupture process and slip distribution of the main shock was estimated from coseismic strong motions and geodetic data. These previous studies suggested that slip of the main shock mainly occurred in the southern part of the aftershock regions. Furthermore, Yukutake et al. (2007) estimated regional stress field before and after the main shock using aftershock focal mechanisms, and proposed that southern part of the aftershock regions may be dramatically weak in friction compared to northern and central parts. However, there are currently few researches attempting to understand regional slip behaviors of both main shock and aftershocks in association with spatial heterogeneity of physical properties of fault materials.

Mineralogical characteristics of rocks is one of the valid candidates that is likely to dominate its physical properties, and in general, increase in amount of frictionally weak minerals can reduce frictional strength of fault rocks. For understanding spatial slip behaviors in aftershock regions of the 2000 Western Tottori earthquake, we first need to investigate spatial variations in mineral composition of fault rocks. We collected more than 100 bulk rock samples from 14 fault-related outcrops, that distribute in northern, central, and southern parts of the aftershock regions. We then acquired XRD profiles of the powdered samples with internal standard (Al_2O_3) of 20 wt.%, and estimated the amount of minerals by using the RockJock software. The results clearly indicate that intact host rocks have similar mineralogical features regardless of sampling locations; they are granitic rocks composed of quartz, K-feldspar, and plagioclase. In contrast, mineral compositions of fault rocks show different characteristics by locations. In northern part of the aftershock regions, fault rocks are poor in K-feldspar and plagioclase and are rich in halloysite. In central part, fault rocks are poor in K-feldspar and plagioclase and are rich in illite. In southern part, fault rocks are poor in plagioclase and are rich in halloysite. These information tell us the representative mineralogical features of fault rocks in each part of the aftershock regions. Future friction experiments, by using representative fault rock samples under in-situ conditions, will give us a direct glimpse into the spatial variations of frictional properties in the aftershock regions of the 2000 Western Tottori earthquake, such as frictional strength and its velocity dependence. All of these information, not only seismological data but also mineral composition and physical properties of fault materials, should be incorporated for understanding the spatial heterogeneity of slip behaviors of the main shock and aftershocks of the 2000 Western Tottori earthquake.

Relationship between seismicity of the 2016 the Central Tottori Earthquake and fault distribution in the aftershock area

*Masayuki Ichimura[1], Hideki Mukoyoshi[2]

1. Graduate School of Natural Science and Technology, Shimane University, 2. Department of Earth Science, Shimane University

The 2016 Central Tottori Earthquake (M6.6) occurred on October 21. The epicenter was Central Tottori and depth of hypocenter was 11km. Earthquake source fault was determined to be left-lateral strike fault developed NNW-SSE direction with WNW-ESE directional maximum principal stress axis. In the region, active fault related to the earthquake was not recognized. Although clarification of the occurrence of faults such strain concentration zone is important, there are no reports about detail field outcrop investigation in the area of this earthquake.
The aim of this study is to reveal relationship between seismicity of the 2016 Central Tottori Earthquake and fault distribution in the aftershock area based on field investigation and description of microstructure of the faults.

In this study area, late Cretaceous-early Paleogene medium-coarse-grained biotite granite is mainly distributed.

As a result of this study, total of 190 faults were observed in the aftershock area. Orientation of faults developed in NNW trending aftershock area were concentrated in NNW. On the other hand, faults in eastern part of aftershock area shows N-S~NE trend. Three-directional striation on the fault plane was observed in the aftershock area and only cataclasite was developed. The fault (strikes NNW) had horizontal striation was confirmed. P-foliation was observed in this fault rocks under the microscopic observation and indicated left-lateral strike slip.

The fault that had experienced strike slip, and shear sense consistent with earthquake source fault was confirmed. This result indicates that this fault had moved in the present stress field. According to previous study related to 2000 Western Tottori Earthquake, it is suggested that NNW trending fault system developed in southern part of the aftershock area was weaker than the surrounding area. With comparing these result, fault system in aftershock area of the 2016 Central Tottori Earthquake also might be weaker faults due to the orientation of faults correspond with the Y surface of the earthquake source fault.

History of fault activity considered from the brittle shear zone and the geological structure near the Cape Otachi, Kumamoto Prefecture

*Keiji Ogashiwa[1], Kenta Kobayashi[1]

1. Niigata University

[Introduction] The Hinagu fault zone is located in the western Kyushu and is an active fault zone extending 81 km roughly in the NE-SW direction. The Hinagu fault zone is a dextral slip fault with the east side uplift [URL]. The fracture zones of the Hinagu fault zone have been reported in two places in the Higo metamorphic rock distribution area and in the lower Cretaceous distribution Area near the cape Otachi (Matsumoto・Kanmera, 1964). The core of the fracture zone at Sabagami pass shows dextral slip and its outer rim shows sinistral slip (Kobayashi・Koshiwa, 2016). In addition, the geological fault parallel to the Hinagu fault is apparent sinistral slip fault (Saito et al., 2005). These facts suggest the possibility that the Hinagu fault zone was active differently from the past and the present. Analysis of the fracture zone and surface survey around the fracture zone are important for elucidating the history of fault zone activity. In addition, since Kyushu is an important area which is the meeting part of the Southwest Japan arc and the Ryukyu arc, clarifying the activity history of the Hinagu fault zone leads to the understanding of the tectonics of Kyushu. In this research, for the purpose of elucidating the history of activity of the Hinagu fault zone from the brittle shear zone and geological structure found near the Cape Otachi, Kumamoto Prefecture, the ground surface survey, the structure observation of the fault rock, the XRD analysis, the small fault Analysis and so on.

[Ground Surface Survey] As a result of the ground survey around the Cape Otachi, small faults constituting the fracture zone were observed in the lower Cretaceous Hinagu Formation, and it was roughly classified into 4 strains from the strike of the fault, the sense, and the cutting relationship. F1 is NNE-SSW trend sinistral slip fault, F2 is NNE-SSW trend dextral slip fault, F3 is NNW-SSE trend sinistral slip fault, F4 is E-W trend dextral slip fault.

F2 is a small fault group found in the brittle shear zone consisting of cataclasite. F1 is seen outside the brittle shear zone and part forms a planar cataclasite zone with a width of 5 cm. F3 and F4 are small fault groups which mutually cut. F3 deform the dike group described later. F4 cuts the brittle shear zone. Apart from the fault, we identified a folding group with a hinge in the ENE-WSW direction on the southeast side of the brittle shear zone. In addition, an andesitic dykes group with a dominant ENE-WSW strike was observed on the east side of the brittle shear zone. We confirmed the cutting and bending of the dike by F3, the injection of dike along the F3. This dike is believed to be related to the Neogene Igneous rocks in Amakusa area (Matsumoto ·Kanmera, 1964).

[Small Fault Analysis by Multiple Inverse Method (Yamaji, 1999)] Compressive Stress Field in NW-SE direction from F1, Compressive Stress Field in ENE-WSW direction from F2, Compressive Stress Field in NW-SE direction from F3 and F4 Was detected.

[Stage Segmentation] The time of formation of the fault, dike and fold observed in the vicinity of the Cape Otachi is divided into three stages, D1, D2, D3 from the stress field obtained from the cutting relation.
In D1, F1 was activated in the compressive stress field in the NNW-SSE direction. Considering the compression axis direction, fold group with fold axis in NE-SW direction is thought to be formed in D1.
In D2, F2 was activated in the compressive stress field in the ENE-WSW direction, forming a wide brittle

©2019. Japan Geoscience Union. All Right Reserved.

shear zone.
In D3, F3 and F4 were active in the compressive stress field in the NW-SE direction.
We thought that the bending and the injection of dike along F3 indicate that the dikes were deformed by F3 before consolidation. Considering the above-mentioned thing, we thought that the dike group had formed between the terminal stage of D2 and the beginning of D3.

Study on fault activity evaluation method (A new attempt to understand fault activities) No.1 - Overall plan and current situation at Shionohira Fault -

*Kazuhiro Aoki[1], Takahiro Watanabe[1], Yukumo Tanaka[1], Kazuyoshi Seshimo[1]

1. Japan Atomic Energy Agency

If there is a "fault that may become active in the future" (hereinafter referred to as “inactive segment”) in the vicinity of a fault that has recently moved (hereinafter referred to as "active segment"), it appears that there is a difference in the stress state and in the "ease of activity" between the two segments. Under the current concept of nuclear regulatory standards, these segments are evaluated as part of the same series of faults due to lack of knowledge about interlocking faults.

Following the April 11, 2011 Fukushima-ken Hamadori Earthquake (4.11 earthquake), co-seismic surface ruptures trending NNW-SSE emerged over a distance of 14km between Nameishi Tabito of Iwaki city and North-west of Tsunaki Ishizumi. The surface rupture was named Shionohira fault by Ishiyama et al. (2011) and is identified to be part of the Itozawa fault (coincides to West trace of Itozawa fault by Tsutsumi and Toda, 2012). According to Imaizumi et al. (2018), the fault is said to continue extending south of the ruptured surface covering the area from Nameishi of Tabito Iwaki city to West of Sakura, Kawabe-cho and from Wakigawa, Yamadama-cho to Kobuki, Sekimoto-cho Kita Ibaraki city. In this study, the area designated as the Shionohira fault which has surfaced after the 4.11 earthquake is called the active segment and the remaining area to the south to be the inactive segment.

The authors aim to develop a fault activity evaluation method in order to clarify whether the inactive segment really moves together with the series of faults including the active section when a fault activity occurs by studying the differences between active and inactive segments in the interlocking of faults.

The authors have been conducting a series of study at the Shionohira fault and its southern extensions, reporting on the outcrop survey results (Kametaka, et al., 2015) and the frictional characteristics of fracture zones (Aoki et al., 2015, 2016). Currently, a fault slip test is carried out to assess the in-situ stress state.
In the fault slip test, a double packer is placed above and below the underground fracture to inject high pressure water from the surface and artificially trigger a slip in the fracture in order to measure the three dimensional deformation amount (micrometer to millimeter) (Guglielmi et al., 2013). This device called the Step-rate Injection Method for Fracture In-situ Properties or SIMFIP probe was designed and manufactured by Guglielmi for underground storage studies of CO2 in France and was first applied at the underground research facility (LSBB) in the south of France (Guglielmi et al., 2015). Subsequently, in-situ tests have been conducted on faults in underground research facilities such as Tournemire in France, Mont Terri in Switzerland, and the gold mine in South Dakota, USA.

This device allows to quantitatively measure the deviation of the fault by increasing the pore water pressure in the section partitioned by double packers, and to also examine the causes for leakage of groundwater, petroleum, CO2, and radioactive waste. In addition, it enables to observe fault displacement, pore pressure, and induced seismic waves at the micrometer scale, and to estimate friction and stress state of fault zones. By deepening understanding of the coupled phenomenon of hydraulics

©2019. Japan Geoscience Union. All Right Reserved.

and dynamics around the fault, the authors believe the method could be useful in elucidating the mechanism of seismic occurrence. It should be noted that this device is being applied for the first time in Japan, and the first time ever for an in-situ test of active faults.

Study on fault activity evaluation method (A new attempt to understand fault activities) No.2
- Injection experiment using a SIMFIP probe at Shionohira Fault and southern fault-

*Takahiro Watanabe[1], Yukumo Tanaka[1], Kazuhiro Aoki[1], Yves Guglielmi[2], Paul Cook[2], Florian Soom[2], Wakahama Hiroshi[3], Noujou Haruka[3], Etsuo Iwasaki[3], Masao Kametaka[3], Kazuyoshi Seshimo[1]

1. Japan Atomic Energy Agency, 2. Laurence Berkley National Laboratory, 3. DIA CONSULTANTS

The Shionohira fault caused the April 11, 2011 Fukushima-ken Hamadori Earthquake of Mw 6.7 which occurred one month after the Tohoku-Oki earthquake of Mw 9.0. Co-seismic surface ruptures trending NNW-SSE allowed to estimate a normal slip faulting with a 2 m maximum displacement. The causes of fault activation might be related to changes in the stress state following the Tohoku-Oki earthquake. The key question is to understand why some fault segments were activated and ruptured the land surface while others remained inactive although being very close and aligned on the same fault zone, which is of importance in better assessing the risk of seismic activation of faults in Japan. This might be related to slight differences in properties between active and inactive segments. This might be related to slight differences in properties between active and inactive segments. Recent laboratory measurements on core sampled across the rupture zone show that there are differences in friction coefficients and smectite and clay mineral contents between segments (Aoki, et. al., 2016, Seshimo, et. al., 2016). These differences may condition the frictional rate and state stability of the fault. In this project, frictional stability and hydraulic permeability of the Shionohira fault are explored in situ from SIMFIP probing of borehole intervals intersecting the fault at depths of about 10-to-30m.

Surface earthquake fault caused the earthquake of April 11, 2011 coincides with the west trace of Itozawa fault (Tsutsumi and Toda, 2012). Imaizumi et. al. (2018) identified the lineament as an active fault from Wakigawa of Yamadama-machi to Obuki of Sekimoto-machi, Kitaibaraki city. No surface rupture was idenfied in this region. This study refers to the part of the fault with surface rupture as an active segment and that without surface rupture as an inactive segment.

At the Shionohira site, vertical borehole of 30 m depth was drilled and test intervals were decided based on core observations, borehole TV and caliper logging data as follows. Test 1 between depths of 7.0 and 11.5m isolated with upper and lower packers and pressurized was conducted above the recently activated fault zone in the unfaulted sandstone layers. Test 2 between depths of 12.8 and 17.3m was conducted across the recently activated fault zone.

At the Minakami-kita site, inclined borehole of 50 degrees from surface with 30 m length was drilled and fracture zones were detected at 20.40 to 23.10 m. In-situ injection experiment using a SIMFIP probe is under going, comparison results will be presented at the conference.

Dynamic rupture simulation of 2018, Hokkaido Eastern Iburi earthquake: Role of non-planar fault geometry

*Tatsuya Hisakawa[1], Ryosuke Ando[1]

1. The University of Tokyo

The 2018, Hokkaido Eastern Iburi, Japan, earthquakeis an event characterized by complexity of rupture process, which may involve both reverse and strike slip depending on the locations on the fault surface. We perform dynamic rupture simulations based on simple physical laws and conditions for stressing and fault friction, taking complexity of the fault into account. The complex fault geometry is numerically treated by the boundary integral equation method accelerated by the fast domain portioning method. We search in a small number of parameter spaces for the stress ratio of the regional stress field and the frictional coefficients assumed to be the same over the fault area, rather than assigning heterogeneous distributions of the stress drop on the fault, to evaluate to what extent relatively simple forward models accounting for realistic fault geometry can explain the characteristics of coseismic observations. The fault geometry is constrained based on the aftershock distribution (NIED, 2018) and characterized primarily by the combination of three fault planes. As the result, we are able to reproduce several observed features of the event including the spatial variation of the fault slip direction, which is inferred from the seismological inversion (Okuwaki and Yagi, 2018), and the ground surface displacement observed by GEONET. The results suggest that the complex rupture event can be reproduced by a relatively simple physical model to some extent if the geometrical complexity of the faults is properly taken into account.

A New Fully-Dynamic Earthquake Cycle Simulator Applicable to Arbitrary Nonplanar Fault Geometries - A Benchmark Test

*Daisuke Sato[1], Nadia Lapusta[2], Hiroyuki Noda[1]

1. Disaster Prevention Research Institute, Kyoto University, 2. California Institute of Technology

The models and data assimilations of the real earthquake cycles are now getting on the track for providing the data beyond the classical empirical laws in the context of the seismic hazard; an example can be seen in the Third California Earthquake Rupture Forecast (UCERF3). Such large modeling is enabled by the rapid development of the earthquake simulators capable of solving the earthquake cycles in the real fault systems (Barbot et al., 2012: Richards-Dinger and Dieterich, 2012). However, there is not a fully dynamic cycle simulator applicable to wide tectonic conditions yet. The applicability of earthquake cycle simulators is thus still largely restricted.

In this research, we propose a new earthquake cycle simulator applicable to arbitrary nonplanar fault geometries. This simulator is based on the fast domain partitioning hierarchical matrices (FDP=H-matrices) (Sato and Ando, 2018), a newly developed algorithm of quasilinear time for dynamic BIEM applicable to nonplanar fault geometries. This cycle simulator thus overcomes the restriction on geometries when solving the elastodynamic fault motions in the coseismic phase, which had been the intrinsic problems for previous methods to solve the dynamic ruptures. In the presentation, after proposing the new method, we run a benchmark test of the SCEC Sequences of Earthquakes and Aseismic Slip project (SEAS) by the new simulator. Obtained results are compared with those of the previous simulators such as ByCycIE (Lapusta et al., 2000) and other simulators of volume-based methods. Simulated cycles on other nonplanar faults will be also demonstrated.

Stress and displacement Green's functions to treat volumetric inelastic strain and elastic inhomogeneity in boundary integral equation method

*Daisuke Sato[1]

1. Disaster Prevention Research Institute, Kyoto University

The boundary integral equation method (BIEM) is a commonly used method to simulate the fault motions accurately. Recent developments are now resolving well known problems of BIEM, such as the numerical cost problem (Sato and Ando, 2018) and the adaptabilities to elastic inhomogeneity (Kame and Kusakabe, 2012; Kusakabe and Kame, 2018). However, while it is shown to be applicable to the media other than homogeneous elastic media, obtained analytic integral kernels for simulating those media are now limited, largely due to its analytic difficulty. In this research, I obtain the the kernel expressions of those advanced BIEM in real space-time coordinate, based on the equivalent inclusion method (Eshelby, 1956; Mori and Tanaka, 1973).

First, the (volume) integral equation method (Barbot and Fialko, 2010) for the volumetric strain is shown to be reduced to BIEM of boundaries partitioning the discretized inelastic volume. Corresponding kernels are then obtained for piecewise-constant volumetric inelastic strain embedded in the three-dimensional homogeneous elastic space. The kernels are preliminarily shown to be equivalent to the part of the kernel for the inhomogeneous elastic media (Kame and Kusakabe, 2012; Kusakabe and Kame, 2018) both in static and dynamic cases.

Second, the surface integral in the representation theorem is reduced to the integral equation of the equivalent eigen-displacement. Consequently, as long as the absolute traction can be expressed with the strain and the eigen-strain, it is suggested that there can be a method to treat the inhomogeneous elastic media only by using the stress Green's function responding to the slip, already obtained analytically (Tada and Madariaga, 2001; Tada, 2006; Ando et al., 2007; Ando, 2016). By comparing the possible method with the method of Kame and Kusakabe (2012) capable of generally treating the elastic inhomogeneity in some examples, the validity of the proposal to treat inhomogeneous elastic media is investigated.

Frictional properties of dolerite and granite at intermediate slip rates and controlled ambient temperatures

*Michiyo Sawai[1], Yuuki Yokoyama[1], Kyuichi Kanagawa[1]

1. Chiba University

High velocity friction experiments (up to several m/s) on many types of rocks have revealed that frictional strength decreases with increasing slip rate at seismic slip rates (e.g., Tsutsumi and Shimamoto, 1997; Di Toro et al., 2011). Coseismic weakening has been attributed to temperature rise including flash heating, melt lubrication or thermal pressurization (e.g., Rice, 2006; Hirose and Shimamoto, 2005). Although the importance of temperature during fault motion are widely recognized, the effects of temperature on frictional properties at intermediate to high slip rates remain unknown. We therefore conducted friction experiments at a wide range of temperatures and investigated the effects of temperature on the friction coefficient (μ).

Experiments were performed on dolerite (Belfast, Northern Ireland) and granite (Aji, Japan) using a rotary shear deformation apparatus at Chiba University. Samples were displaced up to 10 - 20 m at a normal stress of 1 MPa, slip rates of 1 to 300 mm/s, and ambient temperatures of 20 - 500°C in an argon atmosphere with an oxygen concentration of 0.2 %.

At 20°C and 100°C, dolerite showed velocity weakening at slip rates ranging from 1 to 30 mm/s with μ of 0.81 - 0.83 at 1 mm/s and of 0.73 at 30 mm/s. Whereas at high temperatures >300°C, friction is almost constant (μ = 0.81 - 0.85) at < 30 mm/s. At 100 mm/s, the behavior is slight velocity strengthening at 20 °C and 100°C with μ = 0.75 - 0.79 and clear velocity-weakening at more than 300°C with μ = 0.67 - 0.76. At 300 mm/s, the dolerite showed strong velocity weakening at all temperatures investigated. The amount of weakening (i.e., the drop in friction, $\Delta\mu$) increases with increasing temperature ($\Delta\mu$ = 0.1 - 0.38). Thus, the frictional properties of dolerite are affected not only by slip rate but also by ambient temperature.
Experiments using granite to decipher the effect of materials on temperature dependence are in progress. Our preliminary results are summarized as follows. At <30 mm/s, the behavior is slight velocity strengthening at room temperature and velocity-weakening at temperatures of 100-300°C. At >300°C, friction is almost constant. Friction coefficient decreases with increasing temperature of 20-300°C and increase again at >400°C. At >100 mm/s, clear velocity-weakening did not occur except at temperatures of 20°C. More results especially on granite will be reported at the meeting.

Extraction of features of strata using borehole data of geothermal area by multivariate analysis

*Ojima Hiroki[1], Kazuya Ishitsuka[2], Toru Mogi[3], Tatsuya Kajiwara[4], Takeshi Sugimoto[4], Hiroshi Asanuma[5]

1. Department of Socio-Environmental Engineering Hokkaido University, 2. Division of Urban Management, Graduate School of Engineering, Kyoto University, 3. Division of sustainable Resources Engineering, Faculty of Enginieering, Hokkaido University, 4. Geothermal Engineering Co. Ltd, 5. Fukushima Renewable Energy Institute, AIST

In geothermal development, geological characteristics are often estimated qualitatively based on logging data of geothermal wells. On the other hand, the quartz index (QI) has quantitative information on minerals, and the index enables to objectively extract features of the geological formation using a statistical method. Therefore, in this study, from the QI obtained from the core cuttings in a geothermal field, we developed and examined a method to classify and extract geological features along with a well by multivariate analysis (in particular the difference in alteration degree). Specifically, we first carried out a principal component analysis to extract and emphasize the features of the data through dimensionality reduction. Then, their lithological features were classified by clustering using a Gaussian mixture model. In addition, the classification results by our method were compared with electric logs and temperature logs. In this study, we used the data obtained from wells in a geothermal area at Iwate prefecture. The geology of this area consists of andesite tuff and dacite tuff. The QI is defined as the percentage of the strongest X-ray intensity of a certain mineral in the sample from the strongest X-ray intensity of pure quartz measured under the same experimental conditions. This value means the content (weight percentage) in the sample for quartz and the relative quantitative ratio for the other minerals. In order to verify our proposed method, the principal component analysis was performed on the standardized QI data of clay minerals and compared with the results of existing geological classification based on geological interpretation. As a result of the comparison, our classification results agree with the results of existing geological classification, thus the classification of the strata by our method is valid. Next, in order to examine the effect of the dimensionality reduction by a principal component analysis, we compared the following cases: (i) clustering without dimension reduction for all QI, and (ii) clustering after applying the dimensionality reduction to all QI. In the case of dimensionality reduction, we used the principal components with a total contribution total over 95%. As a result of the comparison, the optimal classification number of the strata without the dimensionality reduction (case (i)) was 6. On the other hand, in the case of dimensional reduction (case (ii)) the optimal classification number was 10. The number of the optimal class indicates that more detailed features can be extracted using dimensionality reduction by principal component analysis. Notably, the classification in the depth range from 0 to 1000 m became detailed, highlighting the correspondence between clay, zeolite minerals and the geological formation.

Low-temperature thermochronology of Cretaceous granitoids from the northern Northeast Japan Arc: Towards reconstructing arc-parallel thermal/denudation histories

*Shoma Fukuda[1], Shigeru Sueoka[2], Barry Paul Kohn[3], Noriko Hasebe[4], Akihiro Tamura[5], Tomoaki Morishita[5], Takahiro Tagami[1]

1. Graduate School of Science, Kyoto University , 2. Japan Atomic Energy Agency, 3. School of Earth Sciences, The University of Melbourne, 4. Institute of Nature and Environmental Technology, Kanazawa University, 5. Department of Earth Sciences, Kanazawa University

Northeast (NE) Japan Arc is categorized as an arc-trench system, where volcanism and earthquakes frequently occur. The tectonic history of the NE Japan Arc has been well-investigated based on geomorphic and geologic approaches. Furthermore, the recent multidisciplinary project (Crustal Dynamics) successfully achieved and accumulated geoscientific results by means of GPS, active faults, numerical modeling, friction experiments, etc (see also Iio et al. 2018, EPS). For estimating vertical deformation over long-term timescales (>10^6 yr.), our research group has investigated the thermal/denudation histories on every geomorphic province of the NE Japan Arc by using low-temperature thermochronology.

Thermochronology can reconstruct the time-temperature relationship of rock/mineral samples, based on radiometric ages and closure temperatures specific to the combination of radiometric dating methods and target minerals. Low-temperature thermochronology is useful for understanding upper crustal mountain building processes and has been applied to estimate the tectonic history of major orogens (e.g. European Alps: Wagner et al. 1977, Mem. Inst. Geol. Mineral., Univ. Padova; Himalayas: Blythe et al. 2007, Tectonics). However, the thermochronology approach directly measures cooling processes, rather than denudation/uplift histories. Therefore, it is noteworthy that denudation/uplift histories require some assumptions, such as appropriate geothermal gradients and dynamic equilibrium between denudation and uplift. Long-term uplift rates on >1 Myr time-scales, require estimates from such protocols, which are assumed to be equivalent to the vertical inelastic deformation of the crust (Ikeda et al. 2012, JGS).

Between 2014-2019 we collected over 100 granitic rock samples from the NE Japan Arc. Low-temperature thermochronology has been applied to many of these samples, including the apatite/zircon (U-Th)/He (namely, AHe and ZHe) (Sueoka et al. 2017, EPS) and apatite fission-track(AFT) methods (Fukuda et al. 2019, JAES:X), particularly from Cretaceous-Paleogene granites located in the southern NE Japan Arc. This research elucidated the contrast of thermal/denudation histories among the island arc provinces, i.e., Abukuma mountains, Ou Backbone Range(OBR), and Iide and Asahi mountains. In this presentation, we report results based on AHe/ZHe and AFT thermochronometry from Cretaceous granites in the northern NE Japan Arc, aimed at reconstructing arc-parallel and across-arc thermal/denudation histories.

We obtained AHe ages ranging between 88.6-0.9 Ma, AFT ages from 138.0-2.0 Ma, and ZHe ages from 83.9-7.4 Ma. The ages show contrasting thermal/denudation histories between the fore-arc side, OBR, and back-arc side, which are similar to the southern NE Japan Arc. This observation implies that arc-parallel mountains have approximately the same trend along NE Japan Arc. On the other hand, some differences were observed between the northern and southern NE Japan Arc as follows; (1) significantly

©2019. Japan Geoscience Union. All Right Reserved.

older AFT ages were obtained for Kitakami mountains (130-75 Ma) compared to the Abukuma mountains (80-40 Ma), (2) much younger AFT ages at ~2 Ma were found on the back-arc side, Taihe mountains, and (3) considering the expected relationship between expected closure temperatures, some reversal of coexisting AFT ages compared to AHe/ZHe ages (e.g., FST04, FST05) were observed.

Future work will involve thermal inverse modeling using AFT thermochronometry for estimating more rigorous constraints on thermal histories. This will also involve increasing the number of sampling localities in an attempt to extend our study area.

Uplift and denudation history of the South Fossa Magna region using low-temperature thermochronometric methods

*Yumi Kobayashi[1], Shigeru Sueoka[2], Shoma Fukuda[1], Barry P. Kohn[3], Tatsunori Yokoyama[2], Noriko Hasebe[4], Akihiro Tamura[5], Tomoaki Morishita[5], Takahiro Tagami[1]

1. Graduate School of Science, Kyoto University, 2. Tono Geoscience Center, Japan Atomic Energy Agency, 3. University of Melbourne, 4. Institute of Nature of Environmental Technology, Kanazawa University, 5. Department of Earth Sciences, Kanazawa University

The South Fossa Magna region is located at the junction of the Japan and Izu-Bonin arcs. Up to four crustal blocks of the Izu-Bonin arc, i.e., Kushigatayama, Misaka, Tanzawa, and Izu, collided this region and formed its crustal structures since the middle Miocene (1, 2). The timings of the collision events have been estimated by deposition ages of sediments between each block and the Japan arc. However, these questions remain unresolved.

In this study, we performed apatite fission track (AFT) and apatite (U-Th)/He (AHe) thermochronometric methods and U-Pb dating method to resolve the uplift and denudation history of the South Fossa Magna region.

The AFT ages are estimated to be 14.7 ±4.7 Ma in the Okuchichibu area (c.f., hornblende K-Ar age: 10.5 ±1.5 Ma (3)), 3.0 ±0.5 Ma, 9.2 ±2.2 Ma, and 7.6 ±0.9 Ma in the Kano Mountains (c.f., biotite K-Ar age:i.e., 10.5 ±0.4 Ma (4)), 3.6 ±2.5 Ma in the Minobu area (c.f., biotite K-Ar age: 5.4 ±0.3 Ma (5)). Also, the AFT ages are inferred at 37.0 ±5.9 Ma in Mt. Tsukuba (c.f., Rb-Sr whole rock isochron age: 61.6 ±4.3 Ma (6)), and 44.9 ±4.1 Ma in the Sori granitoid in Gumma Prefecture (c.f., biotite K-Ar age: 92.6 ±0.6 Ma (7)). The rocks which have younger AFT ages than the formation ages may reflect the uplift and denudation events since the rock formation. However, exhumation rates of the Tanzawa mountain, the closest mountain to the Izu block, did not increase before and after the collision of the Izu block (8), which may imply that the collision of the Izu block did not cause the uplift and denudation events significantly.

We also obtained the new AHe ages and U-Pb ages. The AHe ages for Okuchichibu area, Kanto mountains and Minobu area are about 3 Ma. Furthermore, according to the results of the inverse thermal analysis using the apatite FT lengths data, the granites in Okuchichibu area and the southern part of Kanto mountains cooled rapidly since about 3 Ma, and the granites in Minobu area and northern part of Kanto mountains cooled rapidly since about 1 Ma. The results of AHe ages were consistent with the results of inverse analysis. Based only on these ages, the rapid cooling ages of 3 Ma and 1 Ma are comparable to the collision ages of the Tanzawa block and the Izu block, respectively.

Correlation between residual uplift and recurrence interval of the Kanto earthquake based on developmental process of coastal lowland

*Haeng-Yoong Kim[1]

1. Osaka City University, Graduate School of Science, Division of Biology &Geosciences

It is well known that the marine terraces are formed due to uplift of the seabed during the earthquake. The marine terrace consists of a near-flatter terrace surface emerged above sea level during the earthquake and a low terrace riser of less than several meters in height formed after the earthquake and is distributed in a staircase pattern along the coastline. In the previous research, one step of maritime terrace is often recognized as a trace of an earthquake once, and based on this premise, many previous researches were conducted to estimate the reoccurrence interval and the amount of uplift during the earthquake. However, Maemoku (1988) inferred that one step level of flat terrace surface is the topography formed by multiple repetitions of coseismic uplift and interseismic earthquake settlement occurring in the plate subduction zone of the Nankai Trough. And the stepped terrace was formed by the active fault of the land side. We got geomorphological and geological data demonstrating this previous reasoning on the Miura Peninsula located directly above the plate subduction zone of the Sagami trough.

On the rocky coast of the Miura Peninsula, two step of marine terrace surfaces formed in association with the 1923 Taisho and 1703 Genroku earthquakes are observed near 1 m and 2 m above sea level,(Matsuda et al., 1974). In the inner part of the estuary creek, which is formed many in the peninsula, the coastal lowland landfilled with sediments transported from the hinterland into the bay floor is distributed around the altitude of 2 m as similer as 1703 terrace surface. We examined the development process of coastal lowland in the inner part of estuary creek.

As a result of the detailer geomorphological interpretation, a flat coastal lowland apparently spreading as a single face is composed of multiple small maritime terraces, not one terrain. The marine terraces were divided into 5 areas with less than 2.1 m above sea level by topographical interpretation. As a result of investigating the emergent time and the distribution altitude of the marine terrace surface, the marine surface of the 1923 Taisho earthquake in the order of 1.22 m - 1.37 m in the order of younger, the wave erosion shelf surface of the 1703 Genroku earthquake by Nishihata et al. (1988): 2.3 m, the marine surface of the 1293 year pre-earthquake (after 1260-1380 cal.AD): 1.27 m, the marine surface of the earthquake (915 cal.AD to 1150 cal.AD) around the year AD is 1.63 to 1.93 m, Terraced surfaces are distributed until the earlier age.

In this way, the reasons that different formational time of terraces remain in coastal lowlands with extremely altitude is formed in Miura peninsula are as follows, because 1: the coseismic uplift due to the elastic repulsion and the interseismic subsidence accompanying the strain accumulation are repeated (Shimazaki et al., 2011; Kim and Mannen, 2018), therefore 2: a new marine surface is formed near the sea level by the next earthquake (Kim and Mannen, 2018), and 3: there is a condition that the terrace surface is preserved by the coating layer. In addition, because the height of the ground is stable in the long term due to the balance of uplift and subsidence, and it is estimated that wide coastal lowlands, which apparently appear as a continuous ground surface, develop by repetition of uplift and subsidence. Between 1293 and 1703, where the period of occurrence of the earthquake occurred long, the raised surface in 1293 returned to the original altitude, and between 1703 and 1923 in which the occurrence interval of the earthquake was short, the raised surface in 1703 The next Kanto earthquake occurred

before going back to the original altitude.

Mechanics preserving co-seismic uplift and marine terraces: dissymmetric patterns of co-seismic and inter-seismic deformation

*Kyohei Suzuki[1], Junki Komori[1], Ryosuke Ando[1]

1. Graduate School of Science, University of Tokyo

Four large Holocene marine terraces are known in the southern part of the Boso Peninsula and called Numa I - IV. The newest one (Numa IV) was uplifted at the time of the Kanto Genroku earthquake, and from the similarity of the spatial distribution, it was considered that the Numa I-III Ire also formed from uplifts during the Genroku-type events. From this, the amount of coseismic uplift and slip amount were estimated from the height of the terraces (Matsuda et al., 1978; Nakata et al., 1980; Namegaya et al., 2011; Sato et al., 2016 etc.). However, the relationship between Holocene marine terraces and paleoseismic events was doubted in previous studies (Matsu'ura and Sato 1989, Noda et al., 2018). There is Matsu'ura and Sato (1989) model which is a mechanical model explaining the long-term surface uplift. This model expresses seismogenic region by back slip at the interseismic period and forward slip at the coseismic period and givessteady forward slip along the whole plate boundary surface. From this model, the coseismic vertical displacement pattern cancel out and the interseismic one and the uplift accumulation on the surface was attributed only to the effect of the steady-state plate motion.However, this is consequence based on a simple model expressed that slab as one plane in horizontal layered structure and assumed that the amount of back slip at the interseismic period and the amount of forward slip at the coseismic period are equal. The purpose of this study is to verify whether the coseismic uplift amount records the slip amount and remains and accumulates over earthquake cycles, and it affects coastal terrace formation process in a general mechanical model, considering the shape of the slab, the plate motion, and the coseismic fault motion.

As the calculation procedure, first, We give a constant displacement (10 m) to the edge of the oceanic plate and accumulate strain on the plate boundary. Next, We release all accumulated shear stress by coseismic fault slip,and obtain the vertical displacement pattern on the surface and the slip amount on the plate interface. Based on the fact that the principle of superposition is established in the linear elasticity theory, in this study, We separated the boundary conditions of both the interseismic period and the coseismic period,and calculated the respective vertical displacements and the residual amount by taking the sum. To verify the influence of irregularities on the actual plate boundary surface on the spatial pattern of vertical displacement, We also calculated two patterns for the case where irregularities were locally placed on the plate interface.

As a result of the calculation, we found that the interseismic slip amount in the no-cuppled area converged to 0 in the vicinity of the coupled area, and the coseismic slip amount was not uniform, and occurred across the plate boundary surface. This suggests that the slip on the plate boundary is intermittent in the seismic cycle. Next, from the vertical displacement residuals, we found that their spatial patterns at the interseismic period and the coseismic period were different.Furthermore, when local irregularities are placed on the plate boundary surface, it was found that the spatial pattern of the coseismic uplift is different corresponding to the slip amount of each model. This suggests that the height records the slip amount, and the shape of the plate boundary surface attributes actual coastal terrace formation. The consequence of this study is that the slip on the plate boundary is intermittent, and the coastal terraces depend on the coseismic slip.Therefore, the model in this study will give meaning to estimate the paleoseismic image from the height of coastal terraces.

Enhanced resolution of stress tensor inversion by using fault instability analysis

*Katsushi Sato[1]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University

Modern stress tensor inversion techniques for fault-slip analysis are based on the Wallace-Bott hypothesis which assumes that the slip directions and shear stress vectors are parallel. The hypothesis has an advantage in the applicability to high pore fluid pressure conditions and low friction faults, since the magnitudes of shear and normal stresses are not evaluated. However, the hypothesis gives only loose constraint on stress from observed faults in exchange for the wide applicability, which causes poor detectability of stresses.

This study tries to improve the detectability by introducing the fault instability (Vavrycuk et al, 2013; Sato, 2016) into the stress tensor inversion. The fault instability is defined as the nearness of the point representing shear and normal stresses on Mohr diagram to the line of Coulomb failure criteion. The fault instability is imposed on the fitness of a stress candidate to a fault-slip datum as a weight. Since the calculation of fault instability requires the friction coefficient, this study used several values of friction coefficient and compared the results.

The new method was applied to natural meso-scale fault-slip data. The faults cutting the Awa Group (Chiba Prefecture, central Japan) newly gave a reverse-faulting regime of stress in addition to normal faulting ones which can be detected by a conventioanl technique. An E-W trending tensional stress was newly detected from the faults cutting the Sekinan Group in the Beppu-Shimabara graben (Oita Prefecture, southwest Japan) where N-S trending extensional tectonism is ongoing. These resutls showed the improved resolution of stress tensor inversion by the incorporation of fault instability.

Focal mechanisms of the aftershocks of the 2000 Western Tottori Earthquake inferred from P wave first-motion data and spatial stress pattern

*Takaki Iwata[1]

1. Tokiwa University

A Bayesian approach to estimating a spatial stress pattern was developed [Iwata, 2018, JGR] (hereafter IW2018), and as an extension of this approach Iwata [2018, SSJ fall meeting] has proposed a method to infer focal mechanisms from P wave first-motion data and stress pattern estimated with the Bayesian approach. In this study, this method was applied to a real dataset taken from aftershocks of the 2000 Western Tottori earthquake.

The analyzed P wave first-motion dataset was retrieved from Kawanishi et al. [2009, JGR], which complied records from October 15 to November 30 in 2000. This dataset contains 47,570 P wave first-motions of 3592 events (for details see IW2018). The spatial pattern of stress field was taken from the result of IW2018 that also analyzed the same P wave first-motion dataset. The inferred focal mechanisms show rotation of the azimuth of P-axis around the main fault in the southern area; this feature has been seen in Yukutake and Iio [2017, EPS] and will be the reflection of the stress rotation found in the same area revealed by IW2018.

From the inferred focal mechanisms and spatial stress pattern, the normal and shear stress exerted on the fault plane was evaluated. Then, following the method of Terakawa [2010, Geology], fluid pressure for each of the events was estimated. Two datasets of the fluid pressure in the northern and southern areas of the aftershock areas were constructed and examined whether the two datasets follow the same distribution with the Kolmogorov-Smirnov test. Consequently, the test revealed that the fluid pressure in the southern area is significantly larger than that in the northern area, with a P-value of 1.6e-3.

Stress tensor inversion in focal area of the 2016 Mw7.8 Kaikoura earthquake, New Zealand

*Miu Matsuno[1], Tomomi Okada[1], Satoshi Matsumoto[2], Yuta Kawamura[2], Yoshihisa Iio[3], Tadashi Sato[1], Stephen C Bannister[4], John Ristau[4], Martha K Savage[5], John Townend[5], Jarg Pettinga[6], Francesca Ghisetti[7], Richard H Sibson[8]

Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, 3. Disater Prevention Research Institute, Kyoto University, 4. GNS Science, New Zealand, 5. Victoria University of Wellington, Wellington, New Zealand, 6. University of Canterbury, Christchurch, New Zealand, 7. TerraGeologica, Ruby Bay, New Zealand, 8. University of Otago, Dunedin, New Zealand

We study spatio-temporal change of stress field of the 2016 Kaikoura earthquake in the northern area of South Island of New Zealand. Data from both the 51 temporary stations and 22 GEONET stations were used. Data collection was from March 2011 to December 2017. We derived focal mechanisms using HASH (Hardebeck and Shearer, 2002), By focal mechanism solutions of earthquake, we estimated stress fields of main shock of Kaikoura earthquake before and after. We used SATSI (Hardebeck and Michael, 2006] for stress tensor inversion. In our previous result (Sato, 2017 master’ s thesis in Tohoku University), there is possibility that on-fault aftershocks bias the result of stress tensor inversion. Therefore, by using Kagan angle between mainshock fault model and each focal mechanism, we remove aftershock on the faults, and perform stress tensor inversion. We use the fault model by Hamling et al. (2017). In a result, Kagan angles of many earthquakes are large, so this means that many aftershocks occurred off the fault plane. The results do not depend on threshold of Kagan angle. Obtained stress tensor inversion after main shock in areas near London Hill Fault and near Kekerengu fault are strike-slip fault type with SHmax orientation of ~N115E, which is almost same as for before the Kaikoura earthquake (e.g., Sibson et al., 2012; Townend et al., 2012), and stress tensors before and after the mainshock didn't appear to change after the earthquake beyond the estimation error. However, in the area near the hypocenter of the main shock we still cannot get a stable stress tensor. Also we plan to obtain results of a stable stress tensor for before the main shock by increasing the number of focal mechanisms of earthquakes that we examine.

Victoria University of Wellington, Wellington, New Zealand, 6. University of Canterbury, Christchurch, New Zealand, 7. TerraGeologica, Ruby Bay, New Zealand, 8. University of Otago, Dunedin, New Zealand

The Mw7.8 Kaikoura Earthquake struck the northeastern south island, New Zealand, on November 14, 2016. A lot of researchers have tried to explain the cause of this earthquake and revealed the structure in this area. Among variety of prior researches, Clark et al. (2017) argued that this earthquake, which produced surface deformation including uplift and complex surface rupture, was caused by 21 strike-slip, reverse and oblique slip faults. Cesca et al., (2017) proposed an earthquake fault model that consists of three faults in northern, central and southern part, based on the hypocenter distribution of aftershock activity. These studies suggested in common that this earthquake was provoked by multiple faults with complex rupture process.

We had installed 75 temporary seismic stations before the earthquake in the South Island, New Zealand in addition to GEONET stations. The seismic network has successfully recorded the mainshock and the following aftershocks. Here, we relocated the hypocenters of the events associated with the Kaikoura earthquake by using data obtained from the seismic network. The hypocenters was determined by the double difference hypocenter determination algorithm (i.e. HYPODD, Waldhauser and Ellsworth, 2000). The overall distribution of the hypocenters are distinguished into two clusters, northern and southern clusters. The hypocenter distribution in vertical cross section normal to the major alignment of the aftershocks in N54W reveals that the fault in southern part dips to eastward. On the other hand, although we find out a northern cluster in terms of horizontal projection, no obvious faults are recognized in the vertical cross-section, suggesting complex fault structure in the northern cluster.

3-dimensional GPS velocities in Colombia and their implications for interplate coupling

*Sindy Carolina Lizarazo[1], Takeshi Sagiya[2], Hector Mora-Paez[3]

1. Graduate School of Environmental Studies, Nagoya University, 2. Disaster Mitigation Research Center, Nagoya University, 3. Geological Survey of Colombia

Colombia is located in a region of complex interactions among the Caribbean, Nazca and South American plates, as well as the North Andean and Panama-Choco blocks. As a consequence of this tectonic setting, active faulting and intense seismicity are occurring especially in the areas of plate subduction or collision. The GeoRED project by the Geological Survey of Colombia installed a permanent GPS network in Colombia to study the regional kinematics with an intention to improve disaster mitigation activities. An initial velocity field was obtained and discussed by Mora et al. (2019) based on data from 60 sites under the ITRF2008 reference frame.

Here we present an updated result of Colombian GPS velocity field with 80 sites. The daily coordinates are calculated under the ITRF2014 reference frame with GAMIT-GLOBK software. We calculate 3-dimensional velocities with HECTOR software (Bos et al., 2013) based on the daily coordinates for the period from January 2014 to March 2016. There was no earthquake larger than magnitude 6 in Colombia, so the velocity pattern represents that of the interseismic period. For this time period, enhancement of the permanent network provides a better spatial resolution of the deformation pattern in some regions.

The results show a general consistency with the previous study, demonstrating the correctness of the current approach. In addition, vertical components show a slight of coastal uplifts at a few mm/year along the Nazca subduction zone. These signals indicate the lower limit of the plate coupling on the plate interface and we discuss the interplate coupling based on the 3-dimensional velocity data. Also, a significant margin-normal contraction is identified along a part of the Caribbean subduction zone near Colombia-Panama border. However, the vertical signal is not significant compared to the horizontal contraction, indicating that the elastic coupling model may not be applicable to this area.

[S-CG61] Dynamics in mobile belts

convener:Yukitoshi Fukahata(Disaster Prevention Research Institute, Kyoto University), Toru Takeshita(Department of Natural History Sciences, Graduate School of Science, Hokkaido University), Hikaru Iwamori(Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology)

The dynamic behaviours of mobile belts are expressed across a wide range of time scales, from the seismic and volcanic events that impact society during our lifetimes, to orogeny and the formation of large-scale fault systems which can take place over millions of years. Deformation occurs on length scales from microscopic fracture and flow to macroscopic deformation to plate-scale tectonics. To gain a physical understanding of the dynamics of mobile belts, we must determine the relationships between deformation and the driving stresses due to plate motion and other causes, which are connected through the rheological properties of the materials. To understand the full physical system, an integration of geophysics, geomorphology, and geology is necessary, as is the integration of observational, theoretical and experimental approaches. In addition, because rheological properties are greatly affected by fluids in the crust and fluid chemical reactions, petrological and geochemical approaches are also important. After the 2011 great Tohoku-oki earthquake, large-scale changes in seismic activity and regional scale crustal deformation were observed, making present-day Japan a unique natural laboratory for the study of the dynamics of mobile belts. This session welcomes presentations from different disciplines, such as seismology, geodesy, tectonic geomorphology, structural geology, petrology, and hydrology, as well as interdisciplinary studies, that relate to the dynamic behaviours of mobile belts.

Three-dimensional imaging of geo-fluid distribution at NE-Japan forearc using wideband magnetotelluric measurements

*Masato Fukai[1], Yasuo Ogawa[1], Kuo Hsuan Tseng[1], Masahiro Ichiki[2], Shinichi Takakura[3]

1. Tokyo Institute of Technology, 2. Tohoku University, 3. National Institute of Advanced Industrial Science and Technology

In Tohoku Japan, the Pacific plate that subducts under the Eurasian plate is old, thick, and cold. The basalt - eclogite phase transition is expected to occur at a depth of 100 km. The water released in the dehydration reaction forms serpentinite, which is transported to the deeper part. Serpentinite decomposes at a depth of about 150 km and water rises in the mantle due to buoyancy. Therefore, it is believed that there is no rise in water caused by slab mineral dehydration in the Northeast Japan forearc (Kazahaya et al., 2014). In contrast, the seismic tomography in NE Japan fore arc (Zhao et al., 2014) imaged low velocity regions in the forarc which suggests rising fluids from slabs which is called as "Water wall". In this research, we aimed to constrain the rising fluid distribution in the forearc from the 3d electric conductivity structure by magnetotelluric observations in Kitakami Mountains.
In our model, distribution of low resistivity indicating rising fluids from the deep part was not analyzed corresponding to the P wave low velocity region of Zhao et al.(2014). However, vertical low resistivity was analyzed from the volcanic front toward forarc. The conductors spread 30 km east of the volcanic front at depths of 10-40 km. This low resistivity is in good agreement with the low velocity distribution (Zhao et al., 2014; Okada et al., 2015). The low resistivity east of volcanic front is almost vertically continuous from the uppermost mantle to the middle crust. Therefore, this may indicate that the fluid on the mantle flow reaches the uppermost mantle of the forearc and releases fluids in the forearc crust.

Elastic wave velocity and electrical conductivity in brine-saturated rocks and microstructure of pores

*Arina Tomioka[1], Tohru Watanabe[1]

1. University of Toyama

Geophysical mapping of fluids is critical for understanding crustal processes. Seismic velocity and electrical resistivity structures have been studied to reveal the fluid distribution. However, the fluid distribution has been still poorly constrained. Observed velocity and resistivity should be combined to make a quantitative inference on fluid distribution. The combined interpretation requires a thorough understanding of velocity and resistivity in fluid-saturated rocks. We have made measurements of elastic wave velocities and electrical conductivity in brine-saturated rocks under confining pressures, and examined pore structures with SEM.

Measurements and microstructural observations were made on granites (Aji, Kagawa Pref., Ohshima, Ehime Pref.), granodiorite (Enzan, Yamanashi, Pref.) and tonalite (Kadohara, Fukui Pref.). Cylindrical rock samples (D=26 mm, L=30 mm) were filled with 0.1 M KCl aqueous solution, and velocity and conductivity were simultaneously measured by using a 200 MPa hydrostatic pressure vessel. The pore-fluid was electrically insulated from the metal work by using plastic devices. The confining pressure was incrementaly increased up to 150 MPa, while the pore-fluid pressure was kept at 0.1 MPa. It took 3 days or longer for the electrical conductivity to become stationary after increasing the confining pressure.

Rock samples showed moderate increase in velocity and large decrease in conductivity under confining pressures. Electrical conductivity steeply decreased at low pressures (<20 MPa) and then showed gradual decreases. Grain boundary cracks are pervasive in rock samples. The increase in velocity and decrease in conductivity at low pressures must be caused by the closure of grain boundary cracks with small aspect ratios ($<10^{-3}$). SEM images show that the aperture of a grain boundary crack varies along its width. Large aperture parts can be open even under high pressures to be conduction paths. The difference in conductivity at high pressures must reflect the difference in the amount of large aperture parts.

Influence of grain shape and grain size distribution on connectivity of pores in granular materials.

*Katazakai Haruka[1], Tohru Watanabe[1]

1. Toyama University

Transport properties such as electrical conductivity and permeability are sensitive to the connectivity of pores. Pore structure in granular materials varies with the shape and size distribution of grains. In order to understand the influence of the shape and size distribution of grains, electrical conductivity and permeability were measured on granular materials saturated with 0.1 mol/L KCl aqueous solution. Spherical glass beads and oblate quartz sand of various sizes were employed. The ratio of conductivity to porosity was significantly higher in glass beads than in quartz sand. This observation suggests that a higher connectivity of pore is established in glass beads than in quartz sand. The influence of the size distribution of grains was studied on mixtures of small (D=0.2 mm) and large (D=1 mm) glass beads. The porosity deceases from 36% to 22% as the fraction of large grains increases 0% to 60%. Electrical conductivity decreases with decreasing porosity, while permeability shows a small decrease. As the fraction of large grains increases from 60% to 100%, the porosity increases from 22% to 36% and permeability increases by around 2 orders of magnitude. This change suggests that the pore size steeply increases as the fraction of large grains increases from 60%, since permeability strongly depends on the size of pores. X-ray micro CT observation was conducted to examine pore structure.

Change of pore connectivity in granular materials under axial compression

*MAREMICHI ABE[1], Tohru Watanabe[1]

1. Toyama University

The influence of axial compression on the connectivity of pores in granular materials was studied. Electrical conductivity and compressional wave velocity were simultaneously measured on brine-saturated granular materials under uniaxial compression. Spherical glass beads and oblate quartz sand were employed. X-ray micro CT was conducted on granular materials impregnated with epoxy resin to examine microstructure of pores. Compressional wave velocity increases and electrical conductivity decreases with increasing axial stress. When the axial stress was increased from 0 to 5 MPa, compressional wave velocity increased by around 12% in both materials and electrical conductivity decreased by 0.7 and 1.7% in glass beads and quartz sand, respectively. The increase in compressional wave velocity must reflect the increase in contact area between grains, which was observed with X-ray micro CT. The decrease in conductivity must be caused by the decrease in connectivity of pores. X-ray micro CT images show that the connectivity of pores is easily lost under axial compression in quartz sand owing to its oblate shape.

Estimation of crustal strength using residual strain of quartz in deformed conglomerate and inhomogenous strain of conglomerate layer -As an example of multiple collision zone of Izu-Bonin arc, Fujikawa valley, Central Japan-

*Shun Suzuki[1], Kenta Kobayashi[1]

1. Graduate School of Science and Technology, Niigata University

South Fossa Magna is understood as a site where the Izu-Bonin arc on the Philippine Sea plate collides with Honshu arc, and it is the only arc-arc multiple collision zone in the world. Maruyama (2008) reported deformed conglomerate outcrop accompanied by cataclastic flow in the Hamaishidake Formation (late Miocene to Pliocene). Report of them in the collision zone is not limited to the Fujikawa area, but from the Ashigara Group and from the Erimo Formation in the Hidaka collision zone of Hokkaido (Uda, 1976), have been reported. In this study, various analyzes were performed on deformed conglomerates found in the Fujikawa area, and the cause (temperature / pressure condition) and the position in the collision zone were clarified, it aimed to restrict the multiple collision phenomenon and the deformation environment of trench fill sediments.

[Outcrop outline]
It is revealed that the deformed conglomerate outcrops occurred in the geologic body (Fujikawa Shear Zone) which makes a high dip zone in the direction of NW-SE, and they are modifying the initial NS system folding. The long axis direction of the gravel showing N40W trend and the shear fabric of the gravel showing sinistral sense.

[Paleo stress analysis by multiple inverse method]
The result of the MIM analysis (Yamaji et al., 2011) using the slip data of the gravel fault plane with the flow deformation mode shows ENE-WSW compression, which is not consistent with the current Philippine Sea plate motion.

[Restrictions on forming environmental condition of deformed conglomerate]
We tried to guess the maximum heat temperature of the geological body using the carbonaceous material Raman spectrum (Kouketsu et al., 2014), and examination of the differential stress level using the internal strain of the quartz (Takagi et al., 1988). As a result, it is revealed that deformed conglomerate outcrops heated only 150℃ or less, and the maximum heated temperature is rising toward the lower formation of Hamaishidake Formation. When the geothermal gradient is estimated by layer thickness conversion, the value such as 4~5℃ / 100 m is restored, and the depth at which the 150℃ heating can be recorded is about 3~4 km. That is, the deformed conglomerate is found to be a product under shallow and low temperature conditions. On the other hand, the estimated differential stress value is 50-100 MPa, which is strongly deformed despite being a shallow deformation.

[Discussion]
As for the ENE-WSW compression obtained from cataclastic flow slip data, it can not be explained with only the motion of the Philippine Sea plate. If these as deformation events after the deposition age limit (about 5 Ma) of the Hamaishidake Formation, it is necessary to consider the influence of E-W compression from around 3 Ma (Takahashi, 2006) or the ENE movement of Amur Plate (Komatsubara, 2015), and it

©2019. Japan Geoscience Union. All Right Reserved.

means that the tectonics are not only dominated by the Philippine Sea plate. Considering trench fill sediment objects in the Fujikawa Valley as accretionary bodies, since deformed conglomerate occurs near the boundary fault of the middle and upper strata of the Fujikawa Group, it may be a deformation near the Mega Splay Fault branching from the plate boundary fault at the Tanzawa block collision stage. In addition, considering the usual crustal strength (Byerlee, 1978), theoretically it is not possible to record a differential stress value of 100 MPa at 4 km underground. However, according to the data of drilling at the plate boundary Nankai Trough (Hamada et al., 2018), it is pointed out that the differential stress value rises in the Accretionary prism and reaches nearly 100 MPa. In other words, in the geological body near the plate boundary, it is predicted that the crustal strength is large and it is placed in the high differential stress state also in the subsurface shallow part, and the deformed conglomerate is considered to be a product in such a place.

An Introduction to Ryoke Cataclastic Rocks in Tsukide, Mie Prefecture, Japan: An Approach Using 3D Reconstructions From Thin Sections

*Thomas Jing Yi Yeo[1], Toru Takeshita[1]

1. Department of Natural History Sciences, Graduate School of Science, Hokkaido University

The Japan Median Tectonic Line (MTL) is the longest fault system in Japan where it spans from Kyushu Island and extends towards the north east direction up until Ibaraki Prefecture. It has been an active strike slip fault since the Mid-Cretaceous period, which was originally formed as the southern marginal shear zone in the Ryoke belt (e.g. Hara et al., 1980) leading to the formation of mylonite and superposed by cataclasite at the core region.

This study aims to identify the kinematic history of the fault plane and its effect on the cataclastic rocks from a 3D viewpoint. The fieldwork was conducted in the hanging wall section of the MTL in Mie Prefecture, Japan. The hanging wall of the MTL in the study area is characterized by Creataceous Ryoke granitic rocks which was deformed into mylonitic rocks and was later overprinted by cataclasite at the proximal region. The main objective of this project is to identify and relate the kinematics of the MTL and physical conditions during the formation of the cataclasite.

From the thin sections observations, the grain size reduction of the mylonitic clasts was observed and was related with cataclasis. The cataclasite formed at the brittle fault zone enables chemically rich fluids to penetrate. This promotes the growth of foliated phyllosilicate minerals mainly muscovite from the alteration of presumably feldspars. Microstructural features such as riedel shears with C’ -type shear band fabric assist in indicating the sense of motion. Fracture densities and distributions are also quantified in all of the three sides of the sample in order to obtain a clearer view on the brittle properties.

Also, based on the crossed cutting relationship seen in the microstructures of the sample, a schematic deformation history of the sample was constructed. The MTL begins with a sinistral shear sense which causes the mylonitisation of the Ryoke granitoids. Upon the cooling of temperature, cataclasite was formed and transpression of the shear zone causing pressure solution seams to be precipitated which resulted in the formation of phyllonite. Lastly, a late stage reactivation of the pressure solution seams caused faulting to occur.

Furthermore, using the rake angle of the C’ and S fabrics of the Riedel shears, measured from the thin sections representing the different sides of the sample, the orientations of both the C’ and S planes could be reconstructed and plotted as a stereographic projection with values of [278/ 48N] and [124/ 82SW] respectively. The XZ plane which is 90° away from the intersection point of C’ and S planes has an orientation of [031/ 67SE]. By assuming plane strain and with the assistant of the software StrainSim v3, the simple shear strain, γ=0.73, the angular shear, Ψ=36° and material internal friction angle, Φ= 56°. Similarly, the principle stress orientations are found to be at [62°→158], [23°→301] and [15°→037] for σ_1, σ_2 and σ_3 respectively. By combining all the relationships mention above, the motion sense of the fault was identified as the NE block moving NW and downwards with a more dominant dip slip component. This dominant dip slip movement of the fault could be potentially related to the normal faulting movement of the MTL during the Ichinokawa Phase at 63-58Ma.

Moreover, the electron backscatter diffraction (EBSD) analysis of the sample is currently being conducted

Relationships between spacing and growth or linkage of normal faults in the Miyako Island, South Ryukyu arc, Japan

*Sumire Maeda[1], Makoto Otsubo[1], Daisuke Asahina[1], Yuki Furuno [1]

1. Research Institute of Earthquake and Volcano Geology, Geological Survey of Japan/AIST

Estimating interaction and linkage of faults is one of the most important issues to evaluate the long-term activity of future earthquakes. For the long-term evaluation of the major active fault zones, Headquarters for Earthquake Research Promotion (e.g., HERP, 2010) uses so-called 5-km gap threshold (Matsuda,1990) to group and segment the fault traces. However, the fault size may change in the future, so it is necessary to introduce a multilateral index that can evaluate temporal and spatial evolution of faults.
Fault spacing, the horizontal distance between neighboring faults, has been related to stress reduction around faults (e.g., Soliva et al., 2006; Fossen and Rotevatn, 2016). Soliva et al. (2006) investigated the relationship between the fault spacing and the stress reduction area for a series of faults. Their studies show that the fault spacing is linearly related to the mechanical layer thickness. In the evolution process of normal fault, it is assumed that randomly distributed faults start to propagate and couple at the beginning, and the fault spacing becomes regularly distributed. Therefore, it may be possible to estimate the thickness of the mechanical layer in which the faults exist from the regular spacing of the saturated faults.
In this study, we investigated the normal faults in the Miyako Island, South Ryukyu arc, Japan in order to examine the possibility of fault linkage based on the fault spacing and the Coulomb shear stress perturbation. We found that the Miyako Island has three fault groups with different types of strikes, and these fault spacings are almost regularly distributed. The layer thickness of the NW-SE strike fault group can be estimated about 3,500 m based on the faults spacing. This results imply that the fault group extends only to the upper end of the seismogenic zone (3-17 km; HERP, 2012). In addition, the thickness of this fault group is close to the thickness of the Ryukyu Group and Shimajiri Group of the Miyako Island. Large-scale faults beneath the Miyako Island may be branched in the shallow soft-sedimentary rocks.

3D fault architecture along the Median Tectonic Line, eastern Kii Peninsula, SW Japan

*Norio Shigematsu[1], Takuma Katori[1,2], Jun Kameda[3], Ayumu Miyakawa[4]

1. Research Institute of Earthquake and Volcano Geology, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, 2. Graduate School of Science and Technology, Niigata University, 3. Department of Natural History and Sciences, Hokkaido University, 4. Research Institute of Geology and Geoinformation, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

The heterogeneous fault deformation around the brittle-plastic transition possibly affects the fault behavior significantly including the generation of earthquakes (e.g., Scholtz, 2001). To understand the effect, a detailed fault zone architecture is essential. In this study we have tried to construct a 3D fault zone architecture model based on the geological study of an exhumed fault zone, the Median Tectonic Line (MTL) in the western Kii peninsula SW Japan.

Accurate positions were determiend by applying SfM (structure from motion) and MVS (multi-view stereo) calculation (e.g., Furukawa and Hernández, 2013) to photos taken by an UAV (Unmanned Aerial Vehicles), and GNSS (Global Navigation Satellite system) surveying (e.g., Bemis et al., 2014) to reveal the 3D structures. The microstructures, chemical composition of minerals and crystallographic orientations of quartz using an electron back-scatter diffraction (EBSD) (Prior, et al., 1998) were analyzed to characterize the defomation of fault rocks. Based on these deformation features, the 3D fault zone architcture were constructed using a 3D-CAD software.

In the 3D fault zone architecture model, the fault plane of the MTL (lithological boundary) is an almost perfect plane dipping to the North. The structures can be divided into two main structures. One includes mylonite and cataclasite showing sinistral sense of shear. The other structures consist of scaly cataclasite showing dextral sense of shear and further younger structures including the lithological bonadry. The later structures cut the former structures indicating the sequence of deformation within the fault zone.

Scaly cataclasite only apper in the vicinity of the MTL, and is characterized by the strong foliation defined by the alignment of chlorite. Modal fraction chlorite is much larger than that in the surrounding Ryoke drived rocks, and pressure-solution seam is well developed. The estimated temperature based on the chlorite geothermometry is about 300 ºC (Bourdelle et al., 2013).
The deformation of the structures showing sinistral sense of shear varies from mylonite deformed at temperature of about 450 ºC (Higher-T mylonite), that deformed at about 300 ºC (Lower-T mylonite) to cataclasite deformed at about 300 ºC, suggesnting these structures record the brittle-plastic transition. One conspicuous feature in these structures is an altanation zone of black cataclasite and ultramylonite. This zone is a narrow and planar zone with width of 10 m. The cataclasite in this zone is black colored and strongly foliated. The ultramylonite in this zone show almost ramdom CPO (crstallographic preffered orientation) of quartz. We consider that this zone was the fault core when the present exhumed level experienced the brittle-plastic transiton.

Significant of thrust zone at Fuji river basin in the South Fossa Magna, Southern Yamanashi Prefecture, Central Japan
-Study of Structural geology of Minobu and Neguma fault-

*Minami Madoka[1], Kenta Kobayashi[1]

1. Niigata university department of geology science

There are Minobu fault that was certified as major active fault, Itoigawa shizuoka Tectonic Line (ISTL) and Fujikawa Kako Fault Zone (FKFZ) in the South Fossa Magna. The region is very precious to reveal formation of Japan island because the area is collision and accretion zone to Southwest Japan of Izu-Ogasawara arc. Mainly, Fujikawa group is distributed that filled trough made by past collisional block in this study area.
Minobu Fault is high probability to connect ISTL and FKFZ in the blank range of active fault. In recent years, it was shown sinistral fault sense from geomorophological point of view.(Mizumoto,2016) Howevere, nortern Minobu Fault is estimated reverse fault sense because of stratigraphy difference.
We discover and described new Minobu fault outcrops and divide Minobu fault into Segment Ⅰ and Ⅱ. We are obtained datas from stress analysis and XRD analysis in the area.
We will discuss the formation mechanism and history of geological structure deveropment of Minobu and Neguma fault in South Fossa Magna from kinematics of the faults and geological structure.

Mineralogical characteristics of fault rocks in the aftershock regions of the 2000 Western Tottori earthquake and its spatial distribution

*Shunya Kaneki[1], Tetsuro Hirono[1], Hideki Mukoyoshi[2], Kenta Kobayashi[3], Toru Takeshita[4]

1. Graduate School of Science, Osaka University, 2. Graduate School of Science and Engineering, Shimane University, 3. Graduate School of Science and Technology, Niigata University, 4. Graduate School of Science, Hokkaido University

A large earthquake (*Mw*6.6) occurred on 6 October 2000 in the western part of Tottori Prefecture, southwestern Japan. The main shock was considered as an almost left-lateral strike-slip event with the hypocenter located at 35.269 ˚N and 133.357 ˚E. The rupture process and slip distribution of the main shock was estimated from coseismic strong motions and geodetic data. These previous studies suggested that slip of the main shock mainly occurred in the southern part of the aftershock regions. Furthermore, Yukutake et al. (2007) estimated regional stress field before and after the main shock using aftershock focal mechanisms, and proposed that southern part of the aftershock regions may be dramatically weak in friction compared to northern and central parts. However, there are currently few researches attempting to understand regional slip behaviors of both main shock and aftershocks in association with spatial heterogeneity of physical properties of fault materials.

Mineralogical characteristics of rocks is one of the valid candidates that is likely to dominate its physical properties, and in general, increase in amount of frictionally weak minerals can reduce frictional strength of fault rocks. For understanding spatial slip behaviors in aftershock regions of the 2000 Western Tottori earthquake, we first need to investigate spatial variations in mineral composition of fault rocks. We collected more than 100 bulk rock samples from 14 fault-related outcrops, that distribute in northern, central, and southern parts of the aftershock regions. We then acquired XRD profiles of the powdered samples with internal standard (Al_2O_3) of 20 wt.%, and estimated the amount of minerals by using the RockJock software. The results clearly indicate that intact host rocks have similar mineralogical features regardless of sampling locations; they are granitic rocks composed of quartz, K-feldspar, and plagioclase. In contrast, mineral compositions of fault rocks show different characteristics by locations. In northern part of the aftershock regions, fault rocks are poor in K-feldspar and plagioclase and are rich in halloysite. In central part, fault rocks are poor in K-feldspar and plagioclase and are rich in illite. In southern part, fault rocks are poor in plagioclase and are rich in halloysite. These information tell us the representative mineralogical features of fault rocks in each part of the aftershock regions. Future friction experiments, by using representative fault rock samples under in-situ conditions, will give us a direct glimpse into the spatial variations of frictional properties in the aftershock regions of the 2000 Western Tottori earthquake, such as frictional strength and its velocity dependence. All of these information, not only seismological data but also mineral composition and physical properties of fault materials, should be incorporated for understanding the spatial heterogeneity of slip behaviors of the main shock and aftershocks of the 2000 Western Tottori earthquake.

The 2016 Central Tottori Earthquake (M6.6) occurred on October 21. The epicenter was Central Tottori and depth of hypocenter was 11km. Earthquake source fault was determined to be left-lateral strike fault developed NNW-SSE direction with WNW-ESE directional maximum principal stress axis. In the region, active fault related to the earthquake was not recognized. Although clarification of the occurrence of faults such strain concentration zone is important, there are no reports about detail field outcrop investigation in the area of this earthquake.
The aim of this study is to reveal relationship between seismicity of the 2016 Central Tottori Earthquake and fault distribution in the aftershock area based on field investigation and description of microstructure of the faults.

In this study area, late Cretaceous-early Paleogene medium-coarse-grained biotite granite is mainly distributed.

As a result of this study, total of 190 faults were observed in the aftershock area. Orientation of faults developed in NNW trending aftershock area were concentrated in NNW. On the other hand, faults in eastern part of aftershock area shows N-S~NE trend. Three-directional striation on the fault plane was observed in the aftershock area and only cataclasite was developed. The fault (strikes NNW) had horizontal striation was confirmed. P-foliation was observed in this fault rocks under the microscopic observation and indicated left-lateral strike slip.

The fault that had experienced strike slip, and shear sense consistent with earthquake source fault was confirmed. This result indicates that this fault had moved in the present stress field. According to previous study related to 2000 Western Tottori Earthquake, it is suggested that NNW trending fault system developed in southern part of the aftershock area was weaker than the surrounding area. With comparing these result, fault system in aftershock area of the 2016 Central Tottori Earthquake also might be weaker faults due to the orientation of faults correspond with the Y surface of the earthquake source fault.

History of fault activity considered from the brittle shear zone and the geological structure near the Cape Otachi, Kumamoto Prefecture

*Keiji Ogashiwa[1], Kenta Kobayashi[1]

1. Niigata University

[Introduction] The Hinagu fault zone is located in the western Kyushu and is an active fault zone extending 81 km roughly in the NE-SW direction. The Hinagu fault zone is a dextral slip fault with the east side uplift [URL]. The fracture zones of the Hinagu fault zone have been reported in two places in the Higo metamorphic rock distribution area and in the lower Cretaceous distribution Area near the cape Otachi (Matsumoto・Kanmera, 1964). The core of the fracture zone at Sabagami pass shows dextral slip and its outer rim shows sinistral slip (Kobayashi・Koshiwa, 2016). In addition, the geological fault parallel to the Hinagu fault is apparent sinistral slip fault (Saito et al., 2005). These facts suggest the possibility that the Hinagu fault zone was active differently from the past and the present. Analysis of the fracture zone and surface survey around the fracture zone are important for elucidating the history of fault zone activity. In addition, since Kyushu is an important area which is the meeting part of the Southwest Japan arc and the Ryukyu arc, clarifying the activity history of the Hinagu fault zone leads to the understanding of the tectonics of Kyushu. In this research, for the purpose of elucidating the history of activity of the Hinagu fault zone from the brittle shear zone and geological structure found near the Cape Otachi, Kumamoto Prefecture, the ground surface survey, the structure observation of the fault rock, the XRD analysis, the small fault Analysis and so on.

[Ground Surface Survey] As a result of the ground survey around the Cape Otachi, small faults constituting the fracture zone were observed in the lower Cretaceous Hinagu Formation, and it was roughly classified into 4 strains from the strike of the fault, the sense, and the cutting relationship. F1 is NNE-SSW trend sinistral slip fault, F2 is NNE-SSW trend dextral slip fault, F3 is NNW-SSE trend sinistral slip fault, F4 is E-W trend dextral slip fault.

F2 is a small fault group found in the brittle shear zone consisting of cataclasite. F1 is seen outside the brittle shear zone and part forms a planar cataclasite zone with a width of 5 cm. F3 and F4 are small fault groups which mutually cut. F3 deform the dike group described later. F4 cuts the brittle shear zone. Apart from the fault, we identified a folding group with a hinge in the ENE-WSW direction on the southeast side of the brittle shear zone. In addition, an andesitic dykes group with a dominant ENE-WSW strike was observed on the east side of the brittle shear zone. We confirmed the cutting and bending of the dike by F3, the injection of dike along the F3. This dike is believed to be related to the Neogene Igneous rocks in Amakusa area (Matsumoto ·Kanmera, 1964).

[Small Fault Analysis by Multiple Inverse Method (Yamaji, 1999)] Compressive Stress Field in NW-SE direction from F1, Compressive Stress Field in ENE-WSW direction from F2, Compressive Stress Field in NW-SE direction from F3 and F4 Was detected.

[Stage Segmentation] The time of formation of the fault, dike and fold observed in the vicinity of the Cape Otachi is divided into three stages, D1, D2, D3 from the stress field obtained from the cutting relation.
In D1, F1 was activated in the compressive stress field in the NNW-SSE direction. Considering the compression axis direction, fold group with fold axis in NE-SW direction is thought to be formed in D1.
In D2, F2 was activated in the compressive stress field in the ENE-WSW direction, forming a wide brittle

©2019. Japan Geoscience Union. All Right Reserved.

shear zone.
In D3, F3 and F4 were active in the compressive stress field in the NW-SE direction.
We thought that the bending and the injection of dike along F3 indicate that the dikes were deformed by F3 before consolidation. Considering the above-mentioned thing, we thought that the dike group had formed between the terminal stage of D2 and the beginning of D3.

Study on fault activity evaluation method (A new attempt to understand fault activities) No.1 - Overall plan and current situation at Shionohira Fault -

*Kazuhiro Aoki[1], Takahiro Watanabe[1], Yukumo Tanaka[1], Kazuyoshi Seshimo[1]

1. Japan Atomic Energy Agency

If there is a "fault that may become active in the future" (hereinafter referred to as “inactive segment”) in the vicinity of a fault that has recently moved (hereinafter referred to as "active segment"), it appears that there is a difference in the stress state and in the "ease of activity" between the two segments. Under the current concept of nuclear regulatory standards, these segments are evaluated as part of the same series of faults due to lack of knowledge about interlocking faults.

Following the April 11, 2011 Fukushima-ken Hamadori Earthquake (4.11 earthquake), co-seismic surface ruptures trending NNW-SSE emerged over a distance of 14km between Nameishi Tabito of Iwaki city and North-west of Tsunaki Ishizumi. The surface rupture was named Shionohira fault by Ishiyama et al. (2011) and is identified to be part of the Itozawa fault (coincides to West trace of Itozawa fault by Tsutsumi and Toda, 2012). According to Imaizumi et al. (2018), the fault is said to continue extending south of the ruptured surface covering the area from Nameishi of Tabito Iwaki city to West of Sakura, Kawabe-cho and from Wakigawa, Yamadama-cho to Kobuki, Sekimoto-cho Kita Ibaraki city. In this study, the area designated as the Shionohira fault which has surfaced after the 4.11 earthquake is called the active segment and the remaining area to the south to be the inactive segment.

The authors aim to develop a fault activity evaluation method in order to clarify whether the inactive segment really moves together with the series of faults including the active section when a fault activity occurs by studying the differences between active and inactive segments in the interlocking of faults.

The authors have been conducting a series of study at the Shionohira fault and its southern extensions, reporting on the outcrop survey results (Kametaka, et al., 2015) and the frictional characteristics of fracture zones (Aoki et al., 2015, 2016). Currently, a fault slip test is carried out to assess the in-situ stress state.
In the fault slip test, a double packer is placed above and below the underground fracture to inject high pressure water from the surface and artificially trigger a slip in the fracture in order to measure the three dimensional deformation amount (micrometer to millimeter) (Guglielmi et al., 2013). This device called the Step-rate Injection Method for Fracture In-situ Properties or SIMFIP probe was designed and manufactured by Guglielmi for underground storage studies of CO2 in France and was first applied at the underground research facility (LSBB) in the south of France (Guglielmi et al., 2015). Subsequently, in-situ tests have been conducted on faults in underground research facilities such as Tournemire in France, Mont Terri in Switzerland, and the gold mine in South Dakota, USA.

This device allows to quantitatively measure the deviation of the fault by increasing the pore water pressure in the section partitioned by double packers, and to also examine the causes for leakage of groundwater, petroleum, CO2, and radioactive waste. In addition, it enables to observe fault displacement, pore pressure, and induced seismic waves at the micrometer scale, and to estimate friction and stress state of fault zones. By deepening understanding of the coupled phenomenon of hydraulics

©2019. Japan Geoscience Union. All Right Reserved.

and dynamics around the fault, the authors believe the method could be useful in elucidating the mechanism of seismic occurrence. It should be noted that this device is being applied for the first time in Japan, and the first time ever for an in-situ test of active faults.

Study on fault activity evaluation method (A new attempt to understand fault activities) No.2
- Injection experiment using a SIMFIP probe at Shionohira Fault and southern fault-

*Takahiro Watanabe[1], Yukumo Tanaka[1], Kazuhiro Aoki[1], Yves Guglielmi[2], Paul Cook[2], Florian Soom[2], Wakahama Hiroshi[3], Noujou Haruka[3], Etsuo Iwasaki[3], Masao Kametaka[3], Kazuyoshi Seshimo[1]

1. Japan Atomic Energy Agency, 2. Laurence Berkley National Laboratory, 3. DIA CONSULTANTS

The Shionohira fault caused the April 11, 2011 Fukushima-ken Hamadori Earthquake of Mw 6.7 which occurred one month after the Tohoku-Oki earthquake of Mw 9.0. Co-seismic surface ruptures trending NNW-SSE allowed to estimate a normal slip faulting with a 2 m maximum displacement. The causes of fault activation might be related to changes in the stress state following the Tohoku-Oki earthquake. The key question is to understand why some fault segments were activated and ruptured the land surface while others remained inactive although being very close and aligned on the same fault zone, which is of importance in better assessing the risk of seismic activation of faults in Japan. This might be related to slight differences in properties between active and inactive segments. This might be related to slight differences in properties between active and inactive segments. Recent laboratory measurements on core sampled across the rupture zone show that there are differences in friction coefficients and smectite and clay mineral contents between segments (Aoki, et. al., 2016, Seshimo, et. al., 2016). These differences may condition the frictional rate and state stability of the fault. In this project, frictional stability and hydraulic permeability of the Shionohira fault are explored in situ from SIMFIP probing of borehole intervals intersecting the fault at depths of about 10-to-30m.

Surface earthquake fault caused the earthquake of April 11, 2011 coincides with the west trace of Itozawa fault (Tsutsumi and Toda, 2012). Imaizumi et. al. (2018) identified the lineament as an active fault from Wakigawa of Yamadama-machi to Obuki of Sekimoto-machi, Kitaibaraki city. No surface rupture was idenfied in this region. This study refers to the part of the fault with surface rupture as an active segment and that without surface rupture as an inactive segment.

At the Shionohira site, vertical borehole of 30 m depth was drilled and test intervals were decided based on core observations, borehole TV and caliper logging data as follows. Test 1 between depths of 7.0 and 11.5m isolated with upper and lower packers and pressurized was conducted above the recently activated fault zone in the unfaulted sandstone layers. Test 2 between depths of 12.8 and 17.3m was conducted across the recently activated fault zone.

At the Minakami-kita site, inclined borehole of 50 degrees from surface with 30 m length was drilled and fracture zones were detected at 20.40 to 23.10 m. In-situ injection experiment using a SIMFIP probe is under going, comparison results will be presented at the conference.

Dynamic rupture simulation of 2018, Hokkaido Eastern Iburi earthquake: Role of non-planar fault geometry

*Tatsuya Hisakawa[1], Ryosuke Ando[1]

1. The University of Tokyo

The 2018, Hokkaido Eastern Iburi, Japan, earthquakeis an event characterized by complexity of rupture process, which may involve both reverse and strike slip depending on the locations on the fault surface. We perform dynamic rupture simulations based on simple physical laws and conditions for stressing and fault friction, taking complexity of the fault into account. The complex fault geometry is numerically treated by the boundary integral equation method accelerated by the fast domain portioning method. We search in a small number of parameter spaces for the stress ratio of the regional stress field and the frictional coefficients assumed to be the same over the fault area, rather than assigning heterogeneous distributions of the stress drop on the fault, to evaluate to what extent relatively simple forward models accounting for realistic fault geometry can explain the characteristics of coseismic observations. The fault geometry is constrained based on the aftershock distribution (NIED, 2018) and characterized primarily by the combination of three fault planes. As the result, we are able to reproduce several observed features of the event including the spatial variation of the fault slip direction, which is inferred from the seismological inversion (Okuwaki and Yagi, 2018), and the ground surface displacement observed by GEONET. The results suggest that the complex rupture event can be reproduced by a relatively simple physical model to some extent if the geometrical complexity of the faults is properly taken into account.

A New Fully-Dynamic Earthquake Cycle Simulator Applicable to Arbitrary Nonplanar Fault Geometries - A Benchmark Test

*Daisuke Sato[1], Nadia Lapusta[2], Hiroyuki Noda[1]

1. Disaster Prevention Research Institute, Kyoto University, 2. California Institute of Technology

The models and data assimilations of the real earthquake cycles are now getting on the track for providing the data beyond the classical empirical laws in the context of the seismic hazard; an example can be seen in the Third California Earthquake Rupture Forecast (UCERF3). Such large modeling is enabled by the rapid development of the earthquake simulators capable of solving the earthquake cycles in the real fault systems (Barbot et al., 2012: Richards-Dinger and Dieterich, 2012). However, there is not a fully dynamic cycle simulator applicable to wide tectonic conditions yet. The applicability of earthquake cycle simulators is thus still largely restricted.

In this research, we propose a new earthquake cycle simulator applicable to arbitrary nonplanar fault geometries. This simulator is based on the fast domain partitioning hierarchical matrices (FDP=H-matrices) (Sato and Ando, 2018), a newly developed algorithm of quasilinear time for dynamic BIEM applicable to nonplanar fault geometries. This cycle simulator thus overcomes the restriction on geometries when solving the elastodynamic fault motions in the coseismic phase, which had been the intrinsic problems for previous methods to solve the dynamic ruptures. In the presentation, after proposing the new method, we run a benchmark test of the SCEC Sequences of Earthquakes and Aseismic Slip project (SEAS) by the new simulator. Obtained results are compared with those of the previous simulators such as ByCycIE (Lapusta et al., 2000) and other simulators of volume-based methods. Simulated cycles on other nonplanar faults will be also demonstrated.

Stress and displacement Green's functions to treat volumetric inelastic strain and elastic inhomogeneity in boundary integral equation method

*Daisuke Sato[1]

1. Disaster Prevention Research Institute, Kyoto University

The boundary integral equation method (BIEM) is a commonly used method to simulate the fault motions accurately. Recent developments are now resolving well known problems of BIEM, such as the numerical cost problem (Sato and Ando, 2018) and the adaptabilities to elastic inhomogeneity (Kame and Kusakabe, 2012; Kusakabe and Kame, 2018). However, while it is shown to be applicable to the media other than homogeneous elastic media, obtained analytic integral kernels for simulating those media are now limited, largely due to its analytic difficulty. In this research, I obtain the the kernel expressions of those advanced BIEM in real space-time coordinate, based on the equivalent inclusion method (Eshelby, 1956; Mori and Tanaka, 1973).

First, the (volume) integral equation method (Barbot and Fialko, 2010) for the volumetric strain is shown to be reduced to BIEM of boundaries partitioning the discretized inelastic volume. Corresponding kernels are then obtained for piecewise-constant volumetric inelastic strain embedded in the three-dimensional homogeneous elastic space. The kernels are preliminarily shown to be equivalent to the part of the kernel for the inhomogeneous elastic media (Kame and Kusakabe, 2012; Kusakabe and Kame, 2018) both in static and dynamic cases.

