previous report that thermal expansivities of the *a*- and *c*-axes are of similar magnitude, while the *b*-axis shows a much smaller thermal expansion (Brand et al. 2008). The disorder over two orientations of the SO_4 tetrahedra was observed in the present study. At room temperature, the primed and double-primed sites are about 25% and 75% occupied, respectively, which is completely consistent with the result by single-crystal neutron diffraction study (Levy and Lisensky 1978). A clear temperature dependence of the disorder over two orientations was, however, unobserved in the study. It is noteworthy that the SO_4 tetrahedral volume coordinated by primed oxygen atoms showed a pronounced temperature dependence. In the vicinity of dehydration temperature of mirabilite, it approached to that of thenardite (Na_2SO_4), which would be a trigger initiating the dehydration of mirabilite.

Elastic constants of single-crystal topaz studied via sphere-resonance method

*Kako Aradachi[1], Tohru Watanabe[1], Morihisa Hamada[2]

1. University of Toyama, 2. JAMSTEC

Transport of ocean floor sediments by plate motions might play an important role in the circulation of materials within the Earth. Imaging subducted sediments through seismological observations requires a thorough understanding of elastic properties of sediment origin hydrous minerals. Topaz is a hydrous mineral, which can be formed from subducted sediment at high pressures. We have studied elastic constants of single-crystal topaz by the sphere-resonance method.

A sphere sample (D=2.665(1) mm) was made from a topaz single-crystal (Al1.97SiO4(F1.17,OH0.82)) collected from Ouro preto, Mines Gerais, Brazil by the two-pipe method. Lattice parameters are a=4.663, b=8.835, c=8.386 A (orthorhombic). Resonant frequencies were measured at frequencies from 1.6 MHz to 3.5 MHz with different specimen-holding forces. Extrapolating to the specimen-holding force of zero, we obtained frequencies of "free" oscillation. Elastic constants were determined by comparing measured and calculated resonant frequencies. The xyz algorithm (Visscher et al., 1991) was employed to calculate resonant frequencies of the sphere sample. At an ambient temperature, C11=281.2(5), C22=350.3(7), C33=288.4(5), C44=108.8(2), C55=130.9(2), C66=131.4(2), C12=121.3(2), C13=81.6(2), C23=82.1(2) (GPa).

Verification of damage by polishing of sheet-like minerals

*Yui Kouketsu[1], Kota Ando[1], Katsuyoshi Michibayashi[1]

1. Department of Earth & Planetary Sciences, Graduate School of Environmental Studies, Nagoya University

Sheet-like minerals such as mica, serpentine, clay minerals and graphite are affected by shearing due to polishing. In addition, a damage due to electron beam irradiation during observation by the electron microscope also occurs. In this study, the damage due to polishing and irradiation of the electron beam for sheet-like minerals of graphite and serpentine minerals was evaluated by Raman spectroscopic analysis. First, we evaluated the crystallinity change of graphite in each polishing stage. As a result, a decrease in crystallinity was observed in all stages from rough polishing to fine grain polishing by diamond paste. The chemical polishing with colloidal silica also lowered the crystallinity of graphite. In order to reduce the shearing effect to graphite, we tested a low load polishing using the polisher ISPP-1000 (Ikegami Seiki Co., Ltd.) which is controlling the load by a weight. However, it was revealed that even a load of only 25g was damaged to graphite. Next we examined the polishing effect of serpentine minerals. Raman spectroscopic analysis was performed after polishing, however no spectral change at each polishing stage like graphite was detected. On the other hand, the antigorite Raman spectra after SEM-EBSD analysis showed a decrease in intensity at the depth of about 3 micrometre from the surface, suggesting that the crystal structure was damaged by electron beam irradiation. We also tried a low load polishing for serpentine minerals, and we detected an electron backscatter pattern of lizardite for the first time. In the case of pure lizardite sample, a clear Kikuchi band was confirmed. On the other hand, almost no pattern was detected for serpentine minerals (antigorite, lizardite, chrysotile) in the serpentinite samples, because of the contrast of hardness with surrounding hard minerals such as olivine. For analysis of sheet-like minerals contained in rock samples including minerals of various hardness, further improvement of the polishing method or other methods such as ion milling is needed.

Description of Zebra Rock and the pattern formation model

*Kaoru Yoshimura[1], Atsushi Toramaru[2], Mie Ichihara[3], Takaaki Noguchi[4], Toru Matsumoto[5]

1. Department of Earth and Planetary Science, Graduate School of Science, Kyushu University, 2. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, 3. Earthquake Research Institute, University of Tokyu, 4. Department of Arts and Science, Kyushu University, 5. Japan Aerospace Exploration Agency/ Institute of Space and Astronautical Science

Zebra Rock is a sedimentary rock characterized by a pattern consisting of red and whitein color, which is characteristically seen in Australia. Loughnan and Roberts (1990) conclude that the origin of the pattern is due to the diffusion process in a sediment on the basis of their study of the mineral assemblage.However, the mechanism of the specific reaction is not explained, lacking the detailed description. Our aim is to describe Zebra Rock in more detail and to develop a pattern formation model including the reaction of mineral formation.
Six samples taken from the vicinity of Lake Argyle in the East Kimberley region of Western Australia are used. We refer to the characteristic banding pattern consisting of red bands and white bands as Red and White, respectively.
We examined the mineral compositions with XRD (Mac science CuKα radiation) and SEM-EDS (FE-SEM 15 kev, OXFORD Aztec) and the occurrence of minerals with SEM (FE-SEM 15 kev) and TEM (JEM-3200FSk) for each White and Red. By using BSD images, we examined the fraction of minerals, and the characteristics of the spatial correlations between minerals and void for White and Red. As a result, we found that there are two distinctive differences in the mineral abundance and occurrence of iron oxide between White and Red. Red contains more iron oxide than White as shown by previous study. In the occurrence of iron oxide is different. The iron oxide in White takes a shape of planer sheet of polycrystal (<100 μm) which consists of hematite grains (~100 nm), whereas the iron oxides in Red are aligned in interstitial spaces between kaolinite and quartz crystals, as aggregates (<100 μm) which consists of granular hematite grains (~ μm). In addition, from the spatial distribution analysis it is found that the iron oxides concentrate near voids both in White and Red.
Integrating these results,on the basis of the idea that the formation of iron oxide plays an essential role in the formation of zebra pattern,we develop a pattern formation model using a reaction diffusion system. In our model, the pattern is defined as the variation of concentration of ferric irons. We assume the formation process ofhematite in an aqueous solution is simplified as “ferrous ion →goethite (monomers) →goethite (precipitates) →hematite”. We propose an autocatalytic reaction in which ferrous ion are adsorbed in goethite, and thereby the reaction is accelerated. As a result of the linear stability analysis for this simplest model, it is found that the equilibrium point is stable and no pattern forms. Thus, we will develop more complex reaction models to produce the zebra pattern.

Thermal conductivity anomaly of $(Mg,Fe)CO_3$ solid solution across the spin transition

*Keng-Hsien Chao[1], Wen-Pin Hsieh[1,2]

1. Institute of Earth Sciences, Academia Sinica, Taiwan, 2. Department of Geosciences, National Taiwan University, Taiwan

Deep carbon cycle is a process carrying carbon into Earth's interior by subduction of slabs and returning to Earth's surface by volcanic activities. Given the abundance of iron in Earth's interior, it is believed that $(Mg,Fe)CO_3$ solid solution is an important candidate of carbon-hosting mineral in the mantle. Prior studies have shown that the iron in the $(Mg,Fe)CO_3$ solid solution undergoes a pressure-induced spin transition at 40-55 GPa and the iron content has a minor effect on the onset pressure of spin transition. Across the spin transition, the physical properties of $(Mg,Fe)CO_3$ solid solution, e.g. sound velocity and unit cell volume, typically change accordingly. Lattice thermal conductivity of mantle minerals is key to control the heat flux and temperature profile of the mantle. However, the thermal conductivity of $(Mg,Fe)CO_3$ solid solution under relevant mantle pressure-temperature conditions remains largely unknown. Here we used Raman spectroscopy to characterize the extent of spin transition of natural $(Fe_{0.18}Mn_{0.01}Mg_{0.80}Ca_{0.01})CO_3$ ferromagnesite and time-domain thermoreflectance to measure its thermal conductivity from ambient conditions to 65 GPa. Our preliminary study shows that the thermal conductivity of $(Fe_{0.18}Mn_{0.01}Mg_{0.80}Ca_{0.01})CO_3$ ferromagnesite is 20 W m^{-1} K^{-1} at 40 GPa and drastically increases to 80 W m^{-1} K^{-1} at the beginning of spin transition, and then suddenly drops to 20 W m^{-1} K^{-1} during the middle period of spin transition, similar to its iron-rich counterpart, $(Fe_{0.78}Mg_{0.22})CO_3$ siderite, investigated in our previous work. Our results suggest that if the $(Mg,Fe)CO_3$ carbonates can be transported by the subduction slabs to 1400-1800 km depth with iron contents of 18 to 78 %, their thermal conductivity anomalies across the spin transition may induce anomalies in local thermo-chemical profiles in subduction zones, which in turn alter the distribution fields of subducting minerals.

Melting experiments in the $MgSiO_3$ –SiO_2 system under high pressures

*Takuya Moriguti[1], Akira Yoneda[1], Eiji Ito[1]

1. Institute for Planetary Materials, Okayama University

Melting of silicates played important roles in chemical differentiation in a deep magma ocean in the early Earth. Therefore, melting relations of the MgO–SiO_2 system have been extensively studied since a pioneer work by Bowen and Anderson (1914). Furthermore, chemical differentiation in the deep magma ocean has been simulated extensively based on results of high pressure melting experiments (e.g. Kato and Kumazawa, 1985; Ito and Katsura, 1992). However, almost all of these works have been carried out on the compositions ranging from MgO to $MgSiO_3$, assuming that the bulk mantle composition is peridotitic or close to that derived from CI chondrite. Recently, enstatite chondrite (E-chondrite) has been attracted as the bulk earth source material (Javoy et al., 2010) because the isotope systematics of the Earth and Moon are nearly identical to those of E-chondrite over O, N, Mo, Re, Os, and Cr. In E-chondrite, the silicate composition is characterized by SiO_2/(SiO_2+MgO) = ˜0.6, which is substantially higher than that of the peridotitic mantle (˜0.4).

In this context, understanding of the melting relations over compositions between $MgSiO_3$ and SiO_2 is indispensable to clarify the mantle fractionation. That also relates to investigations of chemical compositions of the crust at early stage of the Earth. Nevertheless, there have been very limited works on the pressure effect on melting in the $MgSiO_3$–SiO_2 system. Available information regarding phase relations in the system has been so far limited to 5 GPa (Dalton and Presnall, 1997). In this study, we are determining the melting relations in the $MgSiO_3$–SiO_2 system at pressures 5 to 20 GPa. Here we present the results obtained at 10 GPa.

Melting relations of the Fe-Ni-S-C system and the formation of superdeep diamonds

*Yu Itami[1], Satoru Urakawa[1]

1. Okayama University

Superdeep diamonds derived from the mantle transition zone or the lower mantle have been found in recent years , while most diamonds are thought to form in the upper mantle between 150 and 200 km depth. Smith et al. (2016) discovered solidified Fe-Ni-S-C melt in the inclusions of CLIPPIR diamond, which is one of the superdeep diamonds, and concluded that these diamonds have formed from the metallic liquid in the slabs subducted into the mantle transition zone. In this research, we have performed high-pressure and high-temperature quench experiments of the Fe-Ni-S-C system to investigate diamond formation in the mantle transition zone.

High-pressure and high-temperature experiments were carried out at a pressure of 15 GPa and temperatures of 900-1400 K using a Kawai-type apparatus. Diamonds can coexist with Fe-Ni-S-C melt above 1400 K at 15 GPa. Although the maximum carbon solubility in the liquid coexisting with diamond decreases to 1.5 wt.% with increasing sulfur content up to 12 wt.%, the maximum carbon solubility increases with increasing sulfur content above 12 wt.%. Taking into consideration of the carbon content in the mantle, diamonds can be crystallized from the liquid alloy by supersaturation at 15 GPa when sulfur content in the liquid ranges from 5 to 15 wt.%.

Since the temperature of the mantle transition zone at 450 km depth (15 GPa) is higher than 1400 K, diamonds can form from the Fe-Ni-S-C melt. On the other hand, the diamond cannot form within the top of subducting slab, due to its lower temperature. Thus it is considered that CLIPPIR diamonds have formed in the ancient hotter slab. Meanwhile, in the case that the mantle transition zone has a basaltic composition, it is feasible that the eclogitic diamonds such as CLIPPIR diamonds have been crystallized from liquid alloy in the mantle transition zone.

Effect of ammonia on the stability of methane hydrate under high-pressure and high-temperature

*Hirokazu Kadobayashi[1], Hisako Hirai[2], Hiroaki Ohfuji[1], Hideaki Kawamura[1], Michika Ohtake[3], Yoshitaka Yamamoto[3]

1. Geodynamics Research Center, Ehime University, 2. Department of Environment System, Faculty of Geo-environmental Science, Rissho University, 3. National Institute of Advanced Industrial Science and Technology

Methane hydrate may be present in significant amounts in the interior of Titan and other icy moons and is thought to be a candidate for a source of their atmospheric methane [e.g., Loveday *et al.* (2001); Choukroun *et al.* (2010)]. The icy mantles of these moons mainly consist of water, methane and ammonia, but the stability of methane hydrate coexisting with these components under high-pressure and high-temperature have been still unknown. In this study, we report a high-pressure and high-temperature investigation of the effect of ammonia on the stability of methane hydrate using X-ray diffraction and Raman spectroscopy combined with externally heated diamond anvil cell under 0.2-20 GPa and 298-413 K. X-ray diffraction studies revealed that methane hydrate in water-methane-ammonia system transforms from sI cage structure into sH cage structure at approximately 0.8 GPa at room temperature, and further transforms into a filled-ice Ih structure at approximately 1.8 GPa without decomposition into water ice and solid methane. These transition pressures at room temperature were same as those reported for pure methane hydrate [Hirai *et al.* (2001); Loveday *et al.* (2001); Shimizu *et al.* (2002)]. At higher temperature, the melting temperatures for the sI and sH cage structures below 1.8 GPa determined by in situ Raman spectroscopy were good agreement with those of pure methane hydrate reported by previous studies [Dyadin *et al.* (1997); Bezacier *et al.* (2014)]. On the other hand, the decomposition temperatures of filled-ice Ih above 1.8 GPa were about 10-20 K lower than those of water-methane system reported by Kadobayashi *et al.* (2018). Our results suggest that ammonia has a potential to vary the stability of filled-ice Ih of methane hydrate in the interiors of icy moons. Finally, we briefly discuss the implications of our new results for the fate of methane hydrate in concerned with a source of atmospheric methane in Titan.

Study on magnetite-maghemite-hematite transformation

*Ibuki Kinebuchi[1], Atsushi Kyono[1], Yoshinari Sano[1]

1. University of Tsukuba

Magnetite (Fe_3O_4) widely distributed in the Earth's crust changes into hematite (α-Fe_2O_3) by the oxidization of Fe^{2+} to Fe^{3+}. In the oxidization process, maghemite (γ-Fe_2O_3) with the same spinel structure as magnetite emerges as an intermediate phase. Maghemite differs from magnetite by the presence of cationic vacancies within the octahedral site. It is important to understand the oxidization mechanism of magnetite, however, the local structure change during the oxidization has been still nuclear. In the study, therefore, the phase transition mechanism from magnetite to hematite through maghemite was investigated by using, thermal analysis (TG・DTA), powder X-ray diffraction (XRD) measurement, and high-temperature ex-situ and in-situ X-ray absorption fine structure (XAFS) measurement. The TG・DTA curves of magnetite showed continuous oxidization up to 400 °C.
High-temperature ex-situ EXAFS spectrum of magnetite heated up to 250 °C exhibited weaker peaks concerning Fe_{oct}-O, Fe_{oct}-Fe_{oct}, and Fe_{tet}-Fe_{oct} than those of magnetite. In addition, the averaged Fe-O bond distance appears to become shorter. The results suggest that magnetite is continuously transformed to maghemite in the temperature range from room temperature to 400 °C. The high-temperature ex-situ EXAFS spectrum of magnetite heated up to 500 °C finally displayed characteristic peaks corresponding to hematite, suggesting that the phase transition from magnetite to hematite was completed.
High-temperature in-situ XANES spectrum indicated that the average oxidation number of Fe gradually increased for 135 min from the start of heating at 500 °C, and then became almost constant. The radial structure function obtained from the high-temperature in-situ EXAFS revealed that the peaks of Fe-O, Fe_{oct}-Fe_{oct} and Fe_{tet}-Fe_{oct} become weakened continuously until 70 min from the start of heating. After 80 min peaks corresponding to hematite began to increase. It can be concluded from these results that the phase transition from magnetite to hematite through maghemite starts from the diffusion of the Fe^{2+} in the octahedral sites, resulting in the formations of cationic vacancies and amorphous phase concentrating Fe^{2+}. Subsequently, the reconstruction of the octahedral coordination of Fe and additional oxidization of the amorphous phase lead to the crystallization into hematite.

The Effects of Temperature and Pressure on Hydromagnesite

*Gen-ichiro Yamamoto[1], Atsushi Kyono[1], Jun Abe[2], Takanori Hattori[3], Yoshitaka Matsushita[4], Yasuhiro Yoneda[3]

1. University of Tsukuba, 2. CROSS, 3. JAEA, 4. NIMS

In recent years, the global warming is the most important environment problem. Therefore, attempts of CO_2 geological storage have been made to reduce carbon dioxide in the atmosphere all over the world (Xue and Nakano 2008). Among some CO_2 geological storage methods, the CO_2 mineral trapping can store the carbon dioxide safety for a long time. In the case of geological storage, magnesium carbonate hydrates are important minerals since they precipitate easily from water saturated with carbon dioxide. The major magnesium carbonate hydrates formed from aqueous solution are nesquehonite $MgCO_3 \cdot 3H_2O$ and hydromagnesite $Mg_5(CO_3)_4(OH)_2 \cdot 4H_2O$. The stability of these minerals are critically important factors to assess environmental safety and phase stability over geological time scale, but they have not been fully investigated yet, especially of hydromagnesite. Here, we investigated the effects of pressure and temperature on hydromagnesite by using thermal analysis, high-temperature X-ray diffraction, X-ray total scattering, high-pressure X-ray diffraction, and high-pressure and high-temperature neutron diffraction techniques.

With temperature, hydromagnesite was decomposed into periclase MgO through the poor crystalline phase, accompanied with dehydration, dihydroxylation, and decarbonation of hydromagnesite. The *a* and *c* lattice parameters were monotonously increased as increasing temperature whereas *b* lattice parameter almost remained unchanged. At just before the dehydration reaction, the unit cell was contracted due to the dehydration. With pressure, hydromagnesite structure was maintained up to 8.7 GPa. Decomposition into magnesite $MgCO_3$ or periclase was unobserved up to at least 21.0 GPa. With compression, the unit cell was isotopically contracted. The fit to the Birch-Murnaghan equation of state gives $K_0 = 32(2)$ and $V_0 = 658(4)$ with $K' = 4.0$ (fixed). Under high-pressure and high-temperature conditions, hydromagnesite broke down into magnesite and brucite $Mg(OH)_2$ at 200 $^{\circ}C$ and 1.2 GPa. The unit cell was isotopically expanded up to just before the breakdown. The breakdown of hydromagnesite could be caused by the dissolution by dehydration water, and subsequently magnesite and brucite were hydrothermally grown from the solution at the condition. The results obtained from this study would provide insight the CO_2 geological storage.

Synthesis and crystal structure of Mg-bearing Fe_9O_{11}: New insight in the complexity of Fe-Mg oxides at conditions of the deep upper mantle

*Takayuki Ishii[1], Uenver-Thiele Laura[2], Alan B Woodland[2], Edith Alig[3], Tiziana Boffa Ballaran[1]

1. Bavarian Research Institute, University of Bayreuth, 2. Institut für Geowissenschaften, Goethe-Universität Frankfurt, 3. Institut für Anorganische und Analytische Chemie, Goethe-Universität Frankfurt

The Fe-O system is fundamental for understanding redox processes operating in the Earth's interior. Recent experimental studies have revealed several new mixed-valence Fe-oxides to be stable at high pressures and temperatures, such as the orthorhombic-structured phases $Fe^{2+}_2Fe^{3+}_2O_5$ and $Fe^{2+}_3Fe^{3+}_2O_6$. and the monoclinic-structured $Fe^{2+}_3Fe^{3+}_4O_9$. It has been also demonstrated that Fe_4O_5 and Fe_7O_9 form solid solutions with the Mg-endmembers such as $Mg_2Fe_2O_5$ and $Mg_3Fe_4O_9$, suggesting possible existence of complicated Mg-Fe oxides in the deep mantle. We synthesized a new Mg-Fe oxide with a composition of $Mg_{0.9}Fe_{8.1}O_{11}$. We report the synthesis and crystal structure analyzed by the Rietveld method.

A novel Mg-bearing iron oxide $Mg_{0.87(1)}Fe^{2+}_{4.13(1)}Fe^{3+}_4O_{11}$ was synthesized at 12 GPa and 1300 ˚C using a large volume press. Rietveld structural analysis was conducted with a laboratory X-ray diffraction pattern obtained at ambient conditions.
The crystal structure, which has one oxygen trigonal prism site and four octahedral sites for the cations, was found to be isostructural with $Ca_2Fe_7O_{11}$. The unit-cell lattice parameters are a = 9.8441(5) Å, b = 2.8920(1) Å, c = 14.1760(6) Å, β = 99.956(4)˚, V = 397.50(3) Å, and Z = 2 (monoclinic, $C2/m$). Mg and Fe cations are disordered on the trigonal prism site and on two of the four octahedral sites, and the remaining Fe is accommodated at the other two octahedral sites. The present structure is closely related to the other recently discovered Fe oxide structures, e.g. Fe_4O_5 and Fe_5O_6, by distortion derived either from incorporation (Fe_4O_5) or removal (Fe_5O_6) of an edge-shared FeO_6 single octahedral chain in their structures. The present synthesis at deep upper mantle conditions and the structural relationships observed between various novel Mg-Fe oxides indicate that a series of different phases become stable above 10 GPa and that their relative stabilities (Fe^{2+}/Fe^{3+}) must be controlled by oxygen fugacity.

Changes in specific surface area and morphology of kaolin group minerals with pressure treatment

*Soyeon Kwon[1], Yongjae Lee[1]

1. YONSEI University

Pressure can tailor the properties of a material by changing its atomistic arrangements and/or crystal morphology. We have investigated the changes in the adsorption properties of kaolin group minerals as a function of pressure treatment in gigapascal range. External pressure has been applied using a Large Volume Press (LVP) to kaolinite ($Al_2Si_2O_5(OH)_4$) and halloysite ($H_4Al_2O_9Si_2{\cdot}2H_2O$), which represent natural 2D layered and 1D nanowire structures, respectively. Powdered samples have been compressed up to 3 GPa in 1 GPa steps at room temperature and recovered by up to ~0.35g from each pressure step. The BET (Brunauer, Emmett, Teller) measurement was conducted using N_2 gas to measure the specific surface area, pore size distribution, and pore volume of the pressure-treated samples. Before pressure-treatment, the specific surface area of kaolinite has been measured to be 10.702(m^2g^{-1}), which increases to 12.090(m^2g^{-1}) after 1 GPa, 17.101(m^2g^{-1}) after 2 GPa, and 17.864(m^2g^{-1}) after 3 GPa treatments. These lead to a gradual increase in the total volume of adsorbed pores from 0.01216 (cm^3g^{-1}) at ambient, to 0.01368(cm^3g^{-1}) after 1 GPa, 0.074337(cm^3g^{-1}) after 2 GPa, and 0.09546(cm^3g^{-1}) after 3 GPa treatments. Unlike Kaolinite, the specific surface area of halloysite decreases from 47.476($m2g^{-1}$) from ambient to 44.348(m^2g^{-1}) after 1 GPa, 41.579(m^2g^{-1}) after 2 GPa, and 42.796(m^2g^{-1}) after 3 GPa treatment, which results in overall decrease in the total volume of the pore from 0.1914(cm^3g^{-1}) at ambient to 0.1863(cm^3g^{-1}) after 1 GPa, 0.1572(cm^3g^{-1}) after 2 GPa, and 0.1187(cm^3g^{-1}) after 3 GPa treatments.
We discuss the contrasting effects of pressure-treatment on the two morphologically-distinct kaolin group minerals based on SEM (Scanning Electron Microscope) images and analyses of selected diffraction peaks measured on each recovered material. We observe that the layers in kaolinite separate into smaller units upon increasing pressure treatment, whereas the tubes in halloysite become flattened, which led to the contrasting changes in surface area and pore volume. Further study is in progress to compare these results to when water is used as a pore-penetrating pressure-transmitting medium.

Changes in specific surface area and morphology of kaolin group minerals with pressure treatment

Soyeon Kwon, Yongjae Lee*

Department of Earth System Sciences, Yonsei University

yongjaelee@yonsei.ac.kr

ABSTRACT

Pressure can tailor the properties of a material by changing its atomistic arrangements and/or crystal morphology. We have investigated the changes in the adsorption properties of kaolin group minerals as a function of pressure treatment in gigapascal range. External pressure has been applied using a Large Volume Press (LVP) to kaolinite ($Al_2Si_2O_5(OH)_4$) and halloysite ($H_4Al_2O_9Si_2 \cdot 2H_2O$), which represent natural 2D layered and 1D nanowire structures, respectively. Powdered samples have been compressed up to 3 GPa in 1 GPa steps at room temperature and recovered by up to ~0.35g from each pressure step. The BET (Brunauer, Emmett, Teller) measurement was conducted using N_2 gas to measure the specific surface area, pore size distribution, and pore volume of the pressure-treated samples. Before pressure-treatment, the specific surface area of kaolinite has been measured to be 10.702(m^2g^{-1}), which increases to 12.090(m^2g^{-1}) after 1 GPa, 17.101(m^2g^{-1}) after 2 GPa, and 17.864(m^2g^{-1}) after 3 GPa treatments. These lead to a gradual increase in the total volume of adsorbed pores from 0.01216 (cm^3g^{-1}) at ambient, to 0.01368(cm^3g^{-1}) after 1 GPa, 0.074337(cm^3g^{-1}) after 2 GPa, and 0.09546(cm^3g^{-1}) after 3 GPa treatments. Unlike Kaolinite, the specific surface area of halloysite decreases from 47.476(m2g^{-1}) from ambient to 44.348(m^2g^{-1}) after 1 GPa, 41.579(m^2g^{-1}) after 2 GPa, and 42.796(m^2g^{-1}) after 3 GPa treatment, which results in overall decrease in the total volume of the pore from 0.1914(cm^3g^{-1}) at ambient to 0.1863(cm^3g^{-1}) after 1 GPa, 0.1572(cm^3g^{-1}) after 2 GPa, and 0.1187(cm^3g^{-1}) after 3 GPa treatments.

We discuss the contrasting effects of pressure-treatment on the two morphologically-distinct kaolin group minerals based on SEM (Scanning Electron Microscope) images and analyses of selected diffraction peaks measured on each recovered material. We observe that the layers in kaolinite separate into smaller units upon increasing pressure treatment, whereas the tubes in halloysite become flattened, which led to the contrasting changes in surface area and pore volume. Further study is in progress to compare these results to when water is used as a pore-penetrating pressure-transmitting medium.

Raman spectroscopy of seifertite

*Masahiro KAYAMA[1], Eiji Ohtani[1], Masaaki Miyahara[2], Shohei Kaneko[1], Toshimori Sekine[3], Shin Ozawa[1], Naohisa Hirao[4]

1. Tohoku University, 2. Hiroshima University, 3. HPSTAR, 4. Japan Synchrotron Radiation Research Institute

Seifertite is one of the SiO_2 polymorphs and is a high pressure phase with an α-PbO_2 structure. It is known to lie in lunar and martian meteorites and constrains shock pressure and duration of an impact event that these meteorites have experienced on the host bodies. Seifertite is thermodynamically stable at more than ~100 GPa, which is not realistic for an impact event on the Moon and Mars. However, it can be transformed as a metastable phase from cristobalite at least ~11 GPa and 0.01 s, and can consequently be quenched down to an ambient condition. As a result of this process, seifertite remains present in some of the lunar and martian meteorites. The estimated shock pressure and duration provide valuable information on the size of the crater and impactor that collided don the host bodies. Although Raman spectroscopy has been previously measured for seifertite in meteorites, it was not successful to obtain the seifertite signature because of a potential vitrification or transition into other SiO_2 phase by heating due to the laser irradiation. Therefore, only synchrotron-XRD and TEM analyses allow us to determine the structure, where silica grains are excavated with a focused ion beam (FIB) system from meteorite. Here, Raman spectral signatures of seifertite has been obtained from synthetic and meteoritic silica grains, implying its identification with high-spatial resolution as nondestructive analysis.

Seifertite in silica grains of synthetic samples and lunar (NWA 4734) and martian meteorites (Zagami, NWA 2975) were identifications by a synchrotron XRD analysis at Spring-8 BL-10 and were employed for Raman spectroscopy. Seifertite were synthetized from synthetic cristobalite powders using multi-anvil press at 16 GPa, 673 K and 0.5 hour. Raman spectroscopy were performed for synthetic and meteoritic silica grains using Nd: YAG 532 nm at 20 mW for 3 minutes exposure time.
Raman spectra of synthetic seifertite have pronounced peaks at 380, 515, 564, 739 and 796 cm^{-1} and weak peaks at 401, 496, 539, 547, 606 and 749 cm^{-1}. Similar Raman signature was obtained from seifertite in lunar and martian meteorites. These Raman shifts and relative intensities are well corresponding to the values calculated within the density-functional perturbation theory for seifertite. Based on the calculation, thee Raman peaks at 380, 515, 564, and 796 cm^{-1} are assigned to Ag, those at 401, 496, and 539 cm^{-1} to B1g, 606 and 749 cm^{-1} to B2g, and 547 and 739 cm^{-1} to B3g modes. After laser beam irradiation for 30 minutes, the distinct Raman signature can be detected from synthetic and meteoritic seifertite. Therefore, Raman spectroscopy enables determination of the structure and identification of SiO2 polymorphs with high-spatial resolution and without destruction.

Microtexture and crystallization process of impact diamonds

*Hiroaki Ohfuji[1], Motosuke Nakaya[1]

1. Geodynamics Research Center, Ehime University

Impact diamonds from the Popigai crater located in the central Siberia, Russia show unique nano-polycrystalline texture composed of diamond and a small amount of lonsdaleite of ~50 nm (Ohfuji et al., 2015), which is well comparable to the nano-polycrystalline diamond synthesized by direct conversion of graphite under high pressure and high temperature (Irifune et al., 2003). However, subsequent studies noted that they show a variety of microtexture such as lamellar or layer textures and granular textures. In the present study, we investigated the mineralogical and crystallographic characteristics of the various microtextures shown by the Popigai diamonds by TEM.

The microtextures found in Popigai diamonds are divided into two types, 1) lamellar type and 2) granular type. The former is further classified into two types, 1a) less-mosaiced lamellar and 1b) mosaiced lamellar. The latter can also be divided further into 2a) granular texture composed of fine crystals of <50 nm and 2b) granular texture composed of larger (~100 nm) crystals. Careful textural observations and electron diffraction analysis revealed that the microtextures of Popigai diamonds vary from layered texture to granular texture (1a →1b →2a →2b) as the phase transitions from graphite to lonsdaleite to diamond proceed. The phase transition mechanism also changes from martensitic process involving a lattice relationship (Graphite (001) // Lonsdaleite (100) // Diamond (111)) to diffusion process where the nucleation of new grains and the their growth are promoted.

The most important factor controlling the degree of the phase transitions and the resulting microtexture is probably the shock temperature, which is supposed to have decreased gradually from the center to rim in the crater.

Metamorphic temperature analysis of H chondrites: Using revised Lindsley's pyroxene thermometer

*Ryo Uehara[1], Yoshihiro Kuwahara[1], Kazuhiko Shimada[1], Yoshihiro Nakamuta[1], Seiichiro Uehara[1], Tatsuro Adachi[1]

1. Kyushu university

1. Introduction
The thermal evolution models of asteroids have been proposed and discussed by many researchers to provide insight into the internal structure and thermal history of those (e.g., Wood,1979; Miyamoto et al., 1981; Yomogida and Matsui, 1984; McSween et al., 2002). As important parameters for the thermal evolution models, the highest peak temperatures, ages, and cooling rates of meteorite parent bodies are mentioned (McSween et al., 2002). The peak temperature inside the parent body has been estimated using various thermometers (Olsen and Bunch, 1984; Nakamuta and Motomura, 1999; Kessel et al., 2002; Slater-Reynolds and McSween, 2005). Pyroxene thermometer by Lindsley (1983) has been widely used because it allows us to derive temperatures from both orthopyroxene (Opx) and clinopyroxene (Cpx) in a meteorite. However, the temperatures determined from clinopyroxenes, especially for type 6 chondrites, are systematically 50˚C to 150˚C higher than those from orthopyroxenes (Nakamuta et al., 2017). The Lindsley’s pyroxene thermometer is made empirically for terrestrial rocks and therefore the kosmochlor component is not considered in the calculation. So, Nakamuta et al. (2017) proposed the revised Lindsley’s pyroxene thermometer in which the kosmochlor pyroxene component is added to evaluate the effect of the component on the thermometry. They also showed that the difference in temperature between clinopyroxene and orthopyroxene in LL chondrites using the revised thermometer was less than 20˚C.
In this study, we have attempted to estimate the metamorphic temperatures of H chondrites (type 4 to 7) using the Lindsley’s pyroxene thermometer revised by Nakamuta et al (2017). Here we report the results of the estimation.
2. Samples and method
The chondrite samples used were four types of H chondrite with different metamorphic degrees; Edmondson(b) (H4), Faucett (H5), Faith (H5), Plainview (H5), Mulga(north) (H6), Great Bend (H6) and NWA7875 (H7). Polished thin sections of the seven H chondrites were prepared and observed using transmitted and reflecting light microscopes. Then, chemical compositions of pyroxenes, olivines, and plagioclases in the seven H chondrites were analyzed by an EPMA, JEOL JXA-8530F. Beased on these results, the classification of each meteorite sample was reconfirmed, and metamorphism temperatures estimated using the revised Lindsley pyroxene thermometer.
3. Results and discussion
From results of the texture observation and chemical analysis of the chondrite sample, we reconfirmed that there is no mistake in classification of each meteorites (H4, H5, H6, H7). The temperatures for Edmondson(b) (H4), Faucett (H5), Faith (H5), Plainview (H5), Mulga(north) (H6), Great Bend (H6) and NWA7875 (H7) are 779-1236˚C (Opx-Cpx), 814-875˚C, 832-843˚C, 844-838˚C, 807-797˚C, 811-818˚C and 1183-1247˚C, respectively, using the revised Lindsley pyroxene thermometer. Most of H5 and H6 meteorite samples showed that the difference in temperature between Opx and Cpx was less than 20˚C. This result, this suggests that the revised Lindsley pyroxene thermometer by Nakamuta et al. (2017) is also effective for H chondrite. The metamorphic temperatures of the H5 type chondrite (Faucett, Faith and Plainview) and the H6 type chondrite (Mulga(north), Great Bend) are approximately 840˚C and 810˚C, respectively, while the H4 type Edmondson(b) chondrite is less than 780˚C judging from the temperature

©2019. Japan Geoscience Union. All Right Reserved.

estimated from Opx. Regarding the H7 type NWA7875 chondrite which showed the highest metamorphic temperature and lamella structure in some Cpx crystals, the H7 material that existed already in H5 and/or H6 conditions may have experienced impact metamorphism, redrawing the previous metamorphic temperature and the H5 and/or H6 conditions.
Comparing these estimated temperature data with the results of the model simulation reported by Monnereau et al. (2013), it is estimated that the H chondrite meteorite parent body had an onion shell type internal thermal structure formed when the accumulation period was short (<0.2 Myr).

The occurrence combinations of Zeolites at Chichijima, Ogasawara Islands

Michiharu Ito[1], *Yuki Inoue[1], Mana Yasui[2], Atsushi Yamazaki[2], Hiroshi Hagiya[1]

1. Tokyo City University, 2. Waseda research institute for science and engineering

The Ogasawara Islands are located in the Pacific Ocean about 1000 km south of Tokyo, Japan. These Islands are situated in the outer of the Izu-Bonin-Mariana Arc. The Ogasawara Islands are composed by paleogene submarine volcanic formation, and is well known by andesitic volcanic rock called boninite. Boninite is a feldspar-free and glass-rich olivine-bronzite andesite with higher MgO, SiO_2, H_2O and Cr contents. Zeolites, co-exist with calcite, quartz/chalcedony and celadonite, fill the vesicles of volcanic gas, radial and columnar cooling joint of pillow lava, and also occur in interpillow sediment with large aggregate of crystals.

In this study, various habits of zeolites at Chichijima, Ogasawara Islands are obtained, also more than two-step growth of zeolites in amygdale were confirmed. Between these two-step growth, cation ratio have changed at the border of two faces.

These cation's contents are similar to neighboring rock. It is considered that there is another hydrothermal activity after the first-step growth.

Keywords: Zeolite, boninite, hydrothermal activity, occurrence combinations

Title: Single-crystal X-ray diffraction study of mirabilite ($Na_2SO_4 \cdot 10H_2O$) from 213 to 303 K

*Ryutaro Ikeda[1]

1. University of tsukuba

Introduction

Renewable energy is of increasing importance in modern society due to its low environmental impact, ubiquity and sustainability. Since some renewable energy resources (e.g. sunlight, wind and tides) have variable outputs, storage technologies have great potential for affording the supply from these resources. In recent years, much attention has been paid to phase change materials (PCMs) due to its high energy storage capacity. PCMs are substances with a heat of fusion which can store and releasing large amounts of energy. Mirabilite ($Na_2SO_4 \cdot 10H_2O$) is known as one of the PCMs. With increasing temperature, mirabilite transforms to thenardite (Na_2SO_4) at a dehydration temperature of 306 K. On the contrary, thenardite is rehydrated back to mirabilite at 283 K. The reversible reaction involves large exothermic and endothermic heats. To date, however, there is little information on temperature dependence of crystal structure in mirabilite. The structure of mirabilite contains ribbons consisting of edge-sharing $Na(H_2O)_6$ octahedra along the *c*-axis. These ribbons alternate with chains of the SO_4 tetrahedra and the two H_2O molecules. Levy and Lisensky (1978) identified disorder over two orientations of the SO_4 tetrahedra by single-crystal neutron diffraction measurement at room temperature. The characteristic two orientations, related by a rotation of about 30° about the S×××O5 vector, generate pairs of partially occupied sulfate oxygen sites (O4’/O4’’, O6’/O6’’, and O7’/O7’’). Levy and Lisensky (1978) found that the primed sites are about 25% occupied, and the double-primed sites are about 75% occupied. Recently, Brand et al. (2008) performed powder neutron diffraction measurements on mirabilite ($Na_2SO_4 \cdot 10D_2O$) in the temperature range from 10 to 300 K. They reported that the unit cell of mirabilite is isotopically expanded up to 300 K. The authors however couldn’t observe the two orientations for the SO_4 tetrahedra in the structure, which was previously identified by Levy and Lisensky (1978). In the study, we performed temperature-dependent single-crystal X-ray diffraction measurement of mirabilite in the temperature range between 213 and 303 K. Here, we report the crystal structure change of mirabilite associated with the characteristic exothermic and endothermic heats.

Methods

Single crystals of mirabilite were obtained by slow cooling of a saturated solution of Na_2SO_4. After the synthesis, a single crystal was stored in a 0.7 mm Lindemann glass capillary to avoid dehydration. Temperature dependent single-crystal X-ray diffraction study on mirabilite was performed using a single-crystal diffractometer (APEXII ULTRA, Bruker AXS Inc., Germany) equipped with a liquid nitrogen cryostat, a CCD detector, multilayer optics, and graphite monochromated Mo$K\alpha$ radiation (λ = 0.71073 Å) generated by a rotating anode. The measurements were conducted at temperature ranges between 213 and 303 K with 10 K step in both heating and cooling processes.

Results and Discussion

The *a* and *c* lattice parameters and unit cell volume were monotonously changed with temperature, whereas the *b* lattice parameter remained almost unchanged. The result is entirely consistent with the

©2019. Japan Geoscience Union. All Right Reserved.

previous report that thermal expansivities of the *a*- and *c*-axes are of similar magnitude, while the *b*-axis shows a much smaller thermal expansion (Brand et al. 2008). The disorder over two orientations of the SO_4 tetrahedra was observed in the present study. At room temperature, the primed and double-primed sites are about 25% and 75% occupied, respectively, which is completely consistent with the result by single-crystal neutron diffraction study (Levy and Lisensky 1978). A clear temperature dependence of the disorder over two orientations was, however, unobserved in the study. It is noteworthy that the SO_4 tetrahedral volume coordinated by primed oxygen atoms showed a pronounced temperature dependence. In the vicinity of dehydration temperature of mirabilite, it approached to that of thenardite (Na_2SO_4), which would be a trigger initiating the dehydration of mirabilite.

Elastic constants of single-crystal topaz studied via sphere-resonance method

*Kako Aradachi[1], Tohru Watanabe[1], Morihisa Hamada[2]

1. University of Toyama, 2. JAMSTEC

Transport of ocean floor sediments by plate motions might play an important role in the circulation of materials within the Earth. Imaging subducted sediments through seismological observations requires a thorough understanding of elastic properties of sediment origin hydrous minerals. Topaz is a hydrous mineral, which can be formed from subducted sediment at high pressures. We have studied elastic constants of single-crystal topaz by the sphere-resonance method.

A sphere sample (D=2.665(1) mm) was made from a topaz single-crystal (Al1.97SiO4(F1.17,OH0.82)) collected from Ouro preto, Mines Gerais, Brazil by the two-pipe method. Lattice parameters are a=4.663, b=8.835, c=8.386 A (orthorhombic). Resonant frequencies were measured at frequencies from 1.6 MHz to 3.5 MHz with different specimen-holding forces. Extrapolating to the specimen-holding force of zero, we obtained frequencies of "free" oscillation. Elastic constants were determined by comparing measured and calculated resonant frequencies. The xyz algorithm (Visscher et al., 1991) was employed to calculate resonant frequencies of the sphere sample. At an ambient temperature, C11=281.2(5), C22=350.3(7), C33=288.4(5), C44=108.8(2), C55=130.9(2), C66=131.4(2), C12=121.3(2), C13=81.6(2), C23=82.1(2) (GPa).

Verification of damage by polishing of sheet-like minerals

*Yui Kouketsu[1], Kota Ando[1], Katsuyoshi Michibayashi[1]

1. Department of Earth & Planetary Sciences, Graduate School of Environmental Studies, Nagoya University

Sheet-like minerals such as mica, serpentine, clay minerals and graphite are affected by shearing due to polishing. In addition, a damage due to electron beam irradiation during observation by the electron microscope also occurs. In this study, the damage due to polishing and irradiation of the electron beam for sheet-like minerals of graphite and serpentine minerals was evaluated by Raman spectroscopic analysis. First, we evaluated the crystallinity change of graphite in each polishing stage. As a result, a decrease in crystallinity was observed in all stages from rough polishing to fine grain polishing by diamond paste. The chemical polishing with colloidal silica also lowered the crystallinity of graphite. In order to reduce the shearing effect to graphite, we tested a low load polishing using the polisher ISPP-1000 (Ikegami Seiki Co., Ltd.) which is controlling the load by a weight. However, it was revealed that even a load of only 25g was damaged to graphite. Next we examined the polishing effect of serpentine minerals. Raman spectroscopic analysis was performed after polishing, however no spectral change at each polishing stage like graphite was detected. On the other hand, the antigorite Raman spectra after SEM-EBSD analysis showed a decrease in intensity at the depth of about 3 micrometre from the surface, suggesting that the crystal structure was damaged by electron beam irradiation. We also tried a low load polishing for serpentine minerals, and we detected an electron backscatter pattern of lizardite for the first time. In the case of pure lizardite sample, a clear Kikuchi band was confirmed. On the other hand, almost no pattern was detected for serpentine minerals (antigorite, lizardite, chrysotile) in the serpentinite samples, because of the contrast of hardness with surrounding hard minerals such as olivine. For analysis of sheet-like minerals contained in rock samples including minerals of various hardness, further improvement of the polishing method or other methods such as ion milling is needed.

Keywords: graphite, antigorite, lizardite, low load polish, Raman spectroscopy, EBSD

Description of Zebra Rock and the pattern formation model

*Kaoru Yoshimura[1], Atsushi Toramaru[2], Mie Ichihara[3], Takaaki Noguchi[4], Toru Matsumoto[5]

1. Department of Earth and Planetary Science, Graduate School of Science, Kyushu University, 2. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, 3. Earthquake Research Institute, University of Tokyu, 4. Department of Arts and Science, Kyushu University, 5. Japan Aerospace Exploration Agency/ Institute of Space and Astronautical Science

Zebra Rock is a sedimentary rock characterized by a pattern consisting of red and whitein color, which is characteristically seen in Australia. Loughnan and Roberts (1990) conclude that the origin of the pattern is due to the diffusion process in a sediment on the basis of their study of the mineral assemblage.However, the mechanism of the specific reaction is not explained, lacking the detailed description. Our aim is to describe Zebra Rock in more detail and to develop a pattern formation model including the reaction of mineral formation.
Six samples taken from the vicinity of Lake Argyle in the East Kimberley region of Western Australia are used. We refer to the characteristic banding pattern consisting of red bands and white bands as Red and White, respectively.
We examined the mineral compositions with XRD (Mac science CuKα radiation) and SEM-EDS (FE-SEM 15 kev, OXFORD Aztec) and the occurrence of minerals with SEM (FE-SEM 15 kev) and TEM (JEM-3200FSk) for each White and Red. By using BSD images, we examined the fraction of minerals, and the characteristics of the spatial correlations between minerals and void for White and Red. As a result, we found that there are two distinctive differences in the mineral abundance and occurrence of iron oxide between White and Red. Red contains more iron oxide than White as shown by previous study. In the occurrence of iron oxide is different. The iron oxide in White takes a shape of planer sheet of polycrystal (<100 μm) which consists of hematite grains (~100 nm), whereas the iron oxides in Red are aligned in interstitial spaces between kaolinite and quartz crystals, as aggregates (<100 μm) which consists of granular hematite grains (~ μm). In addition, from the spatial distribution analysis it is found that the iron oxides concentrate near voids both in White and Red.
Integrating these results,on the basis of the idea that the formation of iron oxide plays an essential role in the formation of zebra pattern,we develop a pattern formation model using a reaction diffusion system. In our model, the pattern is defined as the variation of concentration of ferric irons. We assume the formation process ofhematite in an aqueous solution is simplified as “ferrous ion →goethite (monomers) →goethite (precipitates) →hematite”. We propose an autocatalytic reaction in which ferrous ion are adsorbed in goethite, and thereby the reaction is accelerated. As a result of the linear stability analysis for this simplest model, it is found that the equilibrium point is stable and no pattern forms. Thus, we will develop more complex reaction models to produce the zebra pattern.

Keywords: Zebra Rock, pattern formation, reaction diffusion system

Thermal conductivity anomaly of $(Mg,Fe)CO_3$ solid solution across the spin transition

*Keng-Hsien Chao[1], Wen-Pin Hsieh[1,2]

1. Institute of Earth Sciences, Academia Sinica, Taiwan, 2. Department of Geosciences, National Taiwan University, Taiwan

Deep carbon cycle is a process carrying carbon into Earth's interior by subduction of slabs and returning to Earth's surface by volcanic activities. Given the abundance of iron in Earth's interior, it is believed that $(Mg,Fe)CO_3$ solid solution is an important candidate of carbon-hosting mineral in the mantle. Prior studies have shown that the iron in the $(Mg,Fe)CO_3$ solid solution undergoes a pressure-induced spin transition at 40-55 GPa and the iron content has a minor effect on the onset pressure of spin transition. Across the spin transition, the physical properties of $(Mg,Fe)CO_3$ solid solution, e.g. sound velocity and unit cell volume, typically change accordingly. Lattice thermal conductivity of mantle minerals is key to control the heat flux and temperature profile of the mantle. However, the thermal conductivity of $(Mg,Fe)CO_3$ solid solution under relevant mantle pressure-temperature conditions remains largely unknown. Here we used Raman spectroscopy to characterize the extent of spin transition of natural $(Fe_{0.18}Mn_{0.01}Mg_{0.80}Ca_{0.01})CO_3$ ferromagnesite and time-domain thermoreflectance to measure its thermal conductivity from ambient conditions to 65 GPa. Our preliminary study shows that the thermal conductivity of $(Fe_{0.18}Mn_{0.01}Mg_{0.80}Ca_{0.01})CO_3$ ferromagnesite is 20 W m^{-1} K^{-1} at 40 GPa and drastically increases to 80 W m^{-1} K^{-1} at the beginning of spin transition, and then suddenly drops to 20 W m^{-1} K^{-1} during the middle period of spin transition, similar to its iron-rich counterpart, $(Fe_{0.78}Mg_{0.22})CO_3$ siderite, investigated in our previous work. Our results suggest that if the $(Mg,Fe)CO_3$ carbonates can be transported by the subduction slabs to 1400-1800 km depth with iron contents of 18 to 78 %, their thermal conductivity anomalies across the spin transition may induce anomalies in local thermo-chemical profiles in subduction zones, which in turn alter the distribution fields of subducting minerals.

Melting experiments in the $MgSiO_3$ –SiO_2 system under high pressures

*Takuya Moriguti[1], Akira Yoneda[1], Eiji Ito[1]

1. Institute for Planetary Materials, Okayama University

Melting of silicates played important roles in chemical differentiation in a deep magma ocean in the early Earth. Therefore, melting relations of the MgO–SiO_2 system have been extensively studied since a pioneer work by Bowen and Anderson (1914). Furthermore, chemical differentiation in the deep magma ocean has been simulated extensively based on results of high pressure melting experiments (e.g. Kato and Kumazawa, 1985; Ito and Katsura, 1992). However, almost all of these works have been carried out on the compositions ranging from MgO to $MgSiO_3$, assuming that the bulk mantle composition is peridotitic or close to that derived from CI chondrite. Recently, enstatite chondrite (E-chondrite) has been attracted as the bulk earth source material (Javoy et al., 2010) because the isotope systematics of the Earth and Moon are nearly identical to those of E-chondrite over O, N, Mo, Re, Os, and Cr. In E-chondrite, the silicate composition is characterized by SiO_2/(SiO_2+MgO) = ˜0.6, which is substantially higher than that of the peridotitic mantle (˜0.4).

In this context, understanding of the melting relations over compositions between $MgSiO_3$ and SiO_2 is indispensable to clarify the mantle fractionation. That also relates to investigations of chemical compositions of the crust at early stage of the Earth. Nevertheless, there have been very limited works on the pressure effect on melting in the $MgSiO_3$–SiO_2 system. Available information regarding phase relations in the system has been so far limited to 5 GPa (Dalton and Presnall, 1997). In this study, we are determining the melting relations in the $MgSiO_3$–SiO_2 system at pressures 5 to 20 GPa. Here we present the results obtained at 10 GPa.

Melting relations of the Fe-Ni-S-C system and the formation of superdeep diamonds

*Yu Itami[1], Satoru Urakawa[1]

1. Okayama University

Superdeep diamonds derived from the mantle transition zone or the lower mantle have been found in recent years , while most diamonds are thought to form in the upper mantle between 150 and 200 km depth. Smith et al. (2016) discovered solidified Fe-Ni-S-C melt in the inclusions of CLIPPIR diamond, which is one of the superdeep diamonds, and concluded that these diamonds have formed from the metallic liquid in the slabs subducted into the mantle transition zone. In this research, we have performed high-pressure and high-temperature quench experiments of the Fe-Ni-S-C system to investigate diamond formation in the mantle transition zone.

High-pressure and high-temperature experiments were carried out at a pressure of 15 GPa and temperatures of 900-1400 K using a Kawai-type apparatus. Diamonds can coexist with Fe-Ni-S-C melt above 1400 K at 15 GPa. Although the maximum carbon solubility in the liquid coexisting with diamond decreases to 1.5 wt.% with increasing sulfur content up to 12 wt.%, the maximum carbon solubility increases with increasing sulfur content above 12 wt.%. Taking into consideration of the carbon content in the mantle, diamonds can be crystallized from the liquid alloy by supersaturation at 15 GPa when sulfur content in the liquid ranges from 5 to 15 wt.%.

Since the temperature of the mantle transition zone at 450 km depth (15 GPa) is higher than 1400 K, diamonds can form from the Fe-Ni-S-C melt. On the other hand, the diamond cannot form within the top of subducting slab, due to its lower temperature. Thus it is considered that CLIPPIR diamonds have formed in the ancient hotter slab. Meanwhile, in the case that the mantle transition zone has a basaltic composition, it is feasible that the eclogitic diamonds such as CLIPPIR diamonds have been crystallized from liquid alloy in the mantle transition zone.

Effect of ammonia on the stability of methane hydrate under high-pressure and high-temperature

*Hirokazu Kadobayashi[1], Hisako Hirai[2], Hiroaki Ohfuji[1], Hideaki Kawamura[1], Michika Ohtake[3], Yoshitaka Yamamoto[3]

1. Geodynamics Research Center, Ehime University, 2. Department of Environment System, Faculty of Geo-environmental Science, Rissho University, 3. National Institute of Advanced Industrial Science and Technology

Methane hydrate may be present in significant amounts in the interior of Titan and other icy moons and is thought to be a candidate for a source of their atmospheric methane [e.g., Loveday *et al.* (2001); Choukroun *et al.* (2010)]. The icy mantles of these moons mainly consist of water, methane and ammonia, but the stability of methane hydrate coexisting with these components under high-pressure and high-temperature have been still unknown. In this study, we report a high-pressure and high-temperature investigation of the effect of ammonia on the stability of methane hydrate using X-ray diffraction and Raman spectroscopy combined with externally heated diamond anvil cell under 0.2-20 GPa and 298-413 K. X-ray diffraction studies revealed that methane hydrate in water-methane-ammonia system transforms from sI cage structure into sH cage structure at approximately 0.8 GPa at room temperature, and further transforms into a filled-ice Ih structure at approximately 1.8 GPa without decomposition into water ice and solid methane. These transition pressures at room temperature were same as those reported for pure methane hydrate [Hirai *et al.* (2001); Loveday *et al.* (2001); Shimizu *et al.* (2002)]. At higher temperature, the melting temperatures for the sI and sH cage structures below 1.8 GPa determined by in situ Raman spectroscopy were good agreement with those of pure methane hydrate reported by previous studies [Dyadin *et al.* (1997); Bezacier *et al.* (2014)]. On the other hand, the decomposition temperatures of filled-ice Ih above 1.8 GPa were about 10-20 K lower than those of water-methane system reported by Kadobayashi *et al.* (2018). Our results suggest that ammonia has a potential to vary the stability of filled-ice Ih of methane hydrate in the interiors of icy moons. Finally, we briefly discuss the implications of our new results for the fate of methane hydrate in concerned with a source of atmospheric methane in Titan.

Study on magnetite-maghemite-hematite transformation

*Ibuki Kinebuchi[1], Atsushi Kyono[1], Yoshinari Sano[1]

1. University of Tsukuba

Magnetite (Fe_3O_4) widely distributed in the Earth's crust changes into hematite (α-Fe_2O_3) by the oxidization of Fe^{2+} to Fe^{3+}. In the oxidization process, maghemite (γ-Fe_2O_3) with the same spinel structure as magnetite emerges as an intermediate phase. Maghemite differs from magnetite by the presence of cationic vacancies within the octahedral site. It is important to understand the oxidization mechanism of magnetite, however, the local structure change during the oxidization has been still nuclear. In the study, therefore, the phase transition mechanism from magnetite to hematite through maghemite was investigated by using, thermal analysis (TG・DTA), powder X-ray diffraction (XRD) measurement, and high-temperature ex-situ and in-situ X-ray absorption fine structure (XAFS) measurement. The TG・DTA curves of magnetite showed continuous oxidization up to 400 °C.
High-temperature ex-situ EXAFS spectrum of magnetite heated up to 250 °C exhibited weaker peaks concerning Fe_{oct}-O, Fe_{oct}-Fe_{oct}, and Fe_{tet}-Fe_{oct} than those of magnetite. In addition, the averaged Fe-O bond distance appears to become shorter. The results suggest that magnetite is continuously transformed to maghemite in the temperature range from room temperature to 400 °C. The high-temperature ex-situ EXAFS spectrum of magnetite heated up to 500 °C finally displayed characteristic peaks corresponding to hematite, suggesting that the phase transition from magnetite to hematite was completed.
High-temperature in-situ XANES spectrum indicated that the average oxidation number of Fe gradually increased for 135 min from the start of heating at 500 °C, and then became almost constant. The radial structure function obtained from the high-temperature in-situ EXAFS revealed that the peaks of Fe-O, Fe_{oct}-Fe_{oct} and Fe_{tet}-Fe_{oct} become weakened continuously until 70 min from the start of heating. After 80 min peaks corresponding to hematite began to increase. It can be concluded from these results that the phase transition from magnetite to hematite through maghemite starts from the diffusion of the Fe^{2+} in the octahedral sites, resulting in the formations of cationic vacancies and amorphous phase concentrating Fe^{2+}. Subsequently, the reconstruction of the octahedral coordination of Fe and additional oxidization of the amorphous phase lead to the crystallization into hematite.

The Effects of Temperature and Pressure on Hydromagnesite

*Gen-ichiro Yamamoto[1], Atsushi Kyono[1], Jun Abe[2], Takanori Hattori[3], Yoshitaka Matsushita[4], Yasuhiro Yoneda[3]

1. University of Tsukuba, 2. CROSS, 3. JAEA, 4. NIMS

In recent years, the global warming is the most important environment problem. Therefore, attempts of CO_2 geological storage have been made to reduce carbon dioxide in the atmosphere all over the world (Xue and Nakano 2008). Among some CO_2 geological storage methods, the CO_2 mineral trapping can store the carbon dioxide safety for a long time. In the case of geological storage, magnesium carbonate hydrates are important minerals since they precipitate easily from water saturated with carbon dioxide. The major magnesium carbonate hydrates formed from aqueous solution are nesquehonite $MgCO_3 \cdot 3H_2O$ and hydromagnesite $Mg_5(CO_3)_4(OH)_2 \cdot 4H_2O$. The stability of these minerals are critically important factors to assess environmental safety and phase stability over geological time scale, but they have not been fully investigated yet, especially of hydromagnesite. Here, we investigated the effects of pressure and temperature on hydromagnesite by using thermal analysis, high-temperature X-ray diffraction, X-ray total scattering, high-pressure X-ray diffraction, and high-pressure and high-temperature neutron diffraction techniques.

With temperature, hydromagnesite was decomposed into periclase MgO through the poor crystalline phase, accompanied with dehydration, dihydroxylation, and decarbonation of hydromagnesite. The *a* and *c* lattice parameters were monotonously increased as increasing temperature whereas *b* lattice parameter almost remained unchanged. At just before the dehydration reaction, the unit cell was contracted due to the dehydration. With pressure, hydromagnesite structure was maintained up to 8.7 GPa. Decomposition into magnesite $MgCO_3$ or periclase was unobserved up to at least 21.0 GPa. With compression, the unit cell was isotopically contracted. The fit to the Birch-Murnaghan equation of state gives $K_0 = 32(2)$ and $V_0 = 658(4)$ with $K' = 4.0$ (fixed). Under high-pressure and high-temperature conditions, hydromagnesite broke down into magnesite and brucite $Mg(OH)_2$ at 200 $^{\circ}C$ and 1.2 GPa. The unit cell was isotopically expanded up to just before the breakdown. The breakdown of hydromagnesite could be caused by the dissolution by dehydration water, and subsequently magnesite and brucite were hydrothermally grown from the solution at the condition. The results obtained from this study would provide insight the CO_2 geological storage.

Synthesis and crystal structure of Mg-bearing Fe_9O_{11}: New insight in the complexity of Fe-Mg oxides at conditions of the deep upper mantle

*Takayuki Ishii[1], Uenver-Thiele Laura[2], Alan B Woodland[2], Edith Alig[3], Tiziana Boffa Ballaran[1]

The Fe-O system is fundamental for understanding redox processes operating in the Earth's interior. Recent experimental studies have revealed several new mixed-valence Fe-oxides to be stable at high pressures and temperatures, such as the orthorhombic-structured phases $Fe^{2+}_2Fe^{3+}_2O_5$ and $Fe^{2+}_3Fe^{3+}_2O_6$. and the monoclinic-structured $Fe^{2+}_3Fe^{3+}_4O_9$. It has been also demonstrated that Fe_4O_5 and Fe_7O_9 form solid solutions with the Mg-endmembers such as $Mg_2Fe_2O_5$ and $Mg_3Fe_4O_9$, suggesting possible existence of complicated Mg-Fe oxides in the deep mantle. We synthesized a new Mg-Fe oxide with a composition of $Mg_{0.9}Fe_{8.1}O_{11}$. We report the synthesis and crystal structure analyzed by the Rietveld method.

A novel Mg-bearing iron oxide $Mg_{0.87(1)}Fe^{2+}_{4.13(1)}Fe^{3+}_4O_{11}$ was synthesized at 12 GPa and 1300 ˚C using a large volume press. Rietveld structural analysis was conducted with a laboratory X-ray diffraction pattern obtained at ambient conditions.
The crystal structure, which has one oxygen trigonal prism site and four octahedral sites for the cations, was found to be isostructural with $Ca_2Fe_7O_{11}$. The unit-cell lattice parameters are a = 9.8441(5) Å, b = 2.8920(1) Å, c = 14.1760(6) Å, β = 99.956(4)˚, V = 397.50(3) Å, and Z = 2 (monoclinic, $C2/m$). Mg and Fe cations are disordered on the trigonal prism site and on two of the four octahedral sites, and the remaining Fe is accommodated at the other two octahedral sites. The present structure is closely related to the other recently discovered Fe oxide structures, e.g. Fe_4O_5 and Fe_5O_6, by distortion derived either from incorporation (Fe_4O_5) or removal (Fe_5O_6) of an edge-shared FeO_6 single octahedral chain in their structures. The present synthesis at deep upper mantle conditions and the structural relationships observed between various novel Mg-Fe oxides indicate that a series of different phases become stable above 10 GPa and that their relative stabilities (Fe^{2+}/Fe^{3+}) must be controlled by oxygen fugacity.

Changes in specific surface area and morphology of kaolin group minerals with pressure treatment

*Soyeon Kwon[1], Yongjae Lee[1]

1. YONSEI University

Pressure can tailor the properties of a material by changing its atomistic arrangements and/or crystal morphology. We have investigated the changes in the adsorption properties of kaolin group minerals as a function of pressure treatment in gigapascal range. External pressure has been applied using a Large Volume Press (LVP) to kaolinite ($Al_2Si_2O_5(OH)_4$) and halloysite ($H_4Al_2O_9Si_2{\cdot}2H_2O$), which represent natural 2D layered and 1D nanowire structures, respectively. Powdered samples have been compressed up to 3 GPa in 1 GPa steps at room temperature and recovered by up to ~0.35g from each pressure step. The BET (Brunauer, Emmett, Teller) measurement was conducted using N_2 gas to measure the specific surface area, pore size distribution, and pore volume of the pressure-treated samples. Before pressure-treatment, the specific surface area of kaolinite has been measured to be 10.702(m^2g^{-1}), which increases to 12.090(m^2g^{-1}) after 1 GPa, 17.101(m^2g^{-1}) after 2 GPa, and 17.864(m^2g^{-1}) after 3 GPa treatments. These lead to a gradual increase in the total volume of adsorbed pores from 0.01216 (cm^3g^{-1}) at ambient, to 0.01368(cm^3g^{-1}) after 1 GPa, 0.074337(cm^3g^{-1}) after 2 GPa, and 0.09546(cm^3g^{-1}) after 3 GPa treatments. Unlike Kaolinite, the specific surface area of halloysite decreases from 47.476($m2g^{-1}$) from ambient to 44.348(m^2g^{-1}) after 1 GPa, 41.579(m^2g^{-1}) after 2 GPa, and 42.796(m^2g^{-1}) after 3 GPa treatment, which results in overall decrease in the total volume of the pore from 0.1914(cm^3g^{-1}) at ambient to 0.1863(cm^3g^{-1}) after 1 GPa, 0.1572(cm^3g^{-1}) after 2 GPa, and 0.1187(cm^3g^{-1}) after 3 GPa treatments.
We discuss the contrasting effects of pressure-treatment on the two morphologically-distinct kaolin group minerals based on SEM (Scanning Electron Microscope) images and analyses of selected diffraction peaks measured on each recovered material. We observe that the layers in kaolinite separate into smaller units upon increasing pressure treatment, whereas the tubes in halloysite become flattened, which led to the contrasting changes in surface area and pore volume. Further study is in progress to compare these results to when water is used as a pore-penetrating pressure-transmitting medium.

[S-GC40] Volatile Cycles in the Deep Earth - from Subduction Zone to Hot Spot

convener:Hirochika Sumino(Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo), Takeshi Hanyu(Japan Agency for Marine-Earth Science and Technology, Department of Solid Earth Geochemistry), Yuji Sano(Division of Ocean and Earth Systems, Atmosphere and Ocean Research Institute, University of Tokyo), Gray E Bebout(Lehigh University)

Volatiles play an important role in the geodynamics and chemical differentiation in the mantle and crust by drastically changing mineral stability and rheological behavior. Fractionation-processes such as partial melting, hydration, and dehydration are all controlled by volatiles in the rocks. A significant portion of the volatiles in the Earth has been thought to be present in the atmosphere and oceans as a consequence of extensive degassing during accretion and subsequent mantle degassing. On the other hand, it has been recently recognized that substantial amounts of volatiles are recycled back into the mantle at subduction zones, where intensive devolatilization of descended materials during arc magma generation was once thought to act as an effective "subduction barrier". However, fundamental questions still remain, such as: how are volatiles species distributed throughout the early and present Earth? What are the mechanisms for, and rate at which, volatiles are fluxed between the atmosphere, crust, and mantle? And what role have volatiles played in driving the evolution of the Earth? The possible role of the core in storing primordial volatiles is also poorly constrained. We therefore welcome contributions from experimental, observational, and modeling studies that help shed light on the deep cycles of volatiles, such as hydrogen, carbon, nitrogen, noble gases, halogens and sulfur. We particularly encourage studies linking the behavior of multiple volatile elements and their isotopic compositions. Studies investigating the linkage between volatile and solid geochemical tracers, the phase equilibria of volatile-bearing mantle assemblages, and the effect of volatiles on the physical properties of the mantle are also welcome.

Continental growth models demystified

*Jun Korenaga[1]

1. Department of Geology and Geophysics, Yale University

So far proposed models of continental growth exhibit bewildering diversity, but this diversity is rather superficial. By understanding how different growth models are built and what they are meant to constrain, we can gain deeper insight into the evolution of continental crust as well as the dynamics of the early Earth. There are three kinds of growth models: crust-based, mantle-based, and others. Crust-based models provide only the lower bound on net crustal growth, and mantle-based models aim at constraining net crustal growth itself. Other models are also about net crustal growth, but they are subject to greater uncertainty. In the presence of crustal recycling, crust-based models are expected to be different from mantle-based models, and more important, the difference between these two kinds of models provides important constraints on the operation of plate tectonics in the early Earth. Some popular misconceptions in the recent literature are also discussed.

Mass-independent sulfur isotope signature from the 2.7 Ga Belingwe komatiite: Recycling of crustal material in Archean

*Yusuke Kubota[1], Yuichiro Ueno[1,2,3], Kenji Shimizu[3], Fumihiro Matsuura[2], Akira Ishikawa[1,3]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. Earth-Life Science Institute, Tokyo Institute of Technology, 3. Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

Recycling of the Earth's crustal material has long been discussed mainly through the radiogenic isotopes of modern Ocean Island Basalts (OIB). Recent finding of Sulfur Mass Independent Fractionation (S-MIF) from HIMU and EM I basalts supports recycling of crustal material in mantle (Cabral et al., 2013; Delavault et al., 2016). Since photochemical reactions under reducing Archean atmosphere are thought to be a plausible process of large S-MIF generation (Farquhar et al., 2001; Farquhar and Wings, 2003), these discoveries demonstrated that the S-MIF is a useful signature for tracing Archean crustal material. However, it has been difficult to estimate when the subduction started in the history of the Earth. Here, we report multiple sulfur isotope analysis of the 2.7 Ga Belingwe komatiites and related rocks, which has potential to elucidate earlier subduction or recycling of crustal material before 2.7 Ga. The Belingwe komatiite are one of the best-preserved Archean komatiites in the world. The results show clear S-MIF signature in several komatiites and basalts. Sulfide minerals in the S-MIF bearing samples occur as pyrrhotite and chalcopyrite scattered within groundmass around the quenched olivine and pyroxene crystals, indicating that the sulfides crystalized at the time of eruption. The original nature of the sulfide is also supported by the correlation between sulfur contents and magnesium number. Based on Nd, Sr, and Pb isotope composition measured in the previous study (Shimizu et al., 2005), the S-MIF bearing komatiites and basalts are likely to be derived from depleted mantle source, whereas more enriched samples do not show S-MIF. Therefore, the S-MIF component is not likely derived from assimilated crust at the time of the komatiite volcanism, but originally incorporated in the depleted source mantle. Consequently, our results suggest that subduction of S-MIF bearing surface material into the mantle had been operated at least prior to 2.7 Ga.

Determination of halogens in some standard materials using the neutron irradiation noble gas mass spectrometric technique

*Hirochika Sumino[1], Masahiro Kobayashi[2], Takehiko Saito[3], Keisuke Nagao[3]

1. Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo, 2. Tokyo Metropolitan Industrial Technology Research Institute, 3. Geochemical Research Center, Graduate School of Science, University of Tokyo

Halogens are among the most powerful tracers of volatile cycling in subduction zones, because of (i) the large contrast in concentrations between the surface and interior of the Earth [1], (ii) their high affinities to gas- and fluid-phases relative to mineral [2], (iii) distinct elemental and/or isotopic compositions in each reservoir in the Earth [3-7]. However, few analytical techniques can determine trace amounts of halogens, particularly bromine and iodine in mantle-derived samples. Consequently, there have been relatively few previous studies of halogens in mantle-derived samples.

The neutron irradiation noble gas mass spectrometric technique (NI-NGMS) is capable of measuring very low concentrations of halogens (<1 ppb) in very small samples (<1 mg). The NI-NGMS is an extension of the Ar-Ar and I-Xe dating methods [8-10]. Halogens (chlorine, bromine, and iodine) and other elements (potassium, calcium, barium, and uranium) are converted to corresponding isotopes of argon, krypton, and xenon by neutron irradiation in a nuclear reactor. The noble gas isotopes in neutron-irradiated samples are analyzed by noble gas mass spectrometry. Irradiation conditions such as neutron fluence are monitored using standard materials of the Ar-Ar and I-Xe dating methods. Relatively high cross-sections of halogens for neutron capture and high sensitivity of noble gas mass spectrometry enable determination of trace amounts of halogens using NI-NGMS.

We report new halogen concentrations determined for scapolite standards and geological reference materials distributed by Geological Survey of Japan and US Geological Survey using NI-NGMS. Consistent results with those regarded as reference values were obtained from scapolite standards, which indicate that the scapolite standards are reliable in halogen analysis. On the other hand, the halogen concentrations obtained from geological reference materials are systematically lower than the reference values for samples with low concentrations of halogens. The higher concentrations reported for the geological reference materials probably result from contamination on the sample surface during preparation of these reference materials. We also propose a fluorine determination method using NI-NGMS based on neon systematics, although reliable determination of fluorine has been thought to be impossible.

FTIR spectroscopy and noble gas mass spectrometry for a single olivine grain

*Sota Niki[1], Hirochika Sumino[2], Masahiro Kobayashi[3], Hiroyuki Kagi[1], Takafumi Hirata[1], Chris J. Ballentine[4]

1. Geochemical Research Center, Grad. School of Science, Univ. of Tokyo, 2. Dept. of Basic Science, Grad. School of Arts and Sciences, Univ. of Tokyo, 3. Tokyo Metropolitan Industrial Technology Research Institute, 4. Dept. of Earth Sciences, Univ. of Oxford

Volatiles have been degassed from the mantle and recycled back into the mantle at subduction zones. Water is the main component of volatiles and plays a key role in dynamics of the subduction zones because even a small water content in rocks has an influence on the physical and chemical properties of the rocks (e.g. friction coefficient, melting point, etc.) which are closely related to phenomena studied in earth sciences including volcanic or seismic activities. It is still unclear to what extent of water have been subducted into the mantle and released to the Earth’ s surface. To elucidate the volatile recycling, noble gases are powerful tracers because they have unique compositions in geochemical reservoirs. Previous researches have mainly reported results of bulk analysis of mantle peridotites. On the contrary, in this study, FTIR measurements and noble gas analysis of a single olivine grain were conducted to determine the noble gas concentrations in fluid inclusions.

The olivine samples used for this study were separated from mantle xenoliths collected from an intraplate setting (Hualalai in Hawaii) and two subduction zones (the Avacha volcano in the Kamchatka arc and the Pinatubo volcano in the Luzon arc). The Hualalai olivine was expected to show mantle-derived noble gas compositions (Kobayashi et al., G-cubed 2019) and was used for checking the accuracy of noble gas analysis. The Avacha and Pinatubo olivines contained H_2O-rich fluid inclusions and the noble gas concentrations in the inclusions had been estimated from salinities, and halogen and noble gas compositions (Kobayashi et al., EPSL 2017). The Avacha and Pinatubo olivines were used to confirm the accuracy of the analytical method used in this study for determining the noble gas concentrations in the inclusions.

FTIR measurements were conducted to determine the H_2O concentration in the Avacha and Pinatubo olivines. The mantle xenoliths were crushed into 0.5 to 2 mm and olivine grains were separated. The olivine grains were embedded in resin (Ortho Bright) and polished to a thickness of several hundred micrometers. The weight of samples was 0.7 to 16 mg. The H_2O concentration was calculated from the absorbance at 3404 cm^{-1}. After the FTIR measurements, resin was removed from each grain by heating at 50ºC and dissolving in acetone.

Noble gas analysis was conducted using multicollector noble gas mass spectrometers (Helix SFT and Argus, Thermo Fisher Scientific). After the sample loading into a laser heating cell, the cell was baked out with pumping to desorb atmospheric noble gases to achieve low blank levels required for single-grain analysis. Consequently, noble gases were extracted by laser heating (Fusion Diode Stepped Heating System, Teledyne CETAC) at about 1000 ºC for 5 minutes. The gases released from samples were purified by removing active gases using a getter, and then, absorbed on two cryo-traps (one was for helium and neon and the other was for argon, krypton, and xenon). Each noble gas was desorbed from the trap at a certain temperature and introduced into the mass spectrometers. Helium was measured with Helix SFT and other noble gases were measured with Argus. The abundances and isotopic ratios of noble gases in a

©2019. Japan Geoscience Union. All Right Reserved.

single olivine grain were obtained. The accuracy of the isotopic ratios was checked by the Hualalai samples.

The noble gas concentrations in the inclusions obtained will be compared with the previous bulk analysis to discuss the accuracy of the method in this study. This method of determining the noble gas concentrations in fluid inclusions from single-grain analysis has a potential to clarify the heterogeneity of the mantle volatiles in terms of a single-grain mineral and the flux quantification during the volatile recycling.

New halogen incorporation mechanism in serpentine group minerals: Crystal chemical consideration

*Masami Kanzaki[1]

1. Institute for Planetary Matereials, Okayama University

Introduction: Recent geochemical studies revealed that serpentinites contain a significant amount of halogens. However, how halogen ions are incorporated into serpentinites is not well understood. Commonly assumed mechanism is "OH^- substitution" in serpentine group minerals (chrysotile, lizardite and antigorite). Although this mechanism will be fine for F, but may not be adequate for larger halogens (Cl, Br, I). Here, I propose new halogen incorporation mechanism in lizardite and antigorite from crystal chemical point of view.

Calculation methods: In order to assess present new incorporation model, first-principles calculation was conducted. Quantum-Espresso package was used to optimize the halogen incooporated model structures. In the present study, lizardite and antigorite (*m*=17 polysome) are considered. For our proposed mechanism, charge balance should be observed; so $Mg^{2+} = X^- + Al^{3+}$ substitution (X^- = halogen) is assumed to introduce halogen to a vacant site. For lizardite, enthalpy difference between two models (OH^- substitution and our model) was calculated for following equation: $Mg_2AlSi_2O_8XH_2 + H_2O = Mg_2AlSi_2O_9XH_4$. Former corresponds to the OH substituted model (with Al introduced), and latter corresponds to our new model. Although this comparison is crude (as free H_2O is included in the equation), it could provide systematic trend with kinds of halogen atoms. Since antigorite has a very large unit cell and many vacant sites, only $Mg^{2+} = Cl^- + Al^{3+}$ substitute in five vacant sites are considered so far.

Results and Discussion: From close inspection of crystal structures of lizardite and antigorite, vacant sites ideal for halogens are identified. The vacant sites are surrounded by four protons (of OH^-) forming elongated tetrahedon (i.e., XH_4^{3+}) if halogen is located. Such vacant sites provide local structure similar to halogen ions in aqueous solution.

In order to further assess present incorporation mechanism, first-principles calculations of lizardite and antigorite containing halogens in those sites were conducted. The structural optimizations confirmed that halogens could be well accommodated into the tetrahedral vacant sites in lizardite. The calculated enthalpy difference between OH substitution and present models in lizardite revealed that larger halogens prefer our model over the OH substitution model. There is sinlge vacant site in lizardite, but antigorite (*m*=17) has 17 crystallographically different vacant sites. Most sites have local structures more or less similar to that of lizardite (locating in 6-membered SiO_4 ring). But there is another kind of vacant site which is locating in 8-membered SiO_4 ring. This local structure is surrounded by six protons, but it can be regareded as two tetrahedral proton sites with edge sharing. Substitution of Cl^- to this site (one of tetrahedral sites) showed lower enthalpy compared to those of other lizardite-like sites, and can accept more larger ions. Therefore, Cl^- (and other larger halogens) will prefet this site in antigorite (*m*=17). Not all antogorite polysomes have this site.

Present study suggests that our new proposed incorporation mechanism is promising, and it should be further studied experimentally. Present new incorporation mechanism would be important to understand elemental partition behavior of halogens in subduction zones.

Mineralogical and geochemical characteristics of cuttings from Taketomi hot spring

*Noriyuki Shingaki[1], Tomohiro Toki[1], Syogo Oshima[2], Masaaki chinen[3], Arito Sakaguchi[4], Naoto Takahata[5], Yuji Sano[5], Shirai Kotaro[5], Kentaro Tanaka[5]

1. University of the Ryukyus , 2. West Japan Engineering Consultants, Inc., 3. MicroRange, 4. Faculty of Science, Yamaguchi University, 5. Atmosphere and Ocean Research Institute, The University of Tokyo

It is important to grasp carbon cycle on the earth’ s surface for thinking about global environmental change. A hot spring with a maximum temperature of 64℃ is venting with gas containing 70% of methane from several spots on the seafloor at depth of 22 m at 1 km northeast off Taketomi Island. Based on methane and helium isotope ratios in the venting gas, the influence of magmatic gas has been pointed out. In spite of Taketomi Island located on the trench side from island arc, magmatic gas is venting. It suggests the forearc where magma cannot generate, might form new supply path of carbon from the Earth’ s interior. The mass balance from new supply path of carbon may change estimation of carbon cycle on earth’ s surface. Therefore, the purpose of this study is to elucidate venting mechanism and quantitative grasp of magmatic gas from forearc, and the history of hot spring activities will be investigated to predict future activities.

In 2017, the hot spring was drilled up to depth of 940 m in Taketomi Island. The cuttings with muddy water were sampled every 10 m. The thin sections were prepared from cuttings to be observed using polarization microscope, and the chemical compositions of grains were analyzed by SEM-EDX. The ground samples were analyzed for mineral and chemical compositions by XRD and EDX. The clay minerals gathered by levitation were measured for half-value width of illite using XRD. He and CO_2 contained in samples that were crashed in vacuum were measured for isotope ratios by mass spectrometer. Calcite and dolomite collected from the cuttings were measured for the carbon and oxygen isotope ratios by mass spectrometer. The vitrinite in the cuttings was separated by a heavy liquid, and the reflectance was measured by a reflecting microscope.

In the microscopy, the stratum was roughly divided two formations; cryptocrystalline quartz layer and sand stone layer. Carbonaceous materials were observed in most of the stratum. Dolomite was limitedly observed in the vicinity of 800 m. In the XRD analysis, Quartz was detected at all depth. Calcite was detected at shallower depth than 30 m, and dolomite was detected only around 800 m. As a result of the EDX analysis, silicon was the most dominant in all layers, and especially, it was contained around 0-100 m, 300 m and around 900 m over 80%. There was a layer that contained much calcium. Around 0-30 m, 400-500 m and around 800 m, calcite was contained 15 % or more. The half-value width of illite was large, 0.8 $\Delta^\circ 2\theta$, in only 10 m surface, and as low as 0.2 to 0.4 $\Delta^\circ 2\theta$ below 50 m. Vitrinite reflectance was around 5% in the whole layer, close to measurement limit. The helium content was 10^{-14}-10^{-11} mol per 1g of cuttings, and tended to increase with increasing depth. The highest content was detected at 800 m depth. The helium isotope ratio($^3He/^4He$)have value of 0.4-3.6 times that of atmosphere, and tended to increase with increasing depth. Particularly, it was higher at 100 m, 300-400 m and 700-800 m. The CO_2 content per gram of cuttings, was in the range of 10^{-8}-10^{-6} mol in most layers, but it showed

©2019. Japan Geoscience Union. All Right Reserved.

higher values at 400 m and 800 m depth. the water tended to decrease with increasing depth, and showed especially high values at 400 m and 900 m. The carbon isotope ratio ($\delta^{13}C$) of calcite was -4.7‰ VPDB, and the oxygen isotope ratio ($\delta^{18}O$) is -16.3‰VPDB. The $\delta^{13}C$ value of dolomite was -1‰VPDB, and the $\delta^{18}O$ value was -10.9‰VPDB. The $\delta^{13}C$ value of CO_2 from cuttings at 800 m was -7.3‰VPDB, which contained sufficiently amount of carbon to measure carbon isotope ratio.

Variation of helium isotope compositions at Lake Mashu

*Takanori Kagoshima[1], Yuji Sano[1], Atsushi Tanaka[2]

1. Atmosphere and Ocean Research Institute, University of Tokyo, 2. National Institute for Environmental Studies

Helium-3 is one of the most sensitive geochemical tracers which reflects addition of mantle components to gas and fluids in volcanic hydrothermal systems, and $^{3}He/^{4}He$ ratios may be useful to assess temporal change of hydrothermal activity at volcanic lakes. Lake Mashu is a caldera lake which formed around 7000 years ago in Hokkaido. Igarashi et al. (1992) measured He and Ne isotopes in water of Lake Mashu, and concluded that the depth profile of isotopic compositions reflect injection of mantle-derived He due to hot spring activity at the lake bottom. After that, there is no subsequent study reporting He isotope data. The lack of observational data may be due to difficulty of water sampling at caldera lakes. Igarashi et al. (1992) collected water samples into copper tubes. However, this method requires heavy and large sampling tools, and people who can transfer water and seal the tubes properly. In May and September 2017, we investigated Lake Mashu in order to check volcanic activity and practical sampling methods for caldera lakes. We collected water using a Niskin bottle at several depths (surface to 210 m) around the deepest point (211 m). Collected water was immediately transferred into lead-glass containers with vacuum valves at both ends. In Atmosphere and Ocean Research Institute, dissolved gases were extracted by the head space method, and introduced into a purification vacuum line. In the line, He and Ne were purified for isotope analyses. $^{3}He/^{4}He$ and $^{4}He/^{20}Ne$ ratios were measured using Helix-SFT and QMS, respectively. The highest $^{3}He/^{4}He$ ratios were observed at 205-210 m depth, indicating that injection of fluids with the high $^{3}He/^{4}He$ ratio at the bottom. The linear correlation between $^{4}He/^{20}Ne$ and $^{3}He/^{20}Ne$ ratios in water samples indicated mixing of two components: injected fluids and the atmosphere. The estimated $^{3}He/^{4}He$ ratio of the fluid end member was indistinguishable from the value reported by Igarashi et al. (1992), implying a possibility that there was no significant change in volcanic activity at Lake Mashu in the past 30 years.

Helium isotopes in Tachibana Bay and Shimabara Bay, Nagasaki

*Ma. Teresa Escobar[1], Yama Tomonaga[2], Hajime Obata[1], Shigenobu Takeda[3], Naoto Takahata[1], Yuji Sano[1]

Graduate School of Fisheries and Environmental Sciences, Nagasaki University, Nagasaki, Japan

Noble gases are powerful tracers to study physical transport processes in aquatic system. Moreover, helium isotopes have been shown to be very useful to infer the origin of fluids. Shimabara Peninsula is located on western side of the Beppu-Shimabara graben in Kyushu, SW Japan. In the region, there are some hot springs and groundwaters which indicate magmatic helium with high 3He/4He ratio. Although some researchers report helium isotopic ratio on land, there is no data in the sea.

The surrounding bays around Shimabara Peninsula in Nagasaki were recently studied for the existence of hydrothermal springs and vents. Physico-chemical properties characteristic of hydrothermal activity were detected on the seafloor. For this study, we use helium isotopes to detect the occurrence of hydrothermal springs on the seafloor in both Tachibana Bay and Shimabara Bay. Samples were collected using a CTD-CMS system and analyzed using a Noble Gas Mass Spectrometer. Our data supplements the discovery of hydrothermal venting along known faults on the seafloor. We present the results of noble gas measurements conducted on water samples and discuss the relationship between our observations and the tectonic setup of the surrounding region.

[S-GC40] Volatile Cycles in the Deep Earth - from Subduction Zone to Hot Spot

convener:Hirochika Sumino(Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo), Takeshi Hanyu(Japan Agency for Marine-Earth Science and Technology, Department of Solid Earth Geochemistry), Yuji Sano(Division of Ocean and Earth Systems, Atmosphere and Ocean Research Institute, University of Tokyo), Gray E Bebout(Lehigh University)

Volatiles play an important role in the geodynamics and chemical differentiation in the mantle and crust by drastically changing mineral stability and rheological behavior. Fractionation-processes such as partial melting, hydration, and dehydration are all controlled by volatiles in the rocks. A significant portion of the volatiles in the Earth has been thought to be present in the atmosphere and oceans as a consequence of extensive degassing during accretion and subsequent mantle degassing. On the other hand, it has been recently recognized that substantial amounts of volatiles are recycled back into the mantle at subduction zones, where intensive devolatilization of descended materials during arc magma generation was once thought to act as an effective "subduction barrier". However, fundamental questions still remain, such as: how are volatiles species distributed throughout the early and present Earth? What are the mechanisms for, and rate at which, volatiles are fluxed between the atmosphere, crust, and mantle? And what role have volatiles played in driving the evolution of the Earth? The possible role of the core in storing primordial volatiles is also poorly constrained. We therefore welcome contributions from experimental, observational, and modeling studies that help shed light on the deep cycles of volatiles, such as hydrogen, carbon, nitrogen, noble gases, halogens and sulfur. We particularly encourage studies linking the behavior of multiple volatile elements and their isotopic compositions. Studies investigating the linkage between volatile and solid geochemical tracers, the phase equilibria of volatile-bearing mantle assemblages, and the effect of volatiles on the physical properties of the mantle are also welcome.

Continental growth models demystified

*Jun Korenaga[1]

1. Department of Geology and Geophysics, Yale University

So far proposed models of continental growth exhibit bewildering diversity, but this diversity is rather superficial. By understanding how different growth models are built and what they are meant to constrain, we can gain deeper insight into the evolution of continental crust as well as the dynamics of the early Earth. There are three kinds of growth models: crust-based, mantle-based, and others. Crust-based models provide only the lower bound on net crustal growth, and mantle-based models aim at constraining net crustal growth itself. Other models are also about net crustal growth, but they are subject to greater uncertainty. In the presence of crustal recycling, crust-based models are expected to be different from mantle-based models, and more important, the difference between these two kinds of models provides important constraints on the operation of plate tectonics in the early Earth. Some popular misconceptions in the recent literature are also discussed.

Mass-independent sulfur isotope signature from the 2.7 Ga Belingwe komatiite: Recycling of crustal material in Archean

*Yusuke Kubota[1], Yuichiro Ueno[1,2,3], Kenji Shimizu[3], Fumihiro Matsuura[2], Akira Ishikawa[1,3]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. Earth-Life Science Institute, Tokyo Institute of Technology, 3. Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

Recycling of the Earth's crustal material has long been discussed mainly through the radiogenic isotopes of modern Ocean Island Basalts (OIB). Recent finding of Sulfur Mass Independent Fractionation (S-MIF) from HIMU and EM I basalts supports recycling of crustal material in mantle (Cabral et al., 2013; Delavault et al., 2016). Since photochemical reactions under reducing Archean atmosphere are thought to be a plausible process of large S-MIF generation (Farquhar et al., 2001; Farquhar and Wings, 2003), these discoveries demonstrated that the S-MIF is a useful signature for tracing Archean crustal material. However, it has been difficult to estimate when the subduction started in the history of the Earth. Here, we report multiple sulfur isotope analysis of the 2.7 Ga Belingwe komatiites and related rocks, which has potential to elucidate earlier subduction or recycling of crustal material before 2.7 Ga. The Belingwe komatiite are one of the best-preserved Archean komatiites in the world. The results show clear S-MIF signature in several komatiites and basalts. Sulfide minerals in the S-MIF bearing samples occur as pyrrhotite and chalcopyrite scattered within groundmass around the quenched olivine and pyroxene crystals, indicating that the sulfides crystalized at the time of eruption. The original nature of the sulfide is also supported by the correlation between sulfur contents and magnesium number. Based on Nd, Sr, and Pb isotope composition measured in the previous study (Shimizu et al., 2005), the S-MIF bearing komatiites and basalts are likely to be derived from depleted mantle source, whereas more enriched samples do not show S-MIF. Therefore, the S-MIF component is not likely derived from assimilated crust at the time of the komatiite volcanism, but originally incorporated in the depleted source mantle. Consequently, our results suggest that subduction of S-MIF bearing surface material into the mantle had been operated at least prior to 2.7 Ga.

Determination of halogens in some standard materials using the neutron irradiation noble gas mass spectrometric technique

*Hirochika Sumino[1], Masahiro Kobayashi[2], Takehiko Saito[3], Keisuke Nagao[3]

1. Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo, 2. Tokyo Metropolitan Industrial Technology Research Institute, 3. Geochemical Research Center, Graduate School of Science, University of Tokyo

Halogens are among the most powerful tracers of volatile cycling in subduction zones, because of (i) the large contrast in concentrations between the surface and interior of the Earth [1], (ii) their high affinities to gas- and fluid-phases relative to mineral [2], (iii) distinct elemental and/or isotopic compositions in each reservoir in the Earth [3-7]. However, few analytical techniques can determine trace amounts of halogens, particularly bromine and iodine in mantle-derived samples. Consequently, there have been relatively few previous studies of halogens in mantle-derived samples.

The neutron irradiation noble gas mass spectrometric technique (NI-NGMS) is capable of measuring very low concentrations of halogens (<1 ppb) in very small samples (<1 mg). The NI-NGMS is an extension of the Ar-Ar and I-Xe dating methods [8-10]. Halogens (chlorine, bromine, and iodine) and other elements (potassium, calcium, barium, and uranium) are converted to corresponding isotopes of argon, krypton, and xenon by neutron irradiation in a nuclear reactor. The noble gas isotopes in neutron-irradiated samples are analyzed by noble gas mass spectrometry. Irradiation conditions such as neutron fluence are monitored using standard materials of the Ar-Ar and I-Xe dating methods. Relatively high cross-sections of halogens for neutron capture and high sensitivity of noble gas mass spectrometry enable determination of trace amounts of halogens using NI-NGMS.

We report new halogen concentrations determined for scapolite standards and geological reference materials distributed by Geological Survey of Japan and US Geological Survey using NI-NGMS. Consistent results with those regarded as reference values were obtained from scapolite standards, which indicate that the scapolite standards are reliable in halogen analysis. On the other hand, the halogen concentrations obtained from geological reference materials are systematically lower than the reference values for samples with low concentrations of halogens. The higher concentrations reported for the geological reference materials probably result from contamination on the sample surface during preparation of these reference materials. We also propose a fluorine determination method using NI-NGMS based on neon systematics, although reliable determination of fluorine has been thought to be impossible.

FTIR spectroscopy and noble gas mass spectrometry for a single olivine grain

*Sota Niki[1], Hirochika Sumino[2], Masahiro Kobayashi[3], Hiroyuki Kagi[1], Takafumi Hirata[1], Chris J. Ballentine[4]

1. Geochemical Research Center, Grad. School of Science, Univ. of Tokyo, 2. Dept. of Basic Science, Grad. School of Arts and Sciences, Univ. of Tokyo, 3. Tokyo Metropolitan Industrial Technology Research Institute, 4. Dept. of Earth Sciences, Univ. of Oxford

Volatiles have been degassed from the mantle and recycled back into the mantle at subduction zones. Water is the main component of volatiles and plays a key role in dynamics of the subduction zones because even a small water content in rocks has an influence on the physical and chemical properties of the rocks (e.g. friction coefficient, melting point, etc.) which are closely related to phenomena studied in earth sciences including volcanic or seismic activities. It is still unclear to what extent of water have been subducted into the mantle and released to the Earth’ s surface. To elucidate the volatile recycling, noble gases are powerful tracers because they have unique compositions in geochemical reservoirs. Previous researches have mainly reported results of bulk analysis of mantle peridotites. On the contrary, in this study, FTIR measurements and noble gas analysis of a single olivine grain were conducted to determine the noble gas concentrations in fluid inclusions.

The olivine samples used for this study were separated from mantle xenoliths collected from an intraplate setting (Hualalai in Hawaii) and two subduction zones (the Avacha volcano in the Kamchatka arc and the Pinatubo volcano in the Luzon arc). The Hualalai olivine was expected to show mantle-derived noble gas compositions (Kobayashi et al., G-cubed 2019) and was used for checking the accuracy of noble gas analysis. The Avacha and Pinatubo olivines contained H_2O-rich fluid inclusions and the noble gas concentrations in the inclusions had been estimated from salinities, and halogen and noble gas compositions (Kobayashi et al., EPSL 2017). The Avacha and Pinatubo olivines were used to confirm the accuracy of the analytical method used in this study for determining the noble gas concentrations in the inclusions.

FTIR measurements were conducted to determine the H_2O concentration in the Avacha and Pinatubo olivines. The mantle xenoliths were crushed into 0.5 to 2 mm and olivine grains were separated. The olivine grains were embedded in resin (Ortho Bright) and polished to a thickness of several hundred micrometers. The weight of samples was 0.7 to 16 mg. The H_2O concentration was calculated from the absorbance at 3404 cm^{-1}. After the FTIR measurements, resin was removed from each grain by heating at 50ºC and dissolving in acetone.

Noble gas analysis was conducted using multicollector noble gas mass spectrometers (Helix SFT and Argus, Thermo Fisher Scientific). After the sample loading into a laser heating cell, the cell was baked out with pumping to desorb atmospheric noble gases to achieve low blank levels required for single-grain analysis. Consequently, noble gases were extracted by laser heating (Fusion Diode Stepped Heating System, Teledyne CETAC) at about 1000 ºC for 5 minutes. The gases released from samples were purified by removing active gases using a getter, and then, absorbed on two cryo-traps (one was for helium and neon and the other was for argon, krypton, and xenon). Each noble gas was desorbed from the trap at a certain temperature and introduced into the mass spectrometers. Helium was measured with Helix SFT and other noble gases were measured with Argus. The abundances and isotopic ratios of noble gases in a

©2019. Japan Geoscience Union. All Right Reserved.

single olivine grain were obtained. The accuracy of the isotopic ratios was checked by the Hualalai samples.

The noble gas concentrations in the inclusions obtained will be compared with the previous bulk analysis to discuss the accuracy of the method in this study. This method of determining the noble gas concentrations in fluid inclusions from single-grain analysis has a potential to clarify the heterogeneity of the mantle volatiles in terms of a single-grain mineral and the flux quantification during the volatile recycling.

New halogen incorporation mechanism in serpentine group minerals: Crystal chemical consideration

*Masami Kanzaki[1]

1. Institute for Planetary Matereials, Okayama University

Introduction: Recent geochemical studies revealed that serpentinites contain a significant amount of halogens. However, how halogen ions are incorporated into serpentinites is not well understood. Commonly assumed mechanism is "OH^- substitution" in serpentine group minerals (chrysotile, lizardite and antigorite). Although this mechanism will be fine for F, but may not be adequate for larger halogens (Cl, Br, I). Here, I propose new halogen incorporation mechanism in lizardite and antigorite from crystal chemical point of view.

Calculation methods: In order to assess present new incorporation model, first-principles calculation was conducted. Quantum-Espresso package was used to optimize the halogen incooporated model structures. In the present study, lizardite and antigorite (*m*=17 polysome) are considered. For our proposed mechanism, charge balance should be observed; so $Mg^{2+} = X^- + Al^{3+}$ substitution (X^- = halogen) is assumed to introduce halogen to a vacant site. For lizardite, enthalpy difference between two models (OH^- substitution and our model) was calculated for following equation: $Mg_2AlSi_2O_8XH_2 + H_2O = Mg_2AlSi_2O_9XH_4$. Former corresponds to the OH substituted model (with Al introduced), and latter corresponds to our new model. Although this comparison is crude (as free H_2O is included in the equation), it could provide systematic trend with kinds of halogen atoms. Since antigorite has a very large unit cell and many vacant sites, only $Mg^{2+} = Cl^- + Al^{3+}$ substitute in five vacant sites are considered so far.

Results and Discussion: From close inspection of crystal structures of lizardite and antigorite, vacant sites ideal for halogens are identified. The vacant sites are surrounded by four protons (of OH^-) forming elongated tetrahedon (i.e., XH_4^{3+}) if halogen is located. Such vacant sites provide local structure similar to halogen ions in aqueous solution.

In order to further assess present incorporation mechanism, first-principles calculations of lizardite and antigorite containing halogens in those sites were conducted. The structural optimizations confirmed that halogens could be well accommodated into the tetrahedral vacant sites in lizardite. The calculated enthalpy difference between OH substitution and present models in lizardite revealed that larger halogens prefer our model over the OH substitution model. There is sinlge vacant site in lizardite, but antigorite (*m*=17) has 17 crystallographically different vacant sites. Most sites have local structures more or less similar to that of lizardite (locating in 6-membered SiO_4 ring). But there is another kind of vacant site which is locating in 8-membered SiO_4 ring. This local structure is surrounded by six protons, but it can be regareded as two tetrahedral proton sites with edge sharing. Substitution of Cl^- to this site (one of tetrahedral sites) showed lower enthalpy compared to those of other lizardite-like sites, and can accept more larger ions. Therefore, Cl^- (and other larger halogens) will prefet this site in antigorite (*m*=17). Not all antogorite polysomes have this site.

Present study suggests that our new proposed incorporation mechanism is promising, and it should be further studied experimentally. Present new incorporation mechanism would be important to understand elemental partition behavior of halogens in subduction zones.

Mineralogical and geochemical characteristics of cuttings from Taketomi hot spring

*Noriyuki Shingaki[1], Tomohiro Toki[1], Syogo Oshima[2], Masaaki chinen[3], Arito Sakaguchi[4], Naoto Takahata[5], Yuji Sano[5], Shirai Kotaro[5], Kentaro Tanaka[5]

1. University of the Ryukyus , 2. West Japan Engineering Consultants, Inc., 3. MicroRange, 4. Faculty of Science, Yamaguchi University, 5. Atmosphere and Ocean Research Institute, The University of Tokyo

It is important to grasp carbon cycle on the earth’ s surface for thinking about global environmental change. A hot spring with a maximum temperature of 64℃ is venting with gas containing 70% of methane from several spots on the seafloor at depth of 22 m at 1 km northeast off Taketomi Island. Based on methane and helium isotope ratios in the venting gas, the influence of magmatic gas has been pointed out. In spite of Taketomi Island located on the trench side from island arc, magmatic gas is venting. It suggests the forearc where magma cannot generate, might form new supply path of carbon from the Earth’ s interior. The mass balance from new supply path of carbon may change estimation of carbon cycle on earth’ s surface. Therefore, the purpose of this study is to elucidate venting mechanism and quantitative grasp of magmatic gas from forearc, and the history of hot spring activities will be investigated to predict future activities.

In 2017, the hot spring was drilled up to depth of 940 m in Taketomi Island. The cuttings with muddy water were sampled every 10 m. The thin sections were prepared from cuttings to be observed using polarization microscope, and the chemical compositions of grains were analyzed by SEM-EDX. The ground samples were analyzed for mineral and chemical compositions by XRD and EDX. The clay minerals gathered by levitation were measured for half-value width of illite using XRD. He and CO_2 contained in samples that were crashed in vacuum were measured for isotope ratios by mass spectrometer. Calcite and dolomite collected from the cuttings were measured for the carbon and oxygen isotope ratios by mass spectrometer. The vitrinite in the cuttings was separated by a heavy liquid, and the reflectance was measured by a reflecting microscope.

In the microscopy, the stratum was roughly divided two formations; cryptocrystalline quartz layer and sand stone layer. Carbonaceous materials were observed in most of the stratum. Dolomite was limitedly observed in the vicinity of 800 m. In the XRD analysis, Quartz was detected at all depth. Calcite was detected at shallower depth than 30 m, and dolomite was detected only around 800 m. As a result of the EDX analysis, silicon was the most dominant in all layers, and especially, it was contained around 0-100 m, 300 m and around 900 m over 80%. There was a layer that contained much calcium. Around 0-30 m, 400-500 m and around 800 m, calcite was contained 15 % or more. The half-value width of illite was large, 0.8 $\Delta^\circ 2\theta$, in only 10 m surface, and as low as 0.2 to 0.4 $\Delta^\circ 2\theta$ below 50 m. Vitrinite reflectance was around 5% in the whole layer, close to measurement limit. The helium content was 10^{-14}-10^{-11} mol per 1g of cuttings, and tended to increase with increasing depth. The highest content was detected at 800 m depth. The helium isotope ratio($^3He/^4He$)have value of 0.4-3.6 times that of atmosphere, and tended to increase with increasing depth. Particularly, it was higher at 100 m, 300-400 m and 700-800 m. The CO_2 content per gram of cuttings, was in the range of 10^{-8}-10^{-6} mol in most layers, but it showed

©2019. Japan Geoscience Union. All Right Reserved.

higher values at 400 m and 800 m depth. the water tended to decrease with increasing depth, and showed especially high values at 400 m and 900 m. The carbon isotope ratio ($\delta^{13}C$) of calcite was -4.7‰ VPDB, and the oxygen isotope ratio ($\delta^{18}O$) is -16.3‰VPDB. The $\delta^{13}C$ value of dolomite was -1‰VPDB, and the $\delta^{18}O$ value was -10.9‰VPDB. The $\delta^{13}C$ value of CO_2 from cuttings at 800 m was -7.3‰VPDB, which contained sufficiently amount of carbon to measure carbon isotope ratio.

Variation of helium isotope compositions at Lake Mashu

*Takanori Kagoshima[1], Yuji Sano[1], Atsushi Tanaka[2]

1. Atmosphere and Ocean Research Institute, University of Tokyo, 2. National Institute for Environmental Studies

Helium-3 is one of the most sensitive geochemical tracers which reflects addition of mantle components to gas and fluids in volcanic hydrothermal systems, and $^{3}He/^{4}He$ ratios may be useful to assess temporal change of hydrothermal activity at volcanic lakes. Lake Mashu is a caldera lake which formed around 7000 years ago in Hokkaido. Igarashi et al. (1992) measured He and Ne isotopes in water of Lake Mashu, and concluded that the depth profile of isotopic compositions reflect injection of mantle-derived He due to hot spring activity at the lake bottom. After that, there is no subsequent study reporting He isotope data. The lack of observational data may be due to difficulty of water sampling at caldera lakes. Igarashi et al. (1992) collected water samples into copper tubes. However, this method requires heavy and large sampling tools, and people who can transfer water and seal the tubes properly. In May and September 2017, we investigated Lake Mashu in order to check volcanic activity and practical sampling methods for caldera lakes. We collected water using a Niskin bottle at several depths (surface to 210 m) around the deepest point (211 m). Collected water was immediately transferred into lead-glass containers with vacuum valves at both ends. In Atmosphere and Ocean Research Institute, dissolved gases were extracted by the head space method, and introduced into a purification vacuum line. In the line, He and Ne were purified for isotope analyses. $^{3}He/^{4}He$ and $^{4}He/^{20}Ne$ ratios were measured using Helix-SFT and QMS, respectively. The highest $^{3}He/^{4}He$ ratios were observed at 205-210 m depth, indicating that injection of fluids with the high $^{3}He/^{4}He$ ratio at the bottom. The linear correlation between $^{4}He/^{20}Ne$ and $^{3}He/^{20}Ne$ ratios in water samples indicated mixing of two components: injected fluids and the atmosphere. The estimated $^{3}He/^{4}He$ ratio of the fluid end member was indistinguishable from the value reported by Igarashi et al. (1992), implying a possibility that there was no significant change in volcanic activity at Lake Mashu in the past 30 years.

Graduate School of Fisheries and Environmental Sciences, Nagasaki University, Nagasaki, Japan

Noble gases are powerful tracers to study physical transport processes in aquatic system. Moreover, helium isotopes have been shown to be very useful to infer the origin of fluids. Shimabara Peninsula is located on western side of the Beppu-Shimabara graben in Kyushu, SW Japan. In the region, there are some hot springs and groundwaters which indicate magmatic helium with high 3He/4He ratio. Although some researchers report helium isotopic ratio on land, there is no data in the sea.

The surrounding bays around Shimabara Peninsula in Nagasaki were recently studied for the existence of hydrothermal springs and vents. Physico-chemical properties characteristic of hydrothermal activity were detected on the seafloor. For this study, we use helium isotopes to detect the occurrence of hydrothermal springs on the seafloor in both Tachibana Bay and Shimabara Bay. Samples were collected using a CTD-CMS system and analyzed using a Noble Gas Mass Spectrometer. Our data supplements the discovery of hydrothermal venting along known faults on the seafloor. We present the results of noble gas measurements conducted on water samples and discuss the relationship between our observations and the tectonic setup of the surrounding region.

[S-GC40] Volatile Cycles in the Deep Earth - from Subduction Zone to Hot Spot

convener:Hirochika Sumino(Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo), Takeshi Hanyu(Japan Agency for Marine-Earth Science and Technology, Department of Solid Earth Geochemistry), Yuji Sano(Division of Ocean and Earth Systems, Atmosphere and Ocean Research Institute, University of Tokyo), Gray E Bebout(Lehigh University), Chairperson:Takeshi Hanyu, Gray Bebout(Lehigh University), Yuji Sano, Hirochika Sumino

Volatiles play an important role in the geodynamics and chemical differentiation in the mantle and crust by drastically changing mineral stability and rheological behavior. Fractionation-processes such as partial melting, hydration, and dehydration are all controlled by volatiles in the rocks. A significant portion of the volatiles in the Earth has been thought to be present in the atmosphere and oceans as a consequence of extensive degassing during accretion and subsequent mantle degassing. On the other hand, it has been recently recognized that substantial amounts of volatiles are recycled back into the mantle at subduction zones, where intensive devolatilization of descended materials during arc magma generation was once thought to act as an effective "subduction barrier". However, fundamental questions still remain, such as: how are volatiles species distributed throughout the early and present Earth? What are the mechanisms for, and rate at which, volatiles are fluxed between the atmosphere, crust, and mantle? And what role have volatiles played in driving the evolution of the Earth? The possible role of the core in storing primordial volatiles is also poorly constrained. We therefore welcome contributions from experimental, observational, and modeling studies that help shed light on the deep cycles of volatiles, such as hydrogen, carbon, nitrogen, noble gases, halogens and sulfur. We particularly encourage studies linking the behavior of multiple volatile elements and their isotopic compositions. Studies investigating the linkage between volatile and solid geochemical tracers, the phase equilibria of volatile-bearing mantle assemblages, and the effect of volatiles on the physical properties of the mantle are also welcome.

Continental growth, crustal recycling, and global water cycle

*Jun Korenaga[1]

1. Department of Geology and Geophysics, Yale University

The evolution of continental crust provides first-order control on Earth’ s surface environment, but relevant studies on this important issue have long been in a confused state since 1990s. There are mainly two reasons for this situation. First, the volume of the global database of detrital zircons has been continuously growing in the last three decades, and as a result, the most of new crustal growth models have been built solely on such a zircon database. Zircons that have survived to the present day, however, do not constrain the amount of crust that has been lost to the mantle by subduction, so there is no way to reconstruct net crustal growth from zircon data. Second, this situation further deteriorated by two influential papers, Belousova et al. (2010) and Dhuime et al. (2012), with the former introducing an illogical method of using zircon age data to construct a growth model, and the latter claiming falsely that this method can actually reconstruct net crustal growth. The situation has recently been rescued by the development of a sensible method of utilizing zircon age data as well as a new geochemical box modeling of Nd isotope data. These new studies point to the possibility of rapid crustal growth and efficient crustal recycling in early Earth, and such crustal evolution is consistent with the operation of plate tectonics throughout Earth history. In particular, the secular evolution of crustal recycling, when considered jointly with the constancy of continental freeboard, indicates a novel connection between global water cycle and the stability of continental crust, which can naturally explain both the Hadean/Archean and Archean/Proterozoic transitions.

Role of volatiles in magma genesis of ascending mantle plume

*Eiichi Takahashi[1], Jintuan Wang[1], Li Li[1]

1. Guangzhou Institute of Geochemistry, Chinese Academy of Science

It is now widely accepted that recycled former oceanic crust component (eclogite) plays a great role in magma genesis of OIBs and flood basalts (Hauri, 1996; Takahashi et al, 1998; Sobolev et al, 2005). In this study we investigated the effect of H_2O and K_2O in magma genesis of heterogeneous mantle plume that contains large amount of recycled eclogite component. K_2O was studied as a group of volatile component, because it is incompatible to most mantle minerals at P<7 GPa (Tsuruta and Takahashi, 1998) and it drops the solidus of both peridotite and eclogite dramatically (Wang and Takahashi, 1999, 2000).

High-pressure melting experiments were carried out using a piston-cylinder and a 2500 ton cubic-type multi-anvil that have been moved from Tokyo Institute of Technology to Guangzhou Institute of Geochemistry in 2017. In order to understand the melting reaction between recycled eclogite and surrounding peridotite, we investigated melting of layered eclogite/peridotite starting materials both under dry and wet conditions. Spinel lherzolite KLB-1 (Takahashi 1986) was employed as peridotite component in this study. Two basalt components were used as recycled crust component: 1) Columbia River basalt (CRB72-180, Takahashi et al., 1998) which is relatively enriched in K, Ti and LREE (K_2O=1wt%, TiO_2=3.2wt%), N-type MORB (NAM-7, Yasuda et al., 1994). The 2.9GPa experiments (corresponding to about 80km depth which is the top most horizon of the Hawaiian plume head) were carried out with Boyd-England type piston-cylinder apparatus at (1460~1540˚C for dry experiments; 1400~1500˚C for hydrous experiments), The 5GPa and 8 GPa experiments (corresponding to about 150km and 200km depth on the plume axis) were conducted cubic-type multi-anvil apparatus (1550~1650˚C for dry experiments; 1350~1550˚C for hydrous experiments).

Melts formed by reactive melting of dry eclogite and peridotite changes dramatically in the temperature range across the solidus of peridotite KLB-1 from basalt (below dry solidus) to picrite (20-40˚C above dry solidus). Basaltic melts are not saturated with olivine both at 2.9 and 5 GPa and therefore they are separated by peridotite matrix by Opx film. Chemical reaction between the basalt melt and the peridotite matrix proceeds only slowly by solid-diffusion across the Opx film. In hydrous experiments, solidus of peridotite decreases significantly, Opx film was not formed, therefore, the reaction between hydrous melt and the partially molten peridotite matrix proceeds significantly even at temperatures much below peridotite dry solidus.

Melt composition produced by reactive melting of dry basalt and peridotite are similar to basaltic andesite (below peridotite solidus), Hawaiian tholeiite (slightly below peridotite solidus) to picrite (above peridotite dry solidus). On the other hand, melt compositions formed by reactive melting between hydrous basalt and peridotite show a great diversity depending on the amount of H_2O and K_2O. At H_2O-rich conditions (3 to 5 wt.% in bulk), melting took place both in peridotite and eclogite layers and composition of partial melts are similar to silica-deficient basanite and nephelinite at temperatures 1300-1400˚C both at 3 and 5 GPa. At low H_2O conditions (1 wt.% in bulk) partial melts formed in the MORB layer at 1300˚C are similar to silica-rich dacite both at 3 and 5 GPa. On the other hand, partial melts formed in the CRB72-180 layer with 1 wt.% H_2O at 3 and 5 GPa are similar to K-rich alkali acidic magma (phonolite, tracyte, hawaiite).

©2019. Japan Geoscience Union. All Right Reserved.

Post shield stage phonolite and hawaiite magmas in Hawaii were considered to be fractionation product of alkali basalts under crustal magma chambers (e.g., Frey et al, 1990). However, our experimental results demonstrated an alternative scenario that phonolite and hawaiite magma were derived from partial melting of alkali basaltic blocks at deeper part (150-200km) of the plume. On the other hand, basanite and nephelinite which appears in rejuvenated stage in Oahu and Kawai may represent partial melts of peridotite portion of the plume beneath Pacific plate. Volatiles control the solidus and the depth of melting as well as enhancing chemical interaction between the peridotite and entrained eclogite component in the ascending plume. In this presentation, we discuss the role of volatile and K_2O in magma genesis in ascending plume based on our melting experiments and field occurrence of diverse magma types both geographically and in growth history of given shield volcanoes in Hawaii.

DH partitioning experiment among high-pressure polymorph of olivine

*Asami Sano-Furukawa[1], Shoichi Itoh[2], Toru Inoue[3], Masamichi Noda[3]

1. J-PARC center, Japan Atomic Energy Agency, 2. Kyoto University, 3. Hiroshima University

Mantle is known to have homogeneous hydrogen isotope composition with δD = -80 ~ -60 ‰based on the analysis of MORB and OIB [1, 2]. The reason of the depletion of deuterium compared to the present ocean has been explained by the existence of isolated primordial reservoir in the mantle [1], evolution by the subduction of deuterium-poor hydrous mineral through the geological timescale [3], and addition of cometary water after the formation of ocean [4]. Hydrogen isotope partitioning factor among minerals is a key in these discussions, but little is known under high pressure and high temperature of mantle conditions. In this study we focused on DH partitioning between olivine and wadsleyite, which is a main constituent of upper mantle and mantle transition zone (MTZ). High pressure experiments suggest that wadsleyite and its high pressure polymorph of ringwoodite can contain significant amount of water up to 3.3 wt.% thus MTZ has an ability to keep water up to several times of ocean [5]. Finding of Ringwoodite with 1.4 wt.% H_2O in a diamond inclusion also reveals hydrated MTZ at least locally [6].

The partitioning experiment was conducted using Kawai-type multianvil press at GRC, Ehime University. Powder of $Mg(OH)_2$ and $Mg(OD)_2$ was mixed with synthetic olivine so that the starting composition is equivalent to $Mg_{1.8}Fe_{0.2}SiO_4$ + 1.0 wt.% HDO. The sample was sealed in the Au75Pd25 capsule and kept at 1300 ˚C and around 13 GPa, which is the condition of olivine and wadsleyite coexist. The recovered sample was polished and analyzed by micro-focused X-ray diffractometer, Raman spectroscopy and EPMA. Hydrogen isotope composition was determined using SIMS at Kyoto University.

To test for equilibrium, partitioning experiments are made with changing duration times from 1 h to 72 h. The fractionation factor decreases with increasing of duration time. After keeping for 30 h, $1000\ln\alpha_{\text{Olivine-Wadsleyite}}$ seems to reach almost equilibrium around -60 ‰. Assuming that the δD of olivine of upper mantle to -80, the δD of wadsleyite at MTZ become -20 to 0, which is more comparable to the composition of the ocean. The present result shows that the depletion of deuterium of upper mantle can be explained as a result of DH fractionation between upper mantle and MTZ.

Inclusions in deep diamonds provide a window to the actual deep mantle processes. The observation of hydrous ringwoodite with ~1 wt.% H_2O as a diamond inclusion indicates the transition zone is, at least locally, very wet [1]. Furthermore, the recent discovery of Ice-VII and halite inclusions at pressures as high as 24 GPa in diamonds provides direct evidence for the existence of saline fluid at least down to the shallow lower mantle [2]. To understand the interaction of water and Cl with the Fe-bearing lower mantle, we performed experiments to simulate the behavior of volatile-bearing systems in laser-heated diamond anvil cells (DACs) under high pressure-temperature (*P-T*) conditions corresponding to the deep lower mantle. The phase assemblages were determined by a combination of *in-situ* synchrotron-based X-ray diffraction (XRD) and *ex situ* transmission electron microscope (TEM) analysis. In the system MgO-Al_2O_3-Fe_2O_3-SiO_2-H_2O containing ~7 wt.% water, the hydrous Fe-bearing δ-phase coexists with both bridgmanite (Bdg) and post-perovskite (pPv) in a broad *P-T* range of 104-126 GPa and 1900-2500 K, whereas the pyrite-type (py) FeOOH phase was observed coexisting with the pPv phase. *In situ* XRD data further revealed that saline fluid reacts with Fe-bearing pPv to form a previously unknown cubic phase of $FeCl_2$ that adopts the identical space group of *Pa3* with the py-phase FeOOH. The TEM chemical analysis revealed that the composition of the pPv phase contains 3.5 wt.% Na_2O and 16.5 wt.% FeO after the reaction with the oversaturated saline fluid. Formation of the very dense Fe-rich volatile-bearing phases in the lowermost mantle provides clues for the deep storage of water and Cl and may contribute to the chemical heterogeneities in this region.

Ocean island basalts (OIB) are thought to bring information concerning geochemistry and material cycling of the deep mantle. For this reason, OIB have been studied extensively, among which Pitcairn Island in the South Pacific is regarded as a unique and important location as a hotspot volcano. Previous studies reported that the lavas in Pitcairn involve multiple components from DM (depleted mantle) to EM1 (enriched mantle) (Woodhead & McCulloch, 1989), of which EM1 component has been argued to originate from recycling oceanic plate, delaminated lower crust, continental marine sediment and others (Eisele et al., 2002; Garapic et al., 2015). The mechanism to produce the specific isotopic composition of EM1 is still under extensive debate.

We analyzed concentrations of major elements, volatile elements (CO_2, H_2O, F, S, and Cl), and trace elements, as well as lead isotopic ratios, by using SIMS, EPMA and LA - ICP - MS for melt inclusions contained in olivine from basalt and pyroclastic rock in Pitcairn Island. Melt inclusions are thought to retain the volatile elements without losing them upon eruption, which is suitable for discussing the origin of the EM1 component. In this study, four lavas (PC-2, PC-16, PC-38, and PC-40) and a pyroclastic rock collected from the Tedside formation of Pitcairn Island were analyzed. The whole-rock composition of these lavas show EM1 signatures. Melt inclusions in olivine are crystallized, but those of pyroclastic rock are all glassy and homogeneous as they are. The crystalized melt inclusion samples from the four lavas were homogenized at the individual liquidus temperatures (1150 degrees and 1175 degrees). A small amount of H2O loss was found for 10 min heating for homogenization, by comparing the analyses of both melt inclusion with/without reheating of the pyroclastic rock samples. On the other hand, virtually no effect was seen for F and Cl.

Multivariate statistical analysis is useful to extract the geochemical features from these data set. McKenzie et al. (2004) identified the coherence between the trace element concentrations and the isotopic ratios, and argued that such coherence must indicate multiple sources of different origin. Instead of Principal Component Analysis (PCA) as used by McKenzie et al. (2004), we utilize Independent Component Analysis (ICA) to extract geochemically independent features. At the same time, we also performed k-means cluster analysis on the whitened data set (Iwamori et al., 2017) to clarify the multiple sources hidden in the lavas from a small area within the Pitcairn Island. In this paper, we will present the results of the geochemical analyses and statistical analyses to identify and discuss the nature of the sources involved in the Pitcairn volcanism.

[S-GC40] Volatile Cycles in the Deep Earth - from Subduction Zone to Hot Spot

convener:Hirochika Sumino(Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo), Takeshi Hanyu(Japan Agency for Marine-Earth Science and Technology, Department of Solid Earth Geochemistry), Yuji Sano(Division of Ocean and Earth Systems, Atmosphere and Ocean Research Institute, University of Tokyo), Gray E Bebout(Lehigh University), Chairperson:Takeshi Hanyu, Gray Bebout(Lehigh University), Yuji Sano, Hirochika Sumino

Volatiles play an important role in the geodynamics and chemical differentiation in the mantle and crust by drastically changing mineral stability and rheological behavior. Fractionation-processes such as partial melting, hydration, and dehydration are all controlled by volatiles in the rocks. A significant portion of the volatiles in the Earth has been thought to be present in the atmosphere and oceans as a consequence of extensive degassing during accretion and subsequent mantle degassing. On the other hand, it has been recently recognized that substantial amounts of volatiles are recycled back into the mantle at subduction zones, where intensive devolatilization of descended materials during arc magma generation was once thought to act as an effective "subduction barrier". However, fundamental questions still remain, such as: how are volatiles species distributed throughout the early and present Earth? What are the mechanisms for, and rate at which, volatiles are fluxed between the atmosphere, crust, and mantle? And what role have volatiles played in driving the evolution of the Earth? The possible role of the core in storing primordial volatiles is also poorly constrained. We therefore welcome contributions from experimental, observational, and modeling studies that help shed light on the deep cycles of volatiles, such as hydrogen, carbon, nitrogen, noble gases, halogens and sulfur. We particularly encourage studies linking the behavior of multiple volatile elements and their isotopic compositions. Studies investigating the linkage between volatile and solid geochemical tracers, the phase equilibria of volatile-bearing mantle assemblages, and the effect of volatiles on the physical properties of the mantle are also welcome.

Interactions between the Earth’ s mantle and the surface have controlled the evolution of the crust, the oceans, and the atmosphere. The mantle is by many orders of magnitude the largest silicate reservoir for volatiles, and volcanic release of these species has played a major role throughout Earth history in global chemical cycles. Understanding the distribution and geochemical evolution of volatiles in the terrestrial mantle is therefore central to understanding the unique planetary history of Earth. The input and output of volatiles at plate boundaries provides major controls on the cycles of many important elements and exerts long-term controls on habitibale conditions at the surface.

Noble gases have provided key insight into the processes controlling the mantle system. Primordial heavy noble gases in the MORB-source mantle are accompanied by atmosphere noble gases with an elemental composition consistent with subduction of an ocean/pore-fluid signature into the mantle (1). Pore fluid subduction represents an important opportunity to use halogens, in particualr iodine which is highly enriched in marine pore fluids, in conjunction with noble gases as sensitive tracers of water and volatile enrichment processes in the mantle.

To assess the control of subduction zones on the mantle halogen budget we have investigated basaltic glass samples from the Manus Back-Arc Basin as some of the volatiles may survive forearc to subarc devolatilization to depths beyond arcs/back-arcs and contribute to the long term volatile budget of the mantle. We also investigated two sets of samples: one from the Central Indian Ridge (2) containing D(epleted)-MORB, N(ormal)-MORB and E(nriched)-MORB and one from the Siqueiros Transform Fault (STF) known for sampling the depleted upper mantle (3). In contrast to axial MORB, lavas from STF are tapping smaller mantle melt without mixing in large magmatic chambers. These melts provide better estimates of the volatile contents of the potential mantle sources.

Based on new halogen determinations, we show that the volatile budget in the mantle sampled by the mid oceanic ridge basalts is a mixture between the depleted upper mantle and a fluid-modified mantle enriched during its residency in subduction zone. This enables us to revisit the global halogen budget and assess how subduction of halogens has affected the habitability of our planet.

Volatile composition in ocean island basalts

*Takeshi Hanyu[1]

1. Japan Agency for Marine-Earth Science and Technology, Department of Solid Earth Geochemistry

Volatile reservoirs and transport mechanisms in the mantle are one of fundamental questions in mantle geochemistry. The atmosphere and hydrosphere are major volatile reservoirs in the Earth. Portions of volatiles in the surface layers can be incorporated into oceanic crust and sediment by fluidal reaction and organic and inorganic sedimentation, and then they are delivered to the mantle via slab subduction. However, the efficiency of volatile transport against subduction barrier is poorly constrained. Studies of volatiles in ocean island basalts (OIBs) should document the origin and distribution of volatiles in the deep mantle. This presentation provides an overview of previous studies of volatiles on OIBs using submarine quenched glasses and olivine-hosted melt inclusions.

Whether the mantle source of OIBs is enriched in H_2O is measured by taking H_2O/Ce ratio, where Ce is a lithophile element that has similar incompatibility to H_2O during partial melting. While many OIBs exhibit H_2O/Ce that overlap with the MORB range, OIBs with robust EM1, EM2, and HIMU signatures have significantly lower H_2O/Ce. The fact that H_2O/Ce decreases proportionately with increasing $^{87}Sr/^{86}Sr$ for Pitcairn, Kerguelen (EM1), and Society (EM2), and with decreasing $^{207}Pb/^{206}Pb$ for Tuvalu (HIMU) documents that the mantle components with robust EM1, EM2, and HIMU signatures are commonly depleted in H_2O relative to Ce [1-3]. If their precursor was any type of subducted material, fluid or hydrous melt extraction from the subducted slab reasonably explains the low H_2O/Ce. However, an alternative explanation is a contribution from pyroxenite components in the magma sources, where Ce is more efficiently partitioned into pyroxene than H [4].

Enrichment in F (i.e., F/Nd) in the EM1 and EM2 OIBs from Pitcairn and Samoa is equivocal [2,5]. In contrast, melt inclusions from Mangaia HIMU basalts have high F/Nd (~30) as a group relative to the average MORB value (~21) [1,6], which is best explained by the efficient transfer of F to the mantle by F-bearing minerals such as amphibole, serpentinite, mica, and clinohumite in subducted slabs [7]. Detecting Cl enrichment is not always straightforward because shallow-level magma assimilation with seawater, brines, and altered oceanic crust easily alter the Cl composition [8]. Submarine glasses from Pitcairn and Society exhibit decreasing Cl/K with increasing $^{87}Sr/^{86}Sr$ [2]. Such covariation precludes assimilation as the principal cause of Cl/K variation, and therefore low Cl/K is the source feature of EM1 and EM2. Chlorine loss from subducted components due to fluid release or hydrous melt extraction accounts for low Cl/K. In contrast, HIMU OIBs show increase of Cl/K and Cl/Nb along with decreasing $^{207}Pb/^{206}Pb$ (more robust HIMU signature from ancient altered oceanic crust) as observed in olivine-hosted melt inclusions in Raivavae basalts from Austral Islands [9]. Because such correlation is not ascribed to shallow-level assimilation, this fact requires a mechanism to return Cl from the hydrosphere to the HIMU mantle source via altered oceanic crust against subduction dehydration. Although Cl-hosting minerals beyond the sub-arc depth have not been thus far identified, the lattice defects in major minerals or mineral grain boundaries may be a carrier of small amounts of Cl in subducted oceanic crust. Subduction of altered oceanic crust would transfer Cl from seawater to the deep mantle, forming Cl-rich HIMU mantle reservoir in the deep mantle.

Halogen heterogeneity in the subcontinental lithospheric mantle

*Hirochika Sumino[1], Masahiro Kobayashi[2], Ray Burgess[3], Chris J Ballentine[4]

1. Department of Basic Science, Graduate School of Arts and Sciences, University of Tokyo, 2. Tokyo Metropolitan Industrial Technology Research Institute, 3. School of Earth and Environmental Sciences, University of Manchester, 4. Department of Earth Sciences, University of Oxford

Volatile recycling back to the Earth’ s mantle at subduction zones has a significant, yet poorly constrained impact to the volatile budget in the mantle. Halogen and noble gas systematics are powerful tracers of volatile recycling. The presence of noble gases and halogens with seawater and sedimentary pore-fluid signatures in exhumed mantle wedge peridotites from the Sanbagawa-metamorphic belt, southwest Japan [1], and in forearc serpentinites [2] along with seawater-like heavy noble gases (Ar, Kr, and Xe) in the convecting mantle [3] strongly suggest the subduction of sedimentary-pore-fluid-like noble gases and halogens. In order to better constrain how such subduction fluids may modify the halogen composition of subcontinental lithospheric mantle, we have analyzed halogens in mantle-derived xenoliths from volcanic front and back-arc regions of subduction zones, and intraplate continental settings.

In addition to a MORB-like halogen component observed in most of the samples, three other distinct components were identified: (A) a marine-pore-fluid-like component with high Br/Cl and I/Cl ratios similar to mantle wedge peridotites [1], (B) a Cl-enriched component relative to MORB, similar to bulk altered oceanic crust [4]; and (C) a component enriched in Br and moderately in I compared to MORB, which resembles to fluid components in altered oceanic crust and diamonds [4,5].

The component (A) is typically observed in the volcanic front samples containing abundant H_2O-rich fluid inclusions. This suggests that marine pore fluids in deep-sea sediments are carried by serpentine and supplied to the mantle wedge, preserving their original halogen and noble gas compositions. However, the measured Cl/H_2O and $^{36}Ar/H_2O$ in the peridotites are higher than those in sedimentary pore fluids and serpentine in oceanic plates [2]. The halogen/noble gas/H_2O systematics are interpreted within a model where water is incorporated into serpentine in a closed system formed along fracture zones developed at the outer rise, where oceanic plates bend prior to entering subduction zones, preserving Cl/H_2O and $^{36}Ar/H_2O$ values of sedimentary pore fluids. Dehydration-hydration process within the oceanic lithospheric mantle maintains the closed system until the final stage of serpentine dehydration. The sedimentary pore fluid-like halogen and noble gas signatures in fluids released at the final stage of serpentine dehydration are preserved due to highly channelized flow [6].

The samples involving the component (B) have higher Cl concentration and trace elements ratios, whereas the samples involving the component (C) have relatively low Cl concentration and low ratios of highly incompatible elements relative to heavy rare earth elements. Considering that these two components are observed in some back-arc samples having radiogenic/nucleogenic noble gases [7], they could be remnants of metasomatic agents derived from subducted altered oceanic crust, or could result from secondary processes of volatile loss during partial melting and secondary phase formation during interaction with melts [8].

The common primary MORB-like halogen ratios in mantle xenoliths from different parts of the globe indicate that the mantle itself must have a relatively uniform composition over a wide scale. The mantle has maintained its halogen composition over billion year timescales without being affected by I-rich

©2019. Japan Geoscience Union. All Right Reserved.

halogens being transported into the mantle. Mass balance calculations suggest that, in order to maintain the I/Cl ratio of the convecting mantle over 2 Gyr, the I/Cl ratio of the subducted halogens must be no more than several times higher than the present-day mantle value [8].

Efficiency of Deep Carbon Subduction: Input, Metamorphic Records, and Bearing on Estimated Sources of Arc Volcanic Gases

Circum-Pacific and Italian Alps high- and ultrahigh-pressure metasedimentary rocks record the subduction of organic (reduced) and carbonate (oxidized) C through forearcs (10-70 km) to depths approaching those beneath volcanic fronts. Still uncertain are the efficiency of delivery of such sections to subarc depths, as related to varying degrees of accretion and underplating, the mobilization of C during prograde metamorphism and fluid-rock interactions, and the fractions of C recycled in arcs, stored in forearc reservoirs (e.g., the mantle wedge), or added to the deeper mantle.

Franciscan Complex (FC) blueschist-facies rocks, and lower-grade units (lawsonite-albite and lawsonite-blueschist) of the carbonate-poor Catalina Schist (CS), preserve reduced C (RC) concentrations and $\delta^{13}C$, and C:N, similar to those of sediment protoliths, as does the lowest-grade unit of the Schistes Lustres (SL) exposed in the Alps (regardless of carbonate content). In CS units that experienced warmer prograde *P-T* paths (epidote-blueschist grade and higher), RC is shifted in $\delta^{13}C_{VPDB}$ from -25 per mil to as high as -19 per mil, seemingly related to minor loss of C as CH_4 during prograde devolatilization. The higher-grade units of the SL extend, to depths of ~70km, the extremely low-*P/T* trajectory represented by the FC and low-grade CS. Across this range of grade, RC shows little evidence of loss but considerable increase in $\delta^{13}C$ toward mantle values (-5 to -6 per mil) related to isotopic exchange with coexisting carbonate. In SL metashales, RC preserves protolith $\delta^{13}C$ of -24 to -21 per mil independent of grade and degrees of devolatilization. Reduced C occurs as amorphous carbonaceous matter at low grades, and its transformation to graphite at higher grades presumably enhances isotopic exchange with carbonate. This work implies that much of the RC reservoir is retained to depths beneath volcanic fronts and could be available for transfer into the sub-arc mantle wedge, likely via partial melting (K. Kraft, Lehigh Univ. M.S. thesis, 2018).

The blueschist to eclogite facies SL contains carbonate-rich flysch formed prior to and during Eocene subduction of the Piemonte-Liguria Ocean and underplated at 40-70 km depths. We analyzed $\delta^{13}C$ and $\delta^{18}O$ of carbonate in this unit, over a regional scale, and made field and petrographic observations bearing on mechanisms of C mobilization. A study of decarbonation history by Cook-Kollars et al. (2014) for the same suite demonstrated that, depending on extents of open-system infiltration by H_2O-rich fluid, large fractions of initially subducted carbonate could be retained in such rocks to at least 70 km depths. Assessing the magnitude of removal of carbonate via dissolution, at the whole-unit scale, has proven difficult. Isotopic exchange between the reduced and oxidized C reservoirs, and any fractionation during sub-arc mobilization and delivery into the mantle wedge, would have implications for the approach of Sano and Marty (1995) used to estimate proportions of gas from mantle and disparate sediment sources.

Study of along-margin C input flux at the Sunda margin (House et al., 2016; Fall AGU) emphasizes the role of sediment composition, source, and degree of accretion on the nature and size of the deeply subducted C reservoir. Ongoing NSF-funded work on the Hikurangi margin, New Zealand (collaborative with Bruce Christenson-GNS-NZ, Hirochika Sumino-Univ. Tokyo, and Ikuko Wada-Univ. Minnesota), is aimed at resolving C inputs vs. outputs in arc volcanoes and associated hydrothermal systems, in part considering the makeup of the incoming sediment section (based on drilling by IODP Exp. 375), extents of accretion,

©2019. Japan Geoscience Union. All Right Reserved.

along-margin thermal structure, and calculated extents of devolatilization. Studies of the Schistes Lustrés and other HP and UHP suites provide insight regarding the structural and geochemical evolution of sediments similar in composition to those subducting at modern margins (e.g., Sunda).

Helium isotope variations in subduction-type volcanic hydrothermal systems

*Yuji Sano[1], Takanori Kagoshima[1], Naoto Takahata[1], Tetsuji Onoue[2], Tomo Shibata[3], Tobias P Fischer[4]

1. Division of Ocean and Earth Systems, Atmosphere and Ocean Research Institute, University of Tokyo, 2. Department of Earth and Environmental Sciences, Kumamoto University, 3. Institute for Geothermal Sciences, Kyoto University, 4. Department of Earth and Planetary Sciences, University of New Mexico

Large variations of $^{3}He/^{4}He$ ratios of gas and fluid samples were observed in subduction-type modern hydrothermal systems (0.3Ra −8Ra where Ra is the atmospheric ratio of $1.38x10^{-6}$) compared with those of mid-ocean ridge basalt (MORB) glasses (7.5Ra −9.5Ra). These variations are principally attributable to binary mixing of two components: mantle He (8Ra) and crustal helium (0.1Ra). Major source of the latter component could be due to radiogenic helium in the subsurface crustal material. Thus, shallow assimilation would result in helium isotope variations around an isolated volcano. Early case study on the Ontake volcanic hydrothermal system showed that high-Ra was located in hot spring close to the central cone and decreased with distance from the volcano. Subsequent studies around Mt Nevado del Ruiz and Mt Kusatsu-Shirane confirmed the negative correlation between the $^{3}He/^{4}He$ ratio and the distance. There may be three necessary conditions to produce such a tendency. First, the volcano is independent strato-type and there is no other volcano close to the subject. Second, the magma chamber is located just beneath the volcano so that the conduit is not inclined significantly. Third, the hydrothermal system is well developed and the emission of mantle helium is stable for a long time. In order to apply these hypothetical conditions to a caldera volcano, we have carried out helium isotope survey around Aso volcano in Southwest Japan. Mt Aso is the largest active volcano in Japan with a caldera 25 km north-south and 18 km east-west. Post caldera activity is currently observed in central cone at Mt Nakadake. We have collected hot spring gas and fluid samples within the Aso caldera together with the outside and measured $^{3}He/^{4}He$ and $^{4}He/^{20}Ne$ ratios by a noble gas mass spectrometer. The helium isotopes, after correction of air contribution, decrease with the distance from the central cone in the region. The tendency is consistent with those of strato-volcanoes reported in literatures.

Experimental and Simulation Study on the Migration Rule of Arsenic in the Soil of Surface Karst Zone in Southwest China

*bin zeng[1]

1. China University of Geosciences

Karst Underground River is an important water source in southwest China. In addition to entering and polluting the groundwater directly through the sinkholes, arsenic pollutants produced from the industrial production process will also adsorb, remain, and concentrate in the dissolution cracks and gaps in the surface karst zone, and remigrate under certain conditions to become a "secondary pollution source". Taking an arsenic pollution event in Guangxi province as an example, the dynamic adsorption and desorption experiments of arsenic were carried out by using narrow slot physical model device, and the migration rule of arsenic contamination in the soil of surface karst zone was studied, combined with geochemical simulation. The experimental results show that the adsorption of arsenic in the surface karst zone is mainly physical adsorption (diffusion process), and the desorption rate is slow compared with the adsorption process, while the acid solution can promote the desorption process of arsenic compared with deionized water. The results of geochemical simulation show that goethite contributes most to arsenic adsorption in soil minerals, while acid solution weakens the ability of arsenic adsorption by corroding goethite and other minerals. It is concluded that in the karst area of southwest China, once the surface karst zone system is integrated with arsenic pollutants, the desorption process is slow, and it is easy to form the retention and enrichment of arsenic pollutants; while the accelerated desorption and migration process of arsenic under acid rain will increase the pollution risk of groundwater system.

H_2 production and CO_2 storage during peridotite serpentinization under CO_2-rich hydrothermal conditions: Influence of pyroxene

*Jiajie Wang[1], Noriaki Watanabe[1], Atsushi Okamoto[1], Kengo Nakamura[1], Takeshi Komai[1]

1. Tohoku Univ.

Serpentinization of peridotite (mainly includes olivine and pyroxene) usually produces molecular H_2, which may potentially contribute to today’s always-increasing energy demands. On the other hand, peridotite also appears to be a good candidate for CO_2 sequestration by mineralization. Based on this, our previous research has successfully combined the strategies of H_2 production and CO_2 mineralization by olivine alteration in CO_2-rich hydrothermal system. However, olivine may not necessarily act as a peridotite equivalent during alteration, and the pyroxene influence is still poorly understood.
In this study, we examined the reactions in H_2O-olivine/pyroxene-CO_2 systems by performing hydrothermal experiments in 0.5 mol/L $NaHCO_3$ solutions under conditions of 300 °C and 10 MPa. The results show that H_2 was produced when olivine and/or pyroxene reacted in $NaHCO_3$ solution, and the presence of pyroxene in starting material suppressed H_2 production from per kg of mineral. Pyroxene was converted solely to serpentine, rather than brucite and magnesite even in CO_2-contained solutions, which indicates CO_2 mineralization was only realized in olivine-contained systems. In addition, the pyroxene serpentinization process is quicker than olivine. In the experiment with olivine/pyroxene weight ratio of 3/2, all of the pyroxene was altered after 72 h reaction, whereas half of the olivine particles have remained. Based on experimental results, we propose that the presence of pyroxene in starting material will suppress the H_2 production and CO_2 storage during peridotite alteration; however, the inhibition effect will be decreased along the reaction time.

Age determination of spherical carbonate concretions by Sr isotope stratigraphy

*Yoshihiro Asahara[1], Hidekazu Yoshida[2], Koshi Yamamoto[1], Nagayoshi Katsuta[3], Masayo Minami[4], Richard Metcalfe[5]

1. Graduate School of Environmental Studies, Nagoya University, 2. Material Research Section, Nagoya University, University Museum, 3. Faculty of Education, Gifu University, 4. Institute for Space-Earth Environmental Research, Nagoya University, 5. Quintessa UK

Isolated spherical carbonate ($CaCO_3$) concretions are frequently observed in marine clayey sediments but do not always contain index fossils. Although carbonate concretions with fossil inside can be used to estimate sedimentation ages, concretions without fossils inside have never previously been used for age determination. In this study, we used $^{87}Sr/^{86}Sr$ ratios to determine the ages of these spherical concretions.

The studied concretions formed in the Yatsuo Group of Miocene age in central Japan. Some formed post-mortem around tusk-shells (*Fissidentalium*spp.), while other concretions have no shell fossils inside. The concretions formed under highly constrained conditions by reactions between the decay products of organic matter and Ca^{2+} from the marine water (Yoshida et al., 2015; 2018). And the sedimentary structure around the concretions and geochemical analyses reveal that Sr was incorporated into the $CaCO_3$ concretions during their rapid formation.

The $^{87}Sr/^{86}Sr$ ratios of calcite in the tusk-shell concretions lie within 0.70865~0.70867 and vary little. The values are similar to those of tusk-shell aragonite, 0.70865~0.70868. In addition, the isolated carbonate concretions without shell fossils have $^{87}Sr/^{86}Sr$ ratios of 0.70865~0.70868, which are also well consistent with the tusk-shell aragonite values. Based on the Sr isotope stratigraphy (McArthur et al., 2001) and the measured $^{87}Sr/^{86}Sr$ values, the age of the tusk-shell concretions lies within a narrow range of 17.08 (+0.27, −0.28) Ma. The age determined from the $^{87}Sr/^{86}Sr$ of the tusk-shells themselves (16.86 +/− 0.34 Ma) is almost the same. The age determined from the $^{87}Sr/^{86}Sr$ of concretions without fossils, 16.95 (+0.36, −0.37) Ma, is almost the same as that of the tusk-shell concretions. Strontium isotopic stratigraphy using $^{87}Sr/^{86}Sr$ ratios of all concretions with tusk-shell and without fossils indicates an age of 17.02 +/− 0.27 Ma, with higher accuracy than the ages estimated using microfossils from the Yatsuo Group. The results imply that the $^{87}Sr/^{86}Sr$ ratio of isolated spherical carbonate concretions can be applied generally to estimate the ages of all kinds of spherical concretions in marine sediments (Yoshida et al., 2019).

Origin of mantle xenoliths from Kaula Island, Hawaii:Constrains from Os isotope and highly siderophile element compositions

*Ryo Fujita[1], Akira Ishikawa[1], Tetsuya Yokoyama[1], Michael O Garcia[2]

1. Tokyo Institute of Technology, 2. University of Hawaii

The Emperor Seamount-Hawaiian island chain is thought to originate from melting of a heterogeneous mantle plume, although the nature and extent of heterogeneity remain unclear. It has been suggested that some Hawaiian mantle xenoliths with highly unradiogenic Os isotope ratios (down to 187Os/188Os=0.1138) represent the depleted part of ascending Hawaiian plume, and that the depleted materials are more commonly distributed in mantle plumes than has been inferred from the compositions of erupted lavas. To better understand the lithological and geochemical variations of Hawaiian xenoliths and to evaluate the robustness of the above model, we conducted petrological and geochemical studies on 11 peridotite xenoliths (9 lherzolites, 1 dunite, and 1 wehlrite) collected from the island of Kaula, Hawaii. Here we present the results on the whole-rock Re-Os isotope systematics and highly siderophile element compositions in the xenoliths, together with the major element compositions of constituent minerals (olivine, clinopyroxene, orthopyroxene and spinel). The rock texture and mineral compositions indicate that the Kaula peridotites are samples from normal oceanic mantle and residues of variable degrees of melting. However, they have highly unradiogenic Os isotope ratios (down to 187Os/188Os=0.1187) yielding minimum rhenium-depletion ages of up to ~1.3 Ga, which are similar to those of O’ahu peridotites. Such unradiogenic Os isotopic compositions are not found in Hawaiian lavas and in depleted mantles (e.g., mid-oceanic ridge basalts). Importantly, as is observed in the O’ahu peridotites, the 187Os/188Os ratios of Kaula peridotites correlate with the degree of depletion, suggesting that they are related to an ancient melting event. Therefore, the Kaula peridotites are possibly the fragments of a Hawaiian mantle plume that consists of ancient depleted and recycled mantle lithosphere.

Petrological and Geochemical features of Miocene adakitic volcanic rocks in eastern part of Hokuriku region, SW Japan

*Watanabe Syun[1], Toshiro Takahashi[1]

1. Niigata university

Miocene volcanic rocks are widely distribution from the eastern part of Toyama prefecture to the northern part of Fukui prefecture in Hokuriku region, Central Japan. These volcanic rocks are broadly classified in to mafic volcanic rocks and felsic volcanic rocks, and in this study the petrological and geochemical features of mafic volcanic rocks are considered. Mafic volcanic rocks of the Hokuriku region consists of various types that have characteristic petrologic and geochemical features; tholeiitic volcanic rocks, calc-alkaline volcanic rocks, high-magnesia andesite and adakitic andesite (Takahashi and Shuto, 1999; Ishiwatari and Ohama, 1997).

The present study area is in the eastern part of the Miocene volcanic rocks. Volcanic rocks of this study area can be classified into four groups; Group-1 basalts, bulk rock chemical composition of group-1 indicate low SiO_2 (<53 wt %) composition and Nd and Ta depletion. Group-2 tholeiitic andesites, bulk rock chemical composition of group-2 indicate increasing FeO*/MgO ratio with increasing SiO_2. Group-3 calc-alkaline andesites, bulk rock chemical composition of group-3 indicate stable FeO*/MgO ratio with increasing SiO_2. Group-4 Hornblende-bearing andesites, Bulk rock chemical composition of group-4 indicate low FeO*/MgO ratio, high Sr, MgO, Cr, Ni concentration and low LILE and HFSE concentration. All types of volcanic rocks are distributed in Iwaine formation except in Fukuhira formation, only group-1 and group-2 are distributed.

The volcanic rocks of this study area can be classified two types by their isotopic features. First type have nearly bulk earth isotopic composition (SrI=0.7040-0.7060, NdI=0.5125-0.5129) whereas the second type have very enriched isotopic composition (SrI=0.7085-0.7100, NdI=0.5119-0.5125). In terms of rock types Groups-1 to 3 shows both the isotopic composition, whereas only group-4 rocks have only bulk earth isotopic composition.

Here, we focus on petrological and geochemical features, because these features of group-4 is different from other groups. Group-4 have hornblende, plagioclase, clinopyroxene and olthopyroxene phenocrysts. Pyroxene phenocrysts have a wide range of composition (Mg#= Cpx 70-86; Opx 69-85).

It is difficult to explain the petrological features of group-4 by crystallization differentiation of magma that formed group-1 to 3 rocks types. This study uses trace element composition of clinopyroxene phenocryst for magma genesis of group-4. The results indicate that the group-4 magma is a product of magma mixing of high Mg# magma that have adakitic signatures (Defant and Drummond, 1991) and low Mg# magma that have enriched isotopic signature. In general, adakitic volcanic rocks are formed by partial melting of subducted oceanic crust, and so adakitic magma usually have depleted isotopic composition like a subducted oceanic crust (MORB; Castillo, 2012). However, adakitic rocks in this study area has more depleted isotopic signatures. Previous study indicated a model that involves the addition of sediment on subducted basaltic crust melt during slab melting (Sato et al., 2013). However, this model cannot explain the observed isotopic compositions. Therefore, this study proposes a model that involved an enriched component of magma mixing that resulted in the observed isotopic features.