Second, the surface integral in the representation theorem is reduced to the integral equation of the equivalent eigen-displacement. Consequently, as long as the absolute traction can be expressed with the strain and the eigen-strain, it is suggested that there can be a method to treat the inhomogeneous elastic media only by using the stress Green's function responding to the slip, already obtained analytically (Tada and Madariaga, 2001; Tada, 2006; Ando et al., 2007; Ando, 2016). By comparing the possible method with the method of Kame and Kusakabe (2012) capable of generally treating the elastic inhomogeneity in some examples, the validity of the proposal to treat inhomogeneous elastic media is investigated.

Frictional properties of dolerite and granite at intermediate slip rates and controlled ambient temperatures

*Michiyo Sawai[1], Yuuki Yokoyama[1], Kyuichi Kanagawa[1]

1. Chiba University

High velocity friction experiments (up to several m/s) on many types of rocks have revealed that frictional strength decreases with increasing slip rate at seismic slip rates (e.g., Tsutsumi and Shimamoto, 1997; Di Toro et al., 2011). Coseismic weakening has been attributed to temperature rise including flash heating, melt lubrication or thermal pressurization (e.g., Rice, 2006; Hirose and Shimamoto, 2005). Although the importance of temperature during fault motion are widely recognized, the effects of temperature on frictional properties at intermediate to high slip rates remain unknown. We therefore conducted friction experiments at a wide range of temperatures and investigated the effects of temperature on the friction coefficient (μ).

Experiments were performed on dolerite (Belfast, Northern Ireland) and granite (Aji, Japan) using a rotary shear deformation apparatus at Chiba University. Samples were displaced up to 10 - 20 m at a normal stress of 1 MPa, slip rates of 1 to 300 mm/s, and ambient temperatures of 20 - 500°C in an argon atmosphere with an oxygen concentration of 0.2 %.

At 20°C and 100°C, dolerite showed velocity weakening at slip rates ranging from 1 to 30 mm/s with μ of 0.81 - 0.83 at 1 mm/s and of 0.73 at 30 mm/s. Whereas at high temperatures >300°C, friction is almost constant (μ = 0.81 - 0.85) at < 30 mm/s. At 100 mm/s, the behavior is slight velocity strengthening at 20 °C and 100°C with μ = 0.75 - 0.79 and clear velocity-weakening at more than 300°C with μ = 0.67 - 0.76. At 300 mm/s, the dolerite showed strong velocity weakening at all temperatures investigated. The amount of weakening (i.e., the drop in friction, $\Delta\mu$) increases with increasing temperature ($\Delta\mu$ = 0.1 - 0.38). Thus, the frictional properties of dolerite are affected not only by slip rate but also by ambient temperature.
Experiments using granite to decipher the effect of materials on temperature dependence are in progress. Our preliminary results are summarized as follows. At <30 mm/s, the behavior is slight velocity strengthening at room temperature and velocity-weakening at temperatures of 100-300°C. At >300°C, friction is almost constant. Friction coefficient decreases with increasing temperature of 20-300°C and increase again at >400°C. At >100 mm/s, clear velocity-weakening did not occur except at temperatures of 20°C. More results especially on granite will be reported at the meeting.

Extraction of features of strata using borehole data of geothermal area by multivariate analysis

*Ojima Hiroki[1], Kazuya Ishitsuka[2], Toru Mogi[3], Tatsuya Kajiwara[4], Takeshi Sugimoto[4], Hiroshi Asanuma[5]

1. Department of Socio-Environmental Engineering Hokkaido University, 2. Division of Urban Management, Graduate School of Engineering, Kyoto University, 3. Division of sustainable Resources Engineering, Faculty of Enginieering, Hokkaido University, 4. Geothermal Engineering Co. Ltd, 5. Fukushima Renewable Energy Institute, AIST

In geothermal development, geological characteristics are often estimated qualitatively based on logging data of geothermal wells. On the other hand, the quartz index (QI) has quantitative information on minerals, and the index enables to objectively extract features of the geological formation using a statistical method. Therefore, in this study, from the QI obtained from the core cuttings in a geothermal field, we developed and examined a method to classify and extract geological features along with a well by multivariate analysis (in particular the difference in alteration degree). Specifically, we first carried out a principal component analysis to extract and emphasize the features of the data through dimensionality reduction. Then, their lithological features were classified by clustering using a Gaussian mixture model. In addition, the classification results by our method were compared with electric logs and temperature logs. In this study, we used the data obtained from wells in a geothermal area at Iwate prefecture. The geology of this area consists of andesite tuff and dacite tuff. The QI is defined as the percentage of the strongest X-ray intensity of a certain mineral in the sample from the strongest X-ray intensity of pure quartz measured under the same experimental conditions. This value means the content (weight percentage) in the sample for quartz and the relative quantitative ratio for the other minerals. In order to verify our proposed method, the principal component analysis was performed on the standardized QI data of clay minerals and compared with the results of existing geological classification based on geological interpretation. As a result of the comparison, our classification results agree with the results of existing geological classification, thus the classification of the strata by our method is valid. Next, in order to examine the effect of the dimensionality reduction by a principal component analysis, we compared the following cases: (i) clustering without dimension reduction for all QI, and (ii) clustering after applying the dimensionality reduction to all QI. In the case of dimensionality reduction, we used the principal components with a total contribution total over 95%. As a result of the comparison, the optimal classification number of the strata without the dimensionality reduction (case (i)) was 6. On the other hand, in the case of dimensional reduction (case (ii)) the optimal classification number was 10. The number of the optimal class indicates that more detailed features can be extracted using dimensionality reduction by principal component analysis. Notably, the classification in the depth range from 0 to 1000 m became detailed, highlighting the correspondence between clay, zeolite minerals and the geological formation.

Low-temperature thermochronology of Cretaceous granitoids from the northern Northeast Japan Arc: Towards reconstructing arc-parallel thermal/denudation histories

*Shoma Fukuda[1], Shigeru Sueoka[2], Barry Paul Kohn[3], Noriko Hasebe[4], Akihiro Tamura[5], Tomoaki Morishita[5], Takahiro Tagami[1]

1. Graduate School of Science, Kyoto University , 2. Japan Atomic Energy Agency, 3. School of Earth Sciences, The University of Melbourne, 4. Institute of Nature and Environmental Technology, Kanazawa University, 5. Department of Earth Sciences, Kanazawa University

Northeast (NE) Japan Arc is categorized as an arc-trench system, where volcanism and earthquakes frequently occur. The tectonic history of the NE Japan Arc has been well-investigated based on geomorphic and geologic approaches. Furthermore, the recent multidisciplinary project (Crustal Dynamics) successfully achieved and accumulated geoscientific results by means of GPS, active faults, numerical modeling, friction experiments, etc (see also Iio et al. 2018, EPS). For estimating vertical deformation over long-term timescales (>10^6 yr.), our research group has investigated the thermal/denudation histories on every geomorphic province of the NE Japan Arc by using low-temperature thermochronology.

Thermochronology can reconstruct the time-temperature relationship of rock/mineral samples, based on radiometric ages and closure temperatures specific to the combination of radiometric dating methods and target minerals. Low-temperature thermochronology is useful for understanding upper crustal mountain building processes and has been applied to estimate the tectonic history of major orogens (e.g. European Alps: Wagner et al. 1977, Mem. Inst. Geol. Mineral., Univ. Padova; Himalayas: Blythe et al. 2007, Tectonics). However, the thermochronology approach directly measures cooling processes, rather than denudation/uplift histories. Therefore, it is noteworthy that denudation/uplift histories require some assumptions, such as appropriate geothermal gradients and dynamic equilibrium between denudation and uplift. Long-term uplift rates on >1 Myr time-scales, require estimates from such protocols, which are assumed to be equivalent to the vertical inelastic deformation of the crust (Ikeda et al. 2012, JGS).

Between 2014-2019 we collected over 100 granitic rock samples from the NE Japan Arc. Low-temperature thermochronology has been applied to many of these samples, including the apatite/zircon (U-Th)/He (namely, AHe and ZHe) (Sueoka et al. 2017, EPS) and apatite fission-track(AFT) methods (Fukuda et al. 2019, JAES:X), particularly from Cretaceous-Paleogene granites located in the southern NE Japan Arc. This research elucidated the contrast of thermal/denudation histories among the island arc provinces, i.e., Abukuma mountains, Ou Backbone Range(OBR), and Iide and Asahi mountains. In this presentation, we report results based on AHe/ZHe and AFT thermochronometry from Cretaceous granites in the northern NE Japan Arc, aimed at reconstructing arc-parallel and across-arc thermal/denudation histories.

We obtained AHe ages ranging between 88.6-0.9 Ma, AFT ages from 138.0-2.0 Ma, and ZHe ages from 83.9-7.4 Ma. The ages show contrasting thermal/denudation histories between the fore-arc side, OBR, and back-arc side, which are similar to the southern NE Japan Arc. This observation implies that arc-parallel mountains have approximately the same trend along NE Japan Arc. On the other hand, some differences were observed between the northern and southern NE Japan Arc as follows; (1) significantly

©2019. Japan Geoscience Union. All Right Reserved.

older AFT ages were obtained for Kitakami mountains (130-75 Ma) compared to the Abukuma mountains (80-40 Ma), (2) much younger AFT ages at ~2 Ma were found on the back-arc side, Taihe mountains, and (3) considering the expected relationship between expected closure temperatures, some reversal of coexisting AFT ages compared to AHe/ZHe ages (e.g., FST04, FST05) were observed.

Future work will involve thermal inverse modeling using AFT thermochronometry for estimating more rigorous constraints on thermal histories. This will also involve increasing the number of sampling localities in an attempt to extend our study area.

Uplift and denudation history of the South Fossa Magna region using low-temperature thermochronometric methods

*Yumi Kobayashi[1], Shigeru Sueoka[2], Shoma Fukuda[1], Barry P. Kohn[3], Tatsunori Yokoyama[2], Noriko Hasebe[4], Akihiro Tamura[5], Tomoaki Morishita[5], Takahiro Tagami[1]

1. Graduate School of Science, Kyoto University, 2. Tono Geoscience Center, Japan Atomic Energy Agency, 3. University of Melbourne, 4. Institute of Nature of Environmental Technology, Kanazawa University, 5. Department of Earth Sciences, Kanazawa University

The South Fossa Magna region is located at the junction of the Japan and Izu-Bonin arcs. Up to four crustal blocks of the Izu-Bonin arc, i.e., Kushigatayama, Misaka, Tanzawa, and Izu, collided this region and formed its crustal structures since the middle Miocene (1, 2). The timings of the collision events have been estimated by deposition ages of sediments between each block and the Japan arc. However, these questions remain unresolved.

In this study, we performed apatite fission track (AFT) and apatite (U-Th)/He (AHe) thermochronometric methods and U-Pb dating method to resolve the uplift and denudation history of the South Fossa Magna region.

The AFT ages are estimated to be 14.7 ±4.7 Ma in the Okuchichibu area (c.f., hornblende K-Ar age: 10.5 ±1.5 Ma (3)), 3.0 ±0.5 Ma, 9.2 ±2.2 Ma, and 7.6 ±0.9 Ma in the Kano Mountains (c.f., biotite K-Ar age:i.e., 10.5 ±0.4 Ma (4)), 3.6 ±2.5 Ma in the Minobu area (c.f., biotite K-Ar age: 5.4 ±0.3 Ma (5)). Also, the AFT ages are inferred at 37.0 ±5.9 Ma in Mt. Tsukuba (c.f., Rb-Sr whole rock isochron age: 61.6 ±4.3 Ma (6)), and 44.9 ±4.1 Ma in the Sori granitoid in Gumma Prefecture (c.f., biotite K-Ar age: 92.6 ±0.6 Ma (7)). The rocks which have younger AFT ages than the formation ages may reflect the uplift and denudation events since the rock formation. However, exhumation rates of the Tanzawa mountain, the closest mountain to the Izu block, did not increase before and after the collision of the Izu block (8), which may imply that the collision of the Izu block did not cause the uplift and denudation events significantly.

We also obtained the new AHe ages and U-Pb ages. The AHe ages for Okuchichibu area, Kanto mountains and Minobu area are about 3 Ma. Furthermore, according to the results of the inverse thermal analysis using the apatite FT lengths data, the granites in Okuchichibu area and the southern part of Kanto mountains cooled rapidly since about 3 Ma, and the granites in Minobu area and northern part of Kanto mountains cooled rapidly since about 1 Ma. The results of AHe ages were consistent with the results of inverse analysis. Based only on these ages, the rapid cooling ages of 3 Ma and 1 Ma are comparable to the collision ages of the Tanzawa block and the Izu block, respectively.

Correlation between residual uplift and recurrence interval of the Kanto earthquake based on developmental process of coastal lowland

*Haeng-Yoong Kim[1]

1. Osaka City University, Graduate School of Science, Division of Biology &Geosciences

It is well known that the marine terraces are formed due to uplift of the seabed during the earthquake. The marine terrace consists of a near-flatter terrace surface emerged above sea level during the earthquake and a low terrace riser of less than several meters in height formed after the earthquake and is distributed in a staircase pattern along the coastline. In the previous research, one step of maritime terrace is often recognized as a trace of an earthquake once, and based on this premise, many previous researches were conducted to estimate the reoccurrence interval and the amount of uplift during the earthquake. However, Maemoku (1988) inferred that one step level of flat terrace surface is the topography formed by multiple repetitions of coseismic uplift and interseismic earthquake settlement occurring in the plate subduction zone of the Nankai Trough. And the stepped terrace was formed by the active fault of the land side. We got geomorphological and geological data demonstrating this previous reasoning on the Miura Peninsula located directly above the plate subduction zone of the Sagami trough.

On the rocky coast of the Miura Peninsula, two step of marine terrace surfaces formed in association with the 1923 Taisho and 1703 Genroku earthquakes are observed near 1 m and 2 m above sea level,(Matsuda et al., 1974). In the inner part of the estuary creek, which is formed many in the peninsula, the coastal lowland landfilled with sediments transported from the hinterland into the bay floor is distributed around the altitude of 2 m as similer as 1703 terrace surface. We examined the development process of coastal lowland in the inner part of estuary creek.

As a result of the detailer geomorphological interpretation, a flat coastal lowland apparently spreading as a single face is composed of multiple small maritime terraces, not one terrain. The marine terraces were divided into 5 areas with less than 2.1 m above sea level by topographical interpretation. As a result of investigating the emergent time and the distribution altitude of the marine terrace surface, the marine surface of the 1923 Taisho earthquake in the order of 1.22 m - 1.37 m in the order of younger, the wave erosion shelf surface of the 1703 Genroku earthquake by Nishihata et al. (1988): 2.3 m, the marine surface of the 1293 year pre-earthquake (after 1260-1380 cal.AD): 1.27 m, the marine surface of the earthquake (915 cal.AD to 1150 cal.AD) around the year AD is 1.63 to 1.93 m, Terraced surfaces are distributed until the earlier age.

In this way, the reasons that different formational time of terraces remain in coastal lowlands with extremely altitude is formed in Miura peninsula are as follows, because 1: the coseismic uplift due to the elastic repulsion and the interseismic subsidence accompanying the strain accumulation are repeated (Shimazaki et al., 2011; Kim and Mannen, 2018), therefore 2: a new marine surface is formed near the sea level by the next earthquake (Kim and Mannen, 2018), and 3: there is a condition that the terrace surface is preserved by the coating layer. In addition, because the height of the ground is stable in the long term due to the balance of uplift and subsidence, and it is estimated that wide coastal lowlands, which apparently appear as a continuous ground surface, develop by repetition of uplift and subsidence. Between 1293 and 1703, where the period of occurrence of the earthquake occurred long, the raised surface in 1293 returned to the original altitude, and between 1703 and 1923 in which the occurrence interval of the earthquake was short, the raised surface in 1703 The next Kanto earthquake occurred

Mechanics preserving co-seismic uplift and marine terraces: dissymmetric patterns of co-seismic and inter-seismic deformation

*Kyohei Suzuki[1], Junki Komori[1], Ryosuke Ando[1]

1. Graduate School of Science, University of Tokyo

Four large Holocene marine terraces are known in the southern part of the Boso Peninsula and called Numa I - IV. The newest one (Numa IV) was uplifted at the time of the Kanto Genroku earthquake, and from the similarity of the spatial distribution, it was considered that the Numa I-III Ire also formed from uplifts during the Genroku-type events. From this, the amount of coseismic uplift and slip amount were estimated from the height of the terraces (Matsuda et al., 1978; Nakata et al., 1980; Namegaya et al., 2011; Sato et al., 2016 etc.). However, the relationship between Holocene marine terraces and paleoseismic events was doubted in previous studies (Matsu'ura and Sato 1989, Noda et al., 2018). There is Matsu'ura and Sato (1989) model which is a mechanical model explaining the long-term surface uplift. This model expresses seismogenic region by back slip at the interseismic period and forward slip at the coseismic period and givessteady forward slip along the whole plate boundary surface. From this model, the coseismic vertical displacement pattern cancel out and the interseismic one and the uplift accumulation on the surface was attributed only to the effect of the steady-state plate motion.However, this is consequence based on a simple model expressed that slab as one plane in horizontal layered structure and assumed that the amount of back slip at the interseismic period and the amount of forward slip at the coseismic period are equal. The purpose of this study is to verify whether the coseismic uplift amount records the slip amount and remains and accumulates over earthquake cycles, and it affects coastal terrace formation process in a general mechanical model, considering the shape of the slab, the plate motion, and the coseismic fault motion.

As the calculation procedure, first, We give a constant displacement (10 m) to the edge of the oceanic plate and accumulate strain on the plate boundary. Next, We release all accumulated shear stress by coseismic fault slip,and obtain the vertical displacement pattern on the surface and the slip amount on the plate interface. Based on the fact that the principle of superposition is established in the linear elasticity theory, in this study, We separated the boundary conditions of both the interseismic period and the coseismic period,and calculated the respective vertical displacements and the residual amount by taking the sum. To verify the influence of irregularities on the actual plate boundary surface on the spatial pattern of vertical displacement, We also calculated two patterns for the case where irregularities were locally placed on the plate interface.

As a result of the calculation, we found that the interseismic slip amount in the no-cuppled area converged to 0 in the vicinity of the coupled area, and the coseismic slip amount was not uniform, and occurred across the plate boundary surface. This suggests that the slip on the plate boundary is intermittent in the seismic cycle. Next, from the vertical displacement residuals, we found that their spatial patterns at the interseismic period and the coseismic period were different.Furthermore, when local irregularities are placed on the plate boundary surface, it was found that the spatial pattern of the coseismic uplift is different corresponding to the slip amount of each model. This suggests that the height records the slip amount, and the shape of the plate boundary surface attributes actual coastal terrace formation. The consequence of this study is that the slip on the plate boundary is intermittent, and the coastal terraces depend on the coseismic slip.Therefore, the model in this study will give meaning to estimate the paleoseismic image from the height of coastal terraces.

Enhanced resolution of stress tensor inversion by using fault instability analysis

*Katsushi Sato[1]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University

Modern stress tensor inversion techniques for fault-slip analysis are based on the Wallace-Bott hypothesis which assumes that the slip directions and shear stress vectors are parallel. The hypothesis has an advantage in the applicability to high pore fluid pressure conditions and low friction faults, since the magnitudes of shear and normal stresses are not evaluated. However, the hypothesis gives only loose constraint on stress from observed faults in exchange for the wide applicability, which causes poor detectability of stresses.

This study tries to improve the detectability by introducing the fault instability (Vavrycuk et al, 2013; Sato, 2016) into the stress tensor inversion. The fault instability is defined as the nearness of the point representing shear and normal stresses on Mohr diagram to the line of Coulomb failure criteion. The fault instability is imposed on the fitness of a stress candidate to a fault-slip datum as a weight. Since the calculation of fault instability requires the friction coefficient, this study used several values of friction coefficient and compared the results.

The new method was applied to natural meso-scale fault-slip data. The faults cutting the Awa Group (Chiba Prefecture, central Japan) newly gave a reverse-faulting regime of stress in addition to normal faulting ones which can be detected by a conventioanl technique. An E-W trending tensional stress was newly detected from the faults cutting the Sekinan Group in the Beppu-Shimabara graben (Oita Prefecture, southwest Japan) where N-S trending extensional tectonism is ongoing. These resutls showed the improved resolution of stress tensor inversion by the incorporation of fault instability.

Focal mechanisms of the aftershocks of the 2000 Western Tottori Earthquake inferred from P wave first-motion data and spatial stress pattern

*Takaki Iwata[1]

1. Tokiwa University

A Bayesian approach to estimating a spatial stress pattern was developed [Iwata, 2018, JGR] (hereafter IW2018), and as an extension of this approach Iwata [2018, SSJ fall meeting] has proposed a method to infer focal mechanisms from P wave first-motion data and stress pattern estimated with the Bayesian approach. In this study, this method was applied to a real dataset taken from aftershocks of the 2000 Western Tottori earthquake.

The analyzed P wave first-motion dataset was retrieved from Kawanishi et al. [2009, JGR], which complied records from October 15 to November 30 in 2000. This dataset contains 47,570 P wave first-motions of 3592 events (for details see IW2018). The spatial pattern of stress field was taken from the result of IW2018 that also analyzed the same P wave first-motion dataset. The inferred focal mechanisms show rotation of the azimuth of P-axis around the main fault in the southern area; this feature has been seen in Yukutake and Iio [2017, EPS] and will be the reflection of the stress rotation found in the same area revealed by IW2018.

From the inferred focal mechanisms and spatial stress pattern, the normal and shear stress exerted on the fault plane was evaluated. Then, following the method of Terakawa [2010, Geology], fluid pressure for each of the events was estimated. Two datasets of the fluid pressure in the northern and southern areas of the aftershock areas were constructed and examined whether the two datasets follow the same distribution with the Kolmogorov-Smirnov test. Consequently, the test revealed that the fluid pressure in the southern area is significantly larger than that in the northern area, with a P-value of 1.6e-3.

Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, 3. Disater Prevention Research Institute, Kyoto University, 4. GNS Science, New Zealand, 5. Victoria University of Wellington, Wellington, New Zealand, 6. University of Canterbury, Christchurch, New Zealand, 7. TerraGeologica, Ruby Bay, New Zealand, 8. University of Otago, Dunedin, New Zealand

We study spatio-temporal change of stress field of the 2016 Kaikoura earthquake in the northern area of South Island of New Zealand. Data from both the 51 temporary stations and 22 GEONET stations were used. Data collection was from March 2011 to December 2017. We derived focal mechanisms using HASH (Hardebeck and Shearer, 2002), By focal mechanism solutions of earthquake, we estimated stress fields of main shock of Kaikoura earthquake before and after. We used SATSI (Hardebeck and Michael, 2006] for stress tensor inversion. In our previous result (Sato, 2017 master’ s thesis in Tohoku University), there is possibility that on-fault aftershocks bias the result of stress tensor inversion. Therefore, by using Kagan angle between mainshock fault model and each focal mechanism, we remove aftershock on the faults, and perform stress tensor inversion. We use the fault model by Hamling et al. (2017). In a result, Kagan angles of many earthquakes are large, so this means that many aftershocks occurred off the fault plane. The results do not depend on threshold of Kagan angle. Obtained stress tensor inversion after main shock in areas near London Hill Fault and near Kekerengu fault are strike-slip fault type with SHmax orientation of ~N115E, which is almost same as for before the Kaikoura earthquake (e.g., Sibson et al., 2012; Townend et al., 2012), and stress tensors before and after the mainshock didn't appear to change after the earthquake beyond the estimation error. However, in the area near the hypocenter of the main shock we still cannot get a stable stress tensor. Also we plan to obtain results of a stable stress tensor for before the main shock by increasing the number of focal mechanisms of earthquakes that we examine.

Precise hypocenter distribution in the focal area of the 2016 Mw7.8 Kaikorua Earthquake, New Zealand

*Yuta Kawamura[1], Satoshi Matsumoto[1], Tomomi Okada[2], Miu Matsuno[2], Yoshihisa Iio[3], Tadashi Sato[2], Stephen C Bannister[4], John Ristau[4], Martha K Savage[5], John Twonend[5], Jarg Pettinga[6], Francesca Ghisetti[7], Richard H Sibson[8]

Victoria University of Wellington, Wellington, New Zealand, 6. University of Canterbury, Christchurch, New Zealand, 7. TerraGeologica, Ruby Bay, New Zealand, 8. University of Otago, Dunedin, New Zealand

The Mw7.8 Kaikoura Earthquake struck the northeastern south island, New Zealand, on November 14, 2016. A lot of researchers have tried to explain the cause of this earthquake and revealed the structure in this area. Among variety of prior researches, Clark et al. (2017) argued that this earthquake, which produced surface deformation including uplift and complex surface rupture, was caused by 21 strike-slip, reverse and oblique slip faults. Cesca et al., (2017) proposed an earthquake fault model that consists of three faults in northern, central and southern part, based on the hypocenter distribution of aftershock activity. These studies suggested in common that this earthquake was provoked by multiple faults with complex rupture process.

We had installed 75 temporary seismic stations before the earthquake in the South Island, New Zealand in addition to GEONET stations. The seismic network has successfully recorded the mainshock and the following aftershocks. Here, we relocated the hypocenters of the events associated with the Kaikoura earthquake by using data obtained from the seismic network. The hypocenters was determined by the double difference hypocenter determination algorithm (i.e. HYPODD, Waldhauser and Ellsworth, 2000). The overall distribution of the hypocenters are distinguished into two clusters, northern and southern clusters. The hypocenter distribution in vertical cross section normal to the major alignment of the aftershocks in N54W reveals that the fault in southern part dips to eastward. On the other hand, although we find out a northern cluster in terms of horizontal projection, no obvious faults are recognized in the vertical cross-section, suggesting complex fault structure in the northern cluster.

3-dimensional GPS velocities in Colombia and their implications for interplate coupling

*Sindy Carolina Lizarazo[1], Takeshi Sagiya[2], Hector Mora-Paez[3]

1. Graduate School of Environmental Studies, Nagoya University, 2. Disaster Mitigation Research Center, Nagoya University, 3. Geological Survey of Colombia

Colombia is located in a region of complex interactions among the Caribbean, Nazca and South American plates, as well as the North Andean and Panama-Choco blocks. As a consequence of this tectonic setting, active faulting and intense seismicity are occurring especially in the areas of plate subduction or collision. The GeoRED project by the Geological Survey of Colombia installed a permanent GPS network in Colombia to study the regional kinematics with an intention to improve disaster mitigation activities. An initial velocity field was obtained and discussed by Mora et al. (2019) based on data from 60 sites under the ITRF2008 reference frame.

Here we present an updated result of Colombian GPS velocity field with 80 sites. The daily coordinates are calculated under the ITRF2014 reference frame with GAMIT-GLOBK software. We calculate 3-dimensional velocities with HECTOR software (Bos et al., 2013) based on the daily coordinates for the period from January 2014 to March 2016. There was no earthquake larger than magnitude 6 in Colombia, so the velocity pattern represents that of the interseismic period. For this time period, enhancement of the permanent network provides a better spatial resolution of the deformation pattern in some regions.

The results show a general consistency with the previous study, demonstrating the correctness of the current approach. In addition, vertical components show a slight of coastal uplifts at a few mm/year along the Nazca subduction zone. These signals indicate the lower limit of the plate coupling on the plate interface and we discuss the interplate coupling based on the 3-dimensional velocity data. Also, a significant margin-normal contraction is identified along a part of the Caribbean subduction zone near Colombia-Panama border. However, the vertical signal is not significant compared to the horizontal contraction, indicating that the elastic coupling model may not be applicable to this area.

[B-BG02] Microbial ecology in earth and planetary sciences

convener:Michinari Sunamura(University of Tokyo Dept. of Earth & Planetary Science), Yuki Morono(Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology), Natsuko Hamamura(Kyushu University)

Microbes have exerted the great influences on earth environments through the history of earth. Microbial ecology is a study of interaction between microbes and surrounding environments. Research target of Microbial ecology covers most of environments on the earth and planet, e.g. soil, subsurface, subseafloor, ocean, river, lake, air, space, volcano, fault and earthquake, minerals, and more. In this session , we aim to exchange informations of microbial distribution, population dynamics, function, effect on material cycles between microbial ecologist and earth&planetary scientist. We hope effective discussion from interdisciplinary approaches in this session.

1. Kochi University, 2. Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology

Variation of the past geomagnetic field is recorded in marine sediments as a fossil magnetization, called natural remanent magnetization (NRM). NRM is carried not only by detrital and eaolian magnetic grains but also by biogenic magnetic grains originated from magnetotactic bacteria. To investigate characters of NRM carried by biogenic magnetic grains we have cultured the microaerobic bacteria *Magnetospirillum magnetotacticum* MS-1 (here under, MS-1) in laboratory and made sample using them for remanent magnetization measurements by simulating a very early process of sediment formation.

Preliminary reports on properties and characters of the remanent magnetization carried by the samples have been presented in Masaoka et al (2018JpGU; 2018SGEPSS), but MS-1 cells used for making samples rarely contain magnetite grains in these cells (3 percent of the total cells). To try to increase number of the cells containing magnetite grains, we have tested a density separation method using finer density gradients centrifugation and observed separated cells by transmission electron microscope. We will report results of observations together with those magnetic measurements.

Exploring biogeographic patterns of marine planktonic cyanobacteria in coastal habitats- integrating uncultured and cultured approaches

*Punyasloke Bhadury[1]

1. Integrative Taxonomy and Microbial Ecology Research Group, Centre for Climate and Environmental Studies, Indian Institute of Science Education and Research Kolkata

The structure of marine planktonic cyanobacterial communities in coastal habitats can strongly influence rates and fluxes of coastal carbon cycling. Biogeographic patterns of marine planktonic cyanobacterial assemblages were elucidated from four coastal habitats namely, Baltic Sea (BL), Monterey Bay (MB), South China Sea (SCS) and Sundarbans (SB) based on deep phylogeny of 16S rRNA sequences generated using next generation sequencing and Sanger sequencing approaches. Based on 16S rRNA phylogeny, four major taxonomic orders of marine planktonic cyanobacteria were recovered in varying proportions with several novel 16S rRNA sequences in each of the four targeted habitats. Members of the order Synechococcales were dominant in all the habitats (~94% sequences) while the orders Chroococcales and Oscillatoriales were only detected in SB and SCS, respectively. In the phylogenetic tree, *Synechococcus*-like sequences showed overwhelming dominance in SB and they were found in three other habitats. *Prochlorococcus*-like sequences were found in sizeable number in MB and SCS but were absent in SB and coastal BL. *Synechococcus*-like sequences were represented by three major marine clusters (5.1, 5.2, and 5.3). Three novel clades as part of *Synechococcus* cluster were detected only in SB and one novel clade in BL. These clades could have potential functional significance in coastal carbon cycling. Interestingly, cultured based approaches also revealed a new species of *Synechococcus*, *Synechococcus moorigangaii* from SB which has the ability to grow across a range of salinity and metabolize different forms of nitrogen as well as fix di-nitrogen. This reflects the potential vast unexplored functional diversity of marine planktonic cyanobacteria in coastal habitats which needs to be identified and can help towards understanding of export of carbon in coastal oceans. Overall the study has revealed that majority of the marine planktonic cyanobacterial OTUs were found to be exclusive to each habitat, whereas some were shared by two or more habitats based on beta-diversity analysis.

The precise structure of “unsaturated” archaeol derivatives in the halophilic archaea lipid-core

*Noriaki YAMAUCHI[1]

1. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

Archaea has a characteristic lipid-core, archaeol. Further, a characteristic diether lipid-core (C_{20}-C_{25} diether (**1**)) which is constructed from one C_{25} and one C_{20}isoprenoid is produced by halophilic archaea[1]. Recently, Dawson et al. showed the existence of several unsaturated isoprenoid diethers (such as tentative structure **2**) in the lipid-core of several halophilic archaea which was incubated with very high salt concentration[2].
Then, **2**, and the regioisomeric structure about the double bond and ether bond with a glycerol, **3**to **5** were chemically synthesized according to the reported method and the comparison of the mass spectrum of trimethylsilyl (TMS) ether were presented previously at this meeting[3].Further, **3** or **4**may be a possible structure of the real compound Dawson et al. shown at the mass spectrum.
About these unsymmetrical diether. The halophilic archaea *Haloferax sulfrifonis* was incubated and the lipid core was extracted and isolated.The analysis of the lipic core was perforemd by the GC-MS of the TMS ether. At first, **1** was detected as a main core lipid compornent. And the compound almost identical the mass specrum with the synthetic structure **2** was detected with a second minor compornent. Careful analysis of the compornent, the srtucture almost identical with **4** is also detected. This result showed the double bond in the unsaturated archaeol in *H. sulfrifonis*is the mixture of **2** and **4**. Dawson's unsaturated diether does not have a double bond at the methyl group branching position resulting from the usual isoprenoid biosynthesis (e.g. phytol), probably unsaturation is formed after the saturated isoprenoid formation with a unspecific fasion. The result of the analysis of lipid core of the archaea having unsaturated C_{20}-C_{25}diether will be presented.

Estimation of microbial chemosynthesis efficiency in deep sea hydrothermal plume

*Michinari Sunamura[1]

1. University of Tokyo Dept. of Earth & Planetary Science

In the deep sea hydrothermal plume, chemolithotrophic microorganisms producing organic materials from inorganic carbons, such as sulfur oxidizing microorganisms, predominate. There is an estimate that in situ production of organic matter exceeds that of derived from surface photosynthesis. More than 99% of the chemical components contained in the hydrothermal fluids from the seafloor are released into deep-sea water and maximum chemical potential energy is thermodynamically calculated under low temperature condition by mixing hot hydrothermal fluid and sea water. Therefore, it is important for both deep-sea carbon dynamics and deep-sea ecosystems to estimate the microbial production in a hydrothermal plume. To estimate the primary production of microorganisms in a hydrothermal plume, it is necessary to understand the dynamics and functions of chemolitzotrophic microorganisms together with the physicochemical process of hydrothermal plume formation. We analyzed the formation process and chemical environment of hydrothermal plume and combined the dynamics of microorganisms with them to estimate the efficiency of hydrothermal energy use in microbial growth process. The formation process of the hydrothermal plume are regulated by the topography such as caldera, the stirring effect due to the deep ocean current intensity, and the density vertical structure of the water column. The composition of microbial community are known to be defined by chemical components of hydrothermal fluid. However, our result suggested that the energy efficiency and microbial total production of microorganisms is affected by these physical factors.

Variation of the past geomagnetic field is recorded in marine sediments as a fossil magnetization, called natural remanent magnetization (NRM). NRM is carried not only by detrital and eaolian magnetic grains but also by biogenic magnetic grains originated from magnetotactic bacteria. To investigate characters of NRM carried by biogenic magnetic grains we have cultured the microaerobic bacteria *Magnetospirillum magnetotacticum* MS-1 (here under, MS-1) in laboratory and made sample using them for remanent magnetization measurements by simulating a very early process of sediment formation.

Preliminary reports on properties and characters of the remanent magnetization carried by the samples have been presented in Masaoka et al (2018JpGU; 2018SGEPSS), but MS-1 cells used for making samples rarely contain magnetite grains in these cells (3 percent of the total cells). To try to increase number of the cells containing magnetite grains, we have tested a density separation method using finer density gradients centrifugation and observed separated cells by transmission electron microscope. We will report results of observations together with those magnetic measurements.

Exploring biogeographic patterns of marine planktonic cyanobacteria in coastal habitats- integrating uncultured and cultured approaches

*Punyasloke Bhadury[1]

1. Integrative Taxonomy and Microbial Ecology Research Group, Centre for Climate and Environmental Studies, Indian Institute of Science Education and Research Kolkata

The structure of marine planktonic cyanobacterial communities in coastal habitats can strongly influence rates and fluxes of coastal carbon cycling. Biogeographic patterns of marine planktonic cyanobacterial assemblages were elucidated from four coastal habitats namely, Baltic Sea (BL), Monterey Bay (MB), South China Sea (SCS) and Sundarbans (SB) based on deep phylogeny of 16S rRNA sequences generated using next generation sequencing and Sanger sequencing approaches. Based on 16S rRNA phylogeny, four major taxonomic orders of marine planktonic cyanobacteria were recovered in varying proportions with several novel 16S rRNA sequences in each of the four targeted habitats. Members of the order Synechococcales were dominant in all the habitats (~94% sequences) while the orders Chroococcales and Oscillatoriales were only detected in SB and SCS, respectively. In the phylogenetic tree, *Synechococcus*-like sequences showed overwhelming dominance in SB and they were found in three other habitats. *Prochlorococcus*-like sequences were found in sizeable number in MB and SCS but were absent in SB and coastal BL. *Synechococcus*-like sequences were represented by three major marine clusters (5.1, 5.2, and 5.3). Three novel clades as part of *Synechococcus* cluster were detected only in SB and one novel clade in BL. These clades could have potential functional significance in coastal carbon cycling. Interestingly, cultured based approaches also revealed a new species of *Synechococcus*, *Synechococcus moorigangaii* from SB which has the ability to grow across a range of salinity and metabolize different forms of nitrogen as well as fix di-nitrogen. This reflects the potential vast unexplored functional diversity of marine planktonic cyanobacteria in coastal habitats which needs to be identified and can help towards understanding of export of carbon in coastal oceans. Overall the study has revealed that majority of the marine planktonic cyanobacterial OTUs were found to be exclusive to each habitat, whereas some were shared by two or more habitats based on beta-diversity analysis.

The precise structure of “unsaturated” archaeol derivatives in the halophilic archaea lipid-core

*Noriaki YAMAUCHI[1]

1. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

Archaea has a characteristic lipid-core, archaeol. Further, a characteristic diether lipid-core (C_{20}-C_{25} diether (**1**)) which is constructed from one C_{25} and one C_{20}isoprenoid is produced by halophilic archaea[1]. Recently, Dawson et al. showed the existence of several unsaturated isoprenoid diethers (such as tentative structure **2**) in the lipid-core of several halophilic archaea which was incubated with very high salt concentration[2].
Then, **2**, and the regioisomeric structure about the double bond and ether bond with a glycerol, **3**to **5** were chemically synthesized according to the reported method and the comparison of the mass spectrum of trimethylsilyl (TMS) ether were presented previously at this meeting[3].Further, **3** or **4**may be a possible structure of the real compound Dawson et al. shown at the mass spectrum.
About these unsymmetrical diether. The halophilic archaea *Haloferax sulfrifonis* was incubated and the lipid core was extracted and isolated.The analysis of the lipic core was perforemd by the GC-MS of the TMS ether. At first, **1** was detected as a main core lipid compornent. And the compound almost identical the mass specrum with the synthetic structure **2** was detected with a second minor compornent. Careful analysis of the compornent, the srtucture almost identical with **4** is also detected. This result showed the double bond in the unsaturated archaeol in *H. sulfrifonis*is the mixture of **2** and **4**. Dawson's unsaturated diether does not have a double bond at the methyl group branching position resulting from the usual isoprenoid biosynthesis (e.g. phytol), probably unsaturation is formed after the saturated isoprenoid formation with a unspecific fasion. The result of the analysis of lipid core of the archaea having unsaturated C_{20}-C_{25}diether will be presented.

Estimation of microbial chemosynthesis efficiency in deep sea hydrothermal plume

*Michinari Sunamura[1]

1. University of Tokyo Dept. of Earth & Planetary Science

In the deep sea hydrothermal plume, chemolithotrophic microorganisms producing organic materials from inorganic carbons, such as sulfur oxidizing microorganisms, predominate. There is an estimate that in situ production of organic matter exceeds that of derived from surface photosynthesis. More than 99% of the chemical components contained in the hydrothermal fluids from the seafloor are released into deep-sea water and maximum chemical potential energy is thermodynamically calculated under low temperature condition by mixing hot hydrothermal fluid and sea water. Therefore, it is important for both deep-sea carbon dynamics and deep-sea ecosystems to estimate the microbial production in a hydrothermal plume. To estimate the primary production of microorganisms in a hydrothermal plume, it is necessary to understand the dynamics and functions of chemolitzotrophic microorganisms together with the physicochemical process of hydrothermal plume formation. We analyzed the formation process and chemical environment of hydrothermal plume and combined the dynamics of microorganisms with them to estimate the efficiency of hydrothermal energy use in microbial growth process. The formation process of the hydrothermal plume are regulated by the topography such as caldera, the stirring effect due to the deep ocean current intensity, and the density vertical structure of the water column. The composition of microbial community are known to be defined by chemical components of hydrothermal fluid. However, our result suggested that the energy efficiency and microbial total production of microorganisms is affected by these physical factors.

Geochemical studies for seawater/rock interaction recorded on the submarine lava flows of 12 Ma in the *Hokuroku* district in Akita, Japan and their implication to phosphorus cycle on the modern ocean floor

*Tsukasa Sai[1], Takeshi Kakegawa[1]

1. Graduate School of Science, Tohoku University

The phosphorus cycle on the modern surface environments of the Earth's is unclear. Many researchers consider that submarine basaltic rocks scavenge phosphorus by seawater/rock interaction. However, this argument is not supported by global data. In addition, uncertainties exist as to if submarine felsic rocks scavenge phosphorus during seawater/rock interaction. Thus, the purpose of this study is set to examine phosphorus behavior during seawater/rock interaction of submarine basalt and rhyolite, which ages are ca. 12 Ma. The samples are collected in the *Hokuroku* district in Akita prefecture: *Furutobe(basalt)*, *Oshigenaisawa(rhyolite)*, and *Hanaokanashizaka(basalt)*. Differences are examined in minerals and chemical compositions between outer and inner parts of basaltic pillow lava. Mineralogy and chemistry of single rhyolitic lava are examined according with different alteration patterns.
XRF analyses on bulk rock samples suggest basalt and rhyolite lost Si, Na, Ca with progress of submarine alteration. Basalt added Mg and Fe, and rhyolite added Mg and K during the same alteration. These results are consistent with combination of minerals identified by XRD and EPMA. The mobilization of elements in basalts from Furutobe is differ from others because Furutobe basalt suffered additional submarine hydrothrmal alteration.
It was found that basalt lost P, while rhyolite added P. Apatite and microcrystals of P-bearing unknown minerals are observed in basalt. In rhyolite, it is observed euhedral and anhedral crystals of 10-100 μm such as apatite, monazite, and xenotime. Primary apatite is observed in rhyolite phenocrysts, such as quartz, plagioclase, magnetite, ilmenite, and zircon. Secondary phosphate minerals are observed in vein, chalcedony developed in plagioclase pseudomorph, and Fe-bearing minerals. These clearly indicate the addition of phosphorus in altered rhyolite during seawater/rock interaction, and most likely phosphorus was supplied from seawater.
Therefore, it is suggested that basalt can supply phosphorus in ocean water as submarine alteration advanced, and rhyolite is a sink of phosphorus in the ocean floor. This knowledge is different from an established hypothesis that oceanic igneous rocks are sink of phosphorus.

Detection of methylphosphonate and phosphite contained in suspended particles in spring water

*Kazuma Tsuji[1], Masahiro Maruo[3], Hajime Obata[2]

1. Graduate School of Environmental Science, The University of Shiga Prefecture, 2. Atmosphere and Ocean Research Institute, The University of Tokyo, 3. School of Environmental Science, The University of Shiga Prefecture

Introduction

Methylphosphonate and phosphite are included in the process of constituting a biological cycle of phosphorus. Bacteria in the ocean is supposed to produce methylphosphonate and phosphite in the cell (Van Mooy et al., 2015). In freshwater system, it is strongly suggested that *Synechococcus* metabolizes methylphosphonate in subsurface layer of Lake Saiko (Yamanashi, Japan) under strong phosphorus limitation. However, methylphosphonate and phosphite in natural are considered to be dissolved in extremely low concentrations. Therefore, no reports existed that have detected these phosphorus compounds in natural waters. New analytical method for the determination of methylphosphonate and phosphite in natural was developed based on ion chromatography, and it was applied to detect them in waters of Lake Biwa (Shiga Japan) and spring nearby shore of Lake Biwa.

Methods

Ion chromatography was used to detect trace methylphosphonate and phosphite. Eluent condition was modified to separate these compounds from other major anions (chloride, nitrate, and sulfate) based on the condition for trace phosphate determination in waters of Lake Biwa (Maruo et al., 2016: Tsuji et al., in press). Water samples were obtained from Lake Biwa (Nov. 4th, 2018) and springs nearshore of Lake Biwa named “Kanabo”, in Maibara city, Shiga Prefectute (Nov. 6th, 2018). To detect methylphosphonate and phosphite in suspended matter, water samples (each 1.5 L) were filtered with a polycarbonate membrane filter (Nuclepore: Whatman, pore size of 0.2 μm). Then, the filter and MQW 25 mL were put in a glass bottle. The glass bottle was allowed to stand for 1 hour in a water bath (60˚C). After that, the extract solution contained was filtered with a disctype membrane filter (IC ACRODISC, Pall: pore size of 0.2 μm) and an all plastic syringe. The filtrate was injected in ion chromatograph system for the determination of methylphosphonate and phosphite included in suspended particles.
Immediately after collecting the sample water, the sample water was also filtered with a capsule filter (SUPOR Acropak 200 Capsule Filter, Pall: pore size 0.8 / 0.2 μm). Filtrate was used to determine methylphosphonate and phosphite dissolved in water.

Results and Discussion

Methylphosphonate (4.8 nM) and phosphite (3.6 nM) were detected in the solution extracted from suspended particles sampled in spring. Additionally, phosphite (23 nM) was detected in the solution extracted from suspended particles sampled in Lake Biwa. In dissolved fraction, both methylphosphate and phosphite were not detected at both sites. These compounds in dissolved fraction might exist in very low concentration and/or immediately utilized by biota. By ion chromatography, detection of methylphosphonate and phosphite contained in organisms sampled from other water systems is expected.

The Influence of Aerosol Optical Thickness and Mesoscale Eddies on Chlorophyll-a

*xiangguang zhang[1], Yongsheng Xu[1], Ichio Asanuma[2]

1. Institute of Oceanology, Chinese Academy of Sciences, 2. Tokyo University of Information Sciences

Chlorophyll-a concentration (Chl-a) has a close relationship with the nutrients and the atmospheric sedimentation is a good source for the nutrients of the sea. Moreover, the value of aerosol optical thickness (AOT) can stand for atmospheric sediment concentration. So, there should be a coupling relationship between AOT and Chl-a. The correlation analysis between AOT and Chl-a had been early assessed by previous works. For example, in South China Sea and Greenland Sea, the data analysis revealed that AOT had a big impact on the biogeochemistry of the South China Sea and there was a time-lag correlation between AOT and Chl-a in Greenland Sea.

Using 12 years' of AOT and Chl-a data from the NASA/MODIS and SeaWiFS sensors, we've studied the distributions and the coupling relationship between AOT and Chl-a all over the world. The correlation map shows some interesting areas on the earth. It is found that the highest positive correlation areas of the AOT and Chl-a time series are in the east coastal area of Africa, Baltic Sea, Caspian Sea and the band area in the Pacific between south Japan and San Francisco of USA; the highest negative correlation areas of the Chl-a and AOT time series are in The Mediterranean, west-south and east-south coastal areas of Australia.
Moreover, we analyze 10 years of measurements of SSH fields and concurrent satellite measurements of upper-ocean CHL to show that mesoscale eddies exert a strong influence on the CHL field.

Glyoxylate from CO atmosphere via UV photochemistry

*Kenta Isoda[1], Xiaofeng Zang[1], Yuichiro Ueno[1,2]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. Earth Life-Science Institute, Tokyo Institute of Technology

Glyoxylate could be an important compound, which can initiate a simple autocatalytic cycle and may possibly evolve to synthesize amino acids, nucleobase, pentose etc. (Eschenmoser, 2007a). However, constant supply of glyoxylate is an issue for the prebiotic environment. In this study, we aim to understand the possible condition to supply glyoxylate continuously to support such an autocatalytic cycle. First, we have performed experimental study and demonstrated that glyoxylic acid can be synthesized photochemically under carbon monoxide atmosphere. On the other hand, the UV irradiation into formaldehyde solution does not yield glyoxylic acid, except for the presence of CO in the gas phase. These results indicate that glyoxylate is not produced from formaldehyde in solution but from CO in the gas phase probably through the 3 steps: (i) HCO radical is produced from the reaction between CO and H from H_2O photolysis; (ii) The HCO radical dimerize in the gas phase, to form $(CHO)_2$(glyoxal); and (iii) The $(CHO)_2$ is oxidized into HCOCOOH (glyoxylate). An additional experiment demonstrated that UV irradiation into pure glyoxal solution can yield glyoxylate, and thus indicate that the step (iii) can proceed in the solution. Consequently, our experimental results suggests that glyoxylate can be continuously provided from atmosphere into hydrosphere if the atmosphere is rich in CO.

Keywords: atmosphere, photochemistry

Carbon reservoir perturbations in the Indian subcontinent induced by the Deccan volcanism in marine and terrestrial realm

*Sohom Roy[1], Prasanta Sanyal[1], Sambit Ghosh[1]

1. Indian Institute of Science Education and Research Kolkata

The Deccan flood basalt eruption spans across the Cretaceous-Paleogene (K/Pg) Boundary and records the largest
and the longest lava flows in the world. While the volcanism has been linked to the infamous K/Pg extinction,
however, its implications on the regional carbon budget are still not well constrained. Carbon isotope records in marine carbonates ($\delta^{13}C_{carb}$) and bulk organic matter ($\delta^{13}C_{org}$), coupled with carbon and hydrogen isotope records
of *n*-alkane ($\delta^{13}C_{alk}$ and δD_{alk} respectively) have been measured along with *n*-alkanes characterization from two
inter-trappean and one infra-trappean sedimentary sequence exposed south of the city of Rajahmundry, SE India
in order to evaluate the climatic and environmental response exacerbated by the volcanism in the marine and terrestrial realm. Overall, our data demonstrate major perturbations in the terrestrial and marine carbon cycle induced by the Deccan volcanism, with considerable environmental stress predating the K/Pg Boundary. Strong covariance between $\delta^{13}C_{org}$ and $\delta^{13}C_{carb}$ (r=-0.71) suggest that the dissolved inorganic carbon (DIC) in the shallow
marine environment was largely controlled by organic matter (OM) flux. The occurrence of large unresolved complex mixtures (UCM/n-alkane>>4) and hopanes (m/z 191) and steranes (m/z 217) in the limestones OM suggest considerable input from petroleum into the biomass. The upper part of the infra-trappean and lower parts of inter-trappean show considerable decreases in the marine $\delta^{13}C_{carb}$ values and have been inferred to occur from hydrocarbon assimilation by heterotrophs and early diagenesis of OM. Steady temporal increase in $\delta^{13}C_{carb}$ values and total organic carbon (TOC) content throughout the sequence imply increases in primary productivity, with the upper inter-trappean limestone marking the recovery phase. The $\delta^{13}C_{alk}$ values, coupled with the chain-length distribution pattern of *n*-alkanes and spore-pollen records exhibit significant turnovers in the vegetation community structure. High δD_{alk} values (~-110‰) indicate arid conditions before the deposition of mega flow episodes in Rajahmundry. Depletion in δD_{alk} values (~-150‰) observed in the middle part of the inter-trappean signifies a change to a humid condition. The increased rainfall prompted an upsurge in weathering that led to increases in freshwater influx (depletion in $\delta^{18}O_{carb}$ values) and higher terrestrial OM input (increase in long-chain *n*-alkanes). Atmospheric CO_2 concentration reconstructed from two paleosol horizons in the infra- and inter-trappean units respectively indicate major drawdown in pCO_2 across the main flow episode in Rajahmundry. It is speculated that the volcanism induced changes in pCO_2 was one of the main drivers for exacerbating changes in the carbon cycle.

Organic matter around Miocene Kuroko ore deposits: Implications to Archean submarine hydrothermal microbial community

*Takeshi Kakegawa[1]

1. Graduate School of Science, Tohoku University

Kuroko ore deposits were products of black smoker activities at 15 Ma paleo-Japan Sea. Kuroko is often covered by organic-rich sedimentary rocks, but details of these organic matter have not been unclear. Here I report analytical results of stable isotopes, Raman spectroscopy and bitumen compositions of organic matter around Miocene Kuroko deposits.

In general, all geochemical characteristics of organic matter were uniform in the same horizon of Kuroko deposits. On the other hand, H/C ratios and Raman spectroscopic data suggest that organic matter were extensively graphitized by thermal degradation only around Kuroko. More ^{12}C- and ^{14}N-enriched features are found in Kuroko-associated kerogen and bitumen. Such stable isotope data suggest the presence of chemoautotrophs, which utilized hydrothermal $CH_4$and NH_3. However, geochemical and geological characteristics of the examined samples suggest that hydrothermal $CH_4$and NH_3were produced by thermal degradation of sedimentary organic matter, which are mainly derived from photoautotrophs. This further suggests that chemoautotrophs at Kuroko were not independent and had strong connection to surface photoautotrophs.
Organic matter enriched in ^{12}C and ^{14}N are ubiquitous around many middle-Archean Kuroko ore deposits. Such stable isotope compositions also imply the presence of submarine hydrothermal microbial communities. However, ^{12}C- and ^{14}N-depleted organic matter, which most likely represent photoautotrophs, are also common around Archean Kuroko deposits. Such contrast stable isotope characteristics suggest that deep submarine chemoautotrophs already had linkages to surface photoautotrophs since Archean age.

Formation and solubility of hydrous carbonates formed in alkaline lakes under freezing condition

*TAKUMA KITAJIMA[1], Haruna Matsumiya[1], Keisuke Fukushi[1]

1. kanazawa university

Alkaline lakes have functions of absorption of atmospheric CO_2 to natural water and fixation of dissolved carbonate by mineralization. Therefore, it has been considered that alkaline lakes located in arid area inside the continents play important roles in carbon cycle on the earth surface (Finley et al., 2015; Fukushi and Matsumiya, 2018).

The common carbonate minerals are calcite and aragonite in natural environment. On the other hand, monohydrocalcite (MHC) is formed in alkaline lakes as most common carbonate minerals (Fukushi et al.2012). MHC ($CaCO_3 \cdot H_2O$) is metastable carbonate mineral with respect to calcite or aragonite (Munemoto and Fukushi, 2008). The formation of MHC requires the paragenesis of amorphous magnesium carbonate (AMC) (Nishiyama et al., 2013; Fukushi et al., 2017).

Fukushi and Matsumiya, (2018) measured the solubilities of MHC and AMC under the atmosphere at 25 ℃ and reported that MHC and AMC control the water chemistry of alkaline lakes. However, the most of surrounding environment of alkaline lakes are semiarid and cold. The lakes are covered with ice in most of the year.

During the ice forming ice, the lake water must be isolated from the atmosphere, which may lead to the decrease of low partial pressure of CO_2 in lakes. Low temperature may affect the formed mineral species and physicochemical properties of the minerals. Therefore, we can’ t discuss the water chemistry of alkaline lakes only from the knowledge obtained from the ambient condition atmosphere CO_2 pressure and 25 ℃. The purposes of this study are (1) investigation of the carbonate mineral formation from the solution simulated the alkaline lakes under low partial pressure of CO^2 at 5-50 ℃ and (2) measurements of solubilites of these carbonate minerals to estimate of water chemistry of alkaline lakes.

Effect of difference in mineral wettability on water-mineral reaction in rock pores

*Tadashi Yokoyama[1], Naoki Nishiyama[2]

1. Graduate School of Integrated Arts and Sciences, Hiroshima University, 2. Graduate School of Life and Environmental Sciences, University of Tsukuba

When water infiltrates rock pores, dissolution occurs at the contact site of water and mineral. In many cases rock pores near the ground surface are not fully saturated with water and a portion of pores is filled with air. In order to study how the presence of air in pores affects the reactivity of each rock-forming mineral, the amounts of elements leached out from the rock were compared for water-saturated condition and unsaturated condition by using a core of Berea sandstone. The sandstone consists mainly of quartz with several percentages of feldspar, carbonates, and clays. In the case of the saturated condition, initially pores were saturated with water by vacuum treatment, then water was passed through the core at a constant water head difference. In the case of the unsaturated condition, water was passed through a dry core. After the onset of the experiment under the unsaturated condition, water saturation (the fraction at which pore volume is saturated with water) became ~60% almost immediately (air 40%), and gradually increased and reached ~100% after 9 days passed. Dissolution rates of Si and Ca (amount of dissolution per unit time per whole rock) were determined by measuring the concentrations of dissolved Ca and Si in leachates. The difference in dissolution rate between unsaturated condition and saturated condition was generally greater in the case of Ca than that of Si. This appears to be due to the difference of wettability of silicates and carbonate. Probably silicates were more easily wet and many silicate surfaces dissolved even under the presence of air, while dissolution of carbonate was diminished due to the absence of water contact or the insufficient flushing of Ca in the wetting film of the carbonate surface.

Geochemical studies for seawater/rock interaction recorded on the submarine lava flows of 12 Ma in the *Hokuroku* district in Akita, Japan and their implication to phosphorus cycle on the modern ocean floor

*Tsukasa Sai[1], Takeshi Kakegawa[1]

1. Graduate School of Science, Tohoku University

The phosphorus cycle on the modern surface environments of the Earth's is unclear. Many researchers consider that submarine basaltic rocks scavenge phosphorus by seawater/rock interaction. However, this argument is not supported by global data. In addition, uncertainties exist as to if submarine felsic rocks scavenge phosphorus during seawater/rock interaction. Thus, the purpose of this study is set to examine phosphorus behavior during seawater/rock interaction of submarine basalt and rhyolite, which ages are ca. 12 Ma. The samples are collected in the *Hokuroku* district in Akita prefecture: *Furutobe(basalt)*, *Oshigenaisawa(rhyolite)*, and *Hanaokanashizaka(basalt)*. Differences are examined in minerals and chemical compositions between outer and inner parts of basaltic pillow lava. Mineralogy and chemistry of single rhyolitic lava are examined according with different alteration patterns.
XRF analyses on bulk rock samples suggest basalt and rhyolite lost Si, Na, Ca with progress of submarine alteration. Basalt added Mg and Fe, and rhyolite added Mg and K during the same alteration. These results are consistent with combination of minerals identified by XRD and EPMA. The mobilization of elements in basalts from Furutobe is differ from others because Furutobe basalt suffered additional submarine hydrothrmal alteration.
It was found that basalt lost P, while rhyolite added P. Apatite and microcrystals of P-bearing unknown minerals are observed in basalt. In rhyolite, it is observed euhedral and anhedral crystals of 10-100 μm such as apatite, monazite, and xenotime. Primary apatite is observed in rhyolite phenocrysts, such as quartz, plagioclase, magnetite, ilmenite, and zircon. Secondary phosphate minerals are observed in vein, chalcedony developed in plagioclase pseudomorph, and Fe-bearing minerals. These clearly indicate the addition of phosphorus in altered rhyolite during seawater/rock interaction, and most likely phosphorus was supplied from seawater.
Therefore, it is suggested that basalt can supply phosphorus in ocean water as submarine alteration advanced, and rhyolite is a sink of phosphorus in the ocean floor. This knowledge is different from an established hypothesis that oceanic igneous rocks are sink of phosphorus.

Detection of methylphosphonate and phosphite contained in suspended particles in spring water

*Kazuma Tsuji[1], Masahiro Maruo[3], Hajime Obata[2]

1. Graduate School of Environmental Science, The University of Shiga Prefecture, 2. Atmosphere and Ocean Research Institute, The University of Tokyo, 3. School of Environmental Science, The University of Shiga Prefecture

Introduction

Methylphosphonate and phosphite are included in the process of constituting a biological cycle of phosphorus. Bacteria in the ocean is supposed to produce methylphosphonate and phosphite in the cell (Van Mooy et al., 2015). In freshwater system, it is strongly suggested that *Synechococcus* metabolizes methylphosphonate in subsurface layer of Lake Saiko (Yamanashi, Japan) under strong phosphorus limitation. However, methylphosphonate and phosphite in natural are considered to be dissolved in extremely low concentrations. Therefore, no reports existed that have detected these phosphorus compounds in natural waters. New analytical method for the determination of methylphosphonate and phosphite in natural was developed based on ion chromatography, and it was applied to detect them in waters of Lake Biwa (Shiga Japan) and spring nearby shore of Lake Biwa.

Methods

Ion chromatography was used to detect trace methylphosphonate and phosphite. Eluent condition was modified to separate these compounds from other major anions (chloride, nitrate, and sulfate) based on the condition for trace phosphate determination in waters of Lake Biwa (Maruo et al., 2016: Tsuji et al., in press). Water samples were obtained from Lake Biwa (Nov. 4th, 2018) and springs nearshore of Lake Biwa named “Kanabo”, in Maibara city, Shiga Prefectute (Nov. 6th, 2018). To detect methylphosphonate and phosphite in suspended matter, water samples (each 1.5 L) were filtered with a polycarbonate membrane filter (Nuclepore: Whatman, pore size of 0.2 μm). Then, the filter and MQW 25 mL were put in a glass bottle. The glass bottle was allowed to stand for 1 hour in a water bath (60˚C). After that, the extract solution contained was filtered with a disctype membrane filter (IC ACRODISC, Pall: pore size of 0.2 μm) and an all plastic syringe. The filtrate was injected in ion chromatograph system for the determination of methylphosphonate and phosphite included in suspended particles.
Immediately after collecting the sample water, the sample water was also filtered with a capsule filter (SUPOR Acropak 200 Capsule Filter, Pall: pore size 0.8 / 0.2 μm). Filtrate was used to determine methylphosphonate and phosphite dissolved in water.

Results and Discussion

Methylphosphonate (4.8 nM) and phosphite (3.6 nM) were detected in the solution extracted from suspended particles sampled in spring. Additionally, phosphite (23 nM) was detected in the solution extracted from suspended particles sampled in Lake Biwa. In dissolved fraction, both methylphosphate and phosphite were not detected at both sites. These compounds in dissolved fraction might exist in very low concentration and/or immediately utilized by biota. By ion chromatography, detection of methylphosphonate and phosphite contained in organisms sampled from other water systems is expected.

The Influence of Aerosol Optical Thickness and Mesoscale Eddies on Chlorophyll-a

*xiangguang zhang[1], Yongsheng Xu[1], Ichio Asanuma[2]

1. Institute of Oceanology, Chinese Academy of Sciences, 2. Tokyo University of Information Sciences

Chlorophyll-a concentration (Chl-a) has a close relationship with the nutrients and the atmospheric sedimentation is a good source for the nutrients of the sea. Moreover, the value of aerosol optical thickness (AOT) can stand for atmospheric sediment concentration. So, there should be a coupling relationship between AOT and Chl-a. The correlation analysis between AOT and Chl-a had been early assessed by previous works. For example, in South China Sea and Greenland Sea, the data analysis revealed that AOT had a big impact on the biogeochemistry of the South China Sea and there was a time-lag correlation between AOT and Chl-a in Greenland Sea.

Using 12 years' of AOT and Chl-a data from the NASA/MODIS and SeaWiFS sensors, we've studied the distributions and the coupling relationship between AOT and Chl-a all over the world. The correlation map shows some interesting areas on the earth. It is found that the highest positive correlation areas of the AOT and Chl-a time series are in the east coastal area of Africa, Baltic Sea, Caspian Sea and the band area in the Pacific between south Japan and San Francisco of USA; the highest negative correlation areas of the Chl-a and AOT time series are in The Mediterranean, west-south and east-south coastal areas of Australia.
Moreover, we analyze 10 years of measurements of SSH fields and concurrent satellite measurements of upper-ocean CHL to show that mesoscale eddies exert a strong influence on the CHL field.

Glyoxylate from CO atmosphere via UV photochemistry

*Kenta Isoda[1], Xiaofeng Zang[1], Yuichiro Ueno[1,2]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. Earth Life-Science Institute, Tokyo Institute of Technology

Glyoxylate could be an important compound, which can initiate a simple autocatalytic cycle and may possibly evolve to synthesize amino acids, nucleobase, pentose etc. (Eschenmoser, 2007a). However, constant supply of glyoxylate is an issue for the prebiotic environment. In this study, we aim to understand the possible condition to supply glyoxylate continuously to support such an autocatalytic cycle. First, we have performed experimental study and demonstrated that glyoxylic acid can be synthesized photochemically under carbon monoxide atmosphere. On the other hand, the UV irradiation into formaldehyde solution does not yield glyoxylic acid, except for the presence of CO in the gas phase. These results indicate that glyoxylate is not produced from formaldehyde in solution but from CO in the gas phase probably through the 3 steps: (i) HCO radical is produced from the reaction between CO and H from H_2O photolysis; (ii) The HCO radical dimerize in the gas phase, to form $(CHO)_2$(glyoxal); and (iii) The $(CHO)_2$ is oxidized into HCOCOOH (glyoxylate). An additional experiment demonstrated that UV irradiation into pure glyoxal solution can yield glyoxylate, and thus indicate that the step (iii) can proceed in the solution. Consequently, our experimental results suggests that glyoxylate can be continuously provided from atmosphere into hydrosphere if the atmosphere is rich in CO.

Carbon reservoir perturbations in the Indian subcontinent induced by the Deccan volcanism in marine and terrestrial realm

*Sohom Roy[1], Prasanta Sanyal[1], Sambit Ghosh[1]

1. Indian Institute of Science Education and Research Kolkata

The Deccan flood basalt eruption spans across the Cretaceous-Paleogene (K/Pg) Boundary and records the largest
and the longest lava flows in the world. While the volcanism has been linked to the infamous K/Pg extinction,
however, its implications on the regional carbon budget are still not well constrained. Carbon isotope records in marine carbonates ($\delta^{13}C_{carb}$) and bulk organic matter ($\delta^{13}C_{org}$), coupled with carbon and hydrogen isotope records
of *n*-alkane ($\delta^{13}C_{alk}$ and δD_{alk} respectively) have been measured along with *n*-alkanes characterization from two
inter-trappean and one infra-trappean sedimentary sequence exposed south of the city of Rajahmundry, SE India
in order to evaluate the climatic and environmental response exacerbated by the volcanism in the marine and terrestrial realm. Overall, our data demonstrate major perturbations in the terrestrial and marine carbon cycle induced by the Deccan volcanism, with considerable environmental stress predating the K/Pg Boundary. Strong covariance between $\delta^{13}C_{org}$ and $\delta^{13}C_{carb}$ (r=-0.71) suggest that the dissolved inorganic carbon (DIC) in the shallow
marine environment was largely controlled by organic matter (OM) flux. The occurrence of large unresolved complex mixtures (UCM/n-alkane>>4) and hopanes (m/z 191) and steranes (m/z 217) in the limestones OM suggest considerable input from petroleum into the biomass. The upper part of the infra-trappean and lower parts of inter-trappean show considerable decreases in the marine $\delta^{13}C_{carb}$ values and have been inferred to occur from hydrocarbon assimilation by heterotrophs and early diagenesis of OM. Steady temporal increase in $\delta^{13}C_{carb}$ values and total organic carbon (TOC) content throughout the sequence imply increases in primary productivity, with the upper inter-trappean limestone marking the recovery phase. The $\delta^{13}C_{alk}$ values, coupled with the chain-length distribution pattern of *n*-alkanes and spore-pollen records exhibit significant turnovers in the vegetation community structure. High δD_{alk} values (~-110‰) indicate arid conditions before the deposition of mega flow episodes in Rajahmundry. Depletion in δD_{alk} values (~-150‰) observed in the middle part of the inter-trappean signifies a change to a humid condition. The increased rainfall prompted an upsurge in weathering that led to increases in freshwater influx (depletion in $\delta^{18}O_{carb}$ values) and higher terrestrial OM input (increase in long-chain *n*-alkanes). Atmospheric CO_2 concentration reconstructed from two paleosol horizons in the infra- and inter-trappean units respectively indicate major drawdown in pCO_2 across the main flow episode in Rajahmundry. It is speculated that the volcanism induced changes in pCO_2 was one of the main drivers for exacerbating changes in the carbon cycle.

Organic matter around Miocene Kuroko ore deposits: Implications to Archean submarine hydrothermal microbial community

*Takeshi Kakegawa[1]

1. Graduate School of Science, Tohoku University

Kuroko ore deposits were products of black smoker activities at 15 Ma paleo-Japan Sea. Kuroko is often covered by organic-rich sedimentary rocks, but details of these organic matter have not been unclear. Here I report analytical results of stable isotopes, Raman spectroscopy and bitumen compositions of organic matter around Miocene Kuroko deposits.

In general, all geochemical characteristics of organic matter were uniform in the same horizon of Kuroko deposits. On the other hand, H/C ratios and Raman spectroscopic data suggest that organic matter were extensively graphitized by thermal degradation only around Kuroko. More ^{12}C- and ^{14}N-enriched features are found in Kuroko-associated kerogen and bitumen. Such stable isotope data suggest the presence of chemoautotrophs, which utilized hydrothermal $CH_4$and NH_3. However, geochemical and geological characteristics of the examined samples suggest that hydrothermal $CH_4$and NH_3were produced by thermal degradation of sedimentary organic matter, which are mainly derived from photoautotrophs. This further suggests that chemoautotrophs at Kuroko were not independent and had strong connection to surface photoautotrophs.
Organic matter enriched in ^{12}C and ^{14}N are ubiquitous around many middle-Archean Kuroko ore deposits. Such stable isotope compositions also imply the presence of submarine hydrothermal microbial communities. However, ^{12}C- and ^{14}N-depleted organic matter, which most likely represent photoautotrophs, are also common around Archean Kuroko deposits. Such contrast stable isotope characteristics suggest that deep submarine chemoautotrophs already had linkages to surface photoautotrophs since Archean age.

Formation and solubility of hydrous carbonates formed in alkaline lakes under freezing condition

*TAKUMA KITAJIMA[1], Haruna Matsumiya[1], Keisuke Fukushi[1]

1. kanazawa university

Alkaline lakes have functions of absorption of atmospheric CO_2 to natural water and fixation of dissolved carbonate by mineralization. Therefore, it has been considered that alkaline lakes located in arid area inside the continents play important roles in carbon cycle on the earth surface (Finley et al., 2015; Fukushi and Matsumiya, 2018).

The common carbonate minerals are calcite and aragonite in natural environment. On the other hand, monohydrocalcite (MHC) is formed in alkaline lakes as most common carbonate minerals (Fukushi et al.2012). MHC ($CaCO_3 \cdot H_2O$) is metastable carbonate mineral with respect to calcite or aragonite (Munemoto and Fukushi, 2008). The formation of MHC requires the paragenesis of amorphous magnesium carbonate (AMC) (Nishiyama et al., 2013; Fukushi et al., 2017).

Fukushi and Matsumiya, (2018) measured the solubilities of MHC and AMC under the atmosphere at 25 ℃ and reported that MHC and AMC control the water chemistry of alkaline lakes. However, the most of surrounding environment of alkaline lakes are semiarid and cold. The lakes are covered with ice in most of the year.

During the ice forming ice, the lake water must be isolated from the atmosphere, which may lead to the decrease of low partial pressure of CO_2 in lakes. Low temperature may affect the formed mineral species and physicochemical properties of the minerals. Therefore, we can’ t discuss the water chemistry of alkaline lakes only from the knowledge obtained from the ambient condition atmosphere CO_2 pressure and 25 ℃. The purposes of this study are (1) investigation of the carbonate mineral formation from the solution simulated the alkaline lakes under low partial pressure of CO^2 at 5-50 ℃ and (2) measurements of solubilites of these carbonate minerals to estimate of water chemistry of alkaline lakes.

Effect of difference in mineral wettability on water-mineral reaction in rock pores

*Tadashi Yokoyama[1], Naoki Nishiyama[2]

1. Graduate School of Integrated Arts and Sciences, Hiroshima University, 2. Graduate School of Life and Environmental Sciences, University of Tsukuba

When water infiltrates rock pores, dissolution occurs at the contact site of water and mineral. In many cases rock pores near the ground surface are not fully saturated with water and a portion of pores is filled with air. In order to study how the presence of air in pores affects the reactivity of each rock-forming mineral, the amounts of elements leached out from the rock were compared for water-saturated condition and unsaturated condition by using a core of Berea sandstone. The sandstone consists mainly of quartz with several percentages of feldspar, carbonates, and clays. In the case of the saturated condition, initially pores were saturated with water by vacuum treatment, then water was passed through the core at a constant water head difference. In the case of the unsaturated condition, water was passed through a dry core. After the onset of the experiment under the unsaturated condition, water saturation (the fraction at which pore volume is saturated with water) became ~60% almost immediately (air 40%), and gradually increased and reached ~100% after 9 days passed. Dissolution rates of Si and Ca (amount of dissolution per unit time per whole rock) were determined by measuring the concentrations of dissolved Ca and Si in leachates. The difference in dissolution rate between unsaturated condition and saturated condition was generally greater in the case of Ca than that of Si. This appears to be due to the difference of wettability of silicates and carbonate. Probably silicates were more easily wet and many silicate surfaces dissolved even under the presence of air, while dissolution of carbonate was diminished due to the absence of water contact or the insufficient flushing of Ca in the wetting film of the carbonate surface.

Life on Earth is based on a diversity of physical and chemical dynamics and processes throughout the history of the Earth. It can essentially be regarded as the history of interrelation between Life, Water, Mineral (Solid Earth) and Atmosphere. To solve this kind of complex systems problems, interdisciplinary approach, a way of thinking and communication, is necessary. This session will be a cradle for such interdisciplinary researches.

Chemical speciation analysis of the brown and black precipitates observed in the gill chamber of the vent shrimp *Rimicaris kairei*

*Masanari Hikosaka[1], Yoshio Takahashi[2], Chong Chen[3], Robert Jenkins[1]

1. Kanazawa University, 2. Tokyo University, 3. Japan Agency for Marine-Earth Science and Technology

The hydrothermal vent shrimp *Rimicaris* dominates the megafaunal community in many hydrothermal vent ecosystems in the globe, including Mid Atlantic Ridge, the Central Indian Ridge (CIR), and the Caribbean Mid-Cayman Rise. *Rimicaris* harbors numerous strains of episymbiotic bacteria in its gill chamber and depends on them for most of the nutrition as adults. Probably due to the metabolism of this symbiotic bacteria, the tissues in the gill chamber were found to be encrusted with brown or black iron precipitates. The precipitates are removed by molting, but in a few days after molting, *Rimicaris* will be covered with precipitates again. Although *Rimicaris* relies on episymbiotic bacteria nutritionally, it is thought that the precipitates originated from episymbiotic bacteria disturb their swimming activity, nutrient uptake by the host. Thus, the relationship between *Rimicaris* and its epibionts seems to be different from general mutualistic relationship. To understand this symbiotic relationship correctly, it is necessary to clarify the relationship among the host, episymbiotic bacteria, and the precipitates. In this study, iron chemical speciation analysis based on XAFS were performed to black and brown precipitates in the gill chamber of *Rimicaris kairei* in order to clarify the chemical environment in the gill chamber.
Specimens of *Rimicaris kairei* were collected during the YK16-E02 cruise at two hydrothermal vent site, Edmond and Kairei on the CIR. Each tissues were fixed in 99.5 % ethanol, and embedded in Epoxy resin(Epofix, Struers), and both sides polished thin section with a thickness of about 50 μm were obtained. Thin section was subjected to μ-XRF element analysis and Fe K-edge XANES analysis at KEK PF BL-4A to investigate the element distribution and the speciation of iron around the bacteria. Fitting was carried out using a software REX 2000 (Rigaku) using ferrihydrite, goethite, magnetite, $FePO_4$, pyrite, pyrrhotite as reference materials.
By observing the freeze-dried samples by scanning electron microscope (JSM-6100, JEOL) and thin section samples by polarized microscopy, it was observed that the brown precipitates forms crusts of about 50 μm in thickness and covers entirely the inside of the branchiostegite, where black precipitates occur as submicron size microparticles in organic filmy tissues around filamentous bacteria. From the XANES fitting, it was suggested that the brown precipitates contain ferrihydrite, goethite, $FePO_4$, while the black precipitates contain ferrihydrite, goethite, $FePO_4$, and pyrrhotite. It was revealed that iron exists as Fe^{3+} in the brown precipitate, but in the black precipitate, iron exist as a mixture of Fe^{2+} and Fe^{3+}. It is estimated that the brown precipitates were formed in the aerobic environment and the black precipitates were formed in the relatively anaerobic environment. Overall, our suggested that the gill chamber environment was diverse even among the same species. We will perform next-generation sequencing of microbes in the gill chamber, and we need to investigate in detail the precipitation conditions of each mineral and the environment in which the host can grow.

Experimental study on hydrogen generation during low temperature serpentinization by using natural samples

*Shunta Higashino[1], Ryohei Kawakita[1], Tsubasa Otake[2], Tsutomu Sato[2]

1. Graduate School of Engineering, Hokkaido University, 2. Faculty of Engineering, Hokkaido University

Low temperature serpentinization, a reaction between ultramafic rocks and water under ambient conditions, generates hydrogen near Earth's surface environments. This reaction has been considered to play important roles in the origin of life since hydrogen may have been an important reducing gas for building blocks of life as well as early metabolisms. Furthermore, this process may be applicable for industrial hydrogen production that does not emit carbon dioxide during its production or consumption whereas the conventional method for hydrogen production essentially relies on fossil fuels. During serpentinization, hydrogen is generated by the reduction of water accompanied with oxidation of ferrous ion to ferric ion in the primary minerals of ultramafic rocks such as olivine or pyroxene. However, the amount of hydrogen produced during low temperature serpentinization is controlled by various factors, which have not been well understood, particularly, the effect of the formation of secondary minerals (Mayhew et al., 2018). Therefore, we conducted a series of experiments for hydrogen production using 10 ultramafic rock samples (dunites and harzburgites), from Japan (Horoman and Wakamatsu), Oman and Indonesia, showing various lithological features and degrees of serpentinization subjected during obduction. Mineralogical and geochemical characterizations were conducted using XRD, XRF and SEM-EDS. Experiments were then conducted by reacting the samples with water under anaerobic conditions at 90℃, for 2 weeks. After the experiments, gas, solid, and solution obtained from the experiments were analyzed by GC-RGD, XRD, and ICP-AES, respectively.

The results of experiments show that samples with lower degrees of serpentinization tend to generate larger amounts of hydrogen, and that harzburgites tend to generate more hydrogen than dunite when they are at the same degree of serpentinization. However, some highly serpentinized samples also generated large amounts of hydrogen though these results werepooly reproduced. This may have stemmed from the oxidation of trace minerals (e.g., Ni-Fe alloy) or their catalytic effects, in addition to the dissolution of Fe^{2+}-bearing primary minerals, because these minerals were heterogeneously observed by microscopy in the serpentinites. Experiments were also conducted with some additives (e.g., MgO, SiO_2, and magnetite) to investigate the effect of solution chemistry and formation of secondary minerals on hydrogen generation. The results show that hydrogen was generated the most under Si-rich conditions. Solution chemistry suggests that, olivine and pyroxene were likely dissolved more rapidly with Si-rich solutions. This is consistent with the trend that harzburgites generate hydrogen more than dunite because harzburgite contains pyroxene, which dissolved much Si compared to olivine. Moreover, thermodynamic calculations suggest that the precipitation of amorphous Mg-silicate minerals (e.g., M-S-H), which are commonly precursors of serpentine controls the solution chemistry including decreasing pH. Because the dissolution rate of the primary minerals is greater at lower pH, the precipitation of Mg-silicate minerals may have promoted the dissolution cycle of the primary minerals and therefore generation of hydrogen, especially under Si-rich conditions.

Ultramafic rock-water interaction systems attract more interest from the perspective of study for origin of life since the discovery of the hyperalkaline hydrothermal system in the Atlantic Ocean in 2001 (Kelley et al., 2001). These serpentinite-hosted systems are generally characterized by high concentrations of methane (CH_4) and higher hydrocarbons (C^{2+}) regardless of seafloor or on-land (e.g., Schrenk et al., 2013; Etiope and Sherwood-Lollar, 2013). Previous stable carbon and hydrogen isotopic studies have suggested that hydrocarbons could be formed abiotically via polymerization process (Proskurowski et al., 2008; Suda et al., 2017). However, the following is still poorly constrained; when and where hydrocarbons are produced. In this study, to constrain the origin of methane, we determined the radiocarbon (^{14}C) content in CH_4 and the helium isotope obtained from serpentinite-hosted hot spring in Hakuba Happo.
Hakuba Happo hot spring lies on a serpentinized ultramafic rock body in the Shiroumadake area, which belongs to the Hida Marginal Tectonic Belt in central Japan. The hyperalkaline waters (pH>10), with temperatures of approximately 50˚C, are pumped from two borehole wells (Happo #1 and Happo #3). N_2, H_2 and CH_4 are main gas components (Homma and Tsukahara, 2008; Suda et al., 2014). Water chemistry and volatile component are controlled primarily by serpentinization reaction.
Sample collection was conducted in 2015-2018. Hot spring gas samples were collected by a displacement method in water from two borehole wells (Happo #1 and Happo #3). For radiocarbon (^{14}C) analysis of methane, firstly, CH_4 in gas samples was converted to CO_2 by using the custom-built flow-through vacuum line system (similar to Pack et al., 2015) at JAMSTEC. Secondly, the purified CO_2 gas was reduced to graphite by using the graphitization reactor with Fe powder and hydrogen gas, and then the ^{14}C content was determined by using an accelerator mass spectrometry (AMS) at AORI, the University of Tokyo. Noble gas isotope abundances were measured with a noble gas mass spectrometer at GSJ, AIST. The concentrations of CO and CO_2 in gas phase were determined by using a GC-methanizer-FID method, which was suitable for detection of trace amounts of CO and CO_2 (Kaminski et al., 2003). The concentration of dissolved inorganic carbon (DIC) in spring water was measured by using GasBench/IRMS system at GSJ, AIST.
In Hakuba Happo hot spring, CO and CO_2 were below detection limit (<0.0005 vol.%). DIC concentration was <28 μmol/L (upper values because of suspicion of air contamination during sampling), which was lower than dissolved methane concentration (124-664 μmol/L; Suda et al., 2014). Methane is the most abundant carbon compound in Hakuba Happo hot spring. If methane production occurs under on-site condition, the inorganic carbon compounds (CO, CO_2 and DIC) are not likely to be a carbon source for CH_4. The high helium isotope ratio ($^3He/^4He$) was observed in both well sites. The $^3He/^4He$ ratios for Happo #1 and Happo #3 were 4.10 R_{atm} and 4.47 R_{atm}, respectively (where R_{atm} is the atmospheric $^3He/^4He$ ratio of 1.4×10^{-6}). For Happo #1 site, relative contribution of air, mantle and crustal components are estimated to be 47%, 31% and 22%, respectively. For Happo #3 site, 69%, 24% and 8%, respectively. The result of AMS measurements on two CH_4 samples from Hakuba Happo reveals that ^{14}C contents are near the detectable limit, i.e., the ^{14}C ages of CH_4 is at least approximately 50,000 years before present. Radiocarbon evidence rules out a modern carbon compound (e.g., atmospheric CO_2, organics in surface

©2019. Japan Geoscience Union. All Right Reserved.

soil) as the carbon source of CH_4 at Hakuba Happo hot spring system. The helium isotope and $^{14}CH_4$ data could be consistent with deep-derived carbon source of the Hakuba Happo CH_4. Therefore, it will be important to consider a relation between surface reaction system and deep mantle/crustal system.

Inhibition of calcium silicate hydrate formation by lignosulfonate and lignin

*Kanako Toda[1], Tsubasa Otake[1], Tsutomu Sato[1]

1. Laboratory of Environmental Geology, Faculty of Engineering, Hokkaido University

Dams and harbors have frequently dredged in order to secure the water storage capacity and shipping routes. Dredged soils are mostly treated as waste, though utilization of dredged soils for construction resources are economically and environmentally desired. Only a part of the dredged soils has been used for construction materials after mixing with steel slags due to their low physical strength. Mixture's strength development has been known to depend on utilized dredged soil. However, even under the same mixing conditions, some combinations may not be hardened. Soil composition is generally complex as it reflects the result of mineral-water-organic matter-microbe interactions occurred onto components from diverse origin. In solidification of the dredged soils to form construction materials, alkaline activators, steels slags in this case, are added, which triggers the formation of secondary phases such as calcium silicate hydrate (C-S-H). Factors affecting C-S-H formation have been reported previously (e.g., Tremblay et al., 2002; Zhu et al., 2007; Toda et al., 2018). However, inhibition mechanism of authentic organic matter in the soils and the quantitative effects of their functional groups on C-S-H formation are not fully understood.