©2019. Japan Geoscience Union. All Right Reserved.

In general, adakitic magma genesis needs heat source for slab melting. Previous studies suggest that heat source is hot asthenospheric upwelling preceding Japan sea opening (Takahashi and Shuto, 1999). Petrological features of group-4, for example, high MgO, Cr, Ni concentration are similar to bajaite (Rogers et al., 1985). Previous studies suggest that magma genesis of bajaitic magma result from ridge subducting (Tsuchiya et al., 1995). But this study area doesn’ t show evidence of ridge subducting. It is necessary to discuss from more various view point.

Trace element and isotopic characteristics of high Nb basalts from Kyushu arc and back arc

*Bidisha Dey[1], Tomoyuki Shibata[1]

1. Department of Earth and Planetary Systems Science, Hiroshima University

Basalts and basaltic andesites from south-west Japan arc and Back arc region show signature of HFSE enrichment similar to high Nb basalts (HNB) and Nb enriched basalts (NEB) (i.e. Philippines, Castillo et al., 2007; Central America, Hastie et al., 2011).

We use previously published data from Kyushu basalts and basaltic andesites from both arc and back arc setting to compare the geochemical characteristics of these rocks. We observe that the rocks of our interest in this area, show a much higher Nb/Zr and Nb/Hf ratio than that of typical MORB values (0.032, Sun and McDonough, 1989) or of NE Japan arc (similar to MORB, Shibata and Nakamura, 1997). The samples from Kita-Matsuura area as reported by Sakuyama et al (2009, 2014) and Fukuejima- Goto island volcanoes (Uto et al., 2004; Hoang et al., 2013; Kuritani et al., 2017) also show significantly high Nb content, up to 50 ppm and 60 ppm respectively. This type of signature is more common to OIB type mantle than to MORB type mantle (Sun and McDonough, 1989); however, isotopic plots using Sr, Nd and Pb isotopic data in 2D and 3D space show that these rocks are not likely to be related to the enriched mantle (EM1, EM2) or the HIMU components and more likely to be related to MORB type mantle and a mixture with Philippine sea plate (PHS) sediments or slab melt as suggested by Shibata et al. (2014). Samples from Fukuejima islands show the same trend as arc rocks in Pb-Pb isotopic space despite not likely to be affected by PHS plate sediment or slab melt. This suggests that the mantle geochemistry beneath Kyushu is the product of mixing between MORB type mantle and slab or sediment like Pb isotope enriched component, which may have also contributed to the HFSE enrichment. The nature of this component is subject to further investigation.

Evaluation of digestion methods for Molybdenum concentration analysis for geological materials

Yu Mutsushika[1], *Akira Ishikawa[1], Tetsuya Yokoyama[1]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology

Molybdenum, one of redox-sensitive trace elements showing slightly chalcophile and moderately siderophile character, is recognized as a useful element for tracing chemical evolution of the Earth ranging from core-mantle differentiation to low temperatures surface processes. Despite this, determination of Mo concentration is frequently abandoned for the studies of rock samples dominated by silicate materials because formation of insoluble molybdenum oxides in hydrochloric (HCl) or nitric (HNO_3) acid solutions precludes accurate measurements of Mo concentration with ICP-MS in typical multi-element determination methods for other lithophile trace elements such as Rb, Sr, and rare earth elements (REE). Makishima and Nakamura (1999) and Lu et al. (2007) proposed that isotope-dilution ICP-MS (ID-ICP-MS) employing dissolution with hydrofluoric (HF) acid is a well-suited method for the simultaneous determination of Mo and other elements such as W, Sb and high-field strength elements (HFSE). However, most of these elements are hosted in acid resistant minerals such zircon and Cr-spinel in rock samples, high-temperature/pressure HF digestions with longer duration are sometimes required in order to achieve complete recovery of these elements. Here we develop a rapid and universal method for the determination of Mo in geological samples using ID-ICP-MS combined with fused-glass bead digestion (sample + lithium tetraborate). The fused-glass beads were properly dissolved into a diluted HF with spike solution. The optimized procedure and analytical capability using ICP-QMS with HF-resistant setting will be presented by showing results of replicate analyses for reference materials such as volcanic rocks (JB-1, JB-1a, JB-2, JB-3, JA-1, JA-1a, JA-2, JA-3, JR-1, JR-2, JR-3, BIR-1a, BCR-2, BHVO-2 and W-2a), plutonic rocks (JGb-1, JGb-2, WMG-1, JG-1, JG-1a, JG-2, JG-3 andJSy-1), ultramafic rocks (JP-1, JH-1, OKUM, GP-13 and UB-N), sedimentary rocks (SCo-1, SDo-1, Jdo-1, JLs-1, JCp-1, NIST694, JCh-1, JSd-1, JSd-2, JSd-3, JSl-1, JSl-2 and JLk-1) and ore-materials (JF-1, JF-2, JZn-1, JMn-1 and SARM32).

*fs*LA-ICPMS analysis of XRF glass beads

*Q. Chang[1], T. Sato[2], J.-I. Kimura[1]

1. Dept. Solid Earth Geochem., JAMSTEC, 2. R&D Center for Ocean Drilling Sci., JAMSTEC

Analysis of naturally heterogeneous rock samples by ICP-MS requires laborious sample preparation including acid/alkali digestion. Crystalline plutonic rocks or sediments remains as challenging analysis by ICP-MS because of the difficulty in complete digestion of acid resistant minerals which contain significant fraction of high field strength elements (HFSE) or rare earth elements (REE). We tested femto-second laser ablation (fsLA) ICP-MS analysis of glass beads prepared for X-ray fluorescence spectrometry (XRF). This method maintains benefits of no sample digestion by wet chemistry, high sensitivity, high sample throughput and low costs. A comprehensive examination of measurement parameters was made on wave length and repetition rate of the laser beam. Choice of internal standard and external calibration method were also examined. Using high-diluted glass beads (1:10 sample to lithium tetraborate ratio) and optimized in-house developed fsLA system coupled to a quadruple-type ICP-MS (iCAP Qs, ThermoFisher Sci.), the parameters and methods were validated by determining 48 elements including ten major (Si, Ti, Al, Fe, Mn, Mg, Ca, Na, K, P), refractory lithophile (Sr, Ba, REE and HFSE) and volatile (Ga, Rb, Cs, Tl, Pb) elements in well-established geological reference materials (GSJ JB-1, JG-1a, JG-2 and JR-1) and synthetic reference glasses (NIST SRM 612, USGS GSD-1G). Laboratory bias (or trueness by ISO 5725-1) for most elements was better than 10% when compared to the reference or consensus values. Poorly determined or failed elements were P, Sc, V, Ni, Sn, Sb, and W, whose data deviated from the reference values >20%. Volatile elements such as Rb, Cs and Ga showed no substantial loss; however, Tl and Pb exhibited always lower values suggesting their loss during fusion in the glass bead preparation. Repeatability and intermediate precision (ISO 5725-1) of all measured elements were better than 5–7% RSD except Cu, Sn, Sb, Cs and Tl which showed 10–40% RSD due to extremely low abundances or strong spectral interferences. The low limits of detection by this method were comparable to those obtained by solution ICP-MS for most elements of geochemical interests. Our results demonstrate that the fsLA-ICPMS using XRF glass bead can be used for rapid bulk-rock analyses of trace, minor and major elements.

Origin of mantle xenoliths from Kaula Island, Hawaii:Constrains from Os isotope and highly siderophile element compositions

*Ryo Fujita[1], Akira Ishikawa[1], Tetsuya Yokoyama[1], Michael O Garcia[2]

1. Tokyo Institute of Technology, 2. University of Hawaii

The Emperor Seamount-Hawaiian island chain is thought to originate from melting of a heterogeneous mantle plume, although the nature and extent of heterogeneity remain unclear. It has been suggested that some Hawaiian mantle xenoliths with highly unradiogenic Os isotope ratios (down to 187Os/188Os=0.1138) represent the depleted part of ascending Hawaiian plume, and that the depleted materials are more commonly distributed in mantle plumes than has been inferred from the compositions of erupted lavas. To better understand the lithological and geochemical variations of Hawaiian xenoliths and to evaluate the robustness of the above model, we conducted petrological and geochemical studies on 11 peridotite xenoliths (9 lherzolites, 1 dunite, and 1 wehlrite) collected from the island of Kaula, Hawaii. Here we present the results on the whole-rock Re-Os isotope systematics and highly siderophile element compositions in the xenoliths, together with the major element compositions of constituent minerals (olivine, clinopyroxene, orthopyroxene and spinel). The rock texture and mineral compositions indicate that the Kaula peridotites are samples from normal oceanic mantle and residues of variable degrees of melting. However, they have highly unradiogenic Os isotope ratios (down to 187Os/188Os=0.1187) yielding minimum rhenium-depletion ages of up to ~1.3 Ga, which are similar to those of O’ahu peridotites. Such unradiogenic Os isotopic compositions are not found in Hawaiian lavas and in depleted mantles (e.g., mid-oceanic ridge basalts). Importantly, as is observed in the O’ahu peridotites, the 187Os/188Os ratios of Kaula peridotites correlate with the degree of depletion, suggesting that they are related to an ancient melting event. Therefore, the Kaula peridotites are possibly the fragments of a Hawaiian mantle plume that consists of ancient depleted and recycled mantle lithosphere.

Petrological and Geochemical features of Miocene adakitic volcanic rocks in eastern part of Hokuriku region, SW Japan

*Watanabe Syun[1], Toshiro Takahashi[1]

1. Niigata university

Miocene volcanic rocks are widely distribution from the eastern part of Toyama prefecture to the northern part of Fukui prefecture in Hokuriku region, Central Japan. These volcanic rocks are broadly classified in to mafic volcanic rocks and felsic volcanic rocks, and in this study the petrological and geochemical features of mafic volcanic rocks are considered. Mafic volcanic rocks of the Hokuriku region consists of various types that have characteristic petrologic and geochemical features; tholeiitic volcanic rocks, calc-alkaline volcanic rocks, high-magnesia andesite and adakitic andesite (Takahashi and Shuto, 1999; Ishiwatari and Ohama, 1997).

The present study area is in the eastern part of the Miocene volcanic rocks. Volcanic rocks of this study area can be classified into four groups; Group-1 basalts, bulk rock chemical composition of group-1 indicate low SiO_2 (<53 wt %) composition and Nd and Ta depletion. Group-2 tholeiitic andesites, bulk rock chemical composition of group-2 indicate increasing FeO*/MgO ratio with increasing SiO_2. Group-3 calc-alkaline andesites, bulk rock chemical composition of group-3 indicate stable FeO*/MgO ratio with increasing SiO_2. Group-4 Hornblende-bearing andesites, Bulk rock chemical composition of group-4 indicate low FeO*/MgO ratio, high Sr, MgO, Cr, Ni concentration and low LILE and HFSE concentration. All types of volcanic rocks are distributed in Iwaine formation except in Fukuhira formation, only group-1 and group-2 are distributed.

The volcanic rocks of this study area can be classified two types by their isotopic features. First type have nearly bulk earth isotopic composition (SrI=0.7040-0.7060, NdI=0.5125-0.5129) whereas the second type have very enriched isotopic composition (SrI=0.7085-0.7100, NdI=0.5119-0.5125). In terms of rock types Groups-1 to 3 shows both the isotopic composition, whereas only group-4 rocks have only bulk earth isotopic composition.

Here, we focus on petrological and geochemical features, because these features of group-4 is different from other groups. Group-4 have hornblende, plagioclase, clinopyroxene and olthopyroxene phenocrysts. Pyroxene phenocrysts have a wide range of composition (Mg#= Cpx 70-86; Opx 69-85).

It is difficult to explain the petrological features of group-4 by crystallization differentiation of magma that formed group-1 to 3 rocks types. This study uses trace element composition of clinopyroxene phenocryst for magma genesis of group-4. The results indicate that the group-4 magma is a product of magma mixing of high Mg# magma that have adakitic signatures (Defant and Drummond, 1991) and low Mg# magma that have enriched isotopic signature. In general, adakitic volcanic rocks are formed by partial melting of subducted oceanic crust, and so adakitic magma usually have depleted isotopic composition like a subducted oceanic crust (MORB; Castillo, 2012). However, adakitic rocks in this study area has more depleted isotopic signatures. Previous study indicated a model that involves the addition of sediment on subducted basaltic crust melt during slab melting (Sato et al., 2013). However, this model cannot explain the observed isotopic compositions. Therefore, this study proposes a model that involved an enriched component of magma mixing that resulted in the observed isotopic features.

©2019. Japan Geoscience Union. All Right Reserved.

In general, adakitic magma genesis needs heat source for slab melting. Previous studies suggest that heat source is hot asthenospheric upwelling preceding Japan sea opening (Takahashi and Shuto, 1999). Petrological features of group-4, for example, high MgO, Cr, Ni concentration are similar to bajaite (Rogers et al., 1985). Previous studies suggest that magma genesis of bajaitic magma result from ridge subducting (Tsuchiya et al., 1995). But this study area doesn’ t show evidence of ridge subducting. It is necessary to discuss from more various view point.

Trace element and isotopic characteristics of high Nb basalts from Kyushu arc and back arc

*Bidisha Dey[1], Tomoyuki Shibata[1]

1. Department of Earth and Planetary Systems Science, Hiroshima University

Basalts and basaltic andesites from south-west Japan arc and Back arc region show signature of HFSE enrichment similar to high Nb basalts (HNB) and Nb enriched basalts (NEB) (i.e. Philippines, Castillo et al., 2007; Central America, Hastie et al., 2011).

We use previously published data from Kyushu basalts and basaltic andesites from both arc and back arc setting to compare the geochemical characteristics of these rocks. We observe that the rocks of our interest in this area, show a much higher Nb/Zr and Nb/Hf ratio than that of typical MORB values (0.032, Sun and McDonough, 1989) or of NE Japan arc (similar to MORB, Shibata and Nakamura, 1997). The samples from Kita-Matsuura area as reported by Sakuyama et al (2009, 2014) and Fukuejima- Goto island volcanoes (Uto et al., 2004; Hoang et al., 2013; Kuritani et al., 2017) also show significantly high Nb content, up to 50 ppm and 60 ppm respectively. This type of signature is more common to OIB type mantle than to MORB type mantle (Sun and McDonough, 1989); however, isotopic plots using Sr, Nd and Pb isotopic data in 2D and 3D space show that these rocks are not likely to be related to the enriched mantle (EM1, EM2) or the HIMU components and more likely to be related to MORB type mantle and a mixture with Philippine sea plate (PHS) sediments or slab melt as suggested by Shibata et al. (2014). Samples from Fukuejima islands show the same trend as arc rocks in Pb-Pb isotopic space despite not likely to be affected by PHS plate sediment or slab melt. This suggests that the mantle geochemistry beneath Kyushu is the product of mixing between MORB type mantle and slab or sediment like Pb isotope enriched component, which may have also contributed to the HFSE enrichment. The nature of this component is subject to further investigation.

Evaluation of digestion methods for Molybdenum concentration analysis for geological materials

Yu Mutsushika[1], *Akira Ishikawa[1], Tetsuya Yokoyama[1]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology

Molybdenum, one of redox-sensitive trace elements showing slightly chalcophile and moderately siderophile character, is recognized as a useful element for tracing chemical evolution of the Earth ranging from core-mantle differentiation to low temperatures surface processes. Despite this, determination of Mo concentration is frequently abandoned for the studies of rock samples dominated by silicate materials because formation of insoluble molybdenum oxides in hydrochloric (HCl) or nitric (HNO_3) acid solutions precludes accurate measurements of Mo concentration with ICP-MS in typical multi-element determination methods for other lithophile trace elements such as Rb, Sr, and rare earth elements (REE). Makishima and Nakamura (1999) and Lu et al. (2007) proposed that isotope-dilution ICP-MS (ID-ICP-MS) employing dissolution with hydrofluoric (HF) acid is a well-suited method for the simultaneous determination of Mo and other elements such as W, Sb and high-field strength elements (HFSE). However, most of these elements are hosted in acid resistant minerals such zircon and Cr-spinel in rock samples, high-temperature/pressure HF digestions with longer duration are sometimes required in order to achieve complete recovery of these elements. Here we develop a rapid and universal method for the determination of Mo in geological samples using ID-ICP-MS combined with fused-glass bead digestion (sample + lithium tetraborate). The fused-glass beads were properly dissolved into a diluted HF with spike solution. The optimized procedure and analytical capability using ICP-QMS with HF-resistant setting will be presented by showing results of replicate analyses for reference materials such as volcanic rocks (JB-1, JB-1a, JB-2, JB-3, JA-1, JA-1a, JA-2, JA-3, JR-1, JR-2, JR-3, BIR-1a, BCR-2, BHVO-2 and W-2a), plutonic rocks (JGb-1, JGb-2, WMG-1, JG-1, JG-1a, JG-2, JG-3 andJSy-1), ultramafic rocks (JP-1, JH-1, OKUM, GP-13 and UB-N), sedimentary rocks (SCo-1, SDo-1, Jdo-1, JLs-1, JCp-1, NIST694, JCh-1, JSd-1, JSd-2, JSd-3, JSl-1, JSl-2 and JLk-1) and ore-materials (JF-1, JF-2, JZn-1, JMn-1 and SARM32).

*fs*LA-ICPMS analysis of XRF glass beads

*Q. Chang[1], T. Sato[2], J.-I. Kimura[1]

1. Dept. Solid Earth Geochem., JAMSTEC, 2. R&D Center for Ocean Drilling Sci., JAMSTEC

Analysis of naturally heterogeneous rock samples by ICP-MS requires laborious sample preparation including acid/alkali digestion. Crystalline plutonic rocks or sediments remains as challenging analysis by ICP-MS because of the difficulty in complete digestion of acid resistant minerals which contain significant fraction of high field strength elements (HFSE) or rare earth elements (REE). We tested femto-second laser ablation (fsLA) ICP-MS analysis of glass beads prepared for X-ray fluorescence spectrometry (XRF). This method maintains benefits of no sample digestion by wet chemistry, high sensitivity, high sample throughput and low costs. A comprehensive examination of measurement parameters was made on wave length and repetition rate of the laser beam. Choice of internal standard and external calibration method were also examined. Using high-diluted glass beads (1:10 sample to lithium tetraborate ratio) and optimized in-house developed fsLA system coupled to a quadruple-type ICP-MS (iCAP Qs, ThermoFisher Sci.), the parameters and methods were validated by determining 48 elements including ten major (Si, Ti, Al, Fe, Mn, Mg, Ca, Na, K, P), refractory lithophile (Sr, Ba, REE and HFSE) and volatile (Ga, Rb, Cs, Tl, Pb) elements in well-established geological reference materials (GSJ JB-1, JG-1a, JG-2 and JR-1) and synthetic reference glasses (NIST SRM 612, USGS GSD-1G). Laboratory bias (or trueness by ISO 5725-1) for most elements was better than 10% when compared to the reference or consensus values. Poorly determined or failed elements were P, Sc, V, Ni, Sn, Sb, and W, whose data deviated from the reference values >20%. Volatile elements such as Rb, Cs and Ga showed no substantial loss; however, Tl and Pb exhibited always lower values suggesting their loss during fusion in the glass bead preparation. Repeatability and intermediate precision (ISO 5725-1) of all measured elements were better than 5–7% RSD except Cu, Sn, Sb, Cs and Tl which showed 10–40% RSD due to extremely low abundances or strong spectral interferences. The low limits of detection by this method were comparable to those obtained by solution ICP-MS for most elements of geochemical interests. Our results demonstrate that the fsLA-ICPMS using XRF glass bead can be used for rapid bulk-rock analyses of trace, minor and major elements.

[S-VC38] Active Volcanism

convener:Yuta Maeda(Nagoya University), Takahiro Miwa(National research institute for earth science and disaster prevention), Takeshi Nishimura(Department of Geophysics, Graduate School of Science, Tohoku University), Chairperson:Nobukazu Seama, Tetsuo Matsuno

This session discusses various aspects of active volcanisms including, but not limited to, recent and historical eruptions, various phenomena associated with the volcanic activities, underground structures of the volcanoes, and developments of new instruments based on geophysical, geochemical, geological, and multidiscipline approaches. We also welcome studies on understanding and predicting the transitions of the eruptive activities from observational, theoretical, and experimental approaches.

Kikai submarine caldera to the south of the Kyushu Island, SW Japan, had at least three eruptions at 140, 95 and 7.3 ka, and its collapse occurred at 7.3 ka during the latest supereruption (>500 $km^3$of magma) in the Japanese Archipelago. We have conducted series of research cruises using the T/S Fukae-maru in this caldera to understand the melt supply system for the supereruption through tracing past supereruptions, identifying current volcanic activities, and imaging current structure.

The surveys to trace past supereruptions include multi-channel seismic reflection (MCS) surveys, visual observation and sediments sampling using remotely operated vehicle (ROV; SHINDAI-2K), and land observation. The MCS surveys provide high resolution marine seismic reflection images, which are classified into seven seismic units characterized by distinctive seismic facies. We interpreted that the upper most seismic unit should be a candidate layer for Koya ignimbrite due to 7.3 ka Akahoya eruption, because the deposit from the Kagoshima mainland with regressive surface erosion on progradational HST (highstand system tract) locates beneath this seismic unit and the deposit probably corresponds to the last glacial period (18 ka) (Shimizu et al., this meeting). This interpretation is supported by the chemical composition of glass shard samples on the sea floor near the caldera wall, which were obtained by ROV divings. The chemical composition of the glass shards indicates characteristic bimodal SiO_2 contents, which consistent with unique characteristic for the Akahoya eruption (Nakaoka et al., this meeting). This seismic unit distributes around the caldera and its whole volume will be calculated to estimate reliable magma volume during the Akahoya eruption. Further, visual observation of the ocean bottom by ROV (Kiyosugi et al., this meeting) and land observation (Suzuki-Kamata et al., this meeting) suggest eruption styles of submarine volcanoes and ignimbrite deposition modes.

Current volcanic activities and structures are obtained using geophysical approaches. High volcanic activities are identified by five months of seismicity data using five ocean bottom seismometers (OBSs): 1100 volcanic tremor events with its fundamental frequency of 2 Hz, high frequency seismic events with obvious P and S arrival, and monochromatic variation events are detected beneath and/or around the caldera (Seto et al., this meeting). Imaging current structures are provided by multi-beam echosounder mapping with backscatter imaging, gravity analysis, and marine electromagnetic experiment. All these structures outside of the caldera wallshows asymmetric features between the trench side and the back-arc side. The backscatter images show rough morphological features in the back-arc side, suggesting recent local eruptions, in contrast with smooth morphology in the trench side. The gravity analysis indicates that thinner upper crust in the back-arc side than that in the trench side (Morita, 2019). The

©2019. Japan Geoscience Union. All Right Reserved.

electromagnetic field variation data obtained by 10 ocean-bottom electro-magnetometers (OBEMs) observation allowed us to image a 3-D electrical resistivity structure, which also shows asymmetric feature at <5-10 km depths (Matsuno et al., this meeting). These asymmetric features between the trench side and the back-arc side suggest that Kikai submarine caldera formation is basically controlled by the subducting slab.

Kikai caldera, most of which is submerged in the seawater of the south of the Kyusyu Island, southwest Japan, is the Quaternary active caldera volcano. Latest eruption accompanied by caldera collapse taken place in 7.3 ka is the biggest Holocene eruption in Japan Archipelago. The ash-fall known as Akahoya was spread to entire southwest Japan and the pyroclastic flow thought as a low-aspect ratio ignimbrite is distributed in subaerial parts of the surrounding islands 40-80 km away from the source. Such submarine caldera must supplied the products not only in air, but largely in the water which has not been identified yet.

In order to understand the distribution of the pyroclastic-flow deposits beneath the sea around Kikai caldera, we conducted high resolution marine seismic studies from 2016 to 2018 by T/V Fukae-maru. We identified the uppermost unit widely recognized around Kikai caldera as the pyroclastic-flow deposit associated with 7.3-ka Akahoya eruption from the seismic sequence stratigraphic analysis and glass composition of sediments. The uppermost unit, characterized by subparallel to hummocky configurations of high amplitude reflections, covers the slope fan and progradational deposits of shelf edge developed between the Kyusyu Island and Kikai caldera. These secondary deposits under the uppermost unit are interpreted to deposit around the last glacial by reason of the erosion structure seen on the top-lap surface of regressive clinoform at 120 m below current sea level. Since uppermost unit is deposited after the last glacial (18 ka) and shows consistent seismic facies around Kikai caldera, the unit is inferred as products of 7.3-ka eruption. This is supported by analysis of glass composition of the sediments sampled at the seafloors interpreted as the above seismic unit, which shows the bimodal geochemical characteristic of high SiO_2 glass shards and lesser amount of low SiO_2 glass shards by which Koya pyroclastic-flow deposits are characterized (Nakaoka et al., this meeting).

This uppermost seismic unit interpreted as pyroclastic-flow deposit represents Akahoya eruption is distributed with a thickness of ~50 m around Kikai caldera. It maintains a certain amount of thickness until it reaches the shelf edge of the Kyusyu and surrounding islands. At least 40 km radius circle around the caldera, this unit is recognizable in most of the area of the seismic profiles. This result shows that a large amount of volcanic materials are ejected not only in air rather in the water at 7.3-ka Akahoya eruption.

Identification of submarine volcanic ash around the Kikai caldera with the Koya pyroclastic flow deposit inferred from glass composition

*Reina NAKAOKA[1], Keiko Suzuki-Kamata[1,2], Satoshi Shimizu[1], Yoshiyuki Tatsumi[1,2], Katsuya Kaneko[2,1], Koji Kiyosugi[3,1], Nobukazu Seama[2,1], Tetsuo Matsuno[1,2], Kimihiro Nishimura[2], Kazuki Hayashi[2]

1. Kobe Ocean-Bottom Exploration Center, Kobe University, 2. Department of Planetology, Graduate School ofScience, Kobe University, 3. Organization of Advanced Science and Technology, Kobe University

Koya pyroclastic flow deposit (PFD) is large scale ignimbrite generated during formation of the Kikai caldera in Kikai-Akahoya eruption at 7.3 ka. Kikai caldera is located ~50 km south of the Satsuma Peninsula and largely presents at the bottom of sea. Koya PFD is thickly distributed on land of Takeshima and Satsuma-Iwojima which represent subaerial part of the northern rim of the Kikai caldera. It is also thinly distributed over distal area, adjacent islands and mainland of south Kyusyu which is 40-60 km away from the source across the sea. This pyroclastic flow deposit has been suggested to exhibit rather low aspect ratio ignimbrite (Ui, 1973). However, on-land survey revealed that the maximum pumice size tends to decrease with increasing the distance across the sea. This may lead to a hypothesis that a significant amount of pyroclastics was lost during traveling over the sea and deposited on the sea floor (Yamane and Suzuki-Kamata, 2017). Our multi-channel seismic (MCS) reflection experiments around the Kikai caldera further suggested several seismic units (Shimizu et al., 2018). We have concluded that the uppermost unit should be a candidate layer for Koya PFD. This layer is recognized extensive distribution around the proximal islands (~30 m thick) and continuous to the Kagoshima bay (~10 m thick). As mentioned above, the Koya PFD is expected to be thickly distributed on the sea floor around the Kikai caldera. However, identification of submarine deposit with the subaerial Koya PFD is not sufficiently. In this study, we measured chemical composition of glass shards on the sea floor obtained by remotely operated vehicle (ROV) and compared with the subaerial Koya PFD.

The ROV conducted four dives to sea floor where MCS data indicate that uppermost unit is distributed near sea floor around the caldera wall and one dive in the south of the Satsuma Peninsula and collected volcanic ash on the sea floor using nozzle. The chemical composition of glass shards (<200 micrometers) from both subaerial and submarine were measured by Electron Probe Micro Analyzer (EPMA).
The glass shards on the sea floor around the caldera wall show bimodal geochemical characteristic which contain a high proportion of high SiO_2 glass shards (SiO_2=72-78 wt.%) and lesser amount of low SiO_2 glass shards (SiO_2=64-68 wt.%). The low SiO_2 glass was reported by Fujihara and Suzuki-Kamata (2013) and confirmed that it is unique characteristic for the Kikai-Akahoya eruption by glass and whole rock composition of other volcanics of the Kikai caldera. This indicate that the sea floor around the Kikai caldera covered by volcanic ash derived from the Koya PFD. Samples from the sea floor in the south of the Satsuma Peninsula were also confirmed that they contain small amount of glass shard corresponding the Koya PFD. These results correspond to the MCS data showing that candidate layer for the Koya PFD is thickly and widely distributed at uppermost part around the Kikai caldera. The vertical variation for contents of low SiO_2 glass on Takeshima Island, which is proximal area of the Koya PHD with a thickness of ~20 m, shows that the content of low SiO_2 glass lacks at the basal level and increases upward and reaches >10% at early stage (~10% level of the total thickness). While, the contents of low SiO_2 glass at distal areas across the sea tend to increase upward to <5%, which are lesser than value of proximal area. The contents of low SiO_2 glass of the sea floor samples around the caldera rim are >10%. Ash size grains are considered to be less under the influence of segregation by difference of density (Nakaoka and

©2019. Japan Geoscience Union. All Right Reserved.

Suzuki-Kamata, 2018). Thus, the Koya pyroclastic flow reached distal area across the sea between the start of eruption and the beginning of containment of low SiO_2 glass and was waning to not reach distal area and deposit on sea floor after the content of low SiO_2 glass increases to >10%.

Submarine volcanoes are one of the frontiers in volcanology: many volcanoes are located under the sea and most of them are not well studied. Since 2016, the Kobe Ocean-Bottom Exploration Center (KOBEC) at Kobe University has investigated a submarine volcano (the Kikai caldera) to understand the structure of the caldera and the style of the caldera forming eruption. The Kikai caldera is located about 45 km off southern Kyushu Island, Japan. Except two islands on the northern part of the caldera rim, most of the caldera structure is under the sea. The caldera has double caldera structure: the outer caldera has width of 19 km and length of 24 km and the inner caldera has width of 15 km and length of 17 km. The formation of, at least, the inner caldera must be related with one of the largest eruption of this volcano occurred about 7300 years ago. In the inner caldera, a giant rhyolite lava dome (~32 km^3) was created after the caldera collapse (Tatsumi et al., 2018).

A remotely operated vehicle (ROV) is a tethered underwater robot connected with a support surface vessel by a cable for power supply and signal transmission. To observe and sample sea floor material, we introduced a ROV (SHINDAI-2K) in 2016. In this presentation, we show preliminary results of 9 dives of the ROV at 8 sites in the following 3 areas in the Kikai caldera.

Outer caldera: We investigated two sites at the northeastern rim of the outer caldera. At one of the sites, we found a massive angular outcrop of dense rock in the caldera wall. This result and andesitic gravel sampled at this site confirmed the presence of igneous rock expected by our prior multi-channel seismic reflection survey. Another site had a sandy seafloor. We sampled the sediments with the ROV and identified volcanic glass fragments ejected by the caldera forming eruption.

Inner caldera: We had two dives around the inner caldera. At the northeast caldera wall of the inner caldera, basement rock appeared as a massive and angular upright outcrop of dense mudstone which had several centimeters wide horizontal banded structure. On the other hand, at the southeastern site in the inner caldera, the sea floor was covered by sandy or muddy sediments. Volcanic glass fragments ejected by the caldera forming eruption were also identified from the sediments. Furthermore, some isolated vesiculated lava blocks were observed at this site. Those blocks had fractured surface, suggesting chilling of hot ejecta due to lava/water interaction.

Lava dome: We had four dives at the lava dome. The outline of the results was already reported by Tatsumi et al (2018). The most surface of the lava dome was covered by meter-scale vesiculated lava blocks (pillow lobes; Tatsumi et al., 2018). These blocks also had water-chilled structures. Relatively dense angular chilled blocks were observed at the east flank of the lava dome where gully-like features had been determined with our prior bathymetry analysis. Furthermore, a small amount of gas emission was observed at the northern flank of the lava dome where water column was expected in our prior

side-scan sonar acoustic images.

Visual observation and sediments sampling using ROV provides valuable information to understand the history and eruption style of submarine volcanoes. Our preliminary observations suggests that (1) the amount and size of vesiculated lava blocks decrease with distance from the lava dome, showing that they were provided from the dome, (2) basement rock of the volcano is exposed at the sea floor in, at least, some areas of the Kikai caldera, (3) as well as old volcanic edifices in the two islands, old submarine volcanic edifices were cut by the caldera collapse and some of them are exposed in the outer caldera wall. These results and further ROV survey will provide new insight into the eruption history of submarine volcanoes.

Seismic activity beneath Kikai Caldera by using Ocean Bottom Observation

*Yasutomo Seto[1], Hiroko Sugioka[2], Yojiro Yamamoto[3], Tsutomu Takahashi[4]

1. Department of Planetology, Graduate School of Science, Kobe University, 2. Department of Planetology, Kobe University, 3. Japan Agency for Marine-Earth Science and Technology, 4. Research and Developement Center for Earthquake and Tsunami, Japan Agency for Marine-Earth Science and Technology

Kikai submarine caldera located in the southern part of Kagoshima prefecture is located on the volcanic front of the southwestern Japan arc. It was recently revealed that a giant lava dome with a volume of 32km ^{3} is created after super eruption at 7.3 K.a. (Tatsumi et al., 2018). Seismic observation with the T/S Fukae-maru of Kobe University is conducted by five short-period ocean bottom seismographs (OBSs) which were in the deepest part of the caldera from October 19, 2016 to March 14, 2017. As the result, about 1100 volcanic tremors like as swarm with a fundamental frequency of around 2Hz were detected during the period and it was occurred very frequently beneath the caldera. In addition to these low frequency tremors, about 32 high frequency earthquakes with dominant frequency of over 5Hz and many monochromatic tremors were detected, but at the onshore station of Satsuma Iwo-jima no signals corresponding to these volcanic earthquakes have been detected.

In general, volcanoes are strongly inhomogeneous regions compared with ordinary crusts. The seismic waves propagate to stations under the influence of scattering and diffraction due to random inhomogeneities along the seismic ray paths. Actually, the monochromatic tremor observed in the Kikai caldera is detected only at the stations near the place where the hydrothermal activities were observed by the high-performance camera of the remotely operated vehicle (ROV) and multi-beam echosounder mapping, suggesting strong three-dimensional inhomogeneity in the volcanic body. An amplitude envelope method is powerful tool for analyzing seismic waves propagating through such a three-dimensional inhomogeneous medium. In this study, a method based on Takahashi et al. (2007) focusing on peak delay time from direct S-wave onset to the maximum amplitude arrival of its envelope was applied to about 1100 low frequency tremors and about 32 high frequency earthquakes.

For high frequency earthquakes and some low frequency tremors, we picked up the onset times arrival of P- and S-waves recorded clearly to determine the hypocenters. The hypocenters were vertically divided into two parts at a depth of around 10 km, most of which occurred at the shallower parts were laterally expanded within the lava dome. In addition, we measured the peak delay times for S-wave seismograms filtered at four frequency bands of 2-4, 4-8, 8-16 and 16-32 Hz and calculated root mean square envelope for the sum of two components in those bands to investigate a frequency. In this presentation, we will discuss characteristics of the obtained peak delay times.

An investigation of three-dimensional electrical resistivity structure under Kikai Caldera

*Tetsuo Matsuno[1,2], Toki Hirose[2], Yuuki Okizono[3], Nobukazu Seama[2,1], Hiroshi Ichihara[4], Hiroko Sugioka[2,1], Yoshiyuki Tatsumi[1,2]

1. Kobe Ocean Bottom Exploration Center, Kobe University, 2. Department of Planetology, Graduate School of Science, Kobe University, 3. Department of Planetology, Faculty of Science, Kobe University, 4. Graduate school of environmental studies, Nagoya University

We have conducted an electromagnetic experiment to reveal a 3-D electrical resistivity (or conductivity) structure under Kikai Caldera, SW Japan. The electrical resistivity is highly sensitive to thermal structure and the presence of partial melt or magma and fluid in the crust and in the upper mantle. Imaging an electrical resistivity structure provides key constraints on the distribution of magma reservoirs in the crust and in the upper mantle and volcanic structures and activities of this submarine caldera. Our electromagnetic experiment is one part of an integrated marine investigation of Kikai Caldera since October 2016 with T/S Fukae-maru, Kobe University. By semiannual research cruises to the Kikai Caldera region, we have repeatedly deployed and recovered ocean-bottom electro-magnetometers (OBEMs) by changing their locations to obtain a data set that is useful for imaging a 3-D electrical resistivity structure. We set 13 observational sites so far, and we have 10-sites data available for analysis. The 10 sites cover an area of 13 km ×16 km within the submarine double caldera with site-distances of ~5-10 km. The OBEMs measured time variations of electromagnetic fields at sampling rates of 8 Hz and 60 s with instrumental tilts and temperature at seafloor. Data suggested instrumental vibrations during observations, likely because of strong ocean current near the Kuroshio Current or between islands, and unstable positions of OBEMs on very rugged seafloor of lavas in this volcanic area. We carefully checked the time-series data and selected available data terms. We finally obtained magnetotelluric (MT) response functions at the 10 sites at a period range from 21 s to 8192 s, using the BIRRP program [Chave and Thomson, 2004]. For imaging a 3-D electrical resistivity structure, we carried out a 3-D inversion of the MT response functions using an inversion program of Usui et al. [2018]. Undulating seafloor in the study area, which can severely distort the MT responses, was incorporated into a 3-D inversion model with tetrahedron meshes. A preliminary 3-D inversion model (RMS misfit = ~1.7) shows a shallow conductive area of 3-10 Ω-m at <5-10 km depths, which is thin to the west and is thick to the east, and an underlying deep resistive area of 30-300 Ω-m at 10-30 km depths.

[S-VC38] Active Volcanism

convener:Yuta Maeda(Nagoya University), Takahiro Miwa(National research institute for earth science and disaster prevention), Takeshi Nishimura(Department of Geophysics, Graduate School of Science, Tohoku University), Chairperson:Takeshi Ohba, Akihiko Terada

This session discusses various aspects of active volcanisms including, but not limited to, recent and historical eruptions, various phenomena associated with the volcanic activities, underground structures of the volcanoes, and developments of new instruments based on geophysical, geochemical, geological, and multidiscipline approaches. We also welcome studies on understanding and predicting the transitions of the eruptive activities from observational, theoretical, and experimental approaches.

A geochemical observation method that analyzes substances released from magma and hydrothermal systems such as volcanic gas, hot spring water, volcanic ash, etc. is a potentially effective means for predicting steam eruption and elucidating the structure of hydrothermal system. In Hakone volcano, an earthquake swarm began in late April 2015, and a small steam explosion occurred at the end of June. Prior to the earthquake swarm, the stable isotopic ratio of H2O in the volcanic gas declined and fluctuations in the CO2/H20 ratio synchronized with the increase and decrease in the number of earthquakes were observed. Analyzing the volcanic ash released at the end of June 2015 and using the constituent mineral species and the Cl/S ratio of the component adhered on ash surface, it was presumed that the source depth of the volcanic ash was shallower than about 350-500m. Hakone volcano repeats earthquake swarm and the associated volcanic gas anomalies every few years, and it is expected that means to predict the transition of earthquake swarm can be established by ongoing volcanic gas geochemical observation.

We collected and analyzed monthly fumarolic gases T and S, respectively, that are releasing naturally in Owakudani and Kamiyuba, which are geothermal zones developed in the central volcanic cone of Hakone volcano, and obtained the following results. The CO2/H2S ratio of T reached its maximum value around October 2017, and then showed a tendency to gradually decrease toward to January 2019. At T, a similar tendency was also observed for He/CH4 ratio. The CO2/H2S ratio of S remained nearly constant from February 2018 to February 2019, but decreased once in November 2018. The He/CH4 ratio of S showed a declining trend in 2018 like T, but the rate of decline was slower than T. CO2 and He are derived from magma that degas, H2S and CH4 are derived from hydrothermal system. Therefore the declining trend of CO2/H2S ratio and He/CH4 ratio observed in 2018 indicates that the flux of magmatic gas to shallow hydrothermal system was decreasing. The cause of the decreasing trend may be due to the development of the sealing zone surrounding the magma. The declining trend of the CO2/H2S ratio and the He/CH4 ratio in 2018 looks to disappear in 2019. The CO2/H2S ratio of T and S rose slightly from January 2019 to February. Corresponding to the rise, a minor swarm earthquake was observed on Hakone volcano on January 24, 2019 (based on Hot Springs Research Institute of Kanagawa prefecture HP). The N2/He ratio of T and S remained low from 2018 to 2019, but T was exceptionally high in January 2019. N2 is a component derived from the atmosphere, and an increase in N2 in T indicates that the fluid pressure in the shallow part hydrothermal system decreased and a part of atmospheric contamination occurred. The apparent equilibrium temperature (AETD) can be calculated by combining the hydrogen isotope ratios of H2O and H2 contained in T and S. A decline phenomenon preceding the earthquake swarm were observed in 2014 and 2017. From early 2018 to the October, AETD is declining especially for S. The decrease may be a preceding sign of earthquake swarm.

Chemical and isotopic composition of volcanic gases at Mt Kirishima Iwoyama, Japan

*Takeshi Ohba[1], Muga Yaguchi[2], Kotaro Toyama[3], Hirochika Sumino[3], Urumu Tsunogai[4], Masanori Ito[4], Ryo Shingubara[4]

1. Department of chemistry, School of Science, Tokia University, 2. Meteorological Research Institute, 3. The University of Tokyo Graduate School of Arts and Sciences Department of Basic Science, 4. Nagoya University Graduate School of Environmental Studies

INTRODUCTION

At Mt Kirishima Iwoyama, several fumarolic gases appeared in the vicinity of the summit in December 2015, and the discharge of fumarolic gas was enhanced in May 2017. In addition, a small steam eruption occurred in April 2018. Volcanic gas contains components degassed from magma and is useful for evaluating volcanic activity. In this study, from December 2015 to January 2019, fumarolic gases were repeatedly collected and analyzed at Mt Kirishima Iwoyama. We consider the relationship between the variation of the chemical composition and stable isotope ratio of these samples and the recent volcanic activity.

SAMPLING OF FUMAROLIC GAS

Fumarolic gases a, b, c were collected near the summit of Mt. Kirishima Iwoyama. The location of fumarole-a is the place where fumarolic gas first appeared in Dec. 2015. The fumarole-b is located about 40 m south of fumarole-a. The fumarole-c is about 200 m away from the fumarole-a in the south-southwest direction. The outlet temperature of the fumaroles was all close to the boiling point of water and the discharge pressure of fumarolic gases was low.

RESULTS AND DISCUSSIONS

The SO2/H2S ratio of fumarolic gas-a fell sharply from May to October 2018, but again rose in January 2019. The ratio at fumarolic gas-b also rose from October 2018 to January 2019. The Oxygen isotope ratios of H2O rose at three fumarolic gases from October 2018 to January 2019. At all three fumarolic gases, the CO2/H2O and the H2S/H2O ratio fell from October 2018 to January 2019.

In general, CO2 is a component originating in magma, H2S is a component originating in hydrothermal system, and the CO2/H2S ratio rises as the flux of magmatic gas to a shallow hydrothermal system increases. In Mt Kusatsu Shirane and Mt Hakone, the H2S/H2O ratio of the fumaroles is stable in time, and the CO2/H2S ratio could be a good indicator of the magmatic gas flow rate for the shallow hydrothermal system. The H2S/H2O ratio of Mt Kirishima Iwoyama is variable, and the situation is different from Mt Kusatsu Shirane and Mt Hakone. For example, from January to March 2018, the H2S/H2O ratio of fumarolic gas-a changed little, but fumaroles b and c greatly decreased. From March to May 2018 the H2S/H2O ratio dropped greatly in fumarolic gas-a, but in fumarolic gas-c it increased in reverse. Thus, the change in H2S/H2O ratio was not coordinated between fumaroles, and the cause of H2S/H2O ratio change is estimtated to be local. For this reason, it is not appropriate to use the CO2/H2S ratio of fumarolic as an indicator of the flux of magmatic CO2 to the shallow hydrothermal system at Mt Kirishima Iwoyama. The reason why the H2S/H2O ratio of fumarolic gases greatly fluctuates may be

©2019. Japan Geoscience Union. All Right Reserved.

attributed to the insufficient development of shallow hydrothermal system.

The SO2/H2S ratio of fumarolic gas gas was low in January 2018, but it rapidly rose in March 2018 just before the steam eruption. In addition, the increase in SO2/H2S ratio occurred simultaneously in three fumarolic gases. At this time, the apparent equilibrium temperature (AETD) calculated by combining the hydrogen isotopic ratios of H2O and H2 sharply increased to values close to the magmatic temperature at the fumaroles-a and b. A similar increases in SO2/H2S ratio and AETD also occurred in May 2017, when the discharge of fumarolic gas was enhanced. The H2O oxygen isotopic ratios of the three fumaroles have been similarly fluctuated. The oxygen isotopic ratio reached the maximum value in fumaroles a and b in March 2018 just before the eruption in April. Considering the SO2/H2S ratio and the high oxygen isotope ratio in May 2017, it is highly likely that so-called the attempted eruption occurred.

Temporal and spatial variations of helium isotope ratios in volcanic gases in Kirishima volcanic group, Japan

*Kotaro Toyama[1], Hirochika Sumino[1], Kaori Kawana[1], Takeshi Ohba[2], Muga Yaguchi[3], Yoshihide Akiyama[1], Koki Aizawa[4], Kaori Tsukamoto[4]

1. Department of Basic Science, Graduate School of Arts and Sciences, The University of Tokyo, 2. Department of chemistry, School of Science, Tokia University, 3. Meteorological Research Institute, 4. Institute of Seismology and Volcanology, Faculty of Science, Kyushu University

In Kirishima volcanic group in Kyushu, Southwest Japan, Shinmoe-dake is an active volcano and erupted in 2008, 2011, 2017 and 2018, and Iwo-yama also erupted in 2018. For the volcanic disaster preservation, forecasting the timing of the volcanic eruption is required. It is known that the temporal variations in chemical and isotopic compositions of volcanic gases are useful to evaluate the present state of volcanic activity [1]. Especially, helium isotope ratio ($^3He/^4He$) exhibits unique values corresponding to the origin (e.g., 7-8 Ra in the mantle and about 0.02 Ra in the crust, where 1 Ra denotes atmospheric $^3He/^4He$ ratio of 1.4×10^{-6} [2]). Some studies have reported pre-eruptive $^3He/^4He$ anomalies, suggesting the increase of the magmatic helium supply into the hydrothermal system preceding eruption [1, 3, 4].

We report spatial and temporal variations of $^3He/^4He$ ratios of fumaroles and hot spring gases collected from 10 sites in Kirishima volcanic group during 2016 to 2018. The measured $^3He/^4He$ ratios were corrected for atmospheric contamination based on $^4He/^{20}Ne$ ratios. The air-corrected $^3He/^4He$ ratios (6.8 to 7.7 Ra) of the central craters in the active volcanos (i.e., Iwo-yama and Shinmoe-dake) are higher than those (4.3 to 5.3 Ra) of the other sites. These $^3He/^4He$ ratios decrease with the increase of the distance from the magma reservoir, location of which is estimated as pressure source of crustal deformation associated with the 2011 Shinmoe-dake eruption, to each sampling site. This trend reflects that the contribution of radiogenic ^4He in old groundwater increases with migration distance of the gas from the magma to the site [5].

The $^3He/^4He$ ratios of fumaroles in Iwo-yama slightly increase before Shinmoe-dake eruptions, and decrease after the eruption. This variation cannot be accounted for by the contribution of the radiogenic ^4He relative to total helium in the fumaroles before and after the eruptions, because it is estimated that the amount of radiogenic ^4He which volcanic gas can acquire during its migration from magma to the surface is negligible. Alternatively, the variation results from the change in mixing ratio of gases derived from two reservoirs having high and low $^3He/^4He$ ratios. Assuming that the magma chamber has high $^3He/^4He$ ratio, the increase of $^3He/^4He$ ratios of the fumaroles before the eruption would be resulted from increase of the supply of the gas from the chamber to the Iwo-yama fumaroles. Once an eruption occurs at Shinmoe-dake, magmatic gas is effectively released through the volcanic vent, resulting in decrease of its supply to the Iwo-yama fumaroles. Thus, the temporal variation of $^3He/^4He$ ratios in volcanic gases may reflect the pressure variation of the magma chamber.

Emission regions of gaseous elemental mercury around Yugama crater lake at Kusatsu-Shirane volcano, Japan

*Akihiko Terada[1], Noriaki Mizutani[1]

1. Volcanic Fluid Research Center, Faculty of Science, Tokyo Institute of Technology

Kusatsu-Shirane volcano is one of the most active volcanoes in terms of release of a large amount of heat as volcanic gas and thermal hot waters. In addition to a hot crater lake, locally referred to as Yugama, the Shirane pyroclastic cone exhibits thermal features such as steaming grounds and fumaroles. Because many visitors visit around the Shirane pyroclastic cone for sightseeing, risk evaluations of phreatic eruptions are valuable. Gaseous mercury emissions from ground surface at active volcanoes suggest thermal activities such as shallow hydrothermal system. Mercury contained in geothermal hot water separated from hydrothermal reservoirs as a gas phase and is transported to the surface along relatively high permeable zones. Thus, a spacial distribution of gaseous mercury emission rates from ground surface is one of a clue used to detect fracture zones. Such fracture zones may correspond to areas where explosion vents are formed in future. Furthermore, changes in flux of gaseous mercury may reflect temperature changes in a hydrothermal reservoir although mercury flux from ground surface is affected by environmental factors including air temperature, soil moisture content and organic carbon. Recently, portable apparatuses enabling to measure concentrations of gaseous elementary mercury (GEM) have been developed. To detect fracture zones around the Shirane pyroclastic cone, we applied the portable GEM analyzer which is low power consumption and light weight. On the basis of a simple numerical model which we have developed, we calculated GEM flux from GEM density measured around the soil. As a result, two GEM emission zones, A and B were found at the southern flank of the Shirane pyroclastic cone. The zone A corresponds to a locality of fissure vents formed by phreatic eruptions occurred at the beginning of 20 century. No volcanic vents are observed at ground surface at the zone B while its direction is parallel to an orientation of past fissure vents at the bottom of Yugama crater lake. We believe the zone B is fracture zone which was buried by thick ejecta emitted by following eruptions.

This work is supported by Japan Society for the Promotion of Science under the Grants-in-Aid for Scientific Research of 18H01290.

Magnetotelluric images of Kusatsu-Shirane volcano, revisited by 3-D modeling with tetrahedral elements considered topography effect

*Kuo Hsuan Tseng[1], Yasuo Ogawa[1], Nurhassan .[2], Sabri Bulent Tank[3], Akihiko Terada[1], Wataru Kanda[1], Masato Fukai[1]

1. Tokyo Institute of Technology, 2. Bandung Institute of Technology, Indonesia, 3. Bogazici University, Turkey

Mount Kusatsu-Shirane, Japan, is an active volcano with temporary phreatic eruptions. The distribution of subsurface conductor was previously inferred with 2-D inversion of magnetotelluric data which considered the topography effect. We combine the magnetotelluric data from 94 stations which were investigated in 2001-2002 and 8 stations which were investigated in 2017-2018 for inverse modeling. The stations were located on the volcano, mostly around Yugama crater. We selected the data by 15 frequencies for the 3-D inverse modeling. The model was calculated by FEMTIC (Usui, 2015; Usui et al., 2017), considering the topographic effect.

The final model presents two major electric conductive structures. A 0.5-3 ohm-m conductive structure with 500-1000 meters thickness is located at 300 meters depth, beneath Yugama crater and extend to the east slope of Kusatsu-Shirane volcano until Sesshogahara fumarole field. Another conductor at the west of Yugama crater has 600-1000 meters thickness at 1500-2000 meters depth.

Comparing the final model with microseismic data, most of the hypocenters are under a low conductive (<2 ohm-m) structure beneath Yugama crater. This conductive structure infers a hydrothermal deposit of volcano, which cut-off the seismicity as a cap rock. At the north of Mizugama crater, a high resistivity structure at the edge of conductor infers the path of fumarole. The deep conductor between Kusatsu-Shirane volcano and Manza geothermal field infers the geothermal source of Kusatsu-Shirane volcano system.

Magma conduit and associated hydrothermal systems of Aso volcano as revealed by broadband magnetotelluric data

*Nobuo Matsushima[1], Mitsuru Utsugi[2], Shinichi Takakura[1], Tadashi Yamasaki[1], Maki Hata[3], Takeshi Hashimoto[4], Makoto Uyeshima[3]

1. Geological Survey of Japan,AIST, 2. Kyoto University, 3. The University of Tokyo, 4. Hokkaido University

Aso volcano is one of the most active volcanoes in Japan. The caldera forming eruptions occurred from 210 ka to 90 ka, emitting the volcanic product of 600 m^3 in total. The caldera has a dimension of 25 ×18 km^2. After the caldera forming eruptions, post-caldera cones more than 17 were formed at the center of the caldera. Resent eruptions occurred repeatedly at Naka-dake cone. The count of the eruption events from Naka-dake crater was 73 times from 1901 to 2015. These volcanic activities suggest the stable magma supply from deep seated magma source to the surface. To investigate the magma plumbing system, the resistivity structure under Aso volcano was analyzed using the broadband magnetotelluric (MT) data. The four components of MT impedance and two components of tipper vector were used to obtain the resistivity structure by three-dimension inversion (Siripunvaraporn and Egbert, 2009). Overall structure was obtained using 55 measurement sites in and around of Aso caldera (Hata et al., 2016). We observed additional 9 sites near Naka-dake crater and revised the previous model to examine mainly the shallow structure near the active crater. The resistivity structure represents the low resistivity (< a few Ω•m) body which extends from near surface to a depth of 15 km (bsl) with a columnar shape, dipping northward and roughly directs to the epicenter of deep low-frequency earthquakes. The top of the low resistivity body is just located below the Naka-dake crater at sea level, which corresponds to the upper bound of magma depth estimated by melt inclusion analysis (Saito et al., 2018). From these results, we conclude that the low resistivity body indicates the upper part of the magma plumbing system of Aso volcano from deep seated magma source to the present active crater.

[S-CG48] Science of slow earthquakes: Toward unified understandings of whole earthquake process

convener:Satoshi Ide(Department of Earth an Planetary Science, University of Tokyo), Hitoshi Hirose(Research Center for Urban Safety and Security, Kobe University), Kohtaro Ujiie(Graduate School of Life and Environmental Sciences, University of Tsukuba), Takahiro Hatano(Earthquake Research Institute, University of Tokyo), Chairperson:Hitoshi Hirose, Yoshiyuki Tanaka

Accumulating observational studies on various types of slow deformation events, such as tectonic tremors, very low frequency events, and slow slip events, portrays some universal characteristics in generally complex behavior, including interaction among events and influence by various outer loadings. Some of these phenomena seem to have causal relation with the occurrence of very large earthquakes. A unified understanding of these slow and fast earthquake processes requires an approach integrating geophysics, seismology, geodesy, geology, and non-equilibrium statistical physics. We welcome presentations based on, but not limited to, geophysical observation, data analysis, analytical theory, numerical simulation, field study, and laboratory experiments.

Variability of the space-time evolution of slow slip events off the Boso Peninsula, central Japan, from 1996 to 2018

*Jun'ichi Fukuda[1]

1. Earthquake Research Institute, University of Tokyo

Continuous geodetic measurements over the past two decades have identified numerous recurrent slow slip events (SSEs) in subduction zones and other tectonic settings. Many previous studies revealed static source characteristics of SSEs, including the magnitudes, durations, recurrence intervals, and spatial slip distributions. However, our current knowledge of the time-dependent evolution of SSEs and their variability is much more limited.

In this study, we focus on a series of SSEs that occurred off the Boso Peninsula, central Japan. Since the installation of a dense GNSS network in Japan in the early 1990s, six Mw 6.6-6.7 SSEs, accompanied by swarms of regular earthquakes, have been identified on the subducting Philippine Sea Plate interface offshore of the Boso Peninsula in 1996, 2002, 2007, 2011, 2013-2014, and 2018. We invert GNSS time series to estimate the space-time evolution of the six SSEs using a modified version of the Network Inversion Filter (NIF) [Fukuda et al., 2008]. Our analyses reveal the similarities and differences in the time-dependent evolution of the six SSEs. We find that the nucleation style and space-time evolution of slip vary among the SSEs. The 2002, 2007, and 2011 SSEs nucleated more rapidly, with slip accelerations significantly higher than those of the 1996 and 2013-2014 SSEs. Furthermore, the 2002, 2007, and 2011 SSEs exhibited more rapid temporal variations in their slip and slip rates, and showed larger seismic moments and higher maximum slip rates than the 1996 and 2013-2014 SSEs. The along-strike expansion/propagation of slip is identified for the SSEs, revealing that the expansion/propagation patterns vary from event to event. Our results also show that the swarm seismicity accompanying the SSEs is highly correlated in space and time with slip rate, and seismicity only occurred after the slip rate exceeded ~4 m/yr, suggesting that the evolution of seismicity is controlled by the instantaneous stressing rate determined by slip rate.

Finally, we show that the space-time evolution of slow slip obtained here can potentially be used to study mechanisms governing the SSEs. We model the spatiotemporal evolution of shear stress on the plate interface due to slow slip obtained in the NIF analysis using the rate-and-state friction law. The rate-and-state friction parameters and initial state variable are adjusted to reproduce the stress histories. Results show that the rate-and-state friction law well reproduces the spatiotemporal evolution of stress on the plate interface during the SSEs. The critical fault size calculated from the estimated friction parameters is similar to the size of the SSE region, suggesting that the evolution of slow slip is governed by frictional properties near the stability boundary between stable and unstable slip.

Cumulative slip distribution of short-term slow slip events in the western Shikoku area, southwest Japan based on tilt change measurements

*Hitoshi Hirose[1,2], Wakako Tamura[2], Takeshi Kimura[3]

1. Research Center for Urban Safety and Security, Kobe University, 2. Graduate School of Science, Kobe University, 3. National Research Institute for Earth Science and Disaster Resilience

In the western Shikoku area, southwest Japan, so-called short-term slow slip events (SSE) accompanying tremor activities repeatedly occur with an average recurrence interval of about six months (e.g., Obara et al., 2004; Sekine et al., 2010). This activity has been detected by high-sensitivity accelerometers (tiltmeters) equipped at NIED Hi-net stations (Obara et al., 2005). Using the observed tilt records, Sekine et al. (2010) estimated a history of released seismic moment by short-term SSEs and reported that about 65\% of the accumulated moment by the relative plate convergence is released as short-term SSEs in the western Shikoku area. Because this estimation is based on a fault model such that slip is uniform on a plane rectangular fault and a location of the fault, especially a depth of the fault, is an unknown (nonlinear) parameter in their inversion, it is possible that an estimated seismic moment of an SSE could be biased.

In this study, we apply an inversion method that can express a spatial fault slip distribution assuming the slip is on the plate interface to the same tilt change data set that were detected in Sekine et al. (2010). They measured a tilt change caused by a short-term SSE as a difference between two averages of tilt values in one-day-long time interval (this can vary on a case-by-case basis) just before and after the SSE episode. We estimated each slip distribution of 18 short-term SSEs in western Shikoku between January 2001 and March 2008 although a reliable slip distribution is not estimated in a couple of episodes because of the limited number of available stations.

A cumulative slip distribution of the 18 SSEs shows that (1) slip area is localized within a narrow zone with its width of about 30-40~km in dip direction and about 70~km in strike direction of the subducting plate; (2) accumulated moment by the plate subduction is considered as fully released by SSEs at an area with larger cumulative slip; (3) the width of the slip zone is wider in the western part and narrower in the eastern part. The last characteristics is in agreement with the tremor epicenter distribution in this area (e.g., Obara et al., 2010). This suggests that there is a segment boundary that separates the western and eastern part of the SSE area in the western Shikoku region, and these segments likely have different frictional property and/or different pore fluid distribution.

Shallow undersea SSEs off the western Japan monitored by the GNSS-A

*Yusuke Yokota[1], Tadashi Ishikawa[2]

1. Institute of Industrial Science, The University of Tokyo, 2. Hydrographic and Oceanographic department, Japan Coast Guard

In the last two decades, many kinds of SEQs including non-seismic SSE have been detected using the onshore high-precision seismometer and GNSS networks. Along the Nankai Trough having dense seismic and geodetic monitoring network, their relationships were discussed and compared in detail [e.g., Hirose et al., 2010, Science; Obara and Kato, 2016, Science]. Observation of deep and shallow SEQ analogies and differences has multidisciplinary value for the physical properties of the plate boundary, submarine geology and earthquake disaster research. However, comparison between deep underground SEQs and shallow undersea SEQs cannot easily be performed due to the undersea observation technical constraint.

In these several years that the technology has been upgraded, shallow SEQs (tremor, LFE, VLF and short-term SSE) have been detected along the pan-Pacific subduction zones in high-precision onshore seismometers, seafloor seismometers, ocean bottom pressure gauges and submarine borehole strainmeters [e.g., Wallace et al., 2016, Science; Araki et al., 2017, Science]. However, there was no geodetic monitoring technology for detecting undersea longer sequence of SSE than week-scale. Longer-term SSE than week-scale cannot be monitored except for the GNSS-A technique.

Recently, we improved the GNSS-A technology and upgraded observation frequency and precision [Yokota et al., 2017, Rep. Hydro. Ocean. Res; Yokota et al., 2018, MGR]. With the present observation capability, yearly time change of the amount of undersea crustal deformation was newly unclosed. Then, the GNSS-A monitoring uncloses the occurrence situation of undersea SSE which could not be observed by the onshore geodetic network.

We detected SSE signals in the GNSS-A data using c-AIC detection process based on the method of Nishimura et al. [2013, JGR]. Then, SSE rectangle models were estimated by the grid search process using the GNSS-A signals and the onshore GEONET data. The detected models are located off the Kii channel and the Bungo channel at shallow side around the Nankai Trough historical seismogenic zone and strong coupling regions estimated by Yokota et al. [2016, Nature] and Nishimura et al. [2018, Geosphere]. We detected about M_w 6.0 and 6.5 events off the Kii channel and a migration of about M_w 6.1 ~ 6.2 events off the Bungo channel.

Shallow VLF events [NIED and Asano et al., 2008, EPS] were also activated simultaneously with these undersea SSEs. Off the Kii channel, VLF activity in 2009 was a little closer to the western side than 2018. Off the Bungo channel, VLF activity after 2015 was synchronized with the undersea SSEs. These suggest the temporal synchronization and the spatial relationship between SSE and VLF in these regions.

Co- and Post-seismic deformation due to the 2016 moderate earthquake sequence at the Chaman fault

*Fumiko Matsumoto[1], Masato Furuya[1]

1. Hokkaido University

Chaman fault system, located in Pakistan and Afghanistan, forms a transform boundary between Indian and Eurasian plates. Previous geological survey found the relative velocity of the Indian plate to the Eurasian at ~36mm/yr. Chaman fault is the major sinistral strike-slip fault which has ~900km long in the system. However, no large earthquakes (M>7) have been documented on the Chaman fault. Low seismicity results from either a long recurrence interval or aseismic creeping. Recent studies indicate a heterogeneous distribution of locked and creeping segments along the fault. In previous work, Furuya and Satyabala(2008) revealed a long lasted afterslip following a moderate earthquake (M5) in 2005 on the Chaman fault. We examine other earthquakes on the Chaman fault and their behavior comparing with the results in Furuya and Satyabala(2008). We find two moderate events occurred on May 13 and July 10 in 2016, first events larger than M5 on the Chaman fault after the M5 earthquake in 2005. The first event on May 13 was the largest M5-class earthquake since the 2005 M5 event examined by Furuya and Satyabala (2008). According to USGS catalogue, this May 13 event has three earthquakes observed within a few kilometers every minute in a row. We use ascending Sentinel-1 SAR data from March 31, 2016 to January 13, 2017. We generate InSAR images that suggest that the co- and post-seismic deformation of left-lateral strike-slip. Especially the second July 10 event almost implies the same behavior with the results in Furuya and Satyabala(2008). We must pick up real deformation except atmospheric trend, so we stack five InSAR images using different master date for each events before estimation of fault source model.

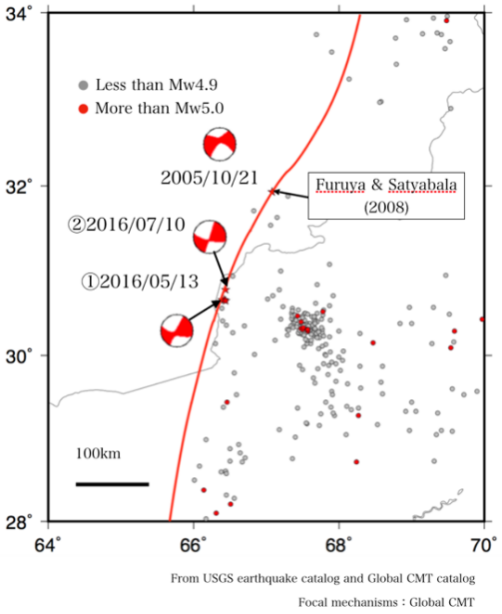

Figure1. Location map of Chaman fault and earthquakes after 2005/10/21. Gray dots show events less than Mw4.9 while red dots show more than Mw5.0. We pick up two events from more than Mw5.0 along the fault.

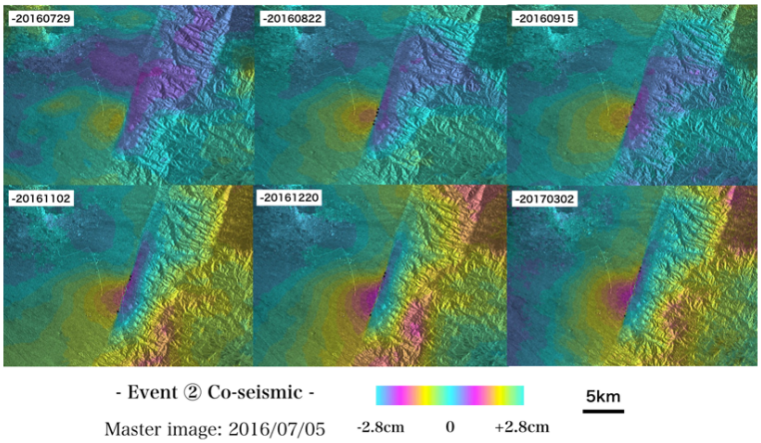

Figure2. Co-seismic deformation regarding the second event on 2016/07/10. There are six interferograms using same master image on 2016/07/05. These patterns are consistent with left lateral deformation. The phase and extent of deformation area gradually become larger.

An attempt to quantify transient fluid flow during slow slip event using GNSS and gravity data-1st report

*Yusuke Umemiya[1], Yoshiyuki Tanaka[1]

1. The University of Tokyo

Slow slip events (SSEs) cause crustal deformation. The observed deformations are usually explained with a fault model based on elasticity dislocation theory and fault slip distributions on plate interfaces have been inferred. On the other hand, a recent study analyzing the temporal gravity change which was obtained in the Tokai area indicates that long-term SSEs could cause transient fluid flow within the fault fracture zone. According to their study, fault slip cannot explain the observed negative gravity anomalies because the density redistribution which is expected from a dislocation theory is too small. However, their fluid-flow model neglects the deformation outside the fault fracture zone for simplicity. Therefore, how large surface deformation occurs due to such fluid flow (if it exists) has not yet been estimated. In this study, we propose a model which can consider the crustal deformation outside the fault fracture zone, which is induced by fluid flow. Instead of poroelasticity theories, we combine Mogi model with an ordinary dislocation model. Our model does not include a physical mechanism to drive the fluid flow itself. However, the kinematic approach allows us to quantify the fluid volume which is injected within the fault fracture zone during the SSEs in a very simple manner, using crustal deformation and gravity anomaly data. A preliminary result indicates that the injected fluid volume is approximately 0.01% if assuming that the thickness of the fault fracture zone is 200 m and the length and the width of the area where the fluid flow occurs are of the fault model of the SSE. For this volume change, our model can explain the crustal deformation and the gravity anomaly simultaneously.

Off the Kii Peninsula Shallow Low Frequency Earthquake in 2004 revealed by Ocean Bottom Seismometer

*Koji Tamaribuchi[1], Akio Kobayashi[1], Takahito Nishimiya[1], Satoshi Annoura[2]

1. Meteorological Research Institute, 2. Japan Meteorological Agency

The 2004 off the Kii Peninsula earthquakes (Mj7.1, 7.4) occurred near the Nankai trough axis, southeast off the Kii Peninsula, Japan, on September 5, 2004. After the earthquakes, the Meteorological Research Institute conducted OBS observation to examine the aftershock distribution accurately. Although the analysis was limited to hypocenter relocation of "ordinary aftershocks", no analysis was done for slow events. In this study, it is shown that many low-frequency earthquakes (LFEs) occurred in "ordinary aftershocks" from the detailed inspection of our observation. During the observation period, the frequency of LFE gradually decreased. Since P- and S-arrival times are unclear, it is difficult to determine the distribution of the hypocenter accurately. However, by using the Amplitude Source Location (ASL; Battaglia and Aki, 2003), the LFEs are located between a splay fault and trench axis. The 2004 OBS stations are located east of the DONET, and many LFEs are detected in the 2004 OBS network. In addition, there are many very-low-frequency events (VLFEs) in the F-net waveforms with very-low-frequency band-pass filter (0.02 - 0.05 Hz) during the observation period. We found that the identified LFEs were associated with VLFEs since their amplitudes seemed to be correlated. This means that the LFEs and VLFEs show the same phenomenon. Our observations might contribute to reveal the relationship between ordinary aftershocks, slow-events, and megathrust events such as Nankai trough earthquake.

The development of pressure vessel on gouges for rock deformation at seismic rates under water-saturated conditions

*Wei-Ting Lin[1], Li-Wei Kuo[1], Wen-Jie Wu[1], Jia-Jyun Dong[1], Yi-Hung Huang[2]

1. National Central University, 2. MATSUKI HYDRAULIC INDUSTRIAL CO. LTD

To understand earthquake mechanism and fault behavior during earthquake ruptures, experimentalists commonly conduct rock deformation tests with rotary shear apparatus (e.g., low-to high-velocity rock friction experiment, LHVR) which allow deformed at seismic rates. In general, the materials utilized for rotary shear apparatus are both cohesive rocks (e.g., gabbro and carbonate) and incohesive rocks (natural fault gouges and synthetic rock powders), while the latter are deformed at seismic rates and, commonly at low normal stresses (0.5 to 2 MPa confining with a plastic Teflon ring). However, using Teflon rings has issues of gouge extrusion and chemical contamination, in particular, at high normal stresses (>3MPa) and water-saturated condition, and the obtained mechanical data and associated experimental products seem to be questionable. Here we develop a metal pressure vessel for LHVR to deform gouges at seismic rates and, importantly, expand the normal stress capability (up to 15 MPa) and under water-saturated condition. Our results show the resistance from the pressure vessel itself (metal-to-metal contact) is extremely low (friction coefficient ≈0.02), and the result of kaolinite is similar to the previously published data. In particular, both gouge-extrusion and water-leaking was not observed deformed at a normal stress of 15 MPa and equivalent velocity 1 m/s. The designed pressure vessel could fill the gap of experimental conditions among the current used pressure vessels and complete the understanding of fault ruptures.

Spatial variations of shallow very low-frequency earthquake activity along the Nankai Trough based on CMT inversion using the 3D heterogeneous model

*Shunsuke Takemura[1], Takanori Matsuzawa[1], Akemi Noda[1], Takashi Tonegawa[2], Youichi Asano[1], Takeshi Kimura[1], Katsuhiko Shiomi[1]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Japan Agency for Marine-Earth Science and Technology

To reveal structural properties around the Philippine Sea plate boundary, we investigated spatial variation of shallow very low-frequency earthquake (SVLFE) activity along the Nankai Trough. By using F-net velocity seismograms for periods of 20-50s, we conducted centroid moment tensor (CMT) inversion of SVLFEs detected by array analysis of Asano et al. (2008 EPS). Our CMT method is basically same as in Takemura et al. (2018 GRL). Source grids were assumed on the boundary of the Philippine Sea plate at horizontal intervals of 0.1°. Green's functions from source grids to F-net stations were evaluated by finite-difference method simulations of seismic wave propagation within the 3D heterogeneous structure model of Takemura et al. (2019 PAGEOPH).

We applied our CMT method to SVLFEs occurred from June 2003 to May 2018. Almost of CMT solutions are low-angle thrust faulting mechanism occurred around the accretionary prism toe. We evaluated spatial variations of SVLFE activity along the Nankai trough by calculating cumulative moment at each source grid. The areas with large cumulative moments appeared near the trench axis of off the Cape Muroto, the Kii Channel and the southeastern Kii Peninsula. We found spatial correlations between cumulative moment, slip-deficit rate (Noda et al. 2018 JGR) and *S*-wave velocities (Tonegawa et al. 2017 Nature Comm.) around the Philippine Sea plate boundary. Such spatial correlations suggest that SVLFEs are effectively activated by mechanically weakening due to pore fluid at surrounding area of strongly locked zone of the Philippine Sea plate.

Acknowledgement
NIED F-net broadband velocity seismograms were used. The catalogs of slow earthquakes were downloaded from the website of slow earthquake database (Kano et al., 2018 SRL). Finite-different method simulations were conducted on the Earth Simulator at the JAMSTEC.

Evaluation of Magnitude and Characteristics of Seismicity of Low Frequency Earthquakes in Parkfield

*Miki Aso[1,3], Naofumi Aso[2], Satoshi Ide[1]

1. Department of Earth and Planetary Science, The University of Tokyo, 2. Tokyo Institute of Technology, School of Science, 3. OYO RMS Corporation

Over a million tectonic low frequency earthquakes (LFEs) have been found in Parkfield along the San Andreas Fault, as 88 families by Shelly and Hardebeck [2010]. Thanks to enormous event detection, interesting characteristics focusing on their event amplitudes have been reported such as the spatial variation along the fault, the exponential frequency distribution for each family, and the relationship with recurrence time [Shelly and Hardebeck, 2010; Shelly, 2010]. However, the relative size of families has not been quantified accurately, because we have to consider various factors such as radiation pattern depending on focal mechanisms, attenuation during wave propagation, and site amplification effects. For quantitative comparison of scale among differently located events, here we estimate the absolute magnitude of each event considered those effects.