In this context, the effects of 1) lignosulfonate and 2) lignin that contain carboxylic, sulfonic and thiol functional groups that have similar structures to soil organic matter and 3) simple organic molecule with one of carboxylic, sulfonic and thiol functional groups on C-S-H formation were investigated in this study. C-S-H was synthesized from $Ca(OH)_2$ and amorphous silica in coexistence of multiple addition ratio of lignosulfonate and lignin to expecting amount of C-S-H formed, in 100 rpm shaker at 50℃ for 10 days. After the syntheses, C-S-H were characterized by X-ray diffraction and FT-IR analysis, and chemical composition of the remaining solutions were analyzed by ICP-AES and TOC analyzer. After syntheses, solution pH were all above 12. The threshold quantity of lignosulfonate and lignin was evaluated to suppress the formation of C-S-H. Above the threshold, XRD peaks assigned to $Ca(OH)_2$ and amorphous silica could still be obtained after synthesis, without C-S-H peaks. Furthermore, below the threshold, the broad diffraction peak assigned to (001) reflection of C-S-H decreased with increasing the added amount of lignosulfonate and lignin. This suggests that lignosulfonate and lignin may suppress the dissolution of initial phases but also C-S-H crystal growth. Both of the indicated inhibition factors could occur due to the surface coverage by negatively charged functional groups in the organic matter under alkaline condition, which may be interacting with positively charged sites such as $Ca(OH)_2$ surface and CaO layer in C-S-H. C-S-H synthesis with simple organic molecule with various functional groups were also conducted to further discuss how the difference in soil organic matter structure in terms of functional group can inhibit C-S-H formation.

Calcium carbonate formation processes on cyanobacterial surface

*Fumito Shiraishi[1], Takeru Omori[1], Naotaka Tomioka[2], Satoko Motai[2], Hiroki Suga[3], Yoshio Takahashi[3]

1. Hiroshima University, 2. JAMSTEC, 3. The University of Tokyo

Cyanobacteria is oxygenic phototroph known to calcify under optimum ambient water chemistry. Fossils of calcified cyanobacteria are widely spread especially during the Phanerozoic, and the fluctuation in their abundance is crucial for reconstructing paleo-ocean chemistry (e.g., pH). Two major mechanisms are suggested for cyanobacterial calcification: 1) the photosynthetic increase in $CaCO_3$ saturation state, and 2) the crystal nucleation sites supplied by acidic groups of extracellular polymeric substances (EPS). Previous study based on natural samples demonstrated that acidic EPS is crucial for controlling the degree and the style of calcification. However, the influence of EPS on crystal morphology, crystal arrangement, and precursor (amorphous calcium carbonate: ACC) formation are still not well understood. The present study, therefore, examined the relationship between physical/chemical characteristics of EPS and calcification styles by using cultivated cyanobacteria.
Four cyanobacteria having different EPS characteristics (*Spirulina*, *Phormidium*, *Scytonema*, and *Leptolyngbya*) were cultivated. Acid-base titrations and lectin binding analysis indicated that all investigated cyanobacteria secreted EPS containing acidic groups. These cyanobacterial cultures were incubated in an aquarium (pH = ca. 8.5, $[Ca^{2+}]$ = 2 mM, DIC = 2 mM) with light supply to cause calcification. Microelectrode measurements (pH, O_2, and Ca^{2+}) showed that all cyanobacterial cultures induced $CaCO_3$ precipitation by photosynthesis, although the degree of precipitation was different. Observations by transmission electron microscopy (TEM) and scanning transmission X-ray microscopy (STXM) revealed that the characteristics of precipitated $CaCO_3$ were significantly different among the investigated cyanobacteria. Especially, calcite formed around *Spirulina*, *Phormidium*, *Scytonema* exhibited specific features including ACC, sub-micron-sized calcite polycrystals, and superstructures, suggesting that the nucleation occurred on acidic EPS via ACC nanoparticles. In contrast, such features were rarely observed in calcite formed around *Leptolyngbya* producing only a few amounts of EPS. From these results, $CaCO_3$ formation processes on cyanobacterial surface is suggested as follows: 1) ACC nanoparticles are formed on acidic EPS, 2) crystallization takes place inside of grown ACC particles to form submicron-sized calcite polycrystals, and 3) these polycrystals grow into calcite single crystal while ACC and polycrystals remain partly.

Mineralogical and geochemical study on sedimentary rock containing microfossils from 1.9 billion years ago(Ga) Gunflint Formation, Canada

*kouhei Sasaki[1], Akizumi Ishida[1], Takeshi Kakegawa[1]

1. Graduate School of Science, Tohoku University

The ca. 1.9 Ga Gunflint microfossils are well studied by previous investigators. On the other hand, no agreements exist for primary producers indicated by microfossils, and their living environments. In this study, we performed geological, mineralogical and geochemical studies on samples from Schreiber and Mink Mountain regions. In addition, detailed morphologies of microfossils in stromatolite were observed. In Schreiber region, we discovered the novel microfossils of cyanobacteria colony, akinete, and endospore. Undiscovered microfossil type with radial wall ornamentation is found, indicating eukaryotic affinities. In particular, in situ analysis of microfossils by NanoSIMS discovered multilayered microstructure of cell wall and heterogeneous distribution of carbon, nitrogen and sulfur possibly associated with biological incorporation of those elements followed by later diagenetic modification. At Mink Mountain region, detailed observations and chemical analyses suggest that iron-oxidizing bacteria were dominant around stromatolites. Fe^{2+} and clays were supplied by local and shallow hydrothermal systems along the paleo-coastal lines. Such hydrothermal environments created local anoxic environments, allowing accumulation of Fe^{2+} followed by microbial oxidation. In summary, microbial life at the Gunflint age was more diverse and evolved than previously thought, cyanobacteria were primary producers in most places, but structure of microbial ecosystems in the Gunflint ocean dynamically changed with environments.

[B-BC03] Interrelation between Life, Water, Mineral, and Atmosphere

convener:Takeshi Kakegawa(Graduate School of Science, Tohoku University), Tadashi Yokoyama(Graduate School of Integrated Arts and Sciences, Hiroshima University), Keisuke Fukushi(Institute of Nature & Environmental Technology, Kanazawa University), Fumito Shiraishi(Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University), Chairperson:Takeshi Kakegawa, Fumito Shiraishi(Hiroshima Univ.)

Life on Earth is based on a diversity of physical and chemical dynamics and processes throughout the history of the Earth. It can essentially be regarded as the history of interrelation between Life, Water, Mineral (Solid Earth) and Atmosphere. To solve this kind of complex systems problems, interdisciplinary approach, a way of thinking and communication, is necessary. This session will be a cradle for such interdisciplinary researches.

Secular variation of multiple sulfur isotopic compositions of sulfate and sulfide during long term incubation of *Desulfovibrio desulfuricans*

*Fumihiro Matsuura[1], Hiroko Makita[2], Ken Takai[3], Yuichiro Ueno[1,3]

1. Tokyo Institute of Technology, 2. Tokyo University of Marine Science and Technology, 3. Japan Agency for Marine-Earth Science & Technology (JAMSTEC)

Incubation experiments of sulfate reducing microbes have been carried out since 1950s to quantify sulfur isotope fractionation. Sulfur isotope fractionation models are constructed from the results of these experiments. These models are applicable only when steady state is accomplished in the cells; thus, most of incubation experiments targeted cells exponential growth phase. We aimed to quantify the isotope fractionation in stationary to death phase of the cells and carried out two series of incubation experiment of sulfate reducing bacteria, *Desulfovibrio desulfuricans* (DSM-642), until c.a. 2000 hours. In addition, we used glucose as electron donor to make cell specific sulfate reduction rate low. Cells grew linearly rather than exponentially until cell concentration became c.a. 2×10^7 cells/mL in the early stage of incubation. Calculated sulfur isotope fractionation increased from 13.5±3.7‰ at the earliest stage of linear growth phase to 70.5±21.0‰ at the middle of linear growth phase. The cell specific sulfate reduction rate was 1.0±0.3 fmol/cell/day when sulfur isotope fractionation became 70.5±21.0‰, consistent with the results of a previous study. In the stationary to death phase, sulfide concentration started decreasing on the contrary to our expectation. Besides, $\delta^{34}S_{sulfide}$ value increased concomitant with the decrease of $\Delta^{33}S'_{sulfide}$ value. The $\delta^{34}S'_{sulfide}$ and $\Delta^{33}S'_{sulfide}$ have good linear correlation, and that indicate a sulfide originated reaction in a closed system with a unique fractionation factor dominates sulfur cycle during stationary to death phase. The calculated enrichment factors of the reaction in the two series experiments are 10.5‰ and 30‰. These enrichment factors are large compared to those of biotic or abiotic sulfide oxidation experiments of previous studies. We checked the reaction occur without cells and infer that the reaction is caused from sulfide oxidation by oxidants containing in the medium or sulfurization of organic matter containing in the medium.

Origins of volcanic SO_2 on Earth

*Hiroshi Ohmoto[1]

1. The Pennsylvania State University

SO_2 is a principal volcanic gas today. The two important questions to be addressed are: (i). the origin of S atoms in volcanic SO_2; and (ii) whether or not SO_2 was an important volcanic gas of early Earth. I have approached these questions from: (a) thermodynamic- and kinetic analyses of various reactions involving S-bearing species in silicate melts, fluids, rocks, minerals, and aqueous solutions at T = 0-1500 ˚C and P = 1-10 kb, and (b) examinations of the chemical and S-isotopic characteristics of volcanic gases and rocks in various tectonic settings on modern Earth. Here are some of the important suggestions from these investigations:

1. All of the S-bearing species from submarine volcanic eruptions have been nearly completely trapped in oceans through reactions such as: $H_2S_{(g)} = H_2S_{(aq)}$; $4SO_{2(g)} + 4H_2O = 3HSO_4^- + H_2S_{(aq)} + 3H^+$; $S_{8(g)} = 8S_{(s)}$; and $7H_2S_{(aq)} + HSO_4^- + 4Fe^{2+} = 4FeS_{2(py)} + 7H^+ + 4H_2O$. S-bearing volcanic gases have only been emitted into the atmospheres by subaerial eruptions. Therefore, on the ocean-covered planets, possibly including the pre-3.0 Ga Earth, S-bearing gases have not been emitted into the atmospheres.

2. The fluids that originated from normal-mantle-derived-magmas (i.e., $\log fO_2$ = FMQ-2 to FMQ+0.5) were initially H_2S-rich and SO_2-poor, whereas those from subduction-related arc magmas (i.e., $\log fO_2$ = FMQ+0.5 to FMQ+3) were initially SO_2- and/or H_2S-rich.

3. H_2S-rich magmatic fluids may become SO_2-rich gas, if: (i) the fluids were derived from high fO_2 magmas (i.e., $\log fO_2$ > FMQ) and ascended slowly through conduits (i.e., diffusive eruptions) and re-equilibrated with wall-rocks at P_{H2O}<10 bars, or (ii) the fluids are oxidized by reactions with an O_2-rich atmosphere, -groundwater and/or high-fO_2 wall-rocks during and/or after the ascent through conduits. In the absence of (i) and (ii), such as the Earth prior to the oxygenation of the atmosphere, H_2S-rich magmatic fluids were not transformed to SO_2 during eruptions.

4. SO_2-rich fluids from arc magmas would remain SO_2-rich during explosive or diffusive eruptions. However, if the fluids cool down to <~700˚C, SO_2 transforms to H_2S.

5. Volcanic SO_2 from arc magmas was transformed from seawater sulfate through the following processes: (i) formation of pyrite, hematite and anhydrite by reactions between SO_4^{2-}-rich seawater and hot basalts on MORs; (ii) devolatilization of H_2O- and SO_2-rich fluids from the subducting oceanic crust; (iii) formation of oxidized- and SO_4^{2-}-rich magmas by partial melting of peridotite in the mantle wedges, and (iv) degassing of SO_2-rich fluids from these magmas. If the oceans were SO_4^{2-}-poor, volcanic gases from arc magmas would be SO_2-poor.

6. Oceanic SO_4^{2-} has been produced mostly by the oxidative weathering of pyrite on land. Therefore, subaerial volcanic gases on planets with O_2-poor atmospheres would be SO_2-poor and H_2S-rich. Then, the current paradigm concerning the origin of mass-independent-fractionations of sulfur isotopes (MIF-S) in Archean-aged sedimentary rocks (i.e., the UV photolysis of volcanic SO_2 in an O_2-poor atmosphere) becomes invalid. Consequently, the MIF-S record in sedimentary rocks is not supportive evidence for the “Great Oxidation Event” at ~2.5 Ga ago. Furthermore, the current atmospheric O_2-evolution models,

©2019. Japan Geoscience Union. All Right Reserved.

which are based on the premise of SO_2-rich volcanic gases throughout geologic time, become invalid.

(7). The MIF-S in the Archean- and younger sedimentary rocks may have been created by the chemisorption isotope effects during thermochemical reductions of seawater sulfates by hydrothermally-generated, very reactive organic matter.

Volcanism, sedimentation, and development of life in a Mesoarchaean intracratonic setting: the Dominion Group, South Africa

*Andrea Agangi[1,2], Axel Hofmann[2], Dora Paprika[2], Andrey Bekker[2,3], Frantz Ossa-Ossa[2,4]

1. Akita University, 2. University of Johannesburg, 3. University of California, 4. University of Tuebingen

The ca. 3 billion-years-old Dominion Group of the Kaapvaal craton, South Africa is a >2 km-thick volcano-sedimentary succession emplaced in an intracontinental setting shortly after craton consolidation. As such, it represents one of the oldest examples of volcanism and sedimentation on stable continental crust. Deposition of the Dominion Group is interpreted to have occurred largely subaerially in a failed rift. In contrast to other Palaeo- to Mesoarchaean successions of the Kaapvaal craton, the Dominion Group is little deformed and was metamorphosed at greenschist facies grade, allowing excellent preservation of rock textures and chemical composition. The succession includes a thin basal conglomerate that marks a major, craton-scale nonconformity, and is overlain by sandstone. Volcanic rocks include intercalated massive to amygdaloidal mafic lavas of tholeiitic affinity, felsic lavas, and ignimbrites with high Fe/Mg.

In the area around the town of Ottosdal, the Dominion Group is represented by felsic volcanic rocks with intercalated, thin sedimentary layers that crop out discontinuously for several km along the strike. The presence of shallow, porphyritic intrusions that developed peperitic contacts with the sediments and the intense alteration developed in sediments underlying (but not in overlying) volcanic rocks indicate deposition of these sediments in a volcanically and hydrothermally active environment, such as volcanic lakes. These sediments are composed of carbonaceous and variably sulfidic shale and minor arenite and have a distinctive aluminium-rich composition (Al_2O_3 up to 36 wt.%) and very low contents of alkaline elements, Ca, and Fe (Na_2O content from below detection limit to 0.3 wt%; Fe_2O_3 = 0.1 to 1.6 wt%). The main mineral components of these sediments are pyrophyllite, diaspore, K-mica, rutile, and pyrite. No carbonate was found.

The total organic carbon content) is up to 1.5 wt%, and bulk-sample isotope analyses indicate strongly ^{13}C-depleted composition ($\delta^{13}C_{VPDB}$ = -45 to -29‰). These isotopic values are diagnostic of biogenic carbon fixation and the lowest, best-preserved values are indicative of methanogenesis and methanotrophy in a redox and chemically stratified shallow basin. Modern examples of volcanic environments hosting methane-producing Archaea, even under low pH and high temperature conditions, are known from Kamchatka, Russia and Argentina.

Our results indicate that restricted and ephemeral lakes that developed in Mesoarchaean volcanic environments shortly after the large-scale emergence of the Kaapvaal craton fostered life and were likely niches for life diversification. This ancient environment might be a better Mars analogue than modern caldera environments on Earth where the impact of advanced biosphere is more pronounced.

New microbial ecology results from genome centered metagenomics studies of iron carbonate and sulfidic hot springs

*Shawn E McGlynn[1], Lewis Ward[2], Takeshi Kakegawa[3], Yuichiro Ueno[1], Mayuko Nakagawa[1]

1. Earth-Life Science Institute, Tokyo Institute of Technology, 2. Harvard University, 3. Tohoku University

The ability to recover microbial genomes from metagenomic datasets has revolutionized how we understand microbial inhabitants in the environment, and is a powerful way to develop detailed hypotheses of community function and evolution. In this talk, I will discuss recent genomes we have recovered from two iron rich, carbonate hot springs in Japan, and contrast these to observations in low iron, sulfidic springs. Surprisingly, despite the different chemistry, some overall trends in phylogeny and physiology are observed, however water chemistry differences such as salinity and the availability of ferrous iron does alter the observed microbial inhabitants and physiologies.
These overall results will be discussed within the context of the possible ability to recognize microbial inhabitation on Earth through time.

Superhabitability in ultradeep rocky environments

*Yohey Suzuki[1]

1. Graduate School of Science, The University of Tokyo

It is challenging for life to proliferate in cold rocky habitats deeply isolated from photosynthetic organic matter. Although fluid circulation is previously considered to be necessary for supplying energy sources and oxidants, it is also considered that substrates available within the rocky environment are diluted by fluid circulation. As the abundance of microbial life within the rock matrix is largely unknown, I developed nanoscale analytical procedures to unveil the distributions of microbial cells, organic matters and low-temperature minerals. As a result of applying the analytical procedures to various deep-sea and subsurface rocky environments such as deep-sea hydrothermal vents, deep-sea ferromanganese crusts and deep subseafloor basaltic rocks, it is unexpectedly unveiled that the rocky habitats are superhabitalble with cell densities locally exceeding 10^{10}cells/cm^3. The superhabitablity might be explained by the coexistence of solid silicate phases such smectite clays that play roles in concentrating nutrients from the ambient fluid.In this presentation, I will introduce the analytical procedures and main results obtained from the ultradeep rocky habitats.

Exploring planetary habitability beneath the oceans

*Fumio Inagaki[1]

1. Japan Agency for Marine-Earth Science and Technology

Since Ocean Drilling Program (ODP) Leg 201 in 2002 off Peru and eastern equatorial Pacific, numerous geochemists and microbiologists have participated in multiple expeditions of scientific ocean drilling to explore subseafloor life and the deep biosphere beneath the oceans. The discovery of diverse microbial life in marine sediments and oceanic crusts worldwide points to a notion that subseafloor microbial ecosystems may have uniquely co-evolved with Earth's dynamics and this inevitable interrelationship has shaped environemnts for more than 3 billion years. Expanding our knowledge of the comprehensive ocean-Earth-life system through scientific ocean drilling inspires new insights into the essence of "planetary habitability"—down to the Earth’s upper mantle, which with today’s drilling technology provides the deepest yet accessible limit. The deep ocean offers windows into thick piles of ocean sediment and the Earth’s interior that has vast potentials for the development of sustainable ocean-Earth-life system in the past but also into the future, yet there is still a large insufficiency in our knowledge of the habitability extent of our own planet. Such explorations towards deep frontiers will lead us to an understanding of how and why life emerged on our planet, as well as an estimation (prediction) of the possible trajectories of life on Earth, and finally, will provide hints as to whether life persists in the other celestial bodies, and which ones are the most likely to be habitable and even inhabited.

[B-CG06] Earth and Planetary Science Frontiers for Life and Global Environment

convener:Yoshinori Takano(Japan Agency for Marine-Earth Science and Technology (JAMSTEC)), Yohey Suzuki(Graduate School of Science, The University of Tokyo), Shingo Kato(RIKEN), Keisuke Fukushi(Institute of Nature & Environmental Technology, Kanazawa University), Chairperson:Yuki Morono(JAMSTEC), Masanori Kaneko(AIST/GSJ), Shingo Kato(RIKEN)

Earth and planetary science is currently capable of sampling from four frontiers: space, polar regions, deep ocean and deep underground for the study of the origin and evolution of life. Next generation sequencing technology of nucleic acids and nanotechnology-driven innovation of solid characterizations are very powerful to expand our understanding of many fields of earth and planetary sciences. It is also important for us to be aware of global warming and climate change that dramatically affect biodiversity, biological activities and elemental cycling. The aim of this session is to cross the border of science sections to explore the frontiers of earth and planetary science.

Earth as an open system to the Universe, and five multi-layered spheres to produce a habitable planet

*Shigenori Maruyama[1]

1. Earth-Life Science Institute, Tokyo Institute of Technology

<Purpose>

To understand the Earth’s history including life, we need to treat the Earth as an open system within the Universe. Such an approach has not yet fully considered. Here, I demonstrate it for the first time.

<Method>

Utilizing data set derived from geological evidences that have been collected through systematic rock sampling from all the continents over 30 years, we consider the Earth system as five multi-layered spheres, 1) atmosphere-ocean, 2) biosphere, 3) crust and upper mantle inn the framework of plate tectonics, 4) lower mantle driven by plume and superplume, and 5) metallic core to cause magnetosphere which protect the life on the surface. And this Earth system is driven by the internal heat of the solid Earth and/or the solar energy for the surface. Mutual interaction between these five spheres produce the Earth’s history including life.

<Result>

The most important key factor to keep mutual interactions between spheres is the function of plate tectonics continuing over 4.4 Gyr, which has been maintaining the Earth system as the robust systematic and dynamic equilibria. Specifically, plate tectonics has circulated carbon between atmosphere-ocean, biosphere, and crust and upper mantle through carbon fixation within sediments to produce a habitable planet. Biosphere plays another significant role as a buffer of CO_2 to stabilize atmospheric temperature within habitable status (not to evolve into Venus-like planet). However, biosphere has been critically influenced by galaxy-galaxy collisions happened at 4.5-4.0 Ga (birth of Earth and Prokaryote), 2.5-2.2Ga (birth of Eukarya), 0.8-0.5 Ga (plants and metazoans) appeared in association with frequent mass extinctions.

<Discussion>

Based on the understanding of Earth’s system and its history, we are able to extend it to our future, and predict the Earth’s history including final event of disappearance of the Earth in 8 billion years. I propose the biggest 20 events of Earth’s history including future Earth.

Holocene Antarctic subglacial weathering and ice-sheet history reconstructed using the $^{10}Be/^{9}Be$ ratios of lake Maruwan Oike sediments

*Adam David Sproson[1], Yusuke Yokoyama[1,2], Yoshinori Takano[2], Yosuke Miyairi[1], Takahiro AZE[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Department of Biogeochemistry, Japan Agency for Marine Science and Technology

Glaciers play an important role in the climate system via freshwater storage and the transportation of various materials from the continents to the oceans. Enhanced discharge of the former during melting events can influence global sea-level, while enhanced silicate weathering resulting from the latter can drive a reduction in atmospheric CO_2. Although these processes are known to be important through geological time, temporal changes in chemical weathering intensity and meltwater flux for the East Antarctic Ice Sheet (EAIS) are not well understood. During the last deglaciation, the EAIS retreated significantly (*1, 2*), forming isolated basins via glacio-hydro-isostatic adjustment (GIA) related crustal uplift. Sediment accumulated in these lakes provide a unique record of subglacial weathering and ice-sheet history throughout deglaciations when global temperatures and pCO_2most notably rose.

Meteoric ^{10}Be is produced in the atmosphere by cosmic rays and delivered to the Earth and ocean surface via dust and precipitation. In Antarctica, these sources of ^{10}Be become locked up in ice sheets and are subsequently released to the continental shelf during periods of melting and freshwater discharge (*3*), where they adhere to suspended particles in the water column and subsequently accumulate on the basin floor (*4, 5*). Stable ^{9}Be is present in silicate rocks and is released during subglacial weathering (*5*), with little simultaneous release of ^{10}Be (*4*), and transported to the oceans via meltwater outflow. When Be is incorporated into the authigenic phase of marine sediments, the $^{10}Be/^{9}Be$ reflects that of the overlying water column (*6*), which in turn reflects the relative dominance of freshwater flux and/or subglacial weathering.

Here, we present authigenic $^{10}Be/^{9}Be$ ratios for a sedimentary core from Lake Maruwan Oike situated at the head of the Rundvåg glacier in the Lützow-Holm Bay area of East Antarctica. Sedimentary material from L. Maruwan Oike provides an ~6,000 year record of subglacial weathering and nutrient input from the nearby glacier (*7*). Authigenic $^{10}Be/^{9}Be$ records reflect variations in freshwater flux and subglacial weathering and indicate several periods of enhanced melting of the Rundvåg glacier. This study provides further constraints on EAIS fluctuations during the Holocene and offers an insight into the behaviour of beryllium in high-latitude subglacial-marine systems.

Chemical speciation and solubility of heavy elements (lead, zinc, copper, arsenic and cadmium) in contaminated soil from Kamegai mine tailing, Toyama, Japan

*Baasansuren Gankhurel[1], Keisuke Fukushi[2], Akitoshi Akehi[1], Yoshio Takahashi[3], Kazuo Kawasaki[4]

1. Graduate School of Natural Science and Technology, Kanazawa University, 2. Instutute of Nature and Environmental Technology, Kanazawa University, 3. Department of Earth and Planetary Science, The University of Tokyo, 4. Graduate School of Science and Engineering for Research, Toyama University

Heavy metals such as lead, zinc, copper, arsenic and cadmium are usually found in surface soils affected by mining or smelting activities, agricultural practices and industrial areas [1,2,3]. Hara et al., [4] showed that some heavy metals including lead, arsenic and cadmium in soil surrounding the mine tailing area in Toyama Prefecture, Japan has largely exceeded the environmental standards. The total amount of trace metals in soils is generally not sufficient to assess environmental impacts of metal contamination. Therefore, chemical forms and binding types of metals enables evaluation of their behavior and bioavailability in the soil environment.The objectives of the present study were to understand the chemical speciation of As, Zn, Cu, Pb and Cd from Kamegai mine tailing area by means of sequential extraction procedure combined with synchrotron based XAFS and electron microscope.

Thirty-two soil samples were analyzed, determining the chemical fractionation of Pb, Cd, As, Zn and Cu using by the five-step sequential extraction (SEP), X-ray absorption fine structure (XAFS), X- ray diffractometer (XRD) and scanning electron microscopy. The results of SEP showed that most of the Pb was associated with non-residual fractions, mainly in crystalline iron oxides (goethite). The Cd appeared mainly associated carbonate fraction in the roots of the dried plants in the soils. The XAFS spectra of the samples showed that Pb in the soil are adsorption forms with Fe-(hydr)oxides surface. Results of XAFS analysis showed Cd in the samples are $CdCO_3$, coprecipitated with $CaCO_3$. Zn, Cu and As appeared mainly associated with the amorphous and crystalline iron oxides. Heavy metals associated with carbonates, amorphous and crystalline iron oxides, thus being potentially more mobile to the environment if conditions were more acidic or reducing.

High-mass resolution molecular imaging of organic compounds on the Murchison meteorite.

*Minako Hashiguchi[1], Hiroshi Naraoka[1,2]

1. Research Center for Planetary Trace Organic Compounds, Kyushu University, 2. Department of Earth and Planetary Sciences, Kyushu University

Introduction: Primitive meteorites contain a wide variety of organic molecules. The CHO, CHNO, CHNOS and CHN species have been identified using high-resolution mass spectroscopy for the solvent extracts of carboneceous chondrites [1-3]. These organic compounds could be synthesized and evolved via interaction of fluid with minerals [3-5]. Therefore, spatial distribution of meteoritic organic compounds is important to reveal the organic-mineral association on the parent bodies. Recently, in-situ analysis of polar organic compounds on the meteorite surface was achieved by desorption electrospray ionization/high-resolution mass spectrometry (DESI/HRMS) [7]. In this study, we further performed the DESI-HRMS imaging on the Murchison meteorite to understand the relationship between spatial distribution of polar organic compounds and minerals.

Experimental: The fragment of the Murchison meteorite (CM2) (~ a few mm) obtained by chipping was embedded in indium (In). The DESI-HRMS imaging was performed using a DESI ion source (Omni Spray 2-D, Presolia) equipped with an Orbitrap mass spectrometer (Q-Exactive Plus, Thermo Scientific) with mass resolution of ~140,000 at *m/z* 200. Methanol (LC-MS grade) was sprayed on the sample surface with a 1 or 2 μl/min flow rate. The spatial resolution was approximately 100 μm. FESEM-EDS analysis was also carried out without coating and polishing after the DESI-HRMS imaging. The surface of the Murchison meteorite fragment embedded in indium was also extracted with MeOH, and the resulting solution was applied for HPLC-HRMS to obtain chemical structural information on the organic compounds.

Results and Discussion: Alkylated homologues of $C_nH_{2n-1}N_2^+$ (n = 7–9) and $C_nH_{2n}NO^+$ (n = 9–14) were detected on the sample surface by the DESI-HRMS imaging. HPLC/HRMS analysis of MeOH extracts from the sample surface after the DESI/HRMS imaging indicated that the $C_nH_{2n-1}N_2^+$ homologues correspond to alkylimidazole, and that a few structural isomers of the $C_nH_{2n}NO^+$ homologues were present in the sample.The alkylimidazoles and $C_nH_{2n}NO^+$ homologues displayed different spatial distributions in the Murchison fragment. Moreover, the distribution pattern of compounds also different among the same homologues. These results may be due to the separation of isomers by similar chromatographic effects, or different synthetic pathways. The alkylimidazoles and $C_nH_{2n}NO^+$ homologues are mainly distributed in the matrix region of the Murchison by mineralogical observations, which is consistent with previous reports. Altered minerals (e.g., Fe-oxide, Fe-sulfide, and carbonates) occurred in this region. However, no clear relationship was found between these minerals and the organic compounds detected by DESI/HRMS imaging. Although this result might be due to scale differences between the spatial resolution of DESI-HRMS imaging and the grain size in the matrix of the Murchison, our results would indicate that alkylimidazoles and the $C_nH_{2n}NO^+$ homologues in the Murchison fragment were mainly synthesized by different processes from hydrothermal alteration on the parent body.

Fe(II) oxidation processes at the surface of bacterially colonized iron deposits

*Fumito Shiraishi[1], Kohei Nakao[1], Chizuru Takashima[2], Akihiro Kano[3], TAKAAKI ITAI[3]

1. Hiroshima University, 2. Saga University, 3. The University of Tokyo

Fe(II) oxidation processes at the surfaces of bacterially colonized iron deposits are examined at three hot springs in Japan for which the chemical profiles of the pH, redox, and O_2 and Fe(II) concentrations at the water/deposit interface are measured via microelectrodes. The three hot springs share similar bulk chemistry with a weakly acidic pH of 5.7–6.3, a high iron concentration of 50–130 μM, and a high dissolved inorganic carbon concentration of 20–60 mM. At the Sambe and Shionoha hot springs where the bulk water O_2 concentration is ca. 80 μM, abiotic Fe(II) oxidation via autocatalysis prevails. At the Okuoku-hachikurou hot spring where the bulk water O_2 concentration is ca. 50 μM, autocatalytic Fe(II) oxidation is suppressed and biotic Fe(II) oxidation induced by cyanobacterial photosynthesis is effective. These observations indicate that an O_2 concentration of ca. 50 μM is the threshold of reversing the relative contribution of biotic and abiotic Fe(II) oxidation. Protons from Fe(II) oxidation are compensated by reactions among the dissolved inorganic carbon species, which sustain the pH condition and continuous Fe(II) oxidation at the deposit surface. The observations of this study provide implications for understanding the deposition of banded iron formations in the geological past.

Heme: The distribution and dynamics of a ubiquitous iron-tetrapyrrole molecule

*Yuta Isaji[1], Yoshinori Takano[1], Nanako O. Ogawa[1], Naohiko Ohkouchi[1]

1. Japan Agency for Marine-Earth Science and Technology

Hemes are Fe(II)-tetrapyrrole complexes that catalyze various electron transfer and redox reactions. They are essential for biological systems, and are possessed by all life forms. Because heme-iron represents as much as 40% of the iron pool in phytoplankton (Gledhill, 2007), hemes in the biomass likely comprise a major fraction in the bioavailable-iron pool which limits primary productivity in over 30% of the world oceans (Moore et al., 2013). They are also expected to be found in the sediments, either as allochthonous compounds deposited from the water column or synthesized in situ by the benthic and subsurface microorganisms. It is noteworthy that etioporphyrin III preserved in various sedimentary rocks, which is supposedly derived from heme, has a highly distinct carbon and nitrogen isotopic compositions ($\delta^{13}C$, $\delta^{15}N$) with respect to other chlorophyll-derived porphyrins in Cretaceous black shales (Ohkouchi et al., unpub. results). As such, hemes are ubiquitous in any environment where life exists, but little is known on their distribution and dynamics in natural environments.

Here, we established a new analytical method to quantify, isolate, and purify heme *b*, a major homolog of hemes, from various environmental samples. Detection of picomole levels of heme *b* is achieved with a photodiode-array detector connected to HPLC, which covers the heme *b* concentration range in particulate (> 0.7 μm; 0.15 nmol L^{-1}) and dissolved organic matter (> 3000 Da; ~0.006 nmol L^{-1}) in the coastal seawater of Tokyo Bay, as well as that in the surface sediments of the Japan Sea (~0.03 μg g^{-1} dry weight). Importantly, concentration of heme *b* in the dissolved phase was contrastingly low with respect to that in the particulate phase of the coastal seawater, which imply that hemes may constitute a major fraction of the regenerated iron in the ocean. The $\delta^{13}C$ and $\delta^{15}N$ values of heme *b* isolated and purified from various environmental samples are determined with our modified EA/IRMS (Ogawa et al., 2010). These isotopic values will be compared with those of chlorophylls and amino acids, which will reveal the sources of hemes in natural environments and the isotopic fractionation associated with their biosynthesis. Our new analytical approach will provide first detailed insights into the ubiquitous iron-tetrapyrrole molecule playing an essential role in biogeochemical cycle.

[B-CG06] Earth and Planetary Science Frontiers for Life and Global Environment

convener:Yoshinori Takano(Japan Agency for Marine-Earth Science and Technology (JAMSTEC)), Yohey Suzuki(Graduate School of Science, The University of Tokyo), Shingo Kato(RIKEN), Keisuke Fukushi(Institute of Nature & Environmental Technology, Kanazawa University), Chairperson:Yoshinori Takano(JAMSTEC), Keisuke Fukushi, Yohey Suzuki(Univ. Tokyo)

Earth and planetary science is currently capable of sampling from four frontiers: space, polar regions, deep ocean and deep underground for the study of the origin and evolution of life. Next generation sequencing technology of nucleic acids and nanotechnology-driven innovation of solid characterizations are very powerful to expand our understanding of many fields of earth and planetary sciences. It is also important for us to be aware of global warming and climate change that dramatically affect biodiversity, biological activities and elemental cycling. The aim of this session is to cross the border of science sections to explore the frontiers of earth and planetary science.

Diversity and evolution of biosynthetic enzymes for chlorophyll pigments

*Yusuke Tsukatani[1]

1. Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

Photosynthesis is the process converting light energy to chemical potential energy. In phototrophic organisms, chlorophyll (Chl) and bacteriochlorophyll (BChl) pigments are essential for harvesting light energy, migrating excited energy, and transferring electrons. How photosynthesis is emerged on early earth is enigmatic, but pigments are theoretically required first in the ancient phototrophs to absorb light and start photo-induced reactions. A classic question on the evolution of pigment biosynthesis is whether Chl was evolved first or BChl first? Chl molecules mainly absorb visible light wavelength, whereas BChls absorb longer wavelength including near-infrared light region. Therefore, to know which pigment is first evolved is important to know atmospheric environment on early earth. The steps diverging to Chl or BChl in pigment biosynthetic pathways are catalyzed by enzymes similar to nitrogenase. One of the nitrogenase-like enzymes is chlorophyllide oxidoreductase which also catalyzes branching steps toward BChl-*a* and BChl-*b*. BChl-*b* absorbs longest light wavelength among naturally occurring pigments. In my talk, pigment structures and their diversified biosynthetic pathways that we recently revealed will be introduced and experimental approach to solve the evolution of chlorophyllous pigments will be presented.

1. Gas Hydrate Research Laboratory, Meiji University, 2. University of Tokyo, 3. AORI, University of Tokyo, 4. University of Aberdeen, Scotland, 5. Tokyo University of Marine Science and Technology

Methane derived authigenic carbonates (MDACs) are commonly found associated with both active and remnant submarine seeps and, under favorable conditions of pressure and temperature, are also found in close contact with marine methane hydrate. Recently, we have discovered microdolomitic aggregates inside of massive Japan Sea gas hydrates. These are fundamentally different, both in chemistry, stable isotopic composition and growth habit to the MDACs encountered outside of the hydrates. Phylogenetic analysis of microbial DNA within the dolomites reveals primarily Bacteriodetes, bacteria whose principal energy source is the degradation of complex macromolecules such as oils. Actual analysis of the oils found inside of the Sea of Japan gas hydrate confirms that they are biodegraded during burial. Previous investigations of MDACs have focused on ANME methane oxidizers (ANME) and sulfate reducing bacteria (SRB) as the primary drivers for MDAC precipitation in shallow sediment. The discovery of microbial dolomites inside saline gas-hydrate inclusions opens up a number of research avenues and applications such as: Mars-analogue studies, microbial remediation of marine oil-spills, and investigations into the role of shallow marine microbes in the conversion of organic carbon into dissolved inorganic carbon. This study was conducted under the commission from AIST as part of the methane hydrate research project funded by the Ministry of Economy, Trade and Industry, Japan. Ongoing work is being carried out thanks to a Grant-in-aid provided by the Japan Society for Promotion of Science and the Japanese Ministry of Education, Culture, Sports, and Technology (Kaken Project # 17K05712).

Discriminative biogeochemical signatures of methanotrophs inhabiting different chemosynthetic fields in an active mud volcano of the Canadian Beaufort Sea

*Dong-Hun Lee[1], Yung Mi Lee[2], Jung-Hyun Kim[2], Young Keun Jin[2], Charles Paull[3], Helge Niemann[4,5], Ji-Hoon Kim[6], Kyung-Hoon Shin[1]

1. Hanyang Univ., 2. KOPRI, 3. MBARI, 4. NIOZ and Utrecht Univ., 5. CAGE, UiT , 6. KIGAM

In this study, we investigated vertical variations in methanotrophic communities in assosication with varying methane fluxes within a mud volcano (420 m water depth, MV420) of the Canadian Beaufort Sea, by analysing geochemical properties, microbial lipids, and nucleic acid signatures. Three push cores were collected from visually discriminative chemosynthetic fields that were (i) bare of organisms (BO) to the naked eye, (ii) covered with bacterial mats (BM), or (iii) siboglinid tubeworms (ST), by using a remotely operated vehicle (ROV). The methane fluxes were highest at the sites of BO (0.06 mmol cm^{-2} y^{-1}) and BM (0.04 mmol cm^{-2} y^{-1}) and substantially lower at the ST site (0.01 mmol cm^{-2} y^{-1}). All MV420 sites showed the presence of aerobic methane oxidation (MOx)- and anaerobic methane oxidation (AOM)-related lipid biomarkers (4-methyl sterols and *sn*-2-hydroxyarchaeol, respectively), which were distinctly different in comparison to the reference site where these compounds could not be detected. Our lipid biomarker results are furthermore in good agreement with 16S rRNA analyses, which revealed the presence of MOx-related bacteria (*Methlyococcales*) and AOM-related archaea (ANME-2 and ANME-3 groups) at the MV420 sites. The 4-methyl sterols derived from *Methlyococcales* were predominant in the surface layer at the BM site with a moderate methane flux, while their occurrence was limited at the BO and ST sites. Notably, the abundances of AOM-related lipid biomarkers were minor at the BO site where the methane flux was highest. However, ANME-3 and sulfate reducing bacteria (*Desulfobacteraceae* and *Desulfobulbaceae*) were abundant in the downcore sediments at the BM site. On the other hand, the abundances of the ^{13}C-depleted *sn*-2-hydroxyarchaeol potentially derived from ANME-2 and/or ANME-3 groups was predominant at the ST site, indicating their co-occurrence under a lower methane flux. Accordingly, our results suggest that a niche diversification within this MV system has shaped distinct methanotrophic communities due to the availability of electron acceptors in association with varying degree of methane fluxes and bioirrigation activity.

Determination of the absolute stereochemistry of the hydroxyl group in 2-hydroxyarchaeol, the main lipid core of methanogenic and methanotrophic archaea

*Noriaki YAMAUCHI[1], Masanori Kaneko[2]

1. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, 2. National Institute of Advanced Industrial Science and Technology

One of the major characteristics of archaea is the lipid core which consist of saturated isoprenoid chain and glycerol with ether bond formation. Furthermore, main lipid core of methanogenic and methanotrophic archaea is hydroxyarchaeol. The saturated isoprenoid is altered to the isoprenoid which has one hydroxyl group in the C-3 of the isoprenoid. Two regioisomeric structures, *sn*-2- and *sn* -3-hydroxyarchaeol (**1**and **2**), are existed depending on the position of the hydroxylated isoprenoid bonding to glycerol.. The distribution of the two isomer is species-dependent [1].
2-Hydroxyarchaeol (**1**) is an important biomarker indicating accumulation of methane hydrate under the seafloor, anoxic oxidation of methane, methane formation at the lake, marsh, and digestive tract of ruminant. Structure determination [1] and analysis of hydroxyarchaeol from the field samples were performed by many researchers [2][3][4], however, the absolute stereochemistry of the hydroxyl group in the ether chain, the most characteristic feature of the molecule had not been determined so far.
The previous study of the author (NY), the synthetic preparation of 2-hydroxyarchaeol equivalent by “racemic” hydroxyl groups revealed that the “racemic” 2-hydroxyarchaeols behave as two equal amounts of the compounds because of the stereochemistry of the hydroxyl group. The result was different from several analysis of field samples which descrived the 2-hydroxylarchaeol as a single compound [5].
For the determination of the stereochemistry of the hydroxyl group of 2-hydroxyarchaeol, asymmetric synthesis of the hydroxyl-group containing ether chain part was conducted and the two stereoisomers of 2-hydroxyarchaol were synthesized.
The stereochemistry of this hydroxyl group was derived from the Katsuki-Shapless epoxidation of phytol. The two isomers were regioselectivity converted to the 2-hydroxyarchaol. The analyses of “racemic” 2-hydroxylarchaeol, two isomers of synthetic 2-hydroxyarchaeol stereoisomer (**3** and **4**), and 2-hydroxyarchaeol from the lipid of *Methanosarcina barkeri* revealed the absolute stereochemistry of the aforementioned hydroxy group is 3*R* (compound **3**). The comparison of the ^{13}C NMR of synthetic 2-hydroxyarchaeol stereoisomer (**3** and **4**), and 2-hydroxyarchaeol from the methanogen culture showed slight difference because of the stereochemistry of methyl group of saturated hydrocarbon of the synthetic isomers. This result may suggest the stereochemistry of methyl group is influenced at the nature of hydroxyarchaeol-containing lipid.

Mineral-Microbe interaction –Identification of extracellular electron transfer mechanisms by using MetaOmics approach

*Shunichi Ishii[1], Shino Suzuki[1], Kenneth H Nealson[2]

1. Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 2. University of Southern California

Microbial reduction of solid minerals such as iron-oxides and manganese-oxides is known to occur as a result of microbial extracellular electron transfer (EET). These electron transfer activities coupled with the oxidation of organic carbon or hydrogen are considered to play important roles within complex microbial communities in soil, sediment, and the deep subsurface environments. The surface redox potentials of solid-phase oxide minerals are known to be highly variable because of variations in the crystal structure, pH, salinity, and levels of hydration, posing major challenges for EET-capable microbes to adapt in the habitats. In fact, the *in situ* redox potentials of solid-state electron acceptors have been regarded as significant geochemical variables linked to the regulation of functional genes in the EET-capable microbes. However, mechanisms that the microbes use to perform respiration of insoluble metal-oxide minerals showing different surface redox potentials are complex and are not yet well understood.

Here, we used bioelectrochemical systems to systematically evaluate the effects of surface redox potentials (e.g. +100 mV, −50 mV, −200 mV vs SHE) on EET-active microbial community development and the overall electron transfer rates. The results clearly indicate that faster biocatalytic rates were observed under electropositive electrode surface potentials than the electronegative potentials. Temporal 16S rRNA-based microbial community analyses showed that *Geobacter* phylotypes were highly diverse and apparently dependent on the surface potentials. The well-known dissimilatory metal-reducing microbes affiliated with *Geobacter metallireducens* clade were associated with lower surface potentials and less current generation, whereas *Geobacter* subsurface clades were associated with higher surface potentials and greater current generation. These results suggest that surface potentials provide a strong selective pressure, at the species and strain level, for solid mineral respirators throughout the EET-active community development.

Next, we show metabolic and transcriptional responses of the EET-active microbial communities established on the three different poised electrodes to changes in the surface redox potentials. Combination of genome-centric stimulus-induced metatranscriptomics and metabolic pathway investigation revealed that nine *Geobacter* / *Pelobacter* microbes performed EET activity differently according to their preferable surface potentials and substrates. While the *Geobacter* / *Pelobacter* microbes coded numerous numbers of multi-heme *c*-type cytochromes and conductive e-pili, wide variations in gene expression were seen in response to altering surrounding substrates and surface potentials, accelerating EET via poised electrode or limiting EET via an open circuit system. These flexible responses suggest that a wide variety of EET-active microbes utilizing diverse EET mechanisms may work together to provide such EET-active communities with an impressive ability to handle major changes in surface potential and carbon source availability.

Conclusively, these results presented here offer a new perspective on the complexity of the EET-active members in the microbial communities that were adapted to the different surface redox conditions, and some initial insights into how they may regulate community function and provide adaptability to the different minerals on the earth. Overall, these results have opened a door toward unraveling the diverse microbial life within the various geological settings especially in the mineral-rich subsurface environments.

Dynamisms and characteristics of dissolved organic matter (DOM) in deep aquifer: A scope for deep biosphere

*Atsushi Urai[1,2], Yoshinori Takano[2], Naohiko Ohkouchi[2]

1. Department of Science and Technology, Graduate School of Medicine, Science and Technology, Shinshu University, 2. Department of Biogeochemistry, Japan Agency for Marine-Earth Science and Technology

Dissolved organic matter (DOM) is generally derived from multiple sources and affected by complicated transformation and degradation reactions. In a general geochemical description of marine environments, high-molecular-weight DOM (HMW-DOM; >1 kDa) particularly represents a unique organic carbon pool, which is accompanied by considerable difference in the molecular and stable isotopic compositions from other organic components such as particulate organic matter (POM) and low-molecular-weight DOM (LMW-DOM; <1 kDa) (e.g., Benner et al., 1997).

To date, formation of DOM fraction and potential microbial interaction in deep aquifer have been particularly poorly understood on the context of prokaryotic ecology. We investigated the molecular composition of DOM fraction including LMW and HMW by an improved method (Urai et al., 2018). The filtered samples are tentatively defined by conventional size scales; macromolecular scale (100 mm >> 40 mm), POM (40 mm >> 0.6 mm), HMW-DOM(0.6 mm>>1kDa), and total-DOM (<0.6 mm). We also have a validation to distinguish the molecular signature between phototrophic primary producers (i.e., fossil molecules) and presently living benthic prokaryotes (i.e., modern molecules; cf. biological methanogenesis, Kaneko et al., 2014). We report a preliminary result of the feasibility study and discuss a perspective from the view of deep biosphere.

Correlations of magnetosome-related genes in Nitrospirae genomes to magnetosome geometry and redox stratification in deep-sea environments

*Shinsaku Nakano[1], Shingo Kato[2], Mariko Kouduka[1], Toshitsugu Yamazaki[3], Yohey Suzuki[1]

1. Graduate School of Science, The University of Tokyo, 2. RIKEN, 3. Atmosphere and Ocean Research Institute, The University of Tokyo

Biogenic magnetic particles are ubiquitously found in deep-sea sediments and important carriers of rock magnetism for reconstructing the Earth’ s past regarding sediment age and geomagnetic field. However, microorganisms responsible for the formation of magnetic particles are largely unknown in the deep-sea environment, because of the difficulty in sampling, cultivation, and magnetic separation of magnetotactic cells for single-cell genomics. In this study, deep-sea sediments from Japan Sea and a metal sulfide chimney from South Mariana Trough were subjected to magnetic separation and subsequent electron microscopic observations. Although teardrop-shaped magnetite (Fe_3O_4) particles without microbial cells and 16S rRNA gene sequences related to magnetotactic Nitrospirae species were previously obtained from Japan Sea sediments with a redox zonation enriched with dissolved Fe(II) (the iron boundary), no magnetotactic cells were observed after the magnetic separation. From the metal sulfide chimney, magnetotactic cells were observed with teardrop-shaped magnetite particles. Metagenomic analysis of the chimney sample revealed that contig sequences encoding genes involved in the formation of magnetosome, membrane-bound magnetic particles, were mostly affiliated within Nitrospirae based on sequence similarity. Previous studies have reported that magnetosome-related genes are clustered together as the magnetosome island (MAI) in known magnetotactic bacteria. However, those genes were scattered in a near-complete Nitrospirae genome reconstructed from the chimney sample. Although magnetotactic bacteria are generally considered to align magnetic particles into a chain for efficiently moving in a vertical redox zonation by orienting the cell along the geomagnetic filed, Nitrospirae-affiliated genes involved in chain formation were not found in the near-complete Nitrospirae genome from the chimney with a horizontal redox zonation. Comparative analysis of near-complete Nitrospirae genomes available from public databases revealed that the chain-related genes were found in the genomes from terrestrial deep aquifers and deep-sea sediments with a vertical redox zonation. As the Nitrospirae species associated with teardrop magnetite and the iron boundary in Japan Sea was closely related to Nitrospirae species with the chain-related genes, the presence of the chain-related genes appears to be correlated with a vertical redox zonation. In addition, our results suggest that the Nitrospirae species without MAI are responsible for the production of teardrop magnetite in deep-sea environment, and that teardrop magnetite is a paleoredox indicator especially for the iron boundary.

Reconstruction of key ecological responses leading to the most recent dead zone formations in Japan Sea through ancient DNA metabarcodring

*Mariko Kouduka[1], Yohey Suzuki[1]

1. Department of Earth and Planetary Science, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo, Japan.

Semi-closed ocean basins are very sensitive to climate changes as recorded in frequent formations of sediments with clearly laminated layers, which was caused by the lack of O_2 available to benthic organisms. This is so-called “dead zone formation” and caused by water stagnation after channel closure and/or nutrient inflow through upwelling and channel opening. In contrast to the hydrologic causes, it remains poorly understood about organismal causes such as enhanced primary production and heterotrophic consumption of O_2. We investigated ancient eukaryotic DNA obtained from a thinly laminated layer deposited in the Japan Sea across the most recent global warming event after Younger Dryas (TL-1). Metabarcoding of 18S rRNA gene sequences clarified that across the transition from oxygenated to anoxic bottom water conditions, dominant protist populations shifted through five stages:

Stage1: Under oxygenated bottom conditions, the most dominant taxonomic group was Marine Stramenopiles Group 9 (MAST-9). MAST-9 encompasses diverse uncharacterized planktonic species, 18S rRNA gene sequences of which were detected from both anoxic and oxic water bodies in Pacific and Atlantic Oceans, Mediterranean Sea and South China Sea.

Stage 2: Before the onset of dead zone formation, the sharp decline of MAST-9 was accompanied with the expansion of marine diatom species of the genus Skeletonema, many members of which are known to be a cause of red tide around the world.

Stage 3: The dead zone formation was synchronized with the expansion of marine radiolarians of the order Chaunacanthida, the members of which are encrusted within $SrSO_4$.

Stage 4: Stages 2 was repeated, whereas the expansion of the Chaunacanthida radiolarians was not evident.

Stage 5: The uncharacterized MAST-9 that was dominant before the dead zone formation was gradually recovered towards oxygenated bottom conditions.

From these results, it is suspected that the expansion of Radiolaria species encrusted with $SrSO_4$ triggered dead zone formation by the accelerated downward transport of dead cells and subsequent heterotrophic consumption of O_2. From bioturbated sediment samples from a maximum depth of 31 mbsf with a depositional age of 100 ka, the Chaunacanthida sequences closely related to that from the laminated sediments have been previously detected.It is therefore suggested the record of the Chaunacanthida species can be reconstructed from sediments with great depth and age.

Search for microbial CH_4 production processes in lake sediments and surface water associated with cyanobacterial bloom

*Makoto Matsushita[1], Yoshinori Takano[1], Hiroyuki Imachi[1], Atsushi Urai[2], Ho-Dong Park[3], Hiroki Iwata[3], Naohiko Ohkouchi[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Department of Science and Technology, Graduate School of Medicine, Science and Technology, Shinshu University, 3. Department of Environmental Sciences, Faculty of Science, Shinshu University

Methane (CH_4) is an important greenhouse gas and contributes substantial budget to global warming. Freshwater lakes are identified as one of the main CH_4 sources, as it is estimated that they contribute to 6-16% of natural CH_4 emissions [1]. The main part of CH_4 released from lakes is considered to be produced by methanogenic archaea in anoxic sediments as terminal step in the degradation of organic matter. The microbial CH_4 production in lake sediments has been mainly investigated by microbiological studies using culture-dependent methods and molecular analysis.

Microbial CH_4 production is still regarded by many as a process limited to anoxic environments. Nevertheless, over the past few decades, increasing evidence of CH_4 accumulation in oxygen-saturated lake and marine surface water has emerged [2]. To explain the enigmatic issues, it has been proposed that CH_4 production by methanogenic archaea takes place in anoxic microenvironments such as detritus and animals' gut. Alternatively, recent studies suggest that some bacteria break down methylphosphonate (MPn) or dimethylsulfoniopropionate (DMSP) and release CH_4 as a biogenic byproduct. These novel microbial CH_4 production processes may play a potential contribution to the total atmospheric carbon cycle.

Oxic CH_4 peaks have been found to be closely associated with phytoplankton dynamics across multiple lakes. Grossart *et al*. [3] found potentially methanogenic archaea associated with cyanobacteria such as *Aphanizomenon* and *Microcystis* in oxygenated surface water. Additionally, Berg *et al*. [4] showed that hydrogen produced during nitrogen fixation by cyanobacteria can be consumed by methanogenic archaea. These studies suggest the presence of a CH_4 production process by methanogenic archaea associated with cyanobacteria in lake surface water. However, it is unclear whether the CH_4 production is taking place in actual environments.

In this study, we investigated microbial CH_4 production in sediments and surface water of Lake Suwa in Nagano Prefecture, Japan, a typical hypertrophic shallow lake, using culture-independent methods. Especially, we focused on cyanobacterial bloom and tried to identify a CH_4 production process by methanogenic archaea associated with cyanobacteria. 16S rRNA gene analyses revealed the presence of methanogenic archaea closely related to the order *Methanobacteriales*, *Methanomicrobiales*, and *Methanosarcinales* in sediment core samples from 30 cm depth. On the other hand, 16S rRNA genes and *mcrA* genes of methanogenic archaea were not detected in bulk DNA from cyanobacterial bloom sample (mainly *Microcystis*)[5]. In order to estimate the potential for methanogenic archaea, we extracted Coenzyme F430, a biomarker for methanogenic archaea, from sediment and bloom samples and determined by using HPLC [6]. F430 was detected from sediment samples, but that from bloom sample was currently below detection limit (<1 pmol).

These results suggest that methanogenic archaea actively produce CH_4 in the sediments of Lake Suwa,

©2019. Japan Geoscience Union. All Right Reserved.

however, its contribution in oxygenated surface water seems to be small. We are currently conducting a more sensitive analysis of F430 using LC-MS/MS [6] with the pre-treatment procedure [7]. The analysis may identify the CH_4 production process by methanogenic archaea associated with cyanobacteria in the surface water. Although this study did not cover other CH_4 production processes such as MPn and DMSP decomposition, our results may also be applicable to estimate the *in situ* contribution of these novel CH_4 source.

Did life emerge in a deep-sea metal sulfide chimney? New insights from an archaeal genome and a nanoscale microbe-silicate assemblage

*Hinako Takamiya[1], Hiroki Mukai[2], Mariko Kouduka[1], Shingo Kato[4], Motoo Ito[3], Yohey Suzuki[1]

1. Earth and Planetary Science Graduate School of Science, The University of Tokyo , 2. National Institute of Advanced Industrial Science and Technology, 3. Kochi Institute for Core Sample Research JAMSTEC, 4. RIKEN

Deep-sea hydrothermal activities have continued for 3.8 billion years on Earth. After the formation of metal sulfide chimneys from high-temperature fluid, their low-temperature interactions with ambient seawater potentially provide the cold, stable habitat for microbial life. In such a challenging habitat with metal toxicity, 16S rRNA gene sequences formerly affiliated within Deep-Sea Hydrothermal Vent Euryarchaeota Subtype 6 (DHVE6) and recently reclassified as Pacearchaeota are dominantly detected by 16S rRNA gene sequence analysis. However, the distribution and metabolic activities of Pacearchaeota in metal sulfide chimneys are largely unknown. In this study, a metal sulfide chimney collected from a deep-sea hydrothermal field in South Mariana Trough was subjected to genome-resolved metagenomics analysis. It was revealed that a near-complete Pacearchaeota genome has carbon metabolism genes involved in glycolysis and pentose phosphate pathway linked to nucleotide salvage pathway with light-independent CO_2incorporating ribulose bisphosphate carboxylase/oxygenase (RubisCO). By comparative analysis of Pacearchaeota genomes from deep-sea metal sulfide deposits and terrestrial subsurface aquifers, the carbon metabolism was commonly found with genes annotated for Cu detoxification. Based on the NanoSIMS ion imaging analysis, we found an evidence of a dense microbial colonization inside the chimney where the surface of chalcopyrite ($CuFeS_2$) was overlayered with a silica-bearing material enriched in CN, S and P. Our results explain the geographically and physicochemically diverse distributions of Pacearchaeota indicated by 16S rRNA gene sequence analysis as well as the predominance of Pacearchaeota in the metal sulfide chimney where energy sources from photosynthesis and hydrothermal fluid are limited. The carbon metabolism operated by Pacearchaeota in one of candidate environments for the origin of life could be relevant to that operated by primitive life on early Earth.

Recent developments of the X-ray computed tomography (CT) reaches to the spatial resolution of down to few tens of nanometers scale, which is enough to visualize single microbial cells, together with those distributions as well as its surrounding environments. In this study, we tried to visualize microbial cells in the environmental samples by using nanometer-scale X-ray CT.
We used anaerobic granular sludge and subseafloor sediments for the test samples. The X-ray CT analyses were conducted at beamlines of BL20XU and BL47XU in synchrotron radiation facility of Spring-8. The soft samples were either freeze-dried or embedded in the epoxy resin for the analysis. Since the high-spatial resolution observation of the X-ray CT analysis requires a higher density of X-ray per field, the samples often deformed during the analysis, which results in the failure of the 3D reconstruction of the data. Optimization of the resin, its polymerization condition, together with the stain of the cells by osmium tetroxide to put heavy element onto the microbial cells, we could successfully visualize single microbial cells in the samples. Also, the observations of the sample at the pre- and post-edge energies of the element (such as Os) enabled specific signal enhancement of osmium-stained cells.
The investigations of subseafloor biosphere have often based on destructive measurements. Although these analyses revealed the large-scale distribution of microbes along the chemical gradients, no previous attempt explored the spatial distribution of microbial cells at their size range. The visualization of microbes with its surrounding environments will give basic but critical information to understand the microbial in-situ ecophysiology.

Carbon signatures in amino acids during deep-sea anoxic methanotrophy

*Yoshinori Takano[1]

1. Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

Microorganisms play a central role in both methane production and consumption in the global carbon cycle. Oceanic methane from global deep-sea sediment is largely consumed through microbially mediated sulfate-coupled oxidation, resulting in 13C-depleted cell biomass of anaerobic methanotrophic archaea (ANME). The general ecological importance of subseafloor ANME has been well recognized in the last two decades. However, the crucial biochemical pathways for the overall anaerobic oxidation of methane (AOM) still remain enigmatic. In the present study, methanotrophic pathways were analyzed to trace 13C-depleted amino acid biosynthesis in two clades of ANME (ANME-1 and ANME-2) from the Black Sea. Compound-specific analysis of ANME-dominated microbial mats showed a significant 13C-depletion trend in association with increasing carbon numbers in protein-derived amino acid families within the pyruvate family in the order of alanine, valine, isoleucine and leucine down to -114‰. This result indicates a stepwise elongation of 13C-depleted carbon during amino acid biosynthesis. The overall results suggest that intracellular protein amino acids and the most 13C-depleted signature of leucine, which has a specific branched-chain structure, are potentially propagated as isoprenoid precursor molecules into archaeal biosynthesis, resulting in the extremely 13C- and 14C-depleted nature of ANME cells in the deep microbial oasis.

Dynamisms and characteristics of dissolved organic matter (DOM) in deep aquifer: A scope for deep biosphere

*Atsushi Urai[1,2], Yoshinori Takano[2], Naohiko Ohkouchi[2]

1. Department of Science and Technology, Graduate School of Medicine, Science and Technology, Shinshu University, 2. Department of Biogeochemistry, Japan Agency for Marine-Earth Science and Technology

Dissolved organic matter (DOM) is generally derived from multiple sources and affected by complicated transformation and degradation reactions. In a general geochemical description of marine environments, high-molecular-weight DOM (HMW-DOM; >1 kDa) particularly represents a unique organic carbon pool, which is accompanied by considerable difference in the molecular and stable isotopic compositions from other organic components such as particulate organic matter (POM) and low-molecular-weight DOM (LMW-DOM; <1 kDa) (e.g., Benner et al., 1997).

To date, formation of DOM fraction and potential microbial interaction in deep aquifer have been particularly poorly understood on the context of prokaryotic ecology. We investigated the molecular composition of DOM fraction including LMW and HMW by an improved method (Urai et al., 2018). The filtered samples are tentatively defined by conventional size scales; macromolecular scale (100 mm >> 40 mm), POM (40 mm >> 0.6 mm), HMW-DOM(0.6 mm>>1kDa), and total-DOM (<0.6 mm). We also have a validation to distinguish the molecular signature between phototrophic primary producers (i.e., fossil molecules) and presently living benthic prokaryotes (i.e., modern molecules; cf. biological methanogenesis, Kaneko et al., 2014). We report a preliminary result of the feasibility study and discuss a perspective from the view of deep biosphere.

Correlations of magnetosome-related genes in Nitrospirae genomes to magnetosome geometry and redox stratification in deep-sea environments

*Shinsaku Nakano[1], Shingo Kato[2], Mariko Kouduka[1], Toshitsugu Yamazaki[3], Yohey Suzuki[1]

1. Graduate School of Science, The University of Tokyo, 2. RIKEN, 3. Atmosphere and Ocean Research Institute, The University of Tokyo

Biogenic magnetic particles are ubiquitously found in deep-sea sediments and important carriers of rock magnetism for reconstructing the Earth’ s past regarding sediment age and geomagnetic field. However, microorganisms responsible for the formation of magnetic particles are largely unknown in the deep-sea environment, because of the difficulty in sampling, cultivation, and magnetic separation of magnetotactic cells for single-cell genomics. In this study, deep-sea sediments from Japan Sea and a metal sulfide chimney from South Mariana Trough were subjected to magnetic separation and subsequent electron microscopic observations. Although teardrop-shaped magnetite (Fe_3O_4) particles without microbial cells and 16S rRNA gene sequences related to magnetotactic Nitrospirae species were previously obtained from Japan Sea sediments with a redox zonation enriched with dissolved Fe(II) (the iron boundary), no magnetotactic cells were observed after the magnetic separation. From the metal sulfide chimney, magnetotactic cells were observed with teardrop-shaped magnetite particles. Metagenomic analysis of the chimney sample revealed that contig sequences encoding genes involved in the formation of magnetosome, membrane-bound magnetic particles, were mostly affiliated within Nitrospirae based on sequence similarity. Previous studies have reported that magnetosome-related genes are clustered together as the magnetosome island (MAI) in known magnetotactic bacteria. However, those genes were scattered in a near-complete Nitrospirae genome reconstructed from the chimney sample. Although magnetotactic bacteria are generally considered to align magnetic particles into a chain for efficiently moving in a vertical redox zonation by orienting the cell along the geomagnetic filed, Nitrospirae-affiliated genes involved in chain formation were not found in the near-complete Nitrospirae genome from the chimney with a horizontal redox zonation. Comparative analysis of near-complete Nitrospirae genomes available from public databases revealed that the chain-related genes were found in the genomes from terrestrial deep aquifers and deep-sea sediments with a vertical redox zonation. As the Nitrospirae species associated with teardrop magnetite and the iron boundary in Japan Sea was closely related to Nitrospirae species with the chain-related genes, the presence of the chain-related genes appears to be correlated with a vertical redox zonation. In addition, our results suggest that the Nitrospirae species without MAI are responsible for the production of teardrop magnetite in deep-sea environment, and that teardrop magnetite is a paleoredox indicator especially for the iron boundary.

Reconstruction of key ecological responses leading to the most recent dead zone formations in Japan Sea through ancient DNA metabarcodring

*Mariko Kouduka[1], Yohey Suzuki[1]

1. Department of Earth and Planetary Science, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo, Japan.

Semi-closed ocean basins are very sensitive to climate changes as recorded in frequent formations of sediments with clearly laminated layers, which was caused by the lack of O_2 available to benthic organisms. This is so-called “dead zone formation” and caused by water stagnation after channel closure and/or nutrient inflow through upwelling and channel opening. In contrast to the hydrologic causes, it remains poorly understood about organismal causes such as enhanced primary production and heterotrophic consumption of O_2. We investigated ancient eukaryotic DNA obtained from a thinly laminated layer deposited in the Japan Sea across the most recent global warming event after Younger Dryas (TL-1). Metabarcoding of 18S rRNA gene sequences clarified that across the transition from oxygenated to anoxic bottom water conditions, dominant protist populations shifted through five stages:

Stage1: Under oxygenated bottom conditions, the most dominant taxonomic group was Marine Stramenopiles Group 9 (MAST-9). MAST-9 encompasses diverse uncharacterized planktonic species, 18S rRNA gene sequences of which were detected from both anoxic and oxic water bodies in Pacific and Atlantic Oceans, Mediterranean Sea and South China Sea.

Stage 2: Before the onset of dead zone formation, the sharp decline of MAST-9 was accompanied with the expansion of marine diatom species of the genus Skeletonema, many members of which are known to be a cause of red tide around the world.

Stage 3: The dead zone formation was synchronized with the expansion of marine radiolarians of the order Chaunacanthida, the members of which are encrusted within $SrSO_4$.

Stage 4: Stages 2 was repeated, whereas the expansion of the Chaunacanthida radiolarians was not evident.

Stage 5: The uncharacterized MAST-9 that was dominant before the dead zone formation was gradually recovered towards oxygenated bottom conditions.

From these results, it is suspected that the expansion of Radiolaria species encrusted with $SrSO_4$ triggered dead zone formation by the accelerated downward transport of dead cells and subsequent heterotrophic consumption of O_2. From bioturbated sediment samples from a maximum depth of 31 mbsf with a depositional age of 100 ka, the Chaunacanthida sequences closely related to that from the laminated sediments have been previously detected.It is therefore suggested the record of the Chaunacanthida species can be reconstructed from sediments with great depth and age.

Search for microbial CH_4 production processes in lake sediments and surface water associated with cyanobacterial bloom

*Makoto Matsushita[1], Yoshinori Takano[1], Hiroyuki Imachi[1], Atsushi Urai[2], Ho-Dong Park[3], Hiroki Iwata[3], Naohiko Ohkouchi[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Department of Science and Technology, Graduate School of Medicine, Science and Technology, Shinshu University, 3. Department of Environmental Sciences, Faculty of Science, Shinshu University

Methane (CH_4) is an important greenhouse gas and contributes substantial budget to global warming. Freshwater lakes are identified as one of the main CH_4 sources, as it is estimated that they contribute to 6-16% of natural CH_4 emissions [1]. The main part of CH_4 released from lakes is considered to be produced by methanogenic archaea in anoxic sediments as terminal step in the degradation of organic matter. The microbial CH_4 production in lake sediments has been mainly investigated by microbiological studies using culture-dependent methods and molecular analysis.

Microbial CH_4 production is still regarded by many as a process limited to anoxic environments. Nevertheless, over the past few decades, increasing evidence of CH_4 accumulation in oxygen-saturated lake and marine surface water has emerged [2]. To explain the enigmatic issues, it has been proposed that CH_4 production by methanogenic archaea takes place in anoxic microenvironments such as detritus and animals' gut. Alternatively, recent studies suggest that some bacteria break down methylphosphonate (MPn) or dimethylsulfoniopropionate (DMSP) and release CH_4 as a biogenic byproduct. These novel microbial CH_4 production processes may play a potential contribution to the total atmospheric carbon cycle.

Oxic CH_4 peaks have been found to be closely associated with phytoplankton dynamics across multiple lakes. Grossart *et al*. [3] found potentially methanogenic archaea associated with cyanobacteria such as *Aphanizomenon* and *Microcystis* in oxygenated surface water. Additionally, Berg *et al*. [4] showed that hydrogen produced during nitrogen fixation by cyanobacteria can be consumed by methanogenic archaea. These studies suggest the presence of a CH_4 production process by methanogenic archaea associated with cyanobacteria in lake surface water. However, it is unclear whether the CH_4 production is taking place in actual environments.

In this study, we investigated microbial CH_4 production in sediments and surface water of Lake Suwa in Nagano Prefecture, Japan, a typical hypertrophic shallow lake, using culture-independent methods. Especially, we focused on cyanobacterial bloom and tried to identify a CH_4 production process by methanogenic archaea associated with cyanobacteria. 16S rRNA gene analyses revealed the presence of methanogenic archaea closely related to the order *Methanobacteriales*, *Methanomicrobiales*, and *Methanosarcinales* in sediment core samples from 30 cm depth. On the other hand, 16S rRNA genes and *mcrA* genes of methanogenic archaea were not detected in bulk DNA from cyanobacterial bloom sample (mainly *Microcystis*)[5]. In order to estimate the potential for methanogenic archaea, we extracted Coenzyme F430, a biomarker for methanogenic archaea, from sediment and bloom samples and determined by using HPLC [6]. F430 was detected from sediment samples, but that from bloom sample was currently below detection limit (<1 pmol).

These results suggest that methanogenic archaea actively produce CH_4 in the sediments of Lake Suwa,

©2019. Japan Geoscience Union. All Right Reserved.

however, its contribution in oxygenated surface water seems to be small. We are currently conducting a more sensitive analysis of F430 using LC-MS/MS [6] with the pre-treatment procedure [7]. The analysis may identify the CH_4 production process by methanogenic archaea associated with cyanobacteria in the surface water. Although this study did not cover other CH_4 production processes such as MPn and DMSP decomposition, our results may also be applicable to estimate the *in situ* contribution of these novel CH_4 source.

Did life emerge in a deep-sea metal sulfide chimney? New insights from an archaeal genome and a nanoscale microbe-silicate assemblage

*Hinako Takamiya[1], Hiroki Mukai[2], Mariko Kouduka[1], Shingo Kato[4], Motoo Ito[3], Yohey Suzuki[1]

Deep-sea hydrothermal activities have continued for 3.8 billion years on Earth. After the formation of metal sulfide chimneys from high-temperature fluid, their low-temperature interactions with ambient seawater potentially provide the cold, stable habitat for microbial life. In such a challenging habitat with metal toxicity, 16S rRNA gene sequences formerly affiliated within Deep-Sea Hydrothermal Vent Euryarchaeota Subtype 6 (DHVE6) and recently reclassified as Pacearchaeota are dominantly detected by 16S rRNA gene sequence analysis. However, the distribution and metabolic activities of Pacearchaeota in metal sulfide chimneys are largely unknown. In this study, a metal sulfide chimney collected from a deep-sea hydrothermal field in South Mariana Trough was subjected to genome-resolved metagenomics analysis. It was revealed that a near-complete Pacearchaeota genome has carbon metabolism genes involved in glycolysis and pentose phosphate pathway linked to nucleotide salvage pathway with light-independent CO_2incorporating ribulose bisphosphate carboxylase/oxygenase (RubisCO). By comparative analysis of Pacearchaeota genomes from deep-sea metal sulfide deposits and terrestrial subsurface aquifers, the carbon metabolism was commonly found with genes annotated for Cu detoxification. Based on the NanoSIMS ion imaging analysis, we found an evidence of a dense microbial colonization inside the chimney where the surface of chalcopyrite ($CuFeS_2$) was overlayered with a silica-bearing material enriched in CN, S and P. Our results explain the geographically and physicochemically diverse distributions of Pacearchaeota indicated by 16S rRNA gene sequence analysis as well as the predominance of Pacearchaeota in the metal sulfide chimney where energy sources from photosynthesis and hydrothermal fluid are limited. The carbon metabolism operated by Pacearchaeota in one of candidate environments for the origin of life could be relevant to that operated by primitive life on early Earth.

Recent developments of the X-ray computed tomography (CT) reaches to the spatial resolution of down to few tens of nanometers scale, which is enough to visualize single microbial cells, together with those distributions as well as its surrounding environments. In this study, we tried to visualize microbial cells in the environmental samples by using nanometer-scale X-ray CT.
We used anaerobic granular sludge and subseafloor sediments for the test samples. The X-ray CT analyses were conducted at beamlines of BL20XU and BL47XU in synchrotron radiation facility of Spring-8. The soft samples were either freeze-dried or embedded in the epoxy resin for the analysis. Since the high-spatial resolution observation of the X-ray CT analysis requires a higher density of X-ray per field, the samples often deformed during the analysis, which results in the failure of the 3D reconstruction of the data. Optimization of the resin, its polymerization condition, together with the stain of the cells by osmium tetroxide to put heavy element onto the microbial cells, we could successfully visualize single microbial cells in the samples. Also, the observations of the sample at the pre- and post-edge energies of the element (such as Os) enabled specific signal enhancement of osmium-stained cells.
The investigations of subseafloor biosphere have often based on destructive measurements. Although these analyses revealed the large-scale distribution of microbes along the chemical gradients, no previous attempt explored the spatial distribution of microbial cells at their size range. The visualization of microbes with its surrounding environments will give basic but critical information to understand the microbial in-situ ecophysiology.

Carbon signatures in amino acids during deep-sea anoxic methanotrophy

*Yoshinori Takano[1]

1. Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

Microorganisms play a central role in both methane production and consumption in the global carbon cycle. Oceanic methane from global deep-sea sediment is largely consumed through microbially mediated sulfate-coupled oxidation, resulting in 13C-depleted cell biomass of anaerobic methanotrophic archaea (ANME). The general ecological importance of subseafloor ANME has been well recognized in the last two decades. However, the crucial biochemical pathways for the overall anaerobic oxidation of methane (AOM) still remain enigmatic. In the present study, methanotrophic pathways were analyzed to trace 13C-depleted amino acid biosynthesis in two clades of ANME (ANME-1 and ANME-2) from the Black Sea. Compound-specific analysis of ANME-dominated microbial mats showed a significant 13C-depletion trend in association with increasing carbon numbers in protein-derived amino acid families within the pyruvate family in the order of alanine, valine, isoleucine and leucine down to -114‰. This result indicates a stepwise elongation of 13C-depleted carbon during amino acid biosynthesis. The overall results suggest that intracellular protein amino acids and the most 13C-depleted signature of leucine, which has a specific branched-chain structure, are potentially propagated as isoprenoid precursor molecules into archaeal biosynthesis, resulting in the extremely 13C- and 14C-depleted nature of ANME cells in the deep microbial oasis.

[B-CG08] Phanerozoic biodiversity change: Extinction and diversification

convener:Yukio Isozaki(Department of Earth Science and Astronomy, Multi-disciplinary Sciences - General Systems Studies, Graduate School of Arts and Sciences, The University of Tokyo), Yusuke Sawaki(The University of Tokyo), Chairperson:Yukio Isozaki(Department of Earth Science and Astronomy, The University of Tokyo), Yusuke Sawaki(The University of Tokyo)

Phanerozoic biodiversity is the consequence of repeated extinctions and following diversifications in the past, which were caused by large-scale environmental changes, in particular, by extremely rapid and drastic forcing that changed the environments of the biosphere. Irreversible and episodic changes in material cycling on the planet and influences of severe galactic cosmic radiation enhanced by encounter with dark cloud are nominated as major driving mechanisms for the alleged rapid, large-scale environmental perturbations. The biodiversity change in the fossiliferous Phanerozoic record is characterized by 5 major mass extinctions within the long-term trend of diversity increase. Nonetheless, each extinction event has been explained rather in ad hoc manner, without any universal explanation. Therefore, ultimate triggers that caused the Phanerozoic biodiversity still remain as unsolved issues. This session discusses the ancient environmental changes related to Phanerozoic biodiversity under a new light of the recent progress in geology.

Discussion

The Ediacaran-Cambrian transition of North China

*Xingliang Zhang[1]

1. State Key Laboratory of Continental Dynamics, Shaanxi Key Laboratory of Early Life and Environments, and Department of Geology, Northwest University

The central mountain range, known as the backbone of China, separates the country into North China and South China, which are different from each other in geology, geography, climate, and culture. The Precambrian-Cambrian transition of South China has received much attention of world scientists for beautiful sections and numerous fantastic fossil-Lagerstätten. However, the Ediacaran-Cambrian sequences of North China have some attractive points as well. The lowermost Cambrian of North China, the Xinji Formation, unconformably overlies Precambrian rocks of various ages, from Archean to late Ediacaran. The Xinji Formation is rich in SSFs of Cambrian Epoch 2 aspects and thus the Terreneuvian is absent throughout North China. The Xinji SSF assemblage is taxonomically dominated by molluscs and hyoliths, which are represented by 26 and 12 species, respectively. A number of molluscan taxa are conspecific with Australia, Antarctic and Laurentia, and thus have biostratigraphical and paleobiogeographical values. Remarkably, shell microstructures are well preserved in molluscs and hyoliths, which demonstrate how these Cambrian animals use minute mineral crystals to build their shells. Additionally, shell microstructures shed new light on the phylogenic links between the groups. Ediacaran rocks developed in marginal regions and cratonic basins. Along the south and west margins of North China, the Dongpo/Tuerkeng Shale/Slate immediately underlies the unconformity and overlies the Luoquan/Zhengmuguan Diamictite which is poorly constrained in age. The shale/slate unit above the diamictite yields a diverse form of macroscopic, soft-bodied fossils, e.g. the annulated tubular form *Shaanxilithes*, the form of a string of beads *Horodyskia*, the WiFi symbol-like form *Palaeopascichnus*, an unnamed form resembling a string of rings (which might be a segmented organism composed of many repetitive units), and small clew-like fossils of unknown affinities. Algal fossils are abundant but simple in complexity and poor in diversity. The presence of *Shaanxilithes* and *Palaeopascichnus* suggests an age of late Ediacaran. New specimens demonstrate that *Shaanxilithes* is composed of a cone-in-cone internal tube encased in a flexible external tube with irregular cross annulations. Such a morphological reconstruction is analogous to the contemporary *Cloudina* and other tubular organisms. New findings in North China would provide new insights into the biotic evolution of the Ediacaran-Cambrian transition.

The Qingjiang biota –An extraordinary new Burgess Shale-type fossil Lagerstätte from the early Cambrian of South China

*Dongjing Fu[1], Xingliang Zhang[1], Robert R. Gains[2]

1. State Key Laboratory of the Continental Dynamics, Shaanxi Key Laboratory of Early Life and Environment, Department of Geology, Northwest University, Xi' an 710069, PR China, 2. Department of Geology, Pomona College, Claremont, CA 91711, USA

Our understanding of the Cambrian explosion and of the fundamental structure of the tree of animal life rests in large part on evidence from a dramatically enhanced fossil record, characterized by the preservation of entire assemblages of soft-bodied fossils. In the one hundred years since Walcott' s original discovery of the Burgess Shale, exceptionally preserved fossil assemblages have been reported from Cambrian strata of almost every paleocontinent. Nevertheless, only the early Cambrian Chengjiang biota of Yunnan Province has matched the Burgess Shale in total diversity of soft-bodied taxa and fidelity of exceptional preservation. Here, we report the discovery of an extraordinary new early Cambrian Burgess Shale-type (BST) fossil Lagerstätte from the Changyang area of South China, which is characterized by high taxonomic diversity (101 metazoan taxa plus 8 algal forms), an unexpectedly large proportion of new taxa (53.2%), and exquisite preservation of fine aspects of labile tissue anatomy. The taxonomic richness of soft-bodied taxa (85%) approaches the top tier of BST deposits, presently occupied only by the Burgess Shale and Chengjiang biotas. Rarefaction analyses suggest that diversity may surpass all other BST biotas. Novel aspects include high abundance of cnidarians, including both medusoid and polypoid forms, new taxa resembling extant kinorhynchs, and abundant larval or juvenile forms. While approximately coeval to the Chengjiang biota, the Qingjiang biota (518 Ma) appears to have occupied a more distal environmental setting, in which a different early Cambrian ecosystem flourished. The uniqueness of the Qingjiang biota in the taxon composition and preservation quality holds special potential to provide new insights into the evolution of early metazoans and the structuring of Cambrian ecosystems across environmental gradients.

Enhanced flux of extraterrestrial ^{3}He across the Permian–Triassic boundary

*Tetsuji Onoue[1], Naoto Takahata[2], Honami Sato[4], Akira Ishikawa[3], Katsuhito Soda[1], Yuji Sano[2], Yukio Isozaki[2]

1. Kumamoto Univ., 2. Univ. Tokyo, 3. Tokyo Inst. Tech., 4. Chiba Inst. Tech.

The Solar System contains abundant submillimetre interplanetary dust particles (IDPs) that are enriched in ^{3}He. ^{3}He concentrations in ancient deep-sea sediments have been used to constrain the flux of IDPs onto the Earth for at least the last 100 Myr. However, the use of ^{3}He in detecting IDP flux is often compromised by the diffusional loss of ^{3}He in sedimentary rocks, with the exception of some Ordovician samples that record a period of unusually high extraterrestrial^{3}He ($^{3}He_{ET}$) flux. In this study, we report for the first time the preservation of extra-terrestrial ^{3}Hein deep-sea bedded chertfrom a continuous Permian-Triassic boundary (PTB) section at Waidani in Japan, which was deposited in the Panthalassa superocean.

High ^{3}He/^{4}He ratios (up to 150 Ra; 1Ra = the atmospheric ratio) were detected from acid-insoluble residues fromthe uppermost Permian deposits, which suggeststhe existence of extraterrestrial He hosted mainly in IDPs. The estimated extraterrestrial fraction of ^{3}He across the PTB revealsthat$^{3}He_{ET}$ concentrations are higher in the topmost ~1.5 m ofthe studied Permian deposits, which is 4–5 times greater than that measured in the overlying Triassic unit. Based on the $^{3}He_{ET}$ concentration and sedimentary mass accumulation rate of the PTB section at Waidani, we calculated $^{3}He_{ET}$ fluxacross the PTB.The data document the presence of an up to 4-fold increase in IDP flux for the last 500 kyr interval of the Permian.This unusual signal suggests a significant increase in the influx of interplanetary dust particles, likely related to an asteroid showerin the inner Solar System. High-resolution stratigraphy indicates that peak IDP flux occurred during the final 500 kyr of the Permian, concurrent with a pre-extinction decline in radiolarian diversity.