We estimate the seismic moment Mo [Nm] and moment magnitude Mw of all LFE events in the catalog of Shelly [2017]. We first stack seismograms of over one million events in the catalog to improve the signal-to-noise (S/N) ratio. Then, we evaluate the absolute amplitude of the original seismograms using the stacked waveforms. Specifically, we evaluate seismic moment Mo by assuming focal mechanisms of each family, attenuation quality factor, site effect estimated by Aso et al. [2019, submitted to JpGU meeting, “Variations of Focal Mechanisms of Low Frequency Earthquake in Parkfield”], and the source time function estimated by Thomas et al. [2016]. Note that we consider the frequency-limited seismic moment Mo, though it is not exactly the same as the original definition of seismic moment measured at a lower frequency than the minimum frequency contained in one phenomenon.

As previously reported by reported by Shelly and Hardebeck [2010], LFEs in the southern part has larger magnitude. We also find that shallower events are smaller than deeper events.

Similarly, most of the frequency distribution for each family shows an exponential distribution which is also reported for LFEs in Cascadia [Sweet et al., 2014] and New Zealand [Chamberlain et al., 2014].

By comparing size and recurrence interval, the events during LFE burst (seconds interval) tend to be larger than the first event of burst, which occurs after hours-to-days quiescence. A similar tendency is found in tremor burst occurring with a longer time scale (~1-week-long) than that of LFEs (~1-minute-long) [Yabe and Ide, 2014]. These might suggest some temporal change in fault rheology and/or some characteristic spatiotemporal behavior such as Brownian slow earthquake processes [Ide, 2008].

Tectonic tremor catalog in the Tohoku-Hokkaido-Oki region using S-net

*Satoshi Ide[1], Tomoaki Nishikawa[2], Takanori Matsuzawa[3], Kazuaki Ohta[2], Naoki Uchida[4], Takuya NISHIMURA[2]

1. Department of Earth an Planetary Science, University of Tokyo, 2. Disaster Prevention Research Institute, Kyoto University, 3. National Research Institute for Earth Science and Disaster Resilience, 4. Graduate School of Science and International Research Institute of Disaster Science, Tohoku University

Recently, various slow earthquakes have discovered in the subduction zone off Tohoku and Hokkaido regions along the Japan Trench. In this presentation, we report the detection of tectonic tremors using the Seafloor Observation Network for Earthquakes and Tsunamis along the Japan Trench (S-net), operated by The National Research Institute for Earth Science and Disaster Resilience (NIED).

We used continuous seismograms from August 2016 to August 2018 recorded by short-period sensors at 150 S-net stations. The original data were converted to envelope waveforms and analyzed using the envelope correlation method coded by Ide (2010), for each 300 s time windows with 150 s overlap. Since the results included many ordinary earthquakes with short durations, we regarded the events with durations longer than 20 s as tremors. This number is twice longer than that used for deep tremors in western Japan, reflecting the long-lasting waves in ocean bottom observation.

We found that the detection completeness is not high due to the high seismic activity in the Japan Trench, especially after the occurrence of large earthquakes, with numerous aftershocks falsely detected. We therefore divided the study area into 18 overlapping sub-regions that cover the locations of tremor activity to solve this problem. We detected tremors in each sub-region and merged the results into one catalogue by removing one of any two events within 10 s and 1 degree of each other, depending on their root-mean-square errors. Some tremor-like signals were found near the triple junction off the Boso Peninsula at approximately 34.8˚N. However, visual inspection revealed these events to be ordinary earthquakes, which we excluded from our tremor catalogue. The resultant tremor catalogue will be available in Slow Earthquake Database (Kano et al., 2018).

Spontaneous Slow Slip and Runaway Slip in Laboratory

*Miki Takahashi[1]

1. Institute of Earthquake and Volcano Geology, Geological Survey of Japan, AIST

Earthquake nucleation and propagation involves the acceleration of slip on a fault from a background, quasi-static, low-velocity state towards meter-per-second values. From shear experiments using brine-saturated simulated gouge composed of 80:20 wt.% mixtures of halite and muscovite (following e.g. Niemeijer & Spiers, 2007, JGR), Takahashi et al., [2017, G-cubed] recently reported a switch in the dominant deformation process, from distributed viscous flow (pressure solution creep) to localized brittle deformation, at a critical velocity V_c (~20 μm/sec). The direct effect which is normally observed upon perturbations in sliding rate disappears for $V > V_c$, suggesting that runaway fault-slip may be achieved when the sliding velocity exceeds V_c.
At relatively low shear stress, flow mechanisms, such as pressure solution creep and dislocation creep, will be fast enough to effectively suppress slip acceleration. However, with increasing the shear stress, there may be a velocity range in which flow mechanisms still works but not as effective. Hypothesizing that, under constant shear stress boundary conditions, this may lead to spontaneous acceleration followed by deceleration, analogous to a slow slip event. Moreover, imposing the constant shear stress with equal or larger value of the maximum strength of the simulated gouge, I also hypothesize that slip acceleration may proceed as $V > V_c$, inducing a dynamic weakening.
To address these hypotheses, I conducted torque-controlled rotary shear experiments, using brine-saturated, 80:20 wt % mixtures of halite (grain size < 75 μm) and muscovite (grain size < 33 μm) powders. Approximately 1.65 g of the gouge mixture was sandwiched between two teethed steel piston rings, forming an initially 1 mm thick layer. The piston rings had an inner diameter of 38 mm, and an outer diameter of 50 mm. I used a high-velocity rotary shear apparatus designed by T. Shimamoto [e.g., Togo and Shimamoto, 2012], and now installed at the Geological Survey of Japan (GSJ). The apparatus was modified to enable torque control with an accuracy of ±0.002 in the friction coefficient (μ), at a normal stress of 5 MPa. Rotation displacement is measured using a potentiometer installed close to the piston ring at the rotating side.
A preliminary result shows the velocity evolution after stepwise changes in the shear stress. At low shear stresses, corresponding to the pressure solution creep-controlled regime, transient increasing velocity towards a steady-state values suggests stable sliding. At $\mu \approx 0.6$, the simulated gouge shows spontaneous acceleration to $V \approx 1$ μm/sec, followed by deceleration. Lastly, under a constant shear stress condition equivalent to $\mu = 0.67$, spontaneous slip acceleration occurred followed by dynamic weakening at $V \approx V_c = 20$ μm/sec. More experiments and microstructural observations will help to elucidate the relationship between the critical velocity and the switch among dominant deformation mechanisms.

Hydration and amorphization of quartz rocks during high-velocity frictional sliding: An examination of fault gouge from friction experiments of synthetic quartz

*Yuko Onoe[1], Hirotaka Iida[2], Akito Tsutsumi[1], Aki Takigawa[1]

1. Graduate School of Science, Kyoto University, 2. Geothermal Engineering Co., Ltd.

Various types of rocks and fault gouges display weakening of frictional strength at high-velocities, and in many cases, it is caused by high-temperature faulting processes such as frictional melting and thermal decomposition of fault materials. On the other hand, siliceous rocks display weakening of frictional strength at relatively slow slip velocity of ~1 mm/s. This weakening is a specific phenomenon because frictional heat is not sufficient to induce the high-temperature transformation reactions in this slip velocity range [Di Toro et al., 2004]. Goldsby and Tullis [2002] proposed gel lubrication model to explain the weakening of siliceous rocks; in which model frictional weakening likely results from production and shearing of hydrated amorphous silica layer along a fault in quartz rocks. But the relationship between the frictional weakening and hydration and amorphization of fault gouge is not clear yet.

This study aims to elucidate the mechanism of the frictional weakening observed for siliceous rocks. We conducted a series of friction experiments on synthetic quartz samples using a rotary-shear, intermediate-to high-velocity friction testing machine. Experiments were carried out under a constant normal stress condition of 1.5 MPa and at slip velocities of 5 μm/s, 10 μm/s, 105 μm/s, 1 mm/s, 10 mm/s and 105 mm/s. In this study effect of drying the sample on the frictional behavior were examined by introducing dry air to the chamber of the sample. After the friction tests, the gouge material on the slip surfaces were collected and analyzed by FTIR.

The frictional behavior of the synthetic quartz differs between room humidity and dry conditions; velocity weakening was observed for both conditions, however, velocity weakening starts at lower slip velocities for the dry experiments. Under DRY conditions, the frictional weakening occurs at slip velocity around 10 μm/s. From the results of the FTIR analysis, hydration of the gouge is confirmed for all the samples tested in this study. The FTIR result also indicates that the faster the slip velocity, the more the crystal structure of the gouge is destructed.
It is showed that under both DRY and Room Humidity conditions, at least the gouge generated on the friction surface of the sample which showed slip weakening is hydrated, consistent with the weakening model of Goldsby and Tullis [2002].

Constraining S Wave Velocity of the Source Region of Shallow Very Low-Frequency Earthquakes

*Takeshi Akuhara[1], Takashi Tonegawa[2]

1. Earthquake Research Institute, The University of Tokyo, 2. Research and Development center for Earthquake and Tsunami, Japan Agency for Marine-Earth Science and Technology

Shallow very low-frequency earthquakes (VLFEs), which are believed to occur in the vicinity of megathrusts, have been often associated with elevated pore fluid pressure. Lines of evidence for this idea include a small amount of stress drop, high tidal sensitivity, and reduced P wave velocity inferred from active source seismic surveys. Revealing the physical properties of the source region of shallow VLFEs will lead to a better understanding of their generation mechanisms. However, the challenge lies in the difficulty of acquiring S wave velocity in fine resolution.

Recent achievements by the authors may help overcome this issue. Akuhara et al. (2019) developed a robust technique to estimate Green's functions of receiver side structures from offshore seismograms, which are typically ill-conditioned due to water reverberations. Tonegawa et al. (2017) inverted Rayleigh wave admittance (i.e., a ratio of ground displacement to hydraulic pressure) for shallow S wave velocity structures beneath DONET seafloor observatories at the Nankai Trough subduction zone. Their velocity models show low-velocity zones that characterize the source regions of shallow VLFEs. However, a smoothing constraint imposed on the models renders their interpretation somewhat difficult.

This study presents preliminary results from transdimensional inversion of receiver-side Green's function estimated by the method of Akuhara et al. (2019), where we adopt a prior constraint by the velocity models of Tonegawa et al. (2017). Complementary to the Rayleigh admittance, the Green's function approach is sensitive to velocity contrasts and thus will offer an improved resolution.

Quantitative relationship between aseismic slip propagation speed and frictional properties

*Keisuke Ariyoshi[1], Jean-Paul Ampuero[2,3], Roland Burgmann[4], Toru Matsuzawa[5], Akira Hasegawa[5], Ryota Hino[5], Takane Hori[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Université Côte d'Azur, 3. California Institute of Technology, 4. University of California, Berkeley, 5. Graduate School of Science, Tohoku University

Recent observations show evidence of propagation of postseismic slip, whose propagation speed may contain information about the mechanical properties of faults. Here, we develop a new analytical relationship between the propagation speed of aseismic slip transients and fault frictional properties, modeled by a rate- and state-dependent friction law. The relationship explains the propagation speed of afterslip in 3-D numerical simulations to first order. Based on this relationship, we identify systematic dependencies of afterslip propagation speed on effective normal stress σ and frictional properties (the coefficients a and a-b which quantify the instantaneous and the steady-state velocity-dependence of friction, respectively, and the characteristic slip distance d_c of fault state evolution). Lower values of the parameter $A=a\sigma$ cause faster propagation in areas where the passage of the postseismic slip front induces large shear stress changes $\Delta\tau$ compared to A, which are typically located near the mainshock rupture. In areas where $\Delta\tau/A$ is small, typically more distant from the mainshock, afterslip propagation speed is more sensitive to (a-b) σ. The propagation speed is proportional to initial slip velocity and inversely proportional to d_c. The relationship developed here should be useful to constrain the frictional properties of faults based on observed propagation speeds, independently of rock laboratory experiments, which can then be used in predictive numerical simulations of aseismic slip phenomena.

Comprehensive detection of very low frequency earthquakes off the Pacific coasts of Hokkaido and Tohoku, northeastern Japan

*Satoru Baba[1], Akiko Takeo[1], Kazushige Obara[1], Takanori Matsuzawa[2], Takuto Maeda[3]

1. Earthquake Research Institute, University of Tokyo, 2. National Research Institute for Earth Science and Disaster Resilience, 3. Graduate School of Science and Technology, Hirosaki University

Very low frequency earthquakes (VLFEs), classified as one type of slow earthquakes, occur near seismogenic zones. VLFEs off the Pacific coasts of Hokkaido and Tohoku in northeastern Japan occur around subducting plate interfaces near trenches. Asano et al. (2008) found VLFEs in the off-Tokachi region, the southern part of the Pacific coast of Hokkaido along the Kuril Trench, by array signal processing using high-sensitivity accelerometers of Hi-net operated by National Research Institute for Earth Science and Disaster Resilience (NIED). In recent years, VLFEs off the Pacific coast of Tohoku were found by visually checking broadband seismograms of F-net operated by NIED and other events were detected by the matched-filter technique using waveforms of detected events as templates (Matsuzawa et al., 2015). However, the number of detected VLFEs may have been limited because of the small number of the VLFE templates in previous studies. Baba et al. (2018, SSJ) set four virtual epicenters off the Pacific coasts of Hokkaido and Tohoku and detected VLFEs by the matched-filter technique using numerically simulated waveforms as templates. We extended virtual epicentral gridsto make more comprehensive detection of VLFEs.

We used continuous seismograms of F-net seismometers from January 2003 to July 2018 after applying a band-pass filter of 0.02–0.05 Hz. We set 123 virtual epicentral grids off the Pacific coasts of Hokkaido and Tohoku, and computed the synthetic waveform from the source at each virtual epicenter by the finite difference method with a three-dimensional velocity structure model, namely, Japan Integrated Velocity Structure Model (Koketsu et al., 2012). The fault mechanisms were assumed to be consistent with the geometry of the plate boundary and a plate motion model, NUVEL-1A. We then calculated station- and component-averaged cross-correlation coefficients (averaged CC) between synthetic waveforms and the data of F-net seismograms every 1 s, and selected the events which have averaged CC above nine times of the median absolute deviation of the distribution. This method is, however, sensitive to regular earthquakes and teleseismic events as well. We then excluded the signal of regular earthquakes by discarding events with the amplitudes of more than 160 nm/s at 1-2 Hz in vertical components at the nearest stations. Moreover, to remove teleseismic events, we used the USGS earthquake catalog and discarded events with high amplitudes and low averaged cross-correlation coefficients.

VLFE activities in the off-Tokachi and off-Aomori regions show synchronized episodic bursts in the interval of several months. VLFEs in the off-Tokachi region was rapidly increased by the afterslip of the 2003 Tokachi-Oki earthquake. Those in the off-Iwate and off-Ibaraki regions, located out of the coseismic slip area of the 2011 off the Pacific coast of Tohoku Earthquake (hereinafter, the Tohoku earthquake), were also rapidly increased by the afterslip of the Tohoku earthquake. VLFE activity in the off-Miyagi region is characterized by episodic bursts in the interval of several months to one year before the Tohoku earthquake, but it became low since then. VLFE activity in the off-Fukushima region show dramatic increase after an Mw 6.9 earthquake at off-Fukushima on July 19, 2008. In the off-Miyagi and off-Fukushima regions, located within or at the edge of the coseismic slip area of the Tohoku earthquake, VLFE activity has been low since the Tohoku earthquake probably because the earthquake released the

©2019. Japan Geoscience Union. All Right Reserved.

stress almost completely. These results suggest that VLFEs are sensitive to the stress perturbation and can be a slip meter that reflect spatiotemporal change of the interplate slip, as has been indicated by previous studies. Consequently, one possible cause of these episodic VLFE bursts in the off-Tokachi, off-Aomori and off-Miyagi regions may be the intermittent release of small portion of stress accumulated by interplate locking between plates in the interval of several months to one year. The interval of episodic bursts is shorter than a periodicity of slow slips ranging from 1 to 6 years off the Pacific coasts of Tohoku indicated by Uchida et al. (2016).

Spatio-temporal evolution of long- and short-term slow slip events in the Tokai region, central Japan estimated from a very dense GNSS network, during 1997-2017

*Hiromu Sakaue[1], Takuya NISHIMURA[2], Jun'ichi Fukuda[3], Teruyuki Kato[4]

1. Graduate School of Science, Kyoto University, 2. Disaster Prevention Research Institute Kyoto University, 3. Earthquake Research Institute,The University of Tokyo, 4. Hot Springs Research Institute of Kanagawa Prefecture

The long-term slow slip events (SSEs) have been reported on the subducting Philippine Sea Plate in the Tokai region, central Japan during 2001-2005 and 2013-2016. Many short-term slow slip events have been also observed there since 1996. We analyzed GNSS data from 1997 to 2017 to estimate spatiotemporal distribution of interplate slip associated with these SSEs in this study. The GIPSY-OASIS II software (version 6.1) was used to estimate daily coordinates of GNSS stations operated by GSI and JUNCO (the Japanese University Consortium for GPS Research). It is well known that GNSS time series have many systematic signals and noises that do not result from SSEs. They include, for example, seasonal variations, co- and post-seismic deformation of the 2004 southeast off Kii Peninsula earthquakes (M_w 7.3/7.4), the 2008 Ibaraki-ken-oki earthquake (M_w6.9), the 2008 Fukushima-ken-oki earthquake (M_w7.0) and the 2011 Tohoku-oki earthquake (M_w9.0), and crustal deformation of volcanic activity on the northern Izu Islands in 2000. After removing them, we applied a modified Network Inversion Filter (NIF) [Fukuda et al., 2008] to estimate daily slip and slip rate on the subduction plate interface.
Our results suggest that not only long-term SSEs (M_w~7.1 and M_w~6.7) in 2000-2005 and 2013-2016, but also short-term SSEs (M_w<6.1). The maximum estimated daily slip rates for short-term SSEs are an order of magnitude larger than those of the long-term SSE, and peak slip for short-term SSEs migrates along strike with LFTs synchronously. It suggests that LFTs are loaded directly by SSEs, and that slip rate regulates LFT genesis. We will present the change of back slip rate between inter short-term SSEs and characteristics of short-term SSEs (e.g. slip rates and recurrence interval) depending on the occurrence of long-term SSE.

Broadband excitation of acoustic emission in granular stick-slip : experiments and spectral analyses

*Hidekazu Fukumizu[1], Ikuro Sumita[2]

1. Earth and Environmental Science Course, Division of Natural System, Graduate school of Natural Science and Technology, Kanazawa University, 2. School of Geosciences and Civil Engineering, Kanazawa University

Slow slip and tremor are observed to occur simultaneously (e.g., Rogers and Dragert, Science, 2003). Such observation can be modelled using granular stick-slip experiments which show that the timing of the slips and acoustic emission (AE) are well correlated (e.g., Johnson et al., GRL, 2013, Jiang et al. GRL, 2017). AE waveforms are complex (e.g., Michlmayr & Or, Gran. Matt., 2014), and we do not fully understand the details of the temporal change of AE during the slip. Here we report the results of granular stick-slip experiments which focus on how their spectra depend on the shear rate, particle size and container size.

We shear glass beads contained in a stainless steel beaker using a rotating viscometer to which a vane spindle is attached (Higashi and Sumita, JGR, 2009), and measure the shear stress and AE at 200kHz. We use broadband accelerometers and microphones to measure AE. Four accelerometers are attached at the outer rim of the beaker, and each are separated by an angle of 90 degrees.

We integrate the acceleration to obtain AE velocity –time series data and analyze their characteristics in broad band. We find that although AE has a broad spectrum, the spectra show that there are two characteristic frequency (f) components ; a high-f (of the order of 100 Hz) and a low-f (of the order of 10Hz) components. The velocity waveforms recorded at antipodal positions, show that the high-f components are in phase, whereas the low-f components are of the opposite phase. This indicates that the mechanism which excite these components differ : the high-f component may correspond to AE excited by particle rearrangement, whereas the low-f component may correspond to the translational motion of the container. Indeed we find that the frequency of the low-f component depends on the container size.

We also conducted experiments using a rheometer in a parallel-plate setup and confirmed that these two different components exist. When the particle size becomes larger, the amplitude of the shear stress and the AE velocity increases. Furthermore we find that the mean frequency of the normalized power spectra rose to a higher frequency, thus correlating with the stress increase.

Our experiments indicate that AE is excited in broadband, and that their frequency components can be used to infer the interparticle stress. Such excitation appear to be analogous to tremors and very low frequency earthquakes that are also excited simultaneously.

Episodic tremor and slip silently invades strongly locked megathrust in the Nankai Trough

*Masayuki Kano[1], Aitaro Kato[2], Kazushige Obara[2]

1. Graduate school of science, Tohoku University, 2. Earthquake Research Institute, The University of Tokyo

Recent seismic and geodetic observations in subduction zones have revealed that slow earthquakes have preceded some large earthquakes (e.g., Kato et al., 2012; Mavrommatis et al., 2014; Ruiz et al., 2014). Characterization of slow earthquakes and their relation to large earthquakes provides important clues to constrain a wide spectrum of slip rates on tectonic faults. In this study, we report new evidence of a slow slip transient at the downdip edge of the strongly locked seismogenic zone in the western Nankai Trough in southwest Japan based on GNSS time series. This slow slip transient was remotely excited during an episodic tremor and slip at the downdip extension of the locked zone. Through this remote triggering, the frequent occurrence of the deep episodic tremor and slip invades the strongly locked megathrust zone and may intermittently increase the probability of large earthquakes in the Nankai Trough.

Spatial distribution of the electrical resistivity beneath western part of Shikoku Island where long-term SSE events have repeatedly occurred

*Makoto Uyeshima[1], Maki Hata[1], Hiroshi Ichihara[2], Ryokei Yoshimura[3], Koki Aizawa[4]

1. Earthquake Research Institute, The University of Tokyo, 2. Graduate School of Environmental Studies, Nagoya University, 3. Disaster Prevention Research Institute, Kyoto University, 4. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University

In the Bungo channel area at the western margin of the Nankai megathrust rupture zones, the long-term slow slip events (SSE) repeatedly occurred about every 6 or 7 years. Since the last large-scale SSE event occurred in 2010, we will have a next large event soon. In order to obtain the electrical resistivity structure in the vicinity of the SSE area and examine its temporal change, we have started the Network-MT survey in the western part of the Shikoku Island facing the Bungo channel since April, 2016. Just before beginning of the observation, a tiny-scale SSE event occurred in the Bungo-channel (Ozawa, 2017, Hirose et al., 2018). We selected 17 areas in the western part of the Shikoku Island and installed 3 or 4 electrodes in the respective areas. The electrical potential differences with typical electrode spacing of several km are measured by using metallic telephone line network. We also measure the geomagnetic field at two stations in the target region. With the aid of the BIRRP code (Chave and Thomson, 2004), we could estimate the frequency-domain Network-MT response functions of good quality between the voltage difference and the magnetic field. The Network-MT response functions were directly inverted to estimate the 3-D resistivity structure in this area with the aid of the DASOCC Network-MT 3-D inversion code (Siripunvaraporn, Uyeshima & Egbert, 2004).

Conductive portions are commonly detected in the mid-crust of the target region. Their roots are just on the upper surface of the subducting Philippine Sea slab. This may suggest dehydration there. Among the spatial distribution of resistivity, that of seismic P-wave attenuation (Kita and Matsubara, 2016), and that of SSE slips (e.g. Ozawa et al., 2013, Yoshioka et al., 2015, Hirose et al., 2018), some mutually related features are detected. Low Qp (high attenuation) areas tend to correspond to highly conductive areas. The low Qp and highly conductive area are detected just above the subducting slab and outside of the SSE area. Inside the SSE area, while Qp takes generally high values, a patchy conductive area is detected in overall resistive background structure.

This study is supported by JSPS KAKENHI Grand Number JP16H06475 in Scientific Research on Innovative Areas "Science of Slow Earthquakes". It is also partly supported by the Ministry of Education, Culture, Sports, Science and Technology (MEXT) of Japan, under its Earthquake and Volcano Hazards Observation and Research Program. We acknowledge staffs of the Nippon Telegraph and Telephone WEST Corporation for their cordial support in the survey. We also thank H. Abe, A. Takeuchi and Y. Suwa for their help in preparing and installing instruments.

Variations of scaling relationships for shallow tremor observed along the Nankai trough

*Masaru Nakano[1], Suguru Yabe[1]

1. Japan Agency for Marine-Earth Science and Technology

Scaling relationships of seismic phenomena is one of keys to understand the source processes. Size distributions of slow earthquakes as low-frequency earthquakes (LFEs), non-volcanic tremor (NVT), very-low-frequency earthquakes (VLFE), and slow-slip events (SSEs) have been studied in many locations. Some studies showed that the size distribution follow an exponential law (e.g. Watanabe et al., 2007; Hiramatsu et al., 2008; Chestler and Creager, 2017), while others showed that power law distributions better explain the observations (e.g. Kao et al., 2010; Bostock et al., 2015; Nakamura and Sunagawa, 2015).

Most of previous studies are for slow earthquakes that occur in regions deeper than the source region of megathrust earthquakes, and only a limited number of studies have been carried out for shallow slow earthquakes beneath accretionary prism as observed along the Nankai trough. Although observed characteristics of shallow and deep ones are very similar, physical conditions as temperature and pressure much differs in these region.

In our previous studies (Nakano et al., 2018SSJ, AGU), we obtained the result that shallow tremor follows a power law distribution with b values of about 1. In this study, we further analyzed tremor activities beneath the Muroto fore-arc basin. using data from DONET2. We estimated the seismic energy of tremor signals using the same method as our previous studies, during intensive activities starting in September 2015, April 2016, February 2017, and February 2018. The source region of each activity is different from each other, spanning between off Shiono-Misaki and off Cape Muroto.

The size distribution of each activity mostly follow power-law distributions, but the b value varies from 0.7 and 1.7. We note that the activity in 2016 is also well fitted by an exponential law, probably due to narrow range of observed event size distribution. Similar result has been obtained in the 2018 activity in Kumano. The size distribution deviate from a power law for largest events as observed in Kumano activities. This deviation at larger events would be due to limited system size, expected from the theoretical stochastic model of tremor by Ide and Yabe (2018). The upper limit of event size, and accordingly the system size, varies from activity to activity.

We also investigated the relation between the seismic energy and duration of tremor events. The relation also follows a power law, with slopes of 2.0 to 2.6 in Kumano, and 1.5 to 3.3 in Muroto. These values are again consistent with the expectation value of 2 from the model of Ide and Yabe (2018).

These investigations represent that the scaling relationships of shallow tremor are mostly consistent with the 2D PCA model by Ide and Yabe (2018). Further studies would be necessary to reproduce the observed variations of the scaling parameters.

Acknowledgments: We used DONET data and JMA and USGS earthquake catalogs in the analysis. This research was supported by JSPS KAKENHI Grant Number 16H06477 in Scientific Research on Innovative Areas “Science of Slow Earthquakes”

Low-frequency earthquakes triggered by teleseismic surface waves by Ryukyu subduction zone.

Ayumi Kinjo[1], *Mamoru Nakamura[1]

1. Faculty of Science, University of the Ryukyus

We investigated low-frequency earthquakes (LFEs) in the Ryukyu Trench region that were triggered by surface waves from teleseismic earthquakes. Although these LFEs in the southwestern Ryukyu arc have previously been explored by Chao et al. (2016), their hypocenter distribution is not known in detail.

We selected 50 earthquakes from January 2004 to December 2016, which had magnitudes greater than 7.5 and epicentral distances between 9–150˚. We used the waveforms of 6 broadband seismometers in the Ryukyu arc from F-net (NIED) to analyze the surface waves. We also used the waveforms of 20 short-period seismometers in the Ryukyu arc from the Japan Meteorological Agency to detect trace LFEs in Ryukyu Island and determine their hypocenters.

The LFEs in the Yaeyama and Okinawa regions were observed. In the former region, during the passage of the surface waves, spindle-shaped LFE waveforms were first observed at Hateruma (south of Yaeyama Islands), and later at other stations in the Yaeyama region. Similarly, for the latter region, during the passage of the surface waves, spindle-shaped LFE waveforms were first observed at ZMM or Tamagusuku (south of Okinawa Island), and later at other stations in the Okinawa region. These observations suggest that the sources of the triggered LFEs were near or south of Hateruma and Tamagusuku.

We subsequently determined the hypocenters of the triggered LFEs. We computed the LFE travel-time difference between two stations using cross-correlations of the waveforms (Obara, 2002). The travel-time difference of waveforms of the LFEs corresponded to travel-time difference of the S-phase because S-waves were dominant in the LFEs, and P-waves were weak. The hypocenters were determined using the grid search method (Chao et al., 2013). In the Yaeyama region, the LFE hypocenters were mainly distributed near Hateruma Island. In the Okinawa region, they were distributed south of Okinawa Island. These positions are similar to the positions of the LFE hypocenters that accompany very low frequency earthquakes (LFE-VLFEs). This suggests that faulting in a cluster of LFE-VLFEs would be active with dynamic stress change.

In the Okinawa and Yaeyama regions, LFEs are triggered when the peak ground velocity of the surface wave is greater than 0.1 cm/s. This threshold value is similar to that for LFEs in Taiwan (Chao et al., 2013), suggesting that the weak friction coefficient at the plate interface of the Ryukyu Trench is similar to that in Taiwan.

Detection of small surface displacement accompanying deep low-frequency tremor in Shikoku region, southwest Japan

*Yutaro Okada[1], Takao Tabei[2]

1. Faculty of Science, Kochi University, 2. Faculty of Science and Technology, Kochi University

In many subduction zones in the world, several types of slow earthquakes occur with different depths on the plate interface and some of them are accompanied by surface displacement. In this study, we focus on small surface displacements coincident with non-volcanic deep low-frequency tremor in Shikoku region in the Nankai subduction zone, southwest Japan.

We use daily coordinates time series from 107 GEONET stations located in Shikoku and tremor catalog compiled by NIED (Maeda and Obara, 2009; Obara et al., 2010) in the period from Jan. 1 2004 to Dec. 31 2008. Since GNSS coordinates changes due to the Bungo Channel long-term slow slip events are well reproduced by S-shaped logistic function, we use the same function to extract small displacement coincident with tremor activity. At first, we convert horizonal components into N50°W direction after removing annual and semiannual variations and common-mode errors. Next, we fit the logistic function to a data segment with variable time window of 5, 7, and 9 days and estimate an amplitude of the function. The fitting is checked by a correlation coefficient between the observation and calculation. We apply this fitting for entire data period at all stations sliding data segment. Finally, we extract displacement when the amplitude of the fitted logistic function exceeds a certain criterion (1.8 mm in this study) and the correlation coefficient is large enough. If the extracted displacement is coincident with tremor activity within 30 m from the GNSS station, we adopt it as the tremor-related displacement. As a result, 225 events are adopted.

Spatial pattern of the tremor-related displacement seems to be related with the location and mechanism of the tremor event though closer inspection is needed. However, we extract much more small displacements by fitting a logistic function, of which the source is unknown. The logistic function is effective to reproduce transient displacement of the surface but we need to reconsider noise reduction of GNSS time series, time constant of logistic function, time window of the fitting, and so on.

Long-term temporal change in crustal resistivity beneath western Shikoku

*Futoshi Yamashita[1], Yoshimori Honkura[1]

1. National Research Institute for Earth Science and Disaster Resilience

In southwest Japan, various slow earthquakes such as deep low-frequency tremor and short/long-term slow slip events occur at the subducting plate interface (e.g. Obara and Kato, 2016, Scinence). In western Shikoku, Magneto-telluric (MT) survey was carried out along the dip direction of subducting Philippine Sea plate. The survey revealed an existence of low-resistivity structure in the lower crust in this region (Yamashita and Obara, 2009, AGU). In order to investigate a relationship between this characteristic structure and the activity of slow earthquakes, NIED has been carrying out continuous MT observations in western Shikoku since 2008. Here we show the observational records over 10 years and then discuss a relationship between observed temporal change in crustal resistivity and activity of the long-term slow slip event (L-SSE). Two observational sites KBN and IKT are available as of 2019. Qualities of data recorded at these sites are relatively fine. However, in order to improve the quality for discussing subtle change in MT parameters, we apply a data processing method same as Honkura *et al.* (2013, Nature comm.); we use only data whose coherency between electric and magnetic field is higher than a threshold. The lowest frequency of processed data is 0.00028 Hz. The processed MT parameters, apparent resistivity and phase, do not show any long-term temporal changes at KBN site even after temporal stops of observation over some months. On the other hand, apparent resistivity at IKT site, which is around 10 km southwest away from KBN site, shows temporal reduction at a frequency lower than 0.0022 Hz between 2010 and the middle of 2012. It is known that L-SSE occurred beneath the Bungo Channel in 2010 (e.g. Yoshioka *et al.*, 2015, GJI), which could induce resistivity change in the lower crust and then it might be detected by our MT observation.

Slow decay of postseismic deformation compared with aftershocks following the 2011 Tohoku-oki Earthquake

*Yuta Mitsui[1], Shunsuke Morikami[2]

1. Department of Geosciences, Shizuoka University, 2. Formerly at Graduate School of Science and Technology, Shizuoka University

In the literature, decays of postseismic deformation rates of large earthquakes were almost comparable to aftershock decays for subduction earthquakes (e.g. Hsu et al. (2006), Lange et al. (2014)). They are characterized by the modified Omori law with p~1, which means "afterslip-triggerred aftershocks". In this study, we focus on the 2011 Tohoku-oki megathrust earthquake using GNSS and seismicity data. On the basis of high-rate analysis of RINEX data and the F3 solution provided by the Geographical Survey Institute (GSI), we clarify the characteristics of postseismic deformation and aftershocks up to five orders of magnitude of time scale. We find that the p value for the postseismic deformation (p_m) is ~0.7, by contrast, that for the aftershocks (p_n) is ~1. Because a rate-and-state-friction model (Helmstetter and Shaw (2009)) predicted $p_m>=p_n$, another or an additional physical mechanism is necessary to explain the data of $p_m<p_n$. One important mechanism is viscoelastic relaxation of asthenosphere, thus we try fitting the postseismic deformation data by combination of afterslip and viscoelastic relaxation (a model of Suito (2017)). The fitting is not poor but fails to reproduce the Omori-like decay. More complex combination models may improve the fitting, but would not make simple Omori-like power-law decays. We need more sophisticated physical model to represent the decay characteristics of postseismic deformation.

Serpentinite dehydration in subduction shear zones formed at source depths of slow earthquakes

*Yasushi Mori[1], Miki Shigeno[1], Kohtaro Ujiie[2], Kazuya Noro[2], Tadao Nishiyama[3]

1. Kitakyushu Museum of Natural History and Human History, 2. University of Tsukuba, 3. Kumamoto University

Long-term slow slip events (L-SSEs) and episodic tremor and slip (ETS) occur along the subduction plate boundary at depths of 30–45 km (Obara, 2002; Shelly et al., 2006). These deep slow earthquakes are probably induced by high pore-fluid pressure. Based on geological study, we propose that the high pore-fluid pressure can be produced by metasomatic dehydration of serpentinite in subduction shear zones at source depths of deep slow earthquakes.

The Nishisonogi metamorphic rocks in Kyushu, Japan, are part of a Late Cretaceous subduction complex metamorphosed at $P \approx 1$ GPa and $T \approx 470$ ˚C. The P-T conditions are close to those of source depths of deep slow earthquakes. Serpentinite mélanges intercalated with the metamorphic rocks contain blocks of metabasite, metapelite and albitite. The mélange matrix consists of chlorite-actinolite schist (CAS), talc schist and schistose serpentinite. Intense shear deformation is concentrated in the CAS, and the serpentinite mélanges have the characteristics of anastomosing shear zones.

Bulk chemical composition of the rocks suggests that the CAS is the metasomatized mixture of serpentinite and metabasite. In addition, chemical mass balance indicates considerable dehydration during the CAS formation, along with a slight increase of solid volume. These findings suggest that the CAS formation involves the build-up of pore-fluid pressure. The high pore-fluid pressure results in the concentration of shear deformation into the weakened CAS.

Dehydration of serpentinite probably plays a key role in deep slow earthquakes (Poulet et al., 2014; Okazaki and Katayama, 2015). Thermal dehydration of serpentinite occurs at ~600 ˚C along the subduction plate boundary (Auzende et al., 2006), which is much higher temperature than that of source depths of deep slow earthquakes. In contrast, metasomatic dehydration of serpentinite described here could occur at source depths of deep slow earthquakes.

Earthquake swarms following very low-frequency earthquakes in the central Ryukyu Trench

*Mamoru Nakamura[1]

1. Faculty of Science, University of the Ryukyus

Earthquake swarms occur frequently from Amami Island to Okinawa Island, near the axis of the central Ryukyu Trench. These earthquake swarms recur every few years and typically followed swarms of very-low frequency earthquakes (VLFE) that occur in a similar area. I have investigated the relationship between the VLFEs and the subsequent earthquake swarms in the central Ryukyu Trench, using the earthquake catalog provided by the Japan Meteorological Agency (JMA). For the VLFEs, I used the catalog by Nakamura and Sunagawa (2015) and the extended catalog to December 2018.

Results show that the VLFE swarms occurred approximately one month before the subsequent earthquake swarms began near the trench axis in this region. Previous noteworthy earthquake swarms occurred on August 2005 (with a maximum magnitude of 4.7), April 2009 (with a maximum magnitude of 5.1), May 2016 (with a maximum magnitude of 5.6), and September 2018 (with a maximum magnitude of 6.2).

Prior to the earthquake swarm that occurred in August 2005, a VLFE swarm started near Okinawa Island three months before and its activity moved intermittently from Okinawa Island to Amami Island. In the case of the earthquake swarm that occurred in April 2009, a VLFE swarm started near Amami Island and the subsequent swarm occurred two weeks after the start of the VLFE swarm. The location of the VLFE swarm moved intermittently closer to Okinawa Island. In the case of the earthquake swarm that occurred on May 2016, the VLFE swarm started near Amami Island and its active cluster moved intermittently towards Okinawa Island. The subsequent earthquake swarm started near the trench axis, approximately twenty days after the occurrence of the VLFE swarm. In the case of the earthquake swarm that occurred in September 2018, the VLFE swarm started near Okinoerabu Island (the midpoint between Amami Island and Okinawa Island) and the activity moved intermittently to Okinawa Island. The earthquake swarm occurred approximately twenty-five days after the start of the VLFE swarm. The location of the cluster of the 2018 earthquake swarm was slightly landward from the trench axis.

The faulting associated with these earthquake swarms was of normal type, corresponding to intra-slab earthquakes in the subducting Philippine Sea plate. I calculated the Coulomb Failure Stress (delta-CFS) assuming that a small slow slip event (SSE) occurred on the plate interface. Our results show that the positive delta-CFS that accelerated the normal faulting could not have occurred in the subducted slab near the trench axis until the slip of the SSE had reached close to the trench axis. This suggests that the SSE propagated from Amami Island to Okinawa Island accompanying the activation of the VLFE swarm, the slip of the SSE then propagated close to the trench axis, and the normal-faulting earthquake swarm in the slab was induced by the positive delta-CFS caused by the SSE.

Seismic imaging in the central Nankai trough, off Shionomisaki to Kii channel

*Yasuyuki Nakamura[1], Shuichi Kodaira[1], Tetsuo No[1], Yuka Kaiho[1], Gou Fujie[1], Seiichi Miura[1], Kazuya Shiraishi[1]

1. Japan Agency for Marine Earth Science and Technology

Shallow very low frequency events (sVLFE) have been reported in the Nankai Trough subduction zone recently. In the central part of the Nankai trough, sVLFE were observed off Kii channel and Shinomisaki, but not reported in the area between them, off western Kii peninsula. We conducted a seismic survey with R/V *Kaimei* in November and December 2018 in Nankai subduction zone off Kii channel to Shonomisaki to investigate the structural features and its possible relationship to the sVLFE. R/V *Kaimei* fired 10600 $inch^3$ air gun array at every 50 m and a streamer cable (4.3 km at shortest, 5.7 km at longest) recorded the seismic signals. We acquired 23 seismic profiles with the length of ~ 75 km in dip direction at 4 km line separation and four profiles of ~ 90 km in strike direction at the shallowest part of the subduction zone. In addition, seven dip profiles with the length of 35 km were acquired off Kii channel to cover the lowermost part of the landward slope densely. The streamer cable was towed at a depth of 25 m to relatively enhance the lower frequency signals for better imaging of the deeper structure. Preliminary processed seismic profiles exhibited the structural variation in the survey area. Deformation of the hanging wall sediments and decollement were well imaged especially ~ 20 –30 km from the trough axis. Top of subducting Philippine Sea plate can be observed through ~ 40 –50 km from the trough axis in some of the obtained profiles. A pair of apparently low angle deep strong reflections were imaged at ~ 7 –8 s two-way time around 40 - 50 km from the trough axis off the western Kii peninsula, which was located slightly east and landward of the area with sVLFE. The shallowest part of the subduction zone in the area where the recent sVLFE activity was not reported, a slope basin with younger sediments deposited over the body of the accretionary prism is imaged, and the deformation was not observed in the slope basin. This suggests the thrust faults within the accretionary prism have not been active recently in this area. We will further process acquired data to obtain clearer seismic images and discuss the structural features and its connection to the observed seismological events in the Nankai Trough.

Attempt to Detect Intra-plate SSEs Based on F3 Solution of GEONET

*Yusaku Tanaka[1]

1. Earthquake Research Institute

Slow earthquakes have been detected all over the world and providing new insights into earthquakes. However, most of slow slip events (SSEs) were detected only on plate boundaries and intra-plate SSE was detected only once in Hokkaido. Thus, I attempt to detect intra-plate SSEs all over Japan using F3 solution of GEONET by GSI. I analyze the F3 data with six steps, i.e., (1) removing outliers by setting a term of mean + two times standard deviation for 1/4+1/4 year before-and-after each datum except for the datum itself and considering it is an outlier when it is out of the term, (2) removing disconnections estimated from the offsets and linear trends of 60+60 days before-and-after each datum with the least square method, (3) searching statistically significant temporal changes of the trends by using AIC, (4) cheking visually the time series in which the temporal changes are detected, (5) estimating the displacements from the trend chagnes, and (6) verifying the deformations by numerical calculation by setting rectangular faults.

As of 18th Feb 2019, my study has proceeded to the step (4). In the JpGU meeting, I will report the results of this analysis.

A new hydrothermal, low to high speed rotary-shearing apparatus: Reproduction of slow/megathrust earthquakes in laboratory

*Takehiro Hirose[1], Wataru Tanikawa[1], Yohei Hamada[1], Keishi Okazaki[1]

1. Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology

Earthquakes involve a wide range of slip rates, from slow/aseismic to fast/seismic slip along faults. Thus, frictional properties of faults over wide slip rates (nm/s to m/s), in particular under hydrothermal conditions similar to those expected in seismogenic zones are essential for a unified understanding of all earthquake events. A new hydrothermal, low to high speed rotary-shearing apparatus has been installed at Kochi/JAMSTEC, in order to study the fault constitutive properties at slow to fast slip rates and the physicochemical mechanisms underlying mechanical responses. The apparatus is currently capable of applying slip rates from 100 nm/s to 2 m/s, normal stress up to 55 MPa, fluid pressure up to 120 MPa and temperature up to 450oC with infinite displacement. We have been improving the apparatus to work as we intended. In pilot tests, we used metamorphic rocks (pelitic and green schists) as starting materials that are potentially distributed at and below seismogenic zones along hot and young subduction zones. We will present our preliminary results with the basic design of the apparatus.

Very low-frequency earthquakes in western Shikoku remotely triggered by the 2016 Mw5.9 off-Kii Peninsula earthquake

*Masatoshi Miyazawa[1]

1. Disaster Prevention Research Institute, Kyoto University

Slow tectonic events are known to be sensitive to external stress perturbations due to passing seismic waves and earth tides. High-amplitude surface waves from large earthquakes have transiently triggered low-frequency earthquakes (LFEs) and slow slip events (SSEs) in subduction zones. However, dynamic triggering of very low-frequency (VLF) earthquakes during the arrival of seismic waves from a large, distant earthquake has not been observed. Because both the VLF earthquake and the surface wave have similar characteristic periods, remote triggering is not easily detected by using existing methods. We developed a particle filter/smoother for time series analysis combined with Markov chain Monte-Carlo methods, to detect seismic signals and estimate the maximum likelihood source parameters of VLF events that might have been remotely triggered. We apply this method to seismic data from the Mw5.9 earthquake, which occurred on 1 April 2016 (UTC), off Kii Peninsula. We found that six VLF events with magnitudes about 4, likely occurred in the seismogenic regions of ambient LFEs, and were likely triggered by the arrivals of high-amplitude surface waves. The triggering stress changes are from 0.4 to 1.5 kPa, which are similar to the values for LFEs triggering reported previously. Since there were no triggered LFEs in western Shikoku following the 2016 earthquake, these VLF earthquakes are more sensitive to stress changes caused by surface waves from large earthquakes.

Underground structure around source region of slow earthquakes in western Shikoku obtained by receiver function analysis

Akira Hikita[1], Aitaro Kato[1], *Kazushige Obara[1], Akiko Takeo[1], Takeshi Akuhara[1]

1. Earthquake Research Institute, The University of Tokyo

Various types of slow earthquakes have been observed at subduction zones surrounding the Pacific Ocean. It has been suggested that elevated pore fluid pressure plays an essential role in the generation of slow earthquakes because low velocity or high Vp/Vs zones have been also reported along the plate boundaries where they occur. In Tokai region of the Nankai subduction zone, Kato et al. (2010) revealed that long-term slow slip event (SSE) occurs at the boundary between the continental lower crust and the subducting Philippine Sea plate and episodic tremor and slip (ETS) occurs between the mantle wedge and the subducting plate. Kato et al (2010) also revealed that oceanic crust indicates higher Vp/Vs in the long-term SSE region than in the ETS region. In contrast, Toya et al. (2017) reported that the oceanic crust indicates higher Vp/Vs in the ETS region than in the long-term SSE region in western Shikoku of the same subduction zone. In this study, we revealed configurations of continental Moho discontinuity and subducting oceanic crust and investigated relationship between slow earthquakes and the surrounding seismic velocity structure by receiver function analysis using a dense seismic array in western Shikoku.

As a result, continuous continental Moho and oceanic crust are clearly imaged along both north-south and east-west oriented seismic lines. The plate boundary in the south part, where the distinct continental Moho is not imaged, has steeper slope than the north part along the north-south line. ETS occurs between the mantle wedge and the subducting plate, and long-term SSE occurs along a contact between the continental crust and the oceanic crust.
We show that the oceanic crust indicates much higher Vp/Vs than the hanging wall by using also the reverberation phases. This high Vp/Vs means the elevated fluid pore pressure within oceanic crust due to dehydration. Vp/Vs in the oceanic crust is higher in the deep part of the long-term SSE region than in the ETS region like as the case of Tokai. It is assumed that fluid would accumulate within the oceanic crust owing to low permeability of the continental crust in the long-term SSE region. In contrast, serpentinization of the mantle wedge just above the ETS region could reduce fluid pressure in the oceanic crust. Furthermore, Vp/Vs in the oceanic crust becomes lower in the deeper part beyond the ETS depths, suggesting that eclogization is completed at the depths.

Hypocenter determination of deep low frequency tremors beneath the Kii Peninsula by backprojection of seismic array data

*Kodai Sagae[1], Hisashi Nakahara[1], Takeshi Nishimura[1], Kazutoshi Imanishi[2]

1. Graduate School of Science,Tohoku University, 2. National Institute of Advanced Industrial Science and Technology (AIST)

A seismic array analysis enables us to detect weak signals if they are coherent. In Cascadia, a high accuracy hypocenter determination of tremors has been carried out by using dense seismic arrays (e.g.,Ghosh et al.,2012). In Southwest Japan, previous studies (e.g.,Ueno et al.,2010) applied the **MU**ltiple **SI**gnal **C**lassification (MUSIC) method (Schmidt,1986) to data of surface seismic arrays at Western Shikoku and carried out the hypocenter determination. However, a quantitative threshold for event detection was not considered. Sagae et al.,(2018 SSJ) introduced an event detection threshold based on the coherence of waveforms among stations, and improved tremor detection by using a surface seismic array installed by AIST at the Kii Peninsula. We applied the MUSIC method to this data in times when tremor events were detected and estimated slownesses and arrival azimuths of tremor signals. Their temporal variations suggested tremor migration. However, we did not carry out hypocenter determination. In this study, we determine hypocenters of tremors by backprojection using the estimated slownesses and arrival azimuths.
The surface seismic array installed by AIST at the Kii Peninsula was composed of 39 three component velocity sensors with a natural frequency of 2.0 Hz and a sampling frequency of 200 Hz. This array had an aperture of about 1.5 km and the sensors were arranged in a cross shape with interval spacings of 50~100 m. We analyze data for 1 year (between July 7,2013 and July 7,2014), because the number of sensors is stable in this period.
We focus on a frequency of 3Hz, which is within the tremor's dominant frequency band of 2-10 Hz. Data processing is described as follows. (1) We calculate averaged coherence of waveforms for all station's pairs. (2) We detect tremor events by setting a detection threshold based on the averaged coherence. (3) We estimate slownesses and arrival azimuths by applying the MUSIC method to the data when tremors are detected. (4) We project them back to the plate boundary (Hirose et al.,2008) and determine source locations by using S wave velocity model JMA2001 (Ueno et al.,2002).
We detected 5 periods of high tremor activities during the 1 year period. We compared the hypocenter distributions determined by our method and those of AIST tremor catalogue which were determined from an envelope cross correlation method. Temporal variation of tremors in this study were almost consistent with the AIST catalogue. We were also able to detect about 2.5 times as many events as the AIST catalogue. It is easier to identify temporal variation of tremors in more detail because our study improved temporal resolution up to 10 sec.
We projected temporal variations of tremor distributions into along-strike and along-dip directions. The results show tremors tend to migrate along the strike in time scales of several days with migration velocities of 6.0~9.3 km/day. Along-dip migrations of tremors with a short timescale of several hours are also detected. When we focused on the initial part of tremor activities, tremors tend to start in deeper parts and gradually migrate to shallow parts. These migration velocities were estimated to be about 1.0 km/hr (24 km/day) in the up-dip direction.
In this study, we were able to improve tremor detection by setting the event detection threshold based on the coherence of seismograms for stations pairs in a surface seismic array. Thanks to this, we were able to locate 2.5 times more tremors than the conventional method. We made it easier to keep track of tremor migrations by improving the temporal resolution of hypocenter determination to 10 sec.
We used the plate boundary model (Hirose et al.,2008). We downloaded the AIST catalogue from Slow

Triggered tremors and stress perturbations due to surface waves

*Ryohei Ikeda[1], Naoki Suda[1]

1. Hiroshima University

Surface waves radiated from distant large earthquakes sometimes trigger a series of deep non-volcanic tremors with intervals of 20-30 seconds, which are the same as dominant periods of surface waves [e.g. Miyazawa & Brodsky 2008]. Understanding the triggering mechanism is important because it provides us clues to the slip process occurring along the transition zone of subducting plate interface. Dynamic stress perturbations due to surface waves that triggered tremors were estimated on the order of 1 to 10 kPa [e.g. Chao & Obara 2016]. To study the relationship between triggered tremors and stress perturbations due to surface waves, we computed theoretical dynamic stresses due to surface waves from large earthquakes by using observed and theoretical surface waves.

We focused on the triggered tremors in the western Shikoku region of the Nankai subduction zone. Most of them occurred in two clusters where tectonic tremors actively occur. We computed theoretical dynamic stress perturbations due to surface waves from 106 earthquakes between 2004 and 2016 with moment magnitudes of 7.0 or grater. The receiver points at which the stress components were computed are at the plate boundary below the N.TSAF and N.KWBH stations, which are the nearest stations of the triggered tremors in F-net and Hi-net, respectively. PREM [Dziewonski & Anderson 1981] and Global CMT catalog [Dziewonski et al. 1981; Ekstrom et al. 2012] were used for the Earth model and the seismic sources for computing theoretical surface waves. Source time functions were approximated with triangular functions whose half durations are equal to the centroid time lags.

The stress change at the plate boundary by the surface wave was estimated based on the method of Spudich et al. (1995). This method consists of two stages: (1) Estimate the stress at the surface from the observed ground velocity and (2) Estimate the stress at the plate boundary from the stress at the surface estimated in (1). In these estimations, we used theoretical proportional relations between the ground velocity and the surface stress and those between the surface and the deep stresses in the frequency domain, which were obtained from the theoretical surface waves. We used the N.TSAF and N.KWBH records as the observed ground velocity. The records from the latter were corrected using the method of Maeda et al. (2011).

The stress components in the source coordinates were transformed to the stress normal to the plate interface and the stress along the possible slip direction of tremor source. The normal and slip directions were obtained from the model plate interface [Baba et al. 2002; Nakajima & Hasegawa 2007; Hirose et al. 2008] and plate convergence vectors [Miyazaki & Heki 2001]. We computed waveforms of the Coulomb failure function (ΔCFF) using a frictional coefficient of 0.2 at periods between 20 and 50 seconds.

©2019. Japan Geoscience Union. All Right Reserved.

Results from the N.TSAF records show that the maximum ΔCFF for the events that triggered tremors are greater than 0.5 kPa. The magnitudes of triggering earthquakes are greater than 7.5. ΔCFFs were generally overestimated when we used the corrected N.KWBH records because the correction did not well work, in particular, for the earthquakes with magnitudes less than 7.5. The important point is that not all of the events that provided the stress perturbations greater than 0.5 kPa triggered tremors. This shows that the stress perturbation due to surface waves cannot be the unique triggering condition: other conditions, for example, stress perturbations due to possible background slow slip events and/or high pore fluid pressure are required.

Numerical modeling of long- and shallow slow slip events including shallow region in Hyuganada and western Nankai, Japan

*Takanori Matsuzawa[1], Bunichiro Shibazaki[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Building Research Institute

Recent studies reported deep long-term slow slip events (SSEs) in the Hyuganada and western Nankai region (e.g., Kobayashi, 2014; Takagi et al., 2016; Ozawa. 2017). Shallow SSEs are also recently reported with low-frequency tremor and very low-frequency earthquakes (e.g., Araki et al., 2017; Nakano et al., 2018). In our previous study, we have numerically reproduced recurring deep long- and short-term SSEs in the Shikoku region (Matsuzawa et al., 2013), considering the actual distribution of slow earthquakes and configuration of the subducting Philippine Sea plate. We aim to reproduce deep long- and short-term SSEs and shallow SSEs in a single numerical model applying a similar approach in Matsuzawa et al. (2013).

We adopt a rate- and state-dependent friction law (RS-law) with cutoff velocities. We assume that (a-b) value in the RS-law is negative within the deep short-term SSE region, and positive outside that region. The deep short-term SSE region is modeled based on the actual distribution of deep low frequency tremor. Deep long-term SSE region is assumed based on the geodetic observation (Hirose et al., 2011). To focus on the Hyuganada and western Nankai region, we assume stable sliding region with positive (a-b) in the south of the Kyushu-Palau ridge. We also assume low cutoff velocity at the depth shallower than 9 km to reproduce shallow SSEs. Low effective normal stress is assumed at the depth of SSEs. Temporal evolution of slip velocity is numerically simulated, introducing elastic response and realistic configuration of the plate interface.

In terms of deep long-term SSEs in Hyuganada, a simple extension of the long-term SSE region in the Bungo Channel cannot reproduce the segments of observed SSEs. Narrowed long-term SSE region in the dip direction between Bungo and southern Hyuganada can reproduce three observed segments of SSEs, i.e., Bungo, northern Hyuganada, and southern Hyuganada. In addition, recurring shallow SSEs along trench in Hyuganada and off Ashizuri are reproduced in our result. Megathrust earthquakes are divided into two regions; off Shikoku and Hyuganada in our result. The segments of these large earthquakes may be attributed to the long-term SSE region in the Bungo Channel. Our model comprehensively reproduces various SSEs and megathrust earthquakes, including newly found long-term SSEs.

Further evidence for the influence of a subducting-ridge on the spatial strain accumulation and release pattern in the shallow eastern Nankai Trough, based on VLFE distribution

*Akiko Toh[1], Chen Wan-Jou [2], Doug Dreger[3], Wu-Cheng Chi[2], Satoshi Ide[1]

1. University of Tokyo, 2. Institute of Earth Sciences, Academia Sinica, 3. UC Berkeley

We investigated the distribution and focal mechanisms of very low frequency earthquakes (VLFEs) located in the shallow part of the eastern Nankai trough. While they are mainly explained as low angle thrust faulting along the plate boundary (Sugioka et al., 2012; Nakano et al, 2016), along the strike variation in their distribution has also been observed, likely caused by a subducting-ridge (Toh et al., 2018). Such variations could be closely related to the strain release pattern, or the tsunamigenic potential, of this region, thus warrant a further comprehensive study.

We used 3 component records of broadband ocean bottom seismometers equipped in Dense Oceanfloor Network system for Earthquakes and Tsunamis 1 (DONET1). Records of VLFE activities that occurred immediately beneath the network in 2015, 2016 and 2017 for 1-2 weeks each year, are used. Through visual inspections, we detected 335 VLFEs whose signals are observed at least 6 stations on vertical component filtered between 16-32s.

Instead of estimating the source parameters for one after another for all the events, we searched for densely located event groups inferred by similarities of the maximum amplitude variations measured per event, and, so far, worked only on the grouped events. The purpose of this event selection process is to get an overview of the distribution using the simple quantity (i.e. max. amplitude variation) that can be evaluated for every VLFE, and to avoid a bias that may be caused by eliminating events that are merely difficult to process (i.e. do not fit synthetic waveforms) mostly due to complicated long source time functions that characterize VLFEs. The grouping is conducted by a hieratical density-based clustering method HDBSCAN (Campello et al., 2003), and 197 events were grouped into 26 groups that consists of 2 to 35 events.

We determined the centroid origin time, location and 5-component of moment tensor of VLFEs that maximize the normalized variance reduction (VR) between the observed and synthetic velocity waveforms. The waveforms are bandpass filtered either between 16-32s or 20-50s, depending on signal duration and S/N per event. The time and location are grid-searched at intervals of 0.01 degree in horizontal, 1 km in depth between 5 and 10km bsl., and 1 s in time. At each grid, the moment tensor is estimated using the code TDMT_INV (Dreger, 2003) that conducts full-waveform linearized inversion in time domain. Green’s functions are calculated using the code by Herrmann (2013) based on wavenumber integration. We used a 1D structural model based on a 2D model obtained by an active source survey (Nakanishi et al., 2008). Although the 1D structure is assumed, the large variations in station elevation (1.9-4.3 km bsl) are considered in Green’s function calculations.

We obtained 50 events with good VR (>65%). Among the 26 groups, 6 groups ended up with no events of high VR, mostly due to being located outside of the network. Almost all the VLFEs are reasonably explained by low angle thrust faulting. From the obtained distribution, the strong influence of the subduction-ridge located on the northwestern side of DONET1 is inferred. On the southwestern side

where there is no ridge-subduction, VLFEs are distributed beneath outer-ridge toward the trench axis. The estimated depths for the ones located beneath the outer-ridge are deep (7–10km with median at 8km), which are consistent with the depth of the plate boundary of this area. In contrast, on the northeastern side, VLFEs are mostly distributed landward of outer-ridge and their estimated depth are shallow (5–8km with the median at 7km) as previously suggested (To et al., 2015). The shallow depths can be explained by the uplifted plate boundary in this area due to the subducting-ridge. Furthermore, they are located to landward of the peak of the subducting-ridge, which can be reasonably explained by the change in shear stresses and pore pressures caused by the subducting-ridge.

Evidence for semi-brittle flow in mantle-wedge serpentinites under high pore fluid pressure and their implications for deep low frequency earthquakes

Kengo Kataoka[1], Yurina Nagata[1], *Ken-ichi Hirauchi[1], Ryosuke Oyanagi[2], Atsushi Okamoto[3], Katsuyoshi Michibayashi[4]

1. Department of Geosciences, Faculty of Science, Shizuoka University, 2. Japan Agency for Marine-Earth Science and Technology, 3. Graduate School of Environmental studies, Tohoku University, 4. Department of Earth and Planetary Sciences, Nagoya University

In southwest Japan, deep low frequency earthquakes occur at the base of the shallow serpentinized mantle wedge. In order to understand deformation styles of the mantle wedge serpentinite, we conducted structural and petrological analysis of a paleo-mantle wedge body that has experienced serpentinization at pressure–temperature conditions corresponding to source areas of low-frequency earthquakes, in the Sanbagawa belt, central Shikoku. The serpentinite body has a block-in-matrix structure that result from pervasive fragmentation. At outcrop and thin section scales, the distribution of blocks follows a power law distribution with exponent $2.32 < D < 2.37$ (2-D). The block has experienced complete serpentinization, characterized by randomly-oriented antigorite aggregates. The matrix also consists of antigorite, which was formed due to dissolution–precipitation process of the block in the presence of H_2O. Antigorite aggregates in the matrix along localized shear planes is characterized by a strong crystallographic preferred orientation with a dominant [010](001) slip system, suggesting dislocation glide on (001) planes. We suggest that deep slow earthquakes occur by semi-plastic deformation of the serpentinized mantle wedge, under low effective normal stresses.

Spatial distribution of slow slip events off the Boso peninsula from 1996 to 2018 under sparsity constraints

*Ryoko Nakata[1], Hideitsu Hino[2], Tatsu Kuwatani[3,4], Takahiro Akiyama[5], Shoichi Yoshioka[6], Masato Okada[7], Takane Hori[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. The Institute of Statistical Mathematics, 3. Department of Solid Earth Geochemistry, Japan Agency for Marine-Earth Science and Technology, 4. PRESTO, Japan Science and Technology Agency, 5. Graduate School of Science, Kobe University, 6. Research Center for Urban Safety and Security, Kobe University, 7. Graduate School of Frontier Sciences, The University of Tokyo

We estimated spatial distribution of the six slow slip events (SSEs) off the Boso peninsula, central Japan, from 1996 to 2018. We have applied an inversion method called fused regularization, a type of sparsity constraint, suitable for detecting discontinuous changes in the model parameters, for evaluation function [Nakata et al., 2017]. In this study, to shorten calculation time, we used a type of approximation method by Obuchi and Kabashima [2016] to search hyperparameters, not LOO-CV (leave-one-out cross validation).

From our tentative results, the maximum slips for the 2002, 2011 and 2018 SSEs were large, and the 1996, 2007 and 2013 SSEs were small. The slip distributions of the 2011 and 2018 SSEs seem to be distributed southward than 2002. It is confirmed by numerical experiments that the difference in slip distribution is not due to GNSS station distribution.

Furthermore, we are conducting numerical simulation of earthquake generation cycles, which modelling SSEs off the Boso peninsula and M~8 earthquakes along the Sagami Trough. We will discuss slip distributions of SSEs and locked area during an interseismic period.

Marine electromagnetic observations around a slow earthquake region in the western Nankai trough

*Hiroshi Ichihara[1], Tada-nori Goto[2], Tetsuo Matsuno[3], Noriko Tada[4], Shinya Sato[2]

1. Earthquake and Volcano Research Center, Nagoya University, 2. Graduate School of Engineering, Kyoto University, 3. Ocean Bottom Exploration Center, Kobe University, 4. JAMSTEC

Slow earthquakes have been believed to relate to fraction of pore fluid around plate boundary. Thus, imaging of electrical resistivity (conductivity) distribution is essential to understand slow earthquakes. However, many of SSE areas are distributed beneath the ocean, we need marine electromagnetic (EM) observations. In this presentation, we report preliminary results of marine EM observations in the western part of Nankai Trough (off Miyazaki prefecture and off western Kochi prefecture, Japan) where SSEs, VLF events and regular earthquakes (e.g. 1968 off-Hyuga earthquake, M7.5) are known. We deployed eight ocean bottom electro-magnetometers (OBEMs) and recovered seven of them between 2017 and 2018. In addition to EM fields, two OBEMs measure absolute pressure to detect short period crustal deformations caused by SSE. We estimated high quality magnetotelluric responses based on Chave and Thomson (2004). However, the responses show strong three-dimensionality of resistivity distribution and strong coast effect (e.g. Key and Constable, 2011). They indicate that we need to apply three-dimensional imaging techniques for seafloor magnetotelluric data.

Dynamics of precipitating injection fronts inside of structured medium

*Yutaka Sumino[1], Shunsuke Tanaka[1], Miyuki Kunihiro[1]

1. Tokyo University of Science

Recent study on a slow earthquake elucidates that the migration of water within a mantle wedge may play relevant roles[1]. The flow inside of confined geometry, such as within a soil, is often described by the Darcy’s law, where flow velocity is described by the gradient of fluid pressure. Interestingly, however, the water within a mantle wedge contains large amount of solid contents, and hence, a precipitation can be formed within the water[2]. For this reason, the dynamics of fluid flow under the effect of precipitation reaction should be explored.

Based on the above motivation, we explored the 2-dimensional confined chemical garden[3] as an analogue experiment for the fluid flow within a mantle wedge[4]. The system consists of two fluids with a quasi-two dimensional thin cell, so called a Hele-Shaw cell. The cell was filled with a fluid, and the other fluid is injected from the center of the cell. The flow in a Hele-Shaw cell can be described by the Darcy’s law. Furthermore, the mixing of these fluids leads to the precipitation. Thus, the flow observed in 2-dimensional confined chemical garden system is analogous to the one of water in a mantle wedge with precipitation formation.

Our previous study[4] showed that a filamentous pattern appears when the injection speed is high enough, whereas the symmetrical circular front was formed for lower injection speed. This results indicates that the propagation radius of injection front can be drastically different depending on the injection speed. In addition, the number of moving filaments saturate whose value is proportional to the injection speed. Such tendency can be understood with our boundary model adopting the effect Laplace pressure and the conservation of precipitation at the boundary. The model further predicts existence of optimal curvature for the moving front with which the required pressure for the motion is minimum. The curvature, and the speed of the optimal boundary motion is independent of the injection speed. These experimental and theoretical study thus worked well in the 2-dimensional Hele-Shaw cell. However, actual condition in a mantle wedge should have quenched structure, which is absent in a Hele-Shaw cell.

In order to fill the gap between actual condition in a mantle wedge and our analogue experiments, we modified our Hele-Shaw cell to have periodic pillar structure. As a control parameter, we changed the pillar to pillar distance, w, as shown in attached figure. The filament pattern showed meandering motion without pillar structures ($w = \infty$). We found that the filament pattern showed straight motion especially when w agreed with the typical filament width. Our modified mathematical model adopting nonlinear response of permeability with precipitation density numerically reproduced such experimental results. This results indicates that the propagation distance of injected fluid can be modified by the locally quenched disorder within a mantle wedge.

In this paper, we show detailed setup for experiments, as well as mathematical model.

Permeability changes of simulated low permeable fault rocks induced by intermediate velocity friction test

*Wataru Tanikawa[1]

1. Japan Agency for Marine-Earth Science and Technology, Kochi Instutute for Core Sample Research

Earthquake events often associate with fluctuations of flow rate, pore pressure and pore fluid chemistry at a subsurface of earthquake rupture zones. The co-seismic hydrological changes are explained by changes in fluid permeability of fault zones during earthquakes, and the permeability change plays an important role for dynamic fault processes as well. Therefore, we newly designed a system to estimate water permeability changes during and after low to high velocity shear deformation using a rotary shear apparatus and simulated fault rocks.

A pair of hollow cylindrical samples made by low permeable Belfast dolerite and Aji granite were used as test specimens. To calculate permeability, a radial flow from the inner wall to the outer wall of the specimen was induced by applying a differential pore pressure (0.01 to 0.2 MPa) between inner and outer walls. We performed friction tests at normal stress of 2 MPa, rotation speed from 0.0003 to 0.6 m/s, and slip displacement of 1 m.

The results showed that permeability increased during sliding at every slip velocity condition, and higher velocity friction caused more abrupt increase in permeability. After the end of sliding, permeability gradually decreased with time and then became nearly constant value. Reduction rate of permeability 5 min after slip increased with slip rate. Fiction coefficient was decreased with sliding velocity. Frictional heating is a key to explain slip velocity dependence of permeability (flow rate). Temperature rise caused by frictional heating will reduce fluid viscosity, therefore, apparent permeability reduction after sliding can be explained by an increase in fluid viscosity by cooling. Pore pressure build-up by frictional heating can increase aperture, therefore, this process can explain permeability enhancement during sliding and velocity dependences on permeability increase and friction coefficient.

Modified relation between the coupling and tremor rates around the Shikoku region

*Tadafumi Ochi[1]

1. Institute of Earthquake and Volcano Geology, Geological Survey of Japan, The National Institute of Advanced Industrial Science and Technology

In Ochi and Takeda (2018, EPS), I examined the relation between the interplate coupling velocity and the number of deep low-frequency tremors in the same place around the Shikoku region, southwest Japan. I found that there were some spot-like points where the coupling and the tremor count were well correlated, and that the regression line required the coupling rate to be the plate convergence rate in this region under conditions of zero tremor count rate. One of the problems to be resolved is the interpretation of the first matter 'spot-like points' mentioned above. According to the pairs of time series of the coupling rate and tremor count rate, some pairs show a time delay, and the others show a small fluctuation in the tremor count rate that seems to be independent of the coupling rate. It is interesting that whether the an ill-correlation just comes from an oversimple model of the linear regression I used in the previous study, or really reflects some physical background. In order to answer this question, I construct the model which allows the fluctuation in the tremor count rate that is independent from the coupling rate and observe the fitness of the model. At this time, some trial models that allow the shorter period fluctuation in the tremor count rate than in the coupling rate and temporal change in the period achieve clear correlations. In the presentation, I will show the results of the various trials.

Spatiotemporal distribution of regular and very low-frequency earthquakes in the northern part of the Ryukyu subduction zone

*Youichi Asano[1], Kazuhiko Goto[2], Hiroshi Yakiwara[3], Shuichiro Hirano[3]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Association for the development of earthquake prediction, 3. Nansei-toko Observatory for Earthquakes and Volcanoes, Kagoshima University

We have investigated detailed spatiotemporal distribution of regular and very low-frequency (VLF) earthquakes including an Mw 6.3 interplate event near Tanegashima along the Ryukyu trench on Jun. 08, 2019. This earthquake was followed four Mw4-5 class regular and many VLF earthquakes by the end of Jan., 2019. At first we estimated centroid moment tensors of these regular and several VLF earthquakes, respectively, from broadband seismograms recorded at the NIED F-net and temporally observation stations. In the next step, the known VLF earthquakes were selected to be template events for searching unknown VLF earthquakes from continuous seismograms. If there are several candidates of VLF earth quake, we select the most coherent event with a maximum cross-correlation coefficient averaged over all stations in every 180 seconds. Finally we estimated locations of the selected events from phase shift of the wavelets between the template and these selected events. Obtained result shows that activity of VLF earthquakes after the Mw 6.3 earthquake was started in the adjacent area east of this Mw 6.3 earthquake; however, the following Mw4-5 regular earthquakes occurred south of this area in the period of Jan. 25-30, 2019. In this period, the front of the VLF activity migrated toward east from these Mw4-5 events. Such a spatiotemporal distribution of regular and VLF earthquakes suggests that the after slip of the Mw 6.3 and/or an SSE caused these regular and VLF earthquakes.

Possible tectonic tremor activities near the VLFE epicenters in the Sanriku-Oki region in 2011

*Hidenobu Takahashi[1], Ryota Hino[1], Yusaku Ohta[1], Naoki Uchida[1], Syuichi Suzuki[1], Masanao Shinohara[2], Takanori Matsuzawa[3]

1. Graduate school of Science Tohoku University , 2. Earthquake Research Institute, University of Tokyo, 3. National Research Institute for Earth Science and Disaster Resilience

Recently various kind of slow earthquakes have been discovered along the Japan Trench subduction zone. Prior to the occurrence of the 2011 Tohoku-oki earthquake, occurrence of slow slip events associated with migration of small earthquake epicenters and tectonic tremors was reported near the hypocenter of the Tohoku-Oki earthquake (e.g. Kato et al., 2012; Ito et al., 2015; Katakami et al., 2018). As a different type of a slow-earthquake family, Very Low Frequency Earthquakes (VLFEs) have been detected in more broad areas (Matsuzawa et al., 2015). Takahashi et al. (in prep.) detected the seismic signals from the VLFEs by short-period ocean bottom seismograms (OBS) deployed in the vicinity of the VLFE epicenters in the Sanriku-Oki region, just after the Tohoku-Oki earthquake. They further identified a number of VLFE-like events, not recognized by the onshore data. Here, we report on possible tectonic tremor activities in the same area based on the OBS data after the 2011 Tohoku-oki earthquake.
We detected four sequences of continuous rises of amplitudes on the OBS records. Each of the sequence has a duration of ~ half a day. The sequences were composed of numerous wave trains with good correlations in their growths and decays in observed amplitudes among the stations, but no distinct P- or S-wave onsets were identified for individual wave trains. Interestingly, the spatial variation of the wave trains amplitudes is similar to those of the previously identified VLFEs. These observations suggest that the sequences were composed of small seismic events closely located each other and to the known VLFEs. It is also notable that some of the VLFE-like events discovered by the OBS data were contained in the sequences. We regard the discovered sequence as a kind of tectonic tremor activity and will inspect their characteristics, such as frequency content and its variability, to clarify their nature and discuss their relevance to slow slip events along the shallow subduction interface, which might promote the activities.

Heterogeneous structure around a region of slow earthquake activity off Ibaraki prefecture along the Japan Trench

*Kimihiro Mochizuki[1], Tomoaki Yamada[1], Masanao Shinohara[1], Ryota Hino[2], Ryosuke Azuma[2], Yoshihiro Ito[3], Yoshio Murai[4], Kenji Uehira[5], Toshinori Sato[6]

1. ERI, Univ. of Tokyo, 2. Graduate School of Science, Tohoku Univ., 3. DPRI, Kyoto Univ., 4. Faculty of Science, Hokkaido Univ., 5. NIED, 6. Graduate School of Science, Chiba Univ.