End-Triassic Mass Extinction: Causes and Consequences

*Wataru Fujisaki[1]

1. Japan Agency for Marine-Earth Science and Technology

The biodiversity crisis across the Triassic-Jurassic boundary (TJB; *ca.* 201 Ma) is characterized by one of the largest mass extinctions in the Phanerozoic. Significant increases in the extinction rate of marine fauna, and major turnovers in terrestrial vegetation and vertebrate groups, have been well documented across the TJB. In addition to the extinction, several unique geological episodes around the TJB were recognized; i.e., the emplacement of the Central Atlantic Magmatic Provinces (CAMP) which is associated with the breakup of Pangea, carbon cycle perturbations, and widespread ocean anoxia and associated deficits of nutrients. In the last decade, based on of the numerous data-set obtained from the shallow-marine shelf sequences around the Pangea, major advances have been made in our understanding of the TJB biotic crisis, related environmental changes, and the CAMP volcanism. However, the casual relationships between the CAMP volcanism and extinction-related environmental changes of global context still remain unclear. Therefore, the deep mid-Panthalassa, which occupied major portion of the global ocean during the Triassic-Jurassic transition, is indispensable for reconstructing the global environmental changes related to the TJB biotic crisis.

Deep-sea bedded cherts in the Mino-Tanba belt in SW Japan provide critical constraints for reconstructing paleo-environmental changes because they preserve extinction-related intervals from the Middle Permian to the Early Jurassic deposited in the deep mid-Panthalassa. Most recently, the stratigraphic $\delta^{13}C_{org}$ variation using Rhaetian (Late Triassic) to Hettangian (Early Jurassic) shales interbedded within deep-sea cherts was established in the Katsuyama section in the Mino-Tanba belt. By obtaining high-resolution Rhaetian to Hettangian $\delta^{13}C_{org}$ values, three negative carbon isotopic excursions (NCIEs) were newly detected before and across the TJB. The mid-Panthalassic NCIEs are well correlated with those in many shallow-marine regions including the base Jurassic GSSP of TJB at Kuhjoch in Austria, suggesting that three NCIEs in the Tethys and mid-Panthalassa likely reflected global perturbations of the carbon cycle, rather than local phenomena. Based on the Os isotopic records correlated with $\delta^{13}C_{org}$ stratigraphic profiles, the mid-Panthalassic NCIEs can be interpreted as the consequences of the multiple emplacements of CAMP volcanism.

On the other hand, despite the oxic deep mid-Panthalassa, widespread ocean anoxia and associated deficits of nutrients around the TJB were recently identified in the Eastern Panthalassa. Since the redox conditions were quite different between shallow-marine regions and mid-Panthalassic sites, information regarding nutrient concentrations in the mid-Panthalassa is required. Oceanic fixed nitrogen is a bio-limiting component in the modern ocean, and total nitrogen isotopic composition ($\delta^{15}N_{TN}$) of sedimentary rocks is a useful tool for the reconstruction of ancient nitrogen cycles. To advance our understanding on the global nitrogen cycle, this study for the first time provides Rhaetian to Hettangian $\delta^{15}N_{TN}$ records in combined with Mo and U concentrations from the shales in the Katsuyama section. Based on the newly obtained data-set, I comprehensively discuss relative concentrations of biologically available nitrogen compounds in the mid-Panthalassa, their possible association with the redox condition, and biodiversity during the Triassic-Jurassic transition.

[B-CG08] Phanerozoic biodiversity change: Extinction and diversification

convener:Yukio Isozaki(Department of Earth Science and Astronomy, Multi-disciplinary Sciences - General Systems Studies, Graduate School of Arts and Sciences, The University of Tokyo), Yusuke Sawaki(The University of Tokyo), Chairperson:Wataru Fujisaki(Japan Agency for Marine-Earth Science and Technology)

Phanerozoic biodiversity is the consequence of repeated extinctions and following diversifications in the past, which were caused by large-scale environmental changes, in particular, by extremely rapid and drastic forcing that changed the environments of the biosphere. Irreversible and episodic changes in material cycling on the planet and influences of severe galactic cosmic radiation enhanced by encounter with dark cloud are nominated as major driving mechanisms for the alleged rapid, large-scale environmental perturbations. The biodiversity change in the fossiliferous Phanerozoic record is characterized by 5 major mass extinctions within the long-term trend of diversity increase. Nonetheless, each extinction event has been explained rather in ad hoc manner, without any universal explanation. Therefore, ultimate triggers that caused the Phanerozoic biodiversity still remain as unsolved issues. This session discusses the ancient environmental changes related to Phanerozoic biodiversity under a new light of the recent progress in geology.

Transition of biodiversity in mobile populations and the small world in local subpopulations

*Kota Imaoka[1], Kazuhito Yamasaki[1]

1. Kobe University Graduate school of Science

Speciation is one of the factors that influences ecological biodiversity on the geological time scale (Gould 1989, Kawata, 2000). So its mechanism is the important paleontological theme that leads to learn evolution. The basic mechanism is reproductive isolation. Allopatric speciation needs geographical barriers that divide the population into two subpopulations and block the genetic flow between them of individuals (Hubbell, 2001). These isolated groups accumulate incompatible genes leading to reproductive. Sympatric speciation happens with ecological interactions in the same niche. Difference of resources and habits leads to disruptive selection and ultimately to speciation (Gavrilets, 2003). Recently, a neutral theory of speciation, without geographical barriers or ecological interactions, has been shown to predict many patterns consistent with the behaviors observed in nature, e.g. species abundance distributions and species-area relationships. This neutral speciation is driven by physical and genetic distances which are essential for assortative mating. As the condition is restricted, speciation is promoted. Such a speciation model is named 'topopatric speciation'. In addition, another factor that influences ecological biodiversity on the geological time scale is radiation (Yamasaki et al., 1999). However, many studies of topopatric speciation consider standing still populations. So we considered mobile populations and the effect of them on speciation and ecological system. Our study may show that mechanism of speciation and how populations increased their biodiversity in the past. Moreover, we considered the spatial structure of each species with networks and quantitatively showed the distribution of populations on the process of speciation. This study uses a multi agent system to simulate the neutral stochastic evolution without natural selection. We consider an initial population of diploid and genetically identical individuals. In reproduction, we extend the Dobzhansky-Muller model to the most general form contains multiple alleles. A species is defined as the concept of ring species (Irwin et al., 2001, 2005). In the simulations, we found not only the number of species in the space, but also species diversity (species abundance distributions) and genetic diversity (heterozygosity). Furthermore, we calculated average path lengths and clustering coefficients by considering individuals as nodes and linking between them which can reproduce. Our simulations showed that the number of species and species diversity, genetic diversity changed depending on the mobile speed in populations. Accordingly, the difference of mobile speed in populations influences on biodiversity. In addition, from our results we predict species abundance distributions and species-area relationships. The highest species richness was found at minimum mobile speed, then average path length is smaller and clustering coefficient is larger. So this shows that the populations have a feature of 'small world' on the network. In the small world, we can communicate quickly each other and have many strong connections. In other words, individuals can exchange genomes quickly each other and have many mates. Thus, speciation is promoted by dividing the population into local subpopulations that form the small world and accumulating genetic variation. Consequently, in mobile population, assortative mate based on isolation by physical and genetic distance without geographical barriers and ecological interactions leads to divide population and speciation.

Rivision of the lowermost Cambrian SSF stratigraphy

*KONO SENA[1], Yukio Isozaki[1], Tomohiko Sato[2], Xingliang Zhang[3], Wei Liu[3]

1. The University of Tokyo School of Arts &Sciences, 2. Earth-Life Science Institute, Tokyo Institute of Technology, 3. Northwest university, China

The earliest Cambrian evolution of animals is marked by the appearance and rapid diversification of small shelly fossils (SSFs). We examined the litho- and bio stratigraphy of the lowermost Cambrian at the Xiaolantian and Hongjiachong sections in the Chengjiang area, eastern Yunnan, South China. By analyzing both outcrop and drilled core samples, we picked up many SSFs from the ca. 30 m-thick phosphorites (Zhongyicun Mb), and obtained the following results.1) the Zhongyicun Mb comprises 6 lithostratigraphic units, which include Unit 3 with characteristic black mudstone beds for a significant key for the mid-Zhongyicun Mb.2)SSFs were found from 26 horizons out of 83 in the Zhongyicun Mb and the overlying Dahai Mb. Five zones were discriminated. Interval 1 with*Acanthocasis orthocanthus, Spirellus* sp., *Protohertzina unguloformis* and*Protohertzina anabarica*(from uppermost of Unit 1 to lower part of Unit 2); Interval 2 with *Ocruranus finial, Purella*sp.and*Yunnanopleura biformis*(from upper part of Unit 2). This marks the first occurrence of cap-shaped SSFs. Interval 3 with *Helcionella*sp.and*Oelandiella korobkovi*(from Unit 3). Interval 4 with *Obtusoconus*sp.,*Conopoconis*sp. and*Erongia acculatus*(from lower part of Unit 6). Interval 5 with*Igorella* sp., *Bemella simplelx*and*Paragloborilus subglobosus*(from upper part of Unit 6). 3) In addition, at the Hongjiachong section, a unique interval with *Halkieria* sp.*,Pteromus* sp.and*Sinosachites delicatus*occurs between Interval 1 and 2.

These results from the Xiaolantian and Hongjiachong sections, the following 6 SSF zones are proposed here. Namely, 1)*Acanthocasis orthocanthus- Protohertzina anabarica*Zone, 2) *Halkieria- Pteromus*Zone, 3) *Ocruranus finial-Yunnanopleura biformis*Zone, 4)*Paracarinachites sinensis-Oelandiella korobkovi*Zone, 5) *Obtusoconus-Conopoconis*Zone, and 6) *Igorella -Bemella simplelx*Zone.Previously the Zhongyicun Mb was divided into two SSF assemblage zones (Steiner et al., 2007); however, the present study offers 6 zones. It is noteworthy that the key bed in the mid-Zhongyicun Mb, restricted within the*Paracarinachites sinensis-Oelandiella korobkovi*Zone,appears useful for regional correlation.

δ^{88}Sr and ^{87}Sr/^{86}Srrecords of the Middle-Late Permian seawater: mass extinction-relevant change in ocean Sr budget

*Tomomi Kani[1], Yukio Isozaki[2], Keiji Misawa[3], Akira Ishikawa[4], Shigekazu Yoneda[5]

1. Kumamoto University, 2. The University of Tokyo, 3. National Institute of Polar Research, 4. Tokyo Tech, School of Science, 5. National Museum of Nature and Science

As Sr isotope compositions in seawater are globally homogeneous, these proxies are useful in checking marine Sr budget change in direct link to global calcium cycle. ^{87}Sr/^{86}Sr valueis mainlydriven by two input fluxes to seawater; riverine flux connected with weathering of time-integrated radiogenic old continent and hydrothermal input flux derived from less radiogenic mantle. δ^{88}Sr in seawaterreflects marine calcium carbonate input/output flux. The marine Sr budget changed dramatically, in particular, during the Guadalupian (Middle Pemian), with the lowest value of seawater ^{87}Sr/^{86}Sr in the Phanerozoic, i.e., “the Capitanian minimum”. This likely reflected a major global environmental change associated with the end-Guadalupian mass extinction. Likewise, the δ^{88}Sr started to decrease in the Early Permian, and reached the Phanerozoic lowest value at the end of Capitanian (late Guadalupian). We measured δ^{88}Sr values of the Middle-Upper Permian marine carbonates with detailed biostratigraphy by TRITONTIMS, with correction of isotope fractionation during mass spectrometry with ^{87}Sr-^{84}Sr double spike. Analyzed samples were from various localities in the world, e.g., the Akasaka paleo-atoll limestone (Japan), and shelf carbonates in S. China. These results confirmed that both in stable δ^{88}Sr and radiogenic ^{87}Sr/^{86}Sr ratios, low values remained throughout the Guadalupian, whereas they increased in the Wuchiapingian. The extremely low δ^{88}Sr value in seawater may reflect the increased dissolution of carbonates and/or reduced carbonate burial, i.e., enhanced carbonate weathering or suppression of reef building on shelf settings according to the coeval global sea-level drop.

Formation of stratiform manganese deposits during the Carnian (Late Triassic) “pluvial event” in the pelagic Panthalassa

*Yuki Tomimatsu[1], Tetsuji Onoue[2], Daisuke Yamashita[3], Tatsuo Nozaki[4,5,6,7], Yutaro Takaya[8]

Department of Resources and Environmental Engineering School of Creative Science and Enginerring, Waseda University

Stratiform manganese deposits have been reported from the Triassic bedded chert sequences in the Japanese accretionary complexes, which are considered to have accumulated in a mid–oceanic basin of the Panthalassa Ocean.However, their precise mineralization age and depositional environment remain poorly understood. In the present study, we investigated lithostratigraphy, conodont and radiolarian ages, and geochemistry of bedded cherts and chert-hosted manganese deposits from the Jurassic accretionary complexes (Chichibu, Mino–Tamba, and Northern Kitakami Belts) in Japan.
The studied sequences are classified into three to four lithostratigraphical units; lower bedded chert, massive chert, manganese ore (30-150 cm thick), and upper bedded chert units in ascending order. Radiolarian fossils from the lower bedded chert unit indicate the Early Carnian age, based on the occurrence of *Capnuchosphaera deweveri*and *C. triassica*, whereas the upper bedded chert unit contains Late Carnian radioralian species, including *Poulpus carcharus*and *Trialatus megacornutus*. Conodonts extracted from the upper bedded chert unit also include Late Carnian species, such as *Paragondolella praelindae*and*Metapolygnathus praecommunisti*. These occurrences of microfossils suggest that the sedimentary age of the manganese ores can be constrained from the late Early Carnian to early Late Carnian. Chemical compositions of the manganese ore are characterized by the enrichments in Mn and low concentrations of Co, Ni, and Zn. These geochemical features are similar to those in modern submarine hydrothermal manganese deposits. On the other hand, highly enrichments in V, Ni, Zn, U, and high U/Th ratio were recognized in the massive chert unit below the manganese ores, which indicate deposition under a reducing depositional environment.
Our biostratigraphic and geochemical analyses indicate that a redox state change from anoxic to oxic environments occurred in a pelagic deep seafloor in the late Early to early Late Carnian. This interval is known as a period of increased rainfall, named the Carnian Pluvial Event (CPE) in the western Tethys. CPE is characterized by the increased continental weathering which led to the increased nutrient flux and triggered the development of anoxia. It is likely that the Upper Triassic manganese deposits may have been formed during recovery from the reducing environment associated with the CPE.

Enrichment of chalcophile elements in Cretaceous–Paleogene boundary clays

*Teruyuki Maruoka[1], Yoshiro Nishio[2]

1. Faculty of Life and Environmental Sciences, University of Tsukuba, 2. Research and Education Faculty, Kochi University

Cretaceous-Paleogene (K-Pg) boundary clays are enriched in chalcophile elements along with siderophile elements [1]. As elemental ratios of siderophile elements in the K-Pg boundary clays are very similar to chondritic values, the enrichment of siderophile elements in the K-Pg boundary clays results from the incorporation of meteorite condensates. On the other hand, it cannot be assumed that the chalcophile elements in the K-Pg boundary clays were supplied by meteorite condensates, because the ratios of chalcophile and siderophile elements in the K-Pg boundary clays, such as Zn/Ir, As/Ir, and Sb/Ir, are one to two orders of magnitude higher than those in chondrites. In this study, to elucidate the processes that could have contributed to the enrichment of chalcophile elements in the K-Pg boundary clays, we analyzed the chemical compositions of major and trace elements in the K-Pg boundary clays from Stevns Klint in Denmark.

The concentrations of major and trace elements in the K-Pg boundary clays varied among the collected samples even from neighboring outcrops. Cross plots of the concentrations of these elements suggested the mixing of three materials with different chemical compositions. The first component was enriched in all chalcophile elements and iron. The second component was depleted in chalcophile elements and enriched in calcium. The third component was enriched particularly in copper, silver, and lead. The first and third components included iridium that was obviously supplied at the K-Pg meteorite impact. Therefore, these two components were produced by phenomena related to the K-Pg meteorite impact. We propose that chalcophile elements were supplied to the K-Pg boundary clays by a combination of impact heating of the target rocks and intense acid rain following the impact.

Iron oxide/hydroxide grains with sizes of one to several tens of nanometers have been previously observed in the K-Pg boundary clays [2]. These likely condensed from the vapor plume that formed by impact heating at the K-Pg meteorite impact. These iron oxides/hydroxides could absorb chalcophile and siderophile elements from seawater. Such materials would have been converted to pyrites incorporating chalcophile elements under the reductive conditions on the seafloor. In addition, the correlations between the concentrations of chalcophile elements and soot have been observed in the K-Pg boundary clays [3]. This soot could have been produced by the impact heating of hydrocarbons in the target rocks. Bacterial sulfate reduction and subsequent pyrite production occur in reducing environments where hydrocarbon deposition occurs, thus resulting in the simultaneous accumulation of pyrite and hydrocarbons. Therefore, chalcophile elements accompanied by soot may have been released by impact heating of pyrite in the target rocks. Both chalcophile elements and iron, which were enriched in the first component, could have been provided by the impact heating of the target rocks.

Copper, silver, and lead, which were concentrated in the third component, are generally concentrated in acid soluble sulfides such as sphalerite and galena. Therefore, the third component was possibly supplied by intense acid rain after the K-Pg impact.

In summary, chalcophile elements in the K-Pg boundary clays comprises two components, one that is enriched in all chalcophile elements and another that is enriched particularly in copper, silver, and lead. These components were likely supplied by phenomena associated with the meteorite impact at the K-Pg boundary, such as the impact heating of the target rocks and intense acid rain.

Mass extinctions: hierarchy of causes and cosmoclimatological perspective

*Yukio Isozaki[1]

1. Department of Earth Science and Astronomy, Multi-disciplinary Sciences - General Systems Studies, Graduate School of Arts and Sciences, The University of Tokyo

This paper reviews possible causes proposed for the double-stepped extinction in regard of the current status of mass extinction studies. Causes of extinction can be grouped into four categories; from small to large scale, Caterogry 1 to Category 4. Category 1 –direct kill mechanism, Category 2 –global environmental change, Category 3 –trigger on the planet’ s surface, and Category 4 –ultimate cause. Among the Big-5 mass extinctions of the Phanerozic, two events in the Paleozoic, i.e.,the Hirnantian (Ordovician) and end-Guadalupian (Permian) events, show significant similarities in various aspects. Biological and non-biological aspects unique to these two distinct events include changes in biodiversity, isotope ratios (C, Sr *etc.*) of seawater, sea level, ocean redox state, episodic volcanism, and geomagnetism. In particular, the similar appearance of global cooling (Category 2) suggests the same cause and processes were likely responsible for the biodiversity drop. In addition to the most prevalent scenario of mantle plume-generated large igneous provinces (LIPs) (Category 3) for the end-Permian extinction, an emerging perspective of cosmoclimatology is introduced with respect to astrobiology. Galactic cosmic radiation (GCR) and solar/terrestrial responses in magnetism (Category 4) could have had a profound impact on Earth’ s climate, in particular, on extensive cloud coverage (irradiance shutdown). Furthermore, the star-burst events detected in the Milky Way Galaxy apparently coincide in timing with the cooling-associated major extinctions of the Phanerozoic and also with the Proterozoic snowball Earth episode. As an ultimate cause (Category 4) for major extinction, the episodic increase in GCR flux from the source (dark clouds derived from star-burst) against the geomagnetic shield likely determined the major climate changes, particularly global cooling in the past. The study of mass extinctions on Earth is entering a new stage with a new astrobiological perspective.

Marine Osmium isotope record across the Aptian/Albian boundary to elucidate the relationship between the Oceanic Anoxic Event 1b and massive volcanic activities at the Southern Kerguelen Plateau

*Hironao Matsumoto[1], Junichiro Kuroda[1], Rodolfo Coccioni[2], Naohiko Ohkouchi[3], Nanako O. Ogawa[3], Saburo Sakai[3], Katsuhiko Suzuki[3], Fabrizio Frontalini[2], Andrea Mazzoli[2]

1. Department of Earth and Planetary Science, The University of Tokyo, 2. DiSPeA, University of Urbino, 3. Japan Agency for Marine-Earth Science and Technology

Several organic-rich sediments (black shales) were deposited in the Tethys and the Atlantic Oceans from the uppermost Aptian to the lower Albian. In particular, four prominent black shale layers have been identified (i.e., Jacob, Kilian, Urbino/Paquier, and Leenhardt levels in stratigraphic order) as the sedimentary expression of Oceanic Anoxic Event (OAE) 1b. The OAE1b is characterized by a major planktic foraminiferal turnover in the Cretaceous period and its exceptionally long duration. In spite of its significant impact on the marine biological evolution, the OAE1b is one of the least studied Cretaceous OAEs. Massive volcanic activities associated with the emplacement of Southern Kerguelen Plateau were ascribed as the trigger mechanisms for the OAE1b. However, the large uncertainties in the radiometric age of Southern Kerguelen Plateau and the sedimentary sequence of OAE1b have however hampered the definition of their causal relationship. Paleo-seawater osmium isotopic record ($^{187}Os/^{188}Os$) is a powerful tool to detect the timing of volcanic pulse. Marine $^{187}Os/^{188}Os$ value mainly reflects the balance between radiogenic osmium flux from the continental crust ($^{187}Os/^{188}Os$ ~1.0-1.5) and unradiogenic osmium flux through hydrothermal activities ($^{187}Os/^{188}Os$ ~0.12). Thus, the relative contribution of hydrothermal activities (or the submarine volcanic activities) can be reconstructed from the paleo-seawater $^{187}Os/^{188}Os$ variation recorded in the sedimentary rocks. In this study, we present a new record of marine Os isotopic record from the Late Aptian to Early Albian to reveal the timing of massive volcanic activities and its relationship with OAE1b.

Pelagic sedimentary rock samples were collected from two sites; 1) Poggio le Guaine (PLG) section (Italy) that was deposited in the central-western Tethys Ocean, and 2) Deep Sea Drilling Project (DSDP) Site 463 drilled at the western Mid-Pacific Mountains in the Pacific Ocean. Based on the micropaleontological study on planktonic foraminifera and carbon isotopic analysis of bulk inorganic carbon, the stratigraphy of these two sections was precisely correlated. Indeed, the stratigraphic interval equivalent to the Jacob and Kilian levels were identified for the first time in the Pacific region. Variations of initial $^{187}Os/^{188}Os$ values were consistent between PLG section and DSDP Site 463 and summarized as follows; 1) relatively stable $^{187}Os/^{188}Os$ values in the pre-OAE1b interval, 2) decline of $^{187}Os/^{188}Os$ values at the onset of OAE1b, (3) a first sharp drop of $^{187}Os/^{188}Os$ at the extinction level, (4) a second sharp drop followed by an abrupt increase in the $^{187}Os/^{188}Os$ values at the Kilian level, and (5) fluctuation of $^{187}Os/^{188}Os$ values above the Kilian level. Combining $^{187}Os/^{188}Os$ data and other geochemical data, we interpreted that the drops of $^{187}Os/^{188}Os$ values at the extinction and Kilian levels were induced by pulses of hydrothermal activities. Massive volcanic eruptions at the Southern Kerguelen Plateau is one of the most likely candidates to have caused the decreases in isotopic composition of osmium of seawater recorded at PLG section and DSDP Site 463. The close correspondence of osmium spikes to the extinction events within the OAE1b would support a causal link between the volcanic eruptions at the Southern Kerguelen Plateau and the biotic turnover recorded across Aptian/Albian boundary.

Rhaetian (Late Triassic) conodont biostratigraphy of the Panthalassa Ocean and the final extinction of conodonts at the end of the Triassic

*Kanna Yamasaki[1], Daisuke Yamashita[2], Tetsuji Onoue[1]

1. Kumamoto University, 2. Satsumasendai City Office

The Rhaetian stage of the Triassic was a period characterized by intense biological, climate and environmental changes, ending with the break-up of the supercontinent Pangaea and the occurrence of the End-Triassic mass Extinction (ETE), one of the big five extinctions documented during the Phanerozoic. It is noteworthy that the ETE seems to be associated with significant $d^{13}C$ perturbations (CIEs), commonly related to the CAMP eruptive phases. The stratigraphic record of these environmental changes has been recently reported from the Upper Triassic bedded chert successions in Japan, deposited within a Paleo-Pacific (Panthalassa) deep basin. The chronology for the Rhaetian pelagic in the Panthalassa Ocean is based on the radiolarian zonation, which is well established in the Upper Triassic bedded chert successions in the Mino Belt, central Japan. Although accurate calibration for the chronostratigraphic stages and substages are established basically by means of ammonites and conodonts, most of the Japanese radiolarian zones were calibrated through correlation with zonal schemes established in other regions, and have not been calibrated conodont biostratigraphy.

Here we present Upper Norian to Rhaetian conodont biostratigraphy of an Upper Triassic bedded chert succession from the Mino belt, central Japan, where the radiolarian biostratigraphy has been investigated (Hori, 1992; Sugiyama, 1997). Based on the stratigraphic distributions of marker species, four conodont zones were defined: the *Mocina bidentata* Zone, the *Misikella hernsteini* Zone, the *M. posthernsteini* zone, and the *M. ultima* zone, in ascending order. These conodont zones are comparable to the standard Late Norian and Rhaetian conodont zones of western Tethys. The Norian/Rhaetian boundary in the study section is tentatively placed between the last occurrence of a Norian radiolarian species (*Betraccium deweveri*) and the first occurrences of Rhaetian conodont species (*M. posthernsteini*). The intercalibrated conodont—radiolarian biostratigraphy from the section accurately calibrates the radiolarian zones in Japan with standard chronostratigraphic stages and substages.

Paleoenvironmental changes across the Permian/Triassic boundary sections in the Mino Belt, central Japan

*Shinya Uemura[1], Tetsuji Onoue[1]

1. Kumamoto University

The ca. 251 Ma Permian/Triassic boundary (PTB) records the largest biotic catastrophe in the Phanerozoic. A considerable amount of work for the PTB event has been done on the Tethyan platforms and peri -Pangean shelves, and some possible causes have been proposed to explain the extinction event: oceanic anoxia, meteorite impact, flood basalt volcanism and global warming. Sano et al. (2010, 2012) reported the stratigraphic variations of TOC, $\delta^{13}C_{org}$ and the number of Permian radiolarian species in the PTB siliceous rock section of the Mino Belt, central Japan, and inferred that a reducing condition in the deep Panthalassic Ocean at the PTB. In this study, we examined the geochemical and mineral compositions of the exactly the same sections of Sano et al. (2010, 2012).
The study sections, namely NF1212F and NF195, consist of Upper Permian chert (Changshingian) and Lower Triassic (Induan) black claystone intermittently with thin chert beds. A total 81 clatstone samples were obtained from the NF1212F and NF195 sections. Powder x-ray diffraction (XRD) analysis shows that the claystones below the PTB contained quartz, magnetite, illite and chlorite, while all the claystone above the boundary only contained quartz and illite. The results of XRF and ICP-MS analysis revealed that redox-sensitive trace-element (vanadium [V], chromium [Cr], molybdenum [Mo], and uranium [U]) increase in the uppermost Permian chert beds. The increasing trend in Mo/U ratio from 150 cm to 25 cm below the PTB indicates shift from anoxic to euxinic conditions. This trend suggests that strong reducing conditions developed just before the end-Permian mass extinction.

Geotectonic history of Mona Complex in Anglesey-Lleyn, Wales

*HISASHI ASANUMA[1], Yusuke Sawaki[1], Shigenori Maruyama[2]

1. The University of Tokyo, 2. Earth-Life Science Institute, Tokyo Institute of Technology

The Mona Complex in Anglesey-Lleyn records a Precambrian subduction-accretion orogeny on the Avalonian margin. It contains an accreted remnant of an oceanic crust and calc-alkaline igneous and high-pressure metamorphic rocks. Their geochronological study plays a key role in comprehension of geotectonic evolution of the Avalonian subduction system. Therefore, we have conducted U-Pb dating of detrital zircons from volcano-sedimentary rocks in the Monian Supergroup, and then K-Ar dating of white micas from pelitic and mafic schists in the Blueschist unit, the Central Shear Zone, and the New Harbour Group. Our new chronological dataset leads to re-interpretation of Anglesey-Lleyn geotectonic framework in terms of a younger analogue of comparable blueschist belts and accretionary orogens in Japan and California.

The evidences of arc-related magmatism are widely distributed in Wales and Central England, and they date back to 760 Ma. Age data of calc-alkaline granites suggest that the Avalonian subduction and its arc-related magmatism had already started by 711–677 Ma. In the period of main arc magmatism (616–555 Ma), a subduction-related accretion of the Gwna Group sediments started (by 578 Ma) on an active margin of Avalonia. Its accretion likely continued to 530 Ma. Moreover, metamorphic rocks of the Blueschist unit and the Central Shear Zone were exhumed from different crustal depths in the interval 578–530 Ma. Afterwards, sedimentation of the New Harbour and South Stack Groups occurred at < 515 ±13 Ma and < 501 ±10 Ma. Sediments of the New Harbour and South Stack Groups were finally accreted underneath the base of the Gwna Group at the accretionary wedge. The greenschist facies metamorphism of the New Harbour Group at 474 Ma constrains its minimum depositional age. In a larger perspective, our new ages are broadly contemporaneous with the calc-alkaline continental arc magmatism in NW Wales and Central England that formed by successive eastward subduction from 711 to 474 Ma.

Radiogenic Sr isotope chemostratigraphy of the Ediacaran Doushantuo Formation in the Yangtze Craton, South China

*Yusuke Sawaki[1]

1. The University of Tokyo

The Ediacaran period records one of the most dramatic biological episodes in Earth's history. To decipher surface environmental changes occurring in the Ediacaran, a variety of geochemical proxies have been reported by a number of studies. Ediacaran sedimentary rocks in South China figure prominently in such studies, because they are fossiliferous and accumulated at various depositional settings from shallow marine to deep basin. Recent extensive geochemical works for the Doushantuo Formation in South China demonstrate that $\delta^{13}C$ values of carbonate were variable depending on the depositional settings. In order to test whether the difference reflect spacial or temporal variation, I focus on $^{87}Sr/^{86}Sr$ ratio as a chemostratigraphic tool. However, the existing $^{87}Sr/^{86}Sr$ values are limited to shallow marine deposits, which leaves ambiguity in a variation of $^{87}Sr/^{86}Sr$ ratios in outer ocean. Our group conducted on-land drilling at Siduping and Tianping sections in South China to obtain completely continuous sedimentary rocks deposited at slope facies. We newly report stratigraphic profiles of the $^{87}Sr/^{86}Sr$ ratios at the sections. $^{87}Sr/^{86}Sr$ chemostratigraphy demonstrated some diachronous natures of $\delta^{13}C$ within the Doushantuo Formation. The enhanced continental weathering during Gaskiers glaciation likely promoted bacterial sulfate reduction and aerobic respiration of organic matter. These resulted in low $\delta^{13}C$ values of dissolved inorganic carbon and accumulations of phosphate and dissolved CO_2 species in seawater, and eventually induced the deposition of phosphorites at the shelf margin. High $^{87}Sr/^{86}Sr$ ratios during the largest negative $\delta^{13}C$ anomaly in the Ediacaran can be also recognized in the continental slope sediment. This fact supports that globally high continental weathering rate led to massive remineralization of organic matter and a consequent significant negative $\delta^{13}C_{carb}$ excursion.

[B-CG08] Phanerozoic biodiversity change: Extinction and diversification

convener:Yukio Isozaki(Department of Earth Science and Astronomy, Multi-disciplinary Sciences - General Systems Studies, Graduate School of Arts and Sciences, The University of Tokyo), Yusuke Sawaki(The University of Tokyo)

Phanerozoic biodiversity is the consequence of repeated extinctions and following diversifications in the past, which were caused by large-scale environmental changes, in particular, by extremely rapid and drastic forcing that changed the environments of the biosphere. Irreversible and episodic changes in material cycling on the planet and influences of severe galactic cosmic radiation enhanced by encounter with dark cloud are nominated as major driving mechanisms for the alleged rapid, large-scale environmental perturbations. The biodiversity change in the fossiliferous Phanerozoic record is characterized by 5 major mass extinctions within the long-term trend of diversity increase. Nonetheless, each extinction event has been explained rather in ad hoc manner, without any universal explanation. Therefore, ultimate triggers that caused the Phanerozoic biodiversity still remain as unsolved issues. This session discusses the ancient environmental changes related to Phanerozoic biodiversity under a new light of the recent progress in geology.

Marine Osmium isotope record across the Aptian/Albian boundary to elucidate the relationship between the Oceanic Anoxic Event 1b and massive volcanic activities at the Southern Kerguelen Plateau

*Hironao Matsumoto[1], Junichiro Kuroda[1], Rodolfo Coccioni[2], Naohiko Ohkouchi[3], Nanako O. Ogawa[3], Saburo Sakai[3], Katsuhiko Suzuki[3], Fabrizio Frontalini[2], Andrea Mazzoli[2]

1. Department of Earth and Planetary Science, The University of Tokyo, 2. DiSPeA, University of Urbino, 3. Japan Agency for Marine-Earth Science and Technology

Several organic-rich sediments (black shales) were deposited in the Tethys and the Atlantic Oceans from the uppermost Aptian to the lower Albian. In particular, four prominent black shale layers have been identified (i.e., Jacob, Kilian, Urbino/Paquier, and Leenhardt levels in stratigraphic order) as the sedimentary expression of Oceanic Anoxic Event (OAE) 1b. The OAE1b is characterized by a major planktic foraminiferal turnover in the Cretaceous period and its exceptionally long duration. In spite of its significant impact on the marine biological evolution, the OAE1b is one of the least studied Cretaceous OAEs. Massive volcanic activities associated with the emplacement of Southern Kerguelen Plateau were ascribed as the trigger mechanisms for the OAE1b. However, the large uncertainties in the radiometric age of Southern Kerguelen Plateau and the sedimentary sequence of OAE1b have however hampered the definition of their causal relationship. Paleo-seawater osmium isotopic record ($^{187}Os/^{188}Os$) is a powerful tool to detect the timing of volcanic pulse. Marine $^{187}Os/^{188}Os$ value mainly reflects the balance between radiogenic osmium flux from the continental crust ($^{187}Os/^{188}Os$ ~1.0-1.5) and unradiogenic osmium flux through hydrothermal activities ($^{187}Os/^{188}Os$ ~0.12). Thus, the relative contribution of hydrothermal activities (or the submarine volcanic activities) can be reconstructed from the paleo-seawater $^{187}Os/^{188}Os$ variation recorded in the sedimentary rocks. In this study, we present a new record of marine Os isotopic record from the Late Aptian to Early Albian to reveal the timing of massive volcanic activities and its relationship with OAE1b.

Pelagic sedimentary rock samples were collected from two sites; 1) Poggio le Guaine (PLG) section (Italy) that was deposited in the central-western Tethys Ocean, and 2) Deep Sea Drilling Project (DSDP) Site 463 drilled at the western Mid-Pacific Mountains in the Pacific Ocean. [M-IS05] New technologies to monitor thunderstorm and severe weather activities

convener:Mitsuteru Sato(Department of Cosmoscience, Hokkaido University), Yukihiro Takahashi(Department of Cosmosciences, Graduate School of Science, Hokkaido University), Hisayuki Kubota(Hokkaido University), Kozo Yamashita(Ashikaga University, Department of Engineering.)

In order to predict the intensity development of severe weather, lightning and thunderstorm are markers of severe weather, often accompanied by precipitation, hail and strong winds that can create significant natural hazards, especially in disaster-prone area. Lightning is also a strong indicator of convection, and it becomes a key parameter to predict the intensity development of tropical cyclones (typhoons and hurricanes). As the climate warms in the first decades of the 21st century, the intensity and frequency of thunderstorms is projected to increase. The need for detecting and monitoring the development of thunderstorms and lightning activities on global, local, and regional scales is therefore clear and urgent.
This session seeks topics presenting new technologies to monitor thunderstorm and severe weather activities. In addition, observational and theoretical contributions on thunderstorm microphysics and dynamics, convective systems and tropical storms are welcome. Present patterns and distributions of lightning and extreme weather events derived from the ground-based networks and satellites, as well as forecasts of future trends, are also of interest. Lightning detecting and monitoring system performance and validation, and early-warning schemes are requested, either in operational or planning phase. The session will also highlight regional and global lightning and atmospheric electricity networks and invite contributions on technological innovations in this field.

Study on monitoring of thunderstorm activity based on multiple electrostatic measurement

*Kozo Yamashita[1], Kakeru Kanno[1], Mitsuteru Sato[2], Yukihiro Takahashi[2]

1. Ashikaga Univ., 2. Hokkaido Univ.

Quantitative evaluation of thundercloud activity is essential for early detection and short-term forecast of severe weather events such as heavy rainfall, lightning stroke, downburst, and so on. In previous researches, lightning observation based on electromagnetic measurement has been focused on as an effective tool for nowcast of thunderstorm activity. Advanced lightning sensors have high sensitivity and makes it possible to detect whole lightning activity. Lightning discharge occurs as a result of vertical atmospheric convection which causes thunderstorm. Preceding studies pointed that lighting occurrence could be an indicator of vertical deep convection in storm region and severe thunderstorm intensity.

Ground-based measurement of electrostatic field has been also considered as an efficient way to detect electrification in thundercloud and monitor development of severe storm. In preceding studies, multiple electrostatic measurement has been examined to estimate charge amount in cloud. One of the difficulties for those studies is to understand correlation between electrostatic field on ground and charges in horizontally extended thunderstorm. In this study, methodology for quantitative evaluation of charge amount in cloud is developed. We newly construct multipoint electrostatic sensor network in Tochigi, Japan. In this region, isolated thunderstorm whose horizontal scale is about 10 km occurs. By analyzing Isolated thunderstorm, we can simplify the correlation between ground-based electrostatic field and charge in cloud. In this presentation, initial result of electrostatic measurement with multiple sensors is summarized.

Department of Aerospace Engineering, Tokyo Metropolitan University, Hino, Japan, 5. Tokyo Gakugei University, Tokyo, Japan, 6. National Institute of Polar Research, Tokyo, Japan

Lightning and precipitation are the main current sources in the global atmospheric electric circuit (GEC). The lightning and precipitation currents maintain the electrical potential gap of ~250 kV between the ionosphere and the Earth’ s surface. However, the contribution of lightning current to the GEC is not well understood due to the difficulty of estimating the global occurrence number of intracloud (IC) discharges. In addition, it is difficult to quantitatively estimate the contribution of the global precipitation current to the GEC due to the difficulty of identifying the rain volume and its global distribution. The purposes of this study are to estimate the global occurrence number of IC discharges and to investigate the contribution of lightning and precipitation currents to the GEC. Firstly, the global Z-value map obtained by the JEM-GLIMS spaced-based mission and the cloud-to-ground (CG) lightning data obtained by the WWLLN were combined to estimate the occurrence number of the global IC discharges with the time resolution of 5 minutes and with the spatial resolution of 0.2º×0.2º. Then, the estimated occurrence number of the global IC and CG discharges and the precipitation data provided by the global precipitation measurement (GPM) project were used as the input parameters in a 3-dimensional model of the GEC, which we have newly developed. In this model, the average column resistance including the influence of the cloud coverage was assumed. Using this model, we estimated the total GEC current and the fair weather electric field at the Syowa station on March 16, July 20, and September 29, 2014. It is found that the average lightning and precipitation currents in the GEC were ~70 A and ~ 670 A, respectively. It is also found that the average fair weather electric field at the Syowa station is ~ 70 V/m. The absolute value of the estimated fair weather electric field is almost consistent with the observational data. From these results, the role of lightning current in the GEC is quantitatively evaluated, and we found that the upward current from thunderclouds to the ionosphere generated by lightning discharges is only 9% while that induced by the precipitation is ~91%.

A method for locating lightning discharges using tweek atmospherics

*Masafumi Kanno[1], Hiroyo Ohya[2], Kazuo Shiokawa[3], Hiroyuki Nakata[2], Toshiaki Takano[2]

1. Graduate School of Science and Engineering, Chiba University, 2. Graduate School of Engineering, Chiba University, 3. Institute for Space-Earth Environmental Research, Nagoya University

Locating accuracy for lightning discharges of world-wide lightning location (WWLLN) is high to be less than 10 km [Rodger et al., 2005], although the accuracy of horizontal propagation distance for tweek atmospherics is low to be ~60 km [Santolik and Kolmasova, 2017]. Tweek atmospherics are very low frequency (VLF)/extremely low frequency (ELF) waves radiated from lightning discharges, and propagate between the Earth surface and the bottom of the ionosphere for a long distance (several thousand kilometers). In this study, we improve the estimation method for the tweek propagation distance, and compare between the lightning location estimated from tweek propagation distance by intersection method with those from the WWLLN data and cloud images derived by the MTSAT-2 satellite. We used two wideband VLF data observed at Kagoshima (31.48˚N, 130.72˚E) and Moshiri (44.37˚N, 142.27˚E), Japan, at 12:20-12:22 UT, on 23 August, 2013. The main point of the improvement was modification for the width of window on dynamic spectra drawn by maximum entropy method. The accuracy of the estimation became higher and the error for the propagation distance became the half of the original estimation, by using narrow window for the beginning, and wide window for the end of the tweek signals. We estimated the lightning location by both automatic and manual methods. In the manual method, the estimated location of lightning for the two-minute data was in good agreement with thick clouds observed by the MTSAT-2 satellite. However, in the automatic method, the location of the lightning was in disagreement with cloud images, because the accuracy of triggered times were not sufficient due to overlapping tweeks or noises such like short pulses just before the tweeks. In the presentation, we discuss the estimation method for the lightning location in detail.

Monitoring for lightning activities and thunder cloud development over the Tokyo metropolitan area during the 2018 summer

*Jun-Ichi Hamada[1], Jun Matsumoto[1], Kozo Yamashita[2], Masashi Kamogawa[3], Yukihiro Takahashi[4]

1. Faculty of Urban Environmental Sciences, Tokyo Metropolitan University, 2. Department of Engineering, Ashikaga University, 3. Department of Physics, Tokyo Gakugei University, 4. Department of Cosmosciences, Graduate School of Science, Hokkaido University

In order to monitor lightning activities and development of thunder cloud, we have established an observational network with electromagnetic and electrostatic field measurements over the Tokyo metropolitan area since 2016. In the summer season of 2018, we observed atmospheric electrostatic field with the electric field monitor (BOLTEK ELF-100) at Hachioji campus of Tokyo Metropolitan University and the surrounding area. Lightning activities were measured with ELV-VLF band radio observation system at a few sites in the area. We also used the worldwide lightning location network (WWLLN) data to indicate temporal and spatial variations of lightning and the climatological characteristics over the area. Lightning observations showed clear intra-seasonal variations of lightning activities over the area during the summer. Significant lightning events at around Hachioji were observed in 6th, 13th, and 27th of August as a synoptic frontal system located in the north from Kanto area. The electrostatic field measurement at Hachioji detected frequent lightning events and developing/approaching of thunder cloud near the site in these days. At the presentation, we will introduce more detail observation results on thunder cloud developments based on the XRAIN (eXtended RAdar Information Network) observation data.

This work was partly supported by Japan Science and Technology Agency (JST) and Japan International Cooperation Agency (JICA) under SATREPS.

[M-IS05] New technologies to monitor thunderstorm and severe weather activities

convener:Mitsuteru Sato(Department of Cosmoscience, Hokkaido University), Yukihiro Takahashi(Department of Cosmosciences, Graduate School of Science, Hokkaido University), Hisayuki Kubota(Hokkaido University), Kozo Yamashita(Ashikaga University, Department of Engineering.)

In order to predict the intensity development of severe weather, lightning and thunderstorm are markers of severe weather, often accompanied by precipitation, hail and strong winds that can create significant natural hazards, especially in disaster-prone area. Lightning is also a strong indicator of convection, and it becomes a key parameter to predict the intensity development of tropical cyclones (typhoons and hurricanes). As the climate warms in the first decades of the 21st century, the intensity and frequency of thunderstorms is projected to increase. The need for detecting and monitoring the development of thunderstorms and lightning activities on global, local, and regional scales is therefore clear and urgent.
This session seeks topics presenting new technologies to monitor thunderstorm and severe weather activities. In addition, observational and theoretical contributions on thunderstorm microphysics and dynamics, convective systems and tropical storms are welcome. Present patterns and distributions of lightning and extreme weather events derived from the ground-based networks and satellites, as well as forecasts of future trends, are also of interest. Lightning detecting and monitoring system performance and validation, and early-warning schemes are requested, either in operational or planning phase. The session will also highlight regional and global lightning and atmospheric electricity networks and invite contributions on technological innovations in this field.

Study on monitoring of thunderstorm activity based on multiple electrostatic measurement

*Kozo Yamashita[1], Kakeru Kanno[1], Mitsuteru Sato[2], Yukihiro Takahashi[2]

1. Ashikaga Univ., 2. Hokkaido Univ.

Quantitative evaluation of thundercloud activity is essential for early detection and short-term forecast of severe weather events such as heavy rainfall, lightning stroke, downburst, and so on. In previous researches, lightning observation based on electromagnetic measurement has been focused on as an effective tool for nowcast of thunderstorm activity. Advanced lightning sensors have high sensitivity and makes it possible to detect whole lightning activity. Lightning discharge occurs as a result of vertical atmospheric convection which causes thunderstorm. Preceding studies pointed that lighting occurrence could be an indicator of vertical deep convection in storm region and severe thunderstorm intensity.

Ground-based measurement of electrostatic field has been also considered as an efficient way to detect electrification in thundercloud and monitor development of severe storm. In preceding studies, multiple electrostatic measurement has been examined to estimate charge amount in cloud. One of the difficulties for those studies is to understand correlation between electrostatic field on ground and charges in horizontally extended thunderstorm. In this study, methodology for quantitative evaluation of charge amount in cloud is developed. We newly construct multipoint electrostatic sensor network in Tochigi, Japan. In this region, isolated thunderstorm whose horizontal scale is about 10 km occurs. By analyzing Isolated thunderstorm, we can simplify the correlation between ground-based electrostatic field and charge in cloud. In this presentation, initial result of electrostatic measurement with multiple sensors is summarized.

We are conducting a SATREPS project “ULAT” and e-ASIA project for the development of extreme weather, including typhoon and individual thunderstorm, monitoring and alert system in the Philippines in 2017-2021 under international cooperation among Japan, Philippines, Indonesia and other SE-Asian countries supported by JST, JICA, PHL-Microsat and other funds. It is well known that intensification of lightning activity is precursor of typhoon growth as well as an indicator of individual thunderstorm activity. In these projects, we apply two new technologies, that is, the lightning activity estimated by the ground-based lightning networks with 12 sites for VLF radio wave measurement in nation-wide of Philippines and with 50 sites for electrostatic field measurement in Metro Manila together with infrasound sensor and automated weather station, and the 3 dimensional capturing of thunderstorms by the on-demand operation of 50-kg micro-satellites, including the Philippine-developed DIWATA-1 and 2, RISESAT, etc. Also few more lightning stations installed in Indonesia and Japan are used. We plan to establish a new methodology to obtain very detail semi-real time information of typhoon and thunderstorm activities that cannot be achieved only with conventional observational equipment. Based on these new observations together with advanced radar measurements and drop/radio sondes campaigns, we will try to construct the cutting-edge observation system to monitor the development of typhoons and thunderstorms, which may greatly contribute to the prediction of disasters and the public alerting system.

By the end of March 2017 we started the test observation for lightning at Quezon city, Philippines, Palau and Guam, forming the network for typhoons. We also succeeded in making 3-D cloud structure with telescope and wide angle spectral camera onboard DIWATA-1, achieving high resolution of ten to several meters. Now we are establishing the real-time target pointing operation with micro-satellites based on the last-minute lightning data measured by ground networks. Adding to DIWATA-1, three more our satellites, namely, RISESAT, MicroDragon and DIWATA-2 with advanced cameras will be used in 2018-2019. In September 2018, drop sonde campaign using aircraft in the eastside of Philippines was carried out under collaboration with Nagoya University team. Here we introduce the latest results of 3-D cloud modeling using images taken by satellite and on the ground together with preliminary lightning analysis, adding to the outline of the project.

Towards the Implementation of the Understanding Lightning and Thunderstorms for Extreme Weather Monitoring and Information Sharing in the Philippines (ULAT) Project

*Glenn Vincent C. Lopez[1]

1. Advanced Science and Technology Institute

Monitoring and understanding thunderstorms are key components of mitigating the effects of torrential rainfall and typhoons. The Philippines, where year-round numerous thunderstorms are experienced, the integration of lightning data has the potential to provide short term forecasts of thunderstorms, further meteorological studies, and supplement disaster risk response strategies.

This presents the activities and updates on the Understanding Lightning and Thunderstorm for Extreme Weather Monitoring and Information Sharing in the Philippines (ULAT) Project. The ULAT Project aims to deploy a highly dense lightning detection network scattered throughout Metro Manila to gather, analyze, and archive lightning data in order to provide thunderstorm “now-casting” and supplement weather-related research and disaster response strategies.

To enable the study of the correlation between lightning activity and localized severe weather disturbances (such as thunderstorms), the Japan International Cooperation Agency (JICA) and Hokkaido University through the Science and Technology Research Partnership for Sustainable Development (SATREPS) Program has partnered with the Department of Science and Technology Institute through the Advanced Science and Technology Institute to develop local expertise and build relevant lighting monitoring infrastructure in the Philippines.

This presents the activities and updates on the Understanding Lightning and Thunderstorm for Extreme Weather Monitoring and Information Sharing in the Philippines (ULAT) Project. The ULAT Project is aimed at the following: a) establishment of a dense network of lightning and weather devices in Metro Manila and nearby municipalities to a) establish of a dense network of lightning and weather devices in the Philippines in order to provide thunderstorm “now-casting” and supplement weather-related research and disaster response studies and strategies; b) establishment of a ground receiving station for direct reception of satellite imagery and utilizing existing ground receiving facilities to develop effective observation methods by comparing to compare 3D structures of thunderclouds from satellite images with lightning/precipitation data; c) establishment of a methodology for short term forecasts; and d) development of software for sharing information on short term forecast weather to concerned agencies.

To further meet the goals of the project, there are challenges during the implementation of the project activities that needs to be addressed in the areas of equipment security, public safety, partnership agreements, site identification and selection, logistics, process, etc. The encountered challenges, alongside with their corresponding solutions, recommendations, next steps and other plans relevant to the project will be also discussed during the meeting.

Airborne observation of Super Typhoon Trami in 2018 for understanding the intensity of tropical cyclone in the Philippine Sea

*Hisayuki Kubota[1], Kazuhisa Tsuboki[2], Hiroyuki Yamada[3], Yukihiro Takahashi[1], Taro Shinoda[2], Tadayasu Ohigashi[4], Munehiko Yamaguchi[5], Kosuke Ito[3], Tetsuo Nakazawa[5], Norio Nagahama[6], Kensaku Shimizu[6], Mitsuteru Sato[1]

1. Hokkaido University, 2. Nagoya University, 3. University of the Ryukyus, 4. National Research Institute for Earth Science and Disaster Resilience, 5. Meteorological Research Institute, 6. Meisei Electronic

Airborne observation of tropical cyclone (TC) had been conducted until 1987 over the western north Pacific region to measure the TC intensity directly. After that TC intensity was estimated by Dvorak technique using satellite data. Here we conducted dropsonde observation by the aircraft in 2018 under the two projects of T-PARCII (Tropical Cyclone-Pacific Asian Research Campaign for Improvement of Intensity estimations/forecasts) and ULAT (Understanding Lightning and Thunderstorm) of SATREPS (Science and Technology Research Partnership for Sustainable Development) in the Philippines and penetrated the eye of Super Typhoon Trami during Sep. 25 to 28. TC Trami reached its mature stage when we observed on Sep. 25. The structure of sharp eyewall and warm core in the eye were observed. On the other hand, the intensity of TC was weakened when we observed on the following day. We need to capture the signal of intensification and decay of TC by combining multiple observations for understanding the structure for a short term forecast of tropical cyclone intensity.

Keywords: Tropical cyclone, Airborne observation, Dropsonde observation

Relation between Lightning and Typhoon Activities (Typhoon LAN) in the Western Pacific Region

*Mitsuteru Sato[1], Yukihiro Takahashi[1], Hisayuki Kubota[1], Kozo Yamashita[2], Jun-Ichi Hamada[3], Joel J. Marciano[4]

1. Department of Cosmoscience, Hokkaido University, 2. Department of Engineering, Ashikaga University, 3. Graduate School of Urban Environmental Sciences, Tokyo Metropolitan University, 4. ASTI, DOST

Recent studies revealed that there is a close relation between the lightning activity and the tropical cyclone intensity, such as the maximum wind velocity and the minimum surface pressure. As many countries in the western Pacific region suffer from the attack of many tropical cyclones (typhoons) and related severe weather events, they have a strong demand to predict the intensity development of these phenomena by means of a cost-effective way. Thus, we started installing the new lightning and weather observation system, named as V-POTEKA, at Guam, Palau, and Manila in the Philippines since September 2017. The lightning observation system consists of a VLF receiver having the sensitivity in the frequency range of 1-5 kHz, an automatic data-processing unit, solar panels, and batteries. Lightning-excited pulse signals detected by the VLF receiver are automatically analyzed by the data-processing unit, and only the extracted information of the trigger time and the pulse amplitude is transmitted to the data server via the 3G data communications. From the V-POTEKA data analysis, we confirmed that there is clear relation between the lightning occurrence number in the typhoon and the maximum wind speed of Typhoon LAN, which is the category-1 weak typhoon. There is ~12-18 h time difference between the peak lightning occurrence number and peak typhoon intensity. At the presentation, we will show the results derived from these lightning observation systems and will present the relation between lightning and typhoon activities more in detail.

Infrasound multi-site observation of thunders 3: preparation process for SATREPS

*Masa-yuki Yamamoto[1]

1. Department of systems engineering, Kochi University of Technology

Infrasound, low-frequency sound of 20 Hz or less, is considered as one of the remote-sensing method of lightning/thunders. Sensor network to be deployed for a SATREPS project, Philippine, is planned in Manila region in early 2019. Here, we will deploy two types of infrasound sensors. Small but impulsive pressure changes caused by the rapid expansion of the heated plasma along the path of lightning strikes can be detected by infrasound sensors with higher sensitivity range of 1 mPa. Thus, we will use multiple film type (DC type) infrasound sensor for low frequency measurements. But for the thunder infrasound signals, lower-cost microphone type (AC type) sensors can be applied for measurements. Thus, we will mainly use many microphone type infrasound sensors in Metro Manila region.
For calibrating the both sensors, in order to evaluate precise pressure level as well as detectable frequency range, we used a chamber with a pushing/pulling mechanism on it. The infrasound multi-site observation can reveal the lightning activities as close as 100 m scale when the infrasound sensors can be installed with a mesh of 10 km scale or shorter by using the speed of sound as a precise remote-sensing scale. Recently, we also checked capability of remote-sensing in Fukui area and Kanazawa area by using real thunder signals with some other methods to compare.
In this talk, we will introduce a possibility of infrasonic remote-sensing and its calibration phase, in order to realize future disaster-mitigation studies.

Data Acquisition System for an Infrasound Network for Thunderstorm Monitoring

*Doreena Karmina Abril Pulutan[1], Yukihiro Takahashi[1], Mitsuteru Sato[1], Hisayuki Kubota[1], Kozo Yamashita[2], Masa-yuki Yamamoto[3]

1. Department of Cosmosciences, Hokkaido University, 2. Department of Engineering, Ashikaga University, 3. Department of Systems Engineering, Kochi University of Technology

Inside a thunderstorm, an updraft pushes ice crystals with positive charge to the top, while a downdraft pushes hailstones with negative charge to the bottom. This charge separation results in lightning. While the electric charge and peak current in lightning events have been extensively studied, they do not indicate the strength of the atmospheric convection that produces thunderstorms. Another parameter, the electrical energy from lightning, has not been thoroughly explored. We will look at the electrical energy from lightning as a possible indicator of the strength of a developing thunderstorm. Electrical energy, however, has not been clearly linked to the peak current of a lightning event. Thus, we cannot rely on peak current measurements to estimate electrical energy. Infrasound emitted by thunderstorms might be a possible way to estimate the electrical energy in lightning events. Microphones can be used to detect infrasound. This work will discuss the development of a data acquisition system that will be used to record and transmit sampled infrasonic data from microphones. This work is being undertaken under the SATREPS/ULAT Project.

[M-IS05] New technologies to monitor thunderstorm and severe weather activities

convener:Mitsuteru Sato(Department of Cosmoscience, Hokkaido University), Yukihiro Takahashi(Department of Cosmosciences, Graduate School of Science, Hokkaido University), Hisayuki Kubota(Hokkaido University), Kozo Yamashita(Ashikaga University, Department of Engineering.), Chairperson:Yukihiro Takahashi(Hokkaido University), Hisayuki Kubota(Department of Cosmoscience, Hokkaido University)

In order to predict the intensity development of severe weather, lightning and thunderstorm are markers of severe weather, often accompanied by precipitation, hail and strong winds that can create significant natural hazards, especially in disaster-prone area. Lightning is also a strong indicator of convection, and it becomes a key parameter to predict the intensity development of tropical cyclones (typhoons and hurricanes). As the climate warms in the first decades of the 21st century, the intensity and frequency of thunderstorms is projected to increase. The need for detecting and monitoring the development of thunderstorms and lightning activities on global, local, and regional scales is therefore clear and urgent.
This session seeks topics presenting new technologies to monitor thunderstorm and severe weather activities. In addition, observational and theoretical contributions on thunderstorm microphysics and dynamics, convective systems and tropical storms are welcome. Present patterns and distributions of lightning and extreme weather events derived from the ground-based networks and satellites, as well as forecasts of future trends, are also of interest. Lightning detecting and monitoring system performance and validation, and early-warning schemes are requested, either in operational or planning phase. The session will also highlight regional and global lightning and atmospheric electricity networks and invite contributions on technological innovations in this field.

The Philippines is one of the most disaster-hit countries in the world. Its location in the western North Pacific (WNP) subjects it to numerous tropical cyclones (TC) each year that pose risk to lives, properties and infrastructures. There has been a significant development in the accuracy of TC track forecast that cross and/or make landfall within the Philippine Area of Responsibility (PAR) over the years with the use of ground-based synoptic observations, weather radars, and meteorological satellites. However, prediction of TC intensity remains a significant challenge. Lightning activity is an indicator of the dynamics and microphysics in thunderstorms, as well as severe weather phenomena, such as TCs and torrential rainfall among others. Recent studies suggest that lightning activity in tropical cyclones can give predictive information about its intensity development. Thus, a ground-based lightning observation system (V-POTEKA) has been developed, and it has been installed at three stations in the Philippines, Guam, and Palau to continuously monitor lightning activity in the WNP region since September 2017. The V-POTEKA system uses an event-trigger method that detects radio wave pulses from lightning discharges in the very low frequency (VLF) range of 1-50 kHz. It also consists of an automatic weather station (AWS), VLF sensors, and an automatic data-processing unit. The V-POTEKA system analyzes lightning data, extracts pertinent information, i.e., peak amplitude and time of the triggered waveform, and transmits data to a server through 3G communication. A geolocation software using the time-of-arrival method is being developed using the 3 sites along the WNP region. Further analysis will be conducted by incorporating data from other stations (Sapporo, Japan and Los Banos, Philippines), and an improved geolocation software will be used to investigate the relationship between the lightning activity and typhoon intensification during the dropsonde observation campaign conducted in September 2018.

Observation system for thunderstorm development using ground lightning detection network and thermal infrared camera onboard satellite LAPAN-A4 in Indonesia

*Purwadi Purwadi[1,2], Yukihiro Takahashi[1], Mitsuteru Sato[1], Kozo Yamashita[3], M. Arif Saifudin[4]

1. Department of Cosmosciences, Hokkaido University, Sapporo 0600810, Japan, 2. Agency for Assessment and Application of Technology (BPPT), Jakarta 10340, Indonesia, 3. Department of Technology, Ashikaga Institute of Technology, Tochigi 3268558, Japan, 4. Indonesian National Institute of Aeronautics and Space (LAPAN), Jawa Barat 16310, Indonesia

Indonesia is the tropical maritime country which has potential disaster risk caused by thunderstorm cloud. In this study, we will observe the thunderstorm development using lightning detection networks and micro-satellite. A previous study has shown that electrification process on the cloud started when the peak of the cloud reaches the threshold height and continue to growth vertical with an upward ~8 m/s (Krehbiel, 1986). With the reverse though, the lightning activity can be used to indicate the updraft presence inside the cloud. Moreover, lightning activity represents the intensity and area of precipitation and/or an updraft area. In this study, the Asia VLF lightning Observation Network (AVON) will be used to detect electromagnetic wave emitted by lightning which has been installed in Manila - Philippines, Palau, and the next will be installed in Serpong and Padang Indonesia. We will show coverage area and ambiguity of lightning geolocation created by this lightning networks. The progress in development of algorithms in the determination of the location of lightning, peak currents, and charge moment changes will also be presented. Adding to the lightning observation, cloud observation using thermal infrared camera onboard LAPAN-A4, which will be launched in 2019 FSY, will provide the temperature distribution with the surface resolution of ~180 meters and field of view of ~ 56.3 x 42.2 kilometer. Using this high resolution thermal infrared camera, the cloud top altitude can be estimated, assuming temperature profile of the ambient atmosphere. By making such observation at some time interval, the developing speed of thunderstorm can be calculated in 3D. The first lightning occurrence detected by AVON, which could be assumed as the timing that the cloud has reached the threshold height to become a thunderstorm, will initiate the micro-satellite observation with the thermal infrared camera, from which we could make a prediction of torrential rainfall.

Remote Sensing Water Quality Determination using Multi-spectral Analysis

*Ahmad Shaqeer Mohamed Thaheer[1], Yukihiro Takahashi[1]

1. Hokkaido University

Wetlands have three distinct features which are the existence of a water body, hydric soil, and specific vegetation that thrived under those conditions as mentioned. The ecosystem provides benefits to the environment and humans as one of the significant natural resources. The contamination of the waters, especially in the river, poses a serious health and environmental risk. The destruction of the catchment area will lead to the deterioration in quality and quantity of the water resource in Malaysia. The Department of Environment (DOE) under the Ministry of Water, Land and Natural Resources (NRE) has identified that the Malaysian rivers are degraded by both point and non-point sources of pollution. The major point sources of pollution in rivers are from sewage treatment plants, agro-based industries, manufacturing industries, sullage or grey water from commercial and residential premises, and pig farms. Non-point source (or diffuse) pollution is largely due to storm runoff after a downpour. Current methods using in-situ measurements are shown to be infeasible while Remote Sensing methods helps to resolve these issues such as cost, time, accessibility, and repeatability effectively. Multi-spectral Imagery has been a useful in analyzing the spectral characteristics of wetlands.

Study of cloud effects on atmospheric electric field during lightning activities and snowfall using the 95-GHz cloud radar FALCON-I

*Hiroyo Ohya[1], Kota Nakamori[1], Masashi Kamogawa[2], Tomoyuki Suzuki[2], Toshiaki Takano[1], Kazuomi Morotomi[3], Hiroyuki Nakata[1], Kazuo Shiokawa[4]

1. Graduate School of Engineering, Chiba University, 2. Tokyo Gakugei University, 3. Japan Radio Co. Ltd., 4. Nagoya University

It is known that cloud-to-ground lightning and precipitations generated from thunderclouds are a generator of global electric circuit (e.g., Williams, 2009). In the fair weather, the atmospheric electric field at the ground is generally 100 V/m and downward (positive). The atmospheric electric field varies during not only lightning/thunderstorms, but also snowfall/blizzard (e.g., Minamoto and Kadokura, 2011). The atmospheric electric field had positive correlations with flush rate (R^2 = 0.67) and clouds of more than 30 dBZ with temperature range of -35~-5˚C (R^2 = 0.62) observed by the TRMM satellite [Lavigne et al., 2017]. However, satellite observations cannot monitor cloud internal structures in detail. In this study, we investigate the variations of the atmospheric electric field during lightning activities of 4 July, 2016, and snowfall of 23-24 November, 2016, using a field mill, the 95 GHz cloud radar, FALCON (FMCW Radar for Cloud Observations)-I, and a X-band radar (9.4 GHz). We have observed the atmospheric electric field with a Boltek field mill, and cloud reflectivity and the Doppler velocity with the FALCON-I in Chiba University, Japan, (CHB, 35.63˚N, 140.10˚E). At 16.2 km southeast from the CHB, a phased array X-band radar operated by Japan Radio Corporation observed precipitations/cloud. During lightning activities of 4 July, 2016, there were two variations in the atmospheric electric field: short pulse signals and slow variations due to passage of thunderclouds. Small increase in the atmospheric electric field in the initial phase was caused by positive charges in anvil using the FALCON-I, although the cause of the initial phase has been regarded as negative charges in the bottom of the thunderclouds so far. The duration of the short pulse signals due to lightning itself had a positive correlation with the lightning peak current (r = 0.44). During the snowfall of 23-24 November, 2016, periodic oscillations in the atmospheric electric field with periods of 70-90 minutes were observed at four observation sites; CHB, Kakioka (KAK, 36.23˚N, 140.19˚E), Tokyo Gakugei University (KGN, Kokubunji, Tokyo, 35.71˚N, 139.49˚E), and Seikei High School (MSN, Musashino, Tokyo, 35.72˚N, 139.57˚E). The distances of CHB-KAK, CHB-TGU, and CHB-SHS are 64.8 km, 55.9 km, and 49.0 km, respectively. This is the first observations of similar oscillations in the atmospheric electric field at different observation sites separated by a long distance of 50-65 km. At the end of snowfall, the periods of the oscillations became shorter to be 20-50 minutes at all sites. Based on the FALCON-I and X-band radar observations, we found that the reflectivity of the snow cloud had the same period of 80 minutes at CHB at 0-2 km heights during the snowfall. In the presentation, we will discuss the cause of the variations in the atmospheric electric field.

Preferred environmental conditions of precipitation systems in and around Bangladesh observed by ground-based radars

*Fumie Murata[1], Shuhei Azuma[2], Toru Terao[3], Quamrul S.M. Hassan[4]

1. Faculty of Science and Technology, Kochi University, 2. Faculty of Science, Kochi University, 3. Faculty of Education, Kagawa University, 4. Bangladesh Meteorological Department

Severe storms tend to occur in Bangladesh. In the pre-monsoon season (March-May) storms with intense rainfall, lightning, hails, and tornadoes are frequently observed. Precipitation systems in the monsoon season (June-September) bring large amount of rainfall and floods tend to occur. The purpose of this study is to elucidate the environmental conditions which cause severe weather. This study analyzed the ground-based radars observed during 2010-2014 with TRMM-based precipitation products and JRA55 reanalysis. The precipitation systems were classified into four types: arc-type (77 cases), line-type (59 cases), scattered-type (178 cases) and broad-type (172 cases) systems. Arc-type systems tended to occur in the pre-monsoon season, and the environmental condition had large vertical shear with dry in the mid troposphere. Line-type systems had no preferred season, and the environmental condition had weak vertical shear. The formation process seemed back building type. The scattered-type systems in the pre-monsoon season occurred in the large vertical shear, whereas that in the monsoon season occurred in the weak vertial shear. Most of the broad-type systems were occurred in the active spells of the intraseasonal variation during the monsoon season, and the scattered-type tended to appear in 1-3 days before the formation of the broad-type systems.

Thundercloud gamma-ray observations at Kashiwazaki aiming at source altitude and beaming measurements and a new trial at Tokyo Skytree in FY2018

*Kazuhiro Nakazawa[1], Takahiro Matsumoto[2], Yuuki Wada[2], Alexia Fabiani[1], Teruaki Enoto[3], Kazufumi Okuda[2], Yoshihiro Furuta[4], Yuki Aizawa[2], Takayuki Yuasa[5], Harufumi Tsuchiya[4], Mitsuteru Sato[6], Kazuo Makishima[7]

1. Nagoya University, 2. University of Tokyo, 3. Kyoto University, 4. JAEA, 5. RIKEN, 6. Hokkaido University, 7. Kalvi IPMU, University of Tokyo

MeV gamma rays from lightning and thundercloud reaching the groud are sometimes observed from the winter thunderstorm activities along the coastline of Japan Sea. We, the Gamma-Ray Observation of Winter Thunderclouds (GROWTH) collaboration, are observing such phenomena from 2006 at Kashiwazaki, Niigata prefecture (e.g. Tsuchiya et al. 2007), and recently increasing the number of observation sites, including Ishikawa prefecture (e.g. Wada et al. at M-IS27 session). Since FY2016, we have been operating new detectors at Kashiwazaki dedicated to measure the altitude and beaming of gamma-ray source in thundercloud. Three collimated detectors aiming at different sky regions are deployed. A minute-long gamma-ray emission (or "long-burst") was observed on Jan 26th, 2019 with the system, and we are analyzing the peaking time difference among the three detectors to perform triangulation using the wind speed. Preliminary results suggest the altitude to be lower than ~300 m, but because the emission was relatively weak and photon statistics are not enough, we are estimating the upper-limit of the source altitude and its beaming. Independently, we also started an observation campaign at the 450 m altitude of Tokyo Skytree, aiming at gamma-ray detection from lightning (so called downward TGF) of summer thunderstorm. The tower is one of the locations most frequently hit by lightning. We had three hits on May-Sep. 2018, but no TGF was observed to date, confirming the fact that not all the lightnings are observationally associated with gamma rays. Because our team is observing several downward TGFs from winter thunderstorms (e.g. Enoto et al. 2017), increasing data will enable us to compare the difference among the lightning with and without TGF. The study will be also boosted with the launch of TARANIS satellite in early 2020, dedicated for simultaneous observation of TGF, electrons, optical and radio emission from lightning.

Fabrication of octacalcium phosphate block through a dissolutionprecipitation reaction and its biological evaluation

*Yuki Sugiura[1], Munar L Melvin[2], Kunio Ishikawa[2]

1. National Institute of Advanced Industrial Science and Technology, 2. Kyushu University

Although octacalcium phosphate (OCP) powder and a collagen/gelatin composite demonstrate good potential as bone substitutes, an OCP block has not been fabricated to date. In this study, the feasibility of fabricating an OCP block was evaluated through a dissolution-precipitation reaction using a calcium sulfate hemihydrate (CSH) block as a precursor. When the block was immersed in a phosphate salt solution, its composition changed to that of OCP, while its structure was maintained. The diametral tensile strength (DTS) of the OCP block was 1.0 ±0.2 MPa. The macroporosity and microporosity of the OCP block were 33.4 ±4.5% and, 69.0 ±1.6%, respectively. New bone attached well to the OCP block, and this block was partially replaced by bone 2 weeks after implantation. Four weeks after implantation, the surface of the OCP block was nearly covered with new bone and ~30% of the block was replaced by new bone, while no replacement by bone was observed in the case of a hydroxyapatite (HAp) block used as a control. It is concluded that OCP blocks are potentially suitable for their use as artificial bone substitutes.

Development of optimized incineration process of fisheries waste for synthesizing a functional heat storage material

*Hidekazu Kobatake[1], SHinji Kirihara[1]

1. Hirosaki University Institute of Regional Innovation

A part of fishery waste, such as scallops or oyster shells, are utilized for fertilizer, feed, soil conditioner, or fishing ground preparations, and most of the shells from aquaculture residue are incinerated as general waste at or above 1273 K using a huge amount of fuels and cost. And the most of the incineration products are used for a landfill disposal. For the establishing the sustainable fisheries industry and local community, the reduction of the incineration cost and utilization of the incineration products are indispensable. In this research, the incineration temperature of fisheries waste was examined for lowering incineration temperature. Addition to the investigation on the incineration temperature of fisheries waste, the properties of the calcium oxide derived from the fisheries waste as heat storage material was also evaluated based on the thermal analysis.

The samples used for thermal decomposition kinetics investigation are 2 species of shells (Scallop *Mizuhopecten yessoensis*, Oyster *Crassostrea gigas*), a spines of a sea urchin *Mesocentrotus nudus*, and calcite reagent (purity 99.95%). The surface deposits on these shells and spines are removed using a wire brush or tweezers, then washed by tap water. The cleaned samples were crushed in a porcelain mortar, then dried in an oven at 383 K. The dried powder particles were allied by their size using a sieve to sort in size in the range between 63 and 125 micron meter. The thermal incineration temperature was investigated using these samples.

Calcite reagent (purity 99.95%) the sorted, shells (Scallop, Oyster, Myoida *Hiatella orietalis*, and Tube worms *Dexiospira foraminosus*), and spines of Sea urchin were thermally decomposed for 1 hour at 1273 K to be converted to calcium oxide and then reacted with distilled water to prepare $Ca(OH)_2$. The thermal decomposition temperature of the $Ca(OH)_2$ of these samples was experimentally investigated for the evaluation of the incineration product as a heat storage material.

The prepared powder samples were put in a platinum container covered with Pt disk and then installed in a Differential Scanning Calorimetry. The samples were heated up with the temperature increasing rate from 5 K /min to 40 K /min in Ar atmosphere (99.9999%).

The thermal decomposition complete temperature is depending on the temperature increasing rate. As increase of the temperature increasing rate, thermal decomposition temperature of each samples became higher. The activation energy and frequency factor of the thermal decomposition were determined from the relation between thermal decomposition complete temperature and the temperature increasing rate. However, there is only 8% difference in the activation energies of thermal decomposition among the all samples. This result implies that the thermal decomposition kinetics is mainly controlled by the frequency factor.

Meanwhile the thermal decomposition temperature of the $Ca(OH)_2$ differs each other depending on the derived specimens. There is a weak positive correlation between the thermal decomposition temperature of calcite and calcium hydroxide. The shells and spines having lower thermal decomposition temperature have lower thermal decomposition temperature of calcium hydroxide. The incineration products from shells and spines have also better reaction property than that of derived from the calcite reagent.

These differences could be caused by the microstructures of the reagent, shells and spines. The adjustment of the particle size of shells during the firing can further reduce the reaction temperature and fuels and control the reaction property as a heat storage material.

Spatiotemporal control of crystallization from a solution is often required for detailed exploration on mechanism of early stage of crystallization because the stochastic nature of nucleation process hinders us to chase its early stage. Recently, laser trapping-induced crystallization technique has received increasing attention as a possible candidate to realize spatiotemporally controllable crystallization.[1] In the technique, the crystallization is induced by trapping molecular clusters in a solution with optical tweezers, in which dielectric tiny particles are captured by electrical field gradient force generated by tightly focusing laser light by optical lens. This technique has actually demonstrated forced nucleation of various organic molecules from an unsaturated mother solution at the focal spot. Although recent progress of nanoscience including research on nucleation dynamics demands precise manipulation of nanoscopic objects, the conventional optical tweezers, electrical field gradient force of which relies on the focusing the laser by optical lens, has a limitation of diffraction limit on focusing the light. To overcome the limit, the use of near-field generated by localized surface plasmon resonance, which is collective oscillation of free electrons on surfaces of metal nanoparticles when light impinges on the nanoparticle, has been proposed. [2] Because the near-field is confined in nanoscale, the light focusing beyond the diffraction limit can be achieved consequently, allowing us to capture the smaller particles much tightly than the conventional method. However, the plasmonic optical tweezers has never been applied to crystallization. Here we applied plasmonic optical tweezers to crystallization of acetaminophen molecule from an aqueous solution.

Figure 1 shows schematic illustration of experimental setup. Periodic Au nanolattice the unit structure of which is gammadion with the size of 500 nm was fabricated on a cover glass by electron beam lithography. An aqueous solution of acetaminophen saturated at room temperature (24^{o}C) was dropped on the Au nanolattice, and then solution thin layer supported by the nanolattice was formed by capillarity. Near-infrared continuous-wave left-handed circularly polarized laser (1064 nm, 6.4×10^{9} W/m^{2}) was focused to the nanolattice supporting the solution thin layer by passing through an objective lens equipped on an inverted polarized-light optical microscope. In-situ microscopic observation for the vicinity of the focal spot was also performed simultaneous with the laser irradiation.

Figure 2 shows time-lapse micrographs of the in-situ observation in the vicinity of the focal spot. After the laser irradiation, crystals with the size of 1000 ~ 2000 nm were precipitated 19 mm away from the focal spot in annular pattern. The position of the annular pattern moved while following the change of in-plane position of the focal spot via dissolution/precipitation process, indicating that position of the crystal is manipulatable. When the plasmon excitation by laser irradiation was stopped, the crystals were disappeared via two-step dissolution process; the crystals first transformed to dense liquid droplets, and then the dense droplet disappeared through molecular diffusion.

©2019. Japan Geoscience Union. All Right Reserved.

Generally, large temperature gradient generates in the vicinity of the focal spot when localized surface plasmon resonance was excited, because of the heat generation through electron-phonon scattering. Thus, the large temperature gradient exerts thermophoretic force outward from the focal spot on acetaminophen molecules. Since the electrical field gradient force attracts the molecules towards the focal spot, the annular-patterned precipitation can be interpreted as the consequence of the balancing the electrical field gradient force as attractive force and the thermophoretic force as repulsive force. Therefore, our observation strongly suggested that plasmonic optical tweezers can precisely control crystallization.

Investigation of liquid cell transmission electron microscopy combined with antisolvent crystallization

*Tomoya Yamazaki[1], Yuki Kimura[1]

1. Institute of Low Temperature Science Hokkkaido University

Crystallization of salts in solutions is a quite common phenomenon in the earth and is important not only for production of materials but also for understanding geochemical processes. However, initial stage of crystallization, called nucleation, is not fully understood and numerous studies to understand the process have been reported. Recently, multistep nucleation pathway, which formations of one or more metastable phases are required on the route to a formation of a crystalline phase, have been proposed. Liquid cell transmission electron microscopy (TEM) is a promising method for observing the nucleation process directly because the spatial resolution of this method is under nanometer scale. More recently, multistep nucleation pathways of the crystals of calcium carbonate [1] and lysozyme protein [2] have been revealed by liquid cell TEM. However, capturing a moment of a nucleation event is quite difficult because the observable area of the method is small ($< 100\ \mu m^2$) and a nucleation event is typically very rare in the tiny volume within the area. In order to observe nucleation events efficiently, a supersaturation of a sample solution should be increased with observing the solution. To create the situation, we applied the anti-solvent crystallization technique, which crystallize the solute to add the solvent with the extremely low solubility of the solute (anti-solvent), to liquid cell TEM and tried to observe the nucleation event of a salt crystal.

We used the TEM holder (Poseidon 300, Protochips Inc.) and the liquid cells of silicon chips equipped with thin silicon nitride windows. Aqueous solution of sodium chlorate under equilibrium at room temperature was enclosed in the liquid cell. The TEM holder has two injection ports of liquid, and one of the ports was filled by acetone as the anti-solvent of sodium chlorate. After starting the observation of the sample solution, acetone was injected by syringe pump for mixing the aqueous solution in the liquid cell.

Using the methods, we succeeded in observing the nucleation events of crystals. In this presentation, we will report the detailed analysis of crystals and the nucleation processes.

DNA-guided crystallization of nanoparticles: optimization of crystallization conditions and structure analysis

*Miho Tagawa[1], Shoko Kojima[1], Hayato Sumi[1], Arisa Nishibu[1], Takumi Isogai[1], Maasa Yokomori[2], Shunta Harada[1], Toru Ujihara[1], Katsuo Tsukamoto[1]

Due to the programmability and self-assembly characteristic, DNA is a powerful tool for guiding the assembly of nanometer-sized particles into large-scale ordered structures. Recently, DNA-guided nanoparticle crystallization has been demonstrated and many types of crystal structures have been created[1-3]. By changing particle size ratio, DNA length and complementarity, particles assemble into different types of crystals. By TEM imaging after silica encapsulations, Mirkin et al. confirmed that some of DNA-guided nanoparticle crystals assembled into wulff polyhedra in solution[3]. However, it is crucially difficult to grow large-scale wulff polyhedral single crystal of DNA-functionalized nanoparticles (DNA-NPs) with size up to several microns. Herein, we demonstrate the optimization of solution composition on DNA-NP crystal growth, specifically the effect of sodium chloride concentration and polyethylene glycol (PEG) addition into DNA-NP colloidal solution.

Au nanoparticles of diameter 7 nm were functionalized with two different sequenced thiolated-DNA strands (DNAa and DNAb), respectively. These DNA-functionalized nanoparticles, DNA-NPa and DNA-NPb, were combined with linker DNA strands, which hybridize to complementary sequences of DNAa and DNAb (Figure 1). The mixed solutions were adjusted under different sodium chloride concentration (100, 300, 500, 700 and 900 mM) and by adding PEG with different molecular weights (1000, 4000 and 8000) and subsequently heated to 65 ºC and then slowly cooled back to 25 ºC. The crystal structure of assembled DNA-NP superlattices were analyzed by small angle x-ray scattering (SAXS) and imaged by scanning electron microscope (SEM).

We confirmed the crystal structure of assembled DNA-NP aggregates was bcc by analyzing peak positions of SAXS 1D curves. The differences were seen in SAXS and SEM data with different samples under different sodium chloride concentrations. Relatively large wulff polyhedral single crystals of DNA-NP superlattices were assembled in buffer solution under 500 mM NaCl. The significant differences were seen in SAXS and SEM data with different samples by adding PEG with different molecular weights. DNA-NP superlattices assembled in the buffer solution with PEG 1000 showed a clear SAXS 1D curve which indicates bcc structure (Figure 2) and a significant increase in average crystal size were confirmed by SEM (Figure 3).

We will also present the recent progress on the formation of lattice using DNA-NPs linked by DNA polyhedral constructs. DNA polyhedron has symmetrical connecting bonds and plays a determining role in the inter-particle bonding; that allows for control of particles coordination. DNA nanostructure-directed crystallization has a power of the proposed approach for assembly of complex nanoparticle lattices[4].

Discussion

Growth mechanism of binary colloidal crystals

*Jun Nozawa[1], Suxia Guo[1], Hiromasa Niinomi[1], Junpei Okada[1], Satoshi Uda[1]

1. Tohoku University

Colloidal crystals have been attracted great attention from wide application fields owing to their unique optical properties. Now, varieties structures of the colloidal crystal, e.g. non-closed packed structure, are significantly demanded for diverse applications. For this ends, to grow binary colloidal crystal is promising method since it displays rich structural diversity. However, in contrast to single component system, growth mechanism of binary system of colloidal crystals is poorly understood. Also, to grow large size of binary colloidal crystals with high crystallinity is still difficult. In this study, in-situ observation is conducted to reveal detailed growth process of binary colloidal crystals. Then, growth mechanism is discussed.
Polystyrene particles are employed in the experiment. Green fluorescent particles with 500 nm and red with 700 nm are employed. Crystallization of colloidal crystals is induced by depletion attraction.
We have found several features on the growth of binary colloidal crystals. First, it grows on substrate. The AB_2 structure (A: 700 nm, B: 500 nm) is found to be grown by utilizing crystals composed only of 700 nm particles. The AB_2 crystals also grow on crystals of 500 nm. The specific crystallographic orientations between those crystals are recognized. Combination of orientations between AB_2 and substrate are classified into four types. Heteroepitaxial growth is found to occur for growth of AB2 structure. Second, growth rate of binary colloidal crystals is quite small compare to that of single component system under the same particle concentration. We think this is attributed to complex structure of the crystals, which requires each particle incorporating to their own site. This process is not required for crystals composed of single component. Third, cluster formation at the interface is recognized. The ordered structure composed only of 500 nm is formed at growing interface. Particles of 700 nm is incorporated into the ordered structure generates AB_2 structure.
These observations provide great hints to reveal overall growth mechanism of binary colloidal crystals, which will lead to establish sophisticated growth technique to grow large and high quality crystals.