Large earthquakes of magnitude (M) ~7 have repeatedly occurred in the Ibaraki-oki region, about 100 km offshore of the Ibaraki prefecture along the Japan Trench, at a constant interval of ~20 years. Mochizuki et al. (2008) conducted a marine seismic survey and revealed that there exists a subducted seamount in the region. They also conducted an offshore seismic observation using ocean bottom seismometers (OBSs) to show that the seismicity in the region can be seen off of the subducted seamount, but not along the plate interface over it. They found that the location of the subducted seamount did not agree with the focal region of the repeating M7 earthquakes. From these results, they argued that the plate interface over the subducted seamount does not constitute an asperity of the repeating M7 earthquakes. Wang and Bilek (2011) introduced an idea that the seamount subduction causes formation of a fracture network within the overriding plate, and such a fracture network would prevent accumulation of large strain energy along the plate interface over the subducted seamount to generate large earthquakes. In addition to the repeating M7 earthquakes, recent studies (e.g. Matsuzawa et al., 2015; Nishikawa and Ide, 2018) have reported activity of slow earthquakes in the region. Relationship between activity of various types of earthquakes and structural features around the plate interface is one of the key topics to better understand controlling factors over earthquake types to be generated.

Recent studies in the Hikurangi subduction margin off the North Island of New Zealand show spatial relationship between variety of fault slips and topographic features of the plate interface. Wallace et al. (2016) successfully observed a large slow slip event just beneath an offshore array of ocean bottom pressure gauges, and precisely determined its slip distribution. They revealed that its slip propagation appeared to have circumvented subducted seamounts that have been imaged by magnetic anomalies as well as seismic reflection sections. Todd et al. (2018), for the first time, detected offshore tremor activity in the Hikurangi margin. The activity appears to have started just after the cessation of the slow slip, and its spatial distribution is only limited within regions of subducted seamounts. These results show that distributions of slow slip and tremor activity do not appear coincident, and thus the physical properties of the plate interface may be different. Further seismic surveys are supposed to provide vital information on structural variations that control physical characteristics of the plate interface.

In February, 2011, we acquired wide-angle reflection and refraction seismic data using 21 OBSs along a 150 km transect in the Ibaraki-oki region during the KH11-2 R/V Hakuho-maru cruise. We also included data from an OBS array that had already been deployed for a long-term seismic observation above the subduction front of the subducted seamount. Thus, we could construct a dense OBS profile above the subducted seamount with a receiver interval of ~3 km to achieve a high spatial resolution, whereas the largest interval is 10 km near both ends of the profile. First arrivals from the airgun sources can be traced up to ~95 km on most of the OBSs. The OBS record sections show significant heterogeneity that may include very rough structural features of the subducting oceanic crust along strike. Such heterogeneity may control seismic activity in the region.

Shallow low-frequency tremor triggered by nearby moderate earthquakes off Sanriku

*Sachiko Tanaka[1], Takanori Matsuzawa[1], Youichi Asano[1]

1. National Research Institute for Earth Science and Disaster Resilience

In the region off Sanriku, we have observed shallow low-frequency tremor, which occurs between the 12 km and 20 km depth contours of the plate interface, applying an envelope correlation method (Obara, 2002) to the records from the Seafloor observation network for earthquakes and tsunamis along the Japan Trench (S-net) (Tanaka et al., 2018). Several episodes of tremor, each of which lasted for half a day to six days, were detected in 2017, with intervals of one to three months. In the present study, we found tremor triggered by nearby moderate earthquakes. On July 24, 2017, an Mw 5.6 earthquake, showing reverse faulting consistent with the slip on the plate interface, occurred at the downdip end of the tremor zone off Sanriku, which was the largest event within 100 km of that tremor zone in the year. Immediately after the Mw 5.6 earthquake, coherent tremor signals were identified at surrounding stations. These signals continued for 20 hours, and the locations of their sources spanned 40 km along strike and 50 km along dip. Similar triggered tremor was observed following an Mw 5.1 earthquake on July 22, two days before the Mw 5.6 earthquake. This tremor activity was smaller and shorter than that triggered by the Mw 5.6 earthquake; tremor was localized to an area of 20 km by 15 km, and lasted for twelve hours. After a quiescence of nearly one day, the Mw 5.6 earthquake occurred at an adjacent area and triggered tremor was detected again. Triggering of tremor by moderate interplate earthquakes in or very close to the tremor zone we observed may imply small-scale (~ a few kilometers) heterogeneities in frictional properties on the plate interface in the area.

Slow slip events in the Bungo Channel over 15 years as inferred from GNSS data (1996-2011)

Takatoshi Yokoi[1], *SHINICHI MIYAZAKI[1], Hiromu Sakaue[1], Jun'ichi Fukuda[2]

1. Graduate School of Science, Kyoto University, 2. Earthquake Research Institute, The University of Tokyo

We estimated space-time evolution of inter-plate slip and slip velocity associated with slow slip events (SSE) in the Bungo Channel over 15 years between January 1, 1996 and February 28, 2011, from GNSS data.

We use GNSS time series at 80 stations around the Bungo Channel out of GEONET stations. Time series were obtained with GIPSY-OASIS II software by Nishimura (personal communication). We removed data during SSE and estimated secular velocities, annual and semi-annual seasonal variations, and offsets associated with earthquakes, SSEs and instrumental events. Then we remove contributions of those components from time series with SSE to prepare time series for the inversion. We constructed plate interface based on iso-depth data by Baba et al. (2002) and Hirose et al. (2008), and setup the model region that is 200km long east to west and 280km long north to south. The model region was subdivided into 719 small triangular patches. We employed the inversion method based on the Monte Carlo Mixture Kalman Filter (Fukuda et al. 2008) and estimated slip and slip velocities on the fault continuously over 15 years.

First, Long-term slow slip events (L-SSE hereafter) that lasted for several months were inferred in 1997, 2003 and 2010 as obtained by, such as, Ozawa et al. (2012, 2017) and Yoshioka et al. (2015). In addition to basic characteristics described in these previous studies, short-term slow slip events (S-SSE hereafter) were inferred just before or just after the main slip event. This result suggests that stress perturbations by SSEs trigger other SSEs. Therefore the inferred cumulative moment in this study was smaller than previous studies because we successfully excluded contributions from S-SSEs. Second, S-SSEs have repeatedly occurred with the interval of about three or four months over 15 years. Those S-SSE were located at depths of about 30-40km and associated with low frequency tremors.

In this presentation, we focus space-time evolutions of L-SSE in 2010 and S-SSE in 2005.

Investigations of sensor orientation and a possibility of detecting crustal deformation based on accelerometer records of S-net

*Ryota Takagi[1], Naoki Uchida[1], Takashi NAKAYAMA[1], Ryosuke Azuma[1], Akira Ishigami[1], Tomomi Okada[1], Yusaku Ohta[1], Ryota Hino[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

Seafloor Observation Network for Earthquakes and Tsunamis along the Japan Trench (S-net) of National Research Institute for Earth Science and Disaster Resilience (NIED) will greatly improve our knowledge of subsurface structure beneath offshore region along Japan trench and understanding of regular and slow earthquakes on the subducting plate boundary. We estimated the orientations of S-net sensors that are fundamental information for further data analysis and investigated the possibility of detecting crustal deformation based on accelerometer records.

We determined three parameters of sensor orientations: tilt angle of the long axis of a cable, rotation angle around the long axis, azimuth of the long axis. We estimated the tilt and rotation angles by assuming the DC components of accelerometers record the gravitational acceleration. The tilt and rotation angles slightly vary within the range of 0.01-0.1 degree during the period from 2016 to 2018 except for coseismic steps of rotation angles larger than 1 degree due to the M6.4 off Sanriku earthquake (August 20, 2016) and M7.4 off Fukushima earthquake (November 20, 2016). The long-axis azimuths are estimated by particle motions of long-period Rayleigh waves. We used the accelerometer records in 30-100 s of 7-14 teleseismic earthquakes with Mw 7.0-8.2. The azimuths are constrained in the range of 5-10 degrees. After correcting waveforms based on the estimated sensor orientation, we found coherent waveforms within the whole S-net stations and separation of Rayleigh and Love waves in radial and transverse components.

The capability of the DC components of accelerometers implies a possibility to detect crustal deformation from accelerometer records. We made time series of tilt and rotation angle with the sampling rate of one hour. During the period without offsets partly due to earthquakes, the root-mean-square (RMS) amplitudes of tilt and rotation angles are about 2 micro radians at most stations. The buried stations shallower than 1500 m show smaller variations and RMS amplitudes are about 0.2 micro radians. Some buried stations show tidal response with amplitude of about 1 micro radians. Since the maximum tilt change of land stations by a slow slip event (SSE) near the Boso Peninsula is about 1 micro radians, it might be possible to detect crustal deformation due to similar SSEs based on the accelerometer records.

Acknowledgement: We used continuous records of S-net managed by NIED. We thank NIED for providing the data.

Spatiotemporal variation of released seismic energy from shallow low-frequency tremor in Hyuga-nada, revealed by ocean bottom seismological observation

*Yusuke Yamashita[1], Saki Watanabe[2], Tomoaki Yamada[3], Masanao Shinohara[3], Takeshi Matsushima[2]

1. Disaster Prevention Research Institute, Kyoto University, 2. Institute of Seismology and Volcanology, Kyushu University, 3. Earthquake Research Institute, The University of Tokyo

In this study, we estimate the released seismic energy by shallow low-frequency tremors (shallow tremors) and clarify spatiotemporal variation of shallow tremor activity in Hyuga-nada, east off Kyushu. We used the data obtained from the temporal ocean bottom seismological observation for 3 months in 2013 [Yamashita *et al*., 2015] and long-term ocean bottom seismological observation from 2014 to 2017. The source location and released seismic energy of each shallow tremor was simultaneously estimated by Hybrid Envelope Cross-correlation Method [Maeda and Obara, 2009]. Observation data were obtained by the long-term continuous ocean bottom seismic observation in Hyuga-nada from 2013 to 2017. Site amplification factors were estimated by the coda normalization method [e.g., Sato and Fehler, 1998].

Spatial distribution of released seismic energy rate (energy rate) shows a heterogeneity although the average value of that is generally 10^4 J/s. The regions where the energy rate is relatively small are roughly coincident with the subducting or passed areas of the Kyushu-Palau Ridge. This result suggests that the structure and/or shape of the subducting plate such as seamounts or ridges may have an effect on the frictional property of the shallow plate interface. The 2013 activity was similar characteristics of shallow tremor location in space and time as the previous study, including two migrations episode. In addition, the characteristics of the released seismic energy were revealed as follows: (1) the energy rate was large at the both initiation point and the front of the migration, (2) the total released energy amount of the first migration was larger than that of the second migration, (3) both migrations were stopped at the region of small amount of released energy. Migration episode occurred while the 2015 activity and similar characteristics were documented.

Migration speed of shallow tremor is a few times faster, and energy rate of that is one or two orders of magnitude greater than the deep tremor. Applying the model of Ando *et al*. [2010, 2012] and Yabe and Ide [2014] to the result in this study, the average fault strength of shallow tremor is stronger than that of deep tremor, which leads up to a faster fault slip both brittle and ductile area. As a result, migration speed may become to be faster than deep tremor.

Acknowledgements: This study is supported by the research project for compound disaster mitigation on the great earthquakes and tsunami around the Nankai trough region, the MEXT of Japan, and JSPS KAKENHI Grant Number JP16H06471, JP16H06472. We thank Dr. Takuto Maeda for valuable discussions and comments. The observation data in 2013 obtained by T/S Nagasaki-maru. We used the JMA unified earthquake catalog and the seismic data obtained by Kagoshima University.

Unified description of fast and slow earthquakes using velocity strengthening patches

*So Ozawa[1], Takahiro Hatano[1]

1. Earthquake Research Institute, the University of Tokyo

In a prevalent view, seismicity in subduction zones is governed by the distribution of the frictional properties of the plate interface. Regions with velocity-weakening (VW) friction generate earthquakes, whereas velocity-strengthening (VS) regions creep aseismically. Although most models consider isolated VW regions (patches) from the idea of asperities (e.g. Dublanchet et al., 2013), isolated VS patches also would exist given the frictional properties on faults are inferred to be complex and hierarchical. Therefore, the role of VS patches is to be studied.

Here we perform 3-D numerical simulation of the seismic cycle of faults governed by the rate and state friction law with the aging law. We distribute randomly circular VS patches on a VW background. We mainly focus on the effect of the ratio of VS and VW areas.

In our preliminary simulation, we identified two important effects. First, the VS patches act as the “stability barriers” during dynamic rupture propagation, which makes the rupture process more complicated than a single propagating crack. Rupture decelerates by encountering a stability barrier, followed by reacceleration due to overcoming the barrier. Such a process gives rise to multiple rupture fronts in the slipping area.

Second, dynamic rupture is inhibited by increasing the number of VS patches, and the fault slips aseismically with strong fluctuation in slip velocity. This is because there are no enough VW regions to accelerate the slip to dynamic rupture. Although a similar mechanism for slow earthquakes is proposed by Skarbek et al. (2012) and Yabe & Ide (2017), our 3-D modeling enables detailed studies on the spatiotemporal evolution of slip. In the presentation, we further discuss our results in the context of the dynamic scaling of rupture growth and the phenomenological law of slow earthquakes.

The b-value of the earthquake swarm activities accompanied by the Boso slow slip events

*Yuki Noda[1], Hitoshi Hirose[2,1]

1. Department of Planetology, Faculty of Science, Kobe University , 2. Research Center for Urban Safety and Security, Kobe University

Slow slip events (SSEs) which are accompanying earthquake swarms repeatedly occur at intervals of about 2 to 7 years off Boso Peninsula (e.g., Sagiya, 2004; Hirose et al., 2012, 2014; Fukuda, 2018). These SSEs and swarms are thought to occur on the upper boundary of the subducting Philippine Sea plate.

As a statistical property of earthquakes, Gutenberg-Righter’ s law is well-known, that is, the relationship between the magnitude and the logarithm of occurrence frequency of earthquakes is expressed well with a straight line a-bM (Gutenberg and Richter, 1944). Although the b-value (slope of the line) often takes values around 1, there are many reports about the temporal changes of the b-value. For example, a decade-scale b-value decrease prior to the 2011 Tohoku Earthquake is reported (Nanjo et al., 2012). Although the relationship between the temporal change of b-value and aseismic slip is suggested, but the lack of near field geodetic observations prevents the direct evidence for the relationship. Here we examine the b-value of the earthquake swarms accompanied by the Boso SSEs, of which the aseismic slip is revealed by geodetic observations.

In this study, we estimate the b-value of the earthquake swarms in 2002, 2007, 2011 and 2014. We use the JMA unified earthquake catalog. As a preliminary analysis, we investigated the earthquakes with focal depths of 5 km to 40 km occurring at 35.05˚ to 35.56˚N in latitude and 140.15˚ to 140.73˚E in longitude. Eventually, “event period” estimated in the previous studies of the crustal deformation by geodetic observation does not necessarily agree with the period of the swarms occurring at the same time. Therefore, in this research, “event period” was redefined from seismic activity and used. In other words, we extracted swarms including a SSE period from crustal deformation studies and the time when the seismicity rate (the number of earthquakes per unit time) is significantly higher than the other time is defined as “event period”. In addition, the period other than the event period is defined as “inter-swarm period”.

We find that the b-values in the event periods tend to be lower than that during inter-swarm period. In more detail, different trends that seem to correspond to the difference in slip zone and location of earthquake activity of each SSE (Hirose et al. 2014) are seen in the b-values for the event periods. A seismic activity near the southern coast of the Boso Peninsula was hardly observed in the 2007 event period, whereas an active seismic activity was seen there in the 2011 event period. In order to clarify the dependence of the b-value on the difference in the location of the earthquakes, we divided the survey area into two areas, that is, the northern area (area A) and the southern area (area B). The seismic activity is observed in all event periods in the area A, whereas an active seismic activity is observed only in the event periods of 2002 and 2011 in the area B. Then a b- value is estimated in each period in the same way. As a result, for the earthquakes occurred in the northern region (area A), there is a tendency that the b-value in each of the event periods is lower by about 0.2-0.4 than that during inter-swarm. On the other hand, such a tendency is not observed in the southern area (area B). Such differences in the northern and southern regions may suggest that the effects of stress changes caused by SSEs vary from region to region.

Three-dimensional thermal modeling associated with subduction of the Philippine Sea plate at the Ryukyu Trench, and its relation to the occurrence of interplate seismic events

*Nobuaki Suenaga[1], Shoichi Yoshioka[2,1], Yinfeng Ji[3]

1. Graduate School of Science, Kobe University, Japan, 2. Research Center for Urban Safety and Security, Kobe University, Japan, 3. Chinese Academy of Science, Beijin, China

Interplate seismic events such as short-term slow slip evens (S-SSEs) (Nakamura, 2017), low-frequency earthquakes (LFEs) (Ando et al., 2012), and shallow very low-frequency earthquakes (VLFEs) (Nakamura et al., 2015) have been identified at the Ryukyu Trench, southwestern Japan. As the specific characteristics of these distributions, depths where S-SSEs and LFEs occur at the plate interface beneath the Okinawa island, whose depth is ranging from 15 km to 25 km, is about 10-20 km shallower than that beneath the Yaeyama islands, whose depth is ranging from 35 km to 50 km.

In this study, we constructed three-dimensional parallelepiped thermal convection model associated with subduction of the Philippine Sea (PHS) plate beneath the Amurian (AM) plate at the Ryukyu subduction zone. We considered subduction history of the PHS plate in the model region, referring to the plate rotation model (Mathews et al., 2016). We performed the numerical simulation as the time-dependent problem in the last 15 Myr to elucidate relationships among calculated thermal structures, dehydrations from the subducting plate, and the interplate seismic events. We used observed heat flow data to constrain thermal structures.

As a result at 0 Ma, we found that interplate temperature where S-SSEs and LFEs occur beneath the Yaeyama islands is lower than that beneath the Okinawa island when compared with the same depth along the direction of the trench axis. This is mainly because the convergence rate (PHS-AM) becomes gradually fast toward the southwest. Therefore, interplate temperatures where S-SSEs and LFEs occur were estimated ranging from 500℃ to 700℃ both beneath the Okinawa island and the Yaeyama islands.

We also calculated water content distribution within the PHS plate, using the calculated thermal structures and the phase diagram of MORB in an oceanic crust (Omori et al., 2008) and ultramafic rock in a slab mantle (Hacker et al., 2003). As for dehydration of MORB, we found that epidote eclogite transforms into amphibole eclogite in the neighboring area where S-SSEs and LFEs occur beneath the Okinawa island, and amphibole eclogite transforms into eclogite beneath the Yaeyama islands. The former and the latter dehydrate a total amount of 1.4 wt% and 0.7 wt% associated with their phase transformations, respectively.

[E] Poster | S (Solid Earth Sciences)：S-CG Complex & General

Wed. May 29, 2019 5:15 PM - 6:30 PM JST | Wed. May 29, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_33

[S-CG48] Science of slow earthquakes: Toward unified understandings of whole earthquake process

convener:Satoshi Ide(Department of Earth an Planetary Science, University of Tokyo), Hitoshi Hirose(Research Center for Urban Safety and Security, Kobe University), Kohtaro Ujiie(Graduate School of Life and Environmental Sciences, University of Tsukuba), Takahiro Hatano(Earthquake Research Institute, University of Tokyo)

Accumulating observational studies on various types of slow deformation events, such as tectonic tremors, very low frequency events, and slow slip events, portrays some universal characteristics in generally complex behavior, including interaction among events and influence by various outer loadings. Some of these phenomena seem to have causal relation with the occurrence of very large earthquakes. A unified understanding of these slow and fast earthquake processes requires an approach integrating geophysics, seismology, geodesy, geology, and non-equilibrium statistical physics. We welcome presentations based on, but not limited to, geophysical observation, data analysis, analytical theory, numerical simulation, field study, and laboratory experiments.

Off the Kii Peninsula Shallow Low Frequency Earthquake in 2004 revealed by Ocean Bottom Seismometer

*Koji Tamaribuchi[1], Akio Kobayashi[1], Takahito Nishimiya[1], Satoshi Annoura[2]

1. Meteorological Research Institute, 2. Japan Meteorological Agency

The 2004 off the Kii Peninsula earthquakes (Mj7.1, 7.4) occurred near the Nankai trough axis, southeast off the Kii Peninsula, Japan, on September 5, 2004. After the earthquakes, the Meteorological Research Institute conducted OBS observation to examine the aftershock distribution accurately. Although the analysis was limited to hypocenter relocation of "ordinary aftershocks", no analysis was done for slow events. In this study, it is shown that many low-frequency earthquakes (LFEs) occurred in "ordinary aftershocks" from the detailed inspection of our observation. During the observation period, the frequency of LFE gradually decreased. Since P- and S-arrival times are unclear, it is difficult to determine the distribution of the hypocenter accurately. However, by using the Amplitude Source Location (ASL; Battaglia and Aki, 2003), the LFEs are located between a splay fault and trench axis. The 2004 OBS stations are located east of the DONET, and many LFEs are detected in the 2004 OBS network. In addition, there are many very-low-frequency events (VLFEs) in the F-net waveforms with very-low-frequency band-pass filter (0.02 - 0.05 Hz) during the observation period. We found that the identified LFEs were associated with VLFEs since their amplitudes seemed to be correlated. This means that the LFEs and VLFEs show the same phenomenon. Our observations might contribute to reveal the relationship between ordinary aftershocks, slow-events, and megathrust events such as Nankai trough earthquake.

The development of pressure vessel on gouges for rock deformation at seismic rates under water-saturated conditions

*Wei-Ting Lin[1], Li-Wei Kuo[1], Wen-Jie Wu[1], Jia-Jyun Dong[1], Yi-Hung Huang[2]

1. National Central University, 2. MATSUKI HYDRAULIC INDUSTRIAL CO. LTD

To understand earthquake mechanism and fault behavior during earthquake ruptures, experimentalists commonly conduct rock deformation tests with rotary shear apparatus (e.g., low-to high-velocity rock friction experiment, LHVR) which allow deformed at seismic rates. In general, the materials utilized for rotary shear apparatus are both cohesive rocks (e.g., gabbro and carbonate) and incohesive rocks (natural fault gouges and synthetic rock powders), while the latter are deformed at seismic rates and, commonly at low normal stresses (0.5 to 2 MPa confining with a plastic Teflon ring). However, using Teflon rings has issues of gouge extrusion and chemical contamination, in particular, at high normal stresses (>3MPa) and water-saturated condition, and the obtained mechanical data and associated experimental products seem to be questionable. Here we develop a metal pressure vessel for LHVR to deform gouges at seismic rates and, importantly, expand the normal stress capability (up to 15 MPa) and under water-saturated condition. Our results show the resistance from the pressure vessel itself (metal-to-metal contact) is extremely low (friction coefficient ≈0.02), and the result of kaolinite is similar to the previously published data. In particular, both gouge-extrusion and water-leaking was not observed deformed at a normal stress of 15 MPa and equivalent velocity 1 m/s. The designed pressure vessel could fill the gap of experimental conditions among the current used pressure vessels and complete the understanding of fault ruptures.

Spatial variations of shallow very low-frequency earthquake activity along the Nankai Trough based on CMT inversion using the 3D heterogeneous model

*Shunsuke Takemura[1], Takanori Matsuzawa[1], Akemi Noda[1], Takashi Tonegawa[2], Youichi Asano[1], Takeshi Kimura[1], Katsuhiko Shiomi[1]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Japan Agency for Marine-Earth Science and Technology

To reveal structural properties around the Philippine Sea plate boundary, we investigated spatial variation of shallow very low-frequency earthquake (SVLFE) activity along the Nankai Trough. By using F-net velocity seismograms for periods of 20-50s, we conducted centroid moment tensor (CMT) inversion of SVLFEs detected by array analysis of Asano et al. (2008 EPS). Our CMT method is basically same as in Takemura et al. (2018 GRL). Source grids were assumed on the boundary of the Philippine Sea plate at horizontal intervals of 0.1°. Green's functions from source grids to F-net stations were evaluated by finite-difference method simulations of seismic wave propagation within the 3D heterogeneous structure model of Takemura et al. (2019 PAGEOPH).

We applied our CMT method to SVLFEs occurred from June 2003 to May 2018. Almost of CMT solutions are low-angle thrust faulting mechanism occurred around the accretionary prism toe. We evaluated spatial variations of SVLFE activity along the Nankai trough by calculating cumulative moment at each source grid. The areas with large cumulative moments appeared near the trench axis of off the Cape Muroto, the Kii Channel and the southeastern Kii Peninsula. We found spatial correlations between cumulative moment, slip-deficit rate (Noda et al. 2018 JGR) and *S*-wave velocities (Tonegawa et al. 2017 Nature Comm.) around the Philippine Sea plate boundary. Such spatial correlations suggest that SVLFEs are effectively activated by mechanically weakening due to pore fluid at surrounding area of strongly locked zone of the Philippine Sea plate.

Acknowledgement
NIED F-net broadband velocity seismograms were used. The catalogs of slow earthquakes were downloaded from the website of slow earthquake database (Kano et al., 2018 SRL). Finite-different method simulations were conducted on the Earth Simulator at the JAMSTEC.

Evaluation of Magnitude and Characteristics of Seismicity of Low Frequency Earthquakes in Parkfield

*Miki Aso[1,3], Naofumi Aso[2], Satoshi Ide[1]

1. Department of Earth and Planetary Science, The University of Tokyo, 2. Tokyo Institute of Technology, School of Science, 3. OYO RMS Corporation

Over a million tectonic low frequency earthquakes (LFEs) have been found in Parkfield along the San Andreas Fault, as 88 families by Shelly and Hardebeck [2010]. Thanks to enormous event detection, interesting characteristics focusing on their event amplitudes have been reported such as the spatial variation along the fault, the exponential frequency distribution for each family, and the relationship with recurrence time [Shelly and Hardebeck, 2010; Shelly, 2010]. However, the relative size of families has not been quantified accurately, because we have to consider various factors such as radiation pattern depending on focal mechanisms, attenuation during wave propagation, and site amplification effects. For quantitative comparison of scale among differently located events, here we estimate the absolute magnitude of each event considered those effects.

We estimate the seismic moment Mo [Nm] and moment magnitude Mw of all LFE events in the catalog of Shelly [2017]. We first stack seismograms of over one million events in the catalog to improve the signal-to-noise (S/N) ratio. Then, we evaluate the absolute amplitude of the original seismograms using the stacked waveforms. Specifically, we evaluate seismic moment Mo by assuming focal mechanisms of each family, attenuation quality factor, site effect estimated by Aso et al. [2019, submitted to JpGU meeting, “Variations of Focal Mechanisms of Low Frequency Earthquake in Parkfield”], and the source time function estimated by Thomas et al. [2016]. Note that we consider the frequency-limited seismic moment Mo, though it is not exactly the same as the original definition of seismic moment measured at a lower frequency than the minimum frequency contained in one phenomenon.

As previously reported by reported by Shelly and Hardebeck [2010], LFEs in the southern part has larger magnitude. We also find that shallower events are smaller than deeper events.

Similarly, most of the frequency distribution for each family shows an exponential distribution which is also reported for LFEs in Cascadia [Sweet et al., 2014] and New Zealand [Chamberlain et al., 2014].

By comparing size and recurrence interval, the events during LFE burst (seconds interval) tend to be larger than the first event of burst, which occurs after hours-to-days quiescence. A similar tendency is found in tremor burst occurring with a longer time scale (~1-week-long) than that of LFEs (~1-minute-long) [Yabe and Ide, 2014]. These might suggest some temporal change in fault rheology and/or some characteristic spatiotemporal behavior such as Brownian slow earthquake processes [Ide, 2008].

Tectonic tremor catalog in the Tohoku-Hokkaido-Oki region using S-net

*Satoshi Ide[1], Tomoaki Nishikawa[2], Takanori Matsuzawa[3], Kazuaki Ohta[2], Naoki Uchida[4], Takuya NISHIMURA[2]

1. Department of Earth an Planetary Science, University of Tokyo, 2. Disaster Prevention Research Institute, Kyoto University, 3. National Research Institute for Earth Science and Disaster Resilience, 4. Graduate School of Science and International Research Institute of Disaster Science, Tohoku University

Recently, various slow earthquakes have discovered in the subduction zone off Tohoku and Hokkaido regions along the Japan Trench. In this presentation, we report the detection of tectonic tremors using the Seafloor Observation Network for Earthquakes and Tsunamis along the Japan Trench (S-net), operated by The National Research Institute for Earth Science and Disaster Resilience (NIED).

We used continuous seismograms from August 2016 to August 2018 recorded by short-period sensors at 150 S-net stations. The original data were converted to envelope waveforms and analyzed using the envelope correlation method coded by Ide (2010), for each 300 s time windows with 150 s overlap. Since the results included many ordinary earthquakes with short durations, we regarded the events with durations longer than 20 s as tremors. This number is twice longer than that used for deep tremors in western Japan, reflecting the long-lasting waves in ocean bottom observation.

We found that the detection completeness is not high due to the high seismic activity in the Japan Trench, especially after the occurrence of large earthquakes, with numerous aftershocks falsely detected. We therefore divided the study area into 18 overlapping sub-regions that cover the locations of tremor activity to solve this problem. We detected tremors in each sub-region and merged the results into one catalogue by removing one of any two events within 10 s and 1 degree of each other, depending on their root-mean-square errors. Some tremor-like signals were found near the triple junction off the Boso Peninsula at approximately 34.8˚N. However, visual inspection revealed these events to be ordinary earthquakes, which we excluded from our tremor catalogue. The resultant tremor catalogue will be available in Slow Earthquake Database (Kano et al., 2018).

Spontaneous Slow Slip and Runaway Slip in Laboratory

*Miki Takahashi[1]

1. Institute of Earthquake and Volcano Geology, Geological Survey of Japan, AIST

Earthquake nucleation and propagation involves the acceleration of slip on a fault from a background, quasi-static, low-velocity state towards meter-per-second values. From shear experiments using brine-saturated simulated gouge composed of 80:20 wt.% mixtures of halite and muscovite (following e.g. Niemeijer & Spiers, 2007, JGR), Takahashi et al., [2017, G-cubed] recently reported a switch in the dominant deformation process, from distributed viscous flow (pressure solution creep) to localized brittle deformation, at a critical velocity V_c (~20 μm/sec). The direct effect which is normally observed upon perturbations in sliding rate disappears for $V > V_c$, suggesting that runaway fault-slip may be achieved when the sliding velocity exceeds V_c.
At relatively low shear stress, flow mechanisms, such as pressure solution creep and dislocation creep, will be fast enough to effectively suppress slip acceleration. However, with increasing the shear stress, there may be a velocity range in which flow mechanisms still works but not as effective. Hypothesizing that, under constant shear stress boundary conditions, this may lead to spontaneous acceleration followed by deceleration, analogous to a slow slip event. Moreover, imposing the constant shear stress with equal or larger value of the maximum strength of the simulated gouge, I also hypothesize that slip acceleration may proceed as $V > V_c$, inducing a dynamic weakening.
To address these hypotheses, I conducted torque-controlled rotary shear experiments, using brine-saturated, 80:20 wt % mixtures of halite (grain size < 75 μm) and muscovite (grain size < 33 μm) powders. Approximately 1.65 g of the gouge mixture was sandwiched between two teethed steel piston rings, forming an initially 1 mm thick layer. The piston rings had an inner diameter of 38 mm, and an outer diameter of 50 mm. I used a high-velocity rotary shear apparatus designed by T. Shimamoto [e.g., Togo and Shimamoto, 2012], and now installed at the Geological Survey of Japan (GSJ). The apparatus was modified to enable torque control with an accuracy of ±0.002 in the friction coefficient (μ), at a normal stress of 5 MPa. Rotation displacement is measured using a potentiometer installed close to the piston ring at the rotating side.
A preliminary result shows the velocity evolution after stepwise changes in the shear stress. At low shear stresses, corresponding to the pressure solution creep-controlled regime, transient increasing velocity towards a steady-state values suggests stable sliding. At $\mu \approx 0.6$, the simulated gouge shows spontaneous acceleration to $V \approx 1$ μm/sec, followed by deceleration. Lastly, under a constant shear stress condition equivalent to $\mu = 0.67$, spontaneous slip acceleration occurred followed by dynamic weakening at $V \approx V_c = 20$ μm/sec. More experiments and microstructural observations will help to elucidate the relationship between the critical velocity and the switch among dominant deformation mechanisms.

Keywords: shear stress control test, spontaneous acceleration/deceleration, dynamic weakening

Hydration and amorphization of quartz rocks during high-velocity frictional sliding: An examination of fault gouge from friction experiments of synthetic quartz

*Yuko Onoe[1], Hirotaka Iida[2], Akito Tsutsumi[1], Aki Takigawa[1]

1. Graduate School of Science, Kyoto University, 2. Geothermal Engineering Co., Ltd.

Various types of rocks and fault gouges display weakening of frictional strength at high-velocities, and in many cases, it is caused by high-temperature faulting processes such as frictional melting and thermal decomposition of fault materials. On the other hand, siliceous rocks display weakening of frictional strength at relatively slow slip velocity of ~1 mm/s. This weakening is a specific phenomenon because frictional heat is not sufficient to induce the high-temperature transformation reactions in this slip velocity range [Di Toro et al., 2004]. Goldsby and Tullis [2002] proposed gel lubrication model to explain the weakening of siliceous rocks; in which model frictional weakening likely results from production and shearing of hydrated amorphous silica layer along a fault in quartz rocks. But the relationship between the frictional weakening and hydration and amorphization of fault gouge is not clear yet.

This study aims to elucidate the mechanism of the frictional weakening observed for siliceous rocks. We conducted a series of friction experiments on synthetic quartz samples using a rotary-shear, intermediate-to high-velocity friction testing machine. Experiments were carried out under a constant normal stress condition of 1.5 MPa and at slip velocities of 5 μm/s, 10 μm/s, 105 μm/s, 1 mm/s, 10 mm/s and 105 mm/s. In this study effect of drying the sample on the frictional behavior were examined by introducing dry air to the chamber of the sample. After the friction tests, the gouge material on the slip surfaces were collected and analyzed by FTIR.

The frictional behavior of the synthetic quartz differs between room humidity and dry conditions; velocity weakening was observed for both conditions, however, velocity weakening starts at lower slip velocities for the dry experiments. Under DRY conditions, the frictional weakening occurs at slip velocity around 10 μm/s. From the results of the FTIR analysis, hydration of the gouge is confirmed for all the samples tested in this study. The FTIR result also indicates that the faster the slip velocity, the more the crystal structure of the gouge is destructed.
It is showed that under both DRY and Room Humidity conditions, at least the gouge generated on the friction surface of the sample which showed slip weakening is hydrated, consistent with the weakening model of Goldsby and Tullis [2002].

Constraining S Wave Velocity of the Source Region of Shallow Very Low-Frequency Earthquakes

*Takeshi Akuhara[1], Takashi Tonegawa[2]

1. Earthquake Research Institute, The University of Tokyo, 2. Research and Development center for Earthquake and Tsunami, Japan Agency for Marine-Earth Science and Technology

Shallow very low-frequency earthquakes (VLFEs), which are believed to occur in the vicinity of megathrusts, have been often associated with elevated pore fluid pressure. Lines of evidence for this idea include a small amount of stress drop, high tidal sensitivity, and reduced P wave velocity inferred from active source seismic surveys. Revealing the physical properties of the source region of shallow VLFEs will lead to a better understanding of their generation mechanisms. However, the challenge lies in the difficulty of acquiring S wave velocity in fine resolution.

Recent achievements by the authors may help overcome this issue. Akuhara et al. (2019) developed a robust technique to estimate Green's functions of receiver side structures from offshore seismograms, which are typically ill-conditioned due to water reverberations. Tonegawa et al. (2017) inverted Rayleigh wave admittance (i.e., a ratio of ground displacement to hydraulic pressure) for shallow S wave velocity structures beneath DONET seafloor observatories at the Nankai Trough subduction zone. Their velocity models show low-velocity zones that characterize the source regions of shallow VLFEs. However, a smoothing constraint imposed on the models renders their interpretation somewhat difficult.

This study presents preliminary results from transdimensional inversion of receiver-side Green's function estimated by the method of Akuhara et al. (2019), where we adopt a prior constraint by the velocity models of Tonegawa et al. (2017). Complementary to the Rayleigh admittance, the Green's function approach is sensitive to velocity contrasts and thus will offer an improved resolution.

Quantitative relationship between aseismic slip propagation speed and frictional properties

*Keisuke Ariyoshi[1], Jean-Paul Ampuero[2,3], Roland Burgmann[4], Toru Matsuzawa[5], Akira Hasegawa[5], Ryota Hino[5], Takane Hori[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Université Côte d'Azur, 3. California Institute of Technology, 4. University of California, Berkeley, 5. Graduate School of Science, Tohoku University

Recent observations show evidence of propagation of postseismic slip, whose propagation speed may contain information about the mechanical properties of faults. Here, we develop a new analytical relationship between the propagation speed of aseismic slip transients and fault frictional properties, modeled by a rate- and state-dependent friction law. The relationship explains the propagation speed of afterslip in 3-D numerical simulations to first order. Based on this relationship, we identify systematic dependencies of afterslip propagation speed on effective normal stress σ and frictional properties (the coefficients a and a-b which quantify the instantaneous and the steady-state velocity-dependence of friction, respectively, and the characteristic slip distance d_c of fault state evolution). Lower values of the parameter $A=a\sigma$ cause faster propagation in areas where the passage of the postseismic slip front induces large shear stress changes $\Delta\tau$ compared to A, which are typically located near the mainshock rupture. In areas where $\Delta\tau/A$ is small, typically more distant from the mainshock, afterslip propagation speed is more sensitive to (a-b) σ. The propagation speed is proportional to initial slip velocity and inversely proportional to d_c. The relationship developed here should be useful to constrain the frictional properties of faults based on observed propagation speeds, independently of rock laboratory experiments, which can then be used in predictive numerical simulations of aseismic slip phenomena.

Comprehensive detection of very low frequency earthquakes off the Pacific coasts of Hokkaido and Tohoku, northeastern Japan

*Satoru Baba[1], Akiko Takeo[1], Kazushige Obara[1], Takanori Matsuzawa[2], Takuto Maeda[3]

1. Earthquake Research Institute, University of Tokyo, 2. National Research Institute for Earth Science and Disaster Resilience, 3. Graduate School of Science and Technology, Hirosaki University

Very low frequency earthquakes (VLFEs), classified as one type of slow earthquakes, occur near seismogenic zones. VLFEs off the Pacific coasts of Hokkaido and Tohoku in northeastern Japan occur around subducting plate interfaces near trenches. Asano et al. (2008) found VLFEs in the off-Tokachi region, the southern part of the Pacific coast of Hokkaido along the Kuril Trench, by array signal processing using high-sensitivity accelerometers of Hi-net operated by National Research Institute for Earth Science and Disaster Resilience (NIED). In recent years, VLFEs off the Pacific coast of Tohoku were found by visually checking broadband seismograms of F-net operated by NIED and other events were detected by the matched-filter technique using waveforms of detected events as templates (Matsuzawa et al., 2015). However, the number of detected VLFEs may have been limited because of the small number of the VLFE templates in previous studies. Baba et al. (2018, SSJ) set four virtual epicenters off the Pacific coasts of Hokkaido and Tohoku and detected VLFEs by the matched-filter technique using numerically simulated waveforms as templates. We extended virtual epicentral gridsto make more comprehensive detection of VLFEs.

We used continuous seismograms of F-net seismometers from January 2003 to July 2018 after applying a band-pass filter of 0.02–0.05 Hz. We set 123 virtual epicentral grids off the Pacific coasts of Hokkaido and Tohoku, and computed the synthetic waveform from the source at each virtual epicenter by the finite difference method with a three-dimensional velocity structure model, namely, Japan Integrated Velocity Structure Model (Koketsu et al., 2012). The fault mechanisms were assumed to be consistent with the geometry of the plate boundary and a plate motion model, NUVEL-1A. We then calculated station- and component-averaged cross-correlation coefficients (averaged CC) between synthetic waveforms and the data of F-net seismograms every 1 s, and selected the events which have averaged CC above nine times of the median absolute deviation of the distribution. This method is, however, sensitive to regular earthquakes and teleseismic events as well. We then excluded the signal of regular earthquakes by discarding events with the amplitudes of more than 160 nm/s at 1-2 Hz in vertical components at the nearest stations. Moreover, to remove teleseismic events, we used the USGS earthquake catalog and discarded events with high amplitudes and low averaged cross-correlation coefficients.

VLFE activities in the off-Tokachi and off-Aomori regions show synchronized episodic bursts in the interval of several months. VLFEs in the off-Tokachi region was rapidly increased by the afterslip of the 2003 Tokachi-Oki earthquake. Those in the off-Iwate and off-Ibaraki regions, located out of the coseismic slip area of the 2011 off the Pacific coast of Tohoku Earthquake (hereinafter, the Tohoku earthquake), were also rapidly increased by the afterslip of the Tohoku earthquake. VLFE activity in the off-Miyagi region is characterized by episodic bursts in the interval of several months to one year before the Tohoku earthquake, but it became low since then. VLFE activity in the off-Fukushima region show dramatic increase after an Mw 6.9 earthquake at off-Fukushima on July 19, 2008. In the off-Miyagi and off-Fukushima regions, located within or at the edge of the coseismic slip area of the Tohoku earthquake, VLFE activity has been low since the Tohoku earthquake probably because the earthquake released the

stress almost completely. These results suggest that VLFEs are sensitive to the stress perturbation and can be a slip meter that reflect spatiotemporal change of the interplate slip, as has been indicated by previous studies. Consequently, one possible cause of these episodic VLFE bursts in the off-Tokachi, off-Aomori and off-Miyagi regions may be the intermittent release of small portion of stress accumulated by interplate locking between plates in the interval of several months to one year. The interval of episodic bursts is shorter than a periodicity of slow slips ranging from 1 to 6 years off the Pacific coasts of Tohoku indicated by Uchida et al. (2016).

Spatio-temporal evolution of long- and short-term slow slip events in the Tokai region, central Japan estimated from a very dense GNSS network, during 1997-2017

*Hiromu Sakaue[1], Takuya NISHIMURA[2], Jun'ichi Fukuda[3], Teruyuki Kato[4]

1. Graduate School of Science, Kyoto University, 2. Disaster Prevention Research Institute Kyoto University, 3. Earthquake Research Institute,The University of Tokyo, 4. Hot Springs Research Institute of Kanagawa Prefecture

The long-term slow slip events (SSEs) have been reported on the subducting Philippine Sea Plate in the Tokai region, central Japan during 2001-2005 and 2013-2016. Many short-term slow slip events have been also observed there since 1996. We analyzed GNSS data from 1997 to 2017 to estimate spatiotemporal distribution of interplate slip associated with these SSEs in this study. The GIPSY-OASIS II software (version 6.1) was used to estimate daily coordinates of GNSS stations operated by GSI and JUNCO (the Japanese University Consortium for GPS Research). It is well known that GNSS time series have many systematic signals and noises that do not result from SSEs. They include, for example, seasonal variations, co- and post-seismic deformation of the 2004 southeast off Kii Peninsula earthquakes (M_w 7.3/7.4), the 2008 Ibaraki-ken-oki earthquake (M_w6.9), the 2008 Fukushima-ken-oki earthquake (M_w7.0) and the 2011 Tohoku-oki earthquake (M_w9.0), and crustal deformation of volcanic activity on the northern Izu Islands in 2000. After removing them, we applied a modified Network Inversion Filter (NIF) [Fukuda et al., 2008] to estimate daily slip and slip rate on the subduction plate interface.
Our results suggest that not only long-term SSEs (M_w~7.1 and M_w~6.7) in 2000-2005 and 2013-2016, but also short-term SSEs (M_w<6.1). The maximum estimated daily slip rates for short-term SSEs are an order of magnitude larger than those of the long-term SSE, and peak slip for short-term SSEs migrates along strike with LFTs synchronously. It suggests that LFTs are loaded directly by SSEs, and that slip rate regulates LFT genesis. We will present the change of back slip rate between inter short-term SSEs and characteristics of short-term SSEs (e.g. slip rates and recurrence interval) depending on the occurrence of long-term SSE.

Broadband excitation of acoustic emission in granular stick-slip : experiments and spectral analyses

*Hidekazu Fukumizu[1], Ikuro Sumita[2]

1. Earth and Environmental Science Course, Division of Natural System, Graduate school of Natural Science and Technology, Kanazawa University, 2. School of Geosciences and Civil Engineering, Kanazawa University

Slow slip and tremor are observed to occur simultaneously (e.g., Rogers and Dragert, Science, 2003). Such observation can be modelled using granular stick-slip experiments which show that the timing of the slips and acoustic emission (AE) are well correlated (e.g., Johnson et al., GRL, 2013, Jiang et al. GRL, 2017). AE waveforms are complex (e.g., Michlmayr & Or, Gran. Matt., 2014), and we do not fully understand the details of the temporal change of AE during the slip. Here we report the results of granular stick-slip experiments which focus on how their spectra depend on the shear rate, particle size and container size.

We shear glass beads contained in a stainless steel beaker using a rotating viscometer to which a vane spindle is attached (Higashi and Sumita, JGR, 2009), and measure the shear stress and AE at 200kHz. We use broadband accelerometers and microphones to measure AE. Four accelerometers are attached at the outer rim of the beaker, and each are separated by an angle of 90 degrees.

We integrate the acceleration to obtain AE velocity –time series data and analyze their characteristics in broad band. We find that although AE has a broad spectrum, the spectra show that there are two characteristic frequency (f) components ; a high-f (of the order of 100 Hz) and a low-f (of the order of 10Hz) components. The velocity waveforms recorded at antipodal positions, show that the high-f components are in phase, whereas the low-f components are of the opposite phase. This indicates that the mechanism which excite these components differ : the high-f component may correspond to AE excited by particle rearrangement, whereas the low-f component may correspond to the translational motion of the container. Indeed we find that the frequency of the low-f component depends on the container size.

We also conducted experiments using a rheometer in a parallel-plate setup and confirmed that these two different components exist. When the particle size becomes larger, the amplitude of the shear stress and the AE velocity increases. Furthermore we find that the mean frequency of the normalized power spectra rose to a higher frequency, thus correlating with the stress increase.

Our experiments indicate that AE is excited in broadband, and that their frequency components can be used to infer the interparticle stress. Such excitation appear to be analogous to tremors and very low frequency earthquakes that are also excited simultaneously.

Episodic tremor and slip silently invades strongly locked megathrust in the Nankai Trough

*Masayuki Kano[1], Aitaro Kato[2], Kazushige Obara[2]

1. Graduate school of science, Tohoku University, 2. Earthquake Research Institute, The University of Tokyo

Recent seismic and geodetic observations in subduction zones have revealed that slow earthquakes have preceded some large earthquakes (e.g., Kato et al., 2012; Mavrommatis et al., 2014; Ruiz et al., 2014). Characterization of slow earthquakes and their relation to large earthquakes provides important clues to constrain a wide spectrum of slip rates on tectonic faults. In this study, we report new evidence of a slow slip transient at the downdip edge of the strongly locked seismogenic zone in the western Nankai Trough in southwest Japan based on GNSS time series. This slow slip transient was remotely excited during an episodic tremor and slip at the downdip extension of the locked zone. Through this remote triggering, the frequent occurrence of the deep episodic tremor and slip invades the strongly locked megathrust zone and may intermittently increase the probability of large earthquakes in the Nankai Trough.

Spatial distribution of the electrical resistivity beneath western part of Shikoku Island where long-term SSE events have repeatedly occurred

*Makoto Uyeshima[1], Maki Hata[1], Hiroshi Ichihara[2], Ryokei Yoshimura[3], Koki Aizawa[4]

1. Earthquake Research Institute, The University of Tokyo, 2. Graduate School of Environmental Studies, Nagoya University, 3. Disaster Prevention Research Institute, Kyoto University, 4. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University

In the Bungo channel area at the western margin of the Nankai megathrust rupture zones, the long-term slow slip events (SSE) repeatedly occurred about every 6 or 7 years. Since the last large-scale SSE event occurred in 2010, we will have a next large event soon. In order to obtain the electrical resistivity structure in the vicinity of the SSE area and examine its temporal change, we have started the Network-MT survey in the western part of the Shikoku Island facing the Bungo channel since April, 2016. Just before beginning of the observation, a tiny-scale SSE event occurred in the Bungo-channel (Ozawa, 2017, Hirose et al., 2018). We selected 17 areas in the western part of the Shikoku Island and installed 3 or 4 electrodes in the respective areas. The electrical potential differences with typical electrode spacing of several km are measured by using metallic telephone line network. We also measure the geomagnetic field at two stations in the target region. With the aid of the BIRRP code (Chave and Thomson, 2004), we could estimate the frequency-domain Network-MT response functions of good quality between the voltage difference and the magnetic field. The Network-MT response functions were directly inverted to estimate the 3-D resistivity structure in this area with the aid of the DASOCC Network-MT 3-D inversion code (Siripunvaraporn, Uyeshima & Egbert, 2004).

Conductive portions are commonly detected in the mid-crust of the target region. Their roots are just on the upper surface of the subducting Philippine Sea slab. This may suggest dehydration there. Among the spatial distribution of resistivity, that of seismic P-wave attenuation (Kita and Matsubara, 2016), and that of SSE slips (e.g. Ozawa et al., 2013, Yoshioka et al., 2015, Hirose et al., 2018), some mutually related features are detected. Low Qp (high attenuation) areas tend to correspond to highly conductive areas. The low Qp and highly conductive area are detected just above the subducting slab and outside of the SSE area. Inside the SSE area, while Qp takes generally high values, a patchy conductive area is detected in overall resistive background structure.

This study is supported by JSPS KAKENHI Grand Number JP16H06475 in Scientific Research on Innovative Areas "Science of Slow Earthquakes". It is also partly supported by the Ministry of Education, Culture, Sports, Science and Technology (MEXT) of Japan, under its Earthquake and Volcano Hazards Observation and Research Program. We acknowledge staffs of the Nippon Telegraph and Telephone WEST Corporation for their cordial support in the survey. We also thank H. Abe, A. Takeuchi and Y. Suwa for their help in preparing and installing instruments.

Variations of scaling relationships for shallow tremor observed along the Nankai trough

*Masaru Nakano[1], Suguru Yabe[1]

1. Japan Agency for Marine-Earth Science and Technology

Scaling relationships of seismic phenomena is one of keys to understand the source processes. Size distributions of slow earthquakes as low-frequency earthquakes (LFEs), non-volcanic tremor (NVT), very-low-frequency earthquakes (VLFE), and slow-slip events (SSEs) have been studied in many locations. Some studies showed that the size distribution follow an exponential law (e.g. Watanabe et al., 2007; Hiramatsu et al., 2008; Chestler and Creager, 2017), while others showed that power law distributions better explain the observations (e.g. Kao et al., 2010; Bostock et al., 2015; Nakamura and Sunagawa, 2015).

Most of previous studies are for slow earthquakes that occur in regions deeper than the source region of megathrust earthquakes, and only a limited number of studies have been carried out for shallow slow earthquakes beneath accretionary prism as observed along the Nankai trough. Although observed characteristics of shallow and deep ones are very similar, physical conditions as temperature and pressure much differs in these region.

In our previous studies (Nakano et al., 2018SSJ, AGU), we obtained the result that shallow tremor follows a power law distribution with b values of about 1. In this study, we further analyzed tremor activities beneath the Muroto fore-arc basin. using data from DONET2. We estimated the seismic energy of tremor signals using the same method as our previous studies, during intensive activities starting in September 2015, April 2016, February 2017, and February 2018. The source region of each activity is different from each other, spanning between off Shiono-Misaki and off Cape Muroto.

The size distribution of each activity mostly follow power-law distributions, but the b value varies from 0.7 and 1.7. We note that the activity in 2016 is also well fitted by an exponential law, probably due to narrow range of observed event size distribution. Similar result has been obtained in the 2018 activity in Kumano. The size distribution deviate from a power law for largest events as observed in Kumano activities. This deviation at larger events would be due to limited system size, expected from the theoretical stochastic model of tremor by Ide and Yabe (2018). The upper limit of event size, and accordingly the system size, varies from activity to activity.

We also investigated the relation between the seismic energy and duration of tremor events. The relation also follows a power law, with slopes of 2.0 to 2.6 in Kumano, and 1.5 to 3.3 in Muroto. These values are again consistent with the expectation value of 2 from the model of Ide and Yabe (2018).

These investigations represent that the scaling relationships of shallow tremor are mostly consistent with the 2D PCA model by Ide and Yabe (2018). Further studies would be necessary to reproduce the observed variations of the scaling parameters.

Acknowledgments: We used DONET data and JMA and USGS earthquake catalogs in the analysis. This research was supported by JSPS KAKENHI Grant Number 16H06477 in Scientific Research on Innovative Areas “Science of Slow Earthquakes”

Low-frequency earthquakes triggered by teleseismic surface waves by Ryukyu subduction zone.

Ayumi Kinjo[1], *Mamoru Nakamura[1]

1. Faculty of Science, University of the Ryukyus

We investigated low-frequency earthquakes (LFEs) in the Ryukyu Trench region that were triggered by surface waves from teleseismic earthquakes. Although these LFEs in the southwestern Ryukyu arc have previously been explored by Chao et al. (2016), their hypocenter distribution is not known in detail.

We selected 50 earthquakes from January 2004 to December 2016, which had magnitudes greater than 7.5 and epicentral distances between 9–150˚. We used the waveforms of 6 broadband seismometers in the Ryukyu arc from F-net (NIED) to analyze the surface waves. We also used the waveforms of 20 short-period seismometers in the Ryukyu arc from the Japan Meteorological Agency to detect trace LFEs in Ryukyu Island and determine their hypocenters.

The LFEs in the Yaeyama and Okinawa regions were observed. In the former region, during the passage of the surface waves, spindle-shaped LFE waveforms were first observed at Hateruma (south of Yaeyama Islands), and later at other stations in the Yaeyama region. Similarly, for the latter region, during the passage of the surface waves, spindle-shaped LFE waveforms were first observed at ZMM or Tamagusuku (south of Okinawa Island), and later at other stations in the Okinawa region. These observations suggest that the sources of the triggered LFEs were near or south of Hateruma and Tamagusuku.

We subsequently determined the hypocenters of the triggered LFEs. We computed the LFE travel-time difference between two stations using cross-correlations of the waveforms (Obara, 2002). The travel-time difference of waveforms of the LFEs corresponded to travel-time difference of the S-phase because S-waves were dominant in the LFEs, and P-waves were weak. The hypocenters were determined using the grid search method (Chao et al., 2013). In the Yaeyama region, the LFE hypocenters were mainly distributed near Hateruma Island. In the Okinawa region, they were distributed south of Okinawa Island. These positions are similar to the positions of the LFE hypocenters that accompany very low frequency earthquakes (LFE-VLFEs). This suggests that faulting in a cluster of LFE-VLFEs would be active with dynamic stress change.

In the Okinawa and Yaeyama regions, LFEs are triggered when the peak ground velocity of the surface wave is greater than 0.1 cm/s. This threshold value is similar to that for LFEs in Taiwan (Chao et al., 2013), suggesting that the weak friction coefficient at the plate interface of the Ryukyu Trench is similar to that in Taiwan.

Detection of small surface displacement accompanying deep low-frequency tremor in Shikoku region, southwest Japan

*Yutaro Okada[1], Takao Tabei[2]

1. Faculty of Science, Kochi University, 2. Faculty of Science and Technology, Kochi University

In many subduction zones in the world, several types of slow earthquakes occur with different depths on the plate interface and some of them are accompanied by surface displacement. In this study, we focus on small surface displacements coincident with non-volcanic deep low-frequency tremor in Shikoku region in the Nankai subduction zone, southwest Japan.

We use daily coordinates time series from 107 GEONET stations located in Shikoku and tremor catalog compiled by NIED (Maeda and Obara, 2009; Obara et al., 2010) in the period from Jan. 1 2004 to Dec. 31 2008. Since GNSS coordinates changes due to the Bungo Channel long-term slow slip events are well reproduced by S-shaped logistic function, we use the same function to extract small displacement coincident with tremor activity. At first, we convert horizonal components into N50°W direction after removing annual and semiannual variations and common-mode errors. Next, we fit the logistic function to a data segment with variable time window of 5, 7, and 9 days and estimate an amplitude of the function. The fitting is checked by a correlation coefficient between the observation and calculation. We apply this fitting for entire data period at all stations sliding data segment. Finally, we extract displacement when the amplitude of the fitted logistic function exceeds a certain criterion (1.8 mm in this study) and the correlation coefficient is large enough. If the extracted displacement is coincident with tremor activity within 30 m from the GNSS station, we adopt it as the tremor-related displacement. As a result, 225 events are adopted.

Spatial pattern of the tremor-related displacement seems to be related with the location and mechanism of the tremor event though closer inspection is needed. However, we extract much more small displacements by fitting a logistic function, of which the source is unknown. The logistic function is effective to reproduce transient displacement of the surface but we need to reconsider noise reduction of GNSS time series, time constant of logistic function, time window of the fitting, and so on.

Long-term temporal change in crustal resistivity beneath western Shikoku

*Futoshi Yamashita[1], Yoshimori Honkura[1]

1. National Research Institute for Earth Science and Disaster Resilience

In southwest Japan, various slow earthquakes such as deep low-frequency tremor and short/long-term slow slip events occur at the subducting plate interface (e.g. Obara and Kato, 2016, Scinence). In western Shikoku, Magneto-telluric (MT) survey was carried out along the dip direction of subducting Philippine Sea plate. The survey revealed an existence of low-resistivity structure in the lower crust in this region (Yamashita and Obara, 2009, AGU). In order to investigate a relationship between this characteristic structure and the activity of slow earthquakes, NIED has been carrying out continuous MT observations in western Shikoku since 2008. Here we show the observational records over 10 years and then discuss a relationship between observed temporal change in crustal resistivity and activity of the long-term slow slip event (L-SSE). Two observational sites KBN and IKT are available as of 2019. Qualities of data recorded at these sites are relatively fine. However, in order to improve the quality for discussing subtle change in MT parameters, we apply a data processing method same as Honkura *et al.* (2013, Nature comm.); we use only data whose coherency between electric and magnetic field is higher than a threshold. The lowest frequency of processed data is 0.00028 Hz. The processed MT parameters, apparent resistivity and phase, do not show any long-term temporal changes at KBN site even after temporal stops of observation over some months. On the other hand, apparent resistivity at IKT site, which is around 10 km southwest away from KBN site, shows temporal reduction at a frequency lower than 0.0022 Hz between 2010 and the middle of 2012. It is known that L-SSE occurred beneath the Bungo Channel in 2010 (e.g. Yoshioka *et al.*, 2015, GJI), which could induce resistivity change in the lower crust and then it might be detected by our MT observation.

Slow decay of postseismic deformation compared with aftershocks following the 2011 Tohoku-oki Earthquake

*Yuta Mitsui[1], Shunsuke Morikami[2]

1. Department of Geosciences, Shizuoka University, 2. Formerly at Graduate School of Science and Technology, Shizuoka University

In the literature, decays of postseismic deformation rates of large earthquakes were almost comparable to aftershock decays for subduction earthquakes (e.g. Hsu et al. (2006), Lange et al. (2014)). They are characterized by the modified Omori law with p~1, which means "afterslip-triggerred aftershocks". In this study, we focus on the 2011 Tohoku-oki megathrust earthquake using GNSS and seismicity data. On the basis of high-rate analysis of RINEX data and the F3 solution provided by the Geographical Survey Institute (GSI), we clarify the characteristics of postseismic deformation and aftershocks up to five orders of magnitude of time scale. We find that the p value for the postseismic deformation (p_m) is ~0.7, by contrast, that for the aftershocks (p_n) is ~1. Because a rate-and-state-friction model (Helmstetter and Shaw (2009)) predicted $p_m>=p_n$, another or an additional physical mechanism is necessary to explain the data of $p_m<p_n$. One important mechanism is viscoelastic relaxation of asthenosphere, thus we try fitting the postseismic deformation data by combination of afterslip and viscoelastic relaxation (a model of Suito (2017)). The fitting is not poor but fails to reproduce the Omori-like decay. More complex combination models may improve the fitting, but would not make simple Omori-like power-law decays. We need more sophisticated physical model to represent the decay characteristics of postseismic deformation.

Serpentinite dehydration in subduction shear zones formed at source depths of slow earthquakes

*Yasushi Mori[1], Miki Shigeno[1], Kohtaro Ujiie[2], Kazuya Noro[2], Tadao Nishiyama[3]

1. Kitakyushu Museum of Natural History and Human History, 2. University of Tsukuba, 3. Kumamoto University

Long-term slow slip events (L-SSEs) and episodic tremor and slip (ETS) occur along the subduction plate boundary at depths of 30–45 km (Obara, 2002; Shelly et al., 2006). These deep slow earthquakes are probably induced by high pore-fluid pressure. Based on geological study, we propose that the high pore-fluid pressure can be produced by metasomatic dehydration of serpentinite in subduction shear zones at source depths of deep slow earthquakes.

The Nishisonogi metamorphic rocks in Kyushu, Japan, are part of a Late Cretaceous subduction complex metamorphosed at $P \approx 1$ GPa and $T \approx 470$ ˚C. The P-T conditions are close to those of source depths of deep slow earthquakes. Serpentinite mélanges intercalated with the metamorphic rocks contain blocks of metabasite, metapelite and albitite. The mélange matrix consists of chlorite-actinolite schist (CAS), talc schist and schistose serpentinite. Intense shear deformation is concentrated in the CAS, and the serpentinite mélanges have the characteristics of anastomosing shear zones.

Bulk chemical composition of the rocks suggests that the CAS is the metasomatized mixture of serpentinite and metabasite. In addition, chemical mass balance indicates considerable dehydration during the CAS formation, along with a slight increase of solid volume. These findings suggest that the CAS formation involves the build-up of pore-fluid pressure. The high pore-fluid pressure results in the concentration of shear deformation into the weakened CAS.

Dehydration of serpentinite probably plays a key role in deep slow earthquakes (Poulet et al., 2014; Okazaki and Katayama, 2015). Thermal dehydration of serpentinite occurs at ~600 ˚C along the subduction plate boundary (Auzende et al., 2006), which is much higher temperature than that of source depths of deep slow earthquakes. In contrast, metasomatic dehydration of serpentinite described here could occur at source depths of deep slow earthquakes.

Earthquake swarms following very low-frequency earthquakes in the central Ryukyu Trench

*Mamoru Nakamura[1]

1. Faculty of Science, University of the Ryukyus

Earthquake swarms occur frequently from Amami Island to Okinawa Island, near the axis of the central Ryukyu Trench. These earthquake swarms recur every few years and typically followed swarms of very-low frequency earthquakes (VLFE) that occur in a similar area. I have investigated the relationship between the VLFEs and the subsequent earthquake swarms in the central Ryukyu Trench, using the earthquake catalog provided by the Japan Meteorological Agency (JMA). For the VLFEs, I used the catalog by Nakamura and Sunagawa (2015) and the extended catalog to December 2018.

Results show that the VLFE swarms occurred approximately one month before the subsequent earthquake swarms began near the trench axis in this region. Previous noteworthy earthquake swarms occurred on August 2005 (with a maximum magnitude of 4.7), April 2009 (with a maximum magnitude of 5.1), May 2016 (with a maximum magnitude of 5.6), and September 2018 (with a maximum magnitude of 6.2).

Prior to the earthquake swarm that occurred in August 2005, a VLFE swarm started near Okinawa Island three months before and its activity moved intermittently from Okinawa Island to Amami Island. In the case of the earthquake swarm that occurred in April 2009, a VLFE swarm started near Amami Island and the subsequent swarm occurred two weeks after the start of the VLFE swarm. The location of the VLFE swarm moved intermittently closer to Okinawa Island. In the case of the earthquake swarm that occurred on May 2016, the VLFE swarm started near Amami Island and its active cluster moved intermittently towards Okinawa Island. The subsequent earthquake swarm started near the trench axis, approximately twenty days after the occurrence of the VLFE swarm. In the case of the earthquake swarm that occurred in September 2018, the VLFE swarm started near Okinoerabu Island (the midpoint between Amami Island and Okinawa Island) and the activity moved intermittently to Okinawa Island. The earthquake swarm occurred approximately twenty-five days after the start of the VLFE swarm. The location of the cluster of the 2018 earthquake swarm was slightly landward from the trench axis.

The faulting associated with these earthquake swarms was of normal type, corresponding to intra-slab earthquakes in the subducting Philippine Sea plate. I calculated the Coulomb Failure Stress (delta-CFS) assuming that a small slow slip event (SSE) occurred on the plate interface. Our results show that the positive delta-CFS that accelerated the normal faulting could not have occurred in the subducted slab near the trench axis until the slip of the SSE had reached close to the trench axis. This suggests that the SSE propagated from Amami Island to Okinawa Island accompanying the activation of the VLFE swarm, the slip of the SSE then propagated close to the trench axis, and the normal-faulting earthquake swarm in the slab was induced by the positive delta-CFS caused by the SSE.

Seismic imaging in the central Nankai trough, off Shionomisaki to Kii channel

*Yasuyuki Nakamura[1], Shuichi Kodaira[1], Tetsuo No[1], Yuka Kaiho[1], Gou Fujie[1], Seiichi Miura[1], Kazuya Shiraishi[1]

1. Japan Agency for Marine Earth Science and Technology

Shallow very low frequency events (sVLFE) have been reported in the Nankai Trough subduction zone recently. In the central part of the Nankai trough, sVLFE were observed off Kii channel and Shinomisaki, but not reported in the area between them, off western Kii peninsula. We conducted a seismic survey with R/V *Kaimei* in November and December 2018 in Nankai subduction zone off Kii channel to Shonomisaki to investigate the structural features and its possible relationship to the sVLFE. R/V *Kaimei* fired 10600 $inch^3$ air gun array at every 50 m and a streamer cable (4.3 km at shortest, 5.7 km at longest) recorded the seismic signals. We acquired 23 seismic profiles with the length of ~ 75 km in dip direction at 4 km line separation and four profiles of ~ 90 km in strike direction at the shallowest part of the subduction zone. In addition, seven dip profiles with the length of 35 km were acquired off Kii channel to cover the lowermost part of the landward slope densely. The streamer cable was towed at a depth of 25 m to relatively enhance the lower frequency signals for better imaging of the deeper structure. Preliminary processed seismic profiles exhibited the structural variation in the survey area. Deformation of the hanging wall sediments and decollement were well imaged especially ~ 20 –30 km from the trough axis. Top of subducting Philippine Sea plate can be observed through ~ 40 –50 km from the trough axis in some of the obtained profiles. A pair of apparently low angle deep strong reflections were imaged at ~ 7 –8 s two-way time around 40 - 50 km from the trough axis off the western Kii peninsula, which was located slightly east and landward of the area with sVLFE. The shallowest part of the subduction zone in the area where the recent sVLFE activity was not reported, a slope basin with younger sediments deposited over the body of the accretionary prism is imaged, and the deformation was not observed in the slope basin. This suggests the thrust faults within the accretionary prism have not been active recently in this area. We will further process acquired data to obtain clearer seismic images and discuss the structural features and its connection to the observed seismological events in the Nankai Trough.

Attempt to Detect Intra-plate SSEs Based on F3 Solution of GEONET

*Yusaku Tanaka[1]

1. Earthquake Research Institute

Slow earthquakes have been detected all over the world and providing new insights into earthquakes. However, most of slow slip events (SSEs) were detected only on plate boundaries and intra-plate SSE was detected only once in Hokkaido. Thus, I attempt to detect intra-plate SSEs all over Japan using F3 solution of GEONET by GSI. I analyze the F3 data with six steps, i.e., (1) removing outliers by setting a term of mean + two times standard deviation for 1/4+1/4 year before-and-after each datum except for the datum itself and considering it is an outlier when it is out of the term, (2) removing disconnections estimated from the offsets and linear trends of 60+60 days before-and-after each datum with the least square method, (3) searching statistically significant temporal changes of the trends by using AIC, (4) cheking visually the time series in which the temporal changes are detected, (5) estimating the displacements from the trend chagnes, and (6) verifying the deformations by numerical calculation by setting rectangular faults.

As of 18th Feb 2019, my study has proceeded to the step (4). In the JpGU meeting, I will report the results of this analysis.

A new hydrothermal, low to high speed rotary-shearing apparatus: Reproduction of slow/megathrust earthquakes in laboratory

*Takehiro Hirose[1], Wataru Tanikawa[1], Yohei Hamada[1], Keishi Okazaki[1]

1. Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology

Earthquakes involve a wide range of slip rates, from slow/aseismic to fast/seismic slip along faults. Thus, frictional properties of faults over wide slip rates (nm/s to m/s), in particular under hydrothermal conditions similar to those expected in seismogenic zones are essential for a unified understanding of all earthquake events. A new hydrothermal, low to high speed rotary-shearing apparatus has been installed at Kochi/JAMSTEC, in order to study the fault constitutive properties at slow to fast slip rates and the physicochemical mechanisms underlying mechanical responses. The apparatus is currently capable of applying slip rates from 100 nm/s to 2 m/s, normal stress up to 55 MPa, fluid pressure up to 120 MPa and temperature up to 450oC with infinite displacement. We have been improving the apparatus to work as we intended. In pilot tests, we used metamorphic rocks (pelitic and green schists) as starting materials that are potentially distributed at and below seismogenic zones along hot and young subduction zones. We will present our preliminary results with the basic design of the apparatus.

Keywords: friction, hydrothermal, slow to fast slip

Very low-frequency earthquakes in western Shikoku remotely triggered by the 2016 Mw5.9 off-Kii Peninsula earthquake

*Masatoshi Miyazawa[1]

1. Disaster Prevention Research Institute, Kyoto University

Slow tectonic events are known to be sensitive to external stress perturbations due to passing seismic waves and earth tides. High-amplitude surface waves from large earthquakes have transiently triggered low-frequency earthquakes (LFEs) and slow slip events (SSEs) in subduction zones. However, dynamic triggering of very low-frequency (VLF) earthquakes during the arrival of seismic waves from a large, distant earthquake has not been observed. Because both the VLF earthquake and the surface wave have similar characteristic periods, remote triggering is not easily detected by using existing methods. We developed a particle filter/smoother for time series analysis combined with Markov chain Monte-Carlo methods, to detect seismic signals and estimate the maximum likelihood source parameters of VLF events that might have been remotely triggered. We apply this method to seismic data from the Mw5.9 earthquake, which occurred on 1 April 2016 (UTC), off Kii Peninsula. We found that six VLF events with magnitudes about 4, likely occurred in the seismogenic regions of ambient LFEs, and were likely triggered by the arrivals of high-amplitude surface waves. The triggering stress changes are from 0.4 to 1.5 kPa, which are similar to the values for LFEs triggering reported previously. Since there were no triggered LFEs in western Shikoku following the 2016 earthquake, these VLF earthquakes are more sensitive to stress changes caused by surface waves from large earthquakes.

Underground structure around source region of slow earthquakes in western Shikoku obtained by receiver function analysis

Akira Hikita[1], Aitaro Kato[1], *Kazushige Obara[1], Akiko Takeo[1], Takeshi Akuhara[1]

1. Earthquake Research Institute, The University of Tokyo

Various types of slow earthquakes have been observed at subduction zones surrounding the Pacific Ocean. It has been suggested that elevated pore fluid pressure plays an essential role in the generation of slow earthquakes because low velocity or high Vp/Vs zones have been also reported along the plate boundaries where they occur. In Tokai region of the Nankai subduction zone, Kato et al. (2010) revealed that long-term slow slip event (SSE) occurs at the boundary between the continental lower crust and the subducting Philippine Sea plate and episodic tremor and slip (ETS) occurs between the mantle wedge and the subducting plate. Kato et al (2010) also revealed that oceanic crust indicates higher Vp/Vs in the long-term SSE region than in the ETS region. In contrast, Toya et al. (2017) reported that the oceanic crust indicates higher Vp/Vs in the ETS region than in the long-term SSE region in western Shikoku of the same subduction zone. In this study, we revealed configurations of continental Moho discontinuity and subducting oceanic crust and investigated relationship between slow earthquakes and the surrounding seismic velocity structure by receiver function analysis using a dense seismic array in western Shikoku.

As a result, continuous continental Moho and oceanic crust are clearly imaged along both north-south and east-west oriented seismic lines. The plate boundary in the south part, where the distinct continental Moho is not imaged, has steeper slope than the north part along the north-south line. ETS occurs between the mantle wedge and the subducting plate, and long-term SSE occurs along a contact between the continental crust and the oceanic crust.
We show that the oceanic crust indicates much higher Vp/Vs than the hanging wall by using also the reverberation phases. This high Vp/Vs means the elevated fluid pore pressure within oceanic crust due to dehydration. Vp/Vs in the oceanic crust is higher in the deep part of the long-term SSE region than in the ETS region like as the case of Tokai. It is assumed that fluid would accumulate within the oceanic crust owing to low permeability of the continental crust in the long-term SSE region. In contrast, serpentinization of the mantle wedge just above the ETS region could reduce fluid pressure in the oceanic crust. Furthermore, Vp/Vs in the oceanic crust becomes lower in the deeper part beyond the ETS depths, suggesting that eclogization is completed at the depths.