Formation of low-crystalline magnesium silicate in natural alkaline environment and flow-through experiments

*Yuto Nishiki[1], Misato Shimbashi[1], Tsutomu Sato[2], Tsubasa Otake[2]

1. Graduate School of Engineering, Hokkaido University, 2. Faculty of Engineering, Hokkaido University

INTRODUCTION

Magnesium silicate formation at low temperature (25-200℃) is receiving a lot of attention in various research fields. Sepiolite and serpentine, crystalline Mg-clay minerals, are known to be formed in MgO-SiO_2-H_2O systems at low temperature. However, some studies have been suggesting that low-crystalline magnesium silicate recently should be formed in this low-temperature condition. These kinds of low-crystalline silicates have actively been studied by many reaserchers and engineers. For instance, calsium and alminium silicates are known as C-S-H (calcium silicate hydrate) and allophane/imogolite, respectively. These are studied for both natural minerals and synthesized materials. On the other hand, studies of the low-crystalline magnesium silicate are still in their infancy and little is known. Therefore, the nature of the low-crystalline magnesium silicate has not been clear yet. Since the magnesium silicate can be utilized in various engineering fields (e.g., improved oil recovery, CO_2 geological storage, geothermal power generation, concrete degradation, mineral clogging in radioactive waste disposal, treatment of environmental pollutions, etc.), the current reserch gaps in the understanding of the low-crystallline magnesium silicate formation need to be addresed so as to contribute positively to the above engineering technologies. Moreover, this study can also be applied to the field of planetary science because low-crystalline magnesium silicate should be observed even on surface of Mars and in interstellar silicate dusts.

ANALYSES OF NATURAL PRODUCTS

Firstly, this study confirmed that low-crystalline magnesium silicate forms in nature. Samples of precipitates were collected from the surface where fluid flows out from serpentinite rocks around Kamuikotan metamorphic belts, Hokkaido, Japan. Although a clear XRD pattern from the bulk samples was not observed, electron microscopy (Field emission scanning electron microscope and Transmission electron microscope; TEM) clearly identified the phase. TEM-energy dispersive X-ray spectrometry indicated that the low-crystalline phase was composed of Mg, Si, and O. Moreover, electron diffraction with TEM showed diffuse halo rings from some particles in the samples, showing the formation of low-crystalline phase. Furthermore, the fluid samples participating in formation of the precipitates were collected and analyzed. From the results, the fluid samples were alkaline ($9.50 < pH < 10.67$) and saturated with low-crystalline magnesium silicate phase (magnesium silicate hydrate reported by Lothernbach et al., 2018).

FLOW-THROUGH EXPERIMENTS

Secondly, to demonstrate the above formation, flow-through experiments in open system were conducted. Alkaline solution with 1.5 mM of dissolved silica was flowed into MgO powder in the reaction cell. TEM observation revealed the low-crystalline magnesium silicate formation as well. Moreover,

©2019. Japan Geoscience Union. All Right Reserved.

dissolution rate of Mg-bearing mineral and formation rate of magnesium silicate were obtained from dissolved silica and magnesium concentrations in the output solutions. These suggested that the magnesium silicate formation was extremely rapid under the oversaturated condition, and that the dissolution of Mg-bearing mineral is the rate-determining step during formation of the low-crystalline magnesium silicate. Although the flow-through experiments used only MgO as a Mg-bearing mineral, the above discussion can be applied to all of Mg-bearing minerals such as olivine and pyroxene because dissolution rate of MgO is greater than any other Mg-bearing minerals. Therefore, the flow-through experiments broaden the kinetical understanding of low-crystalline magnesium silicate formation not only at the Kamuikotan metamorphic belts, but also to other areas where the magnesium silicate is formed from the supply of Mg-bearing minerals in rocks/soil.

Homogeneous Nucleation from Vapor in Al-O Binary System

*Shinnosuke Ishizuka[1], Jun Kawano[2], Tomoya Yamazaki[3], Tetsuya Hama[3], Yuki Kimura[3]

1. National Institute for Environmental Studies, 2. Faculty of Science, Hokkaido University, 3. Institute of Low Temperature Science, Hokkaido University

A gaseous molecule can have a chemical formula that is inconsistent with its ability to act as a building block for crystals; for example, hot AlO and AlO_2 vapors cannot solidify directly to crystals. The contributions of such gases to homogeneous nucleation processes are unknown. Using in situ IR spectroscopy on nucleating nanoparticles, we show that a liquid-like behavior of nucleating nanoparticles in the Al–O system induces immiscible phase segregation. In an oxygen-deficient atmosphere, aluminum oxide nanoparticles formed with a unique shape composed of an Al metal head and an anisotropic Al_2O_3 crystalline tail. The anisotropic nanoparticles are larger than Al_2O_3 nanoparticles formed in a sufficient oxygen condition. Fewer nuclei may be available in the supersaturated gas, indicating that homogeneous nucleation is initiated by oxygen-bearing species. The nuclei grow by incorporation of Al-bearing species, changing the composition of the particle as a whole toward an Al-rich material. In situ IR measurements revealed that the degree of anisotropy continues to increase, suggesting that oxygen-bearing species also formed by oxidation on the surface of the molten Al-rich head. The scenario is supported by quantum-chemical calculations indicating that oxygen-deficient $(AlO)_n$ clusters as few as 16 molecules induce aggregation of Al atoms. Because Al metal has a significantly lower melting temperature than Al_2O_3, the immiscibility of the nucleating nanoparticles leads to vapor–liquid–solid growth. Astronomical implication will be given in the presentation.

Crystal growth hysteresis in birth-and-spread mechanism

*Hitoshi Miura[1]

1. Graduate School of Natural Sciences, Department of Information and Basic Science, Nagoya City University

Crystal growth hysteresis is a remarkable phenomenon induced by impurities: the crystal growth velocity when the driving force (supersaturation or supercooling) is increased is different from that when it is decreased. It has been considered that the growth hysteresis is caused by slow adsorption of impurities onto the crystal surface. On the surface, there are steps in atomic scale that advance independently due to continuous incorporations of growth units, therefore the surface is grown layer by layer (layer-by-layer growth mechanism). The step advancement is inhibited by impurities adsorbed on the surface. However, the amount of the adsorbed impurities is also affected by the step passages: frequent step passages reduce the amount of adsorbed impurities. The competition between two timescales —impurity adsorption timescale and time interval of surface-updating (terrace exposure time)— causes complex nonlinear phenomena such as crystal growth hysteresis.

The mechanism of the crystal growth hysteresis was elucidated by a mean field theory. Punin & Artamonova [1] and Miura & Tsukamoto [2] formulated the following two effects —inhibition of step advancement by adsorbed impurities (pinning effect) and removal of adsorbed impurities by step passages (impurity sweeping)— to clarify the existence of multiple steady solutions that satisfies both of two formulas at a certain range of supersaturation. In the case of constant step interval, numerical simulations based on a phase-field method demonstrated that the growth hysteresis emerges as predicted by the mean field theory even when the physical quantities are fluctuated around these averages [3]. The phase-field simulations also confirmed the emergence of hysteresis in the case that the surface is grown by a screw dislocation [4]. However, the growth hysteresis has not been investigated in the case that the surface is grown by two-dimensional nucleation (birth-and-spread mechanism), which is another mechanism to generate new steps on the surface. The birth-and-spread growth dominates the spiral growth at high supersaturation, so it is important to elucidate the impurity-induced effect for that. In this study, we theoretically investigate the growth hysteresis in the birth-and-spread growth mechanism.

At first, we formulated the interdependence between the step velocity and the amount of adsorbed impurities based on the mean field theory, in the same way in the case of the spiral growth. As the result, we found that multiple steady solutions exist at a certain range of supersaturation. This suggests that the growth hysteresis can emerge even in the birth-and-spread growth in principle. At second, we carried out the phase-field calculation with the equivalent condition of the mean field theory. We confirmed the emergence of growth hysteresis in down-and-up cycles of supersaturation. In addition, we found that the range in supersaturation at which the growth hysteresis is observed depends on the rate of supersaturation variation: slow change in supersaturation makes the hysteresis behavior unclear.

Theoretical Model of Crystallization through Homogeneous Nucleation in Water Droplets

*Kyoko Kitakami Tanaka[1], Yuki Kimura[2]

1. Tohoku University, 2. Hokkaido University, Institute of Low Temperature Science

The crystallization process of water droplets is not only fundamentally important, but is also climate-sensitive and hence relevant to urgent problems such as climate change. However, water crystallization in environments such as cirrus clouds is difficult to explore by conventional experimental approaches. Analytical models of the crystallization process can assist our understanding of ice nucleation and predict the crystallization processes in environments that cannot be replicated in the laboratory. Experimentally, micrometer-sized droplets are known to crystallize at approximately 235 K, regardless of cooling rate and experimental method. However, the crystallization temperature of smaller (nanometer-sized) droplets suddenly drops at high cooling rates (~10^5 K/s). At very high cooling rates (10^{6-7} K/s), liquid water droplets vitrify rather than crystallize. A model that explains all of these characteristics is thus far lacking. Motivated by this knowledge gap, we construct a new model of water-droplet crystallization that evolves the homogenous nucleation and crystal growth in water droplets during cooling (Tanaka & Kimura, PCCP, 21, 2410, 2019). The crystallization process depends on the surface energy at the liquid–solid interface (which determines the liquid-to-sold nucleation rate) and the activation energy of molecular diffusion through the liquid. The model extends our previous model (Tanaka et al. J. Crystal Growth, 310, 1281, 2008) by incorporating the droplet size-dependence of the crystallization process. Especially, smaller droplets begin crystallizing later than larger droplets because they are less likely to form a nucleating center in a given time. We also try two diffusion coefficients: the diffusivity of amorphous ice (ASW) and the diffusivity of supercooled liquid (SCL) water. The model well replicated the results of previous laboratory experiments, especially, the different responses of the crystallization temperatures of the micrometer- and nanometer-sized particles as functions of cooling rate. At low cooling rates, the ASW and SCL diffusivities gave the same results for micrometer-sized particles, because these particles crystallize at temperatures around the homogenous nucleation temperature (235 K), where both diffusivities are identical. However, for nanometer-sized particles, the crystallization temperature is lower and the SCL diffusivity is more accurate than the ASW diffusivity. Calculations on small droplets also provide low-temperature information at high cooling rates, which are sparsely acquired in experiments. The critical cooling rate of vitrification was predicted as 10^{7-8} K/s with SCL diffusivity, consistent with the experimental rates.

Mean Height of the Self-Assembled Faceted Macrosteps: Steady Crystal Growth/Dissolution in a Reaction- (Interface-) Limited Process

*Noriko Akutsu[1]

1. Faculty of Engineering, Osaka Electro-Communication University

Faceted macrosteps are considered to play critical roles in some reaction- (interface-) limited processes of crystal growth/dissolution [1]. For the diffusion-limited crystal growth, step dynamics of macrosteps or bunched steps with rough side surfaces has been studied theoretically and experimentally [2,3]. Whereas, for the reaction-limited crystal growth/dissolution, the step dynamics of macrosteps has not yet been studied sufficiently.

In this paper, the step dynamics of faceted macrosteps in a reaction- (interface-) limited crystal growth/dissolution is studied theoretically by using a Monte Carlo method for the non-conserved systems. The microscopic model for this Monte Carlo study is the restricted solid-on-solid model with a point-contact step-step attraction (p-RSOS model) [4]. Here, the “restricted” means the height difference between the nearest neighbor sites is restricted to {0, ±1}. The step-step attraction is assumed to be the energy gain ε_{int} by forming a bond between the neighboring steps at the meeting point. The eminent point of this p-RSOS model is that the reliable surface tension (surface free energy per unit normal area) can be calculated at equilibrium by using the density-matrix renormalization-group (DMRG) method [5]. The polar graph of the surface tension (the Wulff figure) calculated by the DMRG method is shown in Fig. 1 [6]. A faceted macrostep is self-organizing at equilibrium because of the discontinuous surface tension resulting from the microscopic step-step attraction [6].

In the non-equilibrium steady state, we found that the height of the macrostep decreases as the driving force of dissolution increases [7]. In the step-faceting zone (Fig. 1 (a)), elementary steps detach from the faceted macrostep by way of the two-dimensional (2D) nucleation at the upper edge of the faceted macrostep on the (001) and the (111) surfaces. Near equilibrium, since the kink densities of the (001) and the (111) surfaces are few, the faceted surfaces cannot move. For the large driving force, the vicinal surface roughens kinetically.

In-situ observation of natural snow crystals by optical techniques

*Yuki Kimura[1], Tomoya Yamazaki[1], Takao Maki, Yoshinori Furukawa[1]

1. Institute of Low Temperature Science, Hokkaido University

Natural snow crystals excite our interest because of several reasons such as its beautiful geometry, its symmetricity and variety. Relationship between geometry of snow crystal and its formation environment (temperature and humidity) was investigated by Ukichiro Nakaya and has been well known as Nakaya diagram. After that, the reason of why snow crystal changes their geometry, such as platy, needle and column, with slight difference of temperature and humidity, and the growth mechanisms have been studied [e.g., Sanchez et al. *PNAS* 114 (2017) 227; Brumberg et al., *PNAS* 114 (2017) 5349]. Nevertheless, there are several questions have been remained. For instance; origin of twelve-fold snow can be explained not only by a twin but by contribution of secondary prism plane; and origin of characteristic pattern can be appeared not only by intrinsic defects but also by a result of growth.

To understand snow crystals more, we have performed in-situ observation of natural snow crystals and its sublimation/regrowth experiments in an environment controllable cell under originally designed optical systems at the base of Asahi-dake in the Taisetsu area, Hokkaido, Japan for 15 nights in total for five winter seasons from 2015 to 2019. The environment controllable cell has a Peltier cooling unit, which has a water vapor source with a heater and a chromel-alumel thermocouple on top, windows for optical observation, capillary to handle a snow crystal and a platinum resistance temperature detector for temperature measurement of the cell. The optical systems consist of the modified Mach–Zehnder-type interferometer (Maki-type laser interferometer), the Michelson-type white-light interferometer microscope with a long working distance, the optimized color-filtered optical microscopes, a polarized optical microscope and so on.

We set the optical systems in a snow-lab, which is a handmade igloo-like snow room, also works as a good sound and vibration absorber. Temperature in the Taisetsu area and inside the snow-lab are around -10 to -20°C and -5 to -13°C, respectively. Higher temperature in the snow-lab than outside is due to observers and experimental systems. One advantage of the snow-lab is maintaining the humidity close to 100% because all the walls of the snow-lab have been made of snow.

We collected snow crystals directly on a black felt just outside the snow-lab and selected a snow crystal, which was put onto a glass plate for general observations of the shape and surface textures. A snow crystal is also put onto a tip of a glass rod of 1.4 mm in diameter for the Maki-type laser interferometer. Rates for sublimation and regrowth of a snow crystal were successfully measured in thickness and lateral direction simultaneously at a certain environment, where supersaturation was controlled using the environment controllable cell. In addition, surface topography of both surfaces of a snow crystal, which was put onto a Y-shaped metallic holder, could be observed using the Michelson-type white-light interferometric microscope. Here, we will summarize our attempts of these in-situ observations and the

Visualization of local environment around forming/dissolving carbonate minerals with the fluorescent probe

*Jun Kawano[1], Kotaro Osawa[2], Takashi Toyofuku[3,4], Yukiko Nagai[4,5], Jun-ya Tanaka[6], Takaya Nagai[1]

1. Faculty of Science, Hokkaido University, 2. School of Science, Hokkaido University, 3. JAMSTEC, 4. Tokyo University of Marine Science and Technology, 5. National Museum of Nature and Science of Tokyo, 6. Graduate School of Science, Hokkaido University

To understand the formation or dissolution mechanism of crystal in aqueous solution, it should be important to analyze the local condition of solution just around dissolving or growing crystal. Recently, we have succeeded to visualize the distribution of pH and ionic concentration around carbonate minerals dissolving in inorganic environment, by using the fluorescent probe. In the present study, we have tried to apply this technique to the formation process of calcium carbonate.
Calcium carbonate was synthesized by the counter diffusion method, in which calcium chloride and sodium carbonate solutions were counter-diffused through an agarose gel matrix containing the fluorescent probe like 8-hydroxypyrene-1,3,6-trisul-fonic acid (HPTS). We observed under a microscope that pH in the middle part of gel first increased gradually with time and turn downward after crystals formed. The counter diffusion method with gel media for the carbonate synthesis has attracted attention as a valid tool in the study of biomineralization because the calcification sites in some organisms were recently suggested to have the features of a highly viscous sol or gel matrix. Therefore, the detail observation of the local condition around forming calcium carbonate in gel matrix could provide new insights into the knowledge of biomineralization mechanisms.

Influence of Ammonium Nitrate on Crystallization of Norsethite from Aqueous Solution

*Itaru Echigo[1], Harutoshi Asakawa[1], Hiroshi Uneda, Ryuichi Komatsu[1]

1. Graduate School of Science and Technology for Innovation Yamaguchi University

Since norsethite $BaMg(CO_3)_2$ has birefringence higher than previous piezoelectric and optical crystals, we expect that norsethite can be used as new acousto-optics andwavelength-conversion devices. However, solubility of norsethite is low and it is difficult to control supersaturation. Hence growth of norsethite is difficult. Then, we investigated effects of ammonium nitrate NH_4NO_3 on crystallization of norsethite from aqueous solution. With increasing NH_4NO_3, solubility of norsethite increased. When concentration of NH_4NO_3 reached to 1M, solubility of norsethite became 30 times larger than without the addition of NH_4NO_3 .With further increasing NH_4NO_3, solubility of norsethite remained constant. Next, we measured induction periods of norsethite, when 1M NH_4NO_3 was added. Then, we could confirm norsethite just after mixed at 70°C by XRD measurement only in the case of the addition of 1M NH_4NO_3. Thus, we revealed that the addition of NH_4NO_3 also accelerates norsethite crystallization. This study concluded that addition of NH_4NO_3 is valid for the growth of norsethite.

Direct observation of zeolite nucleation from compacted bentonite under hyperalkaline condition

*Hisao Satoh[1], Mayumi Takazawa[2], Daisuke Hayashi[3], Masaya Ida[3]

1. Naka Energy Research Laboratory, Mitsubishi Materials Corporation, 2. Mitsubishi Materials Corporation, 3. Radioactive Waste Management Funding and Research Center

Since dissolution issue of smectite arose on engineered barrier system using bentonite (absorbent clay from shale consisting mostly of smectite) for radioactive waste repository for past several decades, smectite studies are focusing on (1) dissolution kinetics [1, 2], (2) hydraulic property of smectite in various states (gel to compacted [3]) and (3) alterations into the other clay and zeolites [4]. Former two issues are closely related to undersaturation of pore water and reactive surface area of smectite grains as a function of density. As the result, the pore water produced from locally dissolved smectite can gain the supersaturation with respect to potential secondary phases. The third one, the alteration, can finally lead the total thermodynamic system to the next equilibrium state consisting of secondary phases.

For understanding the alteration, we had carried out direct observation on pure montmorillonite and bentonite composed of montmorillonite, quartz and albite with or without minor amount of zeolite additive under Na, K and Ca hydroxide solution at 70 ˚C (pH 12.1) [2]. Two methods were used: (1) interferometric measurement of montmorillonite dissolution [2, 5]; (2) direct optical observation of new precipitations. The former gave the rate as a function of density, the latter provided information about nucleation. Sooner or later, the pore water likely attained to local equilibrium, as long as solution flow is limited by compaction.

Differed from previous result, dissolution of pure montmorillonite in the rates varied from 1E-9 (density < 0.01) to 1E-13 mol/m^2/s (density > 1.2) [2] did not always derive precipitation of secondary phases. However, the system, bentonite was not the case. Bentonite especially with minor amount of zeolite caused prominent nucleation of secondary zeolite after a long induction period (weeks) after solution-flow was shut-off.

This alteration behavior could be interpreted with heterogeneous nucleation model. Interfacial free energy, $\gamma_{S/L}$ between secondary phases and alkaline solution was evaluated by wetting angle measurements. There are two end-members such as low and high silica zeolite, those are analcime (ANA: $NaAlSi_2O_6$; Si/Al = 2.0) and clinoptilolite (CLP: $(NaKCa)_3Al_3Si_{15}O_{36}$; Si/Al = 5.0). Their $\gamma_{S/L}$ were measured to be and 50.54 and 71.31 mJ/m^2, respectively. Chemical equilibrium calculation predicts that CLP is the most stable phase in this reaction system. Microanalyses, however, identified the product as phillipsite (PHI: $(NaKCa)_4Al_4Si_{12}O_{32}$; Si/Al = 3.0) as intermediate composition between CLP and ANA or laumontite (LAU: $CaAl_2Si_4O_{12}$: Si/Al = 2.0). When PHI was seeded to the bentonite system, secondary zeolite was PHI. Also, the observed induction periods (Inl) mostly correlate with supersaturations ($1/S^2$). However, the I sometimes became longer than that by CLP seeding. Seed crystal with higher $g_{S/L}$ such like CLP has lower solubility and likely promotes PHI nucleation more than CLP itself. Fast PHI nucleation by CLP-seeding was an unusual. Direct observation could give us an interesting information. During the early observation in the presence of CLP seed recognized two-step process in which spherical objects were growing in ten times faster rate (5.6E-3 nm/s) than the later phase evolving to faceted (5.1E-2 nm/s). This may have contributed to shortening the induction. Such an amorphous phase is often observed especially at room temperature reaction.

[M-IS10] Interface- and nano-phenomena on crystal growth and dissolution

convener:Yuki Kimura(Institute of Low Temperature Science, Hokkaido University), Hitoshi Miura(Graduate School of Natural Sciences, Department of Information and Basic Science, Nagoya City University), Hisao Satoh(Naka Energy Research Laboratory, Mitsubishi Materials Corporation), Katsuo Tsukamoto(Graduate School of Engineering, Osaka University)

Recent developments of observations in nano-scale opened a detail discussion concerning mechanisms of crystal growth and dissolution based on interface phenomena including dynamics. In this session, growth and dissolution mechanisms of crystals will be discussed focusing on interface phenomena of minerals in the fields of biological origin, global environment, planets and space in addition to general minerals.

Theoretical Model of Crystallization through Homogeneous Nucleation in Water Droplets

*Kyoko Kitakami Tanaka[1], Yuki Kimura[2]

1. Tohoku University, 2. Hokkaido University, Institute of Low Temperature Science

The crystallization process of water droplets is not only fundamentally important, but is also climate-sensitive and hence relevant to urgent problems such as climate change. However, water crystallization in environments such as cirrus clouds is difficult to explore by conventional experimental approaches. Analytical models of the crystallization process can assist our understanding of ice nucleation and predict the crystallization processes in environments that cannot be replicated in the laboratory. Experimentally, micrometer-sized droplets are known to crystallize at approximately 235 K, regardless of cooling rate and experimental method. However, the crystallization temperature of smaller (nanometer-sized) droplets suddenly drops at high cooling rates (~10^5 K/s). At very high cooling rates (10^{6-7} K/s), liquid water droplets vitrify rather than crystallize. A model that explains all of these characteristics is thus far lacking. Motivated by this knowledge gap, we construct a new model of water-droplet crystallization that evolves the homogenous nucleation and crystal growth in water droplets during cooling (Tanaka & Kimura, PCCP, 21, 2410, 2019). The crystallization process depends on the surface energy at the liquid–solid interface (which determines the liquid-to-sold nucleation rate) and the activation energy of molecular diffusion through the liquid. The model extends our previous model (Tanaka et al. J. Crystal Growth, 310, 1281, 2008) by incorporating the droplet size-dependence of the crystallization process. Especially, smaller droplets begin crystallizing later than larger droplets because they are less likely to form a nucleating center in a given time. We also try two diffusion coefficients: the diffusivity of amorphous ice (ASW) and the diffusivity of supercooled liquid (SCL) water. The model well replicated the results of previous laboratory experiments, especially, the different responses of the crystallization temperatures of the micrometer- and nanometer-sized particles as functions of cooling rate. At low cooling rates, the ASW and SCL diffusivities gave the same results for micrometer-sized particles, because these particles crystallize at temperatures around the homogenous nucleation temperature (235 K), where both diffusivities are identical. However, for nanometer-sized particles, the crystallization temperature is lower and the SCL diffusivity is more accurate than the ASW diffusivity. Calculations on small droplets also provide low-temperature information at high cooling rates, which are sparsely acquired in experiments. The critical cooling rate of vitrification was predicted as 10^{7-8} K/s with SCL diffusivity, consistent with the experimental rates.

Mean Height of the Self-Assembled Faceted Macrosteps: Steady Crystal Growth/Dissolution in a Reaction- (Interface-) Limited Process

*Noriko Akutsu[1]

1. Faculty of Engineering, Osaka Electro-Communication University

Faceted macrosteps are considered to play critical roles in some reaction- (interface-) limited processes of crystal growth/dissolution [1]. For the diffusion-limited crystal growth, step dynamics of macrosteps or bunched steps with rough side surfaces has been studied theoretically and experimentally [2,3]. Whereas, for the reaction-limited crystal growth/dissolution, the step dynamics of macrosteps has not yet been studied sufficiently.

In this paper, the step dynamics of faceted macrosteps in a reaction- (interface-) limited crystal growth/dissolution is studied theoretically by using a Monte Carlo method for the non-conserved systems. The microscopic model for this Monte Carlo study is the restricted solid-on-solid model with a point-contact step-step attraction (p-RSOS model) [4]. Here, the “restricted” means the height difference between the nearest neighbor sites is restricted to {0, ±1}. The step-step attraction is assumed to be the energy gain ε_{int} by forming a bond between the neighboring steps at the meeting point. The eminent point of this p-RSOS model is that the reliable surface tension (surface free energy per unit normal area) can be calculated at equilibrium by using the density-matrix renormalization-group (DMRG) method [5]. The polar graph of the surface tension (the Wulff figure) calculated by the DMRG method is shown in Fig. 1 [6]. A faceted macrostep is self-organizing at equilibrium because of the discontinuous surface tension resulting from the microscopic step-step attraction [6].

In the non-equilibrium steady state, we found that the height of the macrostep decreases as the driving force of dissolution increases [7]. In the step-faceting zone (Fig. 1 (a)), elementary steps detach from the faceted macrostep by way of the two-dimensional (2D) nucleation at the upper edge of the faceted macrostep on the (001) and the (111) surfaces. Near equilibrium, since the kink densities of the (001) and the (111) surfaces are few, the faceted surfaces cannot move. For the large driving force, the vicinal surface roughens kinetically.

Since norsethite $BaMg(CO_3)_2$ has birefringence higher than previous piezoelectric and optical crystals, we expect that norsethite can be used as new acousto-optics andwavelength-conversion devices. However, solubility of norsethite is low and it is difficult to control supersaturation. Hence growth of norsethite is difficult. Then, we investigated effects of ammonium nitrate NH_4NO_3 on crystallization of norsethite from aqueous solution. With increasing NH_4NO_3, solubility of norsethite increased. When concentration of NH_4NO_3 reached to 1M, solubility of norsethite became 30 times larger than without the addition of NH_4NO_3 .With further increasing NH_4NO_3, solubility of norsethite remained constant. Next, we measured induction periods of norsethite, when 1M NH_4NO_3 was added. Then, we could confirm norsethite just after mixed at 70°C by XRD measurement only in the case of the addition of 1M NH_4NO_3. Thus, we revealed that the addition of NH_4NO_3 also accelerates norsethite crystallization. This study concluded that addition of NH_4NO_3 is valid for the growth of norsethite.

Direct observation of zeolite nucleation from compacted bentonite under hyperalkaline condition

*Hisao Satoh[1], Mayumi Takazawa[2], Daisuke Hayashi[3], Masaya Ida[3]

1. Naka Energy Research Laboratory, Mitsubishi Materials Corporation, 2. Mitsubishi Materials Corporation, 3. Radioactive Waste Management Funding and Research Center

Since dissolution issue of smectite arose on engineered barrier system using bentonite (absorbent clay from shale consisting mostly of smectite) for radioactive waste repository for past several decades, smectite studies are focusing on (1) dissolution kinetics [1, 2], (2) hydraulic property of smectite in various states (gel to compacted [3]) and (3) alterations into the other clay and zeolites [4]. Former two issues are closely related to undersaturation of pore water and reactive surface area of smectite grains as a function of density. As the result, the pore water produced from locally dissolved smectite can gain the supersaturation with respect to potential secondary phases. The third one, the alteration, can finally lead the total thermodynamic system to the next equilibrium state consisting of secondary phases.

For understanding the alteration, we had carried out direct observation on pure montmorillonite and bentonite composed of montmorillonite, quartz and albite with or without minor amount of zeolite additive under Na, K and Ca hydroxide solution at 70 ˚C (pH 12.1) [2]. Two methods were used: (1) interferometric measurement of montmorillonite dissolution [2, 5]; (2) direct optical observation of new precipitations. The former gave the rate as a function of density, the latter provided information about nucleation. Sooner or later, the pore water likely attained to local equilibrium, as long as solution flow is limited by compaction.

Differed from previous result, dissolution of pure montmorillonite in the rates varied from 1E-9 (density < 0.01) to 1E-13 mol/m^2/s (density > 1.2) [2] did not always derive precipitation of secondary phases. However, the system, bentonite was not the case. Bentonite especially with minor amount of zeolite caused prominent nucleation of secondary zeolite after a long induction period (weeks) after solution-flow was shut-off.

This alteration behavior could be interpreted with heterogeneous nucleation model. Interfacial free energy, $\gamma_{S/L}$ between secondary phases and alkaline solution was evaluated by wetting angle measurements. There are two end-members such as low and high silica zeolite, those are analcime (ANA: $NaAlSi_2O_6$; Si/Al = 2.0) and clinoptilolite (CLP: $(NaKCa)_3Al_3Si_{15}O_{36}$; Si/Al = 5.0). Their $\gamma_{S/L}$ were measured to be and 50.54 and 71.31 mJ/m^2, respectively. Chemical equilibrium calculation predicts that CLP is the most stable phase in this reaction system. Microanalyses, however, identified the product as phillipsite (PHI: $(NaKCa)_4Al_4Si_{12}O_{32}$; Si/Al = 3.0) as intermediate composition between CLP and ANA or laumontite (LAU: $CaAl_2Si_4O_{12}$: Si/Al = 2.0). When PHI was seeded to the bentonite system, secondary zeolite was PHI. Also, the observed induction periods (Inl) mostly correlate with supersaturations ($1/S^2$). However, the I sometimes became longer than that by CLP seeding. Seed crystal with higher $g_{S/L}$ such like CLP has lower solubility and likely promotes PHI nucleation more than CLP itself. Fast PHI nucleation by CLP-seeding was an unusual. Direct observation could give us an interesting information. During the early observation in the presence of CLP seed recognized two-step process in which spherical objects were growing in ten times faster rate (5.6E-3 nm/s) than the later phase evolving to faceted (5.1E-2 nm/s). This may have contributed to shortening the induction. Such an amorphous phase is often observed especially at room temperature reaction.

The mineral assemblages on asteroids are useful to constrain the aqueous environments, the temperature (T), pressure (P), water to rock ratio (W/R), and bulk chemical composition, existed in them or in their parent bodies. Near- to mid-infrared (IR) reflectance spectroscopy of asteroids contains the information of the surficial minerals in their characteristic absorption features, spectral slopes, and overall brightness or darkness. Recent remote-sensing of asteroids by Hayabusa2, OSIRIS-Rex, and Dawn spacecrafts as well as telescopic observations by AKARI infrared space telescope provided detailed IR reflectance spectra of many types of asteroids. These observations would allow us to discuss the diversity of asteroids in their principle parameter space of paleo-aqueous environments: T, P, W/R, and the bulk chemical compositions. This study aims to connect the observed IR spectra of asteroids to the original bulk compositions and T-Pconditions of them or their parent bodies. We performed a series of chemical equilibrium calculations to obtain the mineral compositions. We computed the model IR reflectance spectra from the obtained mineral compositions. The chemical equilibrium calculations assumed the rocky bulk compositions of CV chondrites. We treated W/R as a parameter (0.2-10). We fixed the relative abundance of volatiles to water. The model IR reflectance spectra were calculated by adopting the radiative transfer theory for granular surfaces. The reflectance of a model mineral assemblage was computed from the weighted average of the single scattering albedos (SSAs) of endmembers. We found that the model reflectance spectra vary according to the equilibrium mineral compositions. Reducing W/R led to the darkening in overall reflectance as the dominant minerals change from bright carbonate to serpentine, gibbsite, and dark phases: pyrite, troilite, magnetite, and organics. The change in the dominant phase is visible in the characteristic absorption features: carbonate at 3.5 micro m and 4.0 micro m and serpentine at 2.7-2.8 micro m. We note that, though carbonate has a broad absorption from 2.7 to 3.2 micro m, the absorption feature of serpentine is sharp and distinguishable.Ammonia-bearing saponite more than a few wt.% shows its characteristic absorption feature at 3.1micro m in the reflectance of mixture. In this presentation, we discuss the implications for Haybusa2 and AKARI observation results.

Estimation of formation mechanism and morphological condition in calcite concretion

*Takayuki Ihara[1], Sin-iti Sirono[1]

1. Nagoya University

Iron oxide concretions were discovered on Meridiani plain by Mars explorer opportunity. The concretion found on Mars is called blueberry, it is spherical and the composition is mainly iron oxide. Concretions similar to them are found on the Navajo sandstone stratum in the United States of Utah , and is Gobi Desert, Mongolia. They are called Fe-oxide concretion. Both Fe-oxide concretion and blueberry have a spherical shell structure of iron oxide. [1] performed field work and analyzed element maps to investigate the mechanism of formation of Fe-oxide concretion of Utah and Gobi. As a result, [1] showed the formation mechanism of spherical Fe-oxide concretion as follows. In an eolian layer spherical calcite concretions were formed as a precursor. Second, acidic groundwater containing iron ions flows into it and reacts with $CaCO_3$ and iron precipitates in a spherical shell shape. Furthermore, [1] indicated that the iron contraction of Mars is a similar mechanism. However, the formation mechanism of spherical calcite concretion as a precursor is not known. If we can clarify the formation mechanism, we can restrict the ancient environment of Earth and Mars.

In this study, we focused on calcite concretion produced in an eolian layer. Calcite concretion of the eolian layer is produced in three forms, spherical, plate-like, fish egg (globular gathering state). It is aimed to clarify the forming mechanism and the forming conditions in indoor experiments. We will report the current experiment status. $CaCO_3$ is precipitated by evaporation in Utah's sand. In order to increase the solubility of the $CaCO_3$ aqueous solution, CO_2 is blown into the solvent. $Ca(HCO_3)_2$ is made in the solvent. By evaporating it $CaCO_3$ is precipitated in the layer of sand to generate a concretion. Then $Ca(HCO_3)_2$ is made in the solvent. It evaporates to precipitate $CaCO_3$ in the layer of sand.Utah's sand has an average particle diameter of 150 μm (Kawakami 2015). The minimum size of calcite concretion and Fe-oxide concretion discovered on Earth is several mm in diameter [2] and experiments are conducted with the aim of creating the size. $CaCO_3$ concentration and evaporation rate are changed as parameters. X-ray CT is used to analyze $CaCO_3$ in the experimental layer. In order to investigate whether $CaCO_3$ and sand can be distinguished from X-ray CT images, a experiment was conducted when $CaCO_3$ precipitated in the sand layer. The simulated sample was prepared by mixing sand from Navajo sandstone and a few mg of $CaCO_3$. As a result of the X-ray CT experiment, it was confirmed that a $CaCO_3$ having a size of 0.50 mm can be discriminated at a resolution of 0.019mm/pixel. It was also found that $CaCO_3$ and sand are close in density, so it can not be determined that $CaCO_3$ is not sufficiently larger than the average particle diameter of sand 150μm.

In the future, we will analyze the samples prepared in the experiment and try experiments under various conditions by adding experimental parameters as well as $CaCO_3$ concentration, evaporation rate and sand filling rate. Then we will clarify the formation mechanism and the morphological condition of calcite concretion in the eolian layer.

Reconstructing groundwater hydrology and water-rock reactions around Gale Crater on early Mars

*Natsumi Noda[1,2], Yasuhito Sekine[1], Shuya Tan[1,2], Takazo Shibuya[3], Hidenori Genda[1]

1. Earth-Life Science Institute, Tokyo Institute of Technology, 2. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, 3. Department of Subsurface Geobiological Analysis and Research, Japan Agency for Marine-Earth Science and Technology

NASA's Mars Science Laboratory Rover, Curiosity, has provided key information on geochemistry and mineralogy of the lacustrine sediments deposited within Gale Crater on early Mars(e.g. Grotzinger et al. 2015, Rampe et al. 2017). Gale's lacustrine mudstones of Murray Formation are characterized by authigenic depositions of high levels of silica (e.g., opal CT and amorphous silica) together with iron oxides (e.g., magnetite and hematite), suggesting inputs of dissolved SiO_2 and Fe^{2+} into the early Gale lake (Hurowitz et al. 2017). One possible source of dissolved SiO_2 and Fe^{2+} is upwelling groundwater. However, little is known about the conditions of both climate and water table capable of upwelling groundwater into Gale Crater. Additionally, the chemical compositions of groundwater on early Mars, particularly the determining factors of concentrations of dissolved SiO_2 and Fe^{2+}, have been poorly constrained.

Here, we perform both hydrological modeling and hydrothermal experiments to interpret the observations. Based on the simulation and experimental results, we discuss the climate, groundwater hydrology, and input fluxes of dissolved SiO_2 and Fe^{2+} of Gale lakes.

In the hydrological modeling, we perform three-dimensional hydrological simulations for the area surrounding Gale Crater using GETFLOWS, which deals with fully-coupled surface and subsurface flows based on the hydro-geophysical equations. We find two modes of the lake distribution and groundwater flow around Gale. One is the high-evaporation mode where multiple shallow lakes can appear at local topographic lows owing to vigorous upwelling of groundwater under (semi-)arid climate conditions. The other is the low-evaporation mode where lake(s) exists only at the lowest place(s) under relatively humid climate conditions. To explain both a closed-basin lake within Gale Crater and some lakes around Gale, the high-evaporation mode is most likely to have occurred on early Mars. Our results suggest (semi-)arid climate conditions around Gale with a shallow water table. Under the arid climate conditions, evaporation of lake water would have caused effective upwelling of groundwater. Given thermal gradient within the crust, such upwelled groundwater would have experienced hydrothermal reactions with the crustal rocks.

In the hydrothermal experiments, we simulate high-temperature water-rock reactions between groundwater and Martian crustal rocks. Hydrothermal reactions at 200ºC between a synthesized Martian rock analog and fluids are performed using a Dickson-type apparatus. Various secondary minerals, such as analcime, quartz, albite, Fe(Mg-)saponite, Fe(Mg-)serpentine, and trace carbonates are also formed via the hydrothermal reactions. We find that dissolved SiO_2 concentration (1–10 mM) is buffered by dissolution of quartz; whereas, that of Fe^{2+} (~10^{-3} mM) is likely controlled by dissolution of Fe-carbonate (siderite).

Combining these simulation and experimental results, we estimate the input fluxes of dissolved SiO_2 and Fe^{2+} contained in upwelled groundwater into Gale lakes. The flux of dissolved SiO_2 corresponds to ~0.02–0.2 mm/year of the deposition rate of silica, implying that the parallel laminae of the lacustrine

©2019. Japan Geoscience Union. All Right Reserved.

mudstone(Grotzinger et al. 2015) may be varve. This further suggests ~10^5 years of warming periods to explain the thickness of Murray Formation. Upwelling groundwater might have also provided Fe^{2+} into the lake, leading to formations of Fe oxides and H_2. Our results suggest that low-latitude deep craters, including Gale, would have played key roles in upwelling deep groundwater at arid climates in the global hydrological cycles, providing reductants and greenhouse effect gas to the surface of early Mars.

Habitable zone for a land planet

*Takanori Kodama[1], Hidenori Genda[2], Ryouta O'ishi[3], Ayako Abe-Ouchi[3]

Most of the studies for habitable planets have focused on Earth-like planets with globally abundant water on the planetary surface. Liquid water vaporizes entirely when planets receive the insolation above a certain critical value, which is called runaway greenhouse threshold. On the other hand, the planetary climate state lapses into a snowball state when planets receive insolation below a certain value, which is called the complete freezing threshold. The habitable zone, in which planets can maintain liquid water on their surface for a long term, is determined by these thresholds.

Abe et al. (2011) focused on so-called land planets with a very small amount of water, and investigated these thresholds using a three-dimensional general circulation model. As results, they found that land planets have a wider habitable zone than Earth-like planets have. However, it is not enough to understand the relationship between the distribution of water and the climate because their range of the amount of water is extremely narrow, leading the almost same distribution of liquid water on the planetary surface.

We assumed various types of the surface water distribution, and investigated the effect of those on both the runaway greenhouse threshold and the complete freezing threshold for Earth-sized planets using a three-dimensional general circulation model. We consider the surface water distributions as longitudinally uniform water distribution and a 1-bar atmosphere whose composition is similar to the current Earth’s atmosphere. As results, both thresholds change gradually depending on the distribution of surface water. Additionally, they are dominated by the atmospheric circulation which determines the surface condition.

A study on the dependence of ocean planet climate on solar constant: influence of oceanic heat transport in the case of large absorption coefficients of gray atmosphere

*Yuta Kawai[1,2], Yoshiyuki O. Takahashi[1], Masaki Ishiwatari[5], Kensuke Nakajima[3], Shin-ichi Takehiro[4], Hiroki Kashimura[1,6], Seiya Nishizawa[2], Hirofumi Tomita[2], Yoshi-Yuki Hayashi[1,6]

1. Introduction

In order to reveal the diversity of climate realized on planets with water and climate stability, our research group has been exploring climates on idealized planets. Ishiwatari et al. (2007) (INTH07) investigated solar constant dependence of climates on swamp ocean planet using a 3-dimensional atmospheric general circulation model, although oceanic heat transport is not considered. Since oceanic heat transport also affects planetary climates, for example, Rose (2015) (R15) explored climates on a planet globally covered with ocean (referred to as “ ocean planet”, here) with a coupled atmosphere-ocean-sea ice model, and showed the importance of oceanic heat transport for the climates. Recently, as an extension of INTH07, we also have investigated solar constant dependence of ocean planet climates with our coupled model. Representing ocean general circulation obviously changes atmospheric fields. However, the displacement of ice-line is small and there is no qualitative change of climate regime diagram which represents the relation between solar constant and ice-line latitude. We imagine the reason is that the variation of temperature with solar constant in partially ice-covered states obtained from gray radiation setting of INTH07 is quite smaller than that in R15. Therefore, we perform further experiments in the case of large absorb coefficients. In this presentation, the experimental results will be shown.

2. Model and Experimental setup

The model used here is our constructing coupled atmosphere-ocean-sea ice model. The atmosphere model is DCPAM, in which the 3-dimensional primitive equations are solved. Most of the atmospheric setting is same as that in INTH07, except absorb coefficients of water vapor and dry air in the gray radiation scheme are replaced with larger values, 1×10^{-1} and 1×10^{-5} [m^2/kg], respectively. The ocean and sea-ice model are zonally averaged 2-dimensional models. In the ocean model, the hydrostatic Boussinesq equations are solved, and mixing due to mesoscale eddies and convection is parameterized. The sea-ice model is a vertically 1-dimensional thermodynamics model, and the transport is represented by horizontal diffusion. The value of surface albedo is 0.5 if surface temperature is lower than 263 K, otherwise 0, but the value on grid-point is given considered the sub-grid distribution of surface temperature. In addition to experiments with the coupled model, in order to evaluate the effect of oceanic heat transport, we also perform experiments in which dynamic ocean is replaced with slab ocean. The number of atmosphere model grid is 64x32x16. The number of grid points on the ocean and sea ice models is 64x60 and 64, respectively. For most cases, the initial condition is a rest atmosphere and ocean with 280 K, but various solutions are also used. The temporal integration for slab ocean cases is basically performed over about 300 years, and, for dynamic ocean cases, over about 30,000 years with periodically synchronous coupling.

3. Results

©2019. Japan Geoscience Union. All Right Reserved.

By specifying absorb coefficients larger than that in INTH07, features of climate regime diagram are significantly changed. In dynamic ocean experiments, partially ice-covered states are obtained over 1040 ≦ S ≦ 1055 W/m^2, where S is the solar constant. The solar constant at which partially ice-covered states are obtained becomes about 300 W/m^2 smaller and the range of solar constant becomes much narrower. We also confirm the appearance of runaway greenhouse state for S > 1070 W/m^2. The latitudinal extent where large ice-cap instability occurs is wider. Although it is not easy to obtain partially ice-covered state whose ice-line is lower than 40 degrees latitude, we can discover stable partially ice-covered state with about 30 degrees ice-line when initial state and variation of solar constant are carefully chosen. Because this behavior indicates two branches for the partially ice-covered state, similar to that in R15, and we will carefully investigate the existence of solutions with low ice-line latitude. In slab ocean experiments, there are no partially ice-covered states. Therefore, we consider partially ice-covered states in dynamic ocean experiments are maintained by oceanic heat transport. Note that the setting here produces the large variation of temperature with solar constant, as calculations in R15, and the parameter range over which partially ice-covered states are obtained is potentially very narrow. It is possible that the resolution and formulation of models strongly affect the results. To evaluate the probabilities, it is necessary to conduct further experiments using slightly different parameters.

It is believed that Mars underwent drastic climate change, changing its environment from warm and wet to cold and dry. This gives rise to the idea that Mars may have hosted life in the past, and indeed, may do so even today. Atmospheric and water evolution is thus an important key to understanding the history of Martian habitability. Mars must somehow have lost most of its atmosphere and water. The evolution of the Mars environment is thought to have proceeded by some combination of atmospheric escape to space and surface-subsurface adsorption. Especially, a lack of global magnetic field on Mars must have a significant impact to the atmospheric escape. The upper atmosphere is the primary reservoir for atmospheric escape. Owing to the technical difficulties associated with observations, datasets of the upper atmosphere are limited. However, the last decade has seen a renewed interest in the upper atmosphere, thanks to the aggressive explorations by the Mars Reconnaissance Orbiter (MRO), Mars Express(MEX), and Mars Volatile Evolution (MAVEN) missions. Recent studies have highlighted various interesting facts related to the efficient of material/water transport from the lower to upper atmospheric reservoir which have an impact on the atmospheric escape or evolution.

High-altitude (above 60 km) H2O was first identified by SPICAM occultations [Maltagliati et al., 2011, 2013] in the southern summer, which happens to be a dusty season at a solar longitude of 240 degree or later. Chaffin et al. [2017] demonstrated that the high-altitude H2O can considerably increase H escape on the weekly timescale, which can potentially explain the observations. Purpose of this study is to clarify the mechanism for upward transport of H2O into the upper atmosphere and formation of the detached layer of H2O and aerosols, by using multi-spacecraft dataset in order to cover whole altitude range from lower to upper atmosphere.

Here we report the detection of an extensive layer of warm air at altitudes 70-100 km on the night side that we interpreted as the result of combinations of aerosol heating, thermal tides, and/or global circulation. Such a strong warm layer for which the current models have no explanation can maintain temperature to evaporate water ice adsorbed on the aerosols and can form the detached layer of water vapor. We also measured the mesospheric distribution sub-micron aerosols is abundant than our expectation at altitudes 70-100 km. Such a detached layer of aerosol can potentially explain the warm layer, and this implies the importance of aerosols for key processes in the Martian water cycle and climate as a whole. The remarkable heating at altitudes 70-80 km was also confirmed by our dedicated ground-based observations during global dust storm 2018. The new pathway of water loss proposed by this implies much higher loss to space, in addition to the diffuse-limited escape of H2.

Observations of lakes, surface modification by fluvial activities, and cloud formation all indicate that Saturn's moon Titan has the only active hydrological cycles known besides Earth [1]. Hydrocarbons such as methane and ethane condense out of a nitrogen-rich thick atmosphere, and precipitate onto the surface [1]. Methane observed in the atmosphere is continuously destroyed and lost by processes such as photolysis and direct escape [1]. Thereby, the persistence of the methane in the atmosphere is dependent on the availability of a hidden methane reservoir, resupplying the lost methane from the surface [1]. Quantifying the volume of the potential sources of methane resupply is one of the key questions of Titan's hydrological cycles [1].

Previous studies on remote-sensing observations of Titan's surface show that the elevations of some lakes and seas located near the north pole are constant from summer to early winter (corresponding to several Earth's years) within the observational errors, implying a connection with a mutual ground-methane table [2]. The preference of clouds at mid-latitudes over high-latitudes suggests that while surface methane is only observed at high latitudes, there may be a significant subsurface methane table at mid-latitudes that is available for exchange with the atmosphere [3]. The influence of subsurface flow on the hydrological cycle has been studied using a two-dimensional (2D) hydrological model, which treats the subsurface as one box at each location [4]. Thus, the 2D models cannot determine the subsurface hydraulic connection among lakes and oceans. They also cannot quantify the total volume of the subsurface methane reservoir, therefore being unable to estimate the extent of the methane-based hydrological cycles.

Here, we calculate the methane-based hydrological cycles using a surface-subsurface coupled three-dimensional hydrological simulator "GETFLOWS". GETFLOWS calculates surface and subsurface flows in a three-dimensional corner-grid blocks using Darcy's law, law of mass conservation, and Manning's equation. The main input parameters are (1) topography, (2) precipitation and evaporation rates, (3) permeability and porosity of the subsurface, and (4) levels of ground-methane table (i.e., the total methane volume in the subsurface). The topographic data was derived by interpolating the data obtained from the Cassini RADAR using the inverse distance weighting method [5]. The precipitation and evaporation data were applied from previous calculation results using general circulation model (GCM), which show good agreements of cloud formation and distribution with the observations [3,6]. The porosity and permeability values were estimated from the observations of the size of the icy grains on Titan's surface [7]. Using this model, we constrain the ground-methane table through reproducing the size and distribution of the lakes and oceans on Titan's surface as well as seasonal changes in their elevation. We discuss (1) whether the lakes and seas in the north-pole regions are hydraulically connected to the groundwater table, (2) what volume of subsurface liquid methane is active in the hydrological cycles, and (3) whether there is a subsurface transport of methane from the high to the low latitudes.

Inclusion of brine into icy shell of Enceladus

*Ryusuke Nishitani[1], Atsushi Tani[2], Sho Sasaki[1], Jun Kimura[1]

1. Department of Earth and Space Sciences, School of Science, Osaka University, 2. Graduate School Human Development and Environment, Kobe University

Investigation of Enceladus plume by Cassini spacecraft showed not only the existence of a subsurface ocean but also ocean included some salts. On the earth, it is known that sea ice includes brine into grain boundary. Similarly, icy shell of Enceladus seems to include sea water. Inclusion of sea water could cause partial melt in icy layer and could affect the geology and thermal evolution. Cox and Weeks (1975) showed that the effective partition coefficient, the ratio of concentration of sodium chloride in formed ice to that in residual liquid, depended on ice growth velocity. While, Gross et al., (1977) reported forced convection made partition coefficient low. To quantify the amount of brine included into icy shell under various condition, we investigated a partition coefficient of sodium chloride to ice by experiment and simulation.

As an experimental apparatus, unidirectional growth method used by Muraoka et al., (2016) was applied. With this method, plate-like ice can be formed in a cell and growth velocity can be controlled by controlling temperature. Ice was formed at a speed between cm/s in 5 % sodium chloride solution. As a result, effective partition coefficient of sodium chloride to ice was 1 approximately at all ice growth velocity.

To evaluate this value, ice growth in sodium chloride solution was simulated by voronoi dynamics simulation suggested by Kawano and Ohashi (2008). When ice grew under the same condition with the experiment, effective partition coefficient was 1 approximately. Next, we introduced Sherwood number into the simulation. It was found that higher Sherwood number made the effective partition coefficient lower. These results indicate that effective partition coefficient reflects condition of convection. When ice grow velocity is faster than diffusion of sodium chloride, effective partition coefficient is near 1. Since convection was not occur in this experiment, the effective partition coefficient was near 1.
In subsurface ocean of Enceladus, effective partition coefficient might be low due to convection, but in crack like tiger stripe, effective partition coefficient might be high because ice growth velocity seems to be high.

Electron irradiations onto ice-salt mixtures at low temperatures: Implications for chemical evolution and oxidant formation on Europa

*Shuya Tan[2,1], Yasuhito Sekine[2], Tetsuya Hama[3]

1. Department of Earth and Planetary Science, Graduate School of Science, the University of Tokyo, 2. Earth-Life Science Institute, Tokyo Institute of Technology, 3. Institute of Low Temperature Science, Hokkaido University

The ice-rich surface of Europa is known to be irradiated with high-energy particles, such as electron, accelerated by the Jovian strong magnetic field (e.g., Paranicas et al., 2009). The high-energy particle irradiations could have caused particular chemical reactions on the surface, possibly including dissociation of H_2O and subsequent oxidation of surface salts, such as chlorides and sulfates/sulfides (e.g., Carlson et al., 2009; Hand et al., 2011). In addition, sputtering of the surface ice and salts by high-energy particles is proposed to be a major source of the tenuous atmosphere on Europa (e.g., Johnson et al., 2009; Brown and Hill, 1999). However, the detailed chemical reactions on Europa’s surface have been poorly constrained.

Here we construct a novel experimental system for irradiation of electron onto ice and salt (e.g., chloride: NaCl and $MgCl_2$) mixtures at low temperatures. Laboratory experiments on electron irradiation onto NaCl salt have been conducted at low temperatures corresponding to Europa’s surface (e.g., Hand and Carlson, 2015). However, no experiments have been performed to simulate the irradiation of electron onto ice and salt mixtures on Europa. Upon electron irradiation onto ice and chloride mixtures, chloride may be oxidized into perchlorate salts. If the surface materials are provided into the subsurface ocean through crustal recycling (e.g., Hand et al., 2007), perchlorate would become an important oxidant to generated redox disequilibria in the ocean. We report preliminary results on the electron irradiation experiments using the newly-constructed system.

Water-rock reactions in the parent body of Ryugu

*Takazo Shibuya[1], Yasuhito Sekine[2], Sakiko Kikuchi[1], Keisuke Fukushi[3], Tomoki Nakamura[4], Sei-ichiro WATANABE[5]

1. Japan Agency for Marine-Earth Science and Technology, 2. Tokyo Institute of Technology, 3. Kanazawa University, 4. Tohoku University, 5. Nagoya University

The recent remote-sensing observation by Hayabusa2 is providing a large amount of data to unravel the origin of Ryugu. The Near Infrared Spectrometer (NIRS3) onboard Haybusa2 revealed that the IR reflectance of the global surface of Ryugu is extremely low (~0.02) and the spectra include small but clear absorption at 2.72 μm. These findings indicate the great abundance of dark materials and the subordinate amount of hydrous minerals in the surface, respectively. These materials on Ryugu are important clues to constrain the conditions of aqueous alteration such as the temperature experienced by the parent body and the original volatile compositions during accretion stage. In this work, we conducted thermodynamic modeling of chondrite-water reactions under various conditions to establish a model explaining the aqueous alteration of the parent body. In the thermodynamic calculations, a mean composition of CV chondrites was assumed for the initial bulk rock (minor amount of carbon, nitrogen and chlorine are also included) (Pearson et al., 2006; Clay et al., 2017). For the initial fluid, four cases were assumed; CO_2 concentration is 0, 1, 3 and 10 mol% (Cases 1–4, respectively) relative to water while the latter three cases also include NH_3 (0.5%) and H_2S (0.5%) additionally (Mumma and Charnley, 2011). The equilibrium temperature and pressure were assumed to be 0, 100, 200, 300 and 350 ˚C, and vapor pressure of water. In the calculations, pyrene was considered as a representative of polycyclic aromatic hydrocarbon while C1 compounds except CH_4 were included as soluble species (Zolotov, 2012).
The calculations showed that stabilities of hydrous/anhydrous minerals, carbonate, pyrene change with temperature and W/R value. In Case 1 (CO_2-free), the altered chondrite consists of serpentine, troilite and subordinate amount of hydrous/anhydrous minerals (e.g., magnetite, saponite, gibbsite and chlorite) at 0–300 ˚C. However, with increasing temperature above 300 ˚C, olivine and clinopyroxene become major phases as the amounts of serpentine, chlorite and magnetite decrease. At 350 ˚C, olivine becomes the most abundant minerals in conjunction with disappearance of serpentine. Similar temperature dependencies of hydrous mineral stabilities were also shown at low W/R in Cases 2–4 (CO_2 =1–10%) whereas carbonate is predominant at high W/R. Although the total amount of hydrous minerals in the surface of Ryugu is still unconfirmed, the calculation results suggest that the temperature of hydrothermal reactions experienced by Ryugu is lower than approximately 300 ˚C if a certain amount of hydrous minerals are present in the surface rocks. In contrast, if the amount of hydrous minerals is relatively small, higher temperatures (>350 ˚C) may account for the observed IR spectra. In this case, the parent body may have undergone high-temperature hydrothermal reactions that could occur in relatively large body. Otherwise, it is also possible that the parent body underwent instantaneous high-temperature events such as impacts after the aqueous alteration.Regarding the discriminating darkness of Ryugu, pyrene and/or magnetite are considered as the abundant dark materials on the surface of Ryugu in the predicted alteration minerals (pyrene is not dark by itself but can be altered to dark organic matter through geologic time). Especially, pyrene can be consolidated through reduction of CO_2in Cases 2–4 because of water-chondrite reactions generate abundant H_2. These solid phases are minor or absent at high W/R where carbonate is predominant but the sum of them exceeds several % at low W/R because water-chondrite reactions at low W/R generate abundant hydrogen. Therefore, the results indicate that the altered chondrites broadly become darker with decreasing W/R. However, if the water-chondrite reactions start under H_2-rich condition, the CO_2 in the fluid would be effectively reduced to form organic

materials (Cases 2–4) even at high W/R, which also potentially contribute the low reflectance of Ryugu.

Investigation of the organic matter in ALH 77307 by STXM

*Hiroki Suga[1], Motoo Ito[2], Yoko Kebukawa[3], Matthew A Marcus[4], Takuji Ohigashi[5], Yoshio Takahashi[1]

1. Graduate School of Science, The University of Tokyo, 2. Kochi Institute for Core Sample Research JAMSTEC, 3. Faculty of Engineering, Yokohama National University, 4. Advanced Light Source, Lawrence Berkeley National Laboratory, 5. UVSOR Synchrotron Facility, Institute for Molecular Science

Organic matter (OM) is one of the most important building blocks of the solar system, it contributes to the planetary evolution and relates to the origin of life. The primitive OM is preserved in the carbonaceous chondrites (CCs), comets, and interplanetary dust particles. However, it is difficult to understand that what is the primitive OM (*e.g.,* information of it such as chemical composition and occurrence). Therefore, various candidates and formation process of OM has being discussed still. Here, we focused on the one of the most pristine CCs, ALH 77307 (petrological type 3.03: less altered). Primitive OM in its matrix and chondrule rim phases were explored using X-ray microscopic analysis. The aim of this study is to find primitive OM in the most primitive CCs.

First, matrix and chondrule rim phases were identified by SEM-EDS elemental imaging. Then, the ultra-thin section of matrix and chondrule rim were prepared using FIB system in the Kochi Institute for Core Sample Research JAMSTEC. After that, prepared ultra-thin sections were analyzed by STXM installed BL4U in IMS UVSOR and beamline 5.3.2.2 in ALS LBNL to investigate OM distributions and their functional groups composition of C, N, and O.

As a result, we found two types of OM in both matrix and chondrule rim. These OM showed the same functional groups composition (aromatic C: C=C, ketonic C: C=O, carboxylic C: C=O[-HO], and graphitic layer structure: C-C) and different functional groups ratio. OMs in the chondrule rim were surrounded the aqueous alteration related secondary minerals such as iron hydroxides and carbonates. Although it was suggested that OM in the chondrule rim have the functional groups composition which related to aqueous alteration (*e.g.,* hydroxyl and aliphatic compounds), these functional groups related peaks could not be identified. Therefore, it was suggested that OM preserved original (before the accretion of the matrix and chondrule rim) information and secondary minerals origin were also before the accretion. From these characteristics, two types of OM in matrix and chondrule rim phase may have different origins such as nanoglobules and primitive insoluble OM (or insoluble OM-like nanoglobules reported in De Gregorio et al., 2013).
In this study, we succeeded in the *in-situ* observation (occurrence-preserved OM analysis with FIB system) to clarified that the original occurrence and functional groups of tow primitive OMs in ALH77307. As for the future plan, H-, C-, N-, and O-isotopic characteristics of these two OMs and carbonates are going to be analyzed by NanoSIMS in Koch Institute for Core Sample Research JAMSTEC. After that, OMs and secondary minerals morphology will be investigated by TEM in the University of Tokyo.

The development of UV spectrometer and preliminary measurement of carbonaceous chondrites

*Akira Igarashi[1], Tomoki Nakamura[1], Shingo Kameda[2], Keiichi Moroi[2]

1. Department of Earth and Planetary Materials Sciences, Faculty of Science, Tohoku University, 2. Department of Physics, Faculty of Science, Rikkyo University

Ultraviolet (UV) reflectance spectra (200-400nm) of carbonaceous chondrites provide new information on organic matters in C-complex asteroids [e. g., 1], but interpretation of UV reflectance spectra of carbonaceous chondrites are not well established [1–3] because of very low reflectivity of the meteorites and the lack of best-suited standards in the UV region.
In this study, we developed a UV spectrometer and made selection of the best-suited standard material for calibration. High sensitivity is required for the spectrometer, because primitive meteorites such as carbonaceous chondrites are very dark in the UV wavelength region. The detector is an Ocean Optics Maya2000 PRO that has sensitivity in a range from 165 to 620 nm and spectral resolution of 0.035–0.68 nm. Light source is Hamamatsu Photonics Deuterium lamp (H2D2 light source unit) L11799 that has intensity in a range from 160 to 400 nm with atmospheric UV-radiation. We set a light source, meteorite sample, and a detector with minimum distance each other with a phase angle of 30 degrees. We tested and evaluated a wide variety of natural and artificial materials as a candidate for a reflectance standard, including $BaSO_4$, CaF_2, and Quartz, in a way similar to those described in [2]. The results of the test measurements suggest that Quartz powder is the best standard in the ultraviolet region, because it shows relatively flat spectrum compared with the other candidates.
For preliminary measurements of carbonaceous chondrites, we measured hydrated and partially- or completely dehydrated CM chondrites (Murray, Murchison, Yamato (Y-) 793321, Jbilet Winselwan, Murchison heated at 600˚C, Belgica (B-) 7904, Y86720). They are classified to heating stages I-IV (stage IV is the highest heating degree) based on mineralogical evidence [4]. They were crushed into a powder with <77 or <155 μm in size and used for spectral measurements. The results show that overall UV reflectance decreases from stage I to II, but increases with increasing heating stages from II to IV, whereas spectral slope in the 200-400nm region decreases with increasing heating degree. These changes are consistent with those observed in [1] and probably attributed to graphitization of IOM (Insoluble Organic Matter) in carbonaceous chondrites with increasing heating temperature.

A coupled experimental and thermodynamic study of chondrite-water interaction under anoxic condition

*Sakiko Kikuchi[1], Takazo Shibuya[1]

1. Japan Agency for Marine-Earth Science and Technology

The presence of hydrous minerals in chondrites have been considered as an important evidence for the former presence of liquid water in parent bodies. However, the detailed evolutionary history of parent bodies (e.g., temperature fluid composition and water/rock ratio) are still poorly constrained, because the alteration processes of chondritic rock are not well defined and very few relevant experimental data are available. Here we investigate alteration process of chondrites by experiments simulating reactions between synthetic chondrite (mixtures of olivine, pyroxene, glass, Fe_{metal}, and troilite) and NH_3-containing solutions at 25 and 80 ˚C under anoxic conditions. We also compared the experimental results with those predicted from thermodynamic calculations to understand the equilibrium and kinetic conditions of chondrite-water interaction.
The experiments up to 7 months showed that the water-rock reactions caused a series of mineral alterations and production of H_2(aq), especially at 80 ˚C. X-ray diffraction analysis revealed that the formation of pyrrhotite was notable during the first few days in the experiment, which was likely resulted from the dissolution of troilite. In contrast, precipitation of saponite was evident after 100 days in the experiment, which was probably caused by the dissolution of Si-rich glass in the synthetic chondrites. Transmission electron microscope observation revealed that the saponite and secondary Si-rich amorphous phases densely covered the surface of the original olivine, glass, pyroxene, and troilite. These results imply that amorphous silica precipitated after the formation of pyrrhotite, followed by the precipitation of saponite. A part of these mineral assemblages obtained from our experiment was inconsistent with those predicted from the thermodynamic equilibrium calculations, suggesting that some metastable alteration minerals occur in the chondrite-water system before the complete equilibrium is achieved.

Keywords: chondrite, saponite, pyrrhotite

Two-dimensional numerical experiments on subduction initiation in oceanic lithosphere: Effects of rheological properties of hydrous minerals

*Miki Izumi[1], Masaki Yoshida[2], Ken-ichi Hirauchi[1]

1. Department of Geosciences, Faculty of Science, Shizuoka University, 2. Department of Deep Earth Structure and Dynamics research, Japan Agency for Marine–Earth Science and Technology –JAMSTEC–

How subduction begins on the Earth remains one of major outstanding problems in plate tectonics. For plate subduction to be initiated, previous numerical studies have assumed a preexisting weak fault with the coefficient of friction (μ) of around zero. When comparing the surface environment of the Earth with other terrestrial planets where plate tectonics is not occurring, only earth has an ocean. If seawater transport deeply along faults between plates, water–rock interaction will occur to form mechanically weak hydrous minerals. Therefore, we focus on effects of rheological properties of hydrous minerals and conduct a two-dimensional numerical simulation of subduction initiation in oceanic lithosphere. We found that plate subduction occurs with an assumption of antigorite flow law (dislocation creep), talc friction (i.e., μ= 0.1), and high pore fluid pressure ratio (λ = 0.9) for the weak fault zone. We also confirm that the maximum average strength of the weak fault for subduction to be initiated must be below 5 MPa. In our models, no oceanic plates sinks deep into the mantle, suggesting that additional effects are needed for the plate to fracture and then subduct into the deep mantle.

Electrical energy generation at hydrothermal environments in the Solar System estimated by fuel cell model experimentations

*Hiroyuki Kashima[1], Masahiro Yamamoto[1], Ken Takai[1]

1. Japan Agency for Marine-Earth Science and Technology

A prime consideration for habitability of planets and moons is to constrain available free energy provided in the environment that could support the extant life and/or could drive chemical evolution. On Earth, primary production of a biosphere have been considered to be supported by phototrophs and chemotrophs with light and chemical energy, but recent studies discovered prokaryotes defined as electrotrophs that are capable of using electrons provided by artificial electrodes as the sole energy source for cellular activities [1]. This suggests that electrical energy could support the formation and evolution of a biosphere, and requires us to consider electrical energy, in addition to light and chemical energies, provided at the environment to estimate the habitability.

Although we have not yet had direct evidence for an electrotrophic ecosystem in a natural setting, spontaneous electrical current through conductive minerals and microbial matrixes that could support a life have been observed in sea floor environments on Earth. A promising example for spontaneous electrical energy generation is the marine hydrothermal environments in which conductive mineral deposits chemically separate hydrothermal fluid and sea water. Studies demonstrated that a marine hydrothermal system being functioning as analogous to a fuel cell generating power where sulfide deposit couples electrochemical oxidation of sulfide in the hydrothermal fluid and reduction of dissolved oxygen in the sea water with its electrocatalytic activity and electrical conductance [2].

As moons in the Solar System such as Enceladus and Europa are suggested to possess oceans with hydrothermal activity, it is hypothesized that those hydrothermal systems also generate electrical energy that provide free energy capable of supporting a biosphere. The present study is to estimate potentials of electrical energy generation at hydrothermal systems in oceans of the Solar System with laboratory electrochemical model experiments reproducing hydrothermal systems. Namely, electrochemical characterizations were conducted by using electrodes covered by sulfide minerals simulating hydrothermal deposits with electrolytes simulating hydrothermal fluids and seawaters. This presentation discusses electrocatalytic properties and potential power production of simulated hydrothermal systems with results of voltammetry tests and fuel cell polarization tests.

Experimental study of abiotic nitrate reduction at a high temperature and high-pressure condition and implication for nitrogen chemistry in Hadean hydrothermal environments

*Manabu Nishizawa[1], Takuya Saito[1], Akiko Makabe[1], Takazo Shibuya[1], Ken Takai[1]

1. Japan Agency for Marine-Earth Science and Technology

Nitrogen is an essential element for life as a major component of biomolecules and electron donor/acceptor for energy metabolism. Currently, nitrogen cycle in surface environments is mainly driven by biological processes including nitrogen fixation, nitrification and denitrification. In contrast, little is known about nitrogen cycle in the pre-biotic Earth and its relation to chemical evolution. This study focuses on nitrate chemistry during water-rock interaction in deep-sea hydrothermal environments to understand the fate of atmospherically-derived nitrate in the Hadean ocean. In experiments, artificial seawater with nitrate was reacted with synthetic komatiite at 350oC and 500 bar. Our experiments show that a substantial amount of nitrate was reduced to ammonium in an experimental condition. This implies that the Hadean deep-sea hydrothermal vents may have been favorable for chemical evolution in that both electron acceptor for energy metabolism (nitrate) and reduced nitrogen for organic synthesis (ammonium) were continuously supplied to the hydrothermal fluid-seawater mixing zone.

Interaction experiments between eucritic glass and 0.1 M NaCl aqueous solution at 300-500℃ and 1.5 kbar: Suggestions on water-rock interactions at the bottom of Europa’s subsurface ocean

*Makoto Nagasawa[1,2], Yutaro Takaya[1]

1. Department of Resources and Environmental Engineering, School of Creative Science and Engineering, Waseda University, 2. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo

Europa, the second satellite of Jupiter, probably has subsurface ocean under its icy crust. The yellow-brown color of its leading anti-Jovian hemisphere could be explained by endogenous substances such as sodium chloride, which suggests the presence of hydrothermal activity (water-rock interaction) [Hand and Carlson, 2015]. In this study, we conducted water-rock interaction experiments to determine the mineral assemblage of altered rock on Europa’s mantle surface and to constrain the amount of available energy for sustaining the putative chemoautotroph-based ecosystems.

In our experiments, eucritic synthesis glass and 0.1 M NaCl aqueous solution were reacted at 300-500℃ and 1.5 kbar for 8, 16 and 32 days, using cold-seal type pressure vessels. The water/rock mass ratio was fixed at 1/1 in all the experiments (50 mg of powdered glass to 50 μL of NaCl solution). Solid products were analyzed by X-ray diffractometer and SEM equipped with EDS. Water chemistry of the reacted solution were determined by ICP-MS.

The mineral assemblages observed in our experiments were as follows.
・Fe-rich smectite (saponite), epistilbite and xonotlite at 300℃ and 1.5 kbar
・Fe-rich smectite (saponite), ferroactinolite, Ca-rich plagioclase and minor amount of magnetite at 400℃ and 1.5 kbar
・Mg-rich smectite, ferroactinolite, Ca-rich plagioclase, magnetite and hydroxyapatite at 500℃ and 1.5 kbar

The formation of magnetite at 400-500℃ suggests that these high-temperature water-rock interactions may generate hydrogen and sustain chemoautotroph-based ecosystems. As a future work, we would like to evaluate the hydrogen generation potential quantitatively.

Relationship between tellurium in the Fe-Mn oxides in the ocean and ambient seawater

*Yusuke Fukami[1], Teruhiko Kashiwabara[1], Hiroshi Amakawa[1], Takazo Shibuya[1], Akira Usui[2], Katsuhiko Suzuki[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Kochi University

Marine ferromanganese crusts (Fe-Mn crusts) are Fe-Mn oxides widely distributed on the seafloor, and important materials for (paleo)oceanographic studies (e.g. Hein et al., 2014). Tellurium (Te) is one of the highly enriched elements in the Fe-Mn crusts by more than ten thousand times relative to that in the continental crusts (Hein et al., 2010). Variation of concentration and isotopic compositions of Te in the Fe-Mn crusts could be a potential indicator for changes in redox condition of seawater, because of two valences of Te in ocean environments (+4 and +6; Lee and Edmond, 1985). In this study, we performed the measurement for concentration and isotopic compositions of Te in the surface layer of the Fe-Mn crusts, which was in contact with ambient seawater. The results were compared with the depth profile of the dissolved oxygen in the sampling site. To investigate the relationship to ambient seawater, the Fe-Mn crusts were sampled from two seamounts located in the Northwest Pacific, which showed different dissolved oxygen profile, and analyzed for Te concentration and isotopic compositions of the surface layer.

The results show that the correlation between the Te concentration and isotopic compositions in the surface layer of the Fe-Mn crusts changes depending on water depths. With increasing depths, the Te concentration decreases more drastically at shallower water depths than at deeper water depths. Moreover, the surface samples from two seamounts show a difference in the water depths where the concentration gradient of Te in the Fe-Mn crusts changes. The changes in the concentration gradient of Te in the Fe-Mn crusts may correspond to the changes in the chemical state of Mn in conjunction with the changes in the dissolved oxygen concentration in ambient seawater. Therefore, the Te concentration in the Fe-Mn oxides potentially indicates the dissolved oxygen concentration in the marine environment. The Fe oxides and Mn oxides are observed on the surface of the Mars by recent observation of exploration vehicles (e.g. Lanza et al., 2016), and the trace elements in these oxides potentially provide the information of water environments when they are formed. In the presentation, the results of the measurement of Te in natural samples, and laboratory experiment for application to Fe-Mn oxides on Mars will be discussed.

Laboratory reproduction of earthquake faulting beneath the internal ocean of Enceladus

*Takehiro Hirose[1], Takazo Shibuya[2]

1. Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology, 2. Japan Agency for Marine-Earth Science and Technology

The discovery of the Na-rich ice particles erupting from the surface of Enceladus indicates the presence of hydrothermal activity in Enceladus' ocean. Knowledge of water chemistry of the interior ocean is crucial for exploring planetary habitability and life. Two different processes of water-rock interaction can define the water chemistry in Enceladus' ocean: one is the static chemical interaction at the hydrothermal regions over geological timescale, and the other is the dynamic chemical interaction associated with seismogenic faulting induced by tidal force between Enceladus and Saturn or neighboring satellites. In this study, we focus on the later short-time disequilibrium interaction between water-rock during faulting. By using high-velocity friction experiment, we plan to reproduce faulting processes that are expected to occur in the interior of Enceladus, and then evaluate quantitatively the effect of the disequilibrium interaction during faulting on the water chemistry of the interior ocean. In the poster, we will present outline of the apparatus and pilot results of the experiments using San Carlos olivine and synthetic chondrite as starting materials.

Keywords: Enceladus, earthquake faulting, hydrothermal

Why does Titan have an atmosphere, and why not Ganymede?—The origin of Titan-Ganymede dichotomy

*Yasuhito Sekine[1], Yuhiko Aoyama[2], Masahiro Ikoma[2], Takayuki Tanigawa[3]

1. Earth-Life Science Insitute, Tokyo Institute of Technology, 2. Dept. of Earth and Planetary Sci., University of Tokyo, 3. Section of Liberal Arts and Sciences, National Inst. of Tech., Ichinoseki College

One of the long-standing issues in planetary science is why Saturn's moon Titan possesses a thick atmosphere and why Jupiter's moon Ganymede not. These satellites are similar in size and mass; however, only Titan has active surface environments, characterized as a thick N_2 atmosphere and liquid CH_4 cycles. Since Titan's atmospheric N_2 originates from NH_3 (Niemann et al., 2005; Sekine et al., 2011), the building materials of Titan may have contained both NH_3 and CH_4 ices in addition to H_2O ice. Previous studies hypothesized that no condensation of NH_3 and CH_4 would have occurred in the circum-Jovian disk since proto-Jupiter might have formed in a relatively warm region of the protoplanetary disk (e.g., disk temperature > 100 K) (Lunine and Stevenson, 1982). However, recent disk models show that even at a few au, the disk temperature would have become sufficiently low (i.e., < 100 K) to form NH_3 and CH_4 ices in the disk (e.g., Dodson-Robinson et al., 2009; Oka et al., 2011), thereby calling for a new explanation. Here we show that gas and solids infalling onto massive proto-Jupiter would have experienced extensive shock heating (~10^4 K) upon accretion. The shock heating is sufficient to dissociate primordial NH_3 and CH_4 to thermochemically stable N_2 and CO, which cannot condensate in the circum-Jovian disk due to their low condensation temperatures. On the other hand, dissociation of NH_3 and CH_4 proceeds only incompletely upon accretion onto less massive proto-Saturn. Accordingly, the building materials of Saturn's icy moons contain abundance of survived NH_3 and CH_4 as ices. We suggest that giant planet's mass is a critical factor to determine the chemical compositions, surface environments, and potential habitability of the icy moons.

Development of observation system of gas hydrate forming in the environment simulated near the bottom of icy shell in icy bodies (2)

*Atsushi Tani[1], Kenshiro Moriyama[1]

1. Graduate School of Human Development and Environment, Kobe University

Gas hydrates are clathrate compounds where hydrogen-bonded water cages include a guest gas molecule. Methane hydrate is one of famous gas hydrates because it is naturally found in deep-sea and permafrost sediments on the Earth. Gas hydrates would exist in icy bodies as well. One of the candidates is Pluto where the presence of subsurface ocean is suggested. Gas hydrates may exist between the ice shell and subsurface ocean and play an important role as insulator to keep warm inside. The presence of subsurface ocean is also suggested in some icy satellites like Enceladus. INMS (Ion and Neutral Mass Spectrometer) aboard the Cassini spacecraft has investigated composition of the plumes there that includes H2O (< 90 %), CH4, CO2, NH3, and other various organic materials. These results could reflect the composition of the subsurface ocean and imply the presence of clathrate hydrates in the ocean. Density of gas hydrates depends on guest gas molecules. For example, methane hydrate is lighter than the water, whereas CO2 hydrate is heavier. If CO2 hydrate forms at the bottom of the icy shell, the average density may become large and the ice (water ice + CO2 hydrate) may start to sink locally. If the size of each gas hydrate become small and granular gas hydrates exist in subsurface ocean, heat can be transfer by not only thermal conduction but also convection. This means that icy bodies may be cooled faster. To elucidate how gas hydrates form in the subsurface ocean in icy bodies, we have developed the observation system of gas hydrate formation and dissociation below the ice sheet. In the presentation, we report the progress of the observation system.

Rheology of non-water ices inferred from diffusion coefficients: A compilation study

*Naoki Noguchi[1]

1. Graduate School of Technology, Industrial and Social Sciences, Tokushima University

Non-water ices such as solid N_2, CO, CO_2, CH_4, and clathrate hydrates are a main constituent of the surfaces and crusts of the icy bodies. Understanding rheological properties of them are essential to understanding the dynamics including thermal convection, flow of glacier, and relaxation of topography. Several researchers investigated the rheological properties of them directly by low-temperature deformation experiments: solid N_2, CH_4 (Yamashita et al. 2010), CO_2 (Yamashita and Kato 1997, Durham et al. 1999), and CH_4 clathrate hydrate (Durham et al. 2003). They revealed the viscosities and plastic deformation mechanisms with a stress exponent of $n > 2$ in the range of 0.1 −100 MPa. However, the deformation experiment at low-stress conditions below 0.1 MPa is technically very difficult. The extrapolation of the plastic-flow law under their mechanisms to the low stress conditions may give an overestimate for the viscosity, because the diffusion creep can dominate in the low stress conditions below 0.1 MPa Under the diffusion creep regime, the viscosity behaves as Newtonian fluid, and is sensitive to the grain size. Although the viscosity under the diffusion creep regime cannot be measured directly, it can be estimated from diffusion coefficients based on the theories of diffusion creep (Frost and Ashby 1982). I will discuss the rheological properties of non-water ices inferred from the diffusion coefficients. There are many non-water ices whose diffusion coefficients have not determined yet by experiments. This substance includes solid CO and clathrate hydrates. In the case of molecular solids, the diffusion enthalpy has a correlation with the sublimation enthalpy (Chadwick and Sherwood 1971). I estimated the diffusion coefficients using the correlation in order to infer the rheological property.

Swelling behavior of magnesium saturated smectites

Morida Koki, Keisuke Fukushi, Hiroshi Sakuma

*Koki Morida[1]

1. Kanazawa University

Smectite belongs to clay minerals formed in the presence of liquid water. Smectites are composed of 2:1 layer with tetrahedral sheet and octahedral sheet. Smectites are categorized to di-octahedral type (e.g., nontronite and montmorillonite) and tri-octahedral type (e.g. saponite). The interlayer between the sheets is occupied by hydrated cations. The interlayer cations are usually Na^{+}, K^{+}, Mg^{2+}, Ca^{2+}. The distances of interlayer (basal spacing) depend on type of interlayer cations and relative humidity (RH). The basal spacing can change from 9 to 15 Å as function of amount of RH. At 0% of RH, basal spacings are around 10 Å when interlayer cation is Na^{+} or K^{+}. That is 12 Å when interlayer cation is Ca^{2+}. On the other hand, the basal spacings ranges from 11 to 14 Å when interlayer cation is Mg^{2+} (Sato et al, 1992; Morodome and Kawamura 2009).

Curiosity rover sent to the Gale crater on mars examines the possibility of existence of life and habitable environment (Vaniman et al, 2014). Water is essential for life. Therefore, in order to estimate possibility of life, it is important to know water quality. Gale crater is thought to be an ancient lake. Curiosity obtained the lacustrine sediment samples and analyzed the mineralogical and geochemical characteristics of the sediments. From the CheMin-XRD analyses, smectites were discovered in JohnKlein and Cumberland sites. The smectites are presumed to be saponite (Vaniman et al, 2014; Bristow et al, 2015). The basal spacing in Cumberland’s saponite exhibited 13.2 Å at RH0%. Now it has been under debates whether the interlayer cation in Cumberland’s saponite is $MgOH^{+}$ or Mg^{2+} ion.

Suquet et al, 1975 showed that basal spacing of Mg^{2+} saturated saponite is 11.4 Å at RH0%. Therefore, Vaniman et al. 2014 and Bristow et al, 2015 presumed that the interlayer cation in Cumberland’s saponite is $MgOH^{+}$ ion. However, basal spacing of some other Mg^{2+} saturated smectites exhibited above 13.2 Å. This study experimentally assess the basal spacing of smectites including saponite under several atomospheric compositions with N_2, air or CO_2.

Possibility of hydrogen peroxide as a warming agent on early Mars with oxidized condition

*Yuichi Ito[1], George HASHIMOTO[2], Yoshiyuki O. Takahashi[3], Masaki Ishiwatari[1], Kiyoshi Kuramoto[1]

1. Department of Cosmosciences, Graduate school of Science, Hokkaido University, 2. Department of Earth Sciences, Okayama University, 3. Graduate School of Science, Kobe University

Recently, Lanza et al. (2016) reported the detection of the high Mn-oxides abundances of Martian rocks in Gale Crater, where preserves the past martian surface environment during 3–4 Ga. This observation suggests that both liquid water and a highly oxidized atmosphere existed on early Mars, since the precipitation of such a Mn-oxide-rich rock requires highly oxidizing condition in water. On the other hand, the Solar luminosity at 4 Ga would be only 75 % of the current value. Due to this, it is thought that additional greenhouse components in CO2–H2O atmospheres could have played a key role for warming on early Mars on the basis of climate models (e.g., Kasting 1991). However, no previous atmospheric models have shown that highly oxidized atmosphere can warm the mean surface temperature of early Mars above 273 K. As a gaseous material oxidizing martian surface, hydrogen peroxide, H2O2, has been received attention (e.g., Zahnle et al. 2008) On the other side, anyone does not focus on H2O2 as a greenhouse gas, owing to the extremely low abundance in the current Martian atmosphere. Although hydrogen peroxide is photo-chemically unstable, its absorption for far-infrared radiation per a molecule is very strong. Thus, hydrogen peroxide might warm early Mars, if the atmosphere was highly oxidized.
To test this idea, we use a 1-D atmospheric energy balance model with a line-by-line radiative transfer calculation. Then, by parameterizing the abundance of H2O2 in a CO2-dominant atmosphere, we estimate how much the surface temperature is warmed. We found that the temperature increased at most only 3 K, in the case of the atmosphere with the saturated abundance of H2O2. On the other hand, when the abundance of condensation nuclei in the upper atmosphere is low, H2O2 is expected to be possibly super-saturated. In the case of the atmosphere with pressure of > 2bar and 1 ppm H2O2, the surface temperature can exceed 273 K. Also, in the case for 10 ppm H2O2, at least 1 bar atmosphere is required to warm the surface temperature above 273 K. In particular, for the 2 bar atmospheres including H2O2 with a molar fraction of 1 ppm and 10 ppm, the surface temperatures increase about 40 K and 80 K from 230 K, respectively. In this presentation, we will discuss about the possibility that H2O2 concentrates to be super-saturated from the view of photochemical production and condensation processes.

Three-dimensional simulations of methane-based hydrological cycles in north-pole regions of Titan

1. Earth-Life Science Institute, Tokyo Institute of Technology, 2. Department of Earth and Planetary Science, University of Tokyo

Observations of lakes, surface modification by fluvial activities, and cloud formation all indicate that Saturn's moon Titan has the only active hydrological cycles known besides Earth [1]. Hydrocarbons such as methane and ethane condense out of a nitrogen-rich thick atmosphere, and precipitate onto the surface [1]. Methane observed in the atmosphere is continuously destroyed and lost by processes such as photolysis and direct escape [1]. Thereby, the persistence of the methane in the atmosphere is dependent on the availability of a hidden methane reservoir, resupplying the lost methane from the surface [1]. Quantifying the volume of the potential sources of methane resupply is one of the key questions of Titan's hydrological cycles [1].

Previous studies on remote-sensing observations of Titan's surface show that the elevations of some lakes and seas located near the north pole are constant from summer to early winter (corresponding to several Earth's years) within the observational errors, implying a connection with a mutual ground-methane table [2]. The preference of clouds at mid-latitudes over high-latitudes suggests that while surface methane is only observed at high latitudes, there may be a significant subsurface methane table at mid-latitudes that is available for exchange with the atmosphere [3]. The influence of subsurface flow on the hydrological cycle has been studied using a two-dimensional (2D) hydrological model, which treats the subsurface as one box at each location [4]. Thus, the 2D models cannot determine the subsurface hydraulic connection among lakes and oceans. They also cannot quantify the total volume of the subsurface methane reservoir, therefore being unable to estimate the extent of the methane-based hydrological cycles.

Here, we calculate the methane-based hydrological cycles using a surface-subsurface coupled three-dimensional hydrological simulator "GETFLOWS". GETFLOWS calculates surface and subsurface flows in a three-dimensional corner-grid blocks using Darcy's law, law of mass conservation, and Manning's equation. The main input parameters are (1) topography, (2) precipitation and evaporation rates, (3) permeability and porosity of the subsurface, and (4) levels of ground-methane table (i.e., the total methane volume in the subsurface). The topographic data was derived by interpolating the data obtained from the Cassini RADAR using the inverse distance weighting method [5]. The precipitation and evaporation data were applied from previous calculation results using general circulation model (GCM), which show good agreements of cloud formation and distribution with the observations [3,6]. The porosity and permeability values were estimated from the observations of the size of the icy grains on Titan's surface [7]. Using this model, we constrain the ground-methane table through reproducing the size and distribution of the lakes and oceans on Titan's surface as well as seasonal changes in their elevation. We discuss (1) whether the lakes and seas in the north-pole regions are hydraulically connected to the groundwater table, (2) what volume of subsurface liquid methane is active in the hydrological cycles, and (3) whether there is a subsurface transport of methane from the high to the low latitudes.

Inclusion of brine into icy shell of Enceladus

*Ryusuke Nishitani[1], Atsushi Tani[2], Sho Sasaki[1], Jun Kimura[1]

1. Department of Earth and Space Sciences, School of Science, Osaka University, 2. Graduate School Human Development and Environment, Kobe University

Investigation of Enceladus plume by Cassini spacecraft showed not only the existence of a subsurface ocean but also ocean included some salts. On the earth, it is known that sea ice includes brine into grain boundary. Similarly, icy shell of Enceladus seems to include sea water. Inclusion of sea water could cause partial melt in icy layer and could affect the geology and thermal evolution. Cox and Weeks (1975) showed that the effective partition coefficient, the ratio of concentration of sodium chloride in formed ice to that in residual liquid, depended on ice growth velocity. While, Gross et al., (1977) reported forced convection made partition coefficient low. To quantify the amount of brine included into icy shell under various condition, we investigated a partition coefficient of sodium chloride to ice by experiment and simulation.

As an experimental apparatus, unidirectional growth method used by Muraoka et al., (2016) was applied. With this method, plate-like ice can be formed in a cell and growth velocity can be controlled by controlling temperature. Ice was formed at a speed between cm/s in 5 % sodium chloride solution. As a result, effective partition coefficient of sodium chloride to ice was 1 approximately at all ice growth velocity.

To evaluate this value, ice growth in sodium chloride solution was simulated by voronoi dynamics simulation suggested by Kawano and Ohashi (2008). When ice grew under the same condition with the experiment, effective partition coefficient was 1 approximately. Next, we introduced Sherwood number into the simulation. It was found that higher Sherwood number made the effective partition coefficient lower. These results indicate that effective partition coefficient reflects condition of convection. When ice grow velocity is faster than diffusion of sodium chloride, effective partition coefficient is near 1. Since convection was not occur in this experiment, the effective partition coefficient was near 1.
In subsurface ocean of Enceladus, effective partition coefficient might be low due to convection, but in crack like tiger stripe, effective partition coefficient might be high because ice growth velocity seems to be high.

Electron irradiations onto ice-salt mixtures at low temperatures: Implications for chemical evolution and oxidant formation on Europa

*Shuya Tan[2,1], Yasuhito Sekine[2], Tetsuya Hama[3]

1. Department of Earth and Planetary Science, Graduate School of Science, the University of Tokyo, 2. Earth-Life Science Institute, Tokyo Institute of Technology, 3. Institute of Low Temperature Science, Hokkaido University

The ice-rich surface of Europa is known to be irradiated with high-energy particles, such as electron, accelerated by the Jovian strong magnetic field (e.g., Paranicas et al., 2009). The high-energy particle irradiations could have caused particular chemical reactions on the surface, possibly including dissociation of H_2O and subsequent oxidation of surface salts, such as chlorides and sulfates/sulfides (e.g., Carlson et al., 2009; Hand et al., 2011). In addition, sputtering of the surface ice and salts by high-energy particles is proposed to be a major source of the tenuous atmosphere on Europa (e.g., Johnson et al., 2009; Brown and Hill, 1999). However, the detailed chemical reactions on Europa’s surface have been poorly constrained.

Here we construct a novel experimental system for irradiation of electron onto ice and salt (e.g., chloride: NaCl and $MgCl_2$) mixtures at low temperatures. Laboratory experiments on electron irradiation onto NaCl salt have been conducted at low temperatures corresponding to Europa’s surface (e.g., Hand and Carlson, 2015). However, no experiments have been performed to simulate the irradiation of electron onto ice and salt mixtures on Europa. Upon electron irradiation onto ice and chloride mixtures, chloride may be oxidized into perchlorate salts. If the surface materials are provided into the subsurface ocean through crustal recycling (e.g., Hand et al., 2007), perchlorate would become an important oxidant to generated redox disequilibria in the ocean. We report preliminary results on the electron irradiation experiments using the newly-constructed system.

Keywords: Irradiation experiment, Europa, chemical evolution

Water-rock reactions in the parent body of Ryugu

*Takazo Shibuya[1], Yasuhito Sekine[2], Sakiko Kikuchi[1], Keisuke Fukushi[3], Tomoki Nakamura[4], Sei-ichiro WATANABE[5]

1. Japan Agency for Marine-Earth Science and Technology, 2. Tokyo Institute of Technology, 3. Kanazawa University, 4. Tohoku University, 5. Nagoya University

The recent remote-sensing observation by Hayabusa2 is providing a large amount of data to unravel the origin of Ryugu. The Near Infrared Spectrometer (NIRS3) onboard Haybusa2 revealed that the IR reflectance of the global surface of Ryugu is extremely low (~0.02) and the spectra include small but clear absorption at 2.72 μm. These findings indicate the great abundance of dark materials and the subordinate amount of hydrous minerals in the surface, respectively. These materials on Ryugu are important clues to constrain the conditions of aqueous alteration such as the temperature experienced by the parent body and the original volatile compositions during accretion stage. In this work, we conducted thermodynamic modeling of chondrite-water reactions under various conditions to establish a model explaining the aqueous alteration of the parent body. In the thermodynamic calculations, a mean composition of CV chondrites was assumed for the initial bulk rock (minor amount of carbon, nitrogen and chlorine are also included) (Pearson et al., 2006; Clay et al., 2017). For the initial fluid, four cases were assumed; CO_2 concentration is 0, 1, 3 and 10 mol% (Cases 1–4, respectively) relative to water while the latter three cases also include NH_3 (0.5%) and H_2S (0.5%) additionally (Mumma and Charnley, 2011). The equilibrium temperature and pressure were assumed to be 0, 100, 200, 300 and 350 ˚C, and vapor pressure of water. In the calculations, pyrene was considered as a representative of polycyclic aromatic hydrocarbon while C1 compounds except CH_4 were included as soluble species (Zolotov, 2012).
The calculations showed that stabilities of hydrous/anhydrous minerals, carbonate, pyrene change with temperature and W/R value. In Case 1 (CO_2-free), the altered chondrite consists of serpentine, troilite and subordinate amount of hydrous/anhydrous minerals (e.g., magnetite, saponite, gibbsite and chlorite) at 0–300 ˚C. However, with increasing temperature above 300 ˚C, olivine and clinopyroxene become major phases as the amounts of serpentine, chlorite and magnetite decrease. At 350 ˚C, olivine becomes the most abundant minerals in conjunction with disappearance of serpentine. Similar temperature dependencies of hydrous mineral stabilities were also shown at low W/R in Cases 2–4 (CO_2 =1–10%) whereas carbonate is predominant at high W/R. Although the total amount of hydrous minerals in the surface of Ryugu is still unconfirmed, the calculation results suggest that the temperature of hydrothermal reactions experienced by Ryugu is lower than approximately 300 ˚C if a certain amount of hydrous minerals are present in the surface rocks. In contrast, if the amount of hydrous minerals is relatively small, higher temperatures (>350 ˚C) may account for the observed IR spectra. In this case, the parent body may have undergone high-temperature hydrothermal reactions that could occur in relatively large body. Otherwise, it is also possible that the parent body underwent instantaneous high-temperature events such as impacts after the aqueous alteration.Regarding the discriminating darkness of Ryugu, pyrene and/or magnetite are considered as the abundant dark materials on the surface of Ryugu in the predicted alteration minerals (pyrene is not dark by itself but can be altered to dark organic matter through geologic time). Especially, pyrene can be consolidated through reduction of CO_2in Cases 2–4 because of water-chondrite reactions generate abundant H_2. These solid phases are minor or absent at high W/R where carbonate is predominant but the sum of them exceeds several % at low W/R because water-chondrite reactions at low W/R generate abundant hydrogen. Therefore, the results indicate that the altered chondrites broadly become darker with decreasing W/R. However, if the water-chondrite reactions start under H_2-rich condition, the CO_2 in the fluid would be effectively reduced to form organic

materials (Cases 2–4) even at high W/R, which also potentially contribute the low reflectance of Ryugu.

Investigation of the organic matter in ALH 77307 by STXM

*Hiroki Suga[1], Motoo Ito[2], Yoko Kebukawa[3], Matthew A Marcus[4], Takuji Ohigashi[5], Yoshio Takahashi[1]

1. Graduate School of Science, The University of Tokyo, 2. Kochi Institute for Core Sample Research JAMSTEC, 3. Faculty of Engineering, Yokohama National University, 4. Advanced Light Source, Lawrence Berkeley National Laboratory, 5. UVSOR Synchrotron Facility, Institute for Molecular Science

Organic matter (OM) is one of the most important building blocks of the solar system, it contributes to the planetary evolution and relates to the origin of life. The primitive OM is preserved in the carbonaceous chondrites (CCs), comets, and interplanetary dust particles. However, it is difficult to understand that what is the primitive OM (*e.g.,* information of it such as chemical composition and occurrence). Therefore, various candidates and formation process of OM has being discussed still. Here, we focused on the one of the most pristine CCs, ALH 77307 (petrological type 3.03: less altered). Primitive OM in its matrix and chondrule rim phases were explored using X-ray microscopic analysis. The aim of this study is to find primitive OM in the most primitive CCs.

First, matrix and chondrule rim phases were identified by SEM-EDS elemental imaging. Then, the ultra-thin section of matrix and chondrule rim were prepared using FIB system in the Kochi Institute for Core Sample Research JAMSTEC. After that, prepared ultra-thin sections were analyzed by STXM installed BL4U in IMS UVSOR and beamline 5.3.2.2 in ALS LBNL to investigate OM distributions and their functional groups composition of C, N, and O.

As a result, we found two types of OM in both matrix and chondrule rim. These OM showed the same functional groups composition (aromatic C: C=C, ketonic C: C=O, carboxylic C: C=O[-HO], and graphitic layer structure: C-C) and different functional groups ratio. OMs in the chondrule rim were surrounded the aqueous alteration related secondary minerals such as iron hydroxides and carbonates. Although it was suggested that OM in the chondrule rim have the functional groups composition which related to aqueous alteration (*e.g.,* hydroxyl and aliphatic compounds), these functional groups related peaks could not be identified. Therefore, it was suggested that OM preserved original (before the accretion of the matrix and chondrule rim) information and secondary minerals origin were also before the accretion. From these characteristics, two types of OM in matrix and chondrule rim phase may have different origins such as nanoglobules and primitive insoluble OM (or insoluble OM-like nanoglobules reported in De Gregorio et al., 2013).
In this study, we succeeded in the *in-situ* observation (occurrence-preserved OM analysis with FIB system) to clarified that the original occurrence and functional groups of tow primitive OMs in ALH77307. As for the future plan, H-, C-, N-, and O-isotopic characteristics of these two OMs and carbonates are going to be analyzed by NanoSIMS in Koch Institute for Core Sample Research JAMSTEC. After that, OMs and secondary minerals morphology will be investigated by TEM in the University of Tokyo.

The development of UV spectrometer and preliminary measurement of carbonaceous chondrites

*Akira Igarashi[1], Tomoki Nakamura[1], Shingo Kameda[2], Keiichi Moroi[2]

1. Department of Earth and Planetary Materials Sciences, Faculty of Science, Tohoku University, 2. Department of Physics, Faculty of Science, Rikkyo University

Ultraviolet (UV) reflectance spectra (200-400nm) of carbonaceous chondrites provide new information on organic matters in C-complex asteroids [e. g., 1], but interpretation of UV reflectance spectra of carbonaceous chondrites are not well established [1–3] because of very low reflectivity of the meteorites and the lack of best-suited standards in the UV region.
In this study, we developed a UV spectrometer and made selection of the best-suited standard material for calibration. High sensitivity is required for the spectrometer, because primitive meteorites such as carbonaceous chondrites are very dark in the UV wavelength region. The detector is an Ocean Optics Maya2000 PRO that has sensitivity in a range from 165 to 620 nm and spectral resolution of 0.035–0.68 nm. Light source is Hamamatsu Photonics Deuterium lamp (H2D2 light source unit) L11799 that has intensity in a range from 160 to 400 nm with atmospheric UV-radiation. We set a light source, meteorite sample, and a detector with minimum distance each other with a phase angle of 30 degrees. We tested and evaluated a wide variety of natural and artificial materials as a candidate for a reflectance standard, including $BaSO_4$, CaF_2, and Quartz, in a way similar to those described in [2]. The results of the test measurements suggest that Quartz powder is the best standard in the ultraviolet region, because it shows relatively flat spectrum compared with the other candidates.
For preliminary measurements of carbonaceous chondrites, we measured hydrated and partially- or completely dehydrated CM chondrites (Murray, Murchison, Yamato (Y-) 793321, Jbilet Winselwan, Murchison heated at 600˚C, Belgica (B-) 7904, Y86720). They are classified to heating stages I-IV (stage IV is the highest heating degree) based on mineralogical evidence [4]. They were crushed into a powder with <77 or <155 μm in size and used for spectral measurements. The results show that overall UV reflectance decreases from stage I to II, but increases with increasing heating stages from II to IV, whereas spectral slope in the 200-400nm region decreases with increasing heating degree. These changes are consistent with those observed in [1] and probably attributed to graphitization of IOM (Insoluble Organic Matter) in carbonaceous chondrites with increasing heating temperature.

A coupled experimental and thermodynamic study of chondrite-water interaction under anoxic condition

*Sakiko Kikuchi[1], Takazo Shibuya[1]

1. Japan Agency for Marine-Earth Science and Technology

The presence of hydrous minerals in chondrites have been considered as an important evidence for the former presence of liquid water in parent bodies. However, the detailed evolutionary history of parent bodies (e.g., temperature fluid composition and water/rock ratio) are still poorly constrained, because the alteration processes of chondritic rock are not well defined and very few relevant experimental data are available. Here we investigate alteration process of chondrites by experiments simulating reactions between synthetic chondrite (mixtures of olivine, pyroxene, glass, Fe_{metal}, and troilite) and NH_3-containing solutions at 25 and 80 ˚C under anoxic conditions. We also compared the experimental results with those predicted from thermodynamic calculations to understand the equilibrium and kinetic conditions of chondrite-water interaction.
The experiments up to 7 months showed that the water-rock reactions caused a series of mineral alterations and production of H_2(aq), especially at 80 ˚C. X-ray diffraction analysis revealed that the formation of pyrrhotite was notable during the first few days in the experiment, which was likely resulted from the dissolution of troilite. In contrast, precipitation of saponite was evident after 100 days in the experiment, which was probably caused by the dissolution of Si-rich glass in the synthetic chondrites. Transmission electron microscope observation revealed that the saponite and secondary Si-rich amorphous phases densely covered the surface of the original olivine, glass, pyroxene, and troilite. These results imply that amorphous silica precipitated after the formation of pyrrhotite, followed by the precipitation of saponite. A part of these mineral assemblages obtained from our experiment was inconsistent with those predicted from the thermodynamic equilibrium calculations, suggesting that some metastable alteration minerals occur in the chondrite-water system before the complete equilibrium is achieved.

Two-dimensional numerical experiments on subduction initiation in oceanic lithosphere: Effects of rheological properties of hydrous minerals

*Miki Izumi[1], Masaki Yoshida[2], Ken-ichi Hirauchi[1]

1. Department of Geosciences, Faculty of Science, Shizuoka University, 2. Department of Deep Earth Structure and Dynamics research, Japan Agency for Marine–Earth Science and Technology –JAMSTEC–

How subduction begins on the Earth remains one of major outstanding problems in plate tectonics. For plate subduction to be initiated, previous numerical studies have assumed a preexisting weak fault with the coefficient of friction (μ) of around zero. When comparing the surface environment of the Earth with other terrestrial planets where plate tectonics is not occurring, only earth has an ocean. If seawater transport deeply along faults between plates, water–rock interaction will occur to form mechanically weak hydrous minerals. Therefore, we focus on effects of rheological properties of hydrous minerals and conduct a two-dimensional numerical simulation of subduction initiation in oceanic lithosphere. We found that plate subduction occurs with an assumption of antigorite flow law (dislocation creep), talc friction (i.e., μ= 0.1), and high pore fluid pressure ratio (λ = 0.9) for the weak fault zone. We also confirm that the maximum average strength of the weak fault for subduction to be initiated must be below 5 MPa. In our models, no oceanic plates sinks deep into the mantle, suggesting that additional effects are needed for the plate to fracture and then subduct into the deep mantle.

Electrical energy generation at hydrothermal environments in the Solar System estimated by fuel cell model experimentations

*Hiroyuki Kashima[1], Masahiro Yamamoto[1], Ken Takai[1]

1. Japan Agency for Marine-Earth Science and Technology

A prime consideration for habitability of planets and moons is to constrain available free energy provided in the environment that could support the extant life and/or could drive chemical evolution. On Earth, primary production of a biosphere have been considered to be supported by phototrophs and chemotrophs with light and chemical energy, but recent studies discovered prokaryotes defined as electrotrophs that are capable of using electrons provided by artificial electrodes as the sole energy source for cellular activities [1]. This suggests that electrical energy could support the formation and evolution of a biosphere, and requires us to consider electrical energy, in addition to light and chemical energies, provided at the environment to estimate the habitability.

Although we have not yet had direct evidence for an electrotrophic ecosystem in a natural setting, spontaneous electrical current through conductive minerals and microbial matrixes that could support a life have been observed in sea floor environments on Earth. A promising example for spontaneous electrical energy generation is the marine hydrothermal environments in which conductive mineral deposits chemically separate hydrothermal fluid and sea water. Studies demonstrated that a marine hydrothermal system being functioning as analogous to a fuel cell generating power where sulfide deposit couples electrochemical oxidation of sulfide in the hydrothermal fluid and reduction of dissolved oxygen in the sea water with its electrocatalytic activity and electrical conductance [2].

As moons in the Solar System such as Enceladus and Europa are suggested to possess oceans with hydrothermal activity, it is hypothesized that those hydrothermal systems also generate electrical energy that provide free energy capable of supporting a biosphere. The present study is to estimate potentials of electrical energy generation at hydrothermal systems in oceans of the Solar System with laboratory electrochemical model experiments reproducing hydrothermal systems. Namely, electrochemical characterizations were conducted by using electrodes covered by sulfide minerals simulating hydrothermal deposits with electrolytes simulating hydrothermal fluids and seawaters. This presentation discusses electrocatalytic properties and potential power production of simulated hydrothermal systems with results of voltammetry tests and fuel cell polarization tests.

Experimental study of abiotic nitrate reduction at a high temperature and high-pressure condition and implication for nitrogen chemistry in Hadean hydrothermal environments

*Manabu Nishizawa[1], Takuya Saito[1], Akiko Makabe[1], Takazo Shibuya[1], Ken Takai[1]

1. Japan Agency for Marine-Earth Science and Technology

Nitrogen is an essential element for life as a major component of biomolecules and electron donor/acceptor for energy metabolism. Currently, nitrogen cycle in surface environments is mainly driven by biological processes including nitrogen fixation, nitrification and denitrification. In contrast, little is known about nitrogen cycle in the pre-biotic Earth and its relation to chemical evolution. This study focuses on nitrate chemistry during water-rock interaction in deep-sea hydrothermal environments to understand the fate of atmospherically-derived nitrate in the Hadean ocean. In experiments, artificial seawater with nitrate was reacted with synthetic komatiite at 350oC and 500 bar. Our experiments show that a substantial amount of nitrate was reduced to ammonium in an experimental condition. This implies that the Hadean deep-sea hydrothermal vents may have been favorable for chemical evolution in that both electron acceptor for energy metabolism (nitrate) and reduced nitrogen for organic synthesis (ammonium) were continuously supplied to the hydrothermal fluid-seawater mixing zone.

Keywords: prebiotic chemistry, nitrogen, deep sea hydrothermal vents

Interaction experiments between eucritic glass and 0.1 M NaCl aqueous solution at 300-500℃ and 1.5 kbar: Suggestions on water-rock interactions at the bottom of Europa’s subsurface ocean

*Makoto Nagasawa[1,2], Yutaro Takaya[1]

1. Department of Resources and Environmental Engineering, School of Creative Science and Engineering, Waseda University, 2. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo

Europa, the second satellite of Jupiter, probably has subsurface ocean under its icy crust. The yellow-brown color of its leading anti-Jovian hemisphere could be explained by endogenous substances such as sodium chloride, which suggests the presence of hydrothermal activity (water-rock interaction) [Hand and Carlson, 2015]. In this study, we conducted water-rock interaction experiments to determine the mineral assemblage of altered rock on Europa’s mantle surface and to constrain the amount of available energy for sustaining the putative chemoautotroph-based ecosystems.

In our experiments, eucritic synthesis glass and 0.1 M NaCl aqueous solution were reacted at 300-500℃ and 1.5 kbar for 8, 16 and 32 days, using cold-seal type pressure vessels. The water/rock mass ratio was fixed at 1/1 in all the experiments (50 mg of powdered glass to 50 μL of NaCl solution). Solid products were analyzed by X-ray diffractometer and SEM equipped with EDS. Water chemistry of the reacted solution were determined by ICP-MS.

The mineral assemblages observed in our experiments were as follows.
・Fe-rich smectite (saponite), epistilbite and xonotlite at 300℃ and 1.5 kbar
・Fe-rich smectite (saponite), ferroactinolite, Ca-rich plagioclase and minor amount of magnetite at 400℃ and 1.5 kbar
・Mg-rich smectite, ferroactinolite, Ca-rich plagioclase, magnetite and hydroxyapatite at 500℃ and 1.5 kbar

The formation of magnetite at 400-500℃ suggests that these high-temperature water-rock interactions may generate hydrogen and sustain chemoautotroph-based ecosystems. As a future work, we would like to evaluate the hydrogen generation potential quantitatively.

Keywords: Europa, Water-rock interaction

Relationship between tellurium in the Fe-Mn oxides in the ocean and ambient seawater

*Yusuke Fukami[1], Teruhiko Kashiwabara[1], Hiroshi Amakawa[1], Takazo Shibuya[1], Akira Usui[2], Katsuhiko Suzuki[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Kochi University

Marine ferromanganese crusts (Fe-Mn crusts) are Fe-Mn oxides widely distributed on the seafloor, and important materials for (paleo)oceanographic studies (e.g. Hein et al., 2014). Tellurium (Te) is one of the highly enriched elements in the Fe-Mn crusts by more than ten thousand times relative to that in the continental crusts (Hein et al., 2010). Variation of concentration and isotopic compositions of Te in the Fe-Mn crusts could be a potential indicator for changes in redox condition of seawater, because of two valences of Te in ocean environments (+4 and +6; Lee and Edmond, 1985). In this study, we performed the measurement for concentration and isotopic compositions of Te in the surface layer of the Fe-Mn crusts, which was in contact with ambient seawater. The results were compared with the depth profile of the dissolved oxygen in the sampling site. To investigate the relationship to ambient seawater, the Fe-Mn crusts were sampled from two seamounts located in the Northwest Pacific, which showed different dissolved oxygen profile, and analyzed for Te concentration and isotopic compositions of the surface layer.

The results show that the correlation between the Te concentration and isotopic compositions in the surface layer of the Fe-Mn crusts changes depending on water depths. With increasing depths, the Te concentration decreases more drastically at shallower water depths than at deeper water depths. Moreover, the surface samples from two seamounts show a difference in the water depths where the concentration gradient of Te in the Fe-Mn crusts changes. The changes in the concentration gradient of Te in the Fe-Mn crusts may correspond to the changes in the chemical state of Mn in conjunction with the changes in the dissolved oxygen concentration in ambient seawater. Therefore, the Te concentration in the Fe-Mn oxides potentially indicates the dissolved oxygen concentration in the marine environment. The Fe oxides and Mn oxides are observed on the surface of the Mars by recent observation of exploration vehicles (e.g. Lanza et al., 2016), and the trace elements in these oxides potentially provide the information of water environments when they are formed. In the presentation, the results of the measurement of Te in natural samples, and laboratory experiment for application to Fe-Mn oxides on Mars will be discussed.

Laboratory reproduction of earthquake faulting beneath the internal ocean of Enceladus

*Takehiro Hirose[1], Takazo Shibuya[2]

1. Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology, 2. Japan Agency for Marine-Earth Science and Technology

The discovery of the Na-rich ice particles erupting from the surface of Enceladus indicates the presence of hydrothermal activity in Enceladus' ocean. Knowledge of water chemistry of the interior ocean is crucial for exploring planetary habitability and life. Two different processes of water-rock interaction can define the water chemistry in Enceladus' ocean: one is the static chemical interaction at the hydrothermal regions over geological timescale, and the other is the dynamic chemical interaction associated with seismogenic faulting induced by tidal force between Enceladus and Saturn or neighboring satellites. In this study, we focus on the later short-time disequilibrium interaction between water-rock during faulting. By using high-velocity friction experiment, we plan to reproduce faulting processes that are expected to occur in the interior of Enceladus, and then evaluate quantitatively the effect of the disequilibrium interaction during faulting on the water chemistry of the interior ocean. In the poster, we will present outline of the apparatus and pilot results of the experiments using San Carlos olivine and synthetic chondrite as starting materials.

Keywords: Enceladus, earthquake faulting, hydrothermal

Why does Titan have an atmosphere, and why not Ganymede?—The origin of Titan-Ganymede dichotomy

*Yasuhito Sekine[1], Yuhiko Aoyama[2], Masahiro Ikoma[2], Takayuki Tanigawa[3]

1. Earth-Life Science Insitute, Tokyo Institute of Technology, 2. Dept. of Earth and Planetary Sci., University of Tokyo, 3. Section of Liberal Arts and Sciences, National Inst. of Tech., Ichinoseki College

One of the long-standing issues in planetary science is why Saturn's moon Titan possesses a thick atmosphere and why Jupiter's moon Ganymede not. These satellites are similar in size and mass; however, only Titan has active surface environments, characterized as a thick N_2 atmosphere and liquid CH_4 cycles. Since Titan's atmospheric N_2 originates from NH_3 (Niemann et al., 2005; Sekine et al., 2011), the building materials of Titan may have contained both NH_3 and CH_4 ices in addition to H_2O ice. Previous studies hypothesized that no condensation of NH_3 and CH_4 would have occurred in the circum-Jovian disk since proto-Jupiter might have formed in a relatively warm region of the protoplanetary disk (e.g., disk temperature > 100 K) (Lunine and Stevenson, 1982). However, recent disk models show that even at a few au, the disk temperature would have become sufficiently low (i.e., < 100 K) to form NH_3 and CH_4 ices in the disk (e.g., Dodson-Robinson et al., 2009; Oka et al., 2011), thereby calling for a new explanation. Here we show that gas and solids infalling onto massive proto-Jupiter would have experienced extensive shock heating (~10^4 K) upon accretion. The shock heating is sufficient to dissociate primordial NH_3 and CH_4 to thermochemically stable N_2 and CO, which cannot condensate in the circum-Jovian disk due to their low condensation temperatures. On the other hand, dissociation of NH_3 and CH_4 proceeds only incompletely upon accretion onto less massive proto-Saturn. Accordingly, the building materials of Saturn's icy moons contain abundance of survived NH_3 and CH_4 as ices. We suggest that giant planet's mass is a critical factor to determine the chemical compositions, surface environments, and potential habitability of the icy moons.

Development of observation system of gas hydrate forming in the environment simulated near the bottom of icy shell in icy bodies (2)

*Atsushi Tani[1], Kenshiro Moriyama[1]

1. Graduate School of Human Development and Environment, Kobe University

Gas hydrates are clathrate compounds where hydrogen-bonded water cages include a guest gas molecule. Methane hydrate is one of famous gas hydrates because it is naturally found in deep-sea and permafrost sediments on the Earth. Gas hydrates would exist in icy bodies as well. One of the candidates is Pluto where the presence of subsurface ocean is suggested. Gas hydrates may exist between the ice shell and subsurface ocean and play an important role as insulator to keep warm inside. The presence of subsurface ocean is also suggested in some icy satellites like Enceladus. INMS (Ion and Neutral Mass Spectrometer) aboard the Cassini spacecraft has investigated composition of the plumes there that includes H2O (< 90 %), CH4, CO2, NH3, and other various organic materials. These results could reflect the composition of the subsurface ocean and imply the presence of clathrate hydrates in the ocean. Density of gas hydrates depends on guest gas molecules. For example, methane hydrate is lighter than the water, whereas CO2 hydrate is heavier. If CO2 hydrate forms at the bottom of the icy shell, the average density may become large and the ice (water ice + CO2 hydrate) may start to sink locally. If the size of each gas hydrate become small and granular gas hydrates exist in subsurface ocean, heat can be transfer by not only thermal conduction but also convection. This means that icy bodies may be cooled faster. To elucidate how gas hydrates form in the subsurface ocean in icy bodies, we have developed the observation system of gas hydrate formation and dissociation below the ice sheet. In the presentation, we report the progress of the observation system.

Rheology of non-water ices inferred from diffusion coefficients: A compilation study

*Naoki Noguchi[1]

1. Graduate School of Technology, Industrial and Social Sciences, Tokushima University

Non-water ices such as solid N_2, CO, CO_2, CH_4, and clathrate hydrates are a main constituent of the surfaces and crusts of the icy bodies. Understanding rheological properties of them are essential to understanding the dynamics including thermal convection, flow of glacier, and relaxation of topography. Several researchers investigated the rheological properties of them directly by low-temperature deformation experiments: solid N_2, CH_4 (Yamashita et al. 2010), CO_2 (Yamashita and Kato 1997, Durham et al. 1999), and CH_4 clathrate hydrate (Durham et al. 2003). They revealed the viscosities and plastic deformation mechanisms with a stress exponent of $n > 2$ in the range of 0.1 −100 MPa. However, the deformation experiment at low-stress conditions below 0.1 MPa is technically very difficult. The extrapolation of the plastic-flow law under their mechanisms to the low stress conditions may give an overestimate for the viscosity, because the diffusion creep can dominate in the low stress conditions below 0.1 MPa Under the diffusion creep regime, the viscosity behaves as Newtonian fluid, and is sensitive to the grain size. Although the viscosity under the diffusion creep regime cannot be measured directly, it can be estimated from diffusion coefficients based on the theories of diffusion creep (Frost and Ashby 1982). I will discuss the rheological properties of non-water ices inferred from the diffusion coefficients. There are many non-water ices whose diffusion coefficients have not determined yet by experiments. This substance includes solid CO and clathrate hydrates. In the case of molecular solids, the diffusion enthalpy has a correlation with the sublimation enthalpy (Chadwick and Sherwood 1971). I estimated the diffusion coefficients using the correlation in order to infer the rheological property.

Smectite belongs to clay minerals formed in the presence of liquid water. Smectites are composed of 2:1 layer with tetrahedral sheet and octahedral sheet. Smectites are categorized to di-octahedral type (e.g., nontronite and montmorillonite) and tri-octahedral type (e.g. saponite). The interlayer between the sheets is occupied by hydrated cations. The interlayer cations are usually Na^{+}, K^{+}, Mg^{2+}, Ca^{2+}. The distances of interlayer (basal spacing) depend on type of interlayer cations and relative humidity (RH). The basal spacing can change from 9 to 15 Å as function of amount of RH. At 0% of RH, basal spacings are around 10 Å when interlayer cation is Na^{+} or K^{+}. That is 12 Å when interlayer cation is Ca^{2+}. On the other hand, the basal spacings ranges from 11 to 14 Å when interlayer cation is Mg^{2+} (Sato et al, 1992; Morodome and Kawamura 2009).

Curiosity rover sent to the Gale crater on mars examines the possibility of existence of life and habitable environment (Vaniman et al, 2014). Water is essential for life. Therefore, in order to estimate possibility of life, it is important to know water quality. Gale crater is thought to be an ancient lake. Curiosity obtained the lacustrine sediment samples and analyzed the mineralogical and geochemical characteristics of the sediments. From the CheMin-XRD analyses, smectites were discovered in JohnKlein and Cumberland sites. The smectites are presumed to be saponite (Vaniman et al, 2014; Bristow et al, 2015). The basal spacing in Cumberland’s saponite exhibited 13.2 Å at RH0%. Now it has been under debates whether the interlayer cation in Cumberland’s saponite is $MgOH^{+}$ or Mg^{2+} ion.

Suquet et al, 1975 showed that basal spacing of Mg^{2+} saturated saponite is 11.4 Å at RH0%. Therefore, Vaniman et al. 2014 and Bristow et al, 2015 presumed that the interlayer cation in Cumberland’s saponite is $MgOH^{+}$ ion. However, basal spacing of some other Mg^{2+} saturated smectites exhibited above 13.2 Å. This study experimentally assess the basal spacing of smectites including saponite under several atomospheric compositions with N_2, air or CO_2.

Possibility of hydrogen peroxide as a warming agent on early Mars with oxidized condition

*Yuichi Ito[1], George HASHIMOTO[2], Yoshiyuki O. Takahashi[3], Masaki Ishiwatari[1], Kiyoshi Kuramoto[1]

1. Department of Cosmosciences, Graduate school of Science, Hokkaido University, 2. Department of Earth Sciences, Okayama University, 3. Graduate School of Science, Kobe University

Recently, Lanza et al. (2016) reported the detection of the high Mn-oxides abundances of Martian rocks in Gale Crater, where preserves the past martian surface environment during 3–4 Ga. This observation suggests that both liquid water and a highly oxidized atmosphere existed on early Mars, since the precipitation of such a Mn-oxide-rich rock requires highly oxidizing condition in water. On the other hand, the Solar luminosity at 4 Ga would be only 75 % of the current value. Due to this, it is thought that additional greenhouse components in CO2–H2O atmospheres could have played a key role for warming on early Mars on the basis of climate models (e.g., Kasting 1991). However, no previous atmospheric models have shown that highly oxidized atmosphere can warm the mean surface temperature of early Mars above 273 K. As a gaseous material oxidizing martian surface, hydrogen peroxide, H2O2, has been received attention (e.g., Zahnle et al. 2008) On the other side, anyone does not focus on H2O2 as a greenhouse gas, owing to the extremely low abundance in the current Martian atmosphere. Although hydrogen peroxide is photo-chemically unstable, its absorption for far-infrared radiation per a molecule is very strong. Thus, hydrogen peroxide might warm early Mars, if the atmosphere was highly oxidized.
To test this idea, we use a 1-D atmospheric energy balance model with a line-by-line radiative transfer calculation. Then, by parameterizing the abundance of H2O2 in a CO2-dominant atmosphere, we estimate how much the surface temperature is warmed. We found that the temperature increased at most only 3 K, in the case of the atmosphere with the saturated abundance of H2O2. On the other hand, when the abundance of condensation nuclei in the upper atmosphere is low, H2O2 is expected to be possibly super-saturated. In the case of the atmosphere with pressure of > 2bar and 1 ppm H2O2, the surface temperature can exceed 273 K. Also, in the case for 10 ppm H2O2, at least 1 bar atmosphere is required to warm the surface temperature above 273 K. In particular, for the 2 bar atmospheres including H2O2 with a molar fraction of 1 ppm and 10 ppm, the surface temperatures increase about 40 K and 80 K from 230 K, respectively. In this presentation, we will discuss about the possibility that H2O2 concentrates to be super-saturated from the view of photochemical production and condensation processes.

[M-IS21] Gas hydrate in environmental-resource sciences

convener:Hitoshi Tomaru(Department of Earth Sciences, Chiba University), Akihiro Hachikubo(Kitami Institute of Technology), Atsushi Tani(Graduate School of Human Development and Environment, Kobe University), Shusaku Goto(Institute for Geo-Resources and Environment National Institute of Advanced Industrial Science and Technology), Chairperson:Naoto Ishida, 戸丸 仁

An increasing number of researches focusing on natural gas hydrates has recently been conducted from the environmental, material, and resource scientific viewpoints. This session aims to share and discuss the latest research results associated with natural/experimental gas hydrates to understand and examine the nature and potential of gas hydrates in the past-present-future of the Earth and the development/application for our life. Because the researches on gas hydrates are interdisciplinary, broad topics from field and experimental researches, modeling, etc. will be presented in this session.

Discussion

Equilibrium pressure of clathrate hydrates encaged $^{13}CH_4$

*Yuki Kikuchi[1], Akihiro Hachikubo[1], Takahiro Ozeki[1], Satoshi Takeya[2]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Methane molecule is composed of carbon and hydrogen, and three kinds of isotopologues, $^{12}CH_4$ (98.9%), $^{13}CH_4$ (1.1%), and CH_3D (0.013%) exist in nature. We often measure stable carbon isotope ($^{13}C/^{12}C$) of methane to understand its gas origin. Since their weight of isotopologues differ with each other, physicochemical properties of them are also different. Pure methane hydrate must be "mixed-gas hydrate" of their isotopologues. Ozeki *et al.* (2018) measured an equilibrium pressure of CH_3D hydrate, but that of $^{13}CH_4$ has not been studied yet. Fractionation of hydrogen isotope of methane during the formation of methane hydrate has been reported by Hachikubo *et al.* (2007) that δ D of hydrate-bound methane becomes several ‰smaller than that of residual methane. This result suggests that the equilibrium pressure of CH_3D hydrate is larger than that of CH_4 hydrate, and Ozeki *et al.* (2018) demonstrated the difference between these equilibrium pressures. Since Hachikubo *et al.* (2007) showed no isotopic fractionation in methane $\delta^{13}C$, the equilibrium pressures of $^{12}CH_4$ and $^{13}CH_4$ hydrates are thought to be almost the same. In this study, we measured the equilibrium pressures of $^{13}CH_4$ hydrate to check the difference from that of $^{12}CH_4$ hydrate.

Methane hydrate samples were synthesized in small pressure cells (volume: 5 mL). Fine ice powder (1g) was put in a pressure cell, and introduced $^{13}CH_4$ (purity: 99.5%, Taiyo-Nissan). Clathrate hydrate was formed by melting the ice powder at the temperature of 273.2K under high pressure of methane. We also prepared normal methane (purity: 99.99% for methane, but 98.9% for $^{12}CH_4$, Takachiho Chemical Industry Co. Ltd.) hydrate as a reference, using the same preparation method. These pressure cells were placed in a temperature-controlled liquid bath, and measured their equilibrium pressures from 269.5K to 277.9K.

The difference in equilibrium pressure between $^{13}CH_4$ and normal methane (mainly $^{12}CH_4$) hydrates was smaller than the measurement error. This results agree with the previous report by Hachikubo *et al.* (2007).

Hydrogen isotopic fractionation of ethane encaged in different crystallographic structure

*Jumpei Matsuda[1], Akihiro Hachikubo[1], Satoshi Takeya[2]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Methane and ethane mixed-gas hydrate forms the cubic structure II in appropriate gas composition. Hachikubo *et al.* (2009) measured isotopic compositions of Lake Baikal gas hydrates and showed that δD of hydrate-bound ethane in the structure II is smaller than that in the structure I. These results might be explained by the difference in hydrogen isotope fractionation between formation processes of the structure I and II. In the last JpGU meeting we reported that the isotopic difference between gas and hydrate phases increased to 9-12‰ in the case of the structure II, whereas the difference was 1-2‰ in the case of the structure I. However, the effect of methane on the isotopic fractionation of ethane is unknown. In this study, we choose argon instead of methane and synthesize argon and ethane mixed-gas hydrates to check the isotopic difference in ethane between gas and hydrate phases.

0.7 g of fine ice powder was introduced in a pressure cell (volume: 30 mL). Argon and ethane mixed-gas were introduced in the cell and gas hydrate sample formed at 274.2 K. Before the retrieval of gas hydrate sample, residual gas was sampled, and then gas hydrate was cooled at the temperature of liquid nitrogen and retrieved the hydrate-bound gas. We controlled the ethane composition of initial gas from 3% to 25%. We measured compositions of argon and ethane by a gas chromatograph, and hydrogen isotopic composition (δD) of ethane by a CF-IRMS. Crystallographic structure of gas hydrate was determined using a Raman spectrometer, because the Raman spectra (around 1000 cm^{-1}) of C-C stretching mode of ethane in hydrate phase provide information of the crystallographic structure.

Because ethane was concentrated into hydrate phase rather than argon, ethane compositions of hydrate-bound gas distributed from 30% to 71%. In the case of low concentration of ethane, crystallographic structure II forms due to the effect of argon (the structure II former). δD of hydrate-bound ethane was about 4-7‰ smaller than that of residual ethane in the case of structure II, where ethane composition was 30-36% in the hydrate phase. On the other hand, in the case of high concentration of ethane (around 70% in the hydrate phase) δD of hydrate-bound ethane was around 2‰ larger than that of residual ethane. In the transition zone between the structures I and II the isotopic difference between hydrate and residual gas phases seemed to be an intermediate value (1-4‰). From these results we can conclude that light ethane (C_2H_6) prefers to be encaged into the structure II clathrate hydrate, compared to heavy ethane (C_2H_5D).

Trend of effect of temperature on C–H symmetric stretching vibrational frequencies of hydrocarbon molecules in 12, 14 and 16-hedra cages of gas hydrates

*Go Fuseya[1], Satoshi Takeya[2], Akihiro Hachikubo[1]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Clathrate hydrates are crystalline inclusion compounds that consist of guest molecules of suitable sizes and shapes trapped in well-defined cages formed by water molecules. Clathrate hydrates with natural gases as guest molecules are commonly known as gas hydrates. Gas hydrates with enclathrated hydrocarbon gases that exist in sea or lake bottom sediments and permafrost layers have attracted considerable interest as a potential source of unconventional natural gas.

There are three common crystallographic structures of hydrates, structure I (sI), structure II (sII), and structure H (sH). The unit cell of sI hydrates are composed of two pentagonal dodecahedral (5^{12}) and six tetrakaidecahedral ($5^{12}6^2$) water cages. The unit cell of sII hydrates are composed of sixteen 512 cages and eight hexakaidecahedral ($5^{12}6^4$) water cages. Small guest molecules such as methane (CH_4) or ethane (C_2H_6) form sI hydrates and larger molecules such as propane (C_3H_8) form sII hydrates.

In this study, we observed the variations of Raman shifts of C–H symmetric stretching vibrations of various hydrocarbons encaged in $5^{12,}$ $5^{12}6^2$ and $5^{12}6^4$ cages of sI and sII hydrates. By changing temperature, we investigated variations of Raman shifts of C–H symmetric stretching vibrations of guest hydrocarbons. It was revealed that the vibrations of guest hydrocarbons in smaller sI 51262 cages were greater than those in bigger sII 51264 cages. These results are inconsistent with our prediction in earlier study (Fuseya et al. 2018), that is, the volume of host water cages increases, and the variations of the Raman shifts of C–H symmetric stretching vibrations of guest hydrocarbon molecules in host water cages due to change temperature increase. Taking into account the facts obtained in this study and in our earlier study, we conclude that the temperature change of Raman shifts of C–H symmetric stretching vibrations is affected by geometric asymmetry of host water cages.

The study on relations of the methane plume and atmospheric methane concentration

*Chiharu Aoyama[1]

1. Tokyo University of Marine Science and Technology

PurposeWhen methane seeps out to the sea from the seabed, the following need to be observed and confirmed if the water concentration remains the same. High methane concentration in the atmosphere directly above the seeping point and separation of methane hydrate into gas and water. Then, by confirming the impact on the environment, we propose a survey method for environmental impact assessment of surface methane hydrate.**Method**The experimental site of this research was Umitaka Spur in offshore Niigata prefecture where a large amount of surface methane hydrate plumes is confirmed and investigated on the DAIIICHI KAIYOMARU(KAIYO Engineering). The experimental period was two days, August 6 and August 7.Atmospheric methane concentration was measured during this experiment using LI-7700 (LI-COR) which introduced Flux measurement to measure ppm of specific substances present in the atmosphere. Methane concentration was measured by LI-7700 which was attached to the upper bridge so it will not be affected by the exhaust of the ship. We measure the concentration of methane in the atmosphere from departure to arrival and graphed the data every hour.Using a quantitative echo sounder, we also explored if methane plumes exist underwater the atmospheric methane concentration becomes higher.**Summary** Methane concentration in the atmosphere of the sea, the area near directly above, in the sea area where the methane seeps from the seabed to the sea tends to rise. **Proposal for environmental impact assessment** When extracting surface methane hydrate and at experimental stages at sea, it is effective to monitor methane concentration on the sea, not in the seawater to detect sudden seepage of methane into seawater as soon as possible. Even if methane hydrate leaks into the sea, there is no change in sodium concentration, so we do not have be concerned about the influence on the environment.

Sampling of Methane Bubble Plumes and Solid Gas Hydrate on the Cascadia Margin, Pacific Northwest

*John E Lupton[1], Tamara Baumberger[1], Robert W. Embley[1], Susan G. Merle[1], Camilla Wilkinson[1], Conrad Young[2]

1. NOAA Pacific Marine Environmental Laboratory, Newport, Oregon, USA, 2. Young Engineering, Ramona, CA. USA

The Cascadia Margin along California, Oregon, and Washington is host to hundreds of offshore methane seeps that produce bubble streams that ascend through the water column. In addition to the bubble streams, seismic reflection studies have detected the presence of extensive methane hydrate deposits beneath the seafloor. There are also a few sites along the Cascadia Margin where hydrate deposits are exposed and visible on the seafloor. During an expedition in 2016, our group used an ROV to collect uncontaminated samples of the bubble stream gas at several Cascadia Margin sites using special gas-tight bottles. Although we have successfully obtained samples of the bubble streams, the question remains as to whether the bubble streams are produced by the dissociation of hydrate, or instead represent free gas ascending through the sediment. We have developed a new sampler in which small samples of hydrate can be hermetically sealed into a small gas-tight volume in-situ while incorporating only a small amount of ambient seawater. The hydrate is then allowed to dissociate in the sample volume without exposure to air or other contaminates. During a return expedition to the Cascadia margin in June 2018 we successfully sampled solid methane hydrate at two sites using this new sampler and also collected additional samples of the free gas bubble streams. The paper will compare the results from these hydrate collections with the composition of the free gas.

In previous studies, methane emissions from the seabed have been reported worldwide. The reports that methane reached the atmosphere are limited to some sea areas with shallow water depths in the Arctic Ocean. Most of the researches reported that methane does not reach the atmosphere in many other sea areas and is decomposed in the water column. However, a methane hydrate shell is formed on the surface of methane bubbles released from the seabed in the gas hydrate stability zone. The methane hydrate shell delays the dissolution of methane in the water column. Therefore, a system efficiently transports methane to a shallow location in the ocean. It is difficult to clarify the amount of methane carried by this transport system and it is pointed out that some methane may release into the atmosphere. As methane is one of the greenhouse gases like carbon dioxide, release to the atmosphere leads to an increase in atmospheric concentrations and can be a cause of climate change. On the other hand, if an increase in atmospheric concentration occurs, there is a possibility that it can help in searching the methane hydrate-bearing area from the observation with the artificial satellite. Our objectives were to investigate the influence of gas seep from the sea floor on atmospheric methane concentration. In this study, we performed continuous measurement of atmospheric methane concentration, observed gas plume and measured water temperature profile by CTD. The survey area is the Japan Sea (7 K 14 and 7 K 15 cruises) where the gas plumes were reported and the Pacific Ocean (MR 15 - 3, KH 16 - 3, KH 17 - 3 cruise) as the control area. The upper limit of the stable region of methane hydrate was estimated from the water temperature profile by CTD and the phase equilibrium curve of methane hydrate in seawater for each sea area. Atmospheric methane concentration observed in the Pacific Ocean at 1.9 ppm slightly higher than the average concentration of the whole earth. Atmospheric methane concentration observed around the Japanese islands was also the mode of 1.9 ppm, which was the highest in methane concentration (> 2.1 ppm) compared with other sea areas only in the Mogami trough and off Abashiri. As gas plume was observed in these two regions, it seems that capture the influence of the gas plume on the atmosphere. However, since the methane concentration observed in other gas plume sites (off Tokachi and off Hidaka) was almost unchanged from those in which no gas plume was observed, all gas plumes did not always influence atmospheric concentrations. A high methane concentration was observed only the surrounding of the gas plume at Mogami trough and off Abashiri. However, high concentrations are not always observed when passing through the same gas plume point, but different concentrations are observed depending on time. This is considered to be caused by the methane discharged from the sea floor is flowed by ocean currents and offshore winds, and the amount of methane discharged has changed. The upper limit of the gas hydrate stability estimated from the water temperature profile was slightly shallow in off Abashiri and Mogami trough. Heeschen et al. (2003) reported that the height of the gas plume coincided with the water depth at the upper limit of the gas hydrate stability, but the gas plume observed shallower than a depth of the upper limit off Abashiri. This results suggested that methane emitted from the seafloor reaches the atmosphere at not only the gas plume with shallow water depth but the gas plume with a shallow upper limit of the gas hydrate stability. This study was conducted under the commission from AIST as a part of the methane hydrate research project funded by METI (the Ministry of Economy, Trade, and Industry, Japan). We appreciate the support of the crew during 7K14, 7K15,

Reaction/fixation/migration of methane within the gas chimney on the Umitaka Spur, eastern margin of the Japan Sea

*Hitoshi Tomaru[1], Ryo Matsumoto[2]

1. Department of Earth Sciences, Chiba University, 2. Gas Hydrate Research Laboratory, Meiji University

Pore water geochemistry has reported that methane is oxidized anaerobically by sulfate (anaerobic oxidation of methane: AOM) at the sulfate-methane interface (SMI), and the methane flux has been estimated using the sulfate gradient or SMI depth. The methane flux is therefore an essential factor for assessing the near-seafloor environment of high methane potential area. Gas chimney, characterized by active methane migration, often associates with methane hydrate accumulation just below the seafloor and methane plume in the overlying water column on the Umitaka Spur, eastern margin of the Japan Sea. However, the behavior of these methane cannot be examined by the change of sulfate concentration, direct measurements of the amount of methane in hydrate phase and methane seepage are required. In this research, we estimated the amount of methane that is 1) oxidized at SMI via AOM, 2) fixed in gas hydrate deposit, and 3) released into water column, using independent data sets recently obtained on the Umitaka Spur, respectively, in order to understand more practically the behavior of methane within the gas chimney.
The methane flux oxidized at the SMI was calculated to be >600 mmol/m^2/yr using the SMI depth of <1 mbsf within the gas chimney. Assuming that the methane flux has been constant and all the methane has formed hydrates of 6×10^8 m^3 within 200×250 m gas chimney in <363 ka (data from METI coring), the methane flux directly associated with hydrate was estimated to be >1500 mmol/m^2/yr. The methane flux released into the water column was calculated to be <5 mmol/m^2/yr using the methane concentration in bottom water of <1500 nM and bottom water current of <10 cm/s. These numbers are still tentative because sedimentation rate within gas chimney is rather variable among sites, gaseous methane in sediment must be accounted, a part of methane hydrate has dissolved during massive accumulation of hydrate body, etc. However, recent intensive researches on the shallow gas hydrate system have provided the better understanding of total methane behavior within the gas chimney.
This study was conducted partially under the commission from AIST as a part of the methane hydrate research project funded by METI (the Ministry of Economy, Trade and Industry, Japan).

Slope failures induced by methane hydrate dissociation: a case of submarine slide in the southwestern Oki Trough, Japan Sea

*Naoto Ishida[1], Shota Morihita[2], Takao Ebinuma[1], Hitoshi Tomaru[3], Ryo Matsumoto[4]

1. Social Systems and Civil Engineering, Graduate School of Engineering, Tottori University, 2. Department of Social Systems and Civil Engineering, Faculty of Engineering, Tottori University, 3. Department of Earth Sciences, Faculty of Science, Chiba University, 4. Gas Hydrate Research Laboratory, Organization for the Strategic Coordination of Research and Intellectual Properties, Meiji University

A huge submarine slide in the Oki Trough, Japan Sea, was examined from the viewpoint of methane hydrate dissociation due to BGHS (Base of Gas Hydrate Stability) fluctuation. The submarine slide, which occurred 34 ka, is located in the southwestern slope of the Oki Trough having a 1.6 degrees slant. Geothermal gradients were measured at the 700 m and 1000 m water depths by the side of the slide as 83.13 mK/m and 99.42 mK/m, respectively. Based on our simulation, the BGHS was situated just below the landslide masses at the time of the slope failure. The response of BGHS to the external factors, e.g. sea-level change, sedimentation, etc., is prominently involved in methane hydrate disassociation, which makes the submarine ground unstable. Relation between the slope failure and the methane hydrate disassociation is strongly suggested in the study case.

Unpublished data by surveys conducted under the commission from AIST as a part of the methane hydrate research project funded by the Ministry of Economy, Trade and Industry, Japan was used in this study.

Origin and evolution of H_2S-bearing methane hydrate in the Sea of Japan

*Ryo Matsumoto[1], Tomoko Fukazawa[2], Akihiro Hiruta[1], Glen Snyder[1]

1. Organization for the Strategic Laboratory of Research and Intellectual Properties, Meiji University, 2. Department of Applied Chemistry, School of Science and Technoloty, Meiji University

Thick massive deposits of hydrates of the Sea of Japan have accumulate in gas chimneys in two steps. The first step is related to a 25 million years' rifting of the Sea of Japan, characterized by a high heat flows, high TOC sediments and a tectonic inversion at a few million years ago. Tectonic inversion has developed deep reverse faults and tight folds with open fracture systems, which facilitated the development of gas chimney structures. Second one is a glacial-interglacial cycles for a few 100 ka. Eustatic sea level fall resulted in a shoal up the base of gas hydrate stability (BGGS), dissociation of deep-seated hydrates, and enhanced methane-flux and massive accumulation of hydrates. Shallow hydrates are characterized by high H2S contents up to a few %v/v, reflecting AOM in shallow subsurface. Shallow H2S-bearing hydrates have repeatedly and intermittently accumulated on the top of gas chimneys at glacial period, while the H2S contents rapidly decreased with depth due to recrystallization perhaps through molecular diffusion during burial diagenesis. Key conditions to develop massive deposits of shallow hydrates are strong flux of mixed-microbial and thermogenic gases and a recycling of deep-seated hydrates during the glacial-interglacial.

Keywords: shallow gas hydrates, H2S, eustatic sea level change

Discovery of gas hydrate at the new point off Abashiri, the Sea of Okhotsk

*Akihiro Hachikubo[1], Jumpei Matsuda[1], Satoshi Yamashita[1], Hirotoshi Sakagami[1], Masaaki Konishi[1], Hirotsugu Minami[1], Kenji Nishina[2], Kenji Sakaguchi[3]

1. Kitami Institute of Technology, 2. Geological Survey of Hokkaido, Hokkaido Research Organization, 3. Kushiro Fisheries Research Institute, Hokkaido Research Organization

To understand environment of near-surface gas hydrates at the sea floor, HKS16, HKS17, and HKS18 cruses were conducted using RV Hokushin-Maru (255t) of the Kushiro Fisheries Research Institute off Abashiri, the Sea of Okhotsk, in a framework of joint research between Kitami Institute of Technology and Hokkaido Research Organization. We report success in retrieval of hydrate-bound sediment cores using a research vessel belonging to Hokkaido Prefecture. In this area, natural gas hydrates have been recovered in the NT13-20 and C020 cruises using RV Natsushima and TS Oshoro-maru, respectively. We also observed gas hydrate crystals with many crabs at the seepage sites using a remotely operated vehicle (ROV, KAIYO3000) in the 1KY17 cruise. In the cruise of HKS18, we got gas hydrate samples from a gas seepage site, located 2 km south from the 1KY17 site.

In the HKS18 cruise, we used a hydrostatic corer optimally tuned for a small vessel and a transponder to know exact position of the corer. We obtained nine sediment cores, including two hydrate-bound cores. Gas hydrate crystals were preserved in liquid nitrogen, and sediment gases were obtained by a headspace gas method. Raman spectroscopic analysis was conducted to know crystallographic structure, hydration number and cage occupancies. Molecular and isotopic compositions of gas samples were measured using a gas chromatograph and an isotope ratio mass spectrometer, respectively.

Crystallographic structure of gas hydrate samples belonged to the structure I, and hydration number was estimated as 6.00±0.02. Hydrate-bound H_2S molecules were also detected in the Raman spectra. Hydrate-bound gas was mainly methane, and C_1 / (C_2 + C_3) distributed between 30,000 and 60,000. C_1 $\delta^{13}C$ and δD were -66‰ and -197‰. These molecular and isotopic compositions of hydrate-bound hydrocarbons suggested microbial origin. The depths of sulfate-methane interface (SMI) in HC1807, HC1808, and HC1810 cores were less than 30 cm, indicating high gas flux. Concentrations of H_2S in the headspace gas samples were in the same order (around 1 mM), therefore process of anaerobic oxidation of methane was active. C_1 / (C_2 + C_3) of headspace gases in the hydrate-bound cores (HC1807 and HC1808) distributed between 4,000 and 9,000, and those of other sediment cores were relatively small, indicating that they are in the oxidation layer above the SMI depth. Headspace gas in the HC1808 core contained a lot of isobutane. It is possible that thermogenic gas supplied from deeper sediment layer partly mixes with microbial gas.

All about gas hydrates and heat flow offshore Chile

*LUCIA ALEJANDRA VILLAR MUNOZ[1], IVAN VARGAS-CORDERO[2], JOAQUIM P. BENTO[3], JAN BEHRMANN[1], UMBERTA TINIVELLA[4], MICHELA GIUSTINIANI[4]

1. Helmholtz Centre for Ocean Research, 2. Universidad Andres Bello , 3. Pontificia Universidad Catolica de Valparaiso, 4. Istituto Nazionale di Oceanografia e di Geofisica Sperimentale

From a geological point of view, Chile lies in an incomparable area of the globe, which include four tectonic plates moving against (Nazca, Antarctic, South American and Scotia plates), two triple junctions (Chile and Fuegian triple junctions), numerous mega-earthquakes and tsunami-related, more than 500 active volcanoes, the Andes, and several mineral resources. One of the last natural resources where the Chilean government and institutions have focused on is in gas hydrate, which is a solid ice-like form of water that contains gas molecules highly-concentrated in methane. Since Chile import most of its gas budget, hence the discovery of this new resource open a new window for the national economy, but also for geosciences, due to methane that escapes from sediments and enter to the ocean or even reach the atmosphere could pose a great environmental threat. To identify the presence of hydrates, in this thesis it was used the bottom-simulating reflector BSR, which has the half amplitude and opposite polarity relative to the seafloor.

Moreover, fluids play a key role in the nucleation and rupture propagation of earthquakes in convergent margins, since are a major agent of advective heat transfer from depth to the Earth’ s surface. If provide enough information for the regional heat flow we will improve our knowledge of these violent shakes of plate motion. For this purpose, it is crucial to know the BSR-depth, which serves to calculate the steady-state heat flow q (mW m^{-2}), and therefore, the heat flow can be envisaged in a regional overview.

This work aims to investigate the tectonic processes of the Chilean forearc through the calculation of the regional BSR-derived heat flow, identification of fluid escape sites, description of the distribution of gas hydrates and estimation of the gas hydrate and free gas reservoirs .

One of the major results is the regional overview of the thermal regime and BSR-based gas hydrate distribution along the Chilean forearc. Here, the BSR was identified into the marine sediments mainly along the accretionary prism between 33˚-57˚S, around 2000 m water depth, and between 90-600 m below seafloor. The heat flow estimated through the forearc on the upper and middle continental slope, from Valparaiso to Chiloe (33˚-43˚S), shows common values of heat flow for the continental basement and overlying slope sediments. However, on the lower slope of the actively deforming accretionary wedge, some places show unexpected values, which indicates that advecting pore fluids from deeper may transport a considerable part of the heat there.

Southern, a second approach was made over a large area of extremely anomalous heat flow that is associated with a major tectonic feature: the Chile Triple Junction. In this unusual place, the Nazca, Antarctic and South American plate converge in a common point; while an active spreading centre (the Chile Rise) is subducting beneath the continental plate. Here, gas hydrates are located in very shallow sediments and the extreme values of heat flow estimated (<280 mW m^{-2}) indicate that the overriding South American Plate is effectively heated by subjacent zero-age oceanic plate material. In order to improve the understanding of the geological risk, in case the methane is released to the ocean/atmosphere system, it was estimated the concentration of gas hydrate in this particular region.

©2019. Japan Geoscience Union. All Right Reserved.

Finally, in the southernmost tip of the continent (offshore Patagonia), the heat flow estimated once again shows a range of values typical for subduction zones of oceanic crust older than 10 Ma. Here, a high concentration of methane hydrate is present beneath the active margin. The average thickness of the gas hydrate layer modelled is almost 300 m and the volume of methane estimated is more than $3x10^{13}$ m^3 at standard pressure-temperature conditions, concluding that the active forearc of the Chilean Patagonia is an important reservoir of methane hydrates.

[J] Poster | M (Multidisciplinary and Interdisciplinary)：M-IS Intersection

Tue. May 28, 2019 3:30 PM - 5:00 PM JST | Tue. May 28, 2019 6:30 AM - 8:00 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_26

[M-IS21] Gas hydrate in environmental-resource sciences

convener:Hitoshi Tomaru(Department of Earth Sciences, Chiba University), Akihiro Hachikubo(Kitami Institute of Technology), Atsushi Tani(Graduate School of Human Development and Environment, Kobe University), Shusaku Goto(Institute for Geo-Resources and Environment National Institute of Advanced Industrial Science and Technology)

An increasing number of researches focusing on natural gas hydrates has recently been conducted from the environmental, material, and resource scientific viewpoints. This session aims to share and discuss the latest research results associated with natural/experimental gas hydrates to understand and examine the nature and potential of gas hydrates in the past-present-future of the Earth and the development/application for our life. Because the researches on gas hydrates are interdisciplinary, broad topics from field and experimental researches, modeling, etc. will be presented in this session.

Raman spectroscopic analysis of isotopologue methane hydrates

*Yuki Kikuchi[1], Jumpei Matsuda[1], Akihiro Hachikubo[1], Satoshi Takeya[2]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Raman spectroscopy is one of the useful tool to get information of gas hydrate crystals. Natural gas hydrates in submarine/sublacustrine sediment mainly encage methane. Methane molecule is composed of carbon and hydrogen, and three kinds of isotopologues, $^{12}CH_4$, $^{13}CH_4$, and CH_3D exist in nature. Ozeki *et al.* (2018) first reported Raman spectra of CH_3D and CD_4 hydrates and compared with CH_4 (mainly $^{12}CH_4$) hydrate. We report Raman spectra of $^{13}CH_4$ hydrate and summarize Raman spectra of isotopologue methane hydrates.

$^{13}CH_4$ hydrate sample was synthesized in a small pressure cell (volume: 5 mL). Fine ice powder (1g) was put in the pressure cell, and introduced appropriate amount of $^{13}CH_4$ (purity: 99.5%, Taiyo-Nissan). $^{13}CH_4$ hydrate was formed by melting the fine ice powder at the temperature of 273.2 K under high pressure of $^{13}CH_4$. We retrieved the hydrate sample at 77 K and its Raman spectra was obtained at 123 K in the range 2,500-3,300 cm^{-1} using a Raman spectrometer (RMP-210, JASCO Corporation). The Raman peaks were fitted in the range 2,800-3,000 cm^{-1} for the C-H stretching peaks of methane using a Voigt function to obtain the integrated intensities of the two peaks corresponding to methane encaged in the large and small cages of the cubic structure I.

Raman shifts for the C-H stretching and bending modes of $^{13}CH_4$ was 0.8 cm^{-1} and 14 cm^{-1} smaller than those of $^{12}CH_4$, respectively, suggesting that ^{13}C-H bonds affect its vibrational frequency. Hydration number of $^{13}CH_4$ was estimated as 6.00±0.02, almost the same as that of $^{12}CH_4$ (6.02±0.02). Therefore, Cage occupancies of $^{13}CH_4$ and $^{12}CH_4$ hydrates showed no difference between them.

Gas origin of hydrate-bound gas in Lake Baikal

*Jumpei Matsuda[1], Yuki Kikuchi[1], Akihiro Hachikubo[1], Oleg Khlystov[2], Gennadiy Kalmychkov[3], Marc De Batist[4], Hirotoshi Sakagami[1], Hirotsugu Minami[1], Satoshi Yamashita[1]

1. Kitami Institute of Technology, 2. Limnological Institute, SB RAS, 3. Vinogradov Institute of Geochemistry, SB RAS, 4. Ghent University

In the framework of international collaboration between Kitami Institute of Technology (Japan), Limnological Institute (Russia), and Ghent University (Belgium), natural gas hydrates have been recovered from lake-bottom sediments at Lake Baikal. Near-surface gas hydrate was first discovered at the Malenky mud volcano at the southern Baikal basin in 2000. Multi-phase Gas Hydrate Project (MHP, 2009-2018) has revealed distribution of near-surface gas hydrates at the southern and central Baikal basins. We found six new places (Enkhelook, Soukhaya, KIT, LIN, PosolCanyon1, and PosolCanyon2) during the VER18-03 cruise in 2018. The total number of places where near-surface gas hydrates were retrieved is 53. In this report, we summarize characteristics of hydrate-bound gases retrieved from all the sites since 2005.

Gas hydrate crystals were recovered from lake-bottom sediment cores, and hydrate-bound gas samples were stored in 5-mL vials. Total number of hydrate-bound gas samples was 626. Molecular and isotopic compositions of hydrate-bound gas were measured using a gas chromatograph and a stable isotope ratio mass spectrometer.

In the Bernard plot, C_1 $\delta^{13}C$ and C_1 / (C_2 + C_3) distributes from -70‰ to -44‰ and from 6 to 100,000, respectively, suggesting that the origin of hydrate-bound gas is microbial, thermogenic, and their mixed-gas. Almost all data are plotted on the mixing line between microbial and thermogenic, however, Gorevoy Utes (oil seep site) showed thermogenic C_1 with small composition of C_2 and C_3. The data concentrates in the microbial field (C_1 $\delta^{13}C$: -66‰ and C_1 / (C_2 + C_3): 1,000-10,000). C_1 δD of thermogenic C_1 increases with C_1 $\delta^{13}C$. C_2 $\delta^{13}C$ distributes from -69‰ to -23‰. 17 sites (ex. Solzan, Talanka, Turka, KIT, etc.) showed microbial C_1 and C_2. 27 sites (Malenky, Oblom, Seep13, Kukuy K6, etc.) showed microbial C_1 and thermogenic C_2, indicating that small amount of thermogenic gas is mixed with microbial gas. Other sites (Mamay, PosolBank, Gorevoy Utes, Kedr, etc.) showed thermogenic C_1 and C_2. The Milkov plot (relation between C_1 $\delta^{13}C$ and C_2 $\delta^{13}C$) can express mixing condition between microbial and thermogenic rather than the Bernard plot. C_2 δD decreased with decrease in C_2 $\delta^{13}C$, therefore microbial C_2 is both depleted in ^{13}C and D. We conclude that hydrate-bound gas at Lake Baikal is mainly microbial gas, and thermogenic gas ascends from deep layer at some areas (Kedr, PosolBank, Kukuy, and Gorevoy Utes) and forms the structure II gas hydrate.

Validation of self-preservation effect of methane and ethane mixed-gas hydrate by Raman spectroscopy

*Yunosuke Hase[1], Jumpei Matsuda[1], Akihiro Hachikubo[1], Satoshi Takeya[2]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Methane hydrate can be stored long time under atmospheric pressure below 273.2K, even though their P-T conditions is unstable, namely "self-preservation effect". On the contrary, Takeya and Ripmeester (2008) reported that ethane hydrate shows no self-preservation. In natural condition, methane and ethane mixed-gas hydrates have been found at Lake Baikal, however, there is no information for the mixed-gas system. In the last JpGU meeting we report self-preservation effect for mixed-gas hydrate, but the conditions of samples are not uniform. Because the size of crystals affect rate of survival at higher temperature, we controlled the specific surface of area of gas hydrate samples in this study.

We put 0.7 g of fine ice balls (diameter: 0.108-0.180 mm) into a pressure cell (volume: 30 mL) and mixed-gas of methane and ethane was introduced. Hydrate crystals formed at 273.2 K. The gas hydrate sample was degased and recovered at the temperature of liquid nitrogen. We controlled the ethane composition of hydrate-bund gas from 0% to 100%, covering the area of methane-rich structure I, ethane-rich structure I, and their intermediate structure II. We measured compositions of methane and ethane by a gas chromatograph (GC-2014, Shimadzu Corporation). Gas hydrate samples were placed on a temperature-controlled device and kept at 80 K. Raman spectra of hydrate samples were obtained using a Raman spectrometer (RMP-210, JASCO Corporation). We checked the Raman spectra of C-H stretching mode at 83 K, and then increased the sample temperature every 10 K until complete dissociation. We calculated the Raman peak area for C-H stretching mode of methane and ethane around 2900 cm^{-1} by a peak fitting method and obtained the survival rate of gas hydrate samples with temperature.

Pure methane hydrate survived well, more than 20% of hydrate still remained at 263 K, whereas pure ethane hydrate completely dissociated at around 200 K. These results agree well with our previous report. As for mixed-gas hydrate composed of methane and ethane, the rates of survival of structure I were lower than that of pure methane hydrate, but the crystals remained till 253 K, suggesting self-preservation. That of structure II well remained at 83-183 K, but quickly disappeared at 213 K. Therefore, it is possible that the survival rate of mixed-gas hydrate composed of methane and ethane depends on not only gas composition but also crystallographic structure.

Experimental study on the phase equilibrium condition of CO_2 hydrate with marine sediment

*Daisuke Maki[1], Hitoshi Tomaru[1]

1. Graduate School of Science and Engineering, Chiba University

Gas hydrate accumulation has been found in the marine sediments around Japan, and has been regarded as an unconventional gas resource because it contains a huge amount of methane. The phase equilibrium condition of gas hydrate provides a key parameter to estimate the distribution and resource potential of gas hydrate. Although the influences of temperature, pressure, gas/water composition, etc. on the phase equilibrium have been studied so far, experimental studies concerning the effect of sediment particles in shallow gas hydrate deposit are not well understood. In this study, we synthesized carbon dioxide hydrate which has similar physicochemical behavior to methane hydrate and examined the phase equilibrium condition with the mud collected near the shallow gas hydrate in the Japan Sea. It was found that the equilibrium condition with mud was significantly reduced; about 0.2℃ lower and about 0.1 MPa higher compare to mud-free environment. Our results strongly indicates that the existence of mud may change the stability condition of gas hydrate in the natural environment and it is necessary to consider this effect for estimating gas hydrate distribution and stability fields.

Raman spectroscopic analysis of structure H gas hydrates encapsulating cyclic hydrocarbons

*Go Fuseya[1], Satoshi Takeya[2], Akihiro Hachikubo[1]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Clathrate hydrates are crystalline inclusion compounds that consist of well-defined cages formed by water molecules and guest molecules of suitable sizes and shapes trapped in the cages. Clathrate hydrates including natural gases as guest molecules are commonly known as gas hydrates. Gas hydrates in sea or lake bottom sediments and permafrost layers have attracted considerable interest as a potential source of unconventional natural gas. There are three common crystallographic structure of hydrates, structure I (sI), structure II (sII) and structure H (sH). In the case of microbially sourced gas hydrate system, the gas hydrates are generally sI CH_4 hydrates. On the other hand, sH hydrate was found at northern Cascadia margin, where thermogenic larger hydrocarbons exist [Lu et al. 2007]. For instance,, cyclohexane (CH), methylcyclopentane (MCP), methylcyclohexane (MCH) and other large hydrocarbons, which is capable of forming sH hydrate with help gas like CH_4, were detected at the area. From the above, study for sH hydrate which encapsulating these large hydrocarbons are important for further understanding of natural gas hydrates.

In this study, sH CH_4 and larger cyclic hydrocarbon (CH, MCP and MCH) mixed hydrates were prepared. We observed the variations of Raman spectra of these cyclic hydrocarbons due to enclathrated water cages of gas hydrate. C–H and C–C stretching regions of enclathrated these cyclic hydrocarbons were measured by the Raman spectroscopic method., The Raman spectra of C–C stretching region of these hydrocarbon are useful for identification of guest molecules in natural gas hydrates because the number of Raman peaks of C–C stretching region are smaller than that of C–H stretching region.

Investigation of self-preservation of argon hydrate by measuring specific surface area

*Yuki Ikeura[1], Daisuke Yahagi[1], Akihiro Hachikubo[1], Satoshi Takeya[2]

1. Kitami institute of technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Self-preservation occurs during the dissociation of gas hydrate and drastically decreases speed of dissociation at around 253K and under atmospheric pressure in the case of methane hydrate. Takeya and Ripmeester (2008) revealed that not only methane but also nitrogen, oxygen, argon, and CO_2 hydrates showed the same self-preservation effect. This phenomena is explained that (1) gas hydrate dissociates below the ice point, (2) ice remains on the surface of crystals, (3) ice layer forms and covers on the surface of hydrate and prevent from further dissociation. We developed a device for measuring specific surface area of snow particles (Hachikubo *et al.*, 2014), and it is also available for gas hydrate crystals. Because self-preservation phenomena depends on temperature, we investigated the change of specific surface area of argon hydrate samples in their dissociation process under various temperature conditions.

Fine ice balls (diameter: 0.108-0.180 mm) were formed in liquid nitrogen using water spray and sieved in a cold room (temperature: 255 K). 3 g of ice balls were put into a pressure cell (volume: 30 mL) and measured their specific surface area. After that, argon was introduced and hydrate crystals formed at 273.2 K. Temperature of the samples were controlled at 226K, 243K, 254K, and 263K, and then the residual gases in the pressure cell were quickly removed. The internal pressure decreased to the atmospheric pressure and the samples started to dissociate. Dissociation times were controlled as 1 minute, 10 minutes, and 100 minutes, and after that the samples were fixed at the temperature of liquid nitrogen and we measured their specific surface area. Their dissociation rate were estimated from weight data of gas and water. Specific surface area of the original fine ice balls and (pure) argon hydrate samples were also measured.

Ice balls were expected to change completely into “hydrate balls”, however, more fine and irregular grains of argon hydrate were observed using an optical microscope Specific surface area of original ice balls was 71±5 [m^2 kg^{-1}], and that of argon hydrate increased to 119 [m^2 kg^{-1}]. When the dissociation period was 1 minute, more than 90% of hydrate still remained at 226-263 K. The rate of dissociation at 254 K was fastest in the case of 10 minutes dissociation (65% of hydrate remained), but about 80% of hydrate sample remained at 263 K. The specific surface area was around 120 [m^2 kg^{-1}] after 10 minutes at 263 K, indicating that the condition of surface was not changed at 263 K. On the other hand, the specific surface area increased to 279 [m^2 kg^{-1}] at 226 K after 10 minutes. Therefore, these results indicate that the self-preservation effect appeared at 263 K and kept the surface of crystals smooth rather than the case at 226 K.

Carbon isotope fractionation of CO_2 during the formation of clathrate hydrate

*Hiromi Kimura[1], Jumpei Matsuda[1], Yuki Kikuchi[1], Akihiro Hachikubo[1], Satoshi Takeya[2]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology

Hydrogen Isotope fractionation in methane during the formation of clathrate hydrate was reported by Hachikubo *et al.* (2007) that δ D of hydrate-bound methane is 4.8±0.4‰ lower than that of residual methane at 274.2K. Although natural methane hydrates distribute widely in the world, natural CO_2 hydrate was only reported at the Okinawa Trough (Sakai *et al.*, 1990). It is also possible that CO_2 hydrate exists in Mars. Isotopic fractionation of guest gas may provide useful information to understand formation processes of gas hydrate. Luzi *et al.* (2011) revealed that CO_2 $\delta^{13}C$ in hydrate-bound gas is 0.9‰ lower than that of residual gas, suggesting that light CO_2 molecules prefer to be encaged into clathrate cages. In this study, we checked the temperature effect on the isotopic difference between residual and hydrate-bound CO_2.

Samples of CO_2 hydrate (weight: 0.7 g) were experimentally prepared in a pressure cell (volume: 30 mL), and the temperature was controlled by a liquid bath (258-274 K) and cold rooms (226-254 K). Isotopic compositions of both residual and hydrate-bound CO_2 were measured by an isotope ratio mass spectrometer (IRMS). Samples were formed in the temperature range from 226 K to 274 K. The carbon isotopic differences between hydrate-bound and residual CO_2 distributed between 1.2‰ and 1.5‰, agreed fairly well with the previous report (Luzi *et al.*, 2011). The difference seemed to be large (1.5-2.0 ‰) at 226 K, indicating that the equilibrium pressure of $^{13}CO_2$ hydrate is slightly larger than that of $^{12}CO_2$ hydrate, and the difference between them becomes large in lower temperature. We will show these equilibrium data for $^{13}CO_2$ and $^{12}CO_2$ hydrates and compare with the results in stable isotope.

Gas hydrate survey off Tokachi (the Pacific Ocean) in the framework of practical education of Kitami Institute of Technology

*Yunosuke Hase[1], Jumpei Matsuda[1], Yuki Ikeura[1], Akihiro Hachikubo[1], Masaaki Konishi[1], Hirotoshi Sakagami[1], Hirotsugu Minami[1], Satoshi Yamashita[1]

1. Kitami Institute of Technology

Distribution of BSR (bottom simulating reflector) has been reported off Tokachi, the Pacific Ocean (Hayashi *et al.*, 2010). Kitami Institute of Technology started gas hydrate survey in this area on 2014, using TS Oshoro-maru of Hokkaido University. This program is conducted in the framework of practical education (name of lecture: “Practical learning about the Okhotsk Region, its history and the natural environment”), and about 40 students participate the cruise. Three cruises (C008, C046, and C061) were executed in 2014-2018. We found many gas seeps ascending from sea floor, those height exceeded 700 m from the sea floor. We recovered gas-rich sediment cores by a gravity and hydrostatic corers. Here, we report characteristics of sediment gas in this area.

Samples of sediment gas, mainly dissolved gases in pore water, were obtained by a headspace gas method. 10 mL sediment was sampled from the sediment core by a plastic syringe (volume: 5 mL) and put into a 25 mL vial. 10 mL NaCl aqueous solution was introduced into the vial by using a micropipette and sealed employing a butyl rubber septum to make a headspace (5 mL volume). To avoid any changes in the headspace, preservative (benzalkonium chloride, BKC) was added and the headspace part was flushed by helium. We roughly checked gas composition of sediment gases onboard using a portable gas chromatograph, and after that we measured the molecular and isotopic compositions of headspace gases using another gas chromatograph and CF-IRMS in our laboratory.

Concentration of C_1 increased with depth, and exceeded 1 [mM] in the bottom of some sediment cores (C008-GC1403, C046-GC1702, and C061-GC1803), indicating that their depths of SMI (sulfate-methane interface) were small and active gas seep existed at the sea floor. The minimum SMI depth was 50 [cmbsf] in C008-GC1403. C_1 / (C_2 + C_3) in these gas-rich layer was from 300 to 700. Concentration of H_2S exceeds 1 [mM] in the bottom of sediment cores. These results indicate that microbial gas is supplied from lower layer and AOM (anaerobic oxidation of methane) processes is active in beneath the sea floor. C_1 $\delta^{13}C$ profiles showed minimum values (lower than -100‰) at the SMI depth in C061-GC1803. C_2 $\delta^{13}C$ distributed between -55‰ and -30‰, suggesting that C_2 seems also microbial origin.

Geochemistry of pore water and gas in shallow sediments from offshore Primorsky Krai, Russia

*Musashi Yokoyama[1], Hitoshi Tomaru[1], Ryo Matsumoto[2], Glen Snyder[2], A.V. Yatsuk[3], D.A Shvalov[3]

1. Department Earth Sciences, Chiba University, 2. Gas Hydrate Research Laboratory, Meiji University, 3. Gas Geochemistry Laboratory, V.I.Ilichev Pacific Oceanological Institute

Offshore region of Primorsky Krai, Russia, in the northern Japan Sea is located in the boundary area between the shallower Tatar Trough on the north and deeper Japan Basin in the south. The marginal area of the Japan Sea has been characterized by the dense distribution of gas chimneys, which are identified by columnar blanking structureon acoustic records, e.g., W-S-E Tsushima Basin, Oki Trough, Joetsu Basin, Mogami Trough, and SW Sakhalin Island. Gas chimney structure delivers hydrocarbon gas, mainly methane, significantly from deep sediment to surface sediment, which may cause gas hydrate accumulation, carbonate precipitation, gas seepage, etc. Therefore it is one of the key structures controlling near-seafloor phenomena. In this research, we analyzed chemical compositions of pore water and gas collected from shallow sediments, off Primorsky, Russia (R/V Akademik M.A. Lavrentyev, Cruise LV81, 2018), and estimated the methane flux to characterize the geochemical environment near the seafloor. The sulfate concentrations linearly decrease with depth and the methane/ethane ratios are as low as ~100 at all sites, reflecting anaerobic oxidation of methane (AOM) is active at the sulfate methane interface (SMI). Decreases in calcium and magnesium were also obvious, indicating carbonate precipitation in response to alkalinity increase due to AOM. The methane flux estimated from SMI depths are generally high in the northern research area compared to southern area, in particular, at shallow gas chimney sites (SMI at ~1.5 mbsf, <1500 mWD). At the northern-most deep gas chimney sites, methane fluxes are relatively low. These results indicate that organic matter was primarily derived along the trough (from north to south) rather than the landward slope off Primorsky, and the methane generated in the sediment of deep area of the trough migrated through the porous layers to the shallow sites where the gas chimney is active. The geochemistry of pore water and gas depicts the shallow geochemical environments associated methane migration in research area.