Hypocenter determination of deep low frequency tremors beneath the Kii Peninsula by backprojection of seismic array data

*Kodai Sagae[1], Hisashi Nakahara[1], Takeshi Nishimura[1], Kazutoshi Imanishi[2]

1. Graduate School of Science,Tohoku University, 2. National Institute of Advanced Industrial Science and Technology (AIST)

A seismic array analysis enables us to detect weak signals if they are coherent. In Cascadia, a high accuracy hypocenter determination of tremors has been carried out by using dense seismic arrays (e.g.,Ghosh et al.,2012). In Southwest Japan, previous studies (e.g.,Ueno et al.,2010) applied the **MU**ltiple **SI**gnal **C**lassification (MUSIC) method (Schmidt,1986) to data of surface seismic arrays at Western Shikoku and carried out the hypocenter determination. However, a quantitative threshold for event detection was not considered. Sagae et al.,(2018 SSJ) introduced an event detection threshold based on the coherence of waveforms among stations, and improved tremor detection by using a surface seismic array installed by AIST at the Kii Peninsula. We applied the MUSIC method to this data in times when tremor events were detected and estimated slownesses and arrival azimuths of tremor signals. Their temporal variations suggested tremor migration. However, we did not carry out hypocenter determination. In this study, we determine hypocenters of tremors by backprojection using the estimated slownesses and arrival azimuths.
The surface seismic array installed by AIST at the Kii Peninsula was composed of 39 three component velocity sensors with a natural frequency of 2.0 Hz and a sampling frequency of 200 Hz. This array had an aperture of about 1.5 km and the sensors were arranged in a cross shape with interval spacings of 50~100 m. We analyze data for 1 year (between July 7,2013 and July 7,2014), because the number of sensors is stable in this period.
We focus on a frequency of 3Hz, which is within the tremor's dominant frequency band of 2-10 Hz. Data processing is described as follows. (1) We calculate averaged coherence of waveforms for all station's pairs. (2) We detect tremor events by setting a detection threshold based on the averaged coherence. (3) We estimate slownesses and arrival azimuths by applying the MUSIC method to the data when tremors are detected. (4) We project them back to the plate boundary (Hirose et al.,2008) and determine source locations by using S wave velocity model JMA2001 (Ueno et al.,2002).
We detected 5 periods of high tremor activities during the 1 year period. We compared the hypocenter distributions determined by our method and those of AIST tremor catalogue which were determined from an envelope cross correlation method. Temporal variation of tremors in this study were almost consistent with the AIST catalogue. We were also able to detect about 2.5 times as many events as the AIST catalogue. It is easier to identify temporal variation of tremors in more detail because our study improved temporal resolution up to 10 sec.
We projected temporal variations of tremor distributions into along-strike and along-dip directions. The results show tremors tend to migrate along the strike in time scales of several days with migration velocities of 6.0~9.3 km/day. Along-dip migrations of tremors with a short timescale of several hours are also detected. When we focused on the initial part of tremor activities, tremors tend to start in deeper parts and gradually migrate to shallow parts. These migration velocities were estimated to be about 1.0 km/hr (24 km/day) in the up-dip direction.
In this study, we were able to improve tremor detection by setting the event detection threshold based on the coherence of seismograms for stations pairs in a surface seismic array. Thanks to this, we were able to locate 2.5 times more tremors than the conventional method. We made it easier to keep track of tremor migrations by improving the temporal resolution of hypocenter determination to 10 sec.
We used the plate boundary model (Hirose et al.,2008). We downloaded the AIST catalogue from Slow

Triggered tremors and stress perturbations due to surface waves

*Ryohei Ikeda[1], Naoki Suda[1]

1. Hiroshima University

Surface waves radiated from distant large earthquakes sometimes trigger a series of deep non-volcanic tremors with intervals of 20-30 seconds, which are the same as dominant periods of surface waves [e.g. Miyazawa & Brodsky 2008]. Understanding the triggering mechanism is important because it provides us clues to the slip process occurring along the transition zone of subducting plate interface. Dynamic stress perturbations due to surface waves that triggered tremors were estimated on the order of 1 to 10 kPa [e.g. Chao & Obara 2016]. To study the relationship between triggered tremors and stress perturbations due to surface waves, we computed theoretical dynamic stresses due to surface waves from large earthquakes by using observed and theoretical surface waves.

We focused on the triggered tremors in the western Shikoku region of the Nankai subduction zone. Most of them occurred in two clusters where tectonic tremors actively occur. We computed theoretical dynamic stress perturbations due to surface waves from 106 earthquakes between 2004 and 2016 with moment magnitudes of 7.0 or grater. The receiver points at which the stress components were computed are at the plate boundary below the N.TSAF and N.KWBH stations, which are the nearest stations of the triggered tremors in F-net and Hi-net, respectively. PREM [Dziewonski & Anderson 1981] and Global CMT catalog [Dziewonski et al. 1981; Ekstrom et al. 2012] were used for the Earth model and the seismic sources for computing theoretical surface waves. Source time functions were approximated with triangular functions whose half durations are equal to the centroid time lags.

The stress change at the plate boundary by the surface wave was estimated based on the method of Spudich et al. (1995). This method consists of two stages: (1) Estimate the stress at the surface from the observed ground velocity and (2) Estimate the stress at the plate boundary from the stress at the surface estimated in (1). In these estimations, we used theoretical proportional relations between the ground velocity and the surface stress and those between the surface and the deep stresses in the frequency domain, which were obtained from the theoretical surface waves. We used the N.TSAF and N.KWBH records as the observed ground velocity. The records from the latter were corrected using the method of Maeda et al. (2011).

The stress components in the source coordinates were transformed to the stress normal to the plate interface and the stress along the possible slip direction of tremor source. The normal and slip directions were obtained from the model plate interface [Baba et al. 2002; Nakajima & Hasegawa 2007; Hirose et al. 2008] and plate convergence vectors [Miyazaki & Heki 2001]. We computed waveforms of the Coulomb failure function (ΔCFF) using a frictional coefficient of 0.2 at periods between 20 and 50 seconds.

©2019. Japan Geoscience Union. All Right Reserved.

Results from the N.TSAF records show that the maximum ΔCFF for the events that triggered tremors are greater than 0.5 kPa. The magnitudes of triggering earthquakes are greater than 7.5. ΔCFFs were generally overestimated when we used the corrected N.KWBH records because the correction did not well work, in particular, for the earthquakes with magnitudes less than 7.5. The important point is that not all of the events that provided the stress perturbations greater than 0.5 kPa triggered tremors. This shows that the stress perturbation due to surface waves cannot be the unique triggering condition: other conditions, for example, stress perturbations due to possible background slow slip events and/or high pore fluid pressure are required.

Numerical modeling of long- and shallow slow slip events including shallow region in Hyuganada and western Nankai, Japan

*Takanori Matsuzawa[1], Bunichiro Shibazaki[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Building Research Institute

Recent studies reported deep long-term slow slip events (SSEs) in the Hyuganada and western Nankai region (e.g., Kobayashi, 2014; Takagi et al., 2016; Ozawa. 2017). Shallow SSEs are also recently reported with low-frequency tremor and very low-frequency earthquakes (e.g., Araki et al., 2017; Nakano et al., 2018). In our previous study, we have numerically reproduced recurring deep long- and short-term SSEs in the Shikoku region (Matsuzawa et al., 2013), considering the actual distribution of slow earthquakes and configuration of the subducting Philippine Sea plate. We aim to reproduce deep long- and short-term SSEs and shallow SSEs in a single numerical model applying a similar approach in Matsuzawa et al. (2013).

We adopt a rate- and state-dependent friction law (RS-law) with cutoff velocities. We assume that (a-b) value in the RS-law is negative within the deep short-term SSE region, and positive outside that region. The deep short-term SSE region is modeled based on the actual distribution of deep low frequency tremor. Deep long-term SSE region is assumed based on the geodetic observation (Hirose et al., 2011). To focus on the Hyuganada and western Nankai region, we assume stable sliding region with positive (a-b) in the south of the Kyushu-Palau ridge. We also assume low cutoff velocity at the depth shallower than 9 km to reproduce shallow SSEs. Low effective normal stress is assumed at the depth of SSEs. Temporal evolution of slip velocity is numerically simulated, introducing elastic response and realistic configuration of the plate interface.

In terms of deep long-term SSEs in Hyuganada, a simple extension of the long-term SSE region in the Bungo Channel cannot reproduce the segments of observed SSEs. Narrowed long-term SSE region in the dip direction between Bungo and southern Hyuganada can reproduce three observed segments of SSEs, i.e., Bungo, northern Hyuganada, and southern Hyuganada. In addition, recurring shallow SSEs along trench in Hyuganada and off Ashizuri are reproduced in our result. Megathrust earthquakes are divided into two regions; off Shikoku and Hyuganada in our result. The segments of these large earthquakes may be attributed to the long-term SSE region in the Bungo Channel. Our model comprehensively reproduces various SSEs and megathrust earthquakes, including newly found long-term SSEs.

Further evidence for the influence of a subducting-ridge on the spatial strain accumulation and release pattern in the shallow eastern Nankai Trough, based on VLFE distribution

*Akiko Toh[1], Chen Wan-Jou [2], Doug Dreger[3], Wu-Cheng Chi[2], Satoshi Ide[1]

1. University of Tokyo, 2. Institute of Earth Sciences, Academia Sinica, 3. UC Berkeley

We investigated the distribution and focal mechanisms of very low frequency earthquakes (VLFEs) located in the shallow part of the eastern Nankai trough. While they are mainly explained as low angle thrust faulting along the plate boundary (Sugioka et al., 2012; Nakano et al, 2016), along the strike variation in their distribution has also been observed, likely caused by a subducting-ridge (Toh et al., 2018). Such variations could be closely related to the strain release pattern, or the tsunamigenic potential, of this region, thus warrant a further comprehensive study.

We used 3 component records of broadband ocean bottom seismometers equipped in Dense Oceanfloor Network system for Earthquakes and Tsunamis 1 (DONET1). Records of VLFE activities that occurred immediately beneath the network in 2015, 2016 and 2017 for 1-2 weeks each year, are used. Through visual inspections, we detected 335 VLFEs whose signals are observed at least 6 stations on vertical component filtered between 16-32s.

Instead of estimating the source parameters for one after another for all the events, we searched for densely located event groups inferred by similarities of the maximum amplitude variations measured per event, and, so far, worked only on the grouped events. The purpose of this event selection process is to get an overview of the distribution using the simple quantity (i.e. max. amplitude variation) that can be evaluated for every VLFE, and to avoid a bias that may be caused by eliminating events that are merely difficult to process (i.e. do not fit synthetic waveforms) mostly due to complicated long source time functions that characterize VLFEs. The grouping is conducted by a hieratical density-based clustering method HDBSCAN (Campello et al., 2003), and 197 events were grouped into 26 groups that consists of 2 to 35 events.

We determined the centroid origin time, location and 5-component of moment tensor of VLFEs that maximize the normalized variance reduction (VR) between the observed and synthetic velocity waveforms. The waveforms are bandpass filtered either between 16-32s or 20-50s, depending on signal duration and S/N per event. The time and location are grid-searched at intervals of 0.01 degree in horizontal, 1 km in depth between 5 and 10km bsl., and 1 s in time. At each grid, the moment tensor is estimated using the code TDMT_INV (Dreger, 2003) that conducts full-waveform linearized inversion in time domain. Green’s functions are calculated using the code by Herrmann (2013) based on wavenumber integration. We used a 1D structural model based on a 2D model obtained by an active source survey (Nakanishi et al., 2008). Although the 1D structure is assumed, the large variations in station elevation (1.9-4.3 km bsl) are considered in Green’s function calculations.

We obtained 50 events with good VR (>65%). Among the 26 groups, 6 groups ended up with no events of high VR, mostly due to being located outside of the network. Almost all the VLFEs are reasonably explained by low angle thrust faulting. From the obtained distribution, the strong influence of the subduction-ridge located on the northwestern side of DONET1 is inferred. On the southwestern side

©2019. Japan Geoscience Union. All Right Reserved.

where there is no ridge-subduction, VLFEs are distributed beneath outer-ridge toward the trench axis. The estimated depths for the ones located beneath the outer-ridge are deep (7–10km with median at 8km), which are consistent with the depth of the plate boundary of this area. In contrast, on the northeastern side, VLFEs are mostly distributed landward of outer-ridge and their estimated depth are shallow (5–8km with the median at 7km) as previously suggested (To et al., 2015). The shallow depths can be explained by the uplifted plate boundary in this area due to the subducting-ridge. Furthermore, they are located to landward of the peak of the subducting-ridge, which can be reasonably explained by the change in shear stresses and pore pressures caused by the subducting-ridge.

Evidence for semi-brittle flow in mantle-wedge serpentinites under high pore fluid pressure and their implications for deep low frequency earthquakes

Kengo Kataoka[1], Yurina Nagata[1], *Ken-ichi Hirauchi[1], Ryosuke Oyanagi[2], Atsushi Okamoto[3], Katsuyoshi Michibayashi[4]

1. Department of Geosciences, Faculty of Science, Shizuoka University, 2. Japan Agency for Marine-Earth Science and Technology, 3. Graduate School of Environmental studies, Tohoku University, 4. Department of Earth and Planetary Sciences, Nagoya University

In southwest Japan, deep low frequency earthquakes occur at the base of the shallow serpentinized mantle wedge. In order to understand deformation styles of the mantle wedge serpentinite, we conducted structural and petrological analysis of a paleo-mantle wedge body that has experienced serpentinization at pressure–temperature conditions corresponding to source areas of low-frequency earthquakes, in the Sanbagawa belt, central Shikoku. The serpentinite body has a block-in-matrix structure that result from pervasive fragmentation. At outcrop and thin section scales, the distribution of blocks follows a power law distribution with exponent $2.32 < D < 2.37$ (2-D). The block has experienced complete serpentinization, characterized by randomly-oriented antigorite aggregates. The matrix also consists of antigorite, which was formed due to dissolution–precipitation process of the block in the presence of H_2O. Antigorite aggregates in the matrix along localized shear planes is characterized by a strong crystallographic preferred orientation with a dominant [010](001) slip system, suggesting dislocation glide on (001) planes. We suggest that deep slow earthquakes occur by semi-plastic deformation of the serpentinized mantle wedge, under low effective normal stresses.

Spatial distribution of slow slip events off the Boso peninsula from 1996 to 2018 under sparsity constraints

*Ryoko Nakata[1], Hideitsu Hino[2], Tatsu Kuwatani[3,4], Takahiro Akiyama[5], Shoichi Yoshioka[6], Masato Okada[7], Takane Hori[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. The Institute of Statistical Mathematics, 3. Department of Solid Earth Geochemistry, Japan Agency for Marine-Earth Science and Technology, 4. PRESTO, Japan Science and Technology Agency, 5. Graduate School of Science, Kobe University, 6. Research Center for Urban Safety and Security, Kobe University, 7. Graduate School of Frontier Sciences, The University of Tokyo

We estimated spatial distribution of the six slow slip events (SSEs) off the Boso peninsula, central Japan, from 1996 to 2018. We have applied an inversion method called fused regularization, a type of sparsity constraint, suitable for detecting discontinuous changes in the model parameters, for evaluation function [Nakata et al., 2017]. In this study, to shorten calculation time, we used a type of approximation method by Obuchi and Kabashima [2016] to search hyperparameters, not LOO-CV (leave-one-out cross validation).

From our tentative results, the maximum slips for the 2002, 2011 and 2018 SSEs were large, and the 1996, 2007 and 2013 SSEs were small. The slip distributions of the 2011 and 2018 SSEs seem to be distributed southward than 2002. It is confirmed by numerical experiments that the difference in slip distribution is not due to GNSS station distribution.

Furthermore, we are conducting numerical simulation of earthquake generation cycles, which modelling SSEs off the Boso peninsula and M~8 earthquakes along the Sagami Trough. We will discuss slip distributions of SSEs and locked area during an interseismic period.

Marine electromagnetic observations around a slow earthquake region in the western Nankai trough

*Hiroshi Ichihara[1], Tada-nori Goto[2], Tetsuo Matsuno[3], Noriko Tada[4], Shinya Sato[2]

1. Earthquake and Volcano Research Center, Nagoya University, 2. Graduate School of Engineering, Kyoto University, 3. Ocean Bottom Exploration Center, Kobe University, 4. JAMSTEC

Slow earthquakes have been believed to relate to fraction of pore fluid around plate boundary. Thus, imaging of electrical resistivity (conductivity) distribution is essential to understand slow earthquakes. However, many of SSE areas are distributed beneath the ocean, we need marine electromagnetic (EM) observations. In this presentation, we report preliminary results of marine EM observations in the western part of Nankai Trough (off Miyazaki prefecture and off western Kochi prefecture, Japan) where SSEs, VLF events and regular earthquakes (e.g. 1968 off-Hyuga earthquake, M7.5) are known. We deployed eight ocean bottom electro-magnetometers (OBEMs) and recovered seven of them between 2017 and 2018. In addition to EM fields, two OBEMs measure absolute pressure to detect short period crustal deformations caused by SSE. We estimated high quality magnetotelluric responses based on Chave and Thomson (2004). However, the responses show strong three-dimensionality of resistivity distribution and strong coast effect (e.g. Key and Constable, 2011). They indicate that we need to apply three-dimensional imaging techniques for seafloor magnetotelluric data.

Dynamics of precipitating injection fronts inside of structured medium

*Yutaka Sumino[1], Shunsuke Tanaka[1], Miyuki Kunihiro[1]

1. Tokyo University of Science

Recent study on a slow earthquake elucidates that the migration of water within a mantle wedge may play relevant roles[1]. The flow inside of confined geometry, such as within a soil, is often described by the Darcy’s law, where flow velocity is described by the gradient of fluid pressure. Interestingly, however, the water within a mantle wedge contains large amount of solid contents, and hence, a precipitation can be formed within the water[2]. For this reason, the dynamics of fluid flow under the effect of precipitation reaction should be explored.

Based on the above motivation, we explored the 2-dimensional confined chemical garden[3] as an analogue experiment for the fluid flow within a mantle wedge[4]. The system consists of two fluids with a quasi-two dimensional thin cell, so called a Hele-Shaw cell. The cell was filled with a fluid, and the other fluid is injected from the center of the cell. The flow in a Hele-Shaw cell can be described by the Darcy’s law. Furthermore, the mixing of these fluids leads to the precipitation. Thus, the flow observed in 2-dimensional confined chemical garden system is analogous to the one of water in a mantle wedge with precipitation formation.

Our previous study[4] showed that a filamentous pattern appears when the injection speed is high enough, whereas the symmetrical circular front was formed for lower injection speed. This results indicates that the propagation radius of injection front can be drastically different depending on the injection speed. In addition, the number of moving filaments saturate whose value is proportional to the injection speed. Such tendency can be understood with our boundary model adopting the effect Laplace pressure and the conservation of precipitation at the boundary. The model further predicts existence of optimal curvature for the moving front with which the required pressure for the motion is minimum. The curvature, and the speed of the optimal boundary motion is independent of the injection speed. These experimental and theoretical study thus worked well in the 2-dimensional Hele-Shaw cell. However, actual condition in a mantle wedge should have quenched structure, which is absent in a Hele-Shaw cell.

In order to fill the gap between actual condition in a mantle wedge and our analogue experiments, we modified our Hele-Shaw cell to have periodic pillar structure. As a control parameter, we changed the pillar to pillar distance, w, as shown in attached figure. The filament pattern showed meandering motion without pillar structures ($w = \infty$). We found that the filament pattern showed straight motion especially when w agreed with the typical filament width. Our modified mathematical model adopting nonlinear response of permeability with precipitation density numerically reproduced such experimental results. This results indicates that the propagation distance of injected fluid can be modified by the locally quenched disorder within a mantle wedge.

In this paper, we show detailed setup for experiments, as well as mathematical model.

Permeability changes of simulated low permeable fault rocks induced by intermediate velocity friction test

*Wataru Tanikawa[1]

1. Japan Agency for Marine-Earth Science and Technology, Kochi Instutute for Core Sample Research

Earthquake events often associate with fluctuations of flow rate, pore pressure and pore fluid chemistry at a subsurface of earthquake rupture zones. The co-seismic hydrological changes are explained by changes in fluid permeability of fault zones during earthquakes, and the permeability change plays an important role for dynamic fault processes as well. Therefore, we newly designed a system to estimate water permeability changes during and after low to high velocity shear deformation using a rotary shear apparatus and simulated fault rocks.

A pair of hollow cylindrical samples made by low permeable Belfast dolerite and Aji granite were used as test specimens. To calculate permeability, a radial flow from the inner wall to the outer wall of the specimen was induced by applying a differential pore pressure (0.01 to 0.2 MPa) between inner and outer walls. We performed friction tests at normal stress of 2 MPa, rotation speed from 0.0003 to 0.6 m/s, and slip displacement of 1 m.

The results showed that permeability increased during sliding at every slip velocity condition, and higher velocity friction caused more abrupt increase in permeability. After the end of sliding, permeability gradually decreased with time and then became nearly constant value. Reduction rate of permeability 5 min after slip increased with slip rate. Fiction coefficient was decreased with sliding velocity. Frictional heating is a key to explain slip velocity dependence of permeability (flow rate). Temperature rise caused by frictional heating will reduce fluid viscosity, therefore, apparent permeability reduction after sliding can be explained by an increase in fluid viscosity by cooling. Pore pressure build-up by frictional heating can increase aperture, therefore, this process can explain permeability enhancement during sliding and velocity dependences on permeability increase and friction coefficient.

Modified relation between the coupling and tremor rates around the Shikoku region

*Tadafumi Ochi[1]

1. Institute of Earthquake and Volcano Geology, Geological Survey of Japan, The National Institute of Advanced Industrial Science and Technology

In Ochi and Takeda (2018, EPS), I examined the relation between the interplate coupling velocity and the number of deep low-frequency tremors in the same place around the Shikoku region, southwest Japan. I found that there were some spot-like points where the coupling and the tremor count were well correlated, and that the regression line required the coupling rate to be the plate convergence rate in this region under conditions of zero tremor count rate. One of the problems to be resolved is the interpretation of the first matter 'spot-like points' mentioned above. According to the pairs of time series of the coupling rate and tremor count rate, some pairs show a time delay, and the others show a small fluctuation in the tremor count rate that seems to be independent of the coupling rate. It is interesting that whether the an ill-correlation just comes from an oversimple model of the linear regression I used in the previous study, or really reflects some physical background. In order to answer this question, I construct the model which allows the fluctuation in the tremor count rate that is independent from the coupling rate and observe the fitness of the model. At this time, some trial models that allow the shorter period fluctuation in the tremor count rate than in the coupling rate and temporal change in the period achieve clear correlations. In the presentation, I will show the results of the various trials.

Spatiotemporal distribution of regular and very low-frequency earthquakes in the northern part of the Ryukyu subduction zone

*Youichi Asano[1], Kazuhiko Goto[2], Hiroshi Yakiwara[3], Shuichiro Hirano[3]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Association for the development of earthquake prediction, 3. Nansei-toko Observatory for Earthquakes and Volcanoes, Kagoshima University

We have investigated detailed spatiotemporal distribution of regular and very low-frequency (VLF) earthquakes including an Mw 6.3 interplate event near Tanegashima along the Ryukyu trench on Jun. 08, 2019. This earthquake was followed four Mw4-5 class regular and many VLF earthquakes by the end of Jan., 2019. At first we estimated centroid moment tensors of these regular and several VLF earthquakes, respectively, from broadband seismograms recorded at the NIED F-net and temporally observation stations. In the next step, the known VLF earthquakes were selected to be template events for searching unknown VLF earthquakes from continuous seismograms. If there are several candidates of VLF earth quake, we select the most coherent event with a maximum cross-correlation coefficient averaged over all stations in every 180 seconds. Finally we estimated locations of the selected events from phase shift of the wavelets between the template and these selected events. Obtained result shows that activity of VLF earthquakes after the Mw 6.3 earthquake was started in the adjacent area east of this Mw 6.3 earthquake; however, the following Mw4-5 regular earthquakes occurred south of this area in the period of Jan. 25-30, 2019. In this period, the front of the VLF activity migrated toward east from these Mw4-5 events. Such a spatiotemporal distribution of regular and VLF earthquakes suggests that the after slip of the Mw 6.3 and/or an SSE caused these regular and VLF earthquakes.

Possible tectonic tremor activities near the VLFE epicenters in the Sanriku-Oki region in 2011

*Hidenobu Takahashi[1], Ryota Hino[1], Yusaku Ohta[1], Naoki Uchida[1], Syuichi Suzuki[1], Masanao Shinohara[2], Takanori Matsuzawa[3]

1. Graduate school of Science Tohoku University , 2. Earthquake Research Institute, University of Tokyo, 3. National Research Institute for Earth Science and Disaster Resilience

Recently various kind of slow earthquakes have been discovered along the Japan Trench subduction zone. Prior to the occurrence of the 2011 Tohoku-oki earthquake, occurrence of slow slip events associated with migration of small earthquake epicenters and tectonic tremors was reported near the hypocenter of the Tohoku-Oki earthquake (e.g. Kato et al., 2012; Ito et al., 2015; Katakami et al., 2018). As a different type of a slow-earthquake family, Very Low Frequency Earthquakes (VLFEs) have been detected in more broad areas (Matsuzawa et al., 2015). Takahashi et al. (in prep.) detected the seismic signals from the VLFEs by short-period ocean bottom seismograms (OBS) deployed in the vicinity of the VLFE epicenters in the Sanriku-Oki region, just after the Tohoku-Oki earthquake. They further identified a number of VLFE-like events, not recognized by the onshore data. Here, we report on possible tectonic tremor activities in the same area based on the OBS data after the 2011 Tohoku-oki earthquake.
We detected four sequences of continuous rises of amplitudes on the OBS records. Each of the sequence has a duration of ~ half a day. The sequences were composed of numerous wave trains with good correlations in their growths and decays in observed amplitudes among the stations, but no distinct P- or S-wave onsets were identified for individual wave trains. Interestingly, the spatial variation of the wave trains amplitudes is similar to those of the previously identified VLFEs. These observations suggest that the sequences were composed of small seismic events closely located each other and to the known VLFEs. It is also notable that some of the VLFE-like events discovered by the OBS data were contained in the sequences. We regard the discovered sequence as a kind of tectonic tremor activity and will inspect their characteristics, such as frequency content and its variability, to clarify their nature and discuss their relevance to slow slip events along the shallow subduction interface, which might promote the activities.

Heterogeneous structure around a region of slow earthquake activity off Ibaraki prefecture along the Japan Trench

*Kimihiro Mochizuki[1], Tomoaki Yamada[1], Masanao Shinohara[1], Ryota Hino[2], Ryosuke Azuma[2], Yoshihiro Ito[3], Yoshio Murai[4], Kenji Uehira[5], Toshinori Sato[6]

1. ERI, Univ. of Tokyo, 2. Graduate School of Science, Tohoku Univ., 3. DPRI, Kyoto Univ., 4. Faculty of Science, Hokkaido Univ., 5. NIED, 6. Graduate School of Science, Chiba Univ.

Large earthquakes of magnitude (M) ~7 have repeatedly occurred in the Ibaraki-oki region, about 100 km offshore of the Ibaraki prefecture along the Japan Trench, at a constant interval of ~20 years. Mochizuki et al. (2008) conducted a marine seismic survey and revealed that there exists a subducted seamount in the region. They also conducted an offshore seismic observation using ocean bottom seismometers (OBSs) to show that the seismicity in the region can be seen off of the subducted seamount, but not along the plate interface over it. They found that the location of the subducted seamount did not agree with the focal region of the repeating M7 earthquakes. From these results, they argued that the plate interface over the subducted seamount does not constitute an asperity of the repeating M7 earthquakes. Wang and Bilek (2011) introduced an idea that the seamount subduction causes formation of a fracture network within the overriding plate, and such a fracture network would prevent accumulation of large strain energy along the plate interface over the subducted seamount to generate large earthquakes. In addition to the repeating M7 earthquakes, recent studies (e.g. Matsuzawa et al., 2015; Nishikawa and Ide, 2018) have reported activity of slow earthquakes in the region. Relationship between activity of various types of earthquakes and structural features around the plate interface is one of the key topics to better understand controlling factors over earthquake types to be generated.

Recent studies in the Hikurangi subduction margin off the North Island of New Zealand show spatial relationship between variety of fault slips and topographic features of the plate interface. Wallace et al. (2016) successfully observed a large slow slip event just beneath an offshore array of ocean bottom pressure gauges, and precisely determined its slip distribution. They revealed that its slip propagation appeared to have circumvented subducted seamounts that have been imaged by magnetic anomalies as well as seismic reflection sections. Todd et al. (2018), for the first time, detected offshore tremor activity in the Hikurangi margin. The activity appears to have started just after the cessation of the slow slip, and its spatial distribution is only limited within regions of subducted seamounts. These results show that distributions of slow slip and tremor activity do not appear coincident, and thus the physical properties of the plate interface may be different. Further seismic surveys are supposed to provide vital information on structural variations that control physical characteristics of the plate interface.

In February, 2011, we acquired wide-angle reflection and refraction seismic data using 21 OBSs along a 150 km transect in the Ibaraki-oki region during the KH11-2 R/V Hakuho-maru cruise. We also included data from an OBS array that had already been deployed for a long-term seismic observation above the subduction front of the subducted seamount. Thus, we could construct a dense OBS profile above the subducted seamount with a receiver interval of ~3 km to achieve a high spatial resolution, whereas the largest interval is 10 km near both ends of the profile. First arrivals from the airgun sources can be traced up to ~95 km on most of the OBSs. The OBS record sections show significant heterogeneity that may include very rough structural features of the subducting oceanic crust along strike. Such heterogeneity may control seismic activity in the region.

Shallow low-frequency tremor triggered by nearby moderate earthquakes off Sanriku

*Sachiko Tanaka[1], Takanori Matsuzawa[1], Youichi Asano[1]

1. National Research Institute for Earth Science and Disaster Resilience

In the region off Sanriku, we have observed shallow low-frequency tremor, which occurs between the 12 km and 20 km depth contours of the plate interface, applying an envelope correlation method (Obara, 2002) to the records from the Seafloor observation network for earthquakes and tsunamis along the Japan Trench (S-net) (Tanaka et al., 2018). Several episodes of tremor, each of which lasted for half a day to six days, were detected in 2017, with intervals of one to three months. In the present study, we found tremor triggered by nearby moderate earthquakes. On July 24, 2017, an Mw 5.6 earthquake, showing reverse faulting consistent with the slip on the plate interface, occurred at the downdip end of the tremor zone off Sanriku, which was the largest event within 100 km of that tremor zone in the year. Immediately after the Mw 5.6 earthquake, coherent tremor signals were identified at surrounding stations. These signals continued for 20 hours, and the locations of their sources spanned 40 km along strike and 50 km along dip. Similar triggered tremor was observed following an Mw 5.1 earthquake on July 22, two days before the Mw 5.6 earthquake. This tremor activity was smaller and shorter than that triggered by the Mw 5.6 earthquake; tremor was localized to an area of 20 km by 15 km, and lasted for twelve hours. After a quiescence of nearly one day, the Mw 5.6 earthquake occurred at an adjacent area and triggered tremor was detected again. Triggering of tremor by moderate interplate earthquakes in or very close to the tremor zone we observed may imply small-scale (~ a few kilometers) heterogeneities in frictional properties on the plate interface in the area.

Slow slip events in the Bungo Channel over 15 years as inferred from GNSS data (1996-2011)

Takatoshi Yokoi[1], *SHINICHI MIYAZAKI[1], Hiromu Sakaue[1], Jun'ichi Fukuda[2]

1. Graduate School of Science, Kyoto University, 2. Earthquake Research Institute, The University of Tokyo

We estimated space-time evolution of inter-plate slip and slip velocity associated with slow slip events (SSE) in the Bungo Channel over 15 years between January 1, 1996 and February 28, 2011, from GNSS data.

We use GNSS time series at 80 stations around the Bungo Channel out of GEONET stations. Time series were obtained with GIPSY-OASIS II software by Nishimura (personal communication). We removed data during SSE and estimated secular velocities, annual and semi-annual seasonal variations, and offsets associated with earthquakes, SSEs and instrumental events. Then we remove contributions of those components from time series with SSE to prepare time series for the inversion. We constructed plate interface based on iso-depth data by Baba et al. (2002) and Hirose et al. (2008), and setup the model region that is 200km long east to west and 280km long north to south. The model region was subdivided into 719 small triangular patches. We employed the inversion method based on the Monte Carlo Mixture Kalman Filter (Fukuda et al. 2008) and estimated slip and slip velocities on the fault continuously over 15 years.

First, Long-term slow slip events (L-SSE hereafter) that lasted for several months were inferred in 1997, 2003 and 2010 as obtained by, such as, Ozawa et al. (2012, 2017) and Yoshioka et al. (2015). In addition to basic characteristics described in these previous studies, short-term slow slip events (S-SSE hereafter) were inferred just before or just after the main slip event. This result suggests that stress perturbations by SSEs trigger other SSEs. Therefore the inferred cumulative moment in this study was smaller than previous studies because we successfully excluded contributions from S-SSEs. Second, S-SSEs have repeatedly occurred with the interval of about three or four months over 15 years. Those S-SSE were located at depths of about 30-40km and associated with low frequency tremors.

In this presentation, we focus space-time evolutions of L-SSE in 2010 and S-SSE in 2005.

Investigations of sensor orientation and a possibility of detecting crustal deformation based on accelerometer records of S-net

*Ryota Takagi[1], Naoki Uchida[1], Takashi NAKAYAMA[1], Ryosuke Azuma[1], Akira Ishigami[1], Tomomi Okada[1], Yusaku Ohta[1], Ryota Hino[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

Seafloor Observation Network for Earthquakes and Tsunamis along the Japan Trench (S-net) of National Research Institute for Earth Science and Disaster Resilience (NIED) will greatly improve our knowledge of subsurface structure beneath offshore region along Japan trench and understanding of regular and slow earthquakes on the subducting plate boundary. We estimated the orientations of S-net sensors that are fundamental information for further data analysis and investigated the possibility of detecting crustal deformation based on accelerometer records.

We determined three parameters of sensor orientations: tilt angle of the long axis of a cable, rotation angle around the long axis, azimuth of the long axis. We estimated the tilt and rotation angles by assuming the DC components of accelerometers record the gravitational acceleration. The tilt and rotation angles slightly vary within the range of 0.01-0.1 degree during the period from 2016 to 2018 except for coseismic steps of rotation angles larger than 1 degree due to the M6.4 off Sanriku earthquake (August 20, 2016) and M7.4 off Fukushima earthquake (November 20, 2016). The long-axis azimuths are estimated by particle motions of long-period Rayleigh waves. We used the accelerometer records in 30-100 s of 7-14 teleseismic earthquakes with Mw 7.0-8.2. The azimuths are constrained in the range of 5-10 degrees. After correcting waveforms based on the estimated sensor orientation, we found coherent waveforms within the whole S-net stations and separation of Rayleigh and Love waves in radial and transverse components.

The capability of the DC components of accelerometers implies a possibility to detect crustal deformation from accelerometer records. We made time series of tilt and rotation angle with the sampling rate of one hour. During the period without offsets partly due to earthquakes, the root-mean-square (RMS) amplitudes of tilt and rotation angles are about 2 micro radians at most stations. The buried stations shallower than 1500 m show smaller variations and RMS amplitudes are about 0.2 micro radians. Some buried stations show tidal response with amplitude of about 1 micro radians. Since the maximum tilt change of land stations by a slow slip event (SSE) near the Boso Peninsula is about 1 micro radians, it might be possible to detect crustal deformation due to similar SSEs based on the accelerometer records.

Acknowledgement: We used continuous records of S-net managed by NIED. We thank NIED for providing the data.

Spatiotemporal variation of released seismic energy from shallow low-frequency tremor in Hyuga-nada, revealed by ocean bottom seismological observation

*Yusuke Yamashita[1], Saki Watanabe[2], Tomoaki Yamada[3], Masanao Shinohara[3], Takeshi Matsushima[2]

1. Disaster Prevention Research Institute, Kyoto University, 2. Institute of Seismology and Volcanology, Kyushu University, 3. Earthquake Research Institute, The University of Tokyo

In this study, we estimate the released seismic energy by shallow low-frequency tremors (shallow tremors) and clarify spatiotemporal variation of shallow tremor activity in Hyuga-nada, east off Kyushu. We used the data obtained from the temporal ocean bottom seismological observation for 3 months in 2013 [Yamashita *et al*., 2015] and long-term ocean bottom seismological observation from 2014 to 2017. The source location and released seismic energy of each shallow tremor was simultaneously estimated by Hybrid Envelope Cross-correlation Method [Maeda and Obara, 2009]. Observation data were obtained by the long-term continuous ocean bottom seismic observation in Hyuga-nada from 2013 to 2017. Site amplification factors were estimated by the coda normalization method [e.g., Sato and Fehler, 1998].

Spatial distribution of released seismic energy rate (energy rate) shows a heterogeneity although the average value of that is generally 10^4 J/s. The regions where the energy rate is relatively small are roughly coincident with the subducting or passed areas of the Kyushu-Palau Ridge. This result suggests that the structure and/or shape of the subducting plate such as seamounts or ridges may have an effect on the frictional property of the shallow plate interface. The 2013 activity was similar characteristics of shallow tremor location in space and time as the previous study, including two migrations episode. In addition, the characteristics of the released seismic energy were revealed as follows: (1) the energy rate was large at the both initiation point and the front of the migration, (2) the total released energy amount of the first migration was larger than that of the second migration, (3) both migrations were stopped at the region of small amount of released energy. Migration episode occurred while the 2015 activity and similar characteristics were documented.

Migration speed of shallow tremor is a few times faster, and energy rate of that is one or two orders of magnitude greater than the deep tremor. Applying the model of Ando *et al*. [2010, 2012] and Yabe and Ide [2014] to the result in this study, the average fault strength of shallow tremor is stronger than that of deep tremor, which leads up to a faster fault slip both brittle and ductile area. As a result, migration speed may become to be faster than deep tremor.

Acknowledgements: This study is supported by the research project for compound disaster mitigation on the great earthquakes and tsunami around the Nankai trough region, the MEXT of Japan, and JSPS KAKENHI Grant Number JP16H06471, JP16H06472. We thank Dr. Takuto Maeda for valuable discussions and comments. The observation data in 2013 obtained by T/S Nagasaki-maru. We used the JMA unified earthquake catalog and the seismic data obtained by Kagoshima University.

Unified description of fast and slow earthquakes using velocity strengthening patches

*So Ozawa[1], Takahiro Hatano[1]

1. Earthquake Research Institute, the University of Tokyo

In a prevalent view, seismicity in subduction zones is governed by the distribution of the frictional properties of the plate interface. Regions with velocity-weakening (VW) friction generate earthquakes, whereas velocity-strengthening (VS) regions creep aseismically. Although most models consider isolated VW regions (patches) from the idea of asperities (e.g. Dublanchet et al., 2013), isolated VS patches also would exist given the frictional properties on faults are inferred to be complex and hierarchical. Therefore, the role of VS patches is to be studied.

Here we perform 3-D numerical simulation of the seismic cycle of faults governed by the rate and state friction law with the aging law. We distribute randomly circular VS patches on a VW background. We mainly focus on the effect of the ratio of VS and VW areas.

In our preliminary simulation, we identified two important effects. First, the VS patches act as the “stability barriers” during dynamic rupture propagation, which makes the rupture process more complicated than a single propagating crack. Rupture decelerates by encountering a stability barrier, followed by reacceleration due to overcoming the barrier. Such a process gives rise to multiple rupture fronts in the slipping area.

Second, dynamic rupture is inhibited by increasing the number of VS patches, and the fault slips aseismically with strong fluctuation in slip velocity. This is because there are no enough VW regions to accelerate the slip to dynamic rupture. Although a similar mechanism for slow earthquakes is proposed by Skarbek et al. (2012) and Yabe & Ide (2017), our 3-D modeling enables detailed studies on the spatiotemporal evolution of slip. In the presentation, we further discuss our results in the context of the dynamic scaling of rupture growth and the phenomenological law of slow earthquakes.

The b-value of the earthquake swarm activities accompanied by the Boso slow slip events

*Yuki Noda[1], Hitoshi Hirose[2,1]

1. Department of Planetology, Faculty of Science, Kobe University , 2. Research Center for Urban Safety and Security, Kobe University

Slow slip events (SSEs) which are accompanying earthquake swarms repeatedly occur at intervals of about 2 to 7 years off Boso Peninsula (e.g., Sagiya, 2004; Hirose et al., 2012, 2014; Fukuda, 2018). These SSEs and swarms are thought to occur on the upper boundary of the subducting Philippine Sea plate.

As a statistical property of earthquakes, Gutenberg-Righter’ s law is well-known, that is, the relationship between the magnitude and the logarithm of occurrence frequency of earthquakes is expressed well with a straight line a-bM (Gutenberg and Richter, 1944). Although the b-value (slope of the line) often takes values around 1, there are many reports about the temporal changes of the b-value. For example, a decade-scale b-value decrease prior to the 2011 Tohoku Earthquake is reported (Nanjo et al., 2012). Although the relationship between the temporal change of b-value and aseismic slip is suggested, but the lack of near field geodetic observations prevents the direct evidence for the relationship. Here we examine the b-value of the earthquake swarms accompanied by the Boso SSEs, of which the aseismic slip is revealed by geodetic observations.

In this study, we estimate the b-value of the earthquake swarms in 2002, 2007, 2011 and 2014. We use the JMA unified earthquake catalog. As a preliminary analysis, we investigated the earthquakes with focal depths of 5 km to 40 km occurring at 35.05˚ to 35.56˚N in latitude and 140.15˚ to 140.73˚E in longitude. Eventually, “event period” estimated in the previous studies of the crustal deformation by geodetic observation does not necessarily agree with the period of the swarms occurring at the same time. Therefore, in this research, “event period” was redefined from seismic activity and used. In other words, we extracted swarms including a SSE period from crustal deformation studies and the time when the seismicity rate (the number of earthquakes per unit time) is significantly higher than the other time is defined as “event period”. In addition, the period other than the event period is defined as “inter-swarm period”.

We find that the b-values in the event periods tend to be lower than that during inter-swarm period. In more detail, different trends that seem to correspond to the difference in slip zone and location of earthquake activity of each SSE (Hirose et al. 2014) are seen in the b-values for the event periods. A seismic activity near the southern coast of the Boso Peninsula was hardly observed in the 2007 event period, whereas an active seismic activity was seen there in the 2011 event period. In order to clarify the dependence of the b-value on the difference in the location of the earthquakes, we divided the survey area into two areas, that is, the northern area (area A) and the southern area (area B). The seismic activity is observed in all event periods in the area A, whereas an active seismic activity is observed only in the event periods of 2002 and 2011 in the area B. Then a b- value is estimated in each period in the same way. As a result, for the earthquakes occurred in the northern region (area A), there is a tendency that the b-value in each of the event periods is lower by about 0.2-0.4 than that during inter-swarm. On the other hand, such a tendency is not observed in the southern area (area B). Such differences in the northern and southern regions may suggest that the effects of stress changes caused by SSEs vary from region to region.

Three-dimensional thermal modeling associated with subduction of the Philippine Sea plate at the Ryukyu Trench, and its relation to the occurrence of interplate seismic events

*Nobuaki Suenaga[1], Shoichi Yoshioka[2,1], Yinfeng Ji[3]

1. Graduate School of Science, Kobe University, Japan, 2. Research Center for Urban Safety and Security, Kobe University, Japan, 3. Chinese Academy of Science, Beijin, China

Interplate seismic events such as short-term slow slip evens (S-SSEs) (Nakamura, 2017), low-frequency earthquakes (LFEs) (Ando et al., 2012), and shallow very low-frequency earthquakes (VLFEs) (Nakamura et al., 2015) have been identified at the Ryukyu Trench, southwestern Japan. As the specific characteristics of these distributions, depths where S-SSEs and LFEs occur at the plate interface beneath the Okinawa island, whose depth is ranging from 15 km to 25 km, is about 10-20 km shallower than that beneath the Yaeyama islands, whose depth is ranging from 35 km to 50 km.

In this study, we constructed three-dimensional parallelepiped thermal convection model associated with subduction of the Philippine Sea (PHS) plate beneath the Amurian (AM) plate at the Ryukyu subduction zone. We considered subduction history of the PHS plate in the model region, referring to the plate rotation model (Mathews et al., 2016). We performed the numerical simulation as the time-dependent problem in the last 15 Myr to elucidate relationships among calculated thermal structures, dehydrations from the subducting plate, and the interplate seismic events. We used observed heat flow data to constrain thermal structures.

As a result at 0 Ma, we found that interplate temperature where S-SSEs and LFEs occur beneath the Yaeyama islands is lower than that beneath the Okinawa island when compared with the same depth along the direction of the trench axis. This is mainly because the convergence rate (PHS-AM) becomes gradually fast toward the southwest. Therefore, interplate temperatures where S-SSEs and LFEs occur were estimated ranging from 500℃ to 700℃ both beneath the Okinawa island and the Yaeyama islands.

We also calculated water content distribution within the PHS plate, using the calculated thermal structures and the phase diagram of MORB in an oceanic crust (Omori et al., 2008) and ultramafic rock in a slab mantle (Hacker et al., 2003). As for dehydration of MORB, we found that epidote eclogite transforms into amphibole eclogite in the neighboring area where S-SSEs and LFEs occur beneath the Okinawa island, and amphibole eclogite transforms into eclogite beneath the Yaeyama islands. The former and the latter dehydrate a total amount of 1.4 wt% and 0.7 wt% associated with their phase transformations, respectively.

[S-CG48] Science of slow earthquakes: Toward unified understandings of whole earthquake process

convener:Satoshi Ide(Department of Earth an Planetary Science, University of Tokyo), Hitoshi Hirose(Research Center for Urban Safety and Security, Kobe University), Kohtaro Ujiie(Graduate School of Life and Environmental Sciences, University of Tsukuba), Takahiro Hatano(Earthquake Research Institute, University of Tokyo), Chairperson:Kazushige Obara(Earthquake Research Institute, University of Tokyo), Aitaro Kato(Earthquake Research Institute, University of Tokyo)

Accumulating observational studies on various types of slow deformation events, such as tectonic tremors, very low frequency events, and slow slip events, portrays some universal characteristics in generally complex behavior, including interaction among events and influence by various outer loadings. Some of these phenomena seem to have causal relation with the occurrence of very large earthquakes. A unified understanding of these slow and fast earthquake processes requires an approach integrating geophysics, seismology, geodesy, geology, and non-equilibrium statistical physics. We welcome presentations based on, but not limited to, geophysical observation, data analysis, analytical theory, numerical simulation, field study, and laboratory experiments.

Interplay between long-term SSE and ETS facilitated by different underground environment

*Kazushige Obara[1]

1. Earthquake Research Institute, The University of Tokyo

Slow earthquakes consist of fault slip phenomena with various characteristic times. Geodetically detected slow earthquakes are mainly classified into two types; short-term and long-term slow slip events (SSEs) with duration from days to weeks and from months to years, respectively. In southwest Japan, at the deeper part from the seismogenic zone along the subducting plate interface, long-term and short-term SSEs are adjacently distributed and they indicate interaction. Because the short-term SSE usually occurs as an Episodic Tremor and Slip (ETS) associated with low-frequency tremor and very-low-frequency earthquake, the interaction is usually observed clearly in ETS tremor seismicity.
In Bungo channel, the long-term SSE is well known to occur at interval of 6-7 years. After the deployment of dense high-sensitivity seismograph network, major long-term SSEs in 2003 and 2010 were accompanied by activation of tremor seismicity. The activated tremor region is limited within a narrow width of 10 km from the updip edge of ETS zone and the tremor activity of the rest downdip part is constant irrespective to the occurrence of the long-term SSE.
In this region, two small long-term SSEs were detected by GNSS in 2014 and 2016; however, the interaction to ETS tremor were different from cases in 2003 and 2010. In 2014, activated tremor was smaller than that in 2010 according to the difference in the magnitude of SSE. On the other hand, there was no tremor activity associated with 2016 SSE. This is because the slip region of SSE was located southward apart from the tremor zone. By the way, a long-term SSE from the end of 2018 continues associated with activation of tremor lasting for several months. This SSE might be expected as a major SSE since 2010.
The main difference between long-term and short-term SSEs is slip rate. The difference in the slip rate may affect to the tremor rate. During the long-term SSE in 2003 and 2010, the temporal change in cumulative number of tremor increased smoothly similar to the GNSS displacement. However, the gradual increase of tremor number was actually composed of superposition of small bursts corresponding to the faster speed slip compared to the long-term SSE. This suggests that the ETS region has a characteristic slip and frictional property different from the long-term SSE region.
A recent receiver function study conducted along a linear seismic array installed at the west of Shikoku besides from Bungo channel has revealed a low velocity oceanic crust and a continental Moho discontinuity just above ETS activity. This indicates that the ETS occur at the boundary between the subducting oceanic plate and the overlying mantle wedge, whereas that long-term SSE occurs at the boundary between oceanic plate and the continental lower crust. The difference of slow earthquake behavior controlled by the structure in the hanging wall is very similar to the Tokai region (Kato et al., 2010). Therefore, the different environment at the plate interface facilitates these SSEs with different characteristic times.

Determination of sVLFE epicenters around the subducted Kyushu-Palau Ridge from coda interferometry

*Takashi Tonegawa[1], Yusuke Yamashita[2], Aki Ito[1], Masanao Shinohara[3], Daisuke Suetsugu[1], Tsutomu Takahashi[1], Yasushi Ishihara[1], Shuichi Kodaira[1], Yoshiyuki Kaneda[4]

Shallow very low frequency earthquakes (sVLFEs) occur at the shallow portion of the plate boundary. The Rayleigh waves at a frequency of 0.03–0.2 Hz radiated from their sources are observed in land and seafloor seismic records. Although sVLFE locations have been estimated from land records, there is a possibility to determine them more precisely if seafloor records near the epicenters are available. In the Hyuga-nada region and off Nansei Islands, ocean bottom seismometer (OBS) arrays were deployed 4 times during 4 years, each of which contained 5–13 OBSs and could observe at least one episode of sVLFE activity. In this study, we estimated the group velocity of the Rayleigh wave in the OBS arrays from coda interferometry, and applied it to the envelope correlation method (ECM) using seafloor seismic records for determining sVLFE epicenters.

As a result, the locations of sVLFE during 2014 and 2016 were determined at the northern edge of the Kyushu-Palau Ridge (KPR) (Yamamoto et al. 2013), while those on 2017 and 2018 were estimated to be the southern edge of the KPR. In particular, the sVLFEs on 2015 firstly occurred at the northern edge of the KPR, but occurred near the trough afterwards. Also, comparing the area of slow slip event (SSE) in the Hyuga-nada region (Ozawa 2017), sVLFE region at the northern part of KPR directly connects to the SSE region, indicating that slow earthquakes potentially occur from deep to shallow plate interface around the KPR.

Detection of slow earthquakes in the microseism frequency band (0.05–1.0 Hz) by large-scale waveform stacking

*Koki Masuda[1], Satoshi Ide[1], Kazuaki Ohta[2]

1. Department of Earth an Planetary Science, University of Tokyo, 2. Disaster Prevention Research Institute, Kyoto University

Slow earthquakes have been intensively studied because of the proximity of their source area to that of megathrust earthquakes and their high sensitivity to regional stress change. They have been classified according to their characteristic time scale into tremors and low frequency earthquake (LFE; >1 Hz), very low frequency earthquake (VLFE; 20-100 sec), and slow slip event (SSE; > 1 day). Microseism noise is dominant in the frequency band between LFE and VLFE, which we call the microseism frequency band, and it is difficult to detect signals of slow earthquakes in this band. As a rare exception, signals in this band accompanied with LFEs and VLFEs were detected on the shallow subduction interface by near-field ocean bottom broadband seismometers with fortuitously low microseism noise (Kaneko et al., 2018). The characteristics of signals in this band are totally unknown for deep slow earthquakes.

In this study, we first report the observation of slow earthquake signals in the microseism frequency band in the western Shikoku region of the Nankai subduction zone, Japan, by stacking a lot of seismograms relative to the timing of high-frequency signals. First, we made synthetic template waveforms and conducted a matched filter analysis using these template waveforms (Ohta & Ide, 2017). Utilizing GPU, we detected about 700,000 events in continuous records at 9 Hi-net stations, operated by National Research Institute for Earth Science and Disaster Resilience, from 2005 to 2015. Their temporal distribution suggests that LFEs are episodic phenomena and their spatial distribution indicates the sources are concentrated in several patches, as reported by previous researches (e.g., Ohta & Ide, 2017). Then we stacked seismograms at the timing of these detected events, after band-pass filtering in different frequency bands (4-8 Hz, 2-4 Hz, 1-2 Hz, 0.5-1 Hz, 0.25-0.5 Hz, and 0.125-0.25 Hz). In-phase waveforms are confirmed in all frequency bands, despite low sensitivity of Hi-net seismometers in lower frequencies than 1 Hz. This result suggests that slow earthquakes radiate broadband signals without characteristic frequencies from 0.125 to 8 Hz.

Source characteristics of low-frequency earthquakes in Nankai subduction zone inferred from analysis of large event dataset

*Natalia Poiata[1], Mariano Supino[1,2], Gaetano Festa[2], Jean-Pierre Vilotte[1], Kazushige Obara[3]

1. Institut de Physique du Globe de Paris, 2. Università degli Studi di Napoli “Federico II”, Napoli, Italy, 3. Earthquake Research Institute, University of Tokyo, Japan

Application of advanced detection and location methods to the analysis of low-frequency earthquakes (LFE) allows building large event catalogues rich in information that can provide a better understanding of their source characteristics. Up to now, LFE characterization in terms of size, stress drop and rupture propagation still remains uncertain, the main difficulty owing to the low signal-to noise ratio of corresponding records.

We present a catalog of LFE in western part of Nankai subduction zone derived by applying a full waveform-based detection and location scheme of Poiata et. al. (2016) to the continuous records form Hi-net seismic stations covering a 3-year period from 2013-2016. The applied method is based on the frequency-selective coherence of signals’ statistical features recorded across the stations of seismic network, not requiring a prior assumption about the event source (i.e., template event). The derived catalog (~ 40000 events) allows to look into the details of LFE space-time activity (i.e., clustering and migration patterns) during the energetic tectonic tremor sequences as well as inter-sequence periods as well as characterize source properties of these events.

We derive source parameters of LFEs extracted from this 3-year catalog by applying the probabilistic approach of Supino et al. (2019) based on the conjunction of states of information between data and model and estimating the joint probability density function of the parameters. The events S-wave displacement amplitude spectrum is described by a circular source model, characterized by a plateau at low frequencies and a coherent decay at high frequencies; the frequency of transition between these two regimes is the corner frequency. Processing of this large LFE data set is performed using accurate quality criteria, allowing to automatically reject noisy data and unconstrained solutions.

The resulted moment magnitudes, estimated from low-frequency plateau, range between Mw 0.9 and 2.2, while corner frequencies vary between 0.8 and 12 Hz, being lower than expected for ordinary earthquakes, as already observed for LFEs. We found that LFE sources exhibit a power-law scaling between corner frequency and seismic moment, with an exponent of -3.5, very similar to the scaling observed for classical earthquakes.

High-frequency radiation prior to semi-volcanic low-frequency earthquake in Eastern Shimane, SW Japan, illuminated by “0.1 manten” Hyper Dense Seismic Observation

*Aitaro Kato[1], Shin'ichi Sakai[1], Satoshi Matsumoto[2], Yoshihisa Iio[3]

1. Earthquake Research Institute, the University of Tokyo, 2. Kyushu University, 3. Kyoto University

Semi-volcanic deep low-frequency earthquake (LFE) that occurs distant from active volcanoes has been investigated by previous several studies [Ohmi and Obara, 2002; Aso et al., 2013]. In eastern Shimane of SW Japan, there is a spot hosting frequent semi-volcanic LFE activity for over 20 years. Above this source area, we installed a thousand of seismic stations from March 2017 to March 2018, which covers an entire aftershock zone of the 2000 Western-Tottori earthquake (Mw 6.7). The spatial interval of each seismic station ranges from 1 to 2 km.

We found out clear arrivals of high-frequency waveforms prior to arrivals of low-frequency signals by a hundred of the dense seismic stations. The differential arrival times between the high- and low-frequency waveforms are approximately 1.5 s. The high-frequency radiation has the strongest amplitude at 28 Hz and 16 Hz and is characterized by stronger P-wave amplitude than faint S-wave. In contrast, the low-frequency component is predominant from 1 to 6 Hz and shows variation of the ratio of P-wave to S-wave with epicentral distance. This observation clarifies that different excitation mechanisms are needed to explain bimodal radiations at the high- and low-frequency bands.

We relocated the high- and low-radiation sources by both visually picked arrival times and Source Scanning Algorithm. Then, each radiation source is located within a cloud of LEFs determined by the JMA. The depth of the high- and low-frequency sources are imaged around the depth of 30 km, namely around Moho discontinuity. But, the high-frequency radiation is slightly deeper than that of the low-frequency with a few km horizontal offset. The origin time of the high-frequency radiation is by 1.5 ~ 2 seconds earlier than that of the low-frequency. This slight spatial gap indicates that the two sources appear to be not collocated, while the spatial separation between the two sources is not so large in terms of the hypocenter accuracy. The present study first shows that the high- and low-frequency radiation sources are close to each other around Moho discontinuity.

Combined with these observations, we interpret that the early high-frequency radiation is derived from brittle breakage of low-permeability seal may arise from hydrothermal cementation. Infiltration of high-pressurized fluids into the bottom of lower crust may trigger slow shear slip or resonance of crustal fluids along a pre-existing fracture.

Variation of Focal Mechanisms of Low Frequency Earthquakes in Parkfield

*Miki Aso[1,3], Naofumi Aso[2], Satoshi Ide[1]

1. Department of Earth and Planetary Science, The University of Tokyo, 2. Tokyo Institute of Technology, School of Science , 3. OYO RMS Corporation

Tectonic low frequency earthquakes (LFEs) occur at plate boundaries around the world, and considered as local slow deformation. LFEs in subduction zones are found to have low-angle thrust fault mechanisms in southwest Japan [Ide et al., 2007], Mexico [Frank et al., 2013], and Cascadia [Royer and Bostock, 2014]. LFEs along Alpine fault, a transform fault in New Zealand, are known to have right-lateral strike slip mechanism [Baratin et al., 2018]. However, the focal mechanisms of LFEs at Parkfield along the San Andreas Fault zone have not been revealed yet, regardless of the frequent activities. The San Andreas Fault is one of the most matured active faults in the world, especially at Parkfield, and large damaging earthquakes also repeatedly occurred in history. Therefore, many seismologists and geologists have been challenging to reveal the cause of earthquakes and LFEs.
In this study, we estimate the focal mechanisms of 88 LFE families in the catalog of Shelly [2017]. We first stack seismograms of over one million events in the catalog to improve the signal-to-noise (S/N) ratio. P-wave polarities of the stacked waveforms suggest the existence of variations in focal mechanisms of the LFE families.
Then, we evaluate the absolute amplitudes of original seismograms using the stacked waveforms. The SH wave amplitudes are inverted to the focal mechanisms for each LFE family. Specifically, the contributions from source radiation, path attenuation, and site amplification are represented by independent terms based on the assumption of simple ray theory, and estimated by solving a two-step inversion problem. The source terms are utilized to determine focal mechanisms. While most of the focal mechanisms are strike-slip consistent with the San Andreas Fault motion, those for families near the central Parkfield and the family off the surface trace contain large dip-slip (Figure 1 and 2). These variations are consistent with tidal sensitivities of LFEs in Parkfield [Thomas et al., 2012]. Our study reveals regional dip-slip focal mechanisms at first glance to be strike-slip along matured San Andreas Fault.

[S-CG48] Science of slow earthquakes: Toward unified understandings of whole earthquake process

convener:Satoshi Ide(Department of Earth an Planetary Science, University of Tokyo), Hitoshi Hirose(Research Center for Urban Safety and Security, Kobe University), Kohtaro Ujiie(Graduate School of Life and Environmental Sciences, University of Tsukuba), Takahiro Hatano(Earthquake Research Institute, University of Tokyo), Chairperson:Satoshi Ide(Graduate School of Science, University of Tokyo), Kazuaki Ohta

Accumulating observational studies on various types of slow deformation events, such as tectonic tremors, very low frequency events, and slow slip events, portrays some universal characteristics in generally complex behavior, including interaction among events and influence by various outer loadings. Some of these phenomena seem to have causal relation with the occurrence of very large earthquakes. A unified understanding of these slow and fast earthquake processes requires an approach integrating geophysics, seismology, geodesy, geology, and non-equilibrium statistical physics. We welcome presentations based on, but not limited to, geophysical observation, data analysis, analytical theory, numerical simulation, field study, and laboratory experiments.

Mapping seismic data to slow slip using machine learning

*Bertrand Rouet-Leduc[1], Claudia Hulbert[2], Ian McBrearty[1], Paul Johnson[1]

1. Los Alamos National Laboratory, USA, 2. Ecole Normale Superieure, France

We show that the Cascadia subduction zone is apparently continuously broadcasting a low-amplitude, tremor-like signal that precisely informs of the fault displacement rate throughout the slow slip cycle. Using a method based on machine learning previously developed in the laboratory, we analysed large amounts of raw seismic data from Vancouver Island to separate this signal from the background seismic noise. We posit that this provides indirect real-time access to fault physics on the down-dip portion of the megathrust, and thus may prove useful in determining if and how a slow slip may couple to or evolve into a major earthquake.

In a parallel approach, we show that tremor can be accurately detected on a single seismic station by a deep convolutional neural network. Seismic tremor is posited to provide information on the physical state of the slowly slipping portion of the megathrust, and a single station tremor detector gives a direct access to the tremor signal and its physical characteristics. A deep learning model trained to detect tremor in Cascadia recognizes catalogued tremor in other subduction zones, arguing for the universality of tremor and slow slip characteristics. The detection rate of a deep learning model trained to recognize tremor in Cascadia and applied on waveforms from Northern Chile shows strong correlation with surface displacement rate, arguing for episodic tremor and slip detection where slow earthquakes and associated tremor had not been seen so far, presumably taking place too deep to have been detected using conventional multi-station methods.

Revealing the slow earthquake activity in the Japan Trench and its relation to the 2011 Tohoku-Oki earthquake

*Tomoaki Nishikawa[1], Takanori Matsuzawa[2], Kazuaki Ohta[1], Naoki Uchida[3], Takuya NISHIMURA[1], Satoshi Ide[4]

1. Disaster Prevention Research Institute, Kyoto University, 2. National Research Institute for Earth Science and Disaster Resilience, 3. Graduate School of Science, Tohoku University, 4. Graduate School of Science, The University of Tokyo

Subduction zone megathrust earthquakes result from the interplay between fast dynamic rupture and slow deformation processes, which are directly observed as various slow earthquakes, including tectonic tremors, very low-frequency earthquake (VLFs) and slow slip events (SSEs), and indirectly suggested by a temporal change in the frequency of repeating earthquakes and the occurrence of episodic earthquake swarms. Some megathrust earthquakes have been preceded by slow earthquakes and terminated near the areas where slow earthquakes were frequently observed. While capturing the entire spectrum of slow earthquake activity is crucial for estimating the occurrence time and rupture extent of future megathrust earthquakes in a given subduction zone, such an observation is generally difficult, and slow earthquake activity is poorly understood in most subduction zones, including the Japan Trench, which hosted the 2011 M_w9.0 Tohoku-Oki earthquake. Here we reveal the slow earthquake activity in the Japan Trench in detail using tectonic tremors, which we detected in the seismograms of a new ocean-bottom seismograph network, VLFs, SSEs, repeating earthquakes, and earthquake swarms. We show that the slow earthquake distribution is complementary to the rupture area of the Tohoku-Oki earthquake and correlates with the structural heterogeneity along the Japan Trench. Concentrated slow earthquake activities were observed in the afterslip area of the Tohoku-Oki earthquake, which is located to the south of the fore-arc geological segment boundary. Our results suggest that the megathrust in the Japan Trench is divided into three segments that are characterised by different frictional properties, and that the rupture of the Tohoku-Oki earthquake, which nucleated in the central segment, was terminated by the two adjacent segments.

Tremor and slow slip associated with afterslip of the 2011 Tohoku earthquake

*Kazuaki Ohta[1], Yoshihiro Ito[1], Ryota Hino[2], Shukei Ohyanagi[1], Takanori Matsuzawa[3], Masanao Shinohara[4], Hajime Shiobara[4]

1. Disaster Prevention Research Institute, Kyoto University, 2. Graduate School of Science, Tohoku University, 3. National Research Institute for Earth Science and Disaster Resilience, 4. Earthquake Research Institute, the University of Tokyo

Characterizing shallow interplate slip is essential for modeling the potential generation of megathrust earthquakes and tsunamis. Large postseismic crustal deformation caused by the 2011 Tohoku-Oki earthquake suggests the occurrence of shallow afterslip, but it is unclear what kind of slip is dominant at the shallow plate interface. Here we report episodic tremor activity south of the primary rupture area based on ocean bottom seismometer observations.
We deployed 24 OBSs at 6 sites close to the trench axis in the Fukushima-Oki region. Three of these sites were small arrays, each consisting of 1 broad-band OBS and 6 short-period (1 Hz) OBSs. The 3 other sites each had 1 short-period OBS. Continuous observations were made from October 2016 to September 2017. For OBS records, we applied the envelope correlation method to detect and locate tremor activity. We also estimate the focal mechanisms of the detected tremor events using S-wave polarization particle motion.
We identified ~ 2000 tremor events in five burst episodes. The duration of each burst ranges from 6 to 18 days, with recurrence intervals of ~60 days. The tremor region largely coincides with the region of very low frequency earthquakes and lies between geodetically observed coseismic and afterslip region of the Tohoku earthquake. Tremor shows clear migration behavior with the speed of ~ 5 km/day and shear mechanisms consistent with plate subduction direction.
The characteristics of the tremor –episodicity, migration and shear mechanisms –strongly suggest that it is accompanied by slow slip events (SSEs). We further approximated the slip amount of SSEs based on the ground displacement of the tremor seismograms. The estimated slip of 1.5 cm/year corresponding to a seismic moment of ~7.4×10^{17} Nm is slightly smaller than but comparable to that of typical short-term SSEs, however, much smaller than that of afterslip. Thus, both SSEs and afterslip exist in the shallow part of the Japan trench. We propose that the tremor and SSE region illuminate the boundary between coseismic slip and stable aseismic slip that could limit the rupture extent of future megathrust earthquakes. Besides, the observed tremor and slow slip activities may also suggest that the interplate stress state has been recovered to the level of that before the Tohoku earthquake.

The Japan Trench is the host to various scale and slip behavior of seismic activities, such as the M9 Tohoku-Oki megathrust earthquake, slow slip events, low frequency tremors and very-low frequency earthquakes (VLFEs). Since these events occur under the seafloor, observation capability of the onshore seismic network is limited due to far distance from their source regions. During 2016 and 2017, we have performed the dense OBS Array of Arrays observation in the offshore Fukushima prefecture near the trench axis to achieve high resolution imaging of the shallow portion of the Japan Trench.
Our network consists of three OBS arrays. Each array consists of one broad band OBS, and six 1Hz short period OBSs. These seven OBSs form a triangular array of 300m to 500m of interstation distance, which results in the array diameter of ~1km. High resolution imaging of complicated seismic phenomena (such as tectonic tremor) is enabled by installing the arrays in the vicinity of the target region.
Based on visual inspection of the observed data, we have identified two episodes of low frequency tremors, triggered dynamically by M7.8 event in offshore Solomon Islands on December 2016, and M7.7 event in offshore Kamchatka Peninsula on July 2017. In both cases, the tremors were accompanied by arrival of Rayleigh waves. The episode of December 2016 lasted 7 minutes, and ceased after passage of Rayleigh wave. On the other hand, the episode of July 2017 continues even after passage of Rayleigh wave, and lasted for more than 12 minutes.
To reveal the origin of these tremors, we apply a beamforming technique to estimate back azimuth and slowness of incoming wave observed by the arrays. Observed tremors are beamformed in horizontal components of OBSs after their absolute orientations are determined using particle-motion of T-phase. From the resulting beam, we have estimated epicenters of the tremors every 60 seconds using only azimuthal information at each array. In this presentation, we are going to discuss about depth of the tremor sources from observed slowness. The tremor activities probably indicate the potential for the occurrence of shallow slow slip events near the Japan Trench, in which VLFEs and after slip were activated after the 2011 Tohoku-Oki earthquake.

The activity of small repeating earthquakes after the 2011 Tohoku-oki earthquake: an examination based on the S-net and land networks

*Naoki Uchida[1], Ryota Takagi[1], Satoshi Hirahara[1], Takashi NAKAYAMA[1], Toru Matsuzawa[1], Sachiko Tanaka[2], Youichi Asano[2]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions Graduate School of Science, Tohoku University, 2. National Research Institute for Earth Science and Disaster Resilience

We examined the activity of repeating earthquakes around the 2011 Tohoku-oki earthquake, Japan based on Seafloor Observation Network for Earthquakes and Tsunamis along the Japan Trench (S-net) and permanent land stations. We used earthquakes located by Japan Meteorological Agency to find repeating earthquakes based on the waveform similarity observed at the same station. The waveform coherences for 40 second window including P and S phases are evaluated and if they are larger than 0.8 we select them as repeating earthquakes. We performed long- and short-term analyses respectively to understand long-term activity change of repeating earthquakes and to compare land-based and offshore (S-net) data analyses. For the long-term analysis, we used earthquakes larger than M2.5 for the period from 1993 to 2018 obtained by the land stations. For the short-term analysis, we analyzed land and S-net stations separately for M2.0 or larger earthquakes for the period from August 2016 to October 2018.

The long-term analysis shows that the coseismic slip area of the 2011 Tohoku-oki earthquake continued to be quiet in the activity of the repeating earthquakes suggesting that the area have not reloaded enough after the earthquake. In the shallow area (depth <= 30km), the activity of repeating earthquakes decay with fluctuations to the north of the coseismic slip but decayed monotonically to the south of the coseismic slip area. In the deep area (depth >= 30km), the repeating earthquake activity also decayed but the activity was still high in 2018 especially in the down-dip part of the coseismic slip area. These results show different behavior of postseismic slip of the Tohoku-oki earthquake.

The short-term analysis that use the same set of earthquakes to detect repeating earthquakes (August 2016 to October 2018, M>=2) by the S-net and the land stations show similar number of detected repeating earthquakes (520 and 684 for S-net and land stations respectively). This is probably because the waveforms of earthquakes that are located by land stations (JMA’s catalogue) have good signal-to-noise ratio for the land stations. Since the completeness of magnitudes of the JMA’s catalogue in far off land area is larger than M2.0, the event detection by S-net will contribute to the detection of more repeating earthquakes in the offshore area. In addition to this, the land-station based long-term analysis has more repeating earthquakes (894 M>=2.5) for the 2.2-year period of the S-net data analysis, suggesting the increase of observation period will contribute for the detection of repeating earthquakes whose intervals are larger than the short analysis period .

[S-CG57] Structure and evolution of Japanese islands - Formation of island arc systems and earthquake cycles

convener:Hiroshi Sato(Earthquake Prediction Research Center, Earthquake Research Institute, The University of Tokyo), Masanao Shinohara(Earthquake Research Institute, University of Tokyo), Masahiro Ishikawa(Graduate School of Environment and Information Sciences Yokohama National University), Makoto MATSUBARA(National Research Institute for Earth Science and Disaster Resilience), Chairperson:Masanao Shinohara(Earthquake Research Institute, The University of Tokyo), Tatsuya Ishiyama(Earthquake Research Institute, University of Tokyo)

Subduction processes such as accretion, back-arc-spreading, and arc-arc collisions have shaped the Japanese island arc. Recent advances in seismic imaging, both passive and controlled source, have produced new images of the crust-mantle structure under Japan and surrounding regions. Through the influence of pre-existing faults and rheological structures, these crust and mantle structures are exerting strong control on active tectonic processes like seismic activity and crustal deformation in the overriding plate. We seek contributions that document and/or model the deformation of the Japanese islands over a variety of time scales from the earthquake cycle to the tectonic evolution of the Japanese island arc, and from a range of research fields including seismology, geology, geochemistry, tectonic geomorphology, and geodynamics. Multidisciplinary studies are encouraged. We also welcome contributions in numerical or analogue geodynamical modeling that explore deformation processes.

Recent Earthquake Activity in Northern Hokkaido, Japan

*Tetsuo Takanami[1,2]

1. Carnegie Institution for Science, 2. Hokkaido Research Center of Geology

In order to understand the future earthquake potential damage in northern Hokkaido, we examined the current seismic activity from the perspective of plate tectonics. An earthquake swarm, with largest earthquake of M_{JMA} 4.3, starting on July 15, 2012 in the town of Nakagawa in northern Hokkaido, Japan, where residents felt the earthquakes of seismic intensity IV three times in 3 days (The Seismological Bulletin of Japan, JMA, 2012). At the same time, a slow earthquake was also detected nearby during the swarm (M. Ohzono et al., 2015; S. Ikeda, 2016). It is inferred from the results that the source area is associated with almost horizontal E-W compressional tectonics. Den and Hotta (1973) first proposed the paleo-tectonic movement of the Okhotsk plate in the Mesozoic to Paleogene time along western Hokkaido and the island of Sakhalin to the north. Nakagawa is located at the western margin of the Okhotsk paleo-plate. The present tectonic movement of the island of Hokkaido is controlled by the triple interaction among the Pacific, the North American and the Eurasian plates. The current activity of an earthquake swarm and slow earthquake near Nakagawa suggests that the tectonic movement on the remnant boundary zone has not completely vanished. Further, according to the geodetic imaging by Loveless and Meade (2010), the slip rates across the corresponding area were estimated as 13.0±2.1 mm/y ~ 8.4±2.1 mm/y of E-W closing or shortening. In order to shed light on the current earthquake behavior in the western boundary of the Okhotsk paleo-plate, we study seismic activity in northern Hokkaido centered on Nakagawa using earthquakes of magnitude 2 or more in the JMA unified catalog from January 1, 1996 to October 30, 2018. The map of epicenters indicates that almost all are inland earthquakes within a western coastal zone extending 40km east-west and 200km north-south with very few earthquakes located in the east side of the Sea of Okhotsk. Here we focus on the earthquake activity in the northern half of the zone (44.2˚N - 45.5˚N; 141.5˚E - 142.5˚E). The topical earthquake swarm and slow earthquake near Nakagawa occurred when the general earthquake activity was at its highest. We apply the Gutenberg-Richter frequency-magnitude formula (G-R law) to our earthquakes set and obtain a b-value of 0.87 that is somewhat small but almost normal. This current seismic activity is also useful in considering future potential damages in northern Hokkaido. The largest earthquake magnitude from the G-R relation is estimated to be about $M_{JMA}5$ consistent with the fact that few moderate to larger earthquakes with magnitude (M_{JMA}) greater than 5 have occurred in the research region. Our results are limited by the number of earthquakes in the region since the installation of the high density network in late 1990. In 2007, the Headquarters for Earthquake Research Promotion, an office of Japanese government estimated the magnitude of the biggest earthquake of $M_{JMA =}$ 7.6 if the Sarobetsu fault zone in northern Hokkaido fails over its entire zone. Since we have a catalog for a certain time interval (2.7 years) the straight line projection to higher magnitudes gives an estimate of the probability of having a larger earthquake. Projecting the line to say M_{max} =7.6 expected gives a value of 0.0055, implying that we could expect one M_{max} =7.6 in 183 years. We are aware that such a long term projection based on a relatively short data interval is subject to significant error. As earthquake data are added in the future, this aspect should be reexamined.

Seismic constraints on the crustal structure off the southwestern coast of Hokkaido, Japan Sea

*Tetsuo No[1], Takeshi Sato[1], Shuichi Kodaira[1], Hiroshi Sato[2], Tatsuya Ishiyama[2]

1. JAMSTEC, 2. ERI, University of Tokyo

Offshore crustal structure studies have been conducted around Japan, with a primary focus on the Pacific side such as the Nankai Trough and Japan Trench via multichannel seismic reflection (MCS) and ocean bottom seismograph (OBS) surveying since the 1990s (e.g. Kodaira, 2009); moreover, seismic surveys have been conducted in the Japan Sea since the 2000s (e.g. Sato et al., 2018a). In 2018, we conducted a MCS and OBS survey off the southwestern coast of Hokkaido, which was one of the unsurveyed areas in the Japan Sea. Our survey area included the source region of the 1993 Hokkaido Nansei-Oki Earthquake, which is the largest earthquake among the shallow earthquakes that occurred in the Japan Sea since the Meiji period. Therefore, as our survey lines were oriented traverse the source region of the 1993 Hokkaido Nansei-Oki earthquake to the east and west, our data provided very important information for studying the relation between this earthquake source fault and its surrounding crustal structure. Furthermore, we targeted the Japan Basin, which is located to the west of the Hokkaido Nansei-Oki Earthquake source region. The Japan Basin is the widest basin in the Japan Sea, with previous studies estimating that it possesses a standard oceanic crustal structure and thickness (e.g. No et al., 2014; Sato et al., 2018b). Our survey area provides another key piece of information for comparison with a previous geomagnetic study because it overlaps with an area that has been defined by a striped pattern of geomagnetic anomalies (e.g. Kinoshita et al., 1995).

We conducted the seismic survey using the JAMSTEC R/V *KAIREI*. The survey area extends from the Okushiri Basin and Shiribeshi Trough to the Okushiri Ridge, the Japan Basin, and comprises nine MCS lines and one seismic refraction line using OBSs. Furthermore, the seismic refraction survey line was extended onshore to link with a land seismic survey in Oshima Peninsula, which was simultaneously conducted by the Earthquake Research Institute, University of Tokyo.

According to the provisional data processing results, clear shortening structures are imaged in the MCS data that cover the Okushiri Basin, Shiribeshi Trough, and the source region of the Hokkaido Nansei-Oki earthquake. However, a sedimentary layer with a thickness of approximately 2 km is observed in the Japan Basin, and clear reflectors, dense normal faults are observed throughout this sedimentary layer. Furthermore, a strong reflector is identified at approximately 7 km under the sedimentary layer, which we presumed to be the Moho. We image clear reflectors in the crust and uppermost mantle. Furthermore, the Moho reflector is poorly defined in the eastern margin of the Japan Basin, with a shortened structure and clear east-dipping crustal reflector imaged in this region.

The results of data analysis of seismic survey using OBSs indicate that the Japan Basin is a relatively homogeneous structure that possesses a standard oceanic crustal structure. However, the P-wave velocity structure indicates a thicker crust to the east of the region where the MCS data confirmed a shortened structure. Additionally, it is suggested that the crust thickens rapidly across the Okushiri Ridge.

Deep seismic reflection profiling across the Oshima Peninsula, SW Hokkaido, Japan

*Hiroshi Sato[1], Tatsuya Ishiyama[1], Naoko Kato[1], Hidehiko Shimizu[2], Takeshi Sato[3], Shinji Kawasaki[2], Tetsuo No[3], Shuichi Kodaira[3], Seiichi Miura[3]

1. Earthquake Research Institute, The University of Tokyo, 2. JGI Inc, 3. Japan Agency for Marine-Earth Acience and Technology

An onshore-offshore seismic data set was collected across the Oshima peninsula, SW Hokkaido to the Japan basin, off SW-Hokkaido to determine the geometry of seismogenic source faults and basic structure of backarc of NE Honshu arc (Sato, T. et al., 2019 JpGU; No et al., 2019, JpGU). Here, we present the result of deep seismic reflection profiling across the Oshima peninsula, high-reslolution seismic reflection survey across the western boundary fault of Hakodate plain and P-wave velocity structure obtained from onshore-offshore integrated seismic processing.

The deep seismic data set was collected across the Oshima peninsula in May, 2018. Vertical land seismometers (GSR) were deployed with a spacing 50 to 200 m along the 54-km-long seismic line using fixed 1119 channel. The seismic source was four to five vibroseis trucks with standard 150 m shot spacing. As high energy shot, 50 stationary sweep were carried out every 5 km along the seismic line. Sweep frequency was 6 to 60 Hz and sweep length was 16 to 20 sec. The obtained seismic data were processed according to a standard common-midpoint (CMP) stacking and a post stack time migration. We used refraction tomography to determine the P-wave velocity structure, that revealed down to 8 km in depth beneath the western part of the seismic line. Obtained P-wave velocity profile demonstrates the geometry of the top surface of pre-Tertiary rocks. The Kamiiso massif and Esashi range marked by high Vp (> 5 km/s) and 2 km of sediment cover are distributed in the Tate and Hakodate Basins. With a pattern of seismic reflection, main geologic structure is interpreted a series of westward dipping Miocene normal faults. The NS-trending Kamiiso massif is an uplifted zone bounded by a high-angle reverse fault, which formed as a normal fault. The high-resolution seismic reflection profiling was performed across the western boundary fault of the Hakodate plain. Seismic source was a viborseis truck and the seismic signal was recorded fixed 845 channel offline recorders (GSR). Shot and receiver intervals are 10 m. The 8-km-long seismic section portrays the geometry of active fault down to 2 km in depth. The fault dips 45 degrees westward in more than one km depth. Judging from the stratigraphy, it is interpreted as a reactivation of normal fault as reverse fault. On the contrary, the shallower part of active fault forms thin-skinned type of deformation associated with wedge-thrust, fault-related fold and flat-ramp structure. The obtained shallow structure is very concordant with the feature of tectonic geomorphology and frontal part of active thrust is presented as a blind thrust. The air-gun shots along the offshore of Oshima peninsula were recorded by fixed recorders on land and integrated P-wave velocity was obtained covering 310 km seismic line. The basic feature is very similar to the velocity model proposed by Sato, T. et al. (2019) JpGU. The velocity structure portrays the detailed structure produced by Miocene backarc extension and formation of the Sea of Japan crust. In spite of the later shortening deformation, basic structure has extensional tectonic features. There no evidence of the subduction of the Sea of Japan crust beneath the Hokkaido continental crust.

Crustal deformation and stress accumulation on source faults around Hokkaido, Japan, due to coupling at the Kuril trench

*Akinori Hashima[1], Hiroshi Sato[1], Tatsuya Ishiyama[1], Andrew M. Freed[2]

1. Earthquake Research Institute, The University of Tokyo, 2. Purdue University

2018 Mw6.7 Hokkaido-Iburi earthquake, Japan, brought about disastrous landslides near epicenter, and a power blackout on the whole Hokkaido island. In order to assess activity of such an intra-plate earthquake, we need to know not only the geometry of local source faults but also stress on them. The geometry model for the source faults over Japan was already published by the Headquarters for Earthquake Research Promotion of the Japanese government. We are now revising the model and adding new source faults in the offshore areas. Stress in the plate interior is essentially formed due to the interplate interaction at plate boundaries. The Kuril trench near Hokkaido has hosted a massive megathrust rupture. GPS observation shows widespread locking region southeast off Hokkaido. Similarities to the preseismic state around the 2011 Mw9.0 Tohoku-oki earthquakes along the Japan trench are pointed out such as decades of subsidence along the southeast Hokkaido and decrease in seismicity in recent years in this region. In order to quantitatively estimate the effect of these plate boundary process, we construct a finite element model (FEM) to estimate regional deformation and stress accumulation rate on source fault around Hokkaido due to the locking along the Kuril trench.

Our model contains the region of 3700 km x 4600 km including the Kuril–Japan trench. The bottom of the model is taken at the depth of 700 km to consider the whole upper mantle. The geometries of the Pacific and Philippine sea slabs under the Northeast Japan –Izu Bonin arcs, and the Southwest Japan –Ryukyu arcs, respectively, are incorporated following the previous studies. The model region is divided into 1000,000 tetrahedral elements. The size of the elements is set 5 km around the slip region and gradually larger close to the boundaries. Fault slip can be modeled by giving constraint equation of displacement discontinuity. Slip region is taken on the upper surface of the Pacific plate shallower than the depth of 80 km. We simply set the Pacific and Philippine sea slabs as the 70-km thick elastic plates over viscoelastic asthenosphere. The continental side is assumed to be elastic-viscoelastic stratified structure. Elastic thickness is tested for the case of 30 and 50 km. Since the interseismic deformation includes the effect of the concurrent viscous relaxation in the asthenosphere, we used response after complete relaxation.

In order to understand the basic feature of crustal deformation around Hokkaido, we compute response to locking of two offshore regions inferred from the past earthquake occurrence: Tokachi and Nemuro. Crustal deformation in Hokkaido obtained from GPS observation shows ~5 cm/yr northwestward movements on the Southeast coast, which decay toward the North and West, except the effect of the 2003 Mw8.0 Tokachi-oki and 2011 Mw9.0 Tohoku-oki earthquakes. This basic feature can be realized in the case of elastic thickness of 50 km and locking rate of 4 cm/yr in Tokachi and 8 cm/yr in Nemuro, respectively. These locking rates form compressive stress fields over the Hokkaido region. The compressive axes are NW-SE in the eastern Hokkaido and E-W in the western Hokkaido. The calculated stress field in the western Hokkaido is consistent with the occurrence of the 2018 Hokkaido-Iburi earthquake. In this study, we also apply the calculated stress field to source fault model around Hokkaido and calculate Coulomb stress to examine the earthquake activities.

Structural Heterogeneity in and around the Source Region of the 2018 Hokkaido Eastern Iburi Earthquake, Central Hokkaido, Japan

*Takaya Iwasaki[1], Noriko Tsumura[2], Tanio Ito[3], Kazunori Arita[4], Makoto Matsubara[5], Hiroshi Sato[1], Eiji Kurashimo[1], Naoshi Hirata[1], Susumu Abe[6], Katsuya Noda[7], Akira Fujiwara[8], Shinsuke Kikuchi[9], Kazuko Suzuki[10]

1. Eathquake Research Institute, the University of Tokyo, 2. Graduate School of Science, Chiba University, 3. Association for the Development of Earthquake Prediction, 4. Hokkaido Research Center of Geology, 5. National Research Institute for Earth Science and Disaster Resilience, 6. JAPEX, 7. GEOSYS Inc., 8. JOGMEC, 9. JGI Inc., 10. Schlumberger Ltd.

Central Hokkaido, Japan, has complicated tectonic history of subduction, accretion and collision processes from Late Jurassic to the present. Since Paleogene or Early Miocene, compressional stress regime has been dominated by the dextral oblique collision between the Eurasia and North America (Okhotsk) Plates and the subsequent westward movement of the Kuril Arc due to the oblique subduction of the Pacific Plate. The latter event was responsible for the formation of the Hidaka Collision Zone (HCZ) and the foreland fold-and-thrust belt with a very thick (>10 km) sedimentary package. The 2018 Hokkaido Eastern Iburi Earthquake (M=6.7) took place at a very deep depth of 37 km under this foreland fold-and thrust belt. To understand the mechanism on the occurrence of such a deep earthquake from the surrounding structural heterogeneity, we reanalyzed controlled source seismic data from the 1998-2000 Hokkaido Transect Project by applying advanced processing techniques including CRS/MDRS stacking methods and integrated refraction/wide-angle reflection analyses.

The seismic reflection processing imaged for the first time the NE Japan Arc underthrust eastward beneath the thick sedimentary package. The refraction/wide-angle reflection data were re-interpreted by tomography and ray-tracing methods. The latter analysis with aid of the new structural information from the reflection processing indicate that the crust is very thin (15-23 km) and the Moho depth is 22-30 km. The Pn velocity is a normal value of around 8 km/s. These structural features are well consistent with those in the offshore area of NE Japan, which belongs to the same geological unit. Based on the structural information mentioned above, the aftershock distribution was carefully investigated. Aftershocks relocated by the 3D structure model (Matsubara, 2017) with appropriate station corrections are distributed in a depth range of 7-45 km showing a steep geometry facing to the east. We cannot find any evidence that the aftershock distribution is related with shallow west-verging active faults developed in the fold-and-thrust belt. We think that the high-angle fault of this earthquake was formed by a certain tectonic event before the collision, maybe in Late Oligocene to Middle Miocene. The relocated aftershocks are separated into the upper (7-20 km) and lower (22-45 km) groups. The seismicity gap between them corresponds to the lower crust of our velocity model, probably representing its ductile property. According to our results, more than 80 % of relocated events occurred within the uppermost mantle of our structure model. Possible explanation for this high seismic activity is the cold crust delaminated from the Kuril Arc side, whose existence was is confirmed by a series of seismic reflection profiling in the southern part of the HCZ (Arita et al., 1998; Tsumura et al., 1999; Ito, 2000, 2002) and seismic tomography by Matsubara et al. (2017). This delaminated crustal body prevents the thermal circulation and upward migration of dehydrated fluid to cool the forearc mantle and generate more favorable environment for the brittle failure.

Electrical resistivity distribution around the middle axis of Hokkaido Island: constraint for tectonics of ultra-mafic rocks

*Hiroshi Ichihara[1], Toru Mogi[1], Yusuke Yamaya[2]

1. Earthquake and Volcano Research Center, Nagoya University, 2. AIST

Middle axis of Hokkaido Island is located on a tectonic boundaries between NE Japan arc and Kurile arc. In the south part of the boundary, collision due to migration of fore-arc aliver is known (Hidaka Collision zone). Huge serpentine rock bodies are exposed in the high P/T metamorphic belt (kamui-kotan belt) located on the NE Japan arc side near the boundary. In addition, a fresh peridotite rock body (Horoman periodotite) is also distributed in the south part around the boundary. However, tectonic process to bring the surface has not been understood although it is the key to understand the tectonics. In this study, we discuss the crustal structure beneath the arc-arc boundary especially for ultra-mafic rock area based on electrical resistivity distribution obtained in following three areas: (1) middle part of Hidaka collision zone where serpentine is exposed, (2) north part of Kamui-kotan belt where serpentine is exposed but the collision is not occurred, and (3) south part of Hidaka collision zone where the Horoman peridotite is distributed. In the area (1) and (2), very low resistivity (1-10 ohm-m) anomalies area found in the depth around 10-40 km beneath the surface serpentine body but they are not significant beneath out of the serpentine area. We interpreted them as high fraction of aqueous fluid area related to serpentine forming and bring them to the surface. In the area (3), we found thin sheet-like high resistivity body near the surface embedded to low resistivity body (Ichihara et al., G3). The surface high resistivity correspond to the peridotite because unaltered igneous rocks are basically resistive. The underlying conductive area possibly reflect cretaceous sedimentary rock based on integrated interpretation of geomagnetic anomaly, gravity anomaly and the resistivity distribution. If these interpretations in the area (3) are true, the Horoman peridotite covers over the sedimentary rock, implying the unknown tectonics processes occurred on the south part of Hidaka collision zone.

Ministry of Education, Culture, Sports, Science and Technology, Japan , 5. Association for the Development of Earthquake Prediction

1. Introduction
We investigate the 3D seismic velocity structure beneath and around Japanese Islands including beneath the Sea of Japan and Pacific Ocean with seismic tomographic method. National Research Institute for Earth Science and Disaster Resilience (NIED) constructed the High-sensitivity seismograph network (Hi-net) after the 1995 Kobe earthquake, the Seafloor observation network for earthquake and tsunamis along the Japan Trench (S-net) after the 2011 Tohoku-oki earthquake on March 11, and the Dense Oceanfloor Network System for Earthquakes and Tsunamis (DONET) constructed by Japan Agency for Marine-earth Science and Technology (JAMSTEC) was transfered to NIED on April 1, 2016. We used arrival time data detected by these networks operated by NIED as well as other organizations and apply the seismic tomography for these data.

2. Data and method
The target region, 20–48˚N and 120–148˚E, covers the Japanese Islands. In addition to the arrival time data used by Matsubara et al. (2017), we used P- and S-wave arrival times for 32952 earthquakes recorded at approximately 1500 stations including the NIED S-net and DONET from April 2016 to June 2018. We also added the arrival time data detected at the stations operated by universities near the coast of the Sea of Japan from 2000 to 2004. Totally 6356481 P arrival data and 3534482 S arrival data from 112631 events are available. The inversion reduces the RMS of the P-wave traveltime residual from 0.245 s to 0.189 s and that of the S-wave data from 0.287 s to 0.236 s after 11 iterations.

3. Result and discussion
We clarified the seismic velocity structure beneath the Sea of Japan at depths of 10-20 km from off Hokkaido to Wakasa Bay. Vp beneath the Okushiri and Sado Islands is low at a depth of 10 km however, Vp beneath the Sea of Japan is high at depths of 10-35 km. Vp along the coast of Sea of Japan in western Japan is moderate. The lithospheric velocity structure in this region is strongly affected by the mid-Tertiary break up and formation of the Sea of Japan. Through the reactivation of the younger compression, tsunamigenic source faults has been developed. The information of the lithospheric structure provides the essential information to the structure of faults.
Due to the contribution of S-net, the velocity structure of the overlying plate beneath Pacific Ocean has been improved. One important feature is the probable Mesozoic rift structure trending NS from the coast of Tohoku to the west of Hidaka collision zone. Recent the 2018 Hokkaido Eastern Iburi Earthquake (M6.7) may related to the reactivation of the rift related structure in the upper mantle to the lower crust, where marked by high-Vp.

Spatio-temporal extent of Cretaceous fore-arc basin in Japan

*Yukio Isozaki[1], Ryo Hasegawa[1], Yukiyasu Tsutsumi[1]

1. Department of Earth Science and Astronomy, Multi-disciplinary Sciences - General Systems Studies, Graduate School of Arts and Sciences, The University of Tokyo

Recent analyses on detrital zircon ages in sandstones calrified various new aspects on characteristics and secular changes in provenance for the fore-arc domain of Cretaceous Japan. The shallow marine to fluvial Cretaceous strata are disrtibuted in multiple zones running almost parallel to the coeval arc-trench system in SW Japan, which is represented by the paired granitoid (Ryoke) and blueschist (Sanbagawa) belts. For example, the Upper Cretaceous Izumi Group in Shikoku and Kii peninsula has been regarded as a typical fore-arc sedimentary package deposited between the coeval grnaitoid and blueschist belts. Much emphasis was given to its origin in a pull-apart setting along an imaginary large strike-slip movement of the Median Textonic Line. Nonetheless, the lastest zircon analyses documented that its spatio-temporal dimentsion was much greater than previously believed, e.g., more than 1000 km along-arc, and nearly 100 km wide across-arc in sapce, and extended up into the Paleocene in age. The Izumi Group likely represnt a remnant of much large sedimentary basin, and its current restircted occurrence, ca. ca. 300 km along arc and ca. 20 km across-arc, was made by large-scale removal of fore-arc crust, probably relevant to the back-arc rifting to open the Japan Sea. The missing fore-arc crust can be properly reconstructed by checking ancient provenance through zircon dating in Kyushu and southern Tohoku district.

Geotectonic identities of dismembered ancient fore-arc clastics: U-Pb dating of detrital zircons in Cretaceous-Paleogene shallow marine/fluvial sandstones sporadically found in Kanto, central Japan

*Ryo Hasegawa[1], Yukio Isozaki[1], Yukiyasu Tsutsumi[2]

1. Department of Earth Science and Astronomy, The University of Tokyo, 2. Department of Geology and Paleontology, National Museum of Nature and Science

For reconstructing the fore-arc basin of Cretaceous arc-trench system in Japan, provenance analysis for sandstones has been carried out by U-Pb dating of detrital zircons, particularly for the “Cretaceous-Paleogene” sandstone-bearing units sporadically occurred in 5 distinct areas in the Kanto Mountains and northern Kanto/southern Tohoku region, i.e. the Shoya Formation in Saku, the Kanohara conglomerate in Shimonita, the Yorii Formation in Yorii (Kanto Mountains), the Nakaminato Group (northern Kanto), and the Futaba Group (southern Tohoku), of which geotectonic identities are ambiguous. The U-Pb dating of detrital zircons from these units constrained the depositional ages of 10 sandstone samples to the Late Cretaceous and early Paleocene, and also their provenance. These results confirmed that 1) the Shoya Fm and the lower-middle Nakaminato Gr are of the Maastrichtian age, which are correlated with the Izumi Group on the Late Cretaceous Ryoke ganitoids in SW Japan, 2) the Kanohara conglomerate, Yorii Fm, and Oarai Fm are of the Danian (early Paleogene) age, which were deposited on the Ryoke belt as well as the Izumi Gr., 3) the Futaba Gr is of the Coniasian age, which is correlated not with the Izumi Gr. but with the coeval units in western Kyushu, i.e., basal Himenoura Group, Kumamoto Gr, and upper Mifune Gr, which were deposited unconformably on a slightly older (Early Cretaceous) granitoids in the same fore-arc domain. These new age data provide new clues in reconstructing paleogegraphy of Cretaceous arc-trench system in Japan, before the Miocene opening of the Japan Sea. The expected discontinutity between pre-Miocene SW and NE Japan crusts in central Japan is currently buried beneath thick Quaternary sediments of the Kanto plain; nonetheless, the present data suggests two candidates, i.e., the seismologically detected major break of the pre-Cenozoic basement along the River Tone and the conventional Tanagura tectonic line to the north.

Laboratory Measurements of Vp, Vs and Vp/Vs for polycrystalline labradorite up to 800˚C and 1GPa

*Satoko Honda[1], Masahiro Ishikawa[1]

1. Graduate School of Environment and Information Sciences, Yokohama National University

In order to estimate the elastic properties of crustal rock-forming minerals at mid-to-lower crustal P-T conditions, we performed simultaneous measurements of compressional-wave (Vp) and shear-wave (Vs) velocities of the labradorite. In this presentation, we report temperature-pressure dependence of the elastic wave velocity for labradorite, intermediate member of plagioclase feldspars, at crustal P-T condition.

The fine-grained pollycrystalline labradorite was fabricated from the nano-sized powders of crushed natural labradorite crystal ($An_{61}Ab_{37}Or_2$, $An_{65}Ab_{34}Or_1$), and was used for the measurements. After milling and forming mineral powders, sintering was carried out at a temperature of 1180–1210˚C with controlled time. Ultrasonic measurements on these samples were conducted up to 1.0 GPa in a temperature range of 25-800˚C with a piston cylinder high pressure apparatus.

The Vp increase rapidly with pressure increase up to 0.40 GPa at room temperature, while it is moderately increasing between 0.40 and 1.00 GPa. At 1.00GPa up to 800 ˚C, the elastic wave velocities decrease with increasing temperature blow 600 ˚C, δVp/δT and δVs/δT of the labradorite sample (An65Ab34Or1) is -1.6×10^{-4} km/s/˚C, -1.0×10^{-4}km/s/˚C . In contrast, above 600 ˚C , the elastic wave velocities show an increasing trend in the range of 600–800 ˚C . At cooling stage, Vp and Vs show an decreasing trend with decreasing temperature above 400˚C.
Previous studies report that elastic wave velocities of polycrystalline anorthite show an increasing trend in the range of 240–640 ˚C (Matsukage et al 2015) and that a polycrystalline plagioclase ($An_{51\pm1}$) at 1.0 GPa show marked increase in Vp and Vs between 700 and 800 ˚C (Kono et al 2008). They suggest that these discontinuous velocity changes in temperature dependence of Vp and Vs would be associated with phase transformation in plagioclase. However, it is unclear whether our measurements results between 650 and 800˚C is phase transformation, because the phase transformation was not determined on our sample using X-ray diffraction analisys. In addition, the temperature conditions of the discontinuous in Vp and Vs at high temperature is not consistent with the phase boundary previously reported. Phase transformation, therefore, would have been only temporary during the experiment.

Shallow to deeper structures of the Median Tectonic Line active fault system in Shikoku illuminated by new hi-resolution seismic reflection profiling, southwest Japan

*Tatsuya Ishiyama[1], Naoko Kato[1], Shin Koshiya[2], Hiroshi Sato[1], Makoto MATSUBARA[3], Tomoko Elizabeth Yano[3], Taro Koike[4], Katsuya Noda[4]

1. Earthquake Research Institute, University of Tokyo, 2. Department of Civil and Environmental Engineering, Faculty of Science and Engineering, Iwate University, 3. National Research Institute for Earth Science and Disaster Resilience, 4. Geosys, Inc.

Median Tectonic Line (MTL) active fault system is one of the most pronounced, trench-parallel active dextral slip faults in SWJapan, extending for approx. 300 km (Okada, 1992). With ubiquitous proximity to the north dipping terrane boundary MTL between Samgawa metamorphic rocks (Sm) and Ryoke granitic rocks to the north, their structural links with active strands of the MTL have been widely discussed. Seismic experiments in Kinki (Wakayama) clearly illuminate that near-surface steeply dipping fault plane appears merge into underlying more shallowly dipping reflectors correlated with top Sm (Sato et al., 2015). In Shikoku, however, previous seismic sections have not fully resolved such structural linkages of the major fault strands of the MTL, whereas pioneering deep seismic experiments successfully imaged northerly dipping MTL (Ito et al., 1995). To define structural characters of the shallow to deeper subsurface geometry, we collected new seismic reflection profiles across MTL active fault system in Shikoku island. Our new, processed seismic profile across the Okamura Fault, Komatsu Fault (Goto and Nakata, 1998), and the MTL and its preliminary interpretation suggest northerly dipping Sambagawa metamorphic rocks beneath the northern flank of the Ishizuchi Mountains and Niihama plain to the north. As is the case with previous seismic results, downward extensions of the MTL apparently dips northward, in contrast to near-surface steep fault planes identified in outcrop and trench exposures. In addition, northerly dipping clouds of microseismicity also suggest its deeper extension. Similarly, in our new seismic profile in Wakimachi, Tokushima, Chichio fault (Okada and Tsutsumi, 1997), active dextral slip fault that dips vertically at ground surface, is apparently underlain by very strong and continuous north dipping reflectors from the top of Sm. This observation also suggests that the Chichio fault may merge into, rather than cut across these Sm reflectors. We will mainly discuss on (1) detailed structural characters identified in the new seismic data, (2) their structural linkages with near-surface structures of the active strands, and (3) implications for overall shallow to deeper geometry of the MTL based on both new and previous seismic data, regional seismicity based on JUICE catalogue (Yano et al., 2017), and crustal structures estimated from seismic tomography (Matsubara et al., 2017).

Cenozoic evolution of the Tsushima Strait and the Fukue Basin, southern Sea of Japan: an interplay of tectonics, palaeo-environment, and volcanism

*Johan S. Claringbould[1], Hiroshi Sato[1], Tatsuya Ishiyama[1], Anne Van Horne[1,2], Shinji Kawasaki[3], Susume Abe[4]

1. Earthquake Research Institute, The University of Tokyo, 2. Department of Geology and Geophysics, University of Wyoming, 3. JGI, Inc., 4. JAPEX

The Japanese island arc is tectonically active with earthquake and tsunami hazard along both the Pacific and Sea of Japan coasts. Following the tsunami disaster from the 2001 Off-Tohoku (M9) earthquake, the Japanese government initiated an extensive evaluation of tsunami hazard around Japan. Since records of prior tsunamis along the southern Japan Sea margin are rare, we here investigate the geologic evolution of the SW Japan back-arc basin to identify and analyse potential tsunami source-faults.

Located between SW Japan and the Korean Peninsula, and connecting the Japan Sea and East China Sea, the Tsushima Strait and the Fukue Basin represent a structurally complex region that formed over the last ~25 Ma as a result of several tectonic phases: (i) back-arc rifting and rotation, (ii) post-rift compression, (iii) weak thrusting, and (iv) subsidence and strike-slip deformation. Syn-depositional volcanism and changes in regional palaeo-environment are known from previous studies surrounding this connecting region, but how these factors fit together in the regional tectonic framework is not well understood. In addition to analysing recent seismic reflection data and detailed gravity data, we here re-evaluate extensive seismic reflection profiles and well data of ten boreholes offshore the SW Japan arc. We observe large basement blocks and igneous bodies, and inverted and cross-cut half grabens filled with syn-kinematic deposits. Clear stratal terminations suggest multiple transitions in regional stress regime. The gravity data allow us to link the syn-depositional igneous bodies to previously-dated volcanism onshore. Additionally, planktonic and calcareous nanno-fossils from the well data provide control on absolute timing of different kinematic stages, while benthic foraminifers and pollen show changes in palaeo-water depth, coeval with local, relative palaeo-climate reversals, respectively.

From ~25 Ma pollen data show warming of the local climate in southern Japan Sea side of the Tsushima Strait, while on the East China Sea side in the Fukue Basin relative cooling is observed. This is related to initial rifting, opening up back-arc basin allowing relative warm water to flow through the Tsushima Strait into the Japan Sea warming the local climate, and relative cold water flowing back cooling the local environment in the Fukue Basin on the opposite side of the Tsushima Strait. Subsequently, negative flower structures and large half-grabens filled with over 5400 m of synrift sediments developed between ~18-16 Ma, containing benthic foraminifera suggesting a deepening marine environment. This is linked to the rapid, clock-wise rotation of SW Japan, which pivot point migrates along a dextral oblique normal fault west of Tsushima. At ~15 Ma rift structures are abruptly inverted or cross-cut by thrust faults and wedge thrusts, with microfossils and pollen on the Japan Sea side suggesting shallowing of the palaeo-waterdepth and cooling of the local climate, respectively. Contrary, in the Fukue Basin, the local climate shows relative warming. We suggest that during this compressional tectonic event a topographic sill developed in the Tsushima Strait that cut off water flow between the cooler Japan Sea and the subtropic East China Sea. From ~6 Ma, the local climate on the Japan Sea side warms again contemporarily with deepening of the marine palaeo-environment and deposition of sub-horizontal

Pliocene sediments, implying a weakening of the compressional stress and renewed water flow through the Tsushima Strait. These observations along with previously published data of the surrounding areas enable us to better understand the connection between the Cenozoic structural development of the SW Japan arc, and the related the palaeo-environment changes and volcanism. As a result, we are better able to identify potential tsunami-source faults along the southern Japan Sea margin based on our understanding of the structural evolution.

[S-CG57] Structure and evolution of Japanese islands - Formation of island arc systems and earthquake cycles

convener:Hiroshi Sato(Earthquake Prediction Research Center, Earthquake Research Institute, The University of Tokyo), Masanao Shinohara(Earthquake Research Institute, University of Tokyo), Masahiro Ishikawa(Graduate School of Environment and Information Sciences Yokohama National University), Makoto MATSUBARA(National Research Institute for Earth Science and Disaster Resilience)

Subduction processes such as accretion, back-arc-spreading, and arc-arc collisions have shaped the Japanese island arc. Recent advances in seismic imaging, both passive and controlled source, have produced new images of the crust-mantle structure under Japan and surrounding regions. Through the influence of pre-existing faults and rheological structures, these crust and mantle structures are exerting strong control on active tectonic processes like seismic activity and crustal deformation in the overriding plate. We seek contributions that document and/or model the deformation of the Japanese islands over a variety of time scales from the earthquake cycle to the tectonic evolution of the Japanese island arc, and from a range of research fields including seismology, geology, geochemistry, tectonic geomorphology, and geodynamics. Multidisciplinary studies are encouraged. We also welcome contributions in numerical or analogue geodynamical modeling that explore deformation processes.

Crustal structure from the Japan Sea back-arc basin to the margin off SW Hokkaido deduced from the seismic survey

*Takeshi Sato[1], Tetsuo No[1], Shuichi Kodaira[1], Seiichi Miura[1], Tatsuya Ishiyama[2], Hiroshi Sato[2]

1. Research and Development Center for Earthquake and Tsunami, Japan Agency for Marine-Earth Science and Technology, 2. ERI, Univ. of Tokyo

The Japan Sea is a back-arc basin in the northwestern Pacific. Along the eastern and southern margins, destructive earthquakes occurred (e.g., the 1983 Nihon-kai-Chubu Earthquake, and the 1993 Hokkaido-Nansei-Oki Earthquake). Moreover, along the eastern margin, fault-fold belts developed as a result of deformation caused by extension associated with the opening of the Japan Sea and by the later compression (e.g., Okamura et al., 1995; Sato, 1994). Results of seismic surveys from the Japan Basin to the eastern margin of this sea indicated that structures related back-arc opening might play a role in the location of large earthquakes and the distribution of the deformation zone including active faults and folds along the margin of the Japan Sea (e.g., No et al., 2014). This result demonstrates that the elucidation of the back-arc opening process is important for understanding not only back-arc extension along the Asian continental margin, but also the mechanism of large earthquakes and the distribution of subsequent deformation in the Japan Sea back-arc basin. In the SW Hokkaido, the 1993 Hokkaido-Nansei-Oki Earthquake (Mj 7.8) occurred and the dip and distribution of active faults show a complication pattern. However, we have little information of detailed opening, deformation processes and mechanism of large earthquakes in this area due to the inadequate detailed crustal structure obtained by sufficiently dense OBS spacing in seismic surveys.

To obtain the crustal structure, we conducted the active-source seismic survey using ocean bottom seismographs (OBSs) and multi-channel streamer (MCS) in the margin of the Japan Sea off southwestern Hokkaido ranging from the Japan Basin to the coastal area on land in 2018. This survey was used at 57 OBSs, a tuned air-gun array having 7,800 cu. inch and MCS system. This survey line has about 243 km length and is a part of an integrated ocean-land seismic survey line.

In record sections of several OBSs, not only the first arrived phases but also later phases reflected from interfaces in the crust and uppermost mantle are visible. Also, the MCS profile clearly images the sedimentary layer and the undulations of the basement. The crustal structure in the Japan Basin resembles the typical oceanic crust (e.g., White et al., 1992). In the transition between the Japan Basin and the southern Okushiri Ridge, the crustal structure drastically changes. The area from the southern Okushiri Ridge to the Okushiri Basin has the upper crust with a P-wave velocity of 5.4-6.2 km/s corresponding to the continental upper crust. Moreover, the P-wave velocity distribution has a variation in this area.

Considering the large slip distribution of the 2004 Sumatra earthquake, possible coseismic rupture area of megathrust earthquakes from the Tokai to Ryukyu cannot be denied. Characteristics of occurrence of great earthquakes is also different between these neighboring subduction zones. Historically, megathrust earthquakes have been generated repeatedly along the Nankai Trough at intervals of approximately 100-200yrs (e.g. Ando, 1975).Along the Ryukyu Trench, although great earthquakes have occurred only twice over the last 300 years: the 1771 Yaeyama earthquakes and the 1911 earthquake off Kikai, recent studies of tsunami deposits indicated that the Ryukyu Islands have been periodically hit by large tsunamis with an interval of several hundred years [e.g. Ando et al., 2017]. Moreover, the coupling condition of the plate interface along the Ryukyu Trench is different from that of the Nankai Trough based on the seismic survey and observations [Arai et al. 2016]. They reported that the Ryukyu Trench is dominated by slow earthquakes at any depths and lacks a typical locked zone such as the Nankai Trough.
To understand relation between the structure around the subducting Philippine Sea plate and seismicity including slow earthquake phenomena, it is necessary to know the geometry and property of the plate boundary from the Nankai to the Ryukyu subduction zone. Three-dimensional plate geometry model will be also important for a precise estimate of the maximum range of the coseismic rupture zone of the Nankai megathrust earthquake. The model is also very useful to construct a new three-dimensional seismic velocity model of the Nankai Trough for depth conversion of interpreted active faults in time section of seismic reflection data [Katsuyama et al., 2019 JPGU].
Based on the result (three-dimensional plate geometry model of the Nankai Trough) from marine active and passive source seismic data [Nakanishi et al., 2018], three-dimensional plate geometry model from Nankai to Ryukyu subduction zone is tried to be constructed using the result of seismic studies around the Ryukyu Trench [Iwasaki et al, 1990; Kodaira et al., 1996; Arai et al., 2016, 2017; Nishizawa et al, 2017; Yamamoto et al., 2018].The model of Nakanishi et al. [2018] is also updated by using the result of deep seismic tomography off the Kii peninsula [Yamamoto et al., 2014, 2017].
In this presentation, a preliminary version of the combined three-dimensional model will be shown.
This study is part of 'Research project for compound disaster mitigation on the great earthquakes and tsunamis around the Nankai trough region' and the project 'Comprehensive evaluation of faults information on offshore Japan' funded by Ministry of Education, Culture, Sports, Science and Technology, Japan.

Trace elements and Sr-Nd-Hf-Pb isotopic composition of Miocene Tomari volcanic rocks, Shimokita Peninsula, Aomori, NE Japan

*Masataka Aizawa[1], Mitsuru Inaba[2], Satoshi Okamura[3,4], Ryuichi Shinjo[5]

1. Graduate School of Engineering and Sience, University of Ryukyus, 2. GeoPuck Association, 3. Hokkaido Education University, 4. Hokkaido Soil Research Co-op., 5. Faculty of Science, University of Ryukyus

Introduction

Tomari volcanic rocks, located in Shimokita Peninsula, Aomori Prefecture, NE Japan, formed volcanic front at Miocene period. They include primitive tholeiitic basalts (Takimoto, 1986), therefore volcanic activity in this area strongly suggest relation to opening Japan Sea back-arc basin caused by upwelling asthenosphere. Volcanic activities divided into 4 stages and their K-Ar dating have been reported 13-15 Ma (Watanabe *et al.*, 1993). This study use boring core sample dug from Shimokita Peninsula (SN-010 core; drilling stop depth is 1484 m). Tomari Formation appear deeper than 308.82 m in this core and it has been reported 13.1-14.5 Ma at 385 m (micro fossils), 16.0 Ma, 24.2 Ma (zircon U-Pb dating) at 467 m and 818 m, respectively (Nuclear Regulatory Agency, 2016).

Lithofacies and occurrence of Tomari volcanic rocks

We collected samples from the 1st and 2nd stage of surface Tomari Formation and 8 depth from SN-010 core. Core samples are volcanic breccia, lava and lapilli tuff. And the 1st stage surface volcanic rocks include reddish rounded gravel and pillow lava fragments into deposition layer with lamination. The 2nd stage surface volcanic rocks mainly erupted as pillow lava and hyaloclastite.

Geochemical characteristics

Shallow core samples (SCS; shallower than 862.26 m) and middle core samples (MCS; 999.00-1003.20 m) show middle-K series and deep core samples (DCS; deeper than 1197.86 m) show low-K series. Incompatible elements (especially LILE) concentrations of SCS and MCS are higher than DCS. Surface 1st and 2nd stage samples are plotted middle-K series. Incompatible elements features are similar as SCS and MCS. Multi-elements diagrams normalized by N-MORB show high LILE, negative Nb-Ta and positive Pb anomalies, they mean these rocks were produced at subduction zone. Sr-Nd isotopic composition of MCS-DCS show more depleted and SCS have more enriched composition. Pb isotopes are plotted into volcanic rocks field of Quaternary volcanic front of NE Japan without difference each strata. Primitive tholeiitic basalts are produced in 2nd stage and they show most enriched isotopic composition (Hanyu *et al.*, 2006). Primitive basalts and SCS-MCS have higher Ba/Nb than DCS.

The relationship to opening Japan Sea event

SN-010 core dating suggest that volcanic activity formed Tomari Formation already started late Oligocene-early Miocene. Whole-rock chemical composition of 563.48 m samples is similar to surface 1st stage volcanic rocks, therefore upper level of core sample may be comparable with surface 1st stage volcanic rocks (Aizawa *et al.*, 2018).

Enriched isotopic composition of primitive basalts cannot be explained by assimilation of lower crust due to their high MgO, Cr, Ni composition. In addition, SCS-MCS and primitive basalts have higher Ba/Nb and MCS-DCS show depleted isotopic composition. Thus, it is considered that partial melting of DMM produced volcanic rocks of MCS-DCS, and MCS (high Ba/Nb) were strongly affected slab derived components. Then, volcanic rocks of SCS and surface samples were originated magma from sub-arc

©2019. Japan Geoscience Union. All Right Reserved.

enriched lithospheric mantle (EM II-like isotopic composition).

Petrography of DCS and MCS suggest volcanic activity on land environment because there are reddish volcanic gravels at 1482.00 m and 1335.87 m, and 999.00 m lapilli tuff matrix color is red. Although SCS have no evidence for judging stationary environment of volcaniclastic rocks, the 1st stage outcrop include rounded reddish volcanic gravels into lamination, and the 2nd stage volcanic rocks are mainly erupted as pillow lava and hyaloclastite. These occurrences suggest the development of lifting at late Oligocene-early Miocene period and stationary environment change from on land to underwater. The change of geochemical features, from depleted to enriched composition, may mean to change partial melting position in sub-arc mantle due to the hot asthenosphere upwelling under this area.

Acceleration of oceanic plate following megathrust earthquakes

*Mohammad Yuzariyadi[1], Kosuke Heki[1]

1. Hokkaido University

Accelerated subduction of tectonic plates following megathrust earthquakes was proposed by D. Anderson (1975, Science). Heki and Mitsui (2013 EPSL) found postseismic enhancements of inter-plate coupling in the adjacent segments of the 2003 Tokachi-Oki and the 2011 Tohoku-Oki earthquakes. They hypothesized that these earthquakes caused accelerated subduction of the Pacific plate slab in addition to already-known postseismic processes such as afterslip and viscous relaxation. Melnick et al. (2017 GRL) found a similar enhancement of coupling to the north of the 2010 Maule earthquake rupture zone, and Loveless (2017 GRL) considered this a common phenomenon after megathrust earthquakes and named it as the super-interseismic phase. Accelerated subduction occurs during a period after the earthquakes, but its duration and amount depend on the magnitude. Here we investigate how long and how much is the acceleration over the time period covering several years after the earthquakes. So far, we have been using data from GNSS stations on arcs near the segments adjacent to megathrust ruptures. In the present study, we use data from GNSS stations on the subducting oceanic plates and on a subducted continental plate.

We present GNSS velocity data from oceanic islands showing post-megathrust accelerations. They include the Marcus Island (1098), Japan, that showed significant acceleration following the Mw 9 2011-3-11 Tohoku-Oki Earthquake. The Cocos Island (COCO), Australia, seems to have been accelerated after the Mw 8.4 2007-9-12 Bengkulu earthquake, Southern Sumatra. The JRGN in the west coast tip of Chile was accelerated after the Mw 8.2 2014-4-1 Iquique Earthquake. We also found there was a certain velocity change in Christmas Island (XMIS), Australia, after the Mw 7.7 2006-7-17 South Java earthquake. All stations are located on the oceanic plate except JRGN that is located on the continental plate.

Marcus Island (1098) GNSS station showed a significant velocity change after the 2011 Tohoku-Oki Earthquake. The maximum transient acceleration occurred in the period 2-3 years following the earthquake with a maximum velocity change of 9.4 mm/yr. After 3.0 years, The acceleration has been decaying, and the original velocity resumed by now. Cocos Island (COCO) GNSS station shows that the maximum transient acceleration occurred between 0.75-1.5 years after the 2007 Bengkulu earthquake with a maximum change of 4.9 mm/yr. After 1.5 years, the acceleration has decayed and has been showing the velocity similar to the value before the earthquake since 4.5 years after the earthquake. Chile (JRGN) GNSS station shows that the transient acceleration reached the maximum in ~1 year after the 2014 Iquique earthquake with a maximum change of 4.7 mm/yr. The accelerated velocity decayed to the original value in 2.5 years after that. The acceleration of the Christmas Island (XMIS) GNSS station was 2.7 mm/yr and occurred in ~1.0 year after the 2006 South Java earthquake. The acceleration seems to have decayed in 2.5 years after the earthquake.

In general, we found that the transient acceleration of oceanic plate occurs shortly after a megathrust earthquake and continue over a certain period. Then it decays, and finally the velocity before earthquake recovers in a few years.

3D velocity model in the region of Nankai Trough

*Minako KATSUYAMA[1], Ayako Nakanishi[1], Rei Arai[1], Shigeyoshi Tanaka[1], Narumi Takahashi[2], Hiromi Kamata[1], Yoshiyuki Kaneda[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Research Institute for Earth Science and Disaster Resilience, 3. Kagawa University

This is a part of the project “Comprehensive evaluation of faults information on offshore Japan”, by the Ministry of Education, Culture, Sports, Science and Technology (MEXT). The project consists of three themes, 1) Collecting seismic survey data and building a database of offshore faults, 2) Interpreting distribution of active faults using seismic data collected, and conducting the seismic re-processing by leading-edge seismic technology for the seismic data obtained in previous decades, 3) Building the fault models for a simulation of strong motion and tsunami disaster, based on the interpreted faults. Our purpose of this study is make a 3D velocity model in the Nankai Trough to provide with the support we needs to interpret faults.

The Nankai Trough, where the Philippine sea plate is subducting beneath the Eurasian plate. Some seamounts and ridges are subducted here.

3D velocity model was constructed by seismic data and ocean bottom seismometer(OBS) refraction survey data which were obtained by a various agencies and private companies. Horizons such as acoustic basment and unconformity were interpreted using reflection seismic sections. Conrad discontinuity and Mohorovicic discontinuity were interpreted on refraction surveys and consulted previous study. Layer structure and velocity model were created on these horizons.

We obtain a result that understands geological structure in Nankai Trough. So in this session, we will take a discussion concerning structural characteristic based on the 3D velocity model.

Depth of seismogenic layer at the 2018 North Osaka and the 2018 Hokkaido Eastern Iburi earthquake sites

*Tomoko Elizabeth Yano[1], Makoto MATSUBARA[1]

1. National Research Institute of Earth Science and Disaster Prevention

Background:
Understanding crustal seismogenic layer on faults is important because it enable us to know the maximum size of possible crustal earthquake on the corresponding fault. Depth of the crustal sesmogenic layer also gives us the depth of brittle zone because it relates to the rheology of the crust. The cutoff depths where total of 95 % of events occurred within the depth column of each grid, referred to as D95, can be calculated from the past microseismicity. We aimed to verify the index, D95, if it indicates as the deeper limit of the seismogenic layer. Using the microeismicity before mainshocks, we investigated if we could foresee the deeper limit of seimogenic layer before the 2018 North Osaka (2018 Osaka) and the 2018 Hokkaido Eastern Iburi (2018 Iburi)earthquakes occurred.

Data and Method:
D95 is calculated from the seismicity before each mainshock. We used JUICE catalog (2001-2012) of the event catalog for miscriseismicity in this study. We calculated D95 from events of M1.5 or greater listed in the JUICE catalog for every grid point of 0.02 degree interval. We only consider when the total number of events within the range of 0.1 degree from the grid point contains 50 events and more.

We also look at the temperature data to see if the estimated depths of 250 degrees (in Celsius), 300 degrees, and 450 degrees correspond to the actual earthquake depth. Using the datasets contain the temperature profile of the depth down to about 300 m and the depth down to about 1000 m from the surface of the earth, we computed the depth at which the crustal temperature reaches 250, 300, 450 degrees (hereafter referred to as D250deg, D300deg, D450deg, respectively).

Result:
For the 2018 Osaka earthquake site, the relocated hypocenter of the mainshock was 13.7 km in depth. Relocated aftershocks are mainly distributed between 8 and 14 km in depth. D95 along the aftershocks was calculated to be between 13 km to 14 km. The range of D250deg to D450deg was between10 km and 24 km. D300deg was about 13 km.

For the 2018 Iburi earthquake site, the relocated hypocenter of the mainshock was 35.9 km in depth. Relocated aftershocks are mainly distributed between 25 to 50 km. D95 was estimated to be around 25 km. The range of D250deg and D400deg is between 10 km and 34 km.

Conclusion/Discussion:
D95 as a seismogenic depth of the 2018 Osaka earthquake site was consistent with the mainshock and aftershock distribution. Conversely, D95 of the 2018 Iburi earthquake was not consistent with an actual event: D95 was about 10 km shallower than the mainshock and about 30 km shallower than the deeper aftershocks. The seismicity on the Ishikari Lowland Eastern edge fault zone (Ishikari Teichi Touen Danso Tai), west from the mainshock site, was used to compute D95 in this study. Therefore, discrepancy in D95 of Iburi earthquake site is due to D95 indicates the seismogenic depth of Ishikari Lowland Eastern edge fault zone but not the fault responsible of the 2018 Ishikari Earthquake.

Seismic reflection profiling across the Median Tectonic Line (MTL) active fault system in Ehime and Tokushima Prefectures

*Naoko Kato[1], Tatsuya Ishiyama[1], Hiroshi Sato[1], Shin Koshiya[2], Taro Koike[3], Katsuya Noda[3]

1. Earthquake Research Institute,University of Tokyo, 2. Faculty of science and engineering, Iwate University, 3. Geosys, Inc.

The Median Tectonic Line (MTL) is the most significant inland fault in SW Japan, which extends more than 1000 km and divides SW Japan into the inner and outer zone. The western part of the MTL shows late Quaternary right-lateral strike-slip movements at several mm/y (eg. Tsutsumi and Okada, 1996). According to the seismic reflection profile, northward gently dipping character of the Median Tectonic Line has already been suggested in the eastern Shikoku (Ito et al., 1996) and eastern Kyushu (Yusa et al., 1992). For the deeper extension of MTL, north-dipping geometry was obtained by low-fold seismic reflection images in Shikoku island (Kawamura et al., 2003; Sato et al., 2005). For the MTL active fault system, the geometry of its deeper extension is poorly understood in Shikoku island. To reveal deeper geometry of fault surface, shallow to deep seismic reflection profiling was performed in Ehime and Tokushima Prefectures. This research was performed as a research program funded by the Ministry of Education, Culture, Sports, Science and Technology, Japan.
Three seismic lines were deployed perpendicular to the MTL and major geologic boundaries. The length of seismic lines is 11 km (Saijo area, Ehime), 4.8 km (Wakimachi area, Tokushima) and 6.4 km (Awa area, Tokushima). To obtain a high-resolution seismic image of the shallow part of MTL, a 10-m spacing receiver array was formed using offline recorders. The seismic source was vibroseis trucks. The sweep signals (5-100 Hz for high resolution reflection profiling, 5-40 Hz for refraction profiling) were recorded 10 Hz vertical geophones. The seismic data were processed using conventional CMP-reflection methods. The high-energy shot gathers at Saijo seismic line clearly demonstrate the reflectors at 1.5, 2-3, 4 sec. (Two-way travel time). The reflectors from 2-3 s (TWT) are interpreted as northward dipping Sambagawa Metamorphic belt. The seismic sections portray the seismic image down to 2 km in Wakimachi and Awa area. The reflectors are interpreted as northward dipping Sambagawa Metamorphic belt. These structural characters found in the seismic section may show that the deeper extension of MTL shows northward dipping in Shikoku.

Wed. May 29, 2019 5:15 PM - 6:30 PM JST | Wed. May 29, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_34

[S-CG57] Structure and evolution of Japanese islands - Formation of island arc systems and earthquake cycles

convener:Hiroshi Sato(Earthquake Prediction Research Center, Earthquake Research Institute, The University of Tokyo), Masanao Shinohara(Earthquake Research Institute, University of Tokyo), Masahiro Ishikawa(Graduate School of Environment and Information Sciences Yokohama National University), Makoto MATSUBARA(National Research Institute for Earth Science and Disaster Resilience)

Subduction processes such as accretion, back-arc-spreading, and arc-arc collisions have shaped the Japanese island arc. Recent advances in seismic imaging, both passive and controlled source, have produced new images of the crust-mantle structure under Japan and surrounding regions. Through the influence of pre-existing faults and rheological structures, these crust and mantle structures are exerting strong control on active tectonic processes like seismic activity and crustal deformation in the overriding plate. We seek contributions that document and/or model the deformation of the Japanese islands over a variety of time scales from the earthquake cycle to the tectonic evolution of the Japanese island arc, and from a range of research fields including seismology, geology, geochemistry, tectonic geomorphology, and geodynamics. Multidisciplinary studies are encouraged. We also welcome contributions in numerical or analogue geodynamical modeling that explore deformation processes.

Crustal structure from the Japan Sea back-arc basin to the margin off SW Hokkaido deduced from the seismic survey

*Takeshi Sato[1], Tetsuo No[1], Shuichi Kodaira[1], Seiichi Miura[1], Tatsuya Ishiyama[2], Hiroshi Sato[2]

1. Research and Development Center for Earthquake and Tsunami, Japan Agency for Marine-Earth Science and Technology, 2. ERI, Univ. of Tokyo

The Japan Sea is a back-arc basin in the northwestern Pacific. Along the eastern and southern margins, destructive earthquakes occurred (e.g., the 1983 Nihon-kai-Chubu Earthquake, and the 1993 Hokkaido-Nansei-Oki Earthquake). Moreover, along the eastern margin, fault-fold belts developed as a result of deformation caused by extension associated with the opening of the Japan Sea and by the later compression (e.g., Okamura et al., 1995; Sato, 1994). Results of seismic surveys from the Japan Basin to the eastern margin of this sea indicated that structures related back-arc opening might play a role in the location of large earthquakes and the distribution of the deformation zone including active faults and folds along the margin of the Japan Sea (e.g., No et al., 2014). This result demonstrates that the elucidation of the back-arc opening process is important for understanding not only back-arc extension along the Asian continental margin, but also the mechanism of large earthquakes and the distribution of subsequent deformation in the Japan Sea back-arc basin. In the SW Hokkaido, the 1993 Hokkaido-Nansei-Oki Earthquake (Mj 7.8) occurred and the dip and distribution of active faults show a complication pattern. However, we have little information of detailed opening, deformation processes and mechanism of large earthquakes in this area due to the inadequate detailed crustal structure obtained by sufficiently dense OBS spacing in seismic surveys.

To obtain the crustal structure, we conducted the active-source seismic survey using ocean bottom seismographs (OBSs) and multi-channel streamer (MCS) in the margin of the Japan Sea off southwestern Hokkaido ranging from the Japan Basin to the coastal area on land in 2018. This survey was used at 57 OBSs, a tuned air-gun array having 7,800 cu. inch and MCS system. This survey line has about 243 km length and is a part of an integrated ocean-land seismic survey line.

In record sections of several OBSs, not only the first arrived phases but also later phases reflected from interfaces in the crust and uppermost mantle are visible. Also, the MCS profile clearly images the sedimentary layer and the undulations of the basement. The crustal structure in the Japan Basin resembles the typical oceanic crust (e.g., White et al., 1992). In the transition between the Japan Basin and the southern Okushiri Ridge, the crustal structure drastically changes. The area from the southern Okushiri Ridge to the Okushiri Basin has the upper crust with a P-wave velocity of 5.4-6.2 km/s corresponding to the continental upper crust. Moreover, the P-wave velocity distribution has a variation in this area.

Considering the large slip distribution of the 2004 Sumatra earthquake, possible coseismic rupture area of megathrust earthquakes from the Tokai to Ryukyu cannot be denied. Characteristics of occurrence of great earthquakes is also different between these neighboring subduction zones. Historically, megathrust earthquakes have been generated repeatedly along the Nankai Trough at intervals of approximately 100-200yrs (e.g. Ando, 1975).Along the Ryukyu Trench, although great earthquakes have occurred only twice over the last 300 years: the 1771 Yaeyama earthquakes and the 1911 earthquake off Kikai, recent studies of tsunami deposits indicated that the Ryukyu Islands have been periodically hit by large tsunamis with an interval of several hundred years [e.g. Ando et al., 2017]. Moreover, the coupling condition of the plate interface along the Ryukyu Trench is different from that of the Nankai Trough based on the seismic survey and observations [Arai et al. 2016]. They reported that the Ryukyu Trench is dominated by slow earthquakes at any depths and lacks a typical locked zone such as the Nankai Trough.
To understand relation between the structure around the subducting Philippine Sea plate and seismicity including slow earthquake phenomena, it is necessary to know the geometry and property of the plate boundary from the Nankai to the Ryukyu subduction zone. Three-dimensional plate geometry model will be also important for a precise estimate of the maximum range of the coseismic rupture zone of the Nankai megathrust earthquake. The model is also very useful to construct a new three-dimensional seismic velocity model of the Nankai Trough for depth conversion of interpreted active faults in time section of seismic reflection data [Katsuyama et al., 2019 JPGU].
Based on the result (three-dimensional plate geometry model of the Nankai Trough) from marine active and passive source seismic data [Nakanishi et al., 2018], three-dimensional plate geometry model from Nankai to Ryukyu subduction zone is tried to be constructed using the result of seismic studies around the Ryukyu Trench [Iwasaki et al, 1990; Kodaira et al., 1996; Arai et al., 2016, 2017; Nishizawa et al, 2017; Yamamoto et al., 2018].The model of Nakanishi et al. [2018] is also updated by using the result of deep seismic tomography off the Kii peninsula [Yamamoto et al., 2014, 2017].
In this presentation, a preliminary version of the combined three-dimensional model will be shown.
This study is part of 'Research project for compound disaster mitigation on the great earthquakes and tsunamis around the Nankai trough region' and the project 'Comprehensive evaluation of faults information on offshore Japan' funded by Ministry of Education, Culture, Sports, Science and Technology, Japan.

Trace elements and Sr-Nd-Hf-Pb isotopic composition of Miocene Tomari volcanic rocks, Shimokita Peninsula, Aomori, NE Japan

*Masataka Aizawa[1], Mitsuru Inaba[2], Satoshi Okamura[3,4], Ryuichi Shinjo[5]

1. Graduate School of Engineering and Sience, University of Ryukyus, 2. GeoPuck Association, 3. Hokkaido Education University, 4. Hokkaido Soil Research Co-op., 5. Faculty of Science, University of Ryukyus

Introduction

Tomari volcanic rocks, located in Shimokita Peninsula, Aomori Prefecture, NE Japan, formed volcanic front at Miocene period. They include primitive tholeiitic basalts (Takimoto, 1986), therefore volcanic activity in this area strongly suggest relation to opening Japan Sea back-arc basin caused by upwelling asthenosphere. Volcanic activities divided into 4 stages and their K-Ar dating have been reported 13-15 Ma (Watanabe *et al.*, 1993). This study use boring core sample dug from Shimokita Peninsula (SN-010 core; drilling stop depth is 1484 m). Tomari Formation appear deeper than 308.82 m in this core and it has been reported 13.1-14.5 Ma at 385 m (micro fossils), 16.0 Ma, 24.2 Ma (zircon U-Pb dating) at 467 m and 818 m, respectively (Nuclear Regulatory Agency, 2016).

Lithofacies and occurrence of Tomari volcanic rocks

We collected samples from the 1st and 2nd stage of surface Tomari Formation and 8 depth from SN-010 core. Core samples are volcanic breccia, lava and lapilli tuff. And the 1st stage surface volcanic rocks include reddish rounded gravel and pillow lava fragments into deposition layer with lamination. The 2nd stage surface volcanic rocks mainly erupted as pillow lava and hyaloclastite.

Geochemical characteristics

Shallow core samples (SCS; shallower than 862.26 m) and middle core samples (MCS; 999.00-1003.20 m) show middle-K series and deep core samples (DCS; deeper than 1197.86 m) show low-K series. Incompatible elements (especially LILE) concentrations of SCS and MCS are higher than DCS. Surface 1st and 2nd stage samples are plotted middle-K series. Incompatible elements features are similar as SCS and MCS. Multi-elements diagrams normalized by N-MORB show high LILE, negative Nb-Ta and positive Pb anomalies, they mean these rocks were produced at subduction zone. Sr-Nd isotopic composition of MCS-DCS show more depleted and SCS have more enriched composition. Pb isotopes are plotted into volcanic rocks field of Quaternary volcanic front of NE Japan without difference each strata. Primitive tholeiitic basalts are produced in 2nd stage and they show most enriched isotopic composition (Hanyu *et al.*, 2006). Primitive basalts and SCS-MCS have higher Ba/Nb than DCS.

The relationship to opening Japan Sea event

SN-010 core dating suggest that volcanic activity formed Tomari Formation already started late Oligocene-early Miocene. Whole-rock chemical composition of 563.48 m samples is similar to surface 1st stage volcanic rocks, therefore upper level of core sample may be comparable with surface 1st stage volcanic rocks (Aizawa *et al.*, 2018).

Enriched isotopic composition of primitive basalts cannot be explained by assimilation of lower crust due to their high MgO, Cr, Ni composition. In addition, SCS-MCS and primitive basalts have higher Ba/Nb and MCS-DCS show depleted isotopic composition. Thus, it is considered that partial melting of DMM produced volcanic rocks of MCS-DCS, and MCS (high Ba/Nb) were strongly affected slab derived components. Then, volcanic rocks of SCS and surface samples were originated magma from sub-arc

©2019. Japan Geoscience Union. All Right Reserved.

enriched lithospheric mantle (EM II-like isotopic composition).

Petrography of DCS and MCS suggest volcanic activity on land environment because there are reddish volcanic gravels at 1482.00 m and 1335.87 m, and 999.00 m lapilli tuff matrix color is red. Although SCS have no evidence for judging stationary environment of volcaniclastic rocks, the 1st stage outcrop include rounded reddish volcanic gravels into lamination, and the 2nd stage volcanic rocks are mainly erupted as pillow lava and hyaloclastite. These occurrences suggest the development of lifting at late Oligocene-early Miocene period and stationary environment change from on land to underwater. The change of geochemical features, from depleted to enriched composition, may mean to change partial melting position in sub-arc mantle due to the hot asthenosphere upwelling under this area.

Acceleration of oceanic plate following megathrust earthquakes

*Mohammad Yuzariyadi[1], Kosuke Heki[1]

1. Hokkaido University

Accelerated subduction of tectonic plates following megathrust earthquakes was proposed by D. Anderson (1975, Science). Heki and Mitsui (2013 EPSL) found postseismic enhancements of inter-plate coupling in the adjacent segments of the 2003 Tokachi-Oki and the 2011 Tohoku-Oki earthquakes. They hypothesized that these earthquakes caused accelerated subduction of the Pacific plate slab in addition to already-known postseismic processes such as afterslip and viscous relaxation. Melnick et al. (2017 GRL) found a similar enhancement of coupling to the north of the 2010 Maule earthquake rupture zone, and Loveless (2017 GRL) considered this a common phenomenon after megathrust earthquakes and named it as the super-interseismic phase. Accelerated subduction occurs during a period after the earthquakes, but its duration and amount depend on the magnitude. Here we investigate how long and how much is the acceleration over the time period covering several years after the earthquakes. So far, we have been using data from GNSS stations on arcs near the segments adjacent to megathrust ruptures. In the present study, we use data from GNSS stations on the subducting oceanic plates and on a subducted continental plate.

We present GNSS velocity data from oceanic islands showing post-megathrust accelerations. They include the Marcus Island (1098), Japan, that showed significant acceleration following the Mw 9 2011-3-11 Tohoku-Oki Earthquake. The Cocos Island (COCO), Australia, seems to have been accelerated after the Mw 8.4 2007-9-12 Bengkulu earthquake, Southern Sumatra. The JRGN in the west coast tip of Chile was accelerated after the Mw 8.2 2014-4-1 Iquique Earthquake. We also found there was a certain velocity change in Christmas Island (XMIS), Australia, after the Mw 7.7 2006-7-17 South Java earthquake. All stations are located on the oceanic plate except JRGN that is located on the continental plate.

Marcus Island (1098) GNSS station showed a significant velocity change after the 2011 Tohoku-Oki Earthquake. The maximum transient acceleration occurred in the period 2-3 years following the earthquake with a maximum velocity change of 9.4 mm/yr. After 3.0 years, The acceleration has been decaying, and the original velocity resumed by now. Cocos Island (COCO) GNSS station shows that the maximum transient acceleration occurred between 0.75-1.5 years after the 2007 Bengkulu earthquake with a maximum change of 4.9 mm/yr. After 1.5 years, the acceleration has decayed and has been showing the velocity similar to the value before the earthquake since 4.5 years after the earthquake. Chile (JRGN) GNSS station shows that the transient acceleration reached the maximum in ~1 year after the 2014 Iquique earthquake with a maximum change of 4.7 mm/yr. The accelerated velocity decayed to the original value in 2.5 years after that. The acceleration of the Christmas Island (XMIS) GNSS station was 2.7 mm/yr and occurred in ~1.0 year after the 2006 South Java earthquake. The acceleration seems to have decayed in 2.5 years after the earthquake.

In general, we found that the transient acceleration of oceanic plate occurs shortly after a megathrust earthquake and continue over a certain period. Then it decays, and finally the velocity before earthquake recovers in a few years.

3D velocity model in the region of Nankai Trough

*Minako KATSUYAMA[1], Ayako Nakanishi[1], Rei Arai[1], Shigeyoshi Tanaka[1], Narumi Takahashi[2], Hiromi Kamata[1], Yoshiyuki Kaneda[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Research Institute for Earth Science and Disaster Resilience, 3. Kagawa University

This is a part of the project “Comprehensive evaluation of faults information on offshore Japan”, by the Ministry of Education, Culture, Sports, Science and Technology (MEXT). The project consists of three themes, 1) Collecting seismic survey data and building a database of offshore faults, 2) Interpreting distribution of active faults using seismic data collected, and conducting the seismic re-processing by leading-edge seismic technology for the seismic data obtained in previous decades, 3) Building the fault models for a simulation of strong motion and tsunami disaster, based on the interpreted faults. Our purpose of this study is make a 3D velocity model in the Nankai Trough to provide with the support we needs to interpret faults.

The Nankai Trough, where the Philippine sea plate is subducting beneath the Eurasian plate. Some seamounts and ridges are subducted here.

3D velocity model was constructed by seismic data and ocean bottom seismometer(OBS) refraction survey data which were obtained by a various agencies and private companies. Horizons such as acoustic basment and unconformity were interpreted using reflection seismic sections. Conrad discontinuity and Mohorovicic discontinuity were interpreted on refraction surveys and consulted previous study. Layer structure and velocity model were created on these horizons.

We obtain a result that understands geological structure in Nankai Trough. So in this session, we will take a discussion concerning structural characteristic based on the 3D velocity model.

Keywords: 3D velocity model , Nankai Trough, subduction zone

Depth of seismogenic layer at the 2018 North Osaka and the 2018 Hokkaido Eastern Iburi earthquake sites

*Tomoko Elizabeth Yano[1], Makoto MATSUBARA[1]

1. National Research Institute of Earth Science and Disaster Prevention

Background:
Understanding crustal seismogenic layer on faults is important because it enable us to know the maximum size of possible crustal earthquake on the corresponding fault. Depth of the crustal sesmogenic layer also gives us the depth of brittle zone because it relates to the rheology of the crust. The cutoff depths where total of 95 % of events occurred within the depth column of each grid, referred to as D95, can be calculated from the past microseismicity. We aimed to verify the index, D95, if it indicates as the deeper limit of the seismogenic layer. Using the microeismicity before mainshocks, we investigated if we could foresee the deeper limit of seimogenic layer before the 2018 North Osaka (2018 Osaka) and the 2018 Hokkaido Eastern Iburi (2018 Iburi)earthquakes occurred.

Data and Method:
D95 is calculated from the seismicity before each mainshock. We used JUICE catalog (2001-2012) of the event catalog for miscriseismicity in this study. We calculated D95 from events of M1.5 or greater listed in the JUICE catalog for every grid point of 0.02 degree interval. We only consider when the total number of events within the range of 0.1 degree from the grid point contains 50 events and more.

We also look at the temperature data to see if the estimated depths of 250 degrees (in Celsius), 300 degrees, and 450 degrees correspond to the actual earthquake depth. Using the datasets contain the temperature profile of the depth down to about 300 m and the depth down to about 1000 m from the surface of the earth, we computed the depth at which the crustal temperature reaches 250, 300, 450 degrees (hereafter referred to as D250deg, D300deg, D450deg, respectively).

Result:
For the 2018 Osaka earthquake site, the relocated hypocenter of the mainshock was 13.7 km in depth. Relocated aftershocks are mainly distributed between 8 and 14 km in depth. D95 along the aftershocks was calculated to be between 13 km to 14 km. The range of D250deg to D450deg was between10 km and 24 km. D300deg was about 13 km.

For the 2018 Iburi earthquake site, the relocated hypocenter of the mainshock was 35.9 km in depth. Relocated aftershocks are mainly distributed between 25 to 50 km. D95 was estimated to be around 25 km. The range of D250deg and D400deg is between 10 km and 34 km.

Conclusion/Discussion:
D95 as a seismogenic depth of the 2018 Osaka earthquake site was consistent with the mainshock and aftershock distribution. Conversely, D95 of the 2018 Iburi earthquake was not consistent with an actual event: D95 was about 10 km shallower than the mainshock and about 30 km shallower than the deeper aftershocks. The seismicity on the Ishikari Lowland Eastern edge fault zone (Ishikari Teichi Touen Danso Tai), west from the mainshock site, was used to compute D95 in this study. Therefore, discrepancy in D95 of Iburi earthquake site is due to D95 indicates the seismogenic depth of Ishikari Lowland Eastern edge fault zone but not the fault responsible of the 2018 Ishikari Earthquake.

Seismic reflection profiling across the Median Tectonic Line (MTL) active fault system in Ehime and Tokushima Prefectures

*Naoko Kato[1], Tatsuya Ishiyama[1], Hiroshi Sato[1], Shin Koshiya[2], Taro Koike[3], Katsuya Noda[3]

1. Earthquake Research Institute,University of Tokyo, 2. Faculty of science and engineering, Iwate University, 3. Geosys, Inc.

The Median Tectonic Line (MTL) is the most significant inland fault in SW Japan, which extends more than 1000 km and divides SW Japan into the inner and outer zone. The western part of the MTL shows late Quaternary right-lateral strike-slip movements at several mm/y (eg. Tsutsumi and Okada, 1996). According to the seismic reflection profile, northward gently dipping character of the Median Tectonic Line has already been suggested in the eastern Shikoku (Ito et al., 1996) and eastern Kyushu (Yusa et al., 1992). For the deeper extension of MTL, north-dipping geometry was obtained by low-fold seismic reflection images in Shikoku island (Kawamura et al., 2003; Sato et al., 2005). For the MTL active fault system, the geometry of its deeper extension is poorly understood in Shikoku island. To reveal deeper geometry of fault surface, shallow to deep seismic reflection profiling was performed in Ehime and Tokushima Prefectures. This research was performed as a research program funded by the Ministry of Education, Culture, Sports, Science and Technology, Japan.
Three seismic lines were deployed perpendicular to the MTL and major geologic boundaries. The length of seismic lines is 11 km (Saijo area, Ehime), 4.8 km (Wakimachi area, Tokushima) and 6.4 km (Awa area, Tokushima). To obtain a high-resolution seismic image of the shallow part of MTL, a 10-m spacing receiver array was formed using offline recorders. The seismic source was vibroseis trucks. The sweep signals (5-100 Hz for high resolution reflection profiling, 5-40 Hz for refraction profiling) were recorded 10 Hz vertical geophones. The seismic data were processed using conventional CMP-reflection methods. The high-energy shot gathers at Saijo seismic line clearly demonstrate the reflectors at 1.5, 2-3, 4 sec. (Two-way travel time). The reflectors from 2-3 s (TWT) are interpreted as northward dipping Sambagawa Metamorphic belt. The seismic sections portray the seismic image down to 2 km in Wakimachi and Awa area. The reflectors are interpreted as northward dipping Sambagawa Metamorphic belt. These structural characters found in the seismic section may show that the deeper extension of MTL shows northward dipping in Shikoku.

Association of drastic climate change and biological evolution during Neoproterozoic is one of the most enigmatic features of the Earth history. The If the Earth’ s surface has been hardly covered with thick ice-cover during the 58-myr-long Sturtian glaciation, the evolution of organisms was mostly reset. However, there is glowing evidence of protozoan fossils immediately after the Sturtian and Marinoan glaciations. This requires the argument that liquid environments as refugia for protozoans must have occurred in tropical zones or around volcanos.
Moroccan Anti-Atlas exposes several Proterozoic inliers surrounded with Ediacaran, Paleeozoic and Mesozoic strata. Accumulated age data of zircon U-Pb indicate that active tectonics had been sustained here during Cryogenian and Ediacaran. Paleogeographic interpretation based on paleomagnetism reconstructed a high latitude of Anti-Atlas. Neoproterozoic sedimentary sequence here is dominated by volcanics and siliciclastics, and carbonate is developed as lentic bodies on granodiorite rock.
This study focuses on two carbonate bodies near Bleida and Ouarzazate in Anti-Atlas. The Blida section exposes a 25-m-thick sequence of bedded and fine-grained dolostone of red color. This overlies 586Ma volcanic rock, and apparently underlies possible diamictite with a fault contact. Dolostone of the lower part of the section contains relics of iron-oxidizing bacteria. Carbon isotope of the dolostone is low as -6‰, but the stratigraphic position negates the correlation to the Shuram negative excursion of late Ediacaran. The low d13C value likely inherited endogenic carbon, and this interpretation is supported by low d18O indicating high water temperature (around 40-50ºC). While, the 30-m-thick carbonate sequence near Ouarzazate consists of red-colored limestone alternated with volcanoclastic sandstone and siltstone. It rests on 580Ma volcanics. The carbonate sequence exhibit stromatolites at least four stratigraphic levels. The higher d13C value (around -1.5‰) was likely reflected from CO2 degassing or gas exchange with the atmosphere. These stromatolites show regular lamination of ~1 mm interval and appears color changes reflected from a redox gradient within a biofilm.
These carbonate sequences in Anti-Atlas are not directly associated with the Snowball glaciations. However, active volcanism that had sustained latest Neoproterozoic might had provided liquid water environments, as biologic refugia during the Marinoan Snowball Earth.