Late Quaternary Total Organic Carbon fluctuation in the eastern Japan Sea and offshore of the Russian maritime provinces

*Yuta Hirano[1], Kyousuke Sakamoto[1], Naoto Ishida[2], Takao Ebinuma[2], Koji Seto[3], Ryo Matsumoto[4]

1. Graduate School of Sustainability Science Methane Hydrate Course ,Tottori University, 2. Tottori Univ., 3. Shimane Univ., 4. Meiji Univ.

In the Sea of Japan, three cores were taken from the Oki Trough (PC1606), Mogami Trough South (PC1726), and the offshore of the Russian Primorye (Lv81-35GC). Total organic carbon (TOC), total nitrogen (TN), and total sulfur (TS) in sediments were measured from these cores, and the organic carbon concentration and the origin of organic matter were clarified. The organic carbon concentration in the sediment reflects the past primary production. All cores have high correlation between TN and TOC. The value of C/N is from 6 to 10. On the other hand, there is no correlation between TS and TOC. The value of C/S varies from 0.2 to 11. The TOC concentration of PC1726 and Lv81-35GC is almost coincide with PC1606. However, the peak around 10 ka detected in PC1606 is unclear in the other cores. In the period of the Last Glacial Maximum, primary production declined at all areas. However, the subsequent reactions were different in each area.

Geochemical behavior of carbon in shallow sediment within the gas chimney in Hidaka Trough, offshore Hokkaido

Tsuyoshi Mamata[1], *Hitoshi Tomaru[1], Ryo Matsumoto[2]

1. Department of Earth Sciences, Chiba University, 2. Gas Hydrate Research Laboratory, Meiji University

The Hidaka Trough, offshore Hokkaido, has recently been characterized by subsurface gas chimney structures associated with mound/pockmark topography and methane plume, which indicate an intensive gas migration from deep sediments to the surface area. In the region where remarkable gas chimneys are developed such as in offshore Joetsu, shallow marine sediments are characterized by the precipitation of authigenic carbonate, massive gas hydrates and development of chemotrophs because of high methane concentration near the seafloor. In these environments, anaerobic oxidation of methane utilizes both methane and sulfate, resulting in sulfate depleted in shallow sediment. Inorganic carbon generated by methane oxidation does not incorporate only with calcium ion to form carbonate but also is reduced by microbially-mediated methanogenic reaction. Carbon is therefore a key substance near the depth of sulfate methane interface (SMI) in high methane flux area. This study aims to figure out the chemical reaction associated with carbon, which characterizes geochemical environment in shallow sediments, by analyzing concentrations of dissolved ions and hydrocarbons, and stable isotopic composition ($\delta^{13}C$) of dissolved carbons collected from shallow sediments with gas chimney structures in the Hidaka Trough, offshore Hokkaido.
In the area of calyptogena community, the SMI locates at shallow depth and indicates reductive environment is established because of sulfate depletion. The sulfate is depleted at shallower depth in the area with carbonates near the seafloor, where the concentration of calcium ion is also lower than other areas. These results indicate carbonate formed at higher rate in the area with higher methane flux. Total organic carbon amount decrease with depth above the SMI, the residual organic matter in sediment generates methane at depth and enhances the methane flux toward the seafloor. Based on the composition of dissolved hydrocarbons and $\delta^{13}C$ of methane, although the methane is generally of biogenic origin over the research areas in the Hidaka Trough, the $\delta^{13}C$ of methane increase rapidly with depth on the mound center, indicating thermogenic methane predominantly migrate from deeper sediments at the site. Biogeochemical behavior of carbon varies not only among sampling sites but also among relative locations on the single gas chimney structure.

[M-IS21] Gas hydrate in environmental-resource sciences

convener:Hitoshi Tomaru(Department of Earth Sciences, Chiba University), Akihiro Hachikubo(Kitami Institute of Technology), Atsushi Tani(Graduate School of Human Development and Environment, Kobe University), Shusaku Goto(Institute for Geo-Resources and Environment National Institute of Advanced Industrial Science and Technology)

An increasing number of researches focusing on natural gas hydrates has recently been conducted from the environmental, material, and resource scientific viewpoints. This session aims to share and discuss the latest research results associated with natural/experimental gas hydrates to understand and examine the nature and potential of gas hydrates in the past-present-future of the Earth and the development/application for our life. Because the researches on gas hydrates are interdisciplinary, broad topics from field and experimental researches, modeling, etc. will be presented in this session.

Raman spectroscopic analysis of isotopologue methane hydrates

*Yuki Kikuchi[1], Jumpei Matsuda[1], Akihiro Hachikubo[1], Satoshi Takeya[2]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Raman spectroscopy is one of the useful tool to get information of gas hydrate crystals. Natural gas hydrates in submarine/sublacustrine sediment mainly encage methane. Methane molecule is composed of carbon and hydrogen, and three kinds of isotopologues, $^{12}CH_4$, $^{13}CH_4$, and CH_3D exist in nature. Ozeki *et al.* (2018) first reported Raman spectra of CH_3D and CD_4 hydrates and compared with CH_4 (mainly $^{12}CH_4$) hydrate. We report Raman spectra of $^{13}CH_4$ hydrate and summarize Raman spectra of isotopologue methane hydrates.

$^{13}CH_4$ hydrate sample was synthesized in a small pressure cell (volume: 5 mL). Fine ice powder (1g) was put in the pressure cell, and introduced appropriate amount of $^{13}CH_4$ (purity: 99.5%, Taiyo-Nissan). $^{13}CH_4$ hydrate was formed by melting the fine ice powder at the temperature of 273.2 K under high pressure of $^{13}CH_4$. We retrieved the hydrate sample at 77 K and its Raman spectra was obtained at 123 K in the range 2,500-3,300 cm^{-1} using a Raman spectrometer (RMP-210, JASCO Corporation). The Raman peaks were fitted in the range 2,800-3,000 cm^{-1} for the C-H stretching peaks of methane using a Voigt function to obtain the integrated intensities of the two peaks corresponding to methane encaged in the large and small cages of the cubic structure I.

Raman shifts for the C-H stretching and bending modes of $^{13}CH_4$ was 0.8 cm^{-1} and 14 cm^{-1} smaller than those of $^{12}CH_4$, respectively, suggesting that ^{13}C-H bonds affect its vibrational frequency. Hydration number of $^{13}CH_4$ was estimated as 6.00±0.02, almost the same as that of $^{12}CH_4$ (6.02±0.02). Therefore, Cage occupancies of $^{13}CH_4$ and $^{12}CH_4$ hydrates showed no difference between them.

Gas origin of hydrate-bound gas in Lake Baikal

*Jumpei Matsuda[1], Yuki Kikuchi[1], Akihiro Hachikubo[1], Oleg Khlystov[2], Gennadiy Kalmychkov[3], Marc De Batist[4], Hirotoshi Sakagami[1], Hirotsugu Minami[1], Satoshi Yamashita[1]

1. Kitami Institute of Technology, 2. Limnological Institute, SB RAS, 3. Vinogradov Institute of Geochemistry, SB RAS, 4. Ghent University

In the framework of international collaboration between Kitami Institute of Technology (Japan), Limnological Institute (Russia), and Ghent University (Belgium), natural gas hydrates have been recovered from lake-bottom sediments at Lake Baikal. Near-surface gas hydrate was first discovered at the Malenky mud volcano at the southern Baikal basin in 2000. Multi-phase Gas Hydrate Project (MHP, 2009-2018) has revealed distribution of near-surface gas hydrates at the southern and central Baikal basins. We found six new places (Enkhelook, Soukhaya, KIT, LIN, PosolCanyon1, and PosolCanyon2) during the VER18-03 cruise in 2018. The total number of places where near-surface gas hydrates were retrieved is 53. In this report, we summarize characteristics of hydrate-bound gases retrieved from all the sites since 2005.

Gas hydrate crystals were recovered from lake-bottom sediment cores, and hydrate-bound gas samples were stored in 5-mL vials. Total number of hydrate-bound gas samples was 626. Molecular and isotopic compositions of hydrate-bound gas were measured using a gas chromatograph and a stable isotope ratio mass spectrometer.

In the Bernard plot, C_1 $\delta^{13}C$ and C_1 / (C_2 + C_3) distributes from -70‰ to -44‰ and from 6 to 100,000, respectively, suggesting that the origin of hydrate-bound gas is microbial, thermogenic, and their mixed-gas. Almost all data are plotted on the mixing line between microbial and thermogenic, however, Gorevoy Utes (oil seep site) showed thermogenic C_1 with small composition of C_2 and C_3. The data concentrates in the microbial field (C_1 $\delta^{13}C$: -66‰ and C_1 / (C_2 + C_3): 1,000-10,000). C_1 δD of thermogenic C_1 increases with C_1 $\delta^{13}C$. C_2 $\delta^{13}C$ distributes from -69‰ to -23‰. 17 sites (ex. Solzan, Talanka, Turka, KIT, etc.) showed microbial C_1 and C_2. 27 sites (Malenky, Oblom, Seep13, Kukuy K6, etc.) showed microbial C_1 and thermogenic C_2, indicating that small amount of thermogenic gas is mixed with microbial gas. Other sites (Mamay, PosolBank, Gorevoy Utes, Kedr, etc.) showed thermogenic C_1 and C_2. The Milkov plot (relation between C_1 $\delta^{13}C$ and C_2 $\delta^{13}C$) can express mixing condition between microbial and thermogenic rather than the Bernard plot. C_2 δD decreased with decrease in C_2 $\delta^{13}C$, therefore microbial C_2 is both depleted in ^{13}C and D. We conclude that hydrate-bound gas at Lake Baikal is mainly microbial gas, and thermogenic gas ascends from deep layer at some areas (Kedr, PosolBank, Kukuy, and Gorevoy Utes) and forms the structure II gas hydrate.

Validation of self-preservation effect of methane and ethane mixed-gas hydrate by Raman spectroscopy

*Yunosuke Hase[1], Jumpei Matsuda[1], Akihiro Hachikubo[1], Satoshi Takeya[2]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Methane hydrate can be stored long time under atmospheric pressure below 273.2K, even though their P-T conditions is unstable, namely "self-preservation effect". On the contrary, Takeya and Ripmeester (2008) reported that ethane hydrate shows no self-preservation. In natural condition, methane and ethane mixed-gas hydrates have been found at Lake Baikal, however, there is no information for the mixed-gas system. In the last JpGU meeting we report self-preservation effect for mixed-gas hydrate, but the conditions of samples are not uniform. Because the size of crystals affect rate of survival at higher temperature, we controlled the specific surface of area of gas hydrate samples in this study.

We put 0.7 g of fine ice balls (diameter: 0.108-0.180 mm) into a pressure cell (volume: 30 mL) and mixed-gas of methane and ethane was introduced. Hydrate crystals formed at 273.2 K. The gas hydrate sample was degased and recovered at the temperature of liquid nitrogen. We controlled the ethane composition of hydrate-bund gas from 0% to 100%, covering the area of methane-rich structure I, ethane-rich structure I, and their intermediate structure II. We measured compositions of methane and ethane by a gas chromatograph (GC-2014, Shimadzu Corporation). Gas hydrate samples were placed on a temperature-controlled device and kept at 80 K. Raman spectra of hydrate samples were obtained using a Raman spectrometer (RMP-210, JASCO Corporation). We checked the Raman spectra of C-H stretching mode at 83 K, and then increased the sample temperature every 10 K until complete dissociation. We calculated the Raman peak area for C-H stretching mode of methane and ethane around 2900 cm^{-1} by a peak fitting method and obtained the survival rate of gas hydrate samples with temperature.

Pure methane hydrate survived well, more than 20% of hydrate still remained at 263 K, whereas pure ethane hydrate completely dissociated at around 200 K. These results agree well with our previous report. As for mixed-gas hydrate composed of methane and ethane, the rates of survival of structure I were lower than that of pure methane hydrate, but the crystals remained till 253 K, suggesting self-preservation. That of structure II well remained at 83-183 K, but quickly disappeared at 213 K. Therefore, it is possible that the survival rate of mixed-gas hydrate composed of methane and ethane depends on not only gas composition but also crystallographic structure.

Experimental study on the phase equilibrium condition of CO_2 hydrate with marine sediment

*Daisuke Maki[1], Hitoshi Tomaru[1]

1. Graduate School of Science and Engineering, Chiba University

Gas hydrate accumulation has been found in the marine sediments around Japan, and has been regarded as an unconventional gas resource because it contains a huge amount of methane. The phase equilibrium condition of gas hydrate provides a key parameter to estimate the distribution and resource potential of gas hydrate. Although the influences of temperature, pressure, gas/water composition, etc. on the phase equilibrium have been studied so far, experimental studies concerning the effect of sediment particles in shallow gas hydrate deposit are not well understood. In this study, we synthesized carbon dioxide hydrate which has similar physicochemical behavior to methane hydrate and examined the phase equilibrium condition with the mud collected near the shallow gas hydrate in the Japan Sea. It was found that the equilibrium condition with mud was significantly reduced; about 0.2℃ lower and about 0.1 MPa higher compare to mud-free environment. Our results strongly indicates that the existence of mud may change the stability condition of gas hydrate in the natural environment and it is necessary to consider this effect for estimating gas hydrate distribution and stability fields.

Raman spectroscopic analysis of structure H gas hydrates encapsulating cyclic hydrocarbons

*Go Fuseya[1], Satoshi Takeya[2], Akihiro Hachikubo[1]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology (AIST)

Clathrate hydrates are crystalline inclusion compounds that consist of well-defined cages formed by water molecules and guest molecules of suitable sizes and shapes trapped in the cages. Clathrate hydrates including natural gases as guest molecules are commonly known as gas hydrates. Gas hydrates in sea or lake bottom sediments and permafrost layers have attracted considerable interest as a potential source of unconventional natural gas. There are three common crystallographic structure of hydrates, structure I (sI), structure II (sII) and structure H (sH). In the case of microbially sourced gas hydrate system, the gas hydrates are generally sI CH_4 hydrates. On the other hand, sH hydrate was found at northern Cascadia margin, where thermogenic larger hydrocarbons exist [Lu et al. 2007]. For instance,, cyclohexane (CH), methylcyclopentane (MCP), methylcyclohexane (MCH) and other large hydrocarbons, which is capable of forming sH hydrate with help gas like CH_4, were detected at the area. From the above, study for sH hydrate which encapsulating these large hydrocarbons are important for further understanding of natural gas hydrates.

In this study, sH CH_4 and larger cyclic hydrocarbon (CH, MCP and MCH) mixed hydrates were prepared. We observed the variations of Raman spectra of these cyclic hydrocarbons due to enclathrated water cages of gas hydrate. C–H and C–C stretching regions of enclathrated these cyclic hydrocarbons were measured by the Raman spectroscopic method., The Raman spectra of C–C stretching region of these hydrocarbon are useful for identification of guest molecules in natural gas hydrates because the number of Raman peaks of C–C stretching region are smaller than that of C–H stretching region.

Self-preservation occurs during the dissociation of gas hydrate and drastically decreases speed of dissociation at around 253K and under atmospheric pressure in the case of methane hydrate. Takeya and Ripmeester (2008) revealed that not only methane but also nitrogen, oxygen, argon, and CO_2 hydrates showed the same self-preservation effect. This phenomena is explained that (1) gas hydrate dissociates below the ice point, (2) ice remains on the surface of crystals, (3) ice layer forms and covers on the surface of hydrate and prevent from further dissociation. We developed a device for measuring specific surface area of snow particles (Hachikubo *et al.*, 2014), and it is also available for gas hydrate crystals. Because self-preservation phenomena depends on temperature, we investigated the change of specific surface area of argon hydrate samples in their dissociation process under various temperature conditions.

Fine ice balls (diameter: 0.108-0.180 mm) were formed in liquid nitrogen using water spray and sieved in a cold room (temperature: 255 K). 3 g of ice balls were put into a pressure cell (volume: 30 mL) and measured their specific surface area. After that, argon was introduced and hydrate crystals formed at 273.2 K. Temperature of the samples were controlled at 226K, 243K, 254K, and 263K, and then the residual gases in the pressure cell were quickly removed. The internal pressure decreased to the atmospheric pressure and the samples started to dissociate. Dissociation times were controlled as 1 minute, 10 minutes, and 100 minutes, and after that the samples were fixed at the temperature of liquid nitrogen and we measured their specific surface area. Their dissociation rate were estimated from weight data of gas and water. Specific surface area of the original fine ice balls and (pure) argon hydrate samples were also measured.

Ice balls were expected to change completely into “hydrate balls”, however, more fine and irregular grains of argon hydrate were observed using an optical microscope Specific surface area of original ice balls was 71±5 [m^2 kg^{-1}], and that of argon hydrate increased to 119 [m^2 kg^{-1}]. When the dissociation period was 1 minute, more than 90% of hydrate still remained at 226-263 K. The rate of dissociation at 254 K was fastest in the case of 10 minutes dissociation (65% of hydrate remained), but about 80% of hydrate sample remained at 263 K. The specific surface area was around 120 [m^2 kg^{-1}] after 10 minutes at 263 K, indicating that the condition of surface was not changed at 263 K. On the other hand, the specific surface area increased to 279 [m^2 kg^{-1}] at 226 K after 10 minutes. Therefore, these results indicate that the self-preservation effect appeared at 263 K and kept the surface of crystals smooth rather than the case at 226 K.

Carbon isotope fractionation of CO_2 during the formation of clathrate hydrate

*Hiromi Kimura[1], Jumpei Matsuda[1], Yuki Kikuchi[1], Akihiro Hachikubo[1], Satoshi Takeya[2]

1. Kitami Institute of Technology, 2. National Institute of Advanced Industrial Science and Technology

Hydrogen Isotope fractionation in methane during the formation of clathrate hydrate was reported by Hachikubo *et al.* (2007) that δ D of hydrate-bound methane is 4.8±0.4‰ lower than that of residual methane at 274.2K. Although natural methane hydrates distribute widely in the world, natural CO_2 hydrate was only reported at the Okinawa Trough (Sakai *et al.*, 1990). It is also possible that CO_2 hydrate exists in Mars. Isotopic fractionation of guest gas may provide useful information to understand formation processes of gas hydrate. Luzi *et al.* (2011) revealed that CO_2 $\delta^{13}C$ in hydrate-bound gas is 0.9‰ lower than that of residual gas, suggesting that light CO_2 molecules prefer to be encaged into clathrate cages. In this study, we checked the temperature effect on the isotopic difference between residual and hydrate-bound CO_2.

Samples of CO_2 hydrate (weight: 0.7 g) were experimentally prepared in a pressure cell (volume: 30 mL), and the temperature was controlled by a liquid bath (258-274 K) and cold rooms (226-254 K). Isotopic compositions of both residual and hydrate-bound CO_2 were measured by an isotope ratio mass spectrometer (IRMS). Samples were formed in the temperature range from 226 K to 274 K. The carbon isotopic differences between hydrate-bound and residual CO_2 distributed between 1.2‰ and 1.5‰, agreed fairly well with the previous report (Luzi *et al.*, 2011). The difference seemed to be large (1.5-2.0 ‰) at 226 K, indicating that the equilibrium pressure of $^{13}CO_2$ hydrate is slightly larger than that of $^{12}CO_2$ hydrate, and the difference between them becomes large in lower temperature. We will show these equilibrium data for $^{13}CO_2$ and $^{12}CO_2$ hydrates and compare with the results in stable isotope.

Gas hydrate survey off Tokachi (the Pacific Ocean) in the framework of practical education of Kitami Institute of Technology

*Yunosuke Hase[1], Jumpei Matsuda[1], Yuki Ikeura[1], Akihiro Hachikubo[1], Masaaki Konishi[1], Hirotoshi Sakagami[1], Hirotsugu Minami[1], Satoshi Yamashita[1]

1. Kitami Institute of Technology

Distribution of BSR (bottom simulating reflector) has been reported off Tokachi, the Pacific Ocean (Hayashi *et al.*, 2010). Kitami Institute of Technology started gas hydrate survey in this area on 2014, using TS Oshoro-maru of Hokkaido University. This program is conducted in the framework of practical education (name of lecture: “Practical learning about the Okhotsk Region, its history and the natural environment”), and about 40 students participate the cruise. Three cruises (C008, C046, and C061) were executed in 2014-2018. We found many gas seeps ascending from sea floor, those height exceeded 700 m from the sea floor. We recovered gas-rich sediment cores by a gravity and hydrostatic corers. Here, we report characteristics of sediment gas in this area.

Samples of sediment gas, mainly dissolved gases in pore water, were obtained by a headspace gas method. 10 mL sediment was sampled from the sediment core by a plastic syringe (volume: 5 mL) and put into a 25 mL vial. 10 mL NaCl aqueous solution was introduced into the vial by using a micropipette and sealed employing a butyl rubber septum to make a headspace (5 mL volume). To avoid any changes in the headspace, preservative (benzalkonium chloride, BKC) was added and the headspace part was flushed by helium. We roughly checked gas composition of sediment gases onboard using a portable gas chromatograph, and after that we measured the molecular and isotopic compositions of headspace gases using another gas chromatograph and CF-IRMS in our laboratory.

Concentration of C_1 increased with depth, and exceeded 1 [mM] in the bottom of some sediment cores (C008-GC1403, C046-GC1702, and C061-GC1803), indicating that their depths of SMI (sulfate-methane interface) were small and active gas seep existed at the sea floor. The minimum SMI depth was 50 [cmbsf] in C008-GC1403. C_1 / (C_2 + C_3) in these gas-rich layer was from 300 to 700. Concentration of H_2S exceeds 1 [mM] in the bottom of sediment cores. These results indicate that microbial gas is supplied from lower layer and AOM (anaerobic oxidation of methane) processes is active in beneath the sea floor. C_1 $\delta^{13}C$ profiles showed minimum values (lower than -100‰) at the SMI depth in C061-GC1803. C_2 $\delta^{13}C$ distributed between -55‰ and -30‰, suggesting that C_2 seems also microbial origin.

Geochemistry of pore water and gas in shallow sediments from offshore Primorsky Krai, Russia

*Musashi Yokoyama[1], Hitoshi Tomaru[1], Ryo Matsumoto[2], Glen Snyder[2], A.V. Yatsuk[3], D.A Shvalov[3]

1. Department Earth Sciences, Chiba University, 2. Gas Hydrate Research Laboratory, Meiji University, 3. Gas Geochemistry Laboratory, V.I.Ilichev Pacific Oceanological Institute

Offshore region of Primorsky Krai, Russia, in the northern Japan Sea is located in the boundary area between the shallower Tatar Trough on the north and deeper Japan Basin in the south. The marginal area of the Japan Sea has been characterized by the dense distribution of gas chimneys, which are identified by columnar blanking structureon acoustic records, e.g., W-S-E Tsushima Basin, Oki Trough, Joetsu Basin, Mogami Trough, and SW Sakhalin Island. Gas chimney structure delivers hydrocarbon gas, mainly methane, significantly from deep sediment to surface sediment, which may cause gas hydrate accumulation, carbonate precipitation, gas seepage, etc. Therefore it is one of the key structures controlling near-seafloor phenomena. In this research, we analyzed chemical compositions of pore water and gas collected from shallow sediments, off Primorsky, Russia (R/V Akademik M.A. Lavrentyev, Cruise LV81, 2018), and estimated the methane flux to characterize the geochemical environment near the seafloor. The sulfate concentrations linearly decrease with depth and the methane/ethane ratios are as low as ~100 at all sites, reflecting anaerobic oxidation of methane (AOM) is active at the sulfate methane interface (SMI). Decreases in calcium and magnesium were also obvious, indicating carbonate precipitation in response to alkalinity increase due to AOM. The methane flux estimated from SMI depths are generally high in the northern research area compared to southern area, in particular, at shallow gas chimney sites (SMI at ~1.5 mbsf, <1500 mWD). At the northern-most deep gas chimney sites, methane fluxes are relatively low. These results indicate that organic matter was primarily derived along the trough (from north to south) rather than the landward slope off Primorsky, and the methane generated in the sediment of deep area of the trough migrated through the porous layers to the shallow sites where the gas chimney is active. The geochemistry of pore water and gas depicts the shallow geochemical environments associated methane migration in research area.

Late Quaternary Total Organic Carbon fluctuation in the eastern Japan Sea and offshore of the Russian maritime provinces

*Yuta Hirano[1], Kyousuke Sakamoto[1], Naoto Ishida[2], Takao Ebinuma[2], Koji Seto[3], Ryo Matsumoto[4]

1. Graduate School of Sustainability Science Methane Hydrate Course ,Tottori University, 2. Tottori Univ., 3. Shimane Univ., 4. Meiji Univ.

In the Sea of Japan, three cores were taken from the Oki Trough (PC1606), Mogami Trough South (PC1726), and the offshore of the Russian Primorye (Lv81-35GC). Total organic carbon (TOC), total nitrogen (TN), and total sulfur (TS) in sediments were measured from these cores, and the organic carbon concentration and the origin of organic matter were clarified. The organic carbon concentration in the sediment reflects the past primary production. All cores have high correlation between TN and TOC. The value of C/N is from 6 to 10. On the other hand, there is no correlation between TS and TOC. The value of C/S varies from 0.2 to 11. The TOC concentration of PC1726 and Lv81-35GC is almost coincide with PC1606. However, the peak around 10 ka detected in PC1606 is unclear in the other cores. In the period of the Last Glacial Maximum, primary production declined at all areas. However, the subsequent reactions were different in each area.

Geochemical behavior of carbon in shallow sediment within the gas chimney in Hidaka Trough, offshore Hokkaido

Tsuyoshi Mamata[1], *Hitoshi Tomaru[1], Ryo Matsumoto[2]

1. Department of Earth Sciences, Chiba University, 2. Gas Hydrate Research Laboratory, Meiji University

The Hidaka Trough, offshore Hokkaido, has recently been characterized by subsurface gas chimney structures associated with mound/pockmark topography and methane plume, which indicate an intensive gas migration from deep sediments to the surface area. In the region where remarkable gas chimneys are developed such as in offshore Joetsu, shallow marine sediments are characterized by the precipitation of authigenic carbonate, massive gas hydrates and development of chemotrophs because of high methane concentration near the seafloor. In these environments, anaerobic oxidation of methane utilizes both methane and sulfate, resulting in sulfate depleted in shallow sediment. Inorganic carbon generated by methane oxidation does not incorporate only with calcium ion to form carbonate but also is reduced by microbially-mediated methanogenic reaction. Carbon is therefore a key substance near the depth of sulfate methane interface (SMI) in high methane flux area. This study aims to figure out the chemical reaction associated with carbon, which characterizes geochemical environment in shallow sediments, by analyzing concentrations of dissolved ions and hydrocarbons, and stable isotopic composition ($\delta^{13}C$) of dissolved carbons collected from shallow sediments with gas chimney structures in the Hidaka Trough, offshore Hokkaido.
In the area of calyptogena community, the SMI locates at shallow depth and indicates reductive environment is established because of sulfate depletion. The sulfate is depleted at shallower depth in the area with carbonates near the seafloor, where the concentration of calcium ion is also lower than other areas. These results indicate carbonate formed at higher rate in the area with higher methane flux. Total organic carbon amount decrease with depth above the SMI, the residual organic matter in sediment generates methane at depth and enhances the methane flux toward the seafloor. Based on the composition of dissolved hydrocarbons and $\delta^{13}C$ of methane, although the methane is generally of biogenic origin over the research areas in the Hidaka Trough, the $\delta^{13}C$ of methane increase rapidly with depth on the mound center, indicating thermogenic methane predominantly migrate from deeper sediments at the site. Biogeochemical behavior of carbon varies not only among sampling sites but also among relative locations on the single gas chimney structure.

[M-IS27] Atmospheric electricity: Applications toward natural disaster mitigation

convener:Yasuhide Hobara(Graduate School of Information and Engineering Department of Communication Engineering and Informatics, The University of Electro-Communications), Masashi Kamogawa(Department of Physics, Tokyo Gakugei University), Chairperson:Takeshi Morimoto

In recent years, various types of natural disasters caused by climate change, earthquake, etc. occur frequently in the world. In 2018 heavy precipitation in various regions of Japan and the earthquakes in Hokkaido and Indonesiaproduced/greater human and economic/damage.

In 2019JpGU Atmospheric Electricity (AE) session, invited experts are going to introduce their scientific challenges in order to monitor, predict and mitigate natural disasters by using knowledge of the atmospheric electricity. For example, monitoring and prediction of extreme weather by the latest weather radar system and lightning observations, electromagnetic phenomena prior to earthquakes, etc. will be included. We certainly welcome contributed papers regarding all topics on atmospheric electricityincluding global circuit, ion and fair weather electricity, thunderstorm electrification, lightning physics, lightning and meteorology, electrical effects of thunderstorms on the middle and upper atmosphere such as transient luminous events and high energy phenomena, lightning protection, terrestrial electromagnetic environment and so on.

Advantage and Disadvantage of the Phased Array Weather Radar

*Tomoo Ushio[1], Tomoaki Mega[1], Hiroshi Kikuchi[2], Eiichi Yoshikawa[3]

1. Tokyo Metropolitan University, 2. University of Electro-Communications, 3. JAXA

Recent progress of information and communication technologies has been enabling us to realize a rapid scanning radar system. In 2012, Toshiba Corporation and Osaka University succeeded in developing a new type of Phased Array Radar (PAR) system (Yoshikawa et al. 2013, Ushio et al. 2015, Mizutani et al. 2018) under a grant of National Institute of Communication and Information Technology (NICT), and installed in Suita Campus, Osaka University. This PAR system can scan the whole sky within 30 seconds up to 60 km in radius over 100 elevation angles with digital beam forming technique, and the initial observation results demonstrate the unique capability of the new PAR system. However, the observation is sometimes seriously contaminated by strong ground clutter through relatively high sidelobes at transmitting stage. In this study, a new clutter mitigation algorithm from adaptive beam forming technique on Minimum Mean Square Error (MMSE) formulation was investigated, and succeeded in suppressing not only the ground clutter but also ghost echo from strong precipitation echo nearby more than 20dB. And also the adaptive algorithm was applied to supress the range sidelobe and showed the sidelobe level of -60dB. In this presentation, the advantages and disadvantages of the PAR will be discussed based on the observation results.

Initial Observations with X-band Dual Polarimetric Phased Array Weather Radar in Tokyo

*Hiroshi Kikuchi[1], Taku Suezawa[2], Yasuhide Hobara[1], Tomoo Ushio[2]

1. The University of Electro-Communications, 2. Tokyo Metropolitan University

The weather radars using parabolic dish antenna generally require 5-10 minutes to mechanically rotate and to tilt upwards as they sample the atmosphere at several different elevation angles. The number of the observable elevation angles is about ten or so. The single polarization phased array weather radar (SP-PAWR), which has been developed in 2012, was designed to conduct precipitation measurement of a radar reflectivity factor, in less than 10 or 30 seconds in a range of 20 or 60 km in real-time, respectively. As a next radar development project, a dual polarimetric phased array weather radar (Multi-parameter phased array radar; MP-PAWR) is being developed. It can provide multi-parameter measurements that reveal detailed microphysics of storms in addition to accurate precipitation estimation, and can improve weather forecasts.
The first made MP-PAWR, which simultaneously transmits pulses of horizontal and vertical polarized radiation, has been developed and installed in December 2017, at Saitama University, Japan. The center of frequency is 9.4GHz (X-band). The MP-PAWR has a scanning scheme similar to the SP-PAWR, which uses the mechanical and electronic scanning in azimuth and elevation angles, respectively. The MP-PAWR provides the polarimetric precipitation measurements in three-dimensional volume scanning in less than 30 or 60 seconds in a range of 60 or 80 km in real-time, respectively.
In this presentation, we will show the initial observation results. To confirm reliability of the measurements and to evaluate the accuracy of the measurements by the MP-PAWR, the initial observation results of the MP-PAWR are compared with an optical disdrometer data.

Three-dimensional total lightning characteristics of convective cells observed by the Tokyo LMA in the summer season in Tokyo Metropolitan area

*Namiko Sakurai[1], Paul R. Krehbiel[2], William Rison[2], Ronald J. Thomas[2], Daniel Rodeheffer[2], Shingo Shimizu[1], Koyuru Iwanami[1], Takeshi Maesaka[1], Kaori Kieda[1], Yasushi Uji[1]

1. National Research Institute For Earth Science and Disaster Resilience, 2. New Mexico Tech.

The National research Institute for Earth science and Disaster resilience, Japan (NIED) has observed three-dimensional total lightning with Lightning Mapping Array in Tokyo metropolitan area (Tokyo LMA) since 2017. In this study, we report various total lightning characteristics of convective cells observed by the Tokyo LMA in the summer season. Three convective cells developed at around 14:00 JST on 30 August 2017 in Tokyo. They were located at a short distance each other, and they merged into a multi-cell thunderstorm after a while. The total lightning characteristics of the three convective cells before they merged into the multi-cell thunderstorm are as follows: in one convective cell which was located in the middle of the cells, IC lightning flashes preceded the first CG lightning for about 20 minutes. On the other hand, a CG lightning flash firstly occurred in another convective cell. In the other convective cell, IC lightning flashes predominated. These three cells and the multi-cell thunderstorm had normal tripole structures. In addition, several bolt-from-the-blue were observed in these three cells.

Estimating rainfall in heavy rain events using lightning data in Japan

*Ogawa Tetsuya[1], Yasuhide Hobara[1], Hiroyuki IWASAKI[2], Stan Heckman[3], Michael Stock[3]

1. University of Electro-Communications, 2. Gunma University, 3. EarthNetworks

In this study, we examined the relationship between total lightning (TL) and heavy rainfall in high spatio-time resolution by using 37 severe thunderstorms in Japan. TL is continuously monitored by the Japanese Total Lightning Network (JTLN) deployed by UEC and operated jointly by UEC and EarthNetworks, whilst high spatio-temporal precipitation data is obtained by eXtended Rader Information Network (XRAIN) operated by Ministry of Land, Infrastructure, Transport and Tourism in Japan. As a result, positive linear relation with rather high cross correlation (r2 ~ 0.54 between TL and Precipitation Volume (PV) [m3] has been obtained. The cross correlation between TL and PV is much higher than that for cloud-to-ground lightning (CG) and PV. Although the slope of linear relation (TL vs. PV) varies depending on heavy rain events, TL can be promising tool to estimate severe rainfall.

The Effect of Lightning Phenomena on Lightning Protection for Objects on the Ground

*Yokoyama Shigeru[1]

1. Shizuoka University

When lightning strikes the transmission line or the distribution line, high voltage is generated between the wire and the earth, discharge occurs in the insulator, and power failure occurs. A high voltage is generated when the peak value of the lightning current is large. Also, as the wave front length of the current is shorter, a higher voltage is generated. On the other hand, the lightning rod fails to catch the lightning discharge and destroys the roof and wall of the building even with the low peak value of the lightning current. Furthermore, damage caused by lightning arrester burnout is not much affected by the length of wave front length, and it is greatly influenced by the duration (charge amount) of the lightning current. Table 1 shows the relationship between the types of lightning damage and lightning parameters. Since lightning properties related to lightning damage of ground structures depend upon the object, it is important to fully understand the lightning phenomena to take countermeasures against lightning damages. Moreover, it is also necessary to clarify the seasonal and local characteristics of lightning from the viewpoint of risk management because there are lightning with significantly different properties from ordinary summer lightning such as the Japanese winter lightning. In this paper I will explain the lightning properties necessary for countermeasures against lightning damage and consider the issues of lightning observations in the future.

In 2018 we established the new permanent observation site in Pahang, Malaysia and started continuous recording of horizontal magnetic waveforms in the Extremely Low Frequency (ELF) band by using high sensitivity search coils. We carried out test measurements at four different locations in Malay peninsula and found out that Pahang is the most electromagnetically quiet place for measurement. Initial results indicate a very good performance registering clear waveforms from lightning discharges. We successfully estimated individual lightning charge moment changes (CMCs) with a small lower bound (~few Ckm) with a lightning location data from total lightning network indicative of deducing spatial and temporal dependence of lightning with CMC over Southeast Asia region.

Discussion

Earthquake precursory electromagnetic phenoma : Summary and prospective

*Masashi Hayakawa[1]

1. Hayakawa Institute of Seismo Electromagnetics.Co. LTD. University of Electro-Communications venture company

This paper describes the overview of electromagnetic phenomena mainly prior to an earthquake (EQ)(so-colled Seismo Electromagnetics). Initially this paper will report on the history of seismo-electromagnetics, findings for the 1995 Kobe EQ and the 2011 Tohoku EQ, recent statistical results, latest achievement (lithosphere-atomosphere-ionosphere coupling), prospective, etc.

Detection of lower ionospheric anomaly preceding earthquake using nonlinear autoregressive neural network

*Kakeru Matsuki[1], Hayato Iibuchi[1], Hendy Santosa[3], Yasuhide Hobara[1], Michael A Balikhin[2]

1. The University of Electro-Communications , 2. University of Sheffield, 3. University of Bengkulu

It is possible to monitor the state of the lower ionosphere by observing the VLF (Very Low Frequency) transmitter radio waves with a frequency band of 10 to 50 kHz propagating between the Earth and the ionosphere. In recent years, NARX - NN (Nonlinear Auto Regressive with eXogenous Input - Neural Network) has been applied as a highly accurate modeling and prediction method of temporal variation of VLF band transmitter radio wave amplitude. As a result, we obtain the extremely high prediction accuracy of cross correlation coefficient 0.9 or more between predicted and observed amplitude. Meanwhile, anomalies in the VLF band transmitter radio wave amplitude have been reported indicating the disturbance of the lower ionosphere at night from a week to few days before large earthquakes. Since the accuracy of anomaly detection is not high yet, this study aims to improve the detection accuracy of the lower ionospheric disturbance by analyzing the nighttime amplitude of the VLF band transmission wave using NARX - NN. By specifying the external factors that affect the lower ionospheric disturbance preceding the earthquakes and statistically investigating the difference between observed and predicted values of the VLF amplitude, we contribute to understand occurrence mechaism of lower seismo ionospheric anomalies.

Analysis of multipoint measurements of plasma turbulence

*Michael A Balikhin[1], Simon N Walker[1]

1. University of Sheffield

The presentation is devoted to the review of advanced methods for the analysis of multipoint measurements of plasma turbulence. Both time and frequency domain methods are reviewed. Using examples of in situ spacecraft observations of plasma turbulence it is shown how the system science based approaches can be used to identify linear and nonlinear dynamical processes within the turbulence.

In strong electric fields of thunderclouds and lightning, electrons are accelerated to relativistic energy, and emit bremsstrahlung gamma rays which are observed by space bourne, airbourne, and on-ground experiments. To reveal the mechanism and condition where the electron acceleration takes place, we have been performing the Gamma-Ray Observation of Winter Thunderclouds (GROWTH) experiments in coastal areas of Japan Sea since 2007. In 2015, we started multi-point observation campaigns with portable radiation detectors in Ishikawa and Niigata Prefectures. So far, we have revealed characteristics of long-lasting gamma-ray bursts from thunderclouds (long bursts: Tsuchiya et al. 2007), and photonuclear reacitons in the atmosphere triggered by terrestrial gamma-ray flashes coincident with lightning discharges (short bursts: Enoto et al. 2017). We are expanding the number of detectors to observe more events of such long and short bursts with multiple detectors. in the 2018-2019 winter season, we operated more than 20 radiation detectors. We are also promoting joint-observation campaigns with low-frequency radio and atmospheric electric-field measurements (Wada et al. 2018). We succeeded in the first simultaneous detection of long and short burst events in Kanazawa. Because the short-burst-triggering LF pulse took place within 1 km from the position where the long burst ceased, it is suggested that the strong electric field responsible for the long burst assisted the short burst. We will report the progress of the GROWTH project and this simultaneous detection event.

Electromagnetic and stroke current observations on rocket-triggered lightning

*Takeshi Morimoto[1], Shinya Kurokawa[1], Yoshitaka Nakamura[2], Kazuo Yamamoto[3]

1. Kindai University, 2. Kobe City College of Technology, 3. Chubu University

Rocket-triggered lightning is the most effective technique for artificial triggering lightning. It involves launching a small rocket trailing a thin grounded wire toward an overhead charged cloud. This technique is incredibly favorable for various lightning observations for example earth currents, leader developments, related electromagnetic and high-energy radiations etc. because a lightning strike is induced at the desired location. In Japan, a number of rocket-triggered lightning experiments were succeeded in winter thunderstorm seasons.

During the winter of 2017-18, the authors conducted a rocket-triggered lightning experiment in Noto Peninsula, facing to the Sea of Japan in Ishikawa Prefecture. A conductive wire was connected to the rocket and launched at faster than 100 m/s. A rope was also connected to prevent the rocket from rising above an altitude of 200 m. The rod-type ground electrode with a diameter of 1 cm was buried at a depth of 1 m.

We were successful in triggering lightning stroke at 1352:28h December 29, 2017. The two types of Rogowski coils to measure lightning current, hi-speed video cameras, RF antennas in VHF and LF bands were equipped around the striking point. The corona current and e-field were measured at about the distance of 50 m from the point. The measured lightning current was reached to -12 kA and continued for 290 ms. The recorded images with high time resolutions against recoded RF radiations and the current will be demonstrated in this talk.

[M-IS27] Atmospheric electricity: Applications toward natural disaster mitigation

convener:Yasuhide Hobara(Graduate School of Information and Engineering Department of Communication Engineering and Informatics, The University of Electro-Communications), Masashi Kamogawa(Department of Physics, Tokyo Gakugei University)

In recent years, various types of natural disasters caused by climate change, earthquake, etc. occur frequently in the world. In 2018 heavy precipitation in various regions of Japan and the earthquakes in Hokkaido and Indonesiaproduced/greater human and economic/damage.

In 2019JpGU Atmospheric Electricity (AE) session, invited experts are going to introduce their scientific challenges in order to monitor, predict and mitigate natural disasters by using knowledge of the atmospheric electricity. For example, monitoring and prediction of extreme weather by the latest weather radar system and lightning observations, electromagnetic phenomena prior to earthquakes, etc. will be included. Design of C-band polarimetric phased array weather radar

*Kento Nakamura[1], Hiroshi Kikuchi[2], Tomoaki Mega[1], Tomoo Ushio[1]

1. Tokyo metropolitan university, 2. The University of Electro-Communications

Most of the severe phenomena, such as a tornado, a downburst, and microburst, are caused by locally generated cumulonimbus cloud in a short time. In order to observe the evolution of the inner structure of the rain cloud that changes on a scale of several minutes, a weather radar with higher spatiotemporal resolution is needed.
A weather radar with polarimetric observations can provide multi-parameter measurements that reveal detailed microphysics of storms in addition to accurate precipitation estimation, and improve weather forecasts. As a next radar development project, we plan to develop a polarimetric weather phased array weather radar. It is expected that the future phased array radar will achieve a polarimetric capability. The transmitted frequency of the under consideration radar is C-band (5GHz).
It is capable of measuring the 3-D rainfall distribution in less than 1 min in a range of several hundred kilometers, respectively.However, it is difficult to maintain high accuracy of observation of polarimetric phased array weather radar because of the following topics.
1) the effect of deterioration of the antenna characteristics, which are formed by the digital beam forming, in oblique direction are deteriorated. 2) the performance of the cross polarization discrimination, which is performance to distinguish between horizontal waves and vertical waves, are reduced in oblique direction. These problems caused the ununiformity of the accuracy of rainfall estimates.In this paper, we proposed the design of C-band antenna elements and array antennas. We designed the three type of the antenna array, which are a planner, a cylinder, and a semi-spherical types. And also a numerical simulation was conducted to evaluate the accuracy of rainfall estimates using three different arrays.

Examination of Improving the Precision of Ionospheric F-Layer Electron Density Estimation Using Thunder-origin Whistler Wave

*Shu Hirai[1], Shogo Kanazawa[1], Yasuhide Hobara[1], Jean-Louis Pincon[2]

1. The University of Electro-Communications, 2. LPC2E/CNRS

The ionosphere temporally and spatially fluctuates by solar activity or an atmospheric weather phenomenon. It is known that the fluctuation of the electron density which constitutes the ionosphere causes the positioning error of GPS or the instability of the communication, so it is important for engineering of investigating the spatiotemporal condition of the ionosphere over the whole world. There are various methods for measuring the electron density of the ionosphere, but it is difficult to obtain the electron density data on sea far from the land because they are almost based on ground observation. To obtain the data over the world, this study focuses on estimation method of the ionosphere F-Layer electron density using whistler wave derived from the thunder generated on both ground and sea. In the previous study, the electron density estimation above the middle latitude almost correspond to the model of the ionosphere (IRI), but the data in low latitude is largely different. As the result of underestimating real propagation distance because of assuming that lightning was generated right under the satellite, it has the possibility to overestimated the electron density estimation.
Therefore, the purpose of this study is to investigate the possibility of improving the precision of ionospheric F-Layer electron density estimation using the whistler wave. Specifically, arrival direction of the whistler wave is determined by using the data of 3 magnetic field components observed by the low altitude satellite DEMETER. We aim to improve the precision of electron density estimation, especially low latitude by considering the propagation distance in the ionosphere which is estimated from the whistler wave’s propagation course.

Rn flux anomaly and local seiemicity around Asahi station,Boso,Japan

*Haruna Kojima[1], Katsumi Hattori[2], Chie Yoshino[2], Michikuni Shimo[3], Toshiharu Konishi[4], Ryuichi Furuya[5]

1. Graduate School of Science and Engineering,Chiba University, 2. Department of Earth Sciences,Graduate School of Scince, 3. Fujita Health University, 4. OHYO KOKEN KOGYO Co.,Ltd, 5. COM SYSTEM Inc.

In recent years, there are many studies reported electromagnetic phenomena preceding earthquakes such as ionospheric anomalies. Lithosphere-Atmosphere-Ionosphere Coupling (LAIC) model has been proposed to explain these phenomena. In this study, to explain the possibility of the chemical channel of LAIC, we have installed sensors for atmospheric electric field (AEF), atmospheric ion concentration (AIC), atmospheric Rn concentration (ARC), ground Rn concentration (GRC), and weather elements at Asahi station, Boso Peninsula, Japan. Because the atmospheric electricity parameters could be mainly influenced by weather factors, it is necessary to remove these influences as much as possible. In this sense, we apply the MSSA (Multi-channel Singular Spectral Analysis) to remove these influences from the GRC variation and estimate the Rn flux from the ground. Then, we investigate the correlation between the changes in the Rn flux and seismicity around the station. As a result, we found the correlation between Rn flux and regional cumulative seismic moment and/or Es index, which indicates the daily seismic energy near the station received at the station. It is highly suggestive of the effectiveness of GRC monitoring in regional seismicity around the station. Further researches such as network observations will be required for the detailed consideration on the correlation between Rn flux and seismicity such as magnitude and distance dependences.

Study on electric energy derivation of lightning using optical observation of lightning from TRMM tropical rainfall observation satellite

*Hirata Kodai[1], Yasuhide Hobara[1], Hiroshi Kikuchi[1]

1. The University of Electro-Communications

Lightning is an electric phenomenon in the atmosphere that occurs on a global scale and its electrical characteristics are extremely important parameters for physically and optically understanding lightning discharge phenomena. Lightning charge moment Qds is a parameter that can represent the magnitude of lightning energy in the electrical characteristics of lightning and its magnitude is due to damage to the wind turbine at the wind power plant. It is understanding that it will affect the damage of natural disasters such as damage and mountain fires. There is a method that can remotely derive Qds by observing the electromagnetic waves radiated at the time of lightning discharge from the ground observation instruments. Especially ELF band transients are progressing to estimate Qds by observation. In recent years, researches have been conducted to estimate Qds from the optical emission intensity of lightning discharge. Using this method, it is expected that Qds can be calculated for lightning discharge occurred all over the world. In this study, therefore, the lightning observation data, which were obtaind by the lightning imaging sensor installed on tropical rain observation satellite TRMM, are used to estimate the derivation of Qds across the whole world by deriving the correlation between the data on the lightning emission intensity obtained from the equipment LIS and the lightning charge moment Qds obtained from the ELF electromagnetic wave ground measurement data. As a result, it was shown that there is a strong positive correlation between the Qds and optical lihgning emission. The correlation coefficient was about 0.9. It was shown that lightning charge moment Qds estimation can be expected from the value of lightning emission intensity. In the future, we will improve the accuracy of deriving the lightning charge moment Qds from the lightning emission intensity. The time-space distribution of lightning charge moment Qds of the world lightning characteristics will be find based on the data of optical observation of lightning by LIS over 19 years.

[M-GI29] Near Surface Investigation and Modeling for Groundwater Resources Assessment and Conservation

convener:Jui-Pin Tsai(National Cheng Kung University, Taiwan), Hwa-Lung Yu(National Taiwan University), Ching-Chung Cheng(National Chiao Tung University Taiwan), Jing-Sen Cai(China University of Geosciences), Chairperson:Jui-Pin Tsai(National Cheng Kung University, Taiwan), Hwa-Lung Yu(National Taiwan University, Taiwan)

Groundwater resources serve as a vital source for regional water supply under the climate change condition. However, improper use of the available groundwater resources leads to serious environmental disasters such as land subsidence or seawater intrusion. Therefore, groundwater management is a key issue for groundwater resources conservation. Before applying any management practice, it is essential to accurately assess the groundwater system in multi-scales. In this session, we focus on the issues associated with the application of near-surface investigation and modeling on groundwater resources assessment. We welcome studies related to numerical modeling, spatiotemporal modeling, data fusion, and field investigation using hydrogeological approaches, geophysical approaches, geochemical approaches, and remote sensing. We also welcome the studies associated with groundwater contamination transport and remediation, geothermal energy exchange, groundwater microorganisms, hot spring, volcanic hydrology, and environmental disasters evaluation and prevention. We especially encourage the pilot groundwater management studies that solve multi-scale and interdisciplinary problems.

Groundwater management for global sustainability

*Makoto Taniguchi[1]

1. Research Institute for Humanity and Nature

Groundwater management is important for global sustainability, because of not only large groundwater footprints through global trade of agricultural/industrial materials, but also climate change impacts on groundwater resources directly and indirectly, and carbon emissions through human activities using groundwater. Interactions between groundwater-food-energy nexus and environmental/economical impacts under the conditions of climate change and urbanization, are essential for global sustainability as the center of information among nature, society and humanity. Natural and social tipping points related to groundwater such as land subsidence and saltwater intrusion, regime shifts, and resilience, are the keys for the future of hydrogeology and a sustainable society. Sustainable groundwater management has cultural dependency because of differences in hydroclimate, hydrogeology, water management, and water culture in each area. Therefore, an interaction between humanity and nature is the most important for finding solutions of groundwater management towards sustainability for the current complicated and wicked global environmental problems.

Building the large-scale specific yields over the Zhuoshui river alluvial fan and Minzhu basin with gravimetric technique

*Ren-Jhih Yang[1], Shen Yu Hsiao[1], Yan-Jyun Lin[1], Zhen-Yu Wu[1]

1. National Chung Hsing University

This study estimates the large-scale specific yields (S_y) of the aquifer in the Zhuoshui river alluvial fan and its upstream, Minzhu basin, by gravity data combined with groundwater level data and electrical resistivity tomography (ERT) data. The S_y results from gravimetric technique are rigorously compared with those from hydraulic technique. There are eight gravity stations over the Zhuoshui river alluvial fan, and four over the Minzhu basin.The distribution of all gravity stations is shown in the attached figure. The ERT data are only used for S_y estimation in the "SMOF" gravity station in the Minzhu basin. The strategies for modeling groundwater level changes include the terrain correction method and the Bouguer correction method. The environmental factors influencing the S_y estimation are also discussed. We expect that the groundwater resources in the Zhuoshui river alluvial fan and Minzhu basin can be accurately explored by this study and the results can provide an important reference for groundwater resource management.

Poro-elastic Deformation of a Heterogenous Geologic Medium due to Groundwater Withdrawal

*Ajit Joshi[1], Masaatsu Aichi[1]

1. Department of Environment Systems, Graduate School of Frontier Sciences, The University of Tokyo

Land subsidence around coastal cities in the world have been recognized as a major concern due to risk of flooding from seawater. As an example, land surface near the Tokyo and surrounding regions in Chiba Prefecture in Japan have been subsiding at rates of few centimeters per year based on data from satellite observations and ground survey measurements. Such changes in land surface elevations may have caused due to subsurface fluid (water/methane) extraction from the Plio-Pleistocene sand reservoirs of the Kanto groundwater basin located in and around Tokyo and Chiba. Fluid removal from subsurface geologic medium can reduce pore fluid pressures underneath and subsequently strain the medium causing pore spaces to collapse. Stratigraphic and lithological interpretation of rocks exposed in outcrops from the Kujukuri region in Chiba showed alternations of sandstone-mudstone units and were characterized by transgressive-regressive cycles of vertical heterogeneity indicating a gradual transition of sediment size from coarse-grained sandstone to fine-grained siltstone/mudstone. The present research hypothesized that presence of local geological heterogeneities in a geologic medium can alter hydraulic properties of the medium affecting its deformation. The main purpose of this research was to determine effect of vertical heterogeneity on rock deformation and to predict land surface subsidence due to groundwater extraction. The research hypothesis was tested using a one-dimensional solution to equations for pore fluid mass conservation and Darcy’ s flow mechanics for a poro-elastic medium saturated with water. Porosity and permeability, both dependent upon clay content, were related by a modified form of Kozeny-Carman equation.

Simulations results for a hypothetical 130 m thick water-saturated porous medium under different geological conditions were compared to investigate heterogeneity effect on deformation. Results showed hydraulic strain in mudstone increased by orders of magnitude higher than less compressible and more diffusive sandstone. Simulation results also confirmed that geological heterogeneity would affect poro-elastic deformation by altering hydraulic diffusivity and bulk compressibility of a geologic medium. Moreover, model predicted land surface subsidence, using stratigraphic sections from the Kanto basin, were in good agreement with field deformation measurements from leveling survey. In addition, local heterogeneity can be more important for a geologic medium saturated with multiple fluids (methane/water) which will be addressed in future research.

Analytical Solution of a Ditch Drainage System for the restoration of waterlogged site considering a Subsurface Source/Sink

*SHUBHAM TIWARI[1], BRIJESH KUMAR YADAV[1], RATAN SARMAH[2]

1. Indian Institute of Technology Roorkee, 2. Indian Institute of Technology Ropar

Drainage plays an important role in the field of agricultural science, as it helps in removing excess water from the soil quickly. An analytical solution is developed for the prediction of transient seepage to a fully penetrating ditch drainage system receiving water from a ponded surface with an influence of subsurface source/sink. The proposed solution is quite versatile to tackle the presence of source and sink effect in the flow domain. A subsurface flow domain of confined nature is assumed as study area which is having finite extends in horizontal and vertical directions. The hydraulic property of the soil matrix is considered as homogeneous and anisotropic in nature. The accuracy of this solution is analyzed by comparing with numerical solution obtained from finite difference method and other existing simplified case on MATLAB programming software. With the imposition of the source and sink term in the flow domain, the path line and travel time of water molecules started deviating from their original position. It was observed that discharge to the drains has a strong influence of the source/sink term. It is expected that the proposed model will help in the understanding of the flow dynamics associated with the ditch drainage system subjected to source/sink in real field conditions.

Variable-density flow and mass transport in unsaturated-saturated aquifers under horizontal groundwater flow conditions

*Jiaqi Liu[1], Tomochika Tokunaga[1]

1. The University of Tokyo

Density-induced fingering is an important mass transport process in a variety of groundwater flow settings. This study numerically investigated density-driven flow and mass transport in a 2-D vertical conceptual model of an unsaturated-saturated aquifer. The modeled domain consisted of 300 m long, with horizontal groundwater flow and vertical injection of dense solute from the top. In total, 158 numerical simulation cases were designed with various configurations of horizontal groundwater flow, the rate of solute injection, aquifer properties, and dispersivity. The numerical code FEFLOW was adopted which can solve both variable-density groundwater flow and unsaturated-saturated flow in porous media. Three dimensionless numbers, the convective ratios M_x and M_z and the Rayleigh number Ra_d, were applied to quantitively evaluate the relative magnitudes among the driving forces in the simulation cases. Three end-member flow regimes were identified that were dominated by the horizontal hydraulically-driven flow, the vertical hydraulically-driven flow, and the vertical density-driven flow, respectively. The plots of the simulation results in the M_x-M_z-Ra_d diagram enabled a clear distinction among the clusters of flow regimes and suggested the dominant driving force of each flow regime. The parameter sensitivity and regime shifts were also analyzed with the M_x-M_z-Ra_d diagram. The classification of flow regimes and the proposed M_x-M_z-Ra_d diagram provided a basic reference and a useful tool for understanding the mechanisms of variable-density flow processes under complex field situations.

A practical approach to evaluating water inflow for underground water-sealed storage cavern

*Jing-Sen Cai[1]

1. China University of Geosciences

A practical approach that has been successfully applied to evaluate the water inflow for the project of underground water-sealed storage cavern in fractured granite in China are introduced. This approach consists of two steps: investigation of the distribution of groundwater flow path and modeling to evaluate the water inflow in the cavern. Firstly, field investigation methods such as geological survey and mapping, engineering drilling, borehole imaging and engineering geophysical prospecting are used to investigate the distribution of fracture zones and faults. Subsequently, the piecewise water pressure test is performed in the existing boreholes to search the seepage passage which is dictated by the section with large permeability coefficient. Based on this, models such as Hirishi Oshima empirical equation, Misaki Sato Kuniki empirical equation and the empirical analytical equation are utilized to evaluate the water inflow in the traffic tunnel, main cavern and shaft during the construction stage. Results indicate that the seepage passage determined by the piecewise water pressure test corresponds well to the location of fracture zones revealed by field investigation. The evaluation results are confirmed by the surrounding rock quality and water inflow location uncovered by the excavation afterward, which demonstrate the validity of this comprehensive approach.

Modelling of self-potential signals associated with groundwater flows

*ayaka ishikawa[1], Katsumi Hattori[1]

1. chiba university

Landslides triggered by rainfall are one of the most dangerous natural disasters which give the loss of lives and properties. Although the importance of the short-term forecast of landslides is widely accepted, it is not achieved. In this research, we pay attention to electro-magnetic approach for monitoring ground water condition under the slope. That is, we understand the processes of the landslide and develop the system for forecast to detect precursory signal through the electromagnetic changes. In this study, we apply the self-potential approach, which is related on electro-kinetic effects or streaming potential. We have conducted several flume tests and sandbox experiments and the results showed the repeatability of the phenomena or correlation between self-potential and ground water condition. Therefore, we will report the model and numerical computation for the sandbox experiment on injection in this presentation.

SP signals measured in the sandbox during pumping experiment are considered to be due to the electro-kinetic effects. The total current density j is $j=sE-l\mathrm{d}h/\mathrm{d}x_i$, where s (in S m^{-1}) is the electrical conductivity, E (in Vm^{-1}) is the electric field, l (in A Pa^{-1} m^{-1}) is the current coupling coefficient, and h (in m) is the hydraulic head. The variation of SP signals of the sandbox gives quasi-instantaneous information on changes of the hydraulic head. Therefore we consider this problem with quasi-static limit condition i.e. div j = 0. It leads $\mathrm{div}(s\,\mathrm{grad}\,phi)=-\mathrm{div}(l\,\mathrm{grad}\,h)$.Where phi (in V) is electric potential. In addition, we assume that s and l are uniform through the sandbox because we assume saturated condition. Finally, the solved equation is $s\mathrm{d}^2phi/dx_i^2=-l\mathrm{d}^2h/dx_i^2$. We simulated distribution of hydraulic head during pumping test using finite element method. Then, we modeled the SP generation.

Consequently, the variation of SP modeled and observed are generally consistent with each other. Therefore, we found that groundwater flows control the occurrence of SP in the sandbox experiment. However, in the detail of time variation, modeled SP differ from those of observed partly. We consider that heterogeneity of soil or necessary of 3D modeling could cause these discordances. Details will be shown in our presentation.

Estimating the Hydraulic Conductivity and Heat Capacity of the Aquifer between the River and Well Site Using Joint Inversion Approach

*Jui-Pin Tsai[1], Chin-Tsai Hsiao[4], Liang-Cheng Chang[2], You-Cheng Chen[2], Chun-Hung Chen[3], Yun-Ta Cheng[3], Jen-Hung Yu[3]

1. National Cheng Kung University, Taiwan , 2. National Chiao Tung University, Taiwan , 3. Water Resources Planning Institute, Water Resources Agency, Taiwan, 4. Department of Information Management, Chung Chou University of Science and Technology

This study continued to measure the water temperature and pressure at the riverbed, agricultural waterway, and groundwater monitoring well from Oct. to Nov. 2018. These observations were then used to estimate the hydraulic conductivity (K) and flux between the river and the aquifer of the well site. The water pressure data reveal that the correlation coefficient between river and groundwater level reaches 0.9 and that between the agricultural waterway and groundwater level is almost 0. This reveals that the groundwater head variation mainly affected by the river stage of the nearby river. The temperature data show that the groundwater temperature is correlated to the temperature of the river water and is uncorrelated to the air temperature. Accordingly, the temperature and head data of the groundwater and river water were used to estimate K and heat capacity of the aquifer between the river and well site using a joint inversion approach. The results show that the estimated K and heat capacity are 67.53 m ⁄ day and 4485000 J ⁄ (m^3–℃), respectively.

Evaluation on Soil Permeability Using Electrical Resistant Tomography

*CHIHPING KUO[1], BONIAN SHEN[1], CHIHWEI HUANG[1], YUCHIAO LEE[1], SHENXIANG HUANG[1], YENLIN CHEN[1]

1. Department and Institute of Civil Engineering and Environmental Informatics, Minghsin University of Science and Technology

The permeability of soil is used to adapt field constant head permeability test or variable head permeability test. The former test is suitable for soil with higher permeability like sand and gravels; the later test is suitable for soil with lower permeability like silt and clays. Both tests need in-situ drilling holes. The required operating time is usually about couple of hours. A widely used geophysical method, Electrical Resistant Tomography (ERT), is adapted here to evaluate the soil permeability. Two types of soil with different permeability were performed, and the results were compared with the result of same samples using traditional permeability test. The result showed that they were very close. The operating time of ERT for one soil was only less than one hour. The idea of evaluating soil permeability using ERT is proposed in this study.

The Potential Study of Open Loop System Geothermal Heat Pump in Gifu City, Japan

*Randa Permanda[1], Tomoyuki Ohtani[2]

1. Department of Civil and Environmental Engineering, Gifu University, 2. Department of Civil Engineering, Gifu University

Geothermal heat pumps (GHPs) are considered to be one of the most energy efficient and environmentally friendly air-conditioning systems for temperate zones. In Japan, the expansive use of GHPs technology is finite, because of insufficient information on the advantages offered by the system and high installation cost. Therefore, the prediction of potential energy of GHPs at the first stage of installation is desirable. Open-loop system is one of GHPs types system which mostly depends on geological and hydrogeological parameter. This system interacts directly with ground and groundwater factor, because it uses groundwater as direct heat transfer medium through extraction and injection wells. Accordingly, groundwater flow with heat transfer is the most important factor that could affect the performance of open-loop GHPs system. Therefore groundwater flow system as well as distribution of subsurface temperature must be comprehended in detail. The aim of this study is to understand the distribution of groundwater flow and heat transport in study area from the simulation study using the program, FEFLOW. FEFLOW is a finite element code which can numerically simulate groundwater flow and heat transport. As the final result, the simulation model can be used to understand of open loop GHPs system in specified area.

The study area is an alluvial fan of the Nagara River, Gifu city, Japan. It is bounded by mountain ranges from north to northeast side and plain area remains. The Nagara River flows in the center of the plain. This alluvial fan is composed of sands and gravels and often intercalate thin fine sand and silt layers. Groundwater flow occur mainly in the Quaternary deposits, which are sand and gravel layers. Alluvial fans are recharge areas of groundwater and rapid groundwater flow are expected. The underground temperature in alluvial fan is affected by rapid groundwater flow recharged from a river. For assessment of potential energy of open loop GHPs, 3D model of groundwater flow with heat transport in Gifu city was developed using FEFLOW program. Model is constructed first by geological and hydrogeological data. The pre-existing geological columns and profile of study area were collected, which consisted of borehole and cross section data. Furthermore, pre-existing hydrogeological data which consist of groundwater table, underground temperature, and temperature of river water data in study area are also compiled to construct the simulation model. Boundary condition of groundwater flow system is defined by water table distribution. Bottom of the model is basement rock, treated as impermeable boundary and lateral sides are set as no flow boundaries. For boundary conditions of heat transport, top and bottom of the model are fixed by constant temperature boundaries, and lateral sides are as insulated. Based on constructed model, the simulation on groundwater flow with heat transport is performed. The effectiveness of heat transport and fluid flow are affected by material properties. Material properties were determined on the basis of formation types. Groundwater temperature were matched against observed temperatures, using the result of groundwater flow simulation. The observed underground temperatures in study area are fluctuated not only near surface but also in aquifer. This temperature change is resulted from lateral flow of the recharged groundwater. The calculated groundwater temperature will be adjusted until simulation result agreed with observed data from field. So that model can represent the groundwater flow system in alluvial fan of the Nagara River, Gifu city, Japan. For future plan, simulation model is used to investigate potential open loop GHPs system resulted from presence flowing groundwater in study area. This

Application of TL-CHERT Smart Characterization Method to Investigate a Groundwater Contaminated Site

*Tzu-Pin Wang[1,2,5], Yao-Tsung Chen[3], Tien-Hsing Tung[3], Chih-Hung Cheng[2], Jie Wang[4]

1. NCU TW, 2. Geophysical Technology and Engineering Co.,Ltd. R.O.C, 3. Apollo Technology Co.,Ltd. R.O.C., 4. Department of Civil Engineering, Chien Hsin University of Science and Technology, Taoyuan City, Taiwan, 5. Disaster Reduction Research Center, Chien Hsin University of Science and Technology, Taoyuan City, Taiwan

The Environmental Protection Administration in Taiwan effectively integrates Cross-Hole Electrical Resistivity Tomography (CHERT) into remediation planning in the anticipatory improvement project of sites with no polluter. During the reagent injection, Time-lapse Cross-Hole Electrical Resistivity (TL-CHERT) data are collected continuously. After data preprocessing and inversion algorithm, the ERT results are presented in images. 4D images could depict the main transmission range of reagent during the reagent injection, and further adjust or revise the second stage of remediation design. Therefore, CHERT could not only improve the remediation of complex groundwater contaminated sites, but also achieve the goal of precise surgical remediation. Besides, setting geophysical exploration equipment together with monitoring wells could greatly increase the use efficiency of the wells. Because groundwater contamination is usually a severe problem, a cross-professional cooperation is necessary. It is expected that this study will provide a worth case study for the survey application of similar contaminated site.

Data Assimilation in Hydraulic Conductivity Identification using Bayesian Statistical Method

*Shih-Yang Cheng[1], Kuo-Chin Hsu[1]

1. National Cheng Kung Univ.

Characterizing spatially heterogeneous hydraulic conductivity plays a crucial role in groundwater resources management and subsurface contaminant remediation. Since the direct measurements of hydraulic conductivity are sparse, the uncertainty is inherent in the estimated parameters. We propose decreasing the uncertainty by assimilating auxiliary data (electrical resistivity) with the direct data (hydraulic conductivity) using Bayesian statistical method. Different from classical geostatistical methods, both linear and nonlinear relations between the direct and auxiliary data can be considered in Bayesian statistical method. A synthetic example is designed to evaluate the method. Results show that the accuracy of hydraulic conductivity is improved through the Bayesian statistical method. Moreover, the effectiveness of auxiliary data in estimation error decrease is more significant when high correlation exists. However, the relation type has little influence on the accuracy. The estimation uncertainty quantified by variance is also compared. The uncertainty is inversely proportional to the amounts of auxiliary data and the correlation in both linear and nonlinear cases. The usefulness of auxiliary data in variance reduction is more obvious in linear cases. A systemic discussion of the sampling strategies of auxiliary data for improving hydraulic conductivity identification is also proposed.

Groundwater recharge estimation by using empirical orthogonal function method

Hua-Ting Zeng [1], *Hwa-Lung Yu[1]

1. National Taiwan University

Groundwater recharge estimation has been challenging due to the limited knowledge of the hyogeological heterogeneity. This issue is particularly important in the areas with high dependence on groundwater resources. This study proposed a data-driven approach along with a simple ODE model to estimate the groundwater recharge in our study area, Cho-shui river aquifer which is one of the most water-abundant aquifers in Taiwan; however, is suffered from the water overdraft. We analyzed the daily groundwater level observations during 2004-2010 from all wells across the entire study area. Based upon our proposed method, we identified two major recharge areas, i.e., proximal fan of the aquifer and Min-Chu basin at its upstream. The two areas obtained about 181.9 million and 78.8million tons of recharge water annually, resectively, in which about 131 million tons of water flowing from Min-Chu basin into Cho-shui aquifer annually. In summary, this study proposed a novel method for the groundwater recharge estimation.

The Application of Drought Early Warning Index for Regional Hydrological Circumstance Analysis

*Chih Chao Ho[1], Ta Wei Chen[2]

1. Construction and Disaster Prevention Research Center, Feng Chia Univ., 2. Taiwan Hsin-Chu Irrigation Association

Recently, rainfall become more unevenly both in special and temporal distribution caused by global climate change. The frequency of drought decrease from once every 17 years to once every 9 years. How to define warning signs of a drought and propose adaptive strategies is one of the key topic for water resources management. The drought can be divided into meteorological drought, agricultural drought and hydrological drought. The study tries to introduces difference Drought Early Warning Index, such as Standardized Precipitation Index, Standardized Groundwater Index, Normalized Difference Vegetation Index etc., to predict drought circumstance. The result can be a reference for development of drought early warning system.

Landslides triggered by rainfall are one of the most dangerous natural disasters which give the loss of lives and properties. Although the importance of the short-term forecast of landslides is widely accepted, it is not achieved. In this research, we pay attention to electro-magnetic approach for monitoring ground water condition under the slope. That is, we understand the processes of the landslide and develop the system for forecast to detect precursory signal through the electromagnetic changes. In this study, we apply the self-potential approach, which is related on electro-kinetic effects or streaming potential. We have conducted several flume tests and sandbox experiments and the results showed the repeatability of the phenomena or correlation between self-potential and ground water condition. Therefore, we will report the model and numerical computation for the sandbox experiment on injection in this presentation.

SP signals measured in the sandbox during pumping experiment are considered to be due to the electro-kinetic effects. The total current density j is $j=sE-l\mathrm{d}h/\mathrm{d}x_i$, where s (in S m^{-1}) is the electrical conductivity, E (in Vm^{-1}) is the electric field, l (in A Pa^{-1} m^{-1}) is the current coupling coefficient, and h (in m) is the hydraulic head. The variation of SP signals of the sandbox gives quasi-instantaneous information on changes of the hydraulic head. Therefore we consider this problem with quasi-static limit condition i.e. div j = 0. It leads $\mathrm{div}(s\,\mathrm{grad}\,phi)=-\mathrm{div}(l\,\mathrm{grad}\,h)$.Where phi (in V) is electric potential. In addition, we assume that s and l are uniform through the sandbox because we assume saturated condition. Finally, the solved equation is $s\mathrm{d}^2phi/dx_i^2=-l\mathrm{d}^2h/dx_i^2$. We simulated distribution of hydraulic head during pumping test using finite element method. Then, we modeled the SP generation.

Consequently, the variation of SP modeled and observed are generally consistent with each other. Therefore, we found that groundwater flows control the occurrence of SP in the sandbox experiment. However, in the detail of time variation, modeled SP differ from those of observed partly. We consider that heterogeneity of soil or necessary of 3D modeling could cause these discordances. Details will be shown in our presentation.

Estimating the Hydraulic Conductivity and Heat Capacity of the Aquifer between the River and Well Site Using Joint Inversion Approach

*Jui-Pin Tsai[1], Chin-Tsai Hsiao[4], Liang-Cheng Chang[2], You-Cheng Chen[2], Chun-Hung Chen[3], Yun-Ta Cheng[3], Jen-Hung Yu[3]

1. National Cheng Kung University, Taiwan , 2. National Chiao Tung University, Taiwan , 3. Water Resources Planning Institute, Water Resources Agency, Taiwan, 4. Department of Information Management, Chung Chou University of Science and Technology

This study continued to measure the water temperature and pressure at the riverbed, agricultural waterway, and groundwater monitoring well from Oct. to Nov. 2018. These observations were then used to estimate the hydraulic conductivity (K) and flux between the river and the aquifer of the well site. The water pressure data reveal that the correlation coefficient between river and groundwater level reaches 0.9 and that between the agricultural waterway and groundwater level is almost 0. This reveals that the groundwater head variation mainly affected by the river stage of the nearby river. The temperature data show that the groundwater temperature is correlated to the temperature of the river water and is uncorrelated to the air temperature. Accordingly, the temperature and head data of the groundwater and river water were used to estimate K and heat capacity of the aquifer between the river and well site using a joint inversion approach. The results show that the estimated K and heat capacity are 67.53 m ⁄ day and 4485000 J ⁄ (m^3–℃), respectively.

Evaluation on Soil Permeability Using Electrical Resistant Tomography

*CHIHPING KUO[1], BONIAN SHEN[1], CHIHWEI HUANG[1], YUCHIAO LEE[1], SHENXIANG HUANG[1], YENLIN CHEN[1]

1. Department and Institute of Civil Engineering and Environmental Informatics, Minghsin University of Science and Technology

The permeability of soil is used to adapt field constant head permeability test or variable head permeability test. The former test is suitable for soil with higher permeability like sand and gravels; the later test is suitable for soil with lower permeability like silt and clays. Both tests need in-situ drilling holes. The required operating time is usually about couple of hours. A widely used geophysical method, Electrical Resistant Tomography (ERT), is adapted here to evaluate the soil permeability. Two types of soil with different permeability were performed, and the results were compared with the result of same samples using traditional permeability test. The result showed that they were very close. The operating time of ERT for one soil was only less than one hour. The idea of evaluating soil permeability using ERT is proposed in this study.

The Potential Study of Open Loop System Geothermal Heat Pump in Gifu City, Japan

*Randa Permanda[1], Tomoyuki Ohtani[2]

1. Department of Civil and Environmental Engineering, Gifu University, 2. Department of Civil Engineering, Gifu University

Geothermal heat pumps (GHPs) are considered to be one of the most energy efficient and environmentally friendly air-conditioning systems for temperate zones. In Japan, the expansive use of GHPs technology is finite, because of insufficient information on the advantages offered by the system and high installation cost. Therefore, the prediction of potential energy of GHPs at the first stage of installation is desirable. Open-loop system is one of GHPs types system which mostly depends on geological and hydrogeological parameter. This system interacts directly with ground and groundwater factor, because it uses groundwater as direct heat transfer medium through extraction and injection wells. Accordingly, groundwater flow with heat transfer is the most important factor that could affect the performance of open-loop GHPs system. Therefore groundwater flow system as well as distribution of subsurface temperature must be comprehended in detail. The aim of this study is to understand the distribution of groundwater flow and heat transport in study area from the simulation study using the program, FEFLOW. FEFLOW is a finite element code which can numerically simulate groundwater flow and heat transport. As the final result, the simulation model can be used to understand of open loop GHPs system in specified area.

The study area is an alluvial fan of the Nagara River, Gifu city, Japan. It is bounded by mountain ranges from north to northeast side and plain area remains. The Nagara River flows in the center of the plain. This alluvial fan is composed of sands and gravels and often intercalate thin fine sand and silt layers. Groundwater flow occur mainly in the Quaternary deposits, which are sand and gravel layers. Alluvial fans are recharge areas of groundwater and rapid groundwater flow are expected. The underground temperature in alluvial fan is affected by rapid groundwater flow recharged from a river. For assessment of potential energy of open loop GHPs, 3D model of groundwater flow with heat transport in Gifu city was developed using FEFLOW program. Model is constructed first by geological and hydrogeological data. The pre-existing geological columns and profile of study area were collected, which consisted of borehole and cross section data. Furthermore, pre-existing hydrogeological data which consist of groundwater table, underground temperature, and temperature of river water data in study area are also compiled to construct the simulation model. Boundary condition of groundwater flow system is defined by water table distribution. Bottom of the model is basement rock, treated as impermeable boundary and lateral sides are set as no flow boundaries. For boundary conditions of heat transport, top and bottom of the model are fixed by constant temperature boundaries, and lateral sides are as insulated. Based on constructed model, the simulation on groundwater flow with heat transport is performed. The effectiveness of heat transport and fluid flow are affected by material properties. Material properties were determined on the basis of formation types. Groundwater temperature were matched against observed temperatures, using the result of groundwater flow simulation. The observed underground temperatures in study area are fluctuated not only near surface but also in aquifer. This temperature change is resulted from lateral flow of the recharged groundwater. The calculated groundwater temperature will be adjusted until simulation result agreed with observed data from field. So that model can represent the groundwater flow system in alluvial fan of the Nagara River, Gifu city, Japan. For future plan, simulation model is used to investigate potential open loop GHPs system resulted from presence flowing groundwater in study area. This

simulation model is effective to predict the natural change of underground temperature, one main factor that affecting heat pumps efficiency.

Application of TL-CHERT Smart Characterization Method to Investigate a Groundwater Contaminated Site

*Tzu-Pin Wang[1,2,5], Yao-Tsung Chen[3], Tien-Hsing Tung[3], Chih-Hung Cheng[2], Jie Wang[4]

1. NCU TW, 2. Geophysical Technology and Engineering Co.,Ltd. R.O.C, 3. Apollo Technology Co.,Ltd. R.O.C., 4. Department of Civil Engineering, Chien Hsin University of Science and Technology, Taoyuan City, Taiwan, 5. Disaster Reduction Research Center, Chien Hsin University of Science and Technology, Taoyuan City, Taiwan

The Environmental Protection Administration in Taiwan effectively integrates Cross-Hole Electrical Resistivity Tomography (CHERT) into remediation planning in the anticipatory improvement project of sites with no polluter. During the reagent injection, Time-lapse Cross-Hole Electrical Resistivity (TL-CHERT) data are collected continuously. After data preprocessing and inversion algorithm, the ERT results are presented in images. 4D images could depict the main transmission range of reagent during the reagent injection, and further adjust or revise the second stage of remediation design. Therefore, CHERT could not only improve the remediation of complex groundwater contaminated sites, but also achieve the goal of precise surgical remediation. Besides, setting geophysical exploration equipment together with monitoring wells could greatly increase the use efficiency of the wells. Because groundwater contamination is usually a severe problem, a cross-professional cooperation is necessary. It is expected that this study will provide a worth case study for the survey application of similar contaminated site.

Data Assimilation in Hydraulic Conductivity Identification using Bayesian Statistical Method

*Shih-Yang Cheng[1], Kuo-Chin Hsu[1]

1. National Cheng Kung Univ.

Characterizing spatially heterogeneous hydraulic conductivity plays a crucial role in groundwater resources management and subsurface contaminant remediation. Since the direct measurements of hydraulic conductivity are sparse, the uncertainty is inherent in the estimated parameters. We propose decreasing the uncertainty by assimilating auxiliary data (electrical resistivity) with the direct data (hydraulic conductivity) using Bayesian statistical method. Different from classical geostatistical methods, both linear and nonlinear relations between the direct and auxiliary data can be considered in Bayesian statistical method. A synthetic example is designed to evaluate the method. Results show that the accuracy of hydraulic conductivity is improved through the Bayesian statistical method. Moreover, the effectiveness of auxiliary data in estimation error decrease is more significant when high correlation exists. However, the relation type has little influence on the accuracy. The estimation uncertainty quantified by variance is also compared. The uncertainty is inversely proportional to the amounts of auxiliary data and the correlation in both linear and nonlinear cases. The usefulness of auxiliary data in variance reduction is more obvious in linear cases. A systemic discussion of the sampling strategies of auxiliary data for improving hydraulic conductivity identification is also proposed.

Groundwater recharge estimation by using empirical orthogonal function method

Hua-Ting Zeng [1], *Hwa-Lung Yu[1]

1. National Taiwan University

Groundwater recharge estimation has been challenging due to the limited knowledge of the hyogeological heterogeneity. This issue is particularly important in the areas with high dependence on groundwater resources. This study proposed a data-driven approach along with a simple ODE model to estimate the groundwater recharge in our study area, Cho-shui river aquifer which is one of the most water-abundant aquifers in Taiwan; however, is suffered from the water overdraft. We analyzed the daily groundwater level observations during 2004-2010 from all wells across the entire study area. Based upon our proposed method, we identified two major recharge areas, i.e., proximal fan of the aquifer and Min-Chu basin at its upstream. The two areas obtained about 181.9 million and 78.8million tons of recharge water annually, resectively, in which about 131 million tons of water flowing from Min-Chu basin into Cho-shui aquifer annually. In summary, this study proposed a novel method for the groundwater recharge estimation.

The Application of Drought Early Warning Index for Regional Hydrological Circumstance Analysis

*Chih Chao Ho[1], Ta Wei Chen[2]

1. Construction and Disaster Prevention Research Center, Feng Chia Univ., 2. Taiwan Hsin-Chu Irrigation Association

Recently, rainfall become more unevenly both in special and temporal distribution caused by global climate change. The frequency of drought decrease from once every 17 years to once every 9 years. How to define warning signs of a drought and propose adaptive strategies is one of the key topic for water resources management. The drought can be divided into meteorological drought, agricultural drought and hydrological drought. The study tries to introduces difference Drought Early Warning Index, such as Standardized Precipitation Index, Standardized Groundwater Index, Normalized Difference Vegetation Index etc., to predict drought circumstance. The result can be a reference for development of drought early warning system.

[M-GI34] Marine Manganese Minerals

convener:Akira Usui(Marine Core Research Center, Kochi University), Yoshio Takahashi(Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo), Katsuhiko Suzuki(Research and Development Center for Submarine Resources, Japan Agency for Marine-Earth Science and Technology), Takashi Ito(Faculty of Education, Ibaraki University)

Marine manganese deposits include nodules and crusts of massive iron-manganese oxide aggregates associated with useful metals. The deposits are known as potential resources of cobalt, copper, nickel, rare earth elements, platinum, and tellurium. However, the controlling parameters on the regional and temporal variations in chemical and mineralogical composition have not been clarified yet. In this session, various factors in the growth of manganese oxides, enrichment and circulation of metals, paleoenvironment, and formation age of manganese deposits will be discussed from viewpoints of geology, mineralogy, paleocean sciences, geochemistry, microbiology, and sea floor engineering.

Microstratigraphy of hydrogenetic ferromanganese crusts in the Takuyo-Daisan and -Daigo seamounts

*Akira Usui[1], An-na Nagaoka[2], Michiko Kawamura[1]

1. Marine Core Research Center, Kochi University, 2. Graduate School of Science, Kochi University

Hydrogenetic ferromanganese crusts cover almost all the rock outcrops on the slopes of the Takuyo #3 and #5 seamounts. The secular variations in physical properties are in some cases correlated with the mineral composition or chemical compositions. The youngest Pliocene Zone is enriched with tiny quartz particles with benthic foraminifers, while the older Miocene zone is characterized by coarser mineral grains of volcanic rock origin. Thus the apparent zoning and correlation patterns are overlapped both with local and regional environmental parameters.

Manganese Crusts with Super Smooth Surface (3S Manganese Crusts) observed at Takuyo No.3 Seamount, Northwest Pacific

*Masaki Saito[1], Takashi Ito[2]

1. Graduate School of Education,Ibaraki University, 2. Department of Education,Ibaraki University

During the research cruises, JAMSTEC KR17-07C and KR 18-11C, the detailed observations based on ROV "Kaiko" revealed that the manganese crusts with several cm order of Mn oxide layer in thickness spread over in the northern ridge of Takuyo No.3 Seamount. In addition, the crusts having super smooth surfaces (3S crusts) were also observed. In general, the surface structure of marine manganese oxide has been classified into two types, s (smooth) and r (rough). However, the smooth surface observed this time is obviously different from the common s type surface structure, and there is a possibility that a new classification in the manganese oxide surface is required.

In this study, the characteristics of the distribution of the 3S manganese crusts and the surface structure were examined preliminary. For examining the characteristics of the distribution, the image data taken with a digital still camera mounted on ROV "Kaiko" Mk - IV was used. These images were taken randomly by onboard operators during each dive. We checked the images one by one and counted the images showing the 3S crusts. Also, the distribution frequency (shots/min.) of the 3S crusts was measured.

As a result of the image analysis, it is clear that the distribution of the 3S crusts at Takuyo No.3 seamount has water depth dependence. The main distribution area of the 3S crusts is between 1400 - 1600m in water depth. The super smooth surface did not spread over the entire surface of each crust but was found on the edges of the side surface of the crusts mainly.

SEM observation of the samples showed a clear difference between the 3S crusts and common s type surfaces. The surface of the super smooth surface was literally extremely smooth even at the level of SEM observation, but it was also confirmed that there were many scratches of several tens of microns in length. This scratches appeared not only in one direction but also in random distribution. We have the plan to clarify the formation process of super smooth surface based on mineral and chemical compositions and micro CT observations in addition to further SEM observations.

Geochemical characteristics of the nuclei of ferromanganese nodules in the Minamitorishima EEZ

*Daiki Terauchi[1], Kentaro Nakamura[1], Ryo Shimomura[1], Koichi Horinouchi[1], Kazutaka Yasukawa[1,2], Shiki Machida[2,1], Yasuhiro Kato[1,2,3]

1. Department of Systems Innovation, School of Engineering, University of Tokyo, 2. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology, 3. Frontier Research Center for Energy and Resources, School of Engineering, The University of Tokyo

Ferromanganese nodules are polymetallic concretion mainly composed of Mn- and Fe-oxyhydroxides with significant concentrations of valuable metals such as Ni, Cu and Co [1, 2]. The nodules can be found on deep-sea sediments worldwide, and their dense distribution has recently been discovered in the Japanese exclusive economic zone (EEZ) around Minamitorishima Island [3, 4].

It is well known that almost all ferromanganese nodules have nuclei, which clearly indicates that growth of a nodule generally starts on nucleus surface. Characterizing the nuclei of the nodules can, thus, provide important information on the conditions for the growth initiation of the nodules. Previous study [5] revealed that the nuclei of the nodules in the Minamitorishima EEZ can be classified into four types (nucleus I ~ IV), and that the majority of the nuclei is consolidated pelagic clay (nucleus I). However, detailed chemical characteristics of the nucleus I, as well as those of the other types of nuclei, have not yet been fully understood.

Here, we performed major and trace element analysis of the nuclei (especially of the nucleus I) in order to reveal their chemical features. In the presentation, we will show the results of the chemical characterization of the nuclei and then will discuss the origin of the nuclei of ferromanganese nodules in the Minamitorishima EEZ.

Micro X-ray fluorescence mapping for the whole cross-section of ferromanganese nodules in the western North Pacific

*Shiki Machida[1,2], Ryo Shimomura[2], Koichi Horinouchi[2], Kentaro Nakamura[2], Tetsu Kogiso[3], Yasuhiro Kato[2,1]

1. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology, 2. University of Tokyo, 3. Kyoto University

A dense field of hydrogenous ferromanganese nodules was discovered on a small seamount approximately 300 km east of Minamitorishima (Marcus) Island, in the western North Pacific [1]. Previous study [1] defined two fundamental features on structure and geochemistry of nodules, as follows. The large nodules generally consist of three concentric layers: the outermost mottled (sediment-filled) layer L0; the massive black layer L1; and the innermost porous (sediment-filled) layer L2. Elements including Fe, Ti, and Co are concentrated in the nodule rim rather than the center. In contrast, Mn, Al, P, Ca, Ni, and Zn are concentrated in the center, and decrease toward the rim.

To further investigate the relationship between structure of oxide layers and its geochemical features, we conducted mapping analysis for polished slab of nodules including nuclei and whole layers of oxide by a microfocus X-ray fluorescence analytical microscope (XGT-7000; HORIBA) at Kyoto University. Analysis was conducted in vacuo, and the intensity of Si, Al, P, Ca, K, Mn, Fe, Ti, Ni, Cu, and Y were determined by an energy-dispersive spectrometer at an accelerating voltage of 50 kV, 100 μm beam, and intervals of approximately 160 μm.

We identified that L2 is further sub-divided into three layers, which correspond to layers obtained by X-ray CT [2]. The most inner part of L2 (around nuclei) is characterized by high intensity of Ti and Fe. In contrast, outer part of L2 is characterized by higher intensity of Mn than that of the inner part. Many spots of high intensity of P, Ca, and Y, indicating particles of calcium phosphate including highly amount of Y (and probably rare-earth elements), are observed in the entire area of L2. We found that L1 is clearly characterized by low Si. Furthermore, we observed thin layers showing high intensity of Cu and Ni at the sediment-filled boundaries between L1 and L2, and L1 and L0. Existence of such thin layers suggests that nodules were fully covered by pelagic sediment at the intervals before formation of L1 and L0.

Here, we performed major and trace element analysis of the nuclei (especially of the nucleus I) in order to reveal their chemical features. In the presentation, we will show the results of the chemical characterization of the nuclei and then will discuss the origin of the nuclei of ferromanganese nodules in the Minamitorishima EEZ.

A dense field of hydrogenous ferromanganese nodules was discovered on a small seamount approximately 300 km east of Minamitorishima (Marcus) Island, in the western North Pacific [1]. Previous study [1] defined two fundamental features on structure and geochemistry of nodules, as follows. The large nodules generally consist of three concentric layers: the outermost mottled (sediment-filled) layer L0; the massive black layer L1; and the innermost porous (sediment-filled) layer L2. Elements including Fe, Ti, and Co are concentrated in the nodule rim rather than the center. In contrast, Mn, Al, P, Ca, Ni, and Zn are concentrated in the center, and decrease toward the rim.

To further investigate the relationship between structure of oxide layers and its geochemical features, we conducted mapping analysis for polished slab of nodules including nuclei and whole layers of oxide by a microfocus X-ray fluorescence analytical microscope (XGT-7000; HORIBA) at Kyoto University. Analysis was conducted in vacuo, and the intensity of Si, Al, P, Ca, K, Mn, Fe, Ti, Ni, Cu, and Y were determined by an energy-dispersive spectrometer at an accelerating voltage of 50 kV, 100 μm beam, and intervals of approximately 160 μm.

We identified that L2 is further sub-divided into three layers, which correspond to layers obtained by X-ray CT [2]. The most inner part of L2 (around nuclei) is characterized by high intensity of Ti and Fe. In contrast, outer part of L2 is characterized by higher intensity of Mn than that of the inner part. Many spots of high intensity of P, Ca, and Y, indicating particles of calcium phosphate including highly amount of Y (and probably rare-earth elements), are observed in the entire area of L2. We found that L1 is clearly characterized by low Si. Furthermore, we observed thin layers showing high intensity of Cu and Ni at the sediment-filled boundaries between L1 and L2, and L1 and L0. Existence of such thin layers suggests that nodules were fully covered by pelagic sediment at the intervals before formation of L1 and L0.

[M-GI34] Marine Manganese Minerals

convener:Akira Usui(Marine Core Research Center, Kochi University), Yoshio Takahashi(Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo), Katsuhiko Suzuki(Research and Development Center for Submarine Resources, Japan Agency for Marine-Earth Science and Technology), Takashi Ito(Faculty of Education, Ibaraki University), Chairperson:takashi ito(Ibaraki Univ.), Yoshio Takahashi(東京大学), Katsuhiko Suzuki(JAMSTEC)

Marine manganese deposits include nodules and crusts of massive iron-manganese oxide aggregates associated with useful metals. The deposits are known as potential resources of cobalt, copper, nickel, rare earth elements, platinum, and tellurium. However, the controlling parameters on the regional and temporal variations in chemical and mineralogical composition have not been clarified yet. In this session, various factors in the growth of manganese oxides, enrichment and circulation of metals, paleoenvironment, and formation age of manganese deposits will be discussed from viewpoints of geology, mineralogy, paleocean sciences, geochemistry, microbiology, and sea floor engineering.

We attempted to apply the method of Shima-Shima-gaku (lamina stratigraphy named by prof. S. Kawakami) on the secular variations in growth structure, chemical and mineralogical properties between the growth columns of the hydrogenetic ferromanganese deposit. The critera for describing each bands or zones based on the macroscopic (=physical) properties are not always consistant with chronological correlations or may not match with mineral/chemical composition. Our microscopic characterization using optical microscope, XRF mapping, XRD, acid-leach, micro-focus X-ray CT proved a possibility of separating local and regional sources of each mineral particle or element which is closely associated the environments of eposition.

Manganese is the third most abundant metallic element, after iron and titanium, in the Earth’ s crust, and ferromanganese minerals are sensitive to changes in redox condition. Assessing the formation and preservation of ferromanganese minerals is important for understanding the global marine cycles of manganese and numerous associated trace elements. The most extensive manganese mineral deposits occur on abyssal plains, including those below open-ocean gyres. However, the extent of ferromanganese minerals buried in subseafloor sediments remains unclear. During the Integrated Ocean Drilling Program (IODP) Expedition 329, we drilled the entire sedimentary sequence at 6 sites in the ultra-oligotrophic region of the South Pacific Gyre (SPG), where dissolved O_2 and aerobic microbial communities are present from the seafloor to the sediment-basement interface [1]. By using high-resolution imaging techniques, we found abundant (10^8-10^9 particles cm^{-3}) micrometer-scale ferromanganese mineral particles (Mn-microparticles) in the oxic pelagic clays of the South Pacific Gyre [2]. Furthermore, we established microparticle separation technique by the combined use of density concentration and flowcytometer/particles sorting techniques. Major and trace element compositional analyses revealed that iron and manganese were the major components of Mn-microparticles, while they also contained rare-earth elements. From the number of Mn-microparticles per unit volume of sediment and the global distribution of oxic pelagic clays, we estimated the number of Mn-microparticles to be 1.5-8.8 $\times 10^{28}$ particles, which accounted for 1.28-7.62 Tt of manganese. This estimate is at least 2 orders of magnitude larger than the manganese budget for manganese nodules and manganese crusts on the seafloor. Along with the examination of manganese input, formation, and preservation, this study provides new insights into the global budget of metallic elements in the abundant Mn-microparticles present in deep subseafloor environments.

Ferromanganese crusts (FMCs) are abyssal benthic chemical sediments that consist mainly of Fe and Mn oxide and hydroxide minerals, enriched with trace and precious metals. Due to their similar physicochemical properties, the elements zirconium (Zr) and hafnium (Hf), which are concentrated in FMCs, have a theoretically uniform ratio (Zr/Hf), which ratio is found in numerous systems. However, recent advances in analytical techniques have allowed observation of significant differences in the fractionation of these elements between seawater (Zr/Hf~45-350; Firdaus et al. 2011) and FMCs (Zr/Hf~57-88; Schmidt et al., 2014). In this study, we conducted adsorption experiments and XAFS analyses to clarify the concentrations and fractionation mechanisms of Zr-Hf in FMCs using synthesized minerals (Ferrihydrite and δ-MnO_2), radio-Zr and Hf tracers, and natural samples.

Six FMCs were collected from the Takuyo-Daigo and Ryusei seamounts, at water depths of from 950 m to 3000 m, using a ROV equipped with a live video camera and manipulators. The near surface layers (less than 1 mm) of all the FMCs were analyzed with XAFS and ICP-MS for Zr, Hf and other elements, and with XRD for mineral composition. Radiotracers were produced using the RIKEN AVF cyclotron for adsorption and co-precipitation experiments. Appropriate amounts of these tracers were added to 0.7 M NaCl solutions containing desferrioxamine B (DFOB) to obtain some Zr and Hf concentrations of solutions. The speciations of these elements in said solutions were confirmed by ESI-TOF-MS. Synthesized Ferrihydrite or δ-MnO_2 was added to the solutions and stirred for three hours at a pH of 8. In addition, Ferrihydrite or δ-MnO_2 was synthesized in said solutions. The activities of radio tracers in the filtered solutions were measured using a Ge detector. The adsorption/co-precipitation amounts to the solid phase were calculated using the differences in the radioactivity of the solution before and after filtration.

The major mineral composition of Fe and Mn in the FMCs did not vary significantly with the water depth of these seamounts. The concentrations of Zr and Hf increased with depth, and their ratios were totally fractionated from those of the seawater (Firdaus et al., 2011). Hf was more enriched in all FMCs than was Zr. The observed Zr chemical states in the FMCs were mainly coprecipitation with Ferrihydrite and coprecipitation with d-MnO2. In our adsorption experiments, the largest adsorption rate was observed in Hf to δ-MnO_2, followed in order by Zr to δ-MnO_2, Hf to Ferrihydrite and Zr to Ferrihydrite. The partition coefficients (K_D values) were calculated using the concentration ranges of Zr and Hf in seawater, where it was clear that Hf adsorbed more on both. Even though complexation rates estimated by RI-TLC were considered, there was no change in the adsorption behaviors in these experiments. For these samples, we found that the bond lengths between Zr-O and Hf-O in the first shells were shortened when they were incorporated into the oxides, with Hf-O becoming more shortened compared to Zr-O. The DFT calculations showed that Zr and Hf adsorbs on Fe and Mn oxides as bidentate-mono nuclear and bidentate-binuclear structures. The calculation results for the binding energies and bond orders of Zr and Hf to minerals gave a reasonable explanation of the fractionation mechanism for Zr-Hf pairs in FMCs.

Isotope fractionation of Mo-like elements during adsorption to ferromanganese oxides

*Masato Tanaka[1], Yoshio Takahashi[1]

1. Graduate School of Science, The University of Tokyo

A large mass-dependent isotope fractionation between seawater and ferromanganese oxides was observed, where lighter isotopes of Mo were preferentially incorporated into ferromanganese oxides. The large isotopic fractionation of molybdenum (Mo) is most likely caused by geometrical change from tetrahedral (Td) to distorted octahedral (Oh) during adsorption on manganese oxides based on X-ray absorption fine structure (XAFS) spectroscopy. The coordination number relates to its ionic radius. Thus, the elements which have similar ionic radius to Mo are expected to show the similar phenomena to Mo, i.e. the large isotope fractionation. Germanium (Ge) and Vanadium (V) can be candidate of such elements because they have similar ionic radius to Mo (Ge(IV): r= 0.53 Å, V(V): r=0.54 Å, and Mo(VI): r=0.59 Åfor 6-hold coordination). In this study, we examine the adsorption structure of Ge and V on Fe-/Mn-(oxyhydr)oxides by XAFS spectroscopy. Furthermore, the isotope fractionation during adsorption on the minerals is estimated by quantum chemical calculations.

XAFS analysis indicated that the adsorbed species of Ge on Fe- and Mn-(oxyhydr)oxides have Td geometry. On the other hand, the adsorbed structure of V on ferrihydrite is Td whereas that on δ-MnO_2 is distorted Oh. This trend of V in adsorbed species is similar to that of Mo. The geometries of hydrated species of Ge and V are Td. Thus, it is expected that a large V isotope fractionation occur during adsorption on Mn oxide, but a small fractionation in the case of Ge. In fact, a large isotope fractionation for V and a small isotope fractionation for Ge were estimated by quantum chemical calculations. This finding indicates that the requirement to show a Mo like large isotope fractionation during adsorption is not only an appropriate ionic radius. Recently, we found that two elemental properties of Mo(VI), namely d^0 electronic configuration and appropriate ionic radius, lead to the large isotope fractionation. In fact, V(V) possesses d^0 electronic configuration, but Ge(IV) does not. Tungsten (W)(VI) also satisfies the two properties and shows a large isotope fractionation during adsorption on Fe-/Mn-(oxyhydr)oxides. Thus, the elements which have the two elemental properties (Mo-like elements) can exhibit a Mo like large isotope fractionation during ferromanganese oxides.

Distinct distribution trends of arsenate and molybdate in marine ferromanganese nodules

*Shitong Yang[1], Soichiro Uesugi[1], Haibo Qin[1], Akira Usui[2], Yoshio Takahashi[1]

1. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, 2. Geology Department, Kochi University

Marine ferromanganese nodules or crusts with the hydrogenetic (HG), diagenetic (DG) and hydrothermal (HT) origins, are important sedimentary substrates for various elements such as lead (Pb), zinc (Zn), cobalt (Co), cerium (Ce), molybdenum (Mo), tungsten (W), arsenic (As), antimony (Sb), tellurium (Te), and etc. However, the distribution behaviors and host phases of tetrahedral arsenate (AsO_4^{3-}) and molybdate (MoO_4^{2-}) oxyanions in the ferromanganese oxides are far from understood. Herein, we combine sequential extraction approach and spectroscopic analyses to explore the mineralogical components of HG ferromanganese nodules collected from the Pacific Ocean and the speciation of arsenate and molybdate therein.

X-ray diffraction (XRD), X-ray absorption near-edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) spectroscopy analyses indicate that the predominant manganese and iron phases were vernadite (δ-MnO_2) and ferrihydrite, respectively. According to the sequential extraction examination, both As and Mo are associated with the iron (oxyhydr)oxide phases. As K-edge EXAFS analyses indicate the immobilization of arsenate by ferrihydrite via forming inner-sphere complexes in double corner-shared form. This result is consistent with the sequential extraction data. However, Mo L_3-edge XANES analyses suggest the adsorption of molybdate on vernadite surfaces via the edge-shared complexation, being contrary to the conclusion derived from the sequential extraction results. This inconsistency reveals the unreliability of sequential extraction approach to verify the host phase of trace elements in complicated natural samples due to the potential occurrence of re-adsorption risk.

According to the spectroscopic analyses, chemical binding (ΔG_{chem}) rather than the previously proposed coulombic interaction (ΔG_{coul}) is the predominant driving force for the retention of arsenate and molybdate by HG ferromanganese nodules. The disparate distribution trends of arsenate and molybdate are attributed to their different intrinsic properties (e.g., averaged dissociation constants of conjugate acids) and the diverse properties (e.g., surface site densify, adsorption equilibrium constant and crystalline structure) of ferrihydrite and vernadite. These research findings will help assess the geochemical behaviors and environmental fate of trace elements in marine environment.

Mineralogical and geochemical characteristics of ferromanganese nodules in the Minamitorishima EEZ

*Kentaro Nakamura[1], Koichi Horinouchi[1], Ryo Shimomura[1], Shiki Machida[2], Kazutaka Yasukawa[1,2], Koichiro Fujinaga[1,2], Yasuhiro Kato[1,2]

1. Department of Systems Innovation, School of Engineering, University of Tokyo, 2. ORCeNG, Chiba Institute of Technology

Ferromanganese nodules are spherical material mainly composed of manganese, iron, and other transition metal (oxyhydro)oxides, which are widely distributed on the deep seafloor around the world [1]. It has been widely accepted that ferromanganese nodules can be classified into three types: hydrogenetic, diagenetic and hydrothermal types [1]. Among them, hydrogenetic nodules are composed of Fe–Mn (oxyhydr)oxides that precipitated from seawater and thus, this type of nodules can be expected to provide proxy paleoceanographic records [2, 3, 4, 5].
In this study, we investigated mineralogy and geochemistry of ferromanganese nodules sampled from the Minamitorishima EEZ for the purpose of elucidating formation environment of the nodules. Both the ferromanganese mineral phase and bulk chemical compositions clearly show that these nodules are hydrogenetic in origin. Based on X-ray CT and micro X-ray mapping analyses, oxide layer of the nodules can be subdivided into five layers [6. 7]. Although ferromanganese mineral is common to all the oxide layers, we found that Mn/Fe and Ni content systematically changed from inner layer to outer layer. The result implies that bottom water of the Minamitorishima EEZ has gradually been oxygenated toward the present.

[M-GI35] Development of computational sciences on planetary formation, evolution and surface environment

convener:Yoshi-Yuki Hayashi(Department of Planetology/CPS, Graduate School of Science, Kobe University), Masaki Ogawa(Division of General Systems Studies, Graduate School of Arts and Sciences, University of Tokyo), Shigeru Ida(Earth-Life Science Institute, Tokyo Institute of Technology), Kanya Kusano(Institute for Space-Earth Environmental Research, Nagoya University), Chairperson:Hiroki Kashimura

Computer simulations have been recognized as one of the fundamental tools in understanding planetary formation, evolution and diversity of surface environment. However, is may be notified that the continuous development of computational abilities in recent years does not seem to be well utilized in improving numerical simulations in those fields; computational efficiency has been improved by 6 orders of magnitude compared from the early 90's, many of our simulations do not seem to catch up qualitatively and quantitatively such improvement. We propose here in this session to ask those who are interested in computational sciences of various fields not only of planetary formation and evolution but also of earth and planetary sciences in general to join. The aim is to discuss various scientific and technical aspects of our numerical simulations to improve our skills to fully utilize those development of computational resources that is realized or will be realized in near future as "K" to "post-K".

Simulation Studies of Solar Activities as a Cause of Solar-Terrestrial Environment Variation

*Kanya Kusano[1], Hideyuki Hotta[2]

1. Institute for Space-Earth Environmental Research, Nagoya University, 2. Faculty of Science and Engineering, Chiba University

Solar activity is the main driver of disturbance of solar-terrestrial environment, and an extreme space weather disaster caused by a giant solar eruption is a potential risk to modern society. The prediction is just a way to mitigate the space weather disaster. In this study, in order to improve our understanding and predictability of the solar-terrestrial environmental variation, we are developing the various types of simulations of solar activities. In this paper, we will report the recent progress of the following two topics. The first topic is for the comprehensive simulation of the whole solar convection zone. Since comprehensive calculation covering whole convection zone has not been carried out ever due to significant temporal and spatial differences between deep and surface layers, our understanding for connection between the solar surface and the deep solar interior has been limited. Here we succeed in carrying out such a calculation for the first time. The results show that the surface region has an unexpectedly small effect on the deep convection zone. The second topic is for the physics-based prediction of imminent giant solar flares. The results indicate that the non-linear force-free modeling based on the vector magnetic field data can be a powerful tool to predict when, where and how large giant solar flares will occur.

Development of a global non-hydrostatic Martian atmospheric model and its high-resolution simulation

*Hiroki Kashimura[1], Hisashi Yashiro[2], Seiya Nishizawa[2], Hirofumi Tomita[2], Kensuke Nakajima[3], Masaki Ishiwatari[4], Yoshiyuki O. Takahashi[1], Yoshi-Yuki Hayashi[1]

1. Kobe University/Center for Planetary Science, 2. RIKEN Center for Computational Science, 3. Kyushu University, 4. Hokkaido University

Scales of atmospheric motions in Earth range from a few meter scale to the planetary scale, and multi-scale phenomena interact with each other. This is a reason for promoting an atmospheric simulation with higher resolution. The situation must be the same in other planets such as Mars. In the Martian atmosphere, dust storms in various scales—from dust devils of tens to hundreds of meter scales, to local dust storm of several tens of kilometer scale, and to global dust storm—have been observed. However, interactions between these scales are unknown. In addition, since Mars has a thin atmosphere and no ocean, the temperature difference between day and night is large and vertical convection should play an essential role in the Martian meteorology, but it is also unknown. To investigate these mysteries, global atmospheric simulations with horizontal resolution as high as few kilometers are required. Additionally, in order to explicitly simulate vertical convection, it is necessary to solve the governing equations without assuming the hydrostatic balance.

We are developing a non-hydrostatic global Martian atmospheric model (Martian SCALE-GM) which is suitable for large-scale parallel computation, targeting to perform high-resolution simulations described above on the post-K computer. SCALE-GM (http://scale.aics.riken.jp/) is being developed by using the dynamical core of NICAM (Tomita and Satoh, 2005; Satoh et al., 2008; Satoh et al., 2014), a non-hydrostatic model using a finite volume method in the icosahedral grid systems (Tomita et al., 2001, 2002), that has been used for simulations of Earth atmosphere and climate, and by aiming at sharing of physical process modules with the regional model (SCALE-RM) and application to other planetary atmospheres. We are developing Martian SCALE-GM by incorporating constants and physical process modules of the Martian atmosphere. The Martian physical modules are taken from DCPAM (https://www.gfd-dennou.org/library/dcpam/), an existing pan-planetary atmospheric general circulation model (GCM). DCPAM is a traditional, hydrostatic GCM using a spectral method for horizontal discretization.

In this study, we ported a Martian atmospheric radiation model (Forget et al., 1999) and a soil model from DCPAM to SCALE-GM and performed a test of temperature evolution in a vertical 1D-atmosphere and soil. The atmosphere model has 100 layers (Δz = 1 km), and distribution of dust is fixed with 0.2 optical depth. The soil model has 18 layers. Soil's heat capacity and thermal conductivity are set to 9.7×10^5 [J K^{-1} kg^{-1}] and 0.076 [W m^{-1} K^{-1}], respectively. Surface albedo is fixed at 0.2. For the calculation of surface fluxes and vertical diffusion, BH91B95 (Beljaars & Holstang, 1991; Beljaars, 1995) and MY2.5 (Mellor & Yamada, 1982) are used, respectively. The initial condition is the 200 K constant temperature atmosphere and soil. We have confirmed that both models (SCALE-GM and DCPAM) show almost the same temperature evolution.

Next, we performed 3D calculations under a Mars-like condition in 7 different horizontal resolutions and checked the dependence of the numerical solutions on the horizontal resolution. Horizontal grid intervals are $240\times(1/2)^n$ [km] (n = 0, 1, 2, 3, 4, 5, 6); i.e., 3.75 km at minimum. The horizontal diffusion

©2019. Japan Geoscience Union. All Right Reserved.

representing turbulent mixing in sub-grid scales is given in the 3rd order Laplacian with the relaxation time for the shortest scale given by $100\times(1/2)^n$ [s]. The atmosphere is divided into 36 layers, which are concentrated near the surface. To avoid wave reflections at the model top, a sponge layer represented by 1st order Laplacian is set above 40 km altitude; the relaxation time for the shortest scale is given by $3600\times(1/4)^n$ [s] except for the case of $\Delta x = 3.75$ km, in which 3 s is used. The 4th order Runge-Kutta method is used for time-integration with a time step of $360\times(1/2)^n$ [s]. The surface albedo is set to 0.5. Neither topography nor condensation processes are included.

Numerical solutions showed that vertical convections due to diurnal solar heating did not appear clearly in the cases with Δx larger than 15 km, whereas they appeared in higher resolution cases. Furthermore, it was confirmed that the horizontal scale and occurrence local-time of the vertical convection are highly dependent on the horizontal resolution at least in this range.

(Figure: Horizontal resolution dependence of vertical wind. Snapshots at 2 km altitude after 30 days from the spring equinox of the Northern hemisphere.)

Numerical simulations on the collision, adhesion, and growth of dust particles in turbulent gas in a protoplanetary disk

*Takashi Ishihara[1], Kohei Hamabata[2], Yoshiki Sakurai[2], Masayuki Umemura[3]

1. Graduate School of Environmental and Life Science, Okayama University, 2. Graduate School of Engineering, Nagoya University, 3. Center for Computational Sciences, University of Tsukuba

In a protoplanetary disk, dust grains, which are icy or rocky microscopic particles, are present at about one percent of gas mass. The dust grains collide and adhere with each other to grow in size repeatedly in turbulent gas of a protoplanetary disk. Planetesimals are widely believed to form as a consequence of this hierarchical coagulation from submicron-size dust particles to kilometer-size bodies in a protoplanetary disk. However, it has been argued that there are several physical barriers such as bouncing and radial drift barriers in the planetesimal formation process, and these remain unresolved, especially for silicate dust. In recent years, as a possible solution to these problems, the effect of turbulent clustering of dust grains has been attracting attentions.

In previous studies, it was pointed out that the clustering of particles by turbulence promotes adhesion growth (Pan et al, ApJ2011), and the statistics such as the collision velocity of dust particles in turbulent flow were investigated by a direct numerical simulation (DNS) of turbulence, solving the Navier–Stokes equations (Pan and Padoan, ApJ 2015). Recently, a series of large-scale DNSs of turbulence was conducted to study the velocity distribution of colliding particles in the turbulent flow and the dependence on flow nonlinearity (Reynolds number) (Ishihara et al, ApJ2018). However, numerical simulations on the coagulation process of dust particles were not performed. Therefore, whether dust grains grow hierarchically has not been clarified.

In this study, we developed a parallel code (using MPI and OpenMP) to simulate the collisional adhesion process of dust particles, in which the critical collision velocity (Wada et al, A & A, 2013) is taken into account, and investigated the adhesion processes of 512^3 dust particles using a large-scale DNS of turbulence.
As a result, we have found the following by the analyses of the obtained data:
(1) Dust particles collides with each other within the critical collision velocity preferentially at positions with smaller enstrophy (intensity of vorticity), while dust particles collide with the critical or higher collision velocity at positions with larger enstrophy.
(2) Even if the average collision speed exceeds the critical collision velocity, the collisions within the critical collision velocity can occur repeatedly, and thus rapidly growing dust grains do exist.
(3) The sticking probability of dust particles directly obtained by our simulations is larger than that estimated by the previous DNS data analysis (Ishihara et al ApJ 2018).
(4) The Reynolds number dependence of the dust motion for grains with long stopping time (the response time to flow change) is very weak. Hence, even in protoplanetary disk turbulence with much larger Reynolds number, the same growth process as in this study is expected.

The reasons and implication of the above results will be discussed by conducting the additional data analysis.

Development of N-body Simulation Code for Planetary System Formation With Particle-Particle Particle-Tree Scheme

*Yota Ishigaki[1,4], Junko Kominami[2], Junichiro Makino[3], Masaki Fujimoto[4]

1. University of Tokyo, 2. Tokyo Institute of Technology, 3. RIKEN AICS, 4. Institite of Space and Astronautical Science, Japan Aerospace Exploration Agency

In general, the planetary system is thought to be formed from protoplanetary disks surrounding the central star. In particular, it is accepted that terrestrial planets and the cores of gas giant planets are formed by accretion of km size objects (planetesimals) in the protoplanetary disk. The accretion process of the planets has been mainly discussed using the gravitational multi-body simulations (N-body simulations) of planetesimal systems. Various unresolved problems have been pointed out in the conventional standard planetary system formation theory.In recent years, new planetary system formation models have been proposed to solve these problems.However, there is no model with no problem even in these new models. Since N-body simulations with sufficient number of particles has not been performed, the generalized planetary system formation theory has not been constructed yet.

We have developed a new N-body simulation code with particle-particle particle-tree (P^3T) scheme for planetary system formation, GPLUM. The code GPLUM uses a fourth-order Hermite scheme to calculate gravitational interactions between particles within a cut-off radius and a Barnes-Hut tree scheme for gravitational interactions from particles beyond. The conventional simulation codes with P^3T scheme has the bottleneck that the calculation speed decreases when the mass ratio among the particles becomes large. We have solved it by implementing an algorithm which determines the cut-off radius based on mass and orbital semi-major axis of particles individually for each particle. The performance of GPLUM is significantly improved for the simulations of particle systems with mass distribution.

By improving the performance of the N-body simulation code, we made it possible to carry out numerous global simulation with various parameters. GPLUM allows us to perform N-body simulations with ~10^6-10^7 particles. By using GPLUM, we will perform N-body simulations with wide range and high resolution and investigate various parameters by perform parameter studies with N-body simulations.

Current status of post-K Exploratory Challenge, computational planetary science

*Junichiro Makino[1,2]

1. Kobe Univ, 2. RIKEN R-CCS

In FY 2016, as one of research project for post-K supercomputer, "Exploratory Challenge 3 Elucidation of the Birth of Exoplanets and the Environmental Variations of Planets in the Solar System" has been started. This FY is the last year for the two-year production phase, even though the post-K computer will not be ready until FY 2021. In this talk, I'll overview this project (we call this project computational planetary science project for short).

The development of post-K supercomputer was started in 2014, and its planed completion year is around 2021, with up to 100 times faster speed on real applications compared to K computer. As one of four "Exploratory Challenges", computational planetary science has been selected, and it is assigned to Kobe University, with other eight research institutes.

The computational planetary science project consists of four sub topics: planetary formation, dynamics and evolution of planets, solar activities and environmental change, and the origin of life. In this talk, I'll overview these topics, computational challenges, and products so far and future prospects.

[J] Poster | M (Multidisciplinary and Interdisciplinary)：M-GI General Geosciences, Information Geosciences & Simulations

Tue. May 28, 2019 3:30 PM - 5:00 PM JST | Tue. May 28, 2019 6:30 AM - 8:00 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_29

[M-GI35] Development of computational sciences on planetary formation, evolution and surface environment

convener:Yoshi-Yuki Hayashi(Department of Planetology/CPS, Graduate School of Science, Kobe University), Masaki Ogawa(Division of General Systems Studies, Graduate School of Arts and Sciences, University of Tokyo), Shigeru Ida(Earth-Life Science Institute, Tokyo Institute of Technology), Kanya Kusano(Institute for Space-Earth Environmental Research, Nagoya University)

Computer simulations have been recognized as one of the fundamental tools in understanding planetary formation, evolution and diversity of surface environment. However, is may be notified that the continuous development of computational abilities in recent years does not seem to be well utilized in improving numerical simulations in those fields; computational efficiency has been improved by 6 orders of magnitude compared from the early 90's, many of our simulations do not seem to catch up qualitatively and quantitatively such improvement. We propose here in this session to ask those who are interested in computational sciences of various fields not only of planetary formation and evolution but also of earth and planetary sciences in general to join. The aim is to discuss various scientific and technical aspects of our numerical simulations to improve our skills to fully utilize those development of computational resources that is realized or will be realized in near future as "K" to "post-K".

Most of the past N-body simulations started from initial conditions that were limited to radially narrow disks, for the limit of the particle number. However, several senarios have been proposed to expain the formation of Solar System, which includes the migration of planets radially with tens of AU. Hence, in order to construct the general formation scenario, we need to carry out simulations which cover the whole disk (~0.5AU - 40AU). We carried out the N-body simulation starting from planetesimal disk ranging from 0.5 - 40 AU. Surface density discontinuity at the ice line and the runaway gas accretion of the gas giant planets were included in the simulation. The initial number of particles was ~570000. Further investigation carrying out more simulations using different parameters are necessary. Here we introduce the first simulation that covers wide area of the disk.

Attempts at numerical modeling of 3-D mantle convection with magmatism and plate tectonics

*Masanori Kameyama[1,2], Masaki Ogawa[3,2], Takehiro Miyagoshi[2], Takatoshi Yanagisawa[2]

1. Geodynamics Research Center, Ehime University, 2. Japan Agency for Marine-Earth Science and Technology, 3. University of Tokyo at Komaba

We are developing 3-D numerical models of mantle convection including the effects of mantle magmatism and plate tectonics, in order to deepen the insights into the thermo-chemical evolution of the mantles of terrestrial bodies. The mantle magmatism is modeled by the generation of liquid phase (magma) owing to the pressure-release melting induced by ascending flows of solid-state convection and the motion of the generated magma as a permeable flow through the solid matrix driven by a buoyancy due to the density difference between the solid and the liquid phases. The coherent motion of tectonic plates is, on the other hand, helped by the narrow zones of low viscosity within the highly viscous "lithosphere" along the top cold surface generated by the stress-history-dependent rheology. However, despite their crucial roles in controlling the overall flow structures, these two mechanisms are incompatible with the solid-state convection of the mantle in essence from the numerical aspects: the localized irregularities caused by them severely deteriorate the large-scale numerical solution of solid-state convection particularly by the multigrid method. In this presentation, we will show the current status and outcrops of our attempts to overcome the numerical difficulty, together with some examples of 3-D experiments running on massive (super)computers.

Surface zonal flows induced by anelastic thermal convection in a rapidly rotating spherical shell

*Youhei SASAKI[1], Shin-ichi Takehiro[2], Keiichi ISHIOKA[3], Takeshi Enomoto[4]

1. Department of Mathematics, Kyoto University, 2. Research Institute for Mathematical Sciences, Kyoto University, 3. Department of Earth and Planetary Sciences, Kyoto University, 4. Disaster Prevention Research Institute, Kyoto University

Banded structures and alternating zonal jets observed in the surface atmospheres of Jupiter and Saturn have attracted many researchers in planetary atmospheric sciences, however, satisfactory physical explanations and understandings are not yet obtained. In this study, we perform massive parallel numerical experiments treating both small scale convection and planetary scale flows simultaneously, solve fine structures of turbulent motions which have not yet been resolved by the previous numerical models so far, and try to illustrate dynamical origin of global scale structures of surface flows of Jovian planets.

For this purpose, we developed and parallelized an anelastic model of thermal convection in a rotating spherical shell considering basic radial density variation. The spectral transformation library used in this model was improved to introduce MPI parallelization not only in the latitude direction but also in the radial direction. As a result, we succeeded in increasing the number of parallel processes which had been limited by the number of latitudinal grid points, and more massive parallel numerical experiments became possible.

Followup and extended numerical experiments of Case 2 in Gastine et al.(2014) were performed with the developed anelastic convection model. When the time integration is as short as viscous diffusion time, the latitudinal profile of induced surface zonal flow is consistent with that of Gastine et al. (2014). However, when time integration is further extended, prograde surface zonal flows in high latitudes start to develop, and become prominent. This result suggests that surface zonal flows obtained by the previous studies may not be statistically steady states.

Protostellar flares driven by accretion in protoplanetary disks

*Shinsuke Takasao[1], Kengo Tomida[2], Shinsuke Takasao[2], Takeru Suzuki[3]

1. Nagoya University, 2. Osaka University, 3. University of Tokyo

X-ray observations reveal that protostars produce huge explosions frequently. There is discussions that protostellar flares may play roles in forming chondrules that are important building blocks of planets. Protostellar flares are similar to solar flares, and are considered as explosions driven by magnetic energy release. However, protostellar flares are much more energetic than solar flares. The huge energy suggests that flare size should be larger than the stellar radius, which implies that a different energy build up process is required. We investigate the mechanism of protostellar flares using 3D MHD simulations. Our simulations revealed that the energy build up is done by the accumulation of magnetic flux by accretion from the protoplanetary disk. In this paper we will discuss the physics on the basis of our simulaitons.

Cross-reference simulations by scalable communication library for the study of wave-particle interactions in planetary magnetospheres

*Yuto Katoh[1], Keiichiro Fukazawa[2], Takeshi Nanri[3], Yohei Miyake[4]

1. Department of Geophysics, Graduate School of Science, Tohoku University, 2. Academic Center for Computing and Media Studies, Kyoto University, 3. Research Institute for Information Technology, Kyushu University, 4. Graduate School of System Informatics, Kobe University

We have been developing a cross-reference simulation code by scalable communication library for the study of wave-particle interactions in planetary magnetospheres. We use Advanced Communication Primitives (ACP; http://ace-project.kyushu-u.ac.jp/main/jp/01_overview/) library for the communication among the simulation codes, which enables us to carry out 'strong' cross-reference simulations; the data exchange among simulation codes is conducted by direct memory access, instead of file output as has been used in conventional 'weak' cross-reference simulations. By a series of electron-hybrid and MHD cross-reference simulations, we study the generation and propagation of whistler-mode chorus emissions in the planetary magnetosphere. Chorus emissions are electromagnetic plasma waves commonly observed in planetary magnetospheres and are a group of coherent wave elements changing their frequency in time. While the generation process of chorus has been reproduced by numerical experiments [e.g., Katoh and Omura, GRL 2007a] and has been explained by the nonlinear wave growth theory [Omura et al., JGR 2008, 2009], previous studies revealed similarities and differences of the spectral characteristics of chorus in planetary magnetospheres, which has not been understood yet. In the cross-reference simulations, we use the MHD code for the investigation of the range of variation of the spatial scale of the planetary magnetosphere. The electron hybrid code is used to reproduce the generation process of chorus emissions under the initial conditions provided from the MHD simulations. An electron fluid code [Katoh, 2014] is also used for the study of the propagation of chorus emissions in the meridional plane of the magnetosphere. We describe the simulation models used in the developing code and show their initial results.

Radiative transfer calculation for various planetary atmospheres: Application to a general circulation model

*Yoshi-Yuki Hayashi[1], George HASHIMOTO[2], Kiyoshi Kuramoto[3], Masaki Ishiwatari[3], Yoshiyuki O. Takahashi[1]

1. Department of Planetology/CPS, Graduate School of Science, Kobe University, 2. Department of Earth Sciences, Okayama University, 3. Department of Cosmosciences, Graduate School of Sciences, Hokkaido University

A lot of exoplanets have been discovered. One of the interesting questions on those exoplanets is its surface environment and circulation structure. A first step to understand surface environments is an investigation of radiative budget of the planets. Further, now a days, several general circulation models are used to simulate surface environments of various planets. But, calculation of radiative transfer of various planets have several difficulties. One of those is huge computational cost, and another is uncertainty of radiative properties of atmospheres which is very different from Earth's atmosphere. In this study, we are developing a radiation model which can be applied to various planetary atmospheres and try to implement it into our general circulation model.

In developing a radiation model for atmospheric circulation models, a line-by-line model is developed, first. The line-by-line calculation requires huge computational cost. In our line-by-line model, we assign several atmospheric layers to each MPI process to perform parallel computation. In typical calculation conditions, number of atmospheric layers is order of 10 to 100. Our calculation scales very well if the computation is performed with this number of processors. In order to validate the model, radiative fluxes and tendencies are calculated for the Earth, Venus, present Mars, and early Mars.

After the validation of the line-by-line calculation, we develop a radiation model based on correlated k-distribution method, which require much fewer computational cost and can be implemented into a general circulation model. In the presentation, comparison of radiative fluxes and tendencies calculated by our model with those by observation and/or by other models will be presented. In addition, some examples of general circulation model simulations will be presented, too.

Effect of the compressibility of turbulent flows on dust particle collision statistics in a protoplanetary disk

*Yoshiki Sakurai[1], Hitomi Furuya[2], Naoki Kobayashi[1], Takashi Ishihara[3], Naoya Okamoto[4], Kenji Shiraishi[5], Masayuki Umemura[6]

1. Graduate School of Engineering, Nagoya University, 2. Doctoral and Master's Programs in Physics, Graduate School of Pure and Applied Sciences, University of Tsukuba, 3. Graduate School of Environmental and Life Science, Okayama University, 4. Center for Computational Science, Graduate School of Engineering, Nagoya University, 5. Institute of Materials and Systems for Sustainability, Nagoya University, 6. Center for Computational Science, University of Tsukuba

Planetesimals are believed to form by hierarchical coagulation from submicron-size dust particles to kilometer-size bodies in turbulent flows in a protoplanetary disk. However, several barriers, e.g., radial drift, bouncing, and fragmentation barriers, in the planetesimal formation process are not completely resolved, especially for silicate dust. To resolve these barriers, it is important to accurately understand the role of turbulence in the coagulation process.

In the Minimum-mass Solar Nebula (MMSN) Model (Hayashi 1981), the Reynolds number (Re) and the Mach number (Ma) of turbulence in protoplanetary disks range Re=10^8~10^11 and Ma=0.01~0.32, respectively. Pan et al. (2011) conducted an approximate simulation of compressible turbulence (Ma~1.0) and showed that turbulent clustering may considerably enhance the particle collision rate. Pan & Padoan (2013, 2014, 2015) and Pan et al.(2014) peformed a direct numerical simulation (DNS) of the Navier–Stokes equations on weakly compressible turbulence (Re~1000 and Ma~0.1) at low Re to study the effect of turbulent clustering. Pan & Padoan (2015) found that the rms relative velocity of particle pairs is smaller by more than a factor of two compared to that by turbulent model (Ormel & Cuzzi 2007). Their studies demonstrated that the turbulent clustering should be taken into account to consider the coagulation process.

Recently, Ishihara et al (2018) performed DNSs of incompressible turbulence at high Re (up to Re=16100) to study the motion of dust particles in turbulence. They showed that the collision statistics of the dust particles with large inertia are not so sensitive to the Reynolds number and confirmed that they are consistent with those by Pan & Padoan or Pan et al at low Re. However, the effect of compressibility of turbulence on the collision statistics is not yet quantitatively investigated.

In this paper, we perform DNSs of incompressible and compressible turbulence with Ma=0.1 and 0.3 and set the ratio of dilatation component (ed) and solenoid component (es) of the mean energy dissipation rate (ed/es) to 0.01 and 0.1 to study quantitatively the effect of compressibility of the inertial particle collision statistics. The motion of inertial particles is characterized by the Stokes number (St=tp/T, where tp is the particle stopping time and T is the time-scale of largest eddies), and we track eight sets of inertial particles with from St=0 to St=0.3. Our results are as follows:

(1) The compressibility of turbulent flow is characterized by both of Ma and ed/es.

©2019. Japan Geoscience Union. All Right Reserved.

(2) In case of Ma=0.3, the local Ma can exceed unity so that shocklets can be generated in the turbulent flow.

(3) The local Mach number is high at positions with higher enstrophy.

(4) In case of Ma=0.1-0.3, relative velocity of colliding particles and collision kernel have weak Mach number dependence but may depend when the value of the ratio of ed/es is large.

Our results show that compressibility considered in protoplanetary disk turbulence has little influence on particle collision statistics.

Algorithms to use accelerators effectively with FDPS and performance of applications

*Daisuke Namekata[1], Masaki Iwasawa[1], Keigo Nitadori[1], Kentaro Nomura[1], Long Wang[3,1], Miyuki Tsubouchi[1], Junichiro Makino[2,1,4]

1. RIKEN Center for Computational Science, 2. Department of Planetology, Graduate School of Science, Kobe University, 3. Helmholtz Institut fur Strahlen und Kernphysik, 4. Earth-Life Science Institute, Tokyo Institute of Technology

Numerical simulations based on particle methods have played an important role in understanding the formation and evolution of planets and planetary systems. Along with the improvement of the computing capacity of computers, more large-scale simulations and simulations taking into consideration various physical phenomena have come to be performed, in order to understand the reality in more detail.

However, it is becoming increasingly difficult to develop a simulation code that runs efficiently on modern HPC (high-performance computing) systems. The main reason for this difficulty is that modern HPC platforms have become very complex, and thus it requires lots of efforts necessary to develop complex programs to make efficient use of such platforms. Typical modern HPC systems are actually a cluster of computing nodes connected a network with a limited communication bandwidth. The number of nodes can reach up to 100,000 in the largest systems at present. Thus, we need to develop simulation code so that it shows a good load balance and requires minimal communication. In recent years, the architecture of large-scale HPC systems have been shifting from homogeneous multi-core processors to accelerator-based systems and heterogeneous multi-core processors for economical reasons. This makes code development more difficult for the following reasons. One is that for many applications, the communication bandwidth between CPUs and accelerators becomes the bottleneck. The second one is that because CPUs and accelerators have separate memory spaces, the programming is complicated and we cannot use existing programs. Thus, the time required for code development has been increasing more and more, which causes stagnation of research.

To improve the situation, we have developed a framework called FDPS (Framework for Developing Particle Simulators), which enables researchers to develop their own high-performance parallel particle-based simulation programs easily. The basic idea of FDPS is to provide a high-performance implementation of parallel algorithms for particle-based simulations in a ``generic" form, so that researchers can define his/her own particle data structure and interparticle interaction functions and supply them to FDPS framework. FDPS framework compiled with user-supplied data type and interaction function provides all necessary functions for parallelization, and using those functions researchers can write their programs as though they are writing simple non-parallel program which runs on their laptop computers. FDPS offers very good performance on large-scale parallel systems consisting of ``homogeneous" multi-core processors, such as K computer and Cray systems based on x86 processors. In FDPS version 2, we have extended FDPS so that it can use accelerators by writing the interaction function that uses the accelerator hardware. However, the efficiency was limited by the latency and bandwidth of communication between the CPU and the accelerator and also by the mismatch between the available degree of parallelism of the interaction function and that of the hardware parallelism, and thus would be rather poor.

In order to make it possible for FDPS to use more efficiently accelerator hardware such as GPGPUs

[J] Poster | M (Multidisciplinary and Interdisciplinary)：M-GI General Geosciences, Information Geosciences & Simulations

Tue. May 28, 2019 5:15 PM - 6:30 PM JST | Tue. May 28, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_49

[M-GI35] Development of computational sciences on planetary formation, evolution and surface environment

convener:Yoshi-Yuki Hayashi(Department of Planetology/CPS, Graduate School of Science, Kobe University), Masaki Ogawa(Division of General Systems Studies, Graduate School of Arts and Sciences, University of Tokyo), Shigeru Ida(Earth-Life Science Institute, Tokyo Institute of Technology), Kanya Kusano(Institute for Space-Earth Environmental Research, Nagoya University)

Computer simulations have been recognized as one of the fundamental tools in understanding planetary formation, evolution and diversity of surface environment. However, is may be notified that the continuous development of computational abilities in recent years does not seem to be well utilized in improving numerical simulations in those fields; computational efficiency has been improved by 6 orders of magnitude compared from the early 90's, many of our simulations do not seem to catch up qualitatively and quantitatively such improvement. We propose here in this session to ask those who are interested in computational sciences of various fields not only of planetary formation and evolution but also of earth and planetary sciences in general to join. The aim is to discuss various scientific and technical aspects of our numerical simulations to improve our skills to fully utilize those development of computational resources that is realized or will be realized in near future as "K" to "post-K".

Most of the past N-body simulations started from initial conditions that were limited to radially narrow disks, for the limit of the particle number. However, several senarios have been proposed to expain the formation of Solar System, which includes the migration of planets radially with tens of AU. Hence, in order to construct the general formation scenario, we need to carry out simulations which cover the whole disk (~0.5AU - 40AU). We carried out the N-body simulation starting from planetesimal disk ranging from 0.5 - 40 AU. Surface density discontinuity at the ice line and the runaway gas accretion of the gas giant planets were included in the simulation. The initial number of particles was ~570000. Further investigation carrying out more simulations using different parameters are necessary. Here we introduce the first simulation that covers wide area of the disk.

Attempts at numerical modeling of 3-D mantle convection with magmatism and plate tectonics

*Masanori Kameyama[1,2], Masaki Ogawa[3,2], Takehiro Miyagoshi[2], Takatoshi Yanagisawa[2]

1. Geodynamics Research Center, Ehime University, 2. Japan Agency for Marine-Earth Science and Technology, 3. University of Tokyo at Komaba

We are developing 3-D numerical models of mantle convection including the effects of mantle magmatism and plate tectonics, in order to deepen the insights into the thermo-chemical evolution of the mantles of terrestrial bodies. The mantle magmatism is modeled by the generation of liquid phase (magma) owing to the pressure-release melting induced by ascending flows of solid-state convection and the motion of the generated magma as a permeable flow through the solid matrix driven by a buoyancy due to the density difference between the solid and the liquid phases. The coherent motion of tectonic plates is, on the other hand, helped by the narrow zones of low viscosity within the highly viscous "lithosphere" along the top cold surface generated by the stress-history-dependent rheology. However, despite their crucial roles in controlling the overall flow structures, these two mechanisms are incompatible with the solid-state convection of the mantle in essence from the numerical aspects: the localized irregularities caused by them severely deteriorate the large-scale numerical solution of solid-state convection particularly by the multigrid method. In this presentation, we will show the current status and outcrops of our attempts to overcome the numerical difficulty, together with some examples of 3-D experiments running on massive (super)computers.

Surface zonal flows induced by anelastic thermal convection in a rapidly rotating spherical shell

*Youhei SASAKI[1], Shin-ichi Takehiro[2], Keiichi ISHIOKA[3], Takeshi Enomoto[4]

1. Department of Mathematics, Kyoto University, 2. Research Institute for Mathematical Sciences, Kyoto University, 3. Department of Earth and Planetary Sciences, Kyoto University, 4. Disaster Prevention Research Institute, Kyoto University

Banded structures and alternating zonal jets observed in the surface atmospheres of Jupiter and Saturn have attracted many researchers in planetary atmospheric sciences, however, satisfactory physical explanations and understandings are not yet obtained. In this study, we perform massive parallel numerical experiments treating both small scale convection and planetary scale flows simultaneously, solve fine structures of turbulent motions which have not yet been resolved by the previous numerical models so far, and try to illustrate dynamical origin of global scale structures of surface flows of Jovian planets.

For this purpose, we developed and parallelized an anelastic model of thermal convection in a rotating spherical shell considering basic radial density variation. The spectral transformation library used in this model was improved to introduce MPI parallelization not only in the latitude direction but also in the radial direction. As a result, we succeeded in increasing the number of parallel processes which had been limited by the number of latitudinal grid points, and more massive parallel numerical experiments became possible.

Followup and extended numerical experiments of Case 2 in Gastine et al.(2014) were performed with the developed anelastic convection model. When the time integration is as short as viscous diffusion time, the latitudinal profile of induced surface zonal flow is consistent with that of Gastine et al. (2014). However, when time integration is further extended, prograde surface zonal flows in high latitudes start to develop, and become prominent. This result suggests that surface zonal flows obtained by the previous studies may not be statistically steady states.

Protostellar flares driven by accretion in protoplanetary disks

*Shinsuke Takasao[1], Kengo Tomida[2], Shinsuke Takasao[2], Takeru Suzuki[3]

1. Nagoya University, 2. Osaka University, 3. University of Tokyo

X-ray observations reveal that protostars produce huge explosions frequently. There is discussions that protostellar flares may play roles in forming chondrules that are important building blocks of planets. Protostellar flares are similar to solar flares, and are considered as explosions driven by magnetic energy release. However, protostellar flares are much more energetic than solar flares. The huge energy suggests that flare size should be larger than the stellar radius, which implies that a different energy build up process is required. We investigate the mechanism of protostellar flares using 3D MHD simulations. Our simulations revealed that the energy build up is done by the accumulation of magnetic flux by accretion from the protoplanetary disk. In this paper we will discuss the physics on the basis of our simulaitons.

Cross-reference simulations by scalable communication library for the study of wave-particle interactions in planetary magnetospheres

*Yuto Katoh[1], Keiichiro Fukazawa[2], Takeshi Nanri[3], Yohei Miyake[4]

1. Department of Geophysics, Graduate School of Science, Tohoku University, 2. Academic Center for Computing and Media Studies, Kyoto University, 3. Research Institute for Information Technology, Kyushu University, 4. Graduate School of System Informatics, Kobe University

We have been developing a cross-reference simulation code by scalable communication library for the study of wave-particle interactions in planetary magnetospheres. We use Advanced Communication Primitives (ACP; http://ace-project.kyushu-u.ac.jp/main/jp/01_overview/) library for the communication among the simulation codes, which enables us to carry out 'strong' cross-reference simulations; the data exchange among simulation codes is conducted by direct memory access, instead of file output as has been used in conventional 'weak' cross-reference simulations. By a series of electron-hybrid and MHD cross-reference simulations, we study the generation and propagation of whistler-mode chorus emissions in the planetary magnetosphere. Chorus emissions are electromagnetic plasma waves commonly observed in planetary magnetospheres and are a group of coherent wave elements changing their frequency in time. While the generation process of chorus has been reproduced by numerical experiments [e.g., Katoh and Omura, GRL 2007a] and has been explained by the nonlinear wave growth theory [Omura et al., JGR 2008, 2009], previous studies revealed similarities and differences of the spectral characteristics of chorus in planetary magnetospheres, which has not been understood yet. In the cross-reference simulations, we use the MHD code for the investigation of the range of variation of the spatial scale of the planetary magnetosphere. The electron hybrid code is used to reproduce the generation process of chorus emissions under the initial conditions provided from the MHD simulations. An electron fluid code [Katoh, 2014] is also used for the study of the propagation of chorus emissions in the meridional plane of the magnetosphere. We describe the simulation models used in the developing code and show their initial results.

Radiative transfer calculation for various planetary atmospheres: Application to a general circulation model

*Yoshi-Yuki Hayashi[1], George HASHIMOTO[2], Kiyoshi Kuramoto[3], Masaki Ishiwatari[3], Yoshiyuki O. Takahashi[1]

1. Department of Planetology/CPS, Graduate School of Science, Kobe University, 2. Department of Earth Sciences, Okayama University, 3. Department of Cosmosciences, Graduate School of Sciences, Hokkaido University

A lot of exoplanets have been discovered. One of the interesting questions on those exoplanets is its surface environment and circulation structure. A first step to understand surface environments is an investigation of radiative budget of the planets. Further, now a days, several general circulation models are used to simulate surface environments of various planets. But, calculation of radiative transfer of various planets have several difficulties. One of those is huge computational cost, and another is uncertainty of radiative properties of atmospheres which is very different from Earth's atmosphere. In this study, we are developing a radiation model which can be applied to various planetary atmospheres and try to implement it into our general circulation model.

In developing a radiation model for atmospheric circulation models, a line-by-line model is developed, first. The line-by-line calculation requires huge computational cost. In our line-by-line model, we assign several atmospheric layers to each MPI process to perform parallel computation. In typical calculation conditions, number of atmospheric layers is order of 10 to 100. Our calculation scales very well if the computation is performed with this number of processors. In order to validate the model, radiative fluxes and tendencies are calculated for the Earth, Venus, present Mars, and early Mars.

After the validation of the line-by-line calculation, we develop a radiation model based on correlated k-distribution method, which require much fewer computational cost and can be implemented into a general circulation model. In the presentation, comparison of radiative fluxes and tendencies calculated by our model with those by observation and/or by other models will be presented. In addition, some examples of general circulation model simulations will be presented, too.

Institute of Materials and Systems for Sustainability, Nagoya University, 6. Center for Computational Science, University of Tsukuba

Planetesimals are believed to form by hierarchical coagulation from submicron-size dust particles to kilometer-size bodies in turbulent flows in a protoplanetary disk. However, several barriers, e.g., radial drift, bouncing, and fragmentation barriers, in the planetesimal formation process are not completely resolved, especially for silicate dust. To resolve these barriers, it is important to accurately understand the role of turbulence in the coagulation process.

In the Minimum-mass Solar Nebula (MMSN) Model (Hayashi 1981), the Reynolds number (Re) and the Mach number (Ma) of turbulence in protoplanetary disks range Re=10^8~10^11 and Ma=0.01~0.32, respectively. Pan et al. (2011) conducted an approximate simulation of compressible turbulence (Ma~1.0) and showed that turbulent clustering may considerably enhance the particle collision rate. Pan & Padoan (2013, 2014, 2015) and Pan et al.(2014) peformed a direct numerical simulation (DNS) of the Navier–Stokes equations on weakly compressible turbulence (Re~1000 and Ma~0.1) at low Re to study the effect of turbulent clustering. Pan & Padoan (2015) found that the rms relative velocity of particle pairs is smaller by more than a factor of two compared to that by turbulent model (Ormel & Cuzzi 2007). Their studies demonstrated that the turbulent clustering should be taken into account to consider the coagulation process.

Recently, Ishihara et al (2018) performed DNSs of incompressible turbulence at high Re (up to Re=16100) to study the motion of dust particles in turbulence. They showed that the collision statistics of the dust particles with large inertia are not so sensitive to the Reynolds number and confirmed that they are consistent with those by Pan & Padoan or Pan et al at low Re. However, the effect of compressibility of turbulence on the collision statistics is not yet quantitatively investigated.

In this paper, we perform DNSs of incompressible and compressible turbulence with Ma=0.1 and 0.3 and set the ratio of dilatation component (ed) and solenoid component (es) of the mean energy dissipation rate (ed/es) to 0.01 and 0.1 to study quantitatively the effect of compressibility of the inertial particle collision statistics. The motion of inertial particles is characterized by the Stokes number (St=tp/T, where tp is the particle stopping time and T is the time-scale of largest eddies), and we track eight sets of inertial particles with from St=0 to St=0.3. Our results are as follows:

(1) The compressibility of turbulent flow is characterized by both of Ma and ed/es.

©2019. Japan Geoscience Union. All Right Reserved.

(2) In case of Ma=0.3, the local Ma can exceed unity so that shocklets can be generated in the turbulent flow.

(3) The local Mach number is high at positions with higher enstrophy.

(4) In case of Ma=0.1-0.3, relative velocity of colliding particles and collision kernel have weak Mach number dependence but may depend when the value of the ratio of ed/es is large.

Our results show that compressibility considered in protoplanetary disk turbulence has little influence on particle collision statistics.

Algorithms to use accelerators effectively with FDPS and performance of applications

*Daisuke Namekata[1], Masaki Iwasawa[1], Keigo Nitadori[1], Kentaro Nomura[1], Long Wang[3,1], Miyuki Tsubouchi[1], Junichiro Makino[2,1,4]

Numerical simulations based on particle methods have played an important role in understanding the formation and evolution of planets and planetary systems. Along with the improvement of the computing capacity of computers, more large-scale simulations and simulations taking into consideration various physical phenomena have come to be performed, in order to understand the reality in more detail.

However, it is becoming increasingly difficult to develop a simulation code that runs efficiently on modern HPC (high-performance computing) systems. The main reason for this difficulty is that modern HPC platforms have become very complex, and thus it requires lots of efforts necessary to develop complex programs to make efficient use of such platforms. Typical modern HPC systems are actually a cluster of computing nodes connected a network with a limited communication bandwidth. The number of nodes can reach up to 100,000 in the largest systems at present. Thus, we need to develop simulation code so that it shows a good load balance and requires minimal communication. In recent years, the architecture of large-scale HPC systems have been shifting from homogeneous multi-core processors to accelerator-based systems and heterogeneous multi-core processors for economical reasons. This makes code development more difficult for the following reasons. One is that for many applications, the communication bandwidth between CPUs and accelerators becomes the bottleneck. The second one is that because CPUs and accelerators have separate memory spaces, the programming is complicated and we cannot use existing programs. Thus, the time required for code development has been increasing more and more, which causes stagnation of research.

To improve the situation, we have developed a framework called FDPS (Framework for Developing Particle Simulators), which enables researchers to develop their own high-performance parallel particle-based simulation programs easily. The basic idea of FDPS is to provide a high-performance implementation of parallel algorithms for particle-based simulations in a ``generic" form, so that researchers can define his/her own particle data structure and interparticle interaction functions and supply them to FDPS framework. FDPS framework compiled with user-supplied data type and interaction function provides all necessary functions for parallelization, and using those functions researchers can write their programs as though they are writing simple non-parallel program which runs on their laptop computers. FDPS offers very good performance on large-scale parallel systems consisting of ``homogeneous" multi-core processors, such as K computer and Cray systems based on x86 processors. In FDPS version 2, we have extended FDPS so that it can use accelerators by writing the interaction function that uses the accelerator hardware. However, the efficiency was limited by the latency and bandwidth of communication between the CPU and the accelerator and also by the mismatch between the available degree of parallelism of the interaction function and that of the hardware parallelism, and thus would be rather poor.

In order to make it possible for FDPS to use more efficiently accelerator hardware such as GPGPUs

[M-ZZ50] Governance for Trans-boundary Volcanic Disaster

convener:Mayumi Sakamoto(Graduate School of Disaster Resilience and Governance, University of Hyogo), Haruhisa Nakamichi(Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University), MASARU ARAKIDA(Asian Disaster Reduction Center)

Volcanic monitoring systems are developed and managed for the purpose to observe a specific volcanic activity in each country based on its own regulation. However, the experience of Icelandic volcano Eyjafjallajokull eruption in 2010 caused huge air traffic disturbances, and left large economic and social impact to international community. In order to reduce possible financial, environmental, health or social damages caused by trans-boundary volcanic disaster, it is important to develop international cooperative system to monitor and share the information of emission, dispersion or deposition of volcanic products. In this session, we discuss trans-boundary effect of volcanic eruption, and how to establish international collaborative mechanism from different research disciplines such as disaster management, volcanology, environmental politics or international law.

Governance for Trans-boundary Volcanic Disaster -a case of 2010 Eyjafjallajökull Eruption-

*Mayumi Sakamoto[1]

1. Graduate School of Disaster Resilience and Governance, University of Hyogo

The volcanic eruption occurred in one country can trigger different effect in other country. The experience of 2010 Icelandic volcano Eyjafjallajökull eruption demonstrated the necessity of international governance for trans-boundary effect caused by eruption. In Iceland, national disaster response was effective to evacuate people from hazardous area and there were no humanitarian damages caused by eruption. However, the estimation of volcanic ash plumes and its dispersion caused huge international air traffic disruption or airport closure, and left large international economic and industrial impact. Followings are problems found through the 2010 eruption.
First, the necessity of international collaboration for observing atmospheric dispersion of volcanic ash. As for 2010 eruption, Icelandic Meteorological Agency (IMO) informed London Volcanic Ash Advisory Center (VAAC) which observes Iceland, about the plume height, ash content and other data. Based on the provided data, London VAAC predicted ash dispersion over Europe. However, there was no detailed discussion between IMO and London VAAC when and how often they communicate prior to eruption. It is important to update forecast using satellite imagery or observation of ashfalls in other countries.
Second, the necessity of immediate information sharing with both local and international medias. During the eruption, there was a huge need for information from international medias. A communication team, composed by professional communicator from various institutions gathered at the National Crisis Coordination and Command Center (NCCCC). Press conference were held and status reports were prepared and distributed. Such an international information sharing system should be discussed prior to disaster.
Disaster management systems are generally developed to respond hazard activity in each country based on its own regulation. However, 2010 experience showed there is no international agreement or regime to respond such a trans-boundary effect. Immediate crisis communication among hazard origin country, international institute and possibly affective country is required to reduce secondary effect, which shows importance or precautionary approaches for trans-boundary volcanic disaster.

Regional Cooperation against Cross-border Disasters

*MASARU ARAKIDA[1]

1. Asian Disaster Reduction Center

Since affected area by disasters such as floods on international scale river, haize by forest fire, and volcanic ejectaare are recognized as no boundaries, there are many benefits of working together through regional cooperation. These include the sharing of best practices for handling major disasters, responding together on search and rescue efforts, and understanding and improving DRR through early warnings, the mutual exchange of information, joint education and training exercises, and joint assistance on disaster response.

Issues of Japan's volcanic disaster prevention system as viewed from overseas alert systems

*Erika Ishimizu[1], Mayumi Sakamoto[1]

1. Graduate School of Disaster Resilience and Governance University of Hyogo

Volcanic alert levels was introduced in Japan in 2007. Thereafter, the level was raised or lowered for several volcanoes, some volcanoes erupted and residents evacuated. Among them, the problem of exploiting volcanic alert levels for evacuation has become clear. In this research, by comparing Japan's warning system with overseas (the United States, Indonesia, New Zealand), we will examine the issues of Japanese volcanic disaster prevention system and future disaster prevention system.
In Japan, several institutions, such as universities and Japan Meteorological Agency (JMA), are conducting observations of volcanic activity. In the volcano where volcanic alert levels is introduced, JMA announces five levels of volcanic alert levels according to the activity of the volcano. Each municipality carries out basic disaster response such as issuance of evacuation information.
In the United States, the United States Geological Survey (USGS) will unite from the observation of a volcano to the announcement of an alarm (4 stages). Basic disaster response is handled by municipalities and counties. If requested, the state government responds, and if it is still difficult, FEMA is asked.
In Indonesia, the Center of Volcanology and Geological Hazard Mitigation (PVMBG) classify active volcanoes into three stages, ranging from A to C class, and is conducting observations. When the volcano becomes active, they present four levels of warning level. The basic disaster response such as the issuance of evacuation information is taken by the Regional Disaster Management Agency in Indonesia (BPBD), and the National Agency for Disaster Countermeasure (BNPB) supports this. If evacuation accompanied with level rise but the eruption does not occur, BNPB bears the expenses.
In New Zealand, GNS Science Corporation conducts observation of volcanic activity and issuance of alarm (6 stages).An evacuation information issuance is made by CDEM which is a collaboration body of local public bodies.
This presentation discusses issues of volcanic disaster prevention system in Japan and future disaster prevention system by comparing systems of each country.

Followings are problems found through the 2010 eruption.
First, the necessity of international collaboration for observing atmospheric dispersion of volcanic ash. As for 2010 eruption, Icelandic Meteorological Agency (IMO) informed London Volcanic Ash Advisory Center (VAAC) which observes Iceland, about the plume height, ash content and other data. Based on the provided data, London VAAC predicted ash dispersion over Europe. However, there was no detailed discussion between IMO and London VAAC when and how often they communicate prior to eruption. It is important to update forecast using satellite imagery or observation of ashfalls in other countries.
Second, the necessity of immediate information sharing with both local and international medias. During the eruption, there was a huge need for information from international medias. A communication team, composed by professional communicator from various institutions gathered at the National Crisis Coordination and Command Center (NCCCC). Press conference were held and status reports were prepared and distributed. Such an international information sharing system should be discussed prior to disaster.
Disaster management systems are generally developed to respond hazard activity in each country based on its own regulation. However, 2010 experience showed there is no international agreement or regime to respond such a trans-boundary effect. Immediate crisis communication among hazard origin country, international institute and possibly affective country is required to reduce secondary effect, which shows importance or precautionary approaches for trans-boundary volcanic disaster.

Regional Cooperation against Cross-border Disasters

*MASARU ARAKIDA[1]

1. Asian Disaster Reduction Center

Since affected area by disasters such as floods on international scale river, haize by forest fire, and volcanic ejectaare are recognized as no boundaries, there are many benefits of working together through regional cooperation. These include the sharing of best practices for handling major disasters, responding together on search and rescue efforts, and understanding and improving DRR through early warnings, the mutual exchange of information, joint education and training exercises, and joint assistance on disaster response.

Issues of Japan's volcanic disaster prevention system as viewed from overseas alert systems

*Erika Ishimizu[1], Mayumi Sakamoto[1]

1. Graduate School of Disaster Resilience and Governance University of Hyogo

Volcanic alert levels was introduced in Japan in 2007. Thereafter, the level was raised or lowered for several volcanoes, some volcanoes erupted and residents evacuated. Among them, the problem of exploiting volcanic alert levels for evacuation has become clear. In this research, by comparing Japan's warning system with overseas (the United States, Indonesia, New Zealand), we will examine the issues of Japanese volcanic disaster prevention system and future disaster prevention system.
In Japan, several institutions, such as universities and Japan Meteorological Agency (JMA), are conducting observations of volcanic activity. In the volcano where volcanic alert levels is introduced, JMA announces five levels of volcanic alert levels according to the activity of the volcano. Each municipality carries out basic disaster response such as issuance of evacuation information.
In the United States, the United States Geological Survey (USGS) will unite from the observation of a volcano to the announcement of an alarm (4 stages). Basic disaster response is handled by municipalities and counties. If requested, the state government responds, and if it is still difficult, FEMA is asked.
In Indonesia, the Center of Volcanology and Geological Hazard Mitigation (PVMBG) classify active volcanoes into three stages, ranging from A to C class, and is conducting observations. When the volcano becomes active, they present four levels of warning level. The basic disaster response such as the issuance of evacuation information is taken by the Regional Disaster Management Agency in Indonesia (BPBD), and the National Agency for Disaster Countermeasure (BNPB) supports this. If evacuation accompanied with level rise but the eruption does not occur, BNPB bears the expenses.
In New Zealand, GNS Science Corporation conducts observation of volcanic activity and issuance of alarm (6 stages).An evacuation information issuance is made by CDEM which is a collaboration body of local public bodies.
This presentation discusses issues of volcanic disaster prevention system in Japan and future disaster prevention system by comparing systems of each country.

[M-ZZ50] Governance for Trans-boundary Volcanic Disaster

convener:Mayumi Sakamoto(Graduate School of Disaster Resilience and Governance, University of Hyogo), Haruhisa Nakamichi(Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University), MASARU ARAKIDA(Asian Disaster Reduction Center), Chairperson:Mayumi Sakamoto(兵庫県立大学大学院減災復興政策研究科), Haruhisa Nakamichi(京都大学防災研究所), Masaru Arakida(アジア防災センター)

Volcanic monitoring systems are developed and managed for the purpose to observe a specific volcanic activity in each country based on its own regulation. However, the experience of Icelandic volcano Eyjafjallajokull eruption in 2010 caused huge air traffic disturbances, and left large economic and social impact to international community. In order to reduce possible financial, environmental, health or social damages caused by trans-boundary volcanic disaster, it is important to develop international cooperative system to monitor and share the information of emission, dispersion or deposition of volcanic products. In this session, we discuss trans-boundary effect of volcanic eruption, and how to establish international collaborative mechanism from different research disciplines such as disaster management, volcanology, environmental politics or international law.

The development of the European collaborative mechanism of volcanic monitoring systems after 2010 Eyjafjallajokull eruption - from the perspective of European Union law -

*Chizu Arashima[1]

1. KOBE GAKUIN UNIVERSITY

The eruption of Icelandic volcano Eyjafjallajokull in 2010 caused huge international air traffic disturbances and left significant economic and social damages to the international society. The lesson learned from the disaster is that not only the estimates by Volcanic Ash Advisory Centre (VAAC) but also the on-going observations are needed to estimate the concentration more accurately. These observations are carried out by various volcanic observatory institutions. They play key roles in reducing/preventing possible economic, environmental, health or social damages caused by such trans-boundary volcanic disaster, by providing key scientific information and interpretation during eruption crises. To address the fragmentation of scientific data and make use of scientific information, the European collaborative mechanism of volcanic monitoring systems to share information should be established on a sufficient financial basis.
At present, European Network of Observatories and Research Infrastructures for Volcanology (EUROVOLC) is coordinated by Icelandic Meteorological Office with 16 other partners from 7 European countries. EUEOVOLC is a 3-year project from February 1 2018 and is funded by the European Commission of the European Union (EU) under “Horizon 2020” with 5 million Euros. Horizon 2020 - the Framework Programme for Research and Innovation (2014-2020) was established by REGULATION (EU) No 1291/2013. Its Article 7 provides association of third countries to Horizon 2020. Associated countries include European Free Trade Association members, including Iceland. Therefore, EUROVOLC is funded by the EU. Horizon 2020 falls under the areas of research, technological development and space where the EU has shared competence with the Member States and the EU “shall have competence to carry out activities, in particular to define and implement programmes; however, the exercise of that competence shall not result in Member States being prevented from exercising theirs” (Article 4(3) of the Treaty on the Functioning of the European Union (TFEU)).
Concerning natural disasters, the 2007 Treaty of Lisbon introduced new provisions of TFEU. They are included both in the areas of civil protection under PART THREE UNION POLICIES AND INTERNAL ACTIONS of TFEU and humanitarian aid under PART FIVE THE UNION'S EXTERNAL ACTION of TFEU. Disaster prevention is provided in the former, as Article 196(1) of TFEU provides that “(t)he Union shall encourage cooperation between Member States in order to improve the effectiveness of systems for preventing and protecting against natural or man-made disasters”. Civil protection is the area where “(t)he Union shall have competence to carry out actions to support, coordinate or supplement the actions of the Member States” (Article 6 of TFEU).
For the implementation, the Directorate-General for European Civil Protection and Humanitarian Aid Operations (ECHO) of the European Commission plays the role. Under ECHO, there is EU Civil Protection Mechanism (UCPM). It was established by DECISION No 1313/2013/EU. Iceland is a participating state of the UCPM. UCPM is not at present a forum to establish a European collaborative mechanism of volcanic monitoring systems. However, it is worthy to note that Proposal for a DECISION amending Decision No 1313/2013/EU in 2017 acknowledges that disaster prevention efforts are crucial to limit the need for crisis and emergency support. It proposes that UCPM "shall support, complement and facilitate coordination of Member States’ action" "to increase the availability and use of scientific knowledge on

©2019. Japan Geoscience Union. All Right Reserved.

disasters". It also proposes that the Commission shall "take actions to improve the knowledge base on disaster risks and facilitate the sharing of knowledge, the results of scientific research, best practices and information, including among Member States that share common risks".
At present, the European collaborative mechanism of volcanic monitoring systems is financially supported by project-based funds of Horizon 2020. However, if the Proposal is adopted and the importance of sharing scientific information in disaster prevention is recognized, more opportunity and regular financial support to develop European collaborative mechanism of volcanic monitoring systems may be given.

Preparing for volcanic disasters: Risk communication issues when dealing with international tourists.

*Ana Maria Cruz Naranjo[1], Giuseppe Aliperti[1]

1. Kyoto University Disaster Prevention Research Institute

This paper provides insights on the risk communication behavior of international tourists visiting Japan. The study builds on the premise that even if tourism-oriented risk communication has been strongly investigated, tourists' risk information seeking and processing has been under-investigated. We thus explore risk information seeking and processing of international tourists in Japan. Japan has been selected as a case study for several reasons. First, the level of exposure of the country to natural hazards, such as volcanic eruptions, tsunamis, earthquakes, and typhoons, is high. Second, due to the increasing presence of tourists in recent years, the number of people exposed to disaster-related risk in Japan has also drastically increased. In the case of a major volcanic eruption with disruption to air traffic, the provision of risk information to tourists already in Japan, as well as those preparing to travel is of critical importance. The overall aim of the study consists on providing cross-country evidence to inform risk-communication strategies and improve tourists' disaster preparedness. In order to investigate the tourists' perspective, we adopted the Risk Information Seeking and Processing (RISP) model.

Mitigation of volcanic hazard in Sakurajima, Japan, through the coordinating committee and through communication with the public

*Haruhisa Nakamichi[1]

1. Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University

The Sakurajima Volcanological Observatory, at present the Sakurajima Volcano Research Center (SVRC), was founded in 1960 as a part of the Disaster Prevention Research Institute, Kyoto University, following the request from local governments and residents of the volcanic area. The SVRC contributes to society by releasing scientific results and knowledge on volcanic hazard to the public, as well as by advising national and local governments on hazard mitigation strategies. Volcano experts are required to issue a warning when a volcanic eruption is ongoing or imminent. The SVRC evaluates volcanic activity using observational data. It communicates and interacts often with local government offices, such as the ones in Kagoshima Prefecture, Kagoshima City, Tarumizu City, local branches of ministries of the national government, the Osumi Office of Rivers and National Highways (OORNH), and the Kagoshima Local Meteorological Office (KLMO). The SVRC and these offices work in close cooperation. For example, the meeting of the Coordinating Committee for Hazard Mitigation of Sakurajima Volcano has been taking place regularly every two months since 2006. The purpose of the Coordinating Committee is to share up-to-date observational results, to cooperate and to examine special topics to respond in terms of hazard mitigation in case of volcanic eruptions of the Sakurajima. The KLMO provides information on the volcanic activity of the Sakurajima as necessary, on the basis of the continuous observation and monitoring conducted in cooperation with the SVRC, OORNH, and other relevant bodies.

The Kyoto University has research facilities located across Japan, and organizes open-doors weeks at these facilities, i.e. the “KYODAI Weeks”, every year in October and November. As a part of this event, the SVRC opens not only the observatory, but also an underground observation tunnel to the public, so that the visitors can understand the instrumentation employed to monitor volcanic phenomena. We installed a group of PC displays at the Sakurajima Visitor Center in March 2017 to show real-time seismic and ground deformation data to the general public visiting Sakurajima. In addition, we explained to “volcano guides” how to interpret these monitoring data, so that they can explain these data from the point of view of volcanology to the general public in a straightforward manner.

An experimental forecasting technique for the ash hazard from Sakurajima volcano, Japan

*Alexandros Panagiotis Poulidis[1], Tetsuya Takemi[1], Masato Iguchi[1]

1. Disaster Prevention Research Institute, Kyoto University

Introduction

The long-lasting activity from Sakurajima volcano introduces hazardous amounts of volcanic ash into the atmosphere, adversely affecting the surrounding areas (e.g. Biass *et al.* (2017), Poulidis *et al.*, (2018)), making accurate localized forecasts a necessity. Here, we present initial results from an experimental forecasting methodology carried out by the Sakurajima Volcanological Observatory (SVO), Kyoto University, focusing on three points: *(i)* high resolution (333m mesh), *(ii)* use of Eruption Source Parameters (ESPs) that are derived from geophysical signals (Iguchi, 2016) and allow for a proactive forecasting approach, and *(iii)* use of dedicated models in order to properly represent the plume structure.

Forecast Methodology

A combined modelling approach is presented: Japan Meteorological Agency (JMA) forecast data are dynamically downscaled to 333m using the Weather Research and Forecasting (WRF) model (Skamarock and Klemp, 2008), while the FALL3D volcanic ash transport and deposition (VATD) model (Folch *et al.*, 2009) is used for the introduction of the plume and dispersal modelling. A quasi-online coupling approach is used here, with WRF data output every 10mins so that the resolved variablity in the wind fields is well-represented in the ash dispersal simulations. In order to study the sensitivity of results to the timing relative to eruption, a total of 5 pseudo-forecast simulations were carried out using data up to 13 hours before the eruption.

June 16, 2018 Eruption

Sakurajima erupted at 0719 JST (JST=UTC+9), June 16 2018, with a reported plume height of 4700 m above the vent. Deposition occurred west and southwest of the volcano, reaching the southern coast of the Satsuma peninsula. Ashfall locations were reported by the JMA, while the SVO carried out a post-eruption survey to collect samples. A comparison of disdrometer observations (which measure airborne ash size) and ground deposits suggest the presence of large aggregates (e.g. Bagheri *et al.*, (2016)), a fact that needs to be accounted for in order to have successful simulations.

Forecast Simulation Results and Conclusions

Initially, a control simulation was carried out using the final mass discharge rate output. Although qualitatively similar to the JMA ash forecast, it offered two key improvements: *(i)* ash deposition over the volcano occured along a narrow path, correctly reproducing the observed pattern, and *(ii)* the observed area of maximum ashfall (>1 mm deposit thickness) was reproduced correctly at a distance from the vent, over the southwestern shore of the volcano.

Forecast time sensitivity simulations showed consistent ash dispersal patterns. Simulation results using forecast data up to 10 hours before the eruption time were qualitatively similar. Up to 4 hours before the eruption, the observation to estimate ratios for the two disdrometers were constrained to factor of 4, allowing for the proposed methodology to be confidently used in forecast timescales.

Utilization of Space Technology for Early Warning and Efficiently Response Against Transboundary Disaster

*Koji Suzuki[1]

1. Asian Disaster Reduction Center, Research Center for Urban Safety and Security Kobe University

Space-based Technology contributes DRR field via Sentinel Asia. It provides near real-time observations from space, delivered online, can be used as early warning, as well as information to guide response and post-disaster recovery planning or operations. Eight space agencies in Asia are providing satellite data to Asian countries for emergency response, mapping, evaluation, and recovery. Furthermore, Michibiki, a kinds of GPS satellite developed by Japan has avility to disseminate early warning message through the local speakers and smartphones.

Discussion -Research Framework for Trans-boudary Disaster

*Mayumi Sakamoto[1]

1. Graduate School of Disaster Resilience and Governance, University of Hyogo

Volcanic disaster occurred in one country may cause different environmental or health effect in other country. In order to mitigate direct or secondary effect caused by eruption, it is important to discuss international collaborative mechanism to share information and take necessary measures. In this session, we discuss about how to establish a research framework for trans-boudary volcanic disaster.