Carbonate carbon isotope stratigraphy of the Paleoproterozoic Francevillian Group in Gabon

*Tomohiko Sato[1], Yusuke Sawaki[2], Hisashi Asanuma[2], Hisahiro Ueda[1], Shigenori Maruyama[1]

1. Tokyo Institute of Technology, 2. The University of Tokyo

The large fluctuations of δ13C_carb in the Paleoproterozoic are important in terms of the speculation on the atmospheric oxygen level and the global stratigraphic correlations. The interval characterized by the generally high values of δ13C_carb up to +10 ‰is called Lomagundi-Jatuli Event (LJE; ca. 2.2-2.0 Ga) and interpreted as reflecting high rates of oxygen production (e.g. Karhu & Holland, 1996; Martin et al., 2011). The drop of δ13C_carb and δ13C_org at the end of LJE are reported from Shunga in Fennoscandia, and the negative shift of δ13C_org is correlated with that of Franceville in Gabon (Kump et al., 2011); however, the δ13C_carb data in Gabon is still missing because of the scarcity of the carbonate rocks. The Paleoproterozoic Francevillian Group in Gabon consists of FA (fluvial sandstones), FB (black shales/carbonates), FC (cherts), FD (black shales), and FE (sandstones) in ascending order. The lithostratigraphic correlation between the Franceville, Lastoursville, and Okondja basins suggests that the FA-FB-FC units are in different depositional settings and the FD-FE units are in common facies, which indicates the final opening of the intracratonic basins. In order to explore the global correlation of δ13C_carb, the analyses in the FD-FE units are required. In this study, we conducted two drillings in the Lastoursville and Okondja basins to obtain the fresh core-samples of FD. The lithological observations clarified that numbers of carbonate layers are intercalated in black shales in the FD unit in the both areas. We analyzed δ13C_carb of these carbonate layers, and filled in the stratigraphic blanks in the FD unit. In this presentation, we will discuss the propriety of the δ13C_carb stratigraphic correlations.

The redox condition of late Paleoproterozoic shallow marine environment: The Cape Smith Belt, Canada

*Kento Motomura[1], Shoichi Kiyokawa[1], Minoru Ikehara[2], Takashi Sano[4], Kentaro Tanaka[3], Tsubasa Miki[3], Yuji Sano[3]

1. Kyushu University, 2. Kochi University, 3. University of Tokyo, 4. National Museum of Nature and Science

The oceanic redox condition strongly affects the chemical compositions of seawater, especially, redox-sensitive elements such as Fe and Mo. Although it is suggested that bio availability of these bio-essential elements have restricted the biological development through Precambrian ocean, the redox conditions and the trigger of its transition at late Paleoproterozoic era are poorly constrained.

In this study, we reconstructed 50 m lithostratigraphy and chemostratigraphy including major and trace element compositions and C-N-S isotopes ($\delta^{13}C_{org}$, $\delta^{15}N$, $\delta^{34}S$) in order to clarify the sedimentary environment and the trigger of its change.

A part of the drilled hole from the Northern Povungnituk Group, Cape Smith belt of Canada is used for geochemical analyses. The sequence consists of the alteration of sandstone and black shale deposited at northern margin of the Superior province at ~1.9 Ga. Two lithological units, lower and upper units, are identified based on sedimentary sequence. The lower unit is characterized by the transition from coarse sandstone dominant to black shale dominant sequence, while, the upper is fine sandstone dominant sequence.

Vanadium concentrations normalized by total organic carbon (TOC) shows clear evidence for the transition of the redox condition. Although V/TOC at the bottom of the sequence (<~50 ppm/%) is lower than that of black shale from the Bravo Lake Formation of Buffin island in which a previous work cleared the black shale deposited under euxinic condition (H_2S-rich), the value increased and reaches the mean of the black shale (~105ppm/%) from the Formation at lower coarse sandstone dominant portion. These increase of V/TOC suggests ocean redox conditions changed from anoxic (weak-reducing) to euxinic (strongly-reducing). This inference is consistent with redox-sensitive element behavior confirmed from the correlation between the V concentration and TOC.

$\delta^{15}N$ of the sequences (~+7 –+9 ‰) are comparable with that of the modern ocean and that indicates nitrification, denitrification and NH_3assimilation keep $\delta^{15}N$ of dissolved N species high. $\delta^{13}C_{org}$and $\delta^{34}S$ change at the same interval ($\delta^{13}C_{org}$: -30.6 –-33.2 ‰, $\delta^{34}S$: +11.9 –-4.1 ‰) and that suggests some trigger which affects $\delta^{13}C_{org}$and $\delta^{34}S$ caused development of strongly-reducing condition. $\delta^{13}C_{org}$and $\delta^{34}S$ transition are likely to represent input of isotopically light $HCO_3^-$and SO_4^{2-}. The activity of large igneous provinces and oxidative weathering of black shale which relates regression suggested by the change of lithofacies are plausible for these isotope change.

Paleovegetation changes reconstructed by terrestrial plant biomarker analyses in the sediments deposited across the Cenomanian/Turonian boundary in the Tomamae area, Hokkaido, Japan

*Masashi A. Ikeda[1], Ken Sawada[2], Takuto Ando[3], Hideto Nakamura[4], Reishi Takashima[5], Hiroshi Nishi[5]

1. Graduate School of Science, Hokkaido University, 2. Department of Earth and Planetary Sciences, Faculty of Science, Hokkaido University, 3. Arctic Research Center, Hokkaido University, 4. Faculty of Science, Osaka City University, 5. The Center for Academic Resources and Archives, The Tohoku University Museum, Tohoku University

The Cretaceous is known as the extreme greenhouse period attributed to the elevated atmospheric CO_2 concentration triggered by the superplume activity. In particular, the Oceanic Anoxic Events (OAEs) caused by the occurrences of the Large Igneous Plateaus (LIPs) in several times during the mid-Cretaceous. Global environmental disturbance events have been extensively investigated in the ocean, but there have been few reports for terrestrial environmental variation during the OAE periods (e.g. Kuypers et al., 2002). In the present study, we analyzed biomarkers of terrestrial plants including lichen and fungi in the sediments deposited across the Cenomanian/Turonian boundary (CTB) from the northern Hokkaido, Japan to reconstruct paleovegetation changes and to evaluate paleoecology of individual plants during environmental disturbance event.

We analyzed sedimentary rocks across the CTB in the Saku Formation,Yezo Group, were collected from the Omagari-zawa sections of the Tomamae area, northern Hokkaido, Japan. The sediments used correspond to the OAE2 intervals (1st build-up, Trough, 2nd build-up and Plateau phases), determined by $\delta^{13}C$ stratigraphy (Omatsu et al., 2014). For the biomarker analysis, the extractions of freeze-dried sediments were fractionated using silica-gel column and analyzed by GC-MS.

By sterane and hopane ratios, we confirmed the high contribution of terrigenous matter input and low maturity of organic matter (vitrinite reflectance ca. 0.4% level; lignite to subbituminous coal rank) in the Omagari-zawa section. These results agree with those reported by Ando et al. (2017). Higher Plant Parameter (HPP) as the vegetation index of higher plants increased in the 1st build-up and 2nd build-up stages, and declined in the Trough and Plateau stages. We interpret that the coniferous vegetation has expanded under arid condition. Moreover, we analyzed the proportion of 1-methyl dibenzofuran in total methyl dibenzofurans as a lichen indicator (1- MDBF ratio), and perylene/ pyrene ratio as a fungal assemblage index. Variations in lichen and fungi vegetation tend to decrease from the 1st build-up to the 2nd build-up stage, which are resemble to those of coniferous vegetation. Thus, it is considered that the vegetation overall declined against the mid-Cretaceous environmental disturbance, especially affected by arid/humid fluctuation.

Deep-sea mud enriched in rare-earth elements and yttrium (REY), termed as REY-rich mud, has been expected as a novel mineral resource for the industrially critical elements [1]. Targeting the Japanese exclusive economic zone around Minamitorishima Island, where highly promising REY-rich mud (total REY content > 5,000 ppm) lies at very shallow depth (2 to 4 m) below the seafloor [2], we have conducted a variety of researches on the mud from both scientific and engineering perspectives.

In the presentation, we report a general overview of the research progress on REY-rich mud, and discuss the importance of the mud from viewpoints of the Japan’s resource security and a new strategy for economic growth.

A cold and alkaline Hadean ocean caused by impact ejecta weathering

*Shintaro Kadoya[1], David C Catling[1]

1. University of Washington

Life probably arose in the Hadean (either on land or in the sea) and then would have spread through the early ocean. Hence, determining constraints on the early marine environment is essential for understanding conditions for the spread of early life, in addition to the history of the Earth itself. In this study, we modelled the evolution of the surface environment of the Earth, including the surface temperature, pCO_2, and oceanic pH.

As revealed by previous works (e.g., Krissansen-Totton et al., 2018, PNAS), Earth's long-term surface environment is controlled by the carbonate-silicate geochemical cycle. This negative feedback has moderated the surface temperature, resulting in the continuous existence of surface liquid water, even when the solar luminosity was smaller in the past than today. To compensate for the faint Sun, the feedback sets a high pCO_2 in the past, which would result in a more acidic ocean. The same mechanism can be applied for modelling the Hadean eon. However, we have to add another factor: impact ejecta weathering. As indicated by impact craters on the Moon, the Earth would also undergo intense meteorite impacts during the Hadean. Since the impact ejecta are easily weathered, they provided an additional sink of CO_2. Hence, previous works (e.g., Sleep & Zahnle et al., 2001, JGR) suggested that the surface temperature and pCO_2 would actually be low, i.e., a cold Hadean Earth –an idea that has been controversial.

In this study, we calculated the evolution of the surface environment by varying parameters in a geologic carbon cycle model within their ranges of uncertainty. Since the ejecta weathering is a source of carbonate alkalinity (i.e., a sink of CO_2), the pCO_2 and surface temperature of cases with ejecta weathering (hereafter, standard cases) are lower than those of cases without ejecta weathering (hereafter, control cases), as shown in Figure 1a and 1b. The surface temperatures of some standard cases are even lower than 273.15 K (Figure 1a). The coldness does not always mean that the Earth was in a snowball state during the early Hadean; instead, it just indicates a high likelihood of a cold climate. The low pCO_2 of standard cases also results in high ocean pH (Figure 1c). In addition, because the high pH results in a high precipitation rate of carbonate, the carbonate alkalinity of standard cases tends to be lower than that of control cases.

For the standard case, such a relatively cold surface and alkaline ocean are confined to the early Hadean, in which the impact flux (i.e., ejecta production rate) is high. However, the impact craters on the Moon also indicate the possibility of an enhanced impact flux around 4 Ga (i.e., the late heavy bombardment; LHB). The estimated impact flux for the LHB is also high enough to result in a cold surface and alkaline ocean. Hence, we should consider the possibility that life existed in a cold and alkaline early ocean.
Fig. 1. Results with control (without ejecta weathering) and standard cases (with ejecta weathering) for the geologic carbon cycle model for (a) atmospheric partial pressure of CO_2, pCO_2, (b) global mean surface temperature, and (c) ocean pH.

At the JpGU Meeting 2017, we reported the discovery of numerous fragments (<~3 mm in size) of stony meteorites and impact spherules of basalt in the lowest (i.e., the earliest) ~70 m section of the submarine Apex Basalt that overlies the ~110 m-thick Marble Bar Chert Member (MBCM; ca. 3.46 Ga in age) in the ABDP #1 drill core, which was recovered in 2003 at Marble Bar, Pilbara, Western Australia. We suggested that the asteroid body that produced the meteorite fragments was >10 km in diameter, impacted at ~40 km E of Marble Bar, terminated the deposition of the MBCM, and created a crater (“The Apex Impact Crater”) more than ~100 km in diameter. To test this hypothesis, in the summer of 2018 we conducted a geological survey of the proposed “Apex Impact Crater” utilizing a drone equipped with a high-resolution (4K) camera.

Our survey has revealed the presence of “impact tsunami deposits” at the boundary of the MBCM and the Apex Basalt. They are ~1-40 m thick, extending at least 20 km along the strike in the Marble Bar area. They contain numerous fragments (<5 mm size) of stony meteorites, together with various-sized (<1 mm to ~10 m), generally angular-shaped, fragments and blocks of the MBCM. We have also discovered ~15-40 m thick “impact tsunami deposits” underlying the Apex Basalt at ~80 km SE of Marble Bar. Numerous fractures (mostly perpendicular to the bedding planes, and many extending to 100s of meter into the underlying Duffer Formation), the dislocations and rotations of the MBCM in ~cm to ~100 m scales, as well as the “impact tsunami deposits”, were most likely created by an asteroid impact. Our survey has provided evidence that the ~3km-thick Apex Basalt represents the crater-filing komatiite/basalt lavas that were generated by the sudden decompression-melting of the mantle peridotites, triggered by a giant impact, and that the Mt. Edgar Batholiths (~3.46-3.43 Ga in ages), which intruded in the crater, probably represent the rebound of the older continental crust and the products of partial melting of the mantle peridotite and oceanic crust.

Our investigations suggest that the greenstone-granite complexes (“granite dome complexes”) that characterize the geology of the East Pilbara district may represent 8 or more craters created by impacts of asteroid bodies 10-30 km in diameter during the Archean. Consequently, the magmatism and tectonics of early Earth may have been dictated by gigantic asteroid impacts, rather than by the plume- and/or plate tectonics.

An evaluation of impact dating for shocked zircons with planar features (PFs) in the Vredefort dome by LA-ICP-MS multi-spot analysis

*Shinji Yamamoto[1], Taiga Kato[1]

1. Graduate School of Environment and Information Sciences, Yohohama National University

Shock-metamorphosed zircons, as an indicator mineral of meteorite impact, have often been utilized for impact dating (e.g. Kamo et al., 2009). Mechanical and thermal effect by impact are thought to lead Pb-loss of shocked zircon, resulting in partly and fully age resetting. The 2.02 Ga Vredefort dome, largest and oldest impact crater, crop out highly-shock metamorphosed basement rocks which include shocked zircons with various shock features such as planar features and granular textures. Previous studies demonstrate that shocked zircons with planar features in the Vredefort show various metamorphic ages from 731 to 3104 Ma, and these ages are interpreted to be correspond to age resetting of regional metamorphism and impact metamorphism. Recent analysis using EBSD, SL and SRIMP for shocked zircon by Moser et al. (2011) reveal that shocked zircons with curvi-planar features have a potential for impact dating in the Vredefort (2.02 Ga), and EBSD misorientation map suggest that deformation of zircon by impact event enhances the age resetting. However, impact dating using shocked zircons with planar features has not been established. Erickson et al. (2013) reported SHRIMP U-Pb ages of detrital shocked zircon with PFs recovered from downriver of the Vredefort dome, and conclude that predominant impact age were identified and that most of shocked zircons record regional metamorphic events. Here we report impact resseting ages from detrital shocked zircons with PFs at the Vaal River sand, cutting along the Vredefort Dome, and identified zircon deformation texture revealed by EBSD misorientation maps. Such deformation in shocked zircon supposed to be formed by impact, and their deformation texture (PFs and EBSD map) may help to identify the ancient impact record.

The short-lived ^{182}Hf–^{182}W decay system has been widely used to understand early Earth chemical evolution. Recently, ^{182}W anomalies have been found from many Archean terranes (e.g., Willbold et al., 2011; Touboul et al., 2012). These W isotope variations should be produced by the chemical fractionation of Hf/W on the Earth while ^{182}Hf was extant, or contribution of extraterrestrial materials having different W isotope compositions after core formation. While the W isotopic anomalies potentially provide valuable insights into processes on the early Earth, the exact cause of the isotopic anomalies is not yet clearly understood. As the possible causes, early silicate differentiation, early metal-silicate equilibrium at various conditions, and late veneer have been proposed, but these hypotheses respectively are inconsistent with the lack of correlations with Nd, Os isotopic data, and highly siderophile elements abundances (e.g., Rizo et al., 2016b; Puchtel et al., 2018; Touboul et al., 2012). Alternatively, the apparent lack of the correlations may be attributed to secondary disturbance in the W isotope compositions of the Archean rocks, given that W is highly fluid-mobile during metasomatism (e.g., Bali et al., 2012).

In this study, we applied an acid-washing method to Eoarchean metamorphosed rocks from the Isua Supracrustal Belt, with the aims to evaluate the possible effect of metasomatism on the W isotope systems, and to obtain their original W isotope compositions. We measured trace element compositions and W isotope ratios of acid-washes and residues of the metamorphosed basalts using ICP–MS.

The acid-washes show enrichments in light REE, whereas the residues exhibit enrichments in heavy REE. This suggests that acid-washing selectively removed a secondary component gained during metasomatism, given that light REE are relatively fluid-mobile as compared to heavy REE. Negative ^{182}W anomalies were found in the washes showing light REE enrichments. By contrast, non-resolvable ^{182}W anomaly was obtained for the residues displaying heavy REE enrichments. These findings suggest that the Isua metamorphosed basalts have a W isotope heterogeneity even in a single rock sample. Moreover, our results imply that the W isotope compositions of Isua supracrustal rocks could have been modified secondarily as a result of metasomatism. This can account for the lack of correlation between W isotopic data and other geochemical or isotopic data.

Limited primary production in the early Archean oceans and its biogeochemical consequenses

*Kazumi Ozaki[1]

1. Toho University

The activity level of the biosphere is a critical factor controlling the chemical composition of the atmosphere. The modern Earth's biosphere is powered by the oxygenic photosynthesis, which utilizes ubiquitous water as their electron donor, with the result that Earth's surface environment is extremely well oxygenated. Before the advent of the oxygenic photosynthesis, in contrast, primary production would have been limited by the geophysical input rate of critical electron donors (e.g., H_2 and Fe^{2+}) from the Earth's interior to the exogenic system. Here, we revisit previous modelling of the global biogeochemical cycles of H, C, and Fe in order to more precisely reconstruct global net primary production (NPP) during an interval of early Archean time before the advent of oxygenic photosynthesis. The biogeochemical model includes a series of metabolic reactions in the primitive anoxic biosphere (e.g., anoxygenic photosynthesis, methanogens, and fermenters) and takes redox (H) balance in the ocean-atmosphere system into account. I explore the effect of a variety of combination of key parameters (e.g., atmospheric CO_2 levels, geophysical input flux of Fe^{2+}, and volcanic outgassing flux of H_2) with a stochastic approach in order to search the possible solutions which allow for creating a warm climate state (>288 K) during the Archean. The results suggest that NPP by anaerobic metabolisms has been a few percent of the modern value. The H-based producers, photoferrotrophs, and CO-consuming acetogens contribute ~80%, ~18%, and ~2% of total NPP, respectively. The estimated extremely low NPP implies the geological fluxes of H_2 and Fe^{2+} as a limiting factor for biological productivity. The results also show that the atmospheric CO_2 levels are needed to be >~70 PAL (present atmospheric level) for maintaining warm climate state and that atmospheric CH_4 levels would have been >100 ppm despite the limited activity of the biosphere.

Behaviors of carbon cycle system and inevitability of the hot climate in the Archean Earth

*Yasuto Watanabe[1], Eiichi Tajika[1], Kazumi Ozaki[2], Peng Hong[3]

1. The University of Tokyo, 2. Toho University, 3. Chiba Institute of Technology

Although the luminosity of the Sun in the Archean (from 4.0 Ga to 2.5 Ga) was dimmer than that of today, geological records of $d^{30}Si$ and $d^{18}O$ from marine cherts suggests that the terrestrial surface environment may have been warm or even hot (328-358 K). Recently, along with these geological records, thermostability of reconstructed ancestral enzymes of cyanobacteria, which reflects the temperature of marine photic zone, also supports the hot surface environment.

To achieve such hot environment under the dimmer Sun, greenhouse effect of carbon dioxide and methane is considered to be necessary. Previous study using a coupled model of atmospheric photochemistry and ocean microbial ecosystem showed that the warm climate can be achieved by non-linearly amplified flux of methane to the atmosphere from the marine ecosystem only when H_2-using photosynthetic bacteria and Fe-using photosynthetic bacteria coexisted in the Archean marine ecosystem. This means that the photochemical processes and the marine microbial processes would have been important in realizing the hot environment under low pO_2 condition in the Archean. However, few studies investigated how these processes affected the global carbon cycle in the Archean.

Here we developed a coupled atmosphere photochemistry-marine microbial ecosystem-global carbon cycle model and assessed how the hot climate suggested from the geologic records can be achieved in the Archean. We found that, there are high pCO_2 (hot climate) stable solutions and low pCO_2 (warm climate) unstable solutions against the range of CO_2 degassing rate similar to that of today. In the low pCO_2 solutions (<~100 PAL), CO_2 is removed from the atmosphere-ocean system as the haze particle, hence such a condition is unstable in the Archean carbon cycle system. This finding strongly supports the results of the hot terrestrial environment in the Archean as suggested from many previous studies. The hot climate may be an inevitable result in the Archean carbon cycle system.

Occurrence and chemical composition of metamorphic carbonate rocks in the Isua supracrustal belt, West Greenland: Implications for the origin of carbonate rocks and compositions of the Eoarchean seawater.

*Yoshida Satoshi[1], Kazutaka Yasukawa[2], Yasuhiro Kato[2], Yusuke Sawaki[3], Tsuyoshi Komiya[3]

The Earth is a unique planet where liquid water and life exist through the geologic time. Therefore, reconstruction of the surface environment of the early Earth is an important issue to consider early life. However, we know little about the early Earth, because the first 500 million years record of the Earth was almost lost.

In recent decades, many studies has been done on the reconstruction of surface environment of the early Earth and early life (c.f. Schidlowski et al., 1979; Ueno et al., 2002; Tashiro et al. 2017). Especially, research on the origin of metamorphic rocks derived from banded iron formation (BIF), carbonate rock and chert in the 3.81 Ga Isua supracrustal belt (ISB), southern West Greenland has been actively carried out in order to reconstruct the surface environment of the early Earth (c.f. Rose et al., 1999; Bolhar et al., 2004; Friend et al., 2008; Nutman et al., 2010).

Recent geochemical studies suggested that the meta-carbonate rock in the ISB originated from a chemical sedimentary rock based on their Post-Archean Average Shale (PAAS)-normalized rare earth element (REE) patterns (Friend et al., 2008; Nutman et al., 2010). They argued that the meta-carbonate rocks have positive La ($[La/La^*]_{PAAS}$; $La^* = 2\,Ce - 2\,Pr$), Eu ($[Eu/Eu^*]_{PAAS}$; $Eu^* = 0.5\,Sm + 0.5\,Gd$) and Y (Y/Ho) anomaly. In the ISB, the carbonate rocks occur with one of three types following rocks: meta-chert, meta-conglomerate and meta-basalt. However, the relationship between the occurrence and the chemical compositons of meta-carbonate rocks is still ambiguous.

We estimated origin of the meta-carbonate rocks with different occurrence, and reconstructed chemical composition of the Eoarchean seawater from geochemistry of the meta-carbonate rocks in the northern part of the ISB. The meta-carbonate layers accompanying the meta-chert are several centimeters thick, and interlayered with meta-chert layer. The meta-carbonate rocks accompanying the meta-conglomerate rock occur as matrix of meta-conglomerate or layer formed centimeter thick. Previous workers considered that those meta-carbonate rocks originated from shallow water sediments (e.g. Dimorth, 1982; Nutman et al., 1984), whereas others interpreted that they formed through metasomatic alteration (e.g. Appel et al., 1998); thus the origin of the meta-carbonate rock are still controversial. The meta-carbonate rocks accompanying meta-basalt occur as veins in the meta-basalt and their thickness are centimeter to tens of centimeters. Those differences in the occurrence are related to their origin.

We analyzed major and trace element (e.g. REE and Zr) contents of the whole rocks of the carbonate rocks with X-ray Fluorescence (XRF) for major elements and High-Resolution Inductively Coupled Plasma Mass Spectrometry (HR-ICP-MS) for trace elements at the University of Tokyo, respectively. Some carbonate rocks have high SiO_2, TiO_2, Al_2O_3, and Zr contents, possibly due to involvement of detrital and

©2019. Japan Geoscience Union. All Right Reserved.

volcanic materials with/without silicification. We selected the carbonate rocks with low SiO_2, TiO_2, Al_2O_3, and Zr contents in order to remove influence of the silicification and contamination of the detrital materials.

The PAAS-normalized REE patterns of meta-carbonate rocks interlayered with the meta-chert show LREE-depleted patterns with positive La (La/La*: 1.18-1.40), Eu (Eu/Eu*: 1.80-5.50) and Y (Y/Ho: 34.9-45.3) anomaly and without Ce anomaly. The meta-carbonate rocks accompanying with meta-conglomerate rocks show LREE-depleted patterns with positive Eu (Eu/Eu*: 1.43-1.91) anomaly, and lack La, Ce and Y anomaly. The meta-carbonate rocks accompanying with the meta-basalt possess LREE-depleted pattern with Eu (Eu/Eu*: 1.35-1.91) anomaly, and lack La, Ce and Y anomaly.

The positive La and Y anomaly indicates that the meta-carbonate rocks were originate from chemical sediments precipitated from seawater (e.g. Webb and Kamber, 1999; Bolhar et al., 2004), and the lack of the Ce anomaly indicates that the Eoarchean seawater was anoxic as many previous works suggested. In addition, the positive Eu anomaly suggests that the meta-carbonate rocks was precipitated from seawater, influenced by hydrothermal activity.
We classified the meta-carbonate rocks in the ISB into two groups based on the occurrence and REE patterns: chemical sedimentary rock and metasomatized rock. The former includes the meta-carbonate rocks interlayered with meta-chert, whereas the latter comprises those accompanied with meta-conglomerate and meta-basalt.

[J] Poster | B (Biogeosciences)：B-CG Complex & General

Wed. May 29, 2019 3:30 PM - 5:00 PM JST | Wed. May 29, 2019 6:30 AM - 8:00 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_21

[B-CG07] Decoding the history of Earth: From Hadean to the present

convener:Tsuyoshi Komiya(Department of Earth Science & Astronomy Graduate School of Arts and Sciences The University of Tokyo), Yasuhiro Kato(Department of Systems Innovation, Graduate School of Engineering, University of Tokyo), Katsuhiko Suzuki(Research and Development Center for Submarine Resources, Japan Agency for Marine-Earth Science and Technology)

The latest results of Earth's evolution and geological processes through 4.6 billion year
s from Hadean to Modern, based on various approaches including fieldworks, chemical
analyses, experiments and computer simulation, will be presented. In this session, we ai
m to discuss and understand causal relationships and interplay among the evolution of
Earth's deep interior, changes in the surface environments, and development and evolut
ion of life. Wide-ranging topics are accepted.

The Nuvvuagittuq supracrustal belt in the northeastern Canada is one of the oldest supracrustal rocks in the world, thus the geological, petrological and geochemical study allows us to constrain the evolution of surface environment and sold earth in the early earth. The belt consists of ultramafic rocks, coarse-graind and fine-grained greenstone, banded iron formation (BIF), siliceous rock, carbonate rock, and conglomerate. The ultramafic rocks and coarse-grained greenstone are considered as ultramafic and grabbroic intrusions, respectively. The fine-grained greensone is classified into three types based on the petrography: cummingtonite-bearing amphibolite (faux-amphibolite), hornblende-bearing amphibolite (green-amphibolite) and actinolite-bearing greenschist. The greenschist occurs only in the southwestern area. The faux- and green-amphibolite are ubiquitously present over the belt. Moreover, O'Neil et al. (2011) classified the amphibolite into three types based on their TiO_2 contents and REE patterns. The BIF mainly occurs in three areas, and has different occurrence and petrography. The BIF in the northwestern area is accompanied with the ultramafic rocks, and comprises interlayering of magnetite and amphibole/serpentine/talc. The BIF in the southwestern area occurs together with fine-grained greenstone, and mainly contains hematite and quartz (jaspillite). Dodd et al. (2017) found possible biogenic fabric, formed by iron-oxiding bacteria in the jaspillite. The BIF in the southeastern part is interlayered with the faux-amphibolite, and occurs above the siliceous rock. It mainly comporises magnetite and quartz.

The belt is intruded by some precursors of orthogneiss, whose igneous ages of *ca.* 3.8 Ga and constrain the minimum age of the belt. O'Neil et al. (2008, 2012) proposed that the igneous age of the fine-grained amphibolite is *ca.* 4.38 Ga based on a putative $^{147}Sm/^{144}Nd$-$^{142}Nd/^{144}Nd$ isochron age. On the other hand, Cates et al. (2013) proposed that a felsic layer within the faux-amphibolite originates from a clastic felsic sedimentary rock, and the maximum age of the belt is *ca.* 3.78 Ga based on ages of the zircons. David et al. (2009) interpreted a felsic layer as a volcanosedimentary rock, and proposed that the supracrustal rock was formd at 3817 Ma based on the ages of zircons.

We made a quite detailed geological map using a drone, which enables easily to trace even tens centimeter layers and intrusions. Many tens centimeter thick intrusions with an intermediate composition are present in the faux-amphibolite, whereas no intrusions are apparently found in the green-amphibolite. The distribution of the two types of amphibolite corresponds to that of three geochemical types of greenstone proposed by O'Neil et al. (2011), suggesting that the geochemical signature is due to secondary alteration. In addition, the apparent isochron on the $^{147}Sm/^{144}Nd$-$^{142}Nd/^{144}Nd$ diagram possibly originates from mixing between the mafic/ultramafic component and secondary intermediate component. O'Neil et al. (2008) proposed that the Nd isochron age of gabbroic dikes is 4.3 Ga. But, the gabboric dikes are younger than 3.8 Ga, and the isochron is putative because our map clearly shows that some thin gabbroic dikes are intruded into ambient orthogneiss, whose age is *ca.* 3.8 Ga. We found many conglomerate layers over the belt, but the layers finally change felsic intrusions. The occurrence means that they are putative conglomerate. In addition, the carbonate rocks occur along the felsic intrusions,

©2019. Japan Geoscience Union. All Right Reserved.

suggesting they also have metasomatic origin. The petrograhy and occurrence of the BIF in the northwestern area indicate that the BIF was formed from metamorphism of the ultramafic rock. The siliceous rock is intruded by many felsic intrusions and quartz veins, but the detailed map can differentiate between the siliceous layers and intrusions, and shows that the siliceous layers originate from siliceous sediment.

Behavior of phosphorus during hydrothermal alteration of basalt under CO_2-rich condition

*Aoi Murakami[1], Yusuke Sawaki[2], Hisahiro Ueda[3], Yuji Orihashi[4], Shiki Machida[5], Tsuyoshi Komiya[2]

1. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, 2. The University of Tokyo, 3. Tokyo Institute of Technology, 4. Hirosaki University, 5. Chiba Institute of Technology

It is well known that a unique environment is created around seafloor hydrothermal systems by element exchange between circulating seawater and surrounding rocks: enrichment in transition elements and sulfide, emission of quite hot water, and even even electric current flow. In addition, a number of hyperthermophilic microorganisms inhabit around hydrothermal vents. 16S rRNA-based phylogenetic tree suggests that the hyperthermophilic organisms are closest to the earliest lineage; thus the hydrothermal environment is one of the candidates for habitat and evolution of early life.

Phosphorus is one of essential elements for life. In order to maintain an early ecosystem around the hydrothermal vent, phosphorus should have been supplied from the hydrothermal vent through high-temperature water-rock reaction. In the modern basalt-hosted hydrothermal systems, phosphorus is removed due to its adsorption to iron oxide precipitated from hydrothermal fluid and/or formation of metamorphic apatite in the hydrothermally metamorphosed basalt. On the other hand, it is well known that middle Archean basaltic rocks, which constituted upper part of oceanic crust, suffered from severe carbonation during hydrothermal alteration due to quite high atmospheric CO_2 content on the early Earth. Under the CO_2-rich condition, calcium was removed from the seawater/hydrothermal fluid due to extensive carbonate formation. Because the carbonate formation inhibits the formation of apatite, the phosphorus might be released from hydrothermally altered rocks. Actually, the hydrothermally altered basaltic rocks in the Archean are more depleted in phosphorus than hydrothermally altered modern mid-ocean ridge basalt.

In order to quantify phosphorus content of fluid supplied from the basalt-hosted hydrothermal system on the early Earth, we conducted hydrothermal experiments involving hypothetical seawater and basalt under both CO_2-free and CO_2-rich conditions at 200 ˚C, 100 bars. The basalt used in this study was collected from the Indian Ocean Marie Celeste Fracture Zone. The initial solution was prepared by mixture of standard reagents by reference to modern seawater, except for Ca and P. The calcium and phosphorus contents in the solution were regulated to 30 mmol/kg and 0.60 ppm, respectively. The latter is ten times higher than the modern equivalent. For the CO_2-rich experiment, $NaHCO_3$ and HCl were added to the hypothetic seawater to substantialize 400 mmol/kg of ΣCO_2 at the beginning of the experiment.

The CO_2 concentration decreased from 400 mmol/kg to 250 mmol/kg as water-rock reaction advanced, indicating precipitation of carbonate minerals. The SEM-EDS observation demonstrated that the run

©2019. Japan Geoscience Union. All Right Reserved.

products contain calcite, dolomite, and magnesite. Phosphorus content of the fluid decreased to *ca.* 0.10 ppm under the CO_2-rich condition and *ca.* 0.04 ppm under the CO_2-free condition, respectively. The pH value of the produced fluid for the CO_2-rich experiment, measured at room temperature, was 6.6, by *ca.* 2 unit higher than that of the CO_2-free experiment. Calcium concentration decreased from 30 mmol/kg to 25 mmol/kg under the CO_2-free condition. On the other hand, calcium concentration of the formed fluid under the CO_2-rich condition decreased to 18 mmol/kg at 96 hours, and then increased to 25 mmol/kg. The formation of high alkaline and Ca-poor fluid under the CO_2-rich condition suggests that the fluid was oversaturated with carbonate, whereas undersaturated with apatite. Because the produced fluid under the CO_2-rich condition contained more phosphorus than the modern seawater, the basalt-hosted hydrothermal system may have served as a source of phosphorus under the CO_2-rich condition, probably on the early earth.

Origin of chromitites in the Akulleq terrane, southern West Greenland

*Kanta Takahashi[1], Tomoaki Morishita[1], Juan Miguel Ramirez Guotana[1], Kenichiro Tani[2], Yumiko Harigane[3], Ikuya Nishio[1], Kristoffer Szilas[4], Akihiro Tamura[1]

1. Kanazawa University, 2. Department of Geology and Paleontology, National Museum of Nature and Science, 3. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST), 4. University of Copenhagen

The studies dealing with the Hadean-Archaean geologic samples are recently expanding. Research on Hadean-Archaean terranes is an important part in reconstructing the geologic past of the Earth which is thought to have differences from the present conditions. Southern West Greenland preserves a wide exposure of ancient geologic materials and structures. This study focuses on chromitites and peridotites from the Ujaragssuit nunāt area in southern West Greenland. The Ujaragssuit nunāt area is about 20 km south from the 3.8 Ga Isua Supracrustal Belt (Moorbath et al., 1977). In Ujaragssuit nunāt, ultramafic rocks occur as lenses of several meters to several hundred meters hosted in silicic gneiss (Chadwick and Crewe, 1986). It is important to understand the origin and processes related to the formation of the peridotites and chromitites in Ujaragssuit nunāt as a contribution to the Archaean magmatic processes and tectonics of the early Earth.

Chromitites are rocks with significant amount of chromites (>20 vol.%) (Arai and Miura, 2016). The unaltered composition of spinel is regarded as a useful petrological indicator (Irvine, 1967). However, chromite composition could be modified as a result of chemical re-equilibration, metamorphism, hydrothermal alteration. The impacts of these processes are evaluated in this study. In Ujaragssuit nunāt, chromitites, dunites and amphibole harzburgites are widely exposed. In some areas, the chromitites occur as layers with thickness ranging from several centimeters to a meter. Massive chromitites (2 m thick) are also exposed. The lithologies present in the area were also described in detail in previous works such as of Rollinson et al. (2002).

Chromites are subhedral and account for about 50-70% of the Ujaragssuit nunāt chromitites. Interstitial grains are mainly phlogopite and minor chlorite and talc. The dunite host consists mainly of olivine (~80%) and accessory spinel and phlogopite. Some spinel grains in the host dunite exhibit zonation as evidenced by darker cores and lighter rims under reflected light microscope and scanning electron microscope observations. The zonation observed is associated with compositional variation from core to rim (Fe enrichment towards the rim). The amphibole harzburgites are mainly composed of amphibole, orthopyroxene, spinel, phlogopite. Orthopyroxenes occur both around olivine and in some parts as inclusions inside olivine grains. Talc replacement of orthopyroxenes is also common. Spinel are surrounded by phlogopite and edenitic amphibole.

Spinel in the host peridotites has a higher Fe^{3+}content. The spinel Fe^{3+} content is higher in samples with higher phlogopite and spinel ratio. This suggests that phlogopite was formed by the reaction of spinel (+olivine) with an alkaline element-rich fluid. Spinel serves as a source of the Al_2O_3 in the phlogopite formation. It is considered that the chemical composition change of spinel is caused by the formation of phlogopite. Furthermore, phlogopite in the sample containing amphiboles has lower K/(K+Na) ratio than samples without amphibole. Amphiboles are also found around the spinel. The K/(K+Na) ratio in the fluid decreases as the alkaline element-rich fluid forms phlogopite and amphibole was formed by the reaction between this differentiated fluid and spinel (+olivine). The abundance of orthopyroxene is higher in the

©2019. Japan Geoscience Union. All Right Reserved.

sample containing amphiboles. The Cr_2O_3- and Al_2O_3- poor characteristic of the orthopyroxenes suggests a secondary origin. The differentiated fluid is also abundant in silica component and reacts with olivine to react to form the secondary orthopyroxenes. Although the possibility of crystal differentiation cannot be completely ruled out, it is thought that these peridotites were originally dunites and chromitites and the chemical composition was modified by alkali alteration.

Metamorphic P–T condition of the Inyoni shear zone rocks in the Barberton Greenstone Belt, South Africa and its significance

*Daichi Kato[1], Kazumasa Aoki[1], Yuta Tsuchiya[2], Shogo Aoki[2], Tsuyoshi Komiya[3]

1. Department of Applied Science,Okayama University of Science, 2. Department of Biosphere-Geosphere Science,Okayama University of Science, 3. Department of Earth Science and Astronomy,University of Tokyo

The metamorphic P–T conditions and processes of the mid-Archean Barberton Greenstone Belt (BGB), South Africa were examined from metamorphosed banded iron formation (BIF) and garnet amphibolite in the Inyoni shear zone (ISZ). Their metamorphic P–T conditions were estimated from thermodynamic calculations combined with several geothermobarometries such as garnet–clinopyroxene geothermometry, Raman geobarometry and Zr-in-sphene geothermometry. Moreover, in order to constrain the protolith age and origin of our studied sample, we conducted zircon U-Pb and trace elements analyses by using Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS).The following results were obtained: the P–T conditions of the meta-BIF changed from ca. 600–680 ˚C and 10–12.7 kbar through ca. 510–540 ˚C and 8–11 kbar to less than 500 ˚C and 4 kbar. On the other hand, the P–T conditions of the garnet amphibolite changed from ca. 9.5–10.5 kbar and 620–660˚C to less than 5 kbar and 500 ˚C. Integration of these new results with previous studies for the BGB suggest that the geothermal gradients of the prograde and retrograde metamorphisms were ca. 15–20 ˚C/km and 20–30 ˚C/km, respectively. Igneous zircon separated from the Garnet amphibolite sample yield ^{207}Pb-^{206}Pb age of ca. 3.4-3.2 Ga. This new data together with previous geochronological data indicate that the protoliths of ISZ rocks began to subduct at ca. 3.37-3.24 Ga. The prograde P-T path was kinked at P = 8.0 kbar and T = 560 ℃ by difference in geothermal gradient between crust and upper mantle. The change of geothermal gradient in the ISZ rocks between prograde and retrograde conditions might have relation to the collision of ca. 3.4 Ga Stoluzburg domain. The last P-T trajectory characterized by isothermal decompression might be caused by the intrusion of the ca. 3.23-3.21 Ga TTG Badplaas pluton attendant on plate subduction.

Discovery of possible traces of asteroid impact within the fossil-bearing carbonaceous chert from the 3.4 Ga Strelley Pool Formation, Pilbara Craton of Western Australia - a preliminary study

*Kenichirio Sugitani[1], Ryoko Senda[3], Tsuyoshi Iizuka[2], Simon Wallis[2]

1. Nagoya University, 2. The University of Tokyo, 3. Kyushu University

Large asteroid impacts are thought to be a common feature of the Archean in particular as a result of the Late Heavy Bombardment (LHB). One line of supporting evidence is the presence of “impact layers” containing silicate spherules that were formed by condensation of rocks vaporized by bombardment events. Two Early Archean impact layers with ages of 3.47 and 3.46 Ga have been identified from the Pilbara greenstone belt, Western Australia (Glikson et al., 2016; Lowe and Byerly, 1986). In contrast 5 separate impact layers with ages of 3.47 to 3.24 Ga have been identified in the Barberton greenstone belt, South Africa (e.g., Lowe et al., 2014; Byerly et al., 2002). Such extraterrestrial impacts likely influenced the Earth’s early environment, including crustal deformation, terrain amalgamation, evaporation of significant volumes of ocean water, and even triggering the development of a modern-like plate tectonic regime (Lowe et al, 2014). It is also reasonable to assume that the early life was influenced significantly by these impacts (Lowe et al., 2003). The early evolution of life might have been accelerated as a consequence of adaptation to such environmental agitations (Kozawa et al., 2018; Oehler et al., 2017). Thus, a close association of traces of life, such as microfossils with cellular preservation, and of impact events recorded in Archean sedimentary successions is of special interest.

In this study we describe the new discovery of traces of asteroid impacts in the ca. 3.4 Ga Strelley Pool Formation (SPF) in the Panorama greenstone belt of the Pilbara Craton, Western Australia. Spherules of possible impact origin were identified in carbonaceous black chert 15 cm thick from which morphologically diverse microfossils have been described (e.g., Sugitani et al., 2013) (Fig. 1). Evidence for an asteroid impact includes the presence of a thin sedimentary layer rich in silicate spherules (Fig. 2) associated with enrichment of platinum-group elements (PGE) (Fig. 3a). However, our detailed analyses revealed that PGE-enrichment is more conspicuous in the lower horizon and are associated with $^{178}Os/^{188}Os$ initial values close to 0.1. In contrast, spherule-rich layers have significantly higher $^{178}Os/^{188}Os$ values ~1.0 (Fig. 3b). One exception is a sample from the upper portion, which has an unusually low value. It is also noteworthy that the spherule-rich layer is enriched in Al and Ti (Fig. 3c). There is a clear higher contribution by clastic materials to this layer, and this feature may explain the apparent contradiction between the PGE-enrichment and Os isotopic values described above. In either case, the layer contains abundant volcanic fragments and clasts in which spherules tend to occur. This occurrence suggests that the spherules were likely reworked from the original site of deposition. A layer composed of carbonaceous grains including rip-up clasts that is found just below the spherule-rich layer (Fig. 1) indicates a steep high-energy depositional environment. This layer contrasts with the fine parallel lamination of carbonaceous chert layers seen at the other horizons, which indicates a quiet depositional environment. We infer that the original impact layer is present below the examined carbonaceous black chert layer and that a high-energy environment related to volcanic activity caused reworking of the spherule-rich deposits, which were transported to the present site of deposition. If this is the case, the high PGE concentrations and the significantly low $^{187}Os/^{188}Os$ initial ratios of the lower cherty samples could be explained as representing the aftermath of an impact event associated with precipitation of vaporized PGE from the atmosphere to the sediment.

Biogeochemical dynamics in during the Great Oxidation Event constrained by a biogeochemical cycle model

*Yuna Miura[1], Kazumi Ozaki[1]

1. Toho University

The accumulated geological and geochemical data indicate that Earth's ocean-atmosphere system has seen a fundamental increase in oxygen abundances from anoxic conditions (pO_2 <10^{-5} present atmospheric level (PAL)) to oxic conditions (pO_2 >10^{-2} PAL) during the Paleoproterozoic. This marked transition, known as the 'Great Oxidation Event (GOE)', may be accompanied by a transient time of relatively high oxygen levels in the atmosphere and ocean (called an 'oxygen overshoot'). However, the ultimate cause and biogeochemical consequences of the GOE remain unclear.
Harada et al. (2015) hypothesized the snowball Earth glaciation at 2.2 Ga as an ultimate cause of the GOE with a prolonged (~10^8 year) oxygen overshoot. Sedimentary record of iron and manganese oxides above the glacial deposit in the Transvaal Supergroup, South Africa, implies an oxygenation of Earth's surface environments just after the glaciation. The red beds and sulfate evaporites (gypsum, $CaSO_4$) also suggest a sustained oxygenation of the Earth surface environment. They constructed a biogeochemical cycle model of carbon, phosphorous and oxygen, and conducted sensitivity experiments to assess the biogeochemical dynamics after the snowball Earth glaciation. By assuming an atmospheric CO_2 level of 0.7 atm required to end the snowball Earth glaciation, they found that an extremely warm climate accelerates chemical weathering on land and phosphorus riverine input. This marked increase in phosphorus input results in a dramatic increase in biospheric oxygen production, with an oxygen overshoot lasting for ~10^8 years. However, it remains unclear whether their calculations are consistent with available geological constraints (e.g., sulfate evaporite depositions and sulfur isotope data), because they ignore the geochemical cycle of sulfur. A recent geochemical study suggests that concentration of sulfate ($[SO_4^{2-}]$) in the ocean may have been unusually high (>10 mM) during the gypsum formation. If correct, this provides a strong constraint on the biogeochemical conditions.
In this study we constructed a sulfur cycle model with a goal of finding the feasible conditions for the geochemical constraint ($[SO_4^{2-}]$ >10 mM). The model consists of three reservoirs—oceanic sulfate, crustal gypsum, and crustal pyrite. Sulfur enters the ocean through weathering of gypsum and pyrite. We assumed that the oxidative weathering of pyrite is a function of atmospheric O_2 levels and that the gypsum weathering is proportional to the global weathering rate. Sulfur is removed from the ocean via deposition of gypsum and pyrite. We assumed that sulfate burial in the ocean is proportional to seawater sulfate levels. Pyrite burial is assumed to be governed by microbial sulfate reduction dependent on marine sulfate content, biological production (i.e., the availability of organic matter), and oceanic O_2 levels. In this study, we performed a series of sensitivity experiment with a Harada et al.'s model, and obtained biogeochemical dynamics (e.g., atmospheric O_2 levels and weathering rates) were used as a forcing for our sulfur cycle model, enabling us to simulate the evolution of oceanic SO_4^{2-} levels after the glaciation. Our sensitivity experiments of a Harada et al.'s model demonstrate that the biogeochemical dynamics after the glaciation depend mainly on the initial value of atmospheric CO_2 levels: >0.2 bar and >0.25 bar of CO_2 are required for the GOE and the occurrence of an oxygen overshoot, respectively. Our sulfur cycle model, however, demonstrates that 0.25 bar of CO_2 is not sufficient to explain the unusually high levels of $[SO_4^{2-}]$ >10 mM during the overshoot. The systematic sensitivity experiments reveal that at least ~0.75 bar of CO_2 will be required. This result provides an additional support for the hypothesis that the severe glaciation was an ultimate cause of the GOE in the Paleoproterozoic.

Composition of seawater before the Sturtian Snowball Earth estimated by the occurrence of late Tonian evaporitic magnesite

*Aya Miyazaki[1], Akihiro Kano[1], Fumito Shiraishi[2]

1. Department of Earth and Planetary Science, The University of Tokyo, 2. Department of Earth and Planetary Systen Sciences, Hiroshima University

Neoproterozoic is an important period for biological evolution when the spread of algae, protozoan, and multicellular animal were radiated. Understanding of climate changes and fossil records after Ediacaran has been largely improved. But environmental background behind how the Earth’ s surface reached the Snowball Earth state has not been understood.
In Flinders Ranges, South Australia, thick shallow marine sequence preserves excellent geological records especially before and after Sturtian glaciation. This study targets Skillogalee Dolomite exposed at Leigh Creek, Northern Flinders Ranges (LC section) which was deposited around 788±7Ma(Late Tonian) before the Sturtian glaciation (Hood and Wallace 2018). The lithology of LC section contains a small amount of siliciclastics, but mainly consists of shallow water carbonate that exhibits various structures including intraformational conglomerate, stromatolite and tepee structure. However, the most remarkable feature is a large quantity of magnesite. Magnesite alternates with dolostone and occurs as layers of ~1m in thickness or crusts of intraformational conglomerate. The Tepee structure indicates an evaporative environment, and higher d13C and d18O of magnesite indicates that the magnesite deposited after the dolomite. These rocks lack gypsum pseudomorphs.
Evaportive mineral assemblage of the Skillogalee Dolomite can be recognized only in Proterozoic. While the Phanerozoic evaporate sequence starts from Ca carbonate-dolomite, follows to gypsum and halite, but does not include magnesite (Hardie and Eugster 1980). In order to explain this specific mineral assemblage, we made model calculations about the order of precipitated minerals, which expected by continuous evaporation of seawater. Then, we found the Skillogalee mineral sequence was achieved only from seawater of Mg/Ca > 10 and Mg > Alkalinity > Ca. We used sulfate concentration of the modern seawater, but it does no influence to the result. Alkalinity over 10 times higher than the modern level likely reflects from high partial pressure of carbon dioxide or low Ca concentration in seawater. Possible causes of high Mg/Ca ratio were inactive seawater circulation at low mid-ocean ridge, active carbonate sedimentation, or Ca depletion due to extensive evaporite formation including gypsum around 800 Ma. If pH of seawater has been controlled by the solubility equilibrium of CaCO3, the drastic decrease in Ca concentration would encouraged pH rise of sea water and lead to decline of atmospheric carbon dioxide.

Geochemical characteristics of black shales in the Japanese accretionary complex across the Permian-Triassic boundary extracted by independent component analysis

*Moei Yano[1], Kazutaka Yasukawa[1,3], Koichiro Fujinaga[3,2], Kentaro Nakamura[1], Yasuhiro Kato[2,1,3]

1. Department of Systems Innvation, School of Engineering, The University of Tokyo, 2. Frontier Research Center for Energy and Resources, School of Engineering, The University of Tokyo, 3. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology

The Permian-Triassic boundary (PTB) is characterized by an oxygen-depleted condition in the superocean Panthalassa. However, the degree of the oxygen depletion in deep-sea environments remains an open question.Deep-sea sediments that deposited from the latest Permian to early Triassic constitute black shale within the accretionary complexes of Japan, showing a distinct enrichment of redox sensitive trace metals (e.g., V, Mo, U) that precipitate under reducing conditions.In contrast to the Panthalassa at the PTB, the modern ocean is generally oxygenated from the surface to the bottom due to a sufficiently strong global ocean circulation. However, oxygen-depleted water masses can develop in some specific areas such as restricted basins and coastal upwelling areas, and blackish sediments in these areas show laminated facies and/or high total organic carbon contents reflecting oxygen-depleted conditions.Comparing the black shales at the PTB with the other sediments that deposited in oxygen-depleted conditions can characterize the Panthalassa across the PTB in a context of a broad spectrum of oceanic environmental changes throughout the Earth’ s history. To this end, clarifying geochemical features of multiple elements, especially of redox sensitive trace metals, is quite a useful approach to extract the information of the oceanic environments involving variations in redox conditions. Here we applied independent component analysis to the multi-elemental data set composed of major- and trace-element contents of the samples from the PTB sections within the accretionary complexes of Japan, and black mud and shale of other geological times obtained by scientific drillings in the modern oceans. We will discuss the geochemical characteristics of the PTB black shales and the other blackish sediments, and oceanic environmental conditions across the PTB.

The Distribution of the Ejecta Deposit derived from Australasian Tektite Event: Implication for the Location of the Impact

*Toshihiro Tada[1], Ryuji Tada[1,2], Paul Carling[3], Wickanet Songtham[4], Le Xuan Thuyen[5], Yu Chang, Eiichi Tajika[1]

1. Department of Earth and Planetary Science, 2. Yunnan University, 3. Geography and Environment, University of Southampton, 4. Northeastern Research institute of Petrified Wood and Mineral Resources, Nakhon Ratchasima Rajabhat University, 5. Ho Chi Minh City University of Science

Tektites are glass spherules formed by large extra-terrestrial impacts and so far reported from 4 strewn fields on the Earth (e.g, McCall, 2001). Australasian tektites—distributed widely from Southeast Asia to Antarctica—are considered to be formed by an impact event at ca. 0.79 Ma in Southeast Asia. This impact event is the youngest among large (diameter of a projectile larger than 1 km) impact events. Because of its young age, it is expected that evidence of the impact (impact crater and ejecta deposits) and the record of environmental perturbation by the impact are well preserved. Therefore, this impact event would serve as an important case study to understand the environmental effects of large impact events on the Earth.

Based on the wide distribution of the tektite—larger than 10% of the Earth’ s surface —the magnitude of the impact has been estimated as large enough to make 30–120 km sized impact crater (e.g., Prasad et al., 2007). The biggest mystery, however, is that no crater has been found and precise location and magnitude of the impact are not well understood.

The location of the impact has been estimated mainly based on the distribution of the tektites. The layered tektites, which are considered to be proximal to the source crater because of their large sizes (larger than 10 cm) and internal inhomogeneity, are distributed in the limited area in Thailand, Laos and Vietnam (Shnetzler, 1992). The number of microtektites per unit area in marine sediment cores decrease with the distance from Indochina peninsula (e.g., Prasad et al., 2007). Such distribution of tektites suggests that the location of the impact is somewhere in the eastern part of Indochina peninsula.

For more precisely constraining the location of the impact, the distribution of the ejecta deposit is important. The ejecta deposit, which is formed by deposition of materials ejected from the source crater, increases its thickness toward the location of the impact. It is also known that the abundance and size of shock-metamorphosed minerals in ejecta deposit increase towards the location of the impact (e.g., Morgan et al., 2006). The ejecta deposit of this impact event, however, has not been reported on the Indochina Peninsula.

In order to identify the ejecta deposit and clarify its distribution in the Indochina Peninsula, we have conducted field surveys in northeastern Thailand, central Vietnam, and southern Laos. We discovered shocked quartz grains—one of the most diagnostic evidence of impact—from the Quaternary sediment unconformably covering the basement rock, and identify the ejecta deposit at Huai Om section located near the border between northeastern Thailand and southern Laos. The ejecta deposit at Huai Om section can be divided into three units: silt–sand layers containing lip-up clasts of the basement rock (Unit 1, approximately 1 m in thickness), a tektite-bearing gravel layer (Unit 2, 20 cm–1 m in thickness), and a massive sand layer (Unit 3, approximately 3 m in thickness), in ascending order.

The tektite bearing gravel layer and the massive sand layer (corresponding to Units 2 and 3 at Huai Om

©2019. Japan Geoscience Union. All Right Reserved.

section) are distributed widely in the eastern part of Indochina Peninsula. Especially, the thickness of the tektite bearing gravel layer (Unit 2) increases toward the area around the southern part of the border between Thailand and Laos. We have measured abundance and size of shocked quartz grains at three sites in northeastern Thailand including Huai Om section. Although the size of shocked quartz grains is similar (approximately 200 μm) among these sites, its abundance varies between 5 and 10% and increases toward the area around the southern part of the border between Thailand and Laos. The distribution of the tektite-bearing gravel layer and abundance of shocked quartz grains indicate that the location of the impact is close to this area.
We are measuring the abundance and size of shocked quartz grains at additional sites in Thailand, Vietnam and Laos. In this presentation, we will report the distribution of the thickness of the ejecta deposit, abundance and size of shocked quartz in the eastern part of Indochina Peninsula to further constrain the location of the impact.

Tectonic-sedimentation reconstruction of Neoproterozoic metavolcanic sequences; the El-Dabbah area, Central Eastern Desert, Egypt

*Shoichi Kiyokawa[1], TAISHI SUZUKI[1], Maher Dawoud[3], El-Hasan Mohamed[3], Kenji Horie[2], Mami Takehara[2]

1. Department of Earth and Planetary Sciences Faculty of sciences, Kyuushu University, 2. National Institute of Polar Research, 3. Department of Geology, Faculty of Science, Menoufiya University,

In the Eastern Desert of Egypt, Neoproterozoic island arc sequence with Banded Iron Formations (BIFs) are reported within volcano-sedimentary sequence whose geological structure and stratigraphy are not well understood. In this study, the geological structure was established to reconstruct the stratigraphy in El Dabbah in the Central Eastern Desert.

It preserves a sequence of relatively undeformed lower greenschist-facies rocks, overlain by subaerial sedimentary strata deposited in strike-slip basins (the Atsham Formation and the Hammamat Group). Reconstructed a stratigraphic–tectonic history of this metavolcanic sequence is understand the Neoproterozoic iron formation stratigraphy and characteristics, which related snowball earth event or not. New geochronological data are used to date the crystallization of granite at *ca.*638.1±2.9 Ma and a rhyodacite at 659.6±3.0 Ma. Four generations of structural deformation have been identified in this area: accretional phase (D_1: 700–680 Ma); strike-slip deformation with transtension, normal faulting, and strong left-lateral shear after the Atsham Formation deposition (D_2: 650–640 Ma); and subaerial sedimentation of the Hammamat Group coincident with the activity of a strike-slip fault and formation of a pull-apart basin (D_3: 638–600 Ma) and followed by extensional deformation. Hear we show stratigraphic and structural interpretation in low grade metamorphosed sequence at the El-Dabbah area, in Central Eastern Desert in Arabian-Nubian Shield.

Wed. May 29, 2019 5:15 PM - 6:30 PM JST | Wed. May 29, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_35

[B-CG07] Decoding the history of Earth: From Hadean to the present

convener:Tsuyoshi Komiya(Department of Earth Science & Astronomy Graduate School of Arts and Sciences The University of Tokyo), Yasuhiro Kato(Department of Systems Innovation, Graduate School of Engineering, University of Tokyo), Katsuhiko Suzuki(Research and Development Center for Submarine Resources, Japan Agency for Marine-Earth Science and Technology)

The latest results of Earth's evolution and geological processes through 4.6 billion year
s from Hadean to Modern, based on various approaches including fieldworks, chemical
analyses, experiments and computer simulation, will be presented. In this session, we ai
m to discuss and understand causal relationships and interplay among the evolution of
Earth's deep interior, changes in the surface environments, and development and evolut
ion of life. Wide-ranging topics are accepted.

The Nuvvuagittuq supracrustal belt in the northeastern Canada is one of the oldest supracrustal rocks in the world, thus the geological, petrological and geochemical study allows us to constrain the evolution of surface environment and sold earth in the early earth. The belt consists of ultramafic rocks, coarse-graind and fine-grained greenstone, banded iron formation (BIF), siliceous rock, carbonate rock, and conglomerate. The ultramafic rocks and coarse-grained greenstone are considered as ultramafic and grabbroic intrusions, respectively. The fine-grained greensone is classified into three types based on the petrography: cummingtonite-bearing amphibolite (faux-amphibolite), hornblende-bearing amphibolite (green-amphibolite) and actinolite-bearing greenschist. The greenschist occurs only in the southwestern area. The faux- and green-amphibolite are ubiquitously present over the belt. Moreover, O'Neil et al. (2011) classified the amphibolite into three types based on their TiO_2 contents and REE patterns. The BIF mainly occurs in three areas, and has different occurrence and petrography. The BIF in the northwestern area is accompanied with the ultramafic rocks, and comprises interlayering of magnetite and amphibole/serpentine/talc. The BIF in the southwestern area occurs together with fine-grained greenstone, and mainly contains hematite and quartz (jaspillite). Dodd et al. (2017) found possible biogenic fabric, formed by iron-oxiding bacteria in the jaspillite. The BIF in the southeastern part is interlayered with the faux-amphibolite, and occurs above the siliceous rock. It mainly comporises magnetite and quartz.

The belt is intruded by some precursors of orthogneiss, whose igneous ages of *ca.* 3.8 Ga and constrain the minimum age of the belt. O'Neil et al. (2008, 2012) proposed that the igneous age of the fine-grained amphibolite is *ca.* 4.38 Ga based on a putative $^{147}Sm/^{144}Nd$-$^{142}Nd/^{144}Nd$ isochron age. On the other hand, Cates et al. (2013) proposed that a felsic layer within the faux-amphibolite originates from a clastic felsic sedimentary rock, and the maximum age of the belt is *ca.* 3.78 Ga based on ages of the zircons. David et al. (2009) interpreted a felsic layer as a volcanosedimentary rock, and proposed that the supracrustal rock was formd at 3817 Ma based on the ages of zircons.

We made a quite detailed geological map using a drone, which enables easily to trace even tens centimeter layers and intrusions. Many tens centimeter thick intrusions with an intermediate composition are present in the faux-amphibolite, whereas no intrusions are apparently found in the green-amphibolite. The distribution of the two types of amphibolite corresponds to that of three geochemical types of greenstone proposed by O'Neil et al. (2011), suggesting that the geochemical signature is due to secondary alteration. In addition, the apparent isochron on the $^{147}Sm/^{144}Nd$-$^{142}Nd/^{144}Nd$ diagram possibly originates from mixing between the mafic/ultramafic component and secondary intermediate component. O'Neil et al. (2008) proposed that the Nd isochron age of gabbroic dikes is 4.3 Ga. But, the gabboric dikes are younger than 3.8 Ga, and the isochron is putative because our map clearly shows that some thin gabbroic dikes are intruded into ambient orthogneiss, whose age is *ca.* 3.8 Ga. We found many conglomerate layers over the belt, but the layers finally change felsic intrusions. The occurrence means that they are putative conglomerate. In addition, the carbonate rocks occur along the felsic intrusions,

©2019. Japan Geoscience Union. All Right Reserved.

suggesting they also have metasomatic origin. The petrograhy and occurrence of the BIF in the northwestern area indicate that the BIF was formed from metamorphism of the ultramafic rock. The siliceous rock is intruded by many felsic intrusions and quartz veins, but the detailed map can differentiate between the siliceous layers and intrusions, and shows that the siliceous layers originate from siliceous sediment.

Behavior of phosphorus during hydrothermal alteration of basalt under CO_2-rich condition

*Aoi Murakami[1], Yusuke Sawaki[2], Hisahiro Ueda[3], Yuji Orihashi[4], Shiki Machida[5], Tsuyoshi Komiya[2]

1. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, 2. The University of Tokyo, 3. Tokyo Institute of Technology, 4. Hirosaki University, 5. Chiba Institute of Technology

It is well known that a unique environment is created around seafloor hydrothermal systems by element exchange between circulating seawater and surrounding rocks: enrichment in transition elements and sulfide, emission of quite hot water, and even even electric current flow. In addition, a number of hyperthermophilic microorganisms inhabit around hydrothermal vents. 16S rRNA-based phylogenetic tree suggests that the hyperthermophilic organisms are closest to the earliest lineage; thus the hydrothermal environment is one of the candidates for habitat and evolution of early life.

Phosphorus is one of essential elements for life. In order to maintain an early ecosystem around the hydrothermal vent, phosphorus should have been supplied from the hydrothermal vent through high-temperature water-rock reaction. In the modern basalt-hosted hydrothermal systems, phosphorus is removed due to its adsorption to iron oxide precipitated from hydrothermal fluid and/or formation of metamorphic apatite in the hydrothermally metamorphosed basalt. On the other hand, it is well known that middle Archean basaltic rocks, which constituted upper part of oceanic crust, suffered from severe carbonation during hydrothermal alteration due to quite high atmospheric CO_2 content on the early Earth. Under the CO_2-rich condition, calcium was removed from the seawater/hydrothermal fluid due to extensive carbonate formation. Because the carbonate formation inhibits the formation of apatite, the phosphorus might be released from hydrothermally altered rocks. Actually, the hydrothermally altered basaltic rocks in the Archean are more depleted in phosphorus than hydrothermally altered modern mid-ocean ridge basalt.

In order to quantify phosphorus content of fluid supplied from the basalt-hosted hydrothermal system on the early Earth, we conducted hydrothermal experiments involving hypothetical seawater and basalt under both CO_2-free and CO_2-rich conditions at 200 ˚C, 100 bars. The basalt used in this study was collected from the Indian Ocean Marie Celeste Fracture Zone. The initial solution was prepared by mixture of standard reagents by reference to modern seawater, except for Ca and P. The calcium and phosphorus contents in the solution were regulated to 30 mmol/kg and 0.60 ppm, respectively. The latter is ten times higher than the modern equivalent. For the CO_2-rich experiment, $NaHCO_3$ and HCl were added to the hypothetic seawater to substantialize 400 mmol/kg of ΣCO_2 at the beginning of the experiment.

The CO_2 concentration decreased from 400 mmol/kg to 250 mmol/kg as water-rock reaction advanced, indicating precipitation of carbonate minerals. The SEM-EDS observation demonstrated that the run

©2019. Japan Geoscience Union. All Right Reserved.

products contain calcite, dolomite, and magnesite. Phosphorus content of the fluid decreased to *ca.* 0.10 ppm under the CO_2-rich condition and *ca.* 0.04 ppm under the CO_2-free condition, respectively. The pH value of the produced fluid for the CO_2-rich experiment, measured at room temperature, was 6.6, by *ca.* 2 unit higher than that of the CO_2-free experiment. Calcium concentration decreased from 30 mmol/kg to 25 mmol/kg under the CO_2-free condition. On the other hand, calcium concentration of the formed fluid under the CO_2-rich condition decreased to 18 mmol/kg at 96 hours, and then increased to 25 mmol/kg. The formation of high alkaline and Ca-poor fluid under the CO_2-rich condition suggests that the fluid was oversaturated with carbonate, whereas undersaturated with apatite. Because the produced fluid under the CO_2-rich condition contained more phosphorus than the modern seawater, the basalt-hosted hydrothermal system may have served as a source of phosphorus under the CO_2-rich condition, probably on the early earth.

Origin of chromitites in the Akulleq terrane, southern West Greenland

*Kanta Takahashi[1], Tomoaki Morishita[1], Juan Miguel Ramirez Guotana[1], Kenichiro Tani[2], Yumiko Harigane[3], Ikuya Nishio[1], Kristoffer Szilas[4], Akihiro Tamura[1]

1. Kanazawa University, 2. Department of Geology and Paleontology, National Museum of Nature and Science, 3. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST), 4. University of Copenhagen

The studies dealing with the Hadean-Archaean geologic samples are recently expanding. Research on Hadean-Archaean terranes is an important part in reconstructing the geologic past of the Earth which is thought to have differences from the present conditions. Southern West Greenland preserves a wide exposure of ancient geologic materials and structures. This study focuses on chromitites and peridotites from the Ujaragssuit nunāt area in southern West Greenland. The Ujaragssuit nunāt area is about 20 km south from the 3.8 Ga Isua Supracrustal Belt (Moorbath et al., 1977). In Ujaragssuit nunāt, ultramafic rocks occur as lenses of several meters to several hundred meters hosted in silicic gneiss (Chadwick and Crewe, 1986). It is important to understand the origin and processes related to the formation of the peridotites and chromitites in Ujaragssuit nunāt as a contribution to the Archaean magmatic processes and tectonics of the early Earth.

Chromitites are rocks with significant amount of chromites (>20 vol.%) (Arai and Miura, 2016). The unaltered composition of spinel is regarded as a useful petrological indicator (Irvine, 1967). However, chromite composition could be modified as a result of chemical re-equilibration, metamorphism, hydrothermal alteration. The impacts of these processes are evaluated in this study. In Ujaragssuit nunāt, chromitites, dunites and amphibole harzburgites are widely exposed. In some areas, the chromitites occur as layers with thickness ranging from several centimeters to a meter. Massive chromitites (2 m thick) are also exposed. The lithologies present in the area were also described in detail in previous works such as of Rollinson et al. (2002).

Chromites are subhedral and account for about 50-70% of the Ujaragssuit nunāt chromitites. Interstitial grains are mainly phlogopite and minor chlorite and talc. The dunite host consists mainly of olivine (~80%) and accessory spinel and phlogopite. Some spinel grains in the host dunite exhibit zonation as evidenced by darker cores and lighter rims under reflected light microscope and scanning electron microscope observations. The zonation observed is associated with compositional variation from core to rim (Fe enrichment towards the rim). The amphibole harzburgites are mainly composed of amphibole, orthopyroxene, spinel, phlogopite. Orthopyroxenes occur both around olivine and in some parts as inclusions inside olivine grains. Talc replacement of orthopyroxenes is also common. Spinel are surrounded by phlogopite and edenitic amphibole.

Spinel in the host peridotites has a higher Fe^{3+}content. The spinel Fe^{3+} content is higher in samples with higher phlogopite and spinel ratio. This suggests that phlogopite was formed by the reaction of spinel (+olivine) with an alkaline element-rich fluid. Spinel serves as a source of the Al_2O_3 in the phlogopite formation. It is considered that the chemical composition change of spinel is caused by the formation of phlogopite. Furthermore, phlogopite in the sample containing amphiboles has lower K/(K+Na) ratio than samples without amphibole. Amphiboles are also found around the spinel. The K/(K+Na) ratio in the fluid decreases as the alkaline element-rich fluid forms phlogopite and amphibole was formed by the reaction between this differentiated fluid and spinel (+olivine). The abundance of orthopyroxene is higher in the

©2019. Japan Geoscience Union. All Right Reserved.

sample containing amphiboles. The Cr_2O_3- and Al_2O_3- poor characteristic of the orthopyroxenes suggests a secondary origin. The differentiated fluid is also abundant in silica component and reacts with olivine to react to form the secondary orthopyroxenes. Although the possibility of crystal differentiation cannot be completely ruled out, it is thought that these peridotites were originally dunites and chromitites and the chemical composition was modified by alkali alteration.

Metamorphic P–T condition of the Inyoni shear zone rocks in the Barberton Greenstone Belt, South Africa and its significance

*Daichi Kato[1], Kazumasa Aoki[1], Yuta Tsuchiya[2], Shogo Aoki[2], Tsuyoshi Komiya[3]

1. Department of Applied Science,Okayama University of Science, 2. Department of Biosphere-Geosphere Science,Okayama University of Science, 3. Department of Earth Science and Astronomy,University of Tokyo

The metamorphic P–T conditions and processes of the mid-Archean Barberton Greenstone Belt (BGB), South Africa were examined from metamorphosed banded iron formation (BIF) and garnet amphibolite in the Inyoni shear zone (ISZ). Their metamorphic P–T conditions were estimated from thermodynamic calculations combined with several geothermobarometries such as garnet–clinopyroxene geothermometry, Raman geobarometry and Zr-in-sphene geothermometry. Moreover, in order to constrain the protolith age and origin of our studied sample, we conducted zircon U-Pb and trace elements analyses by using Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS).The following results were obtained: the P–T conditions of the meta-BIF changed from ca. 600–680 ˚C and 10–12.7 kbar through ca. 510–540 ˚C and 8–11 kbar to less than 500 ˚C and 4 kbar. On the other hand, the P–T conditions of the garnet amphibolite changed from ca. 9.5–10.5 kbar and 620–660˚C to less than 5 kbar and 500 ˚C. Integration of these new results with previous studies for the BGB suggest that the geothermal gradients of the prograde and retrograde metamorphisms were ca. 15–20 ˚C/km and 20–30 ˚C/km, respectively. Igneous zircon separated from the Garnet amphibolite sample yield ^{207}Pb-^{206}Pb age of ca. 3.4-3.2 Ga. This new data together with previous geochronological data indicate that the protoliths of ISZ rocks began to subduct at ca. 3.37-3.24 Ga. The prograde P-T path was kinked at P = 8.0 kbar and T = 560 ℃ by difference in geothermal gradient between crust and upper mantle. The change of geothermal gradient in the ISZ rocks between prograde and retrograde conditions might have relation to the collision of ca. 3.4 Ga Stoluzburg domain. The last P-T trajectory characterized by isothermal decompression might be caused by the intrusion of the ca. 3.23-3.21 Ga TTG Badplaas pluton attendant on plate subduction.

Discovery of possible traces of asteroid impact within the fossil-bearing carbonaceous chert from the 3.4 Ga Strelley Pool Formation, Pilbara Craton of Western Australia - a preliminary study

*Kenichirio Sugitani[1], Ryoko Senda[3], Tsuyoshi Iizuka[2], Simon Wallis[2]

1. Nagoya University, 2. The University of Tokyo, 3. Kyushu University

Large asteroid impacts are thought to be a common feature of the Archean in particular as a result of the Late Heavy Bombardment (LHB). One line of supporting evidence is the presence of “impact layers” containing silicate spherules that were formed by condensation of rocks vaporized by bombardment events. Two Early Archean impact layers with ages of 3.47 and 3.46 Ga have been identified from the Pilbara greenstone belt, Western Australia (Glikson et al., 2016; Lowe and Byerly, 1986). In contrast 5 separate impact layers with ages of 3.47 to 3.24 Ga have been identified in the Barberton greenstone belt, South Africa (e.g., Lowe et al., 2014; Byerly et al., 2002). Such extraterrestrial impacts likely influenced the Earth’s early environment, including crustal deformation, terrain amalgamation, evaporation of significant volumes of ocean water, and even triggering the development of a modern-like plate tectonic regime (Lowe et al, 2014). It is also reasonable to assume that the early life was influenced significantly by these impacts (Lowe et al., 2003). The early evolution of life might have been accelerated as a consequence of adaptation to such environmental agitations (Kozawa et al., 2018; Oehler et al., 2017). Thus, a close association of traces of life, such as microfossils with cellular preservation, and of impact events recorded in Archean sedimentary successions is of special interest.

In this study we describe the new discovery of traces of asteroid impacts in the ca. 3.4 Ga Strelley Pool Formation (SPF) in the Panorama greenstone belt of the Pilbara Craton, Western Australia. Spherules of possible impact origin were identified in carbonaceous black chert 15 cm thick from which morphologically diverse microfossils have been described (e.g., Sugitani et al., 2013) (Fig. 1). Evidence for an asteroid impact includes the presence of a thin sedimentary layer rich in silicate spherules (Fig. 2) associated with enrichment of platinum-group elements (PGE) (Fig. 3a). However, our detailed analyses revealed that PGE-enrichment is more conspicuous in the lower horizon and are associated with $^{178}Os/^{188}Os$ initial values close to 0.1. In contrast, spherule-rich layers have significantly higher $^{178}Os/^{188}Os$ values ~1.0 (Fig. 3b). One exception is a sample from the upper portion, which has an unusually low value. It is also noteworthy that the spherule-rich layer is enriched in Al and Ti (Fig. 3c). There is a clear higher contribution by clastic materials to this layer, and this feature may explain the apparent contradiction between the PGE-enrichment and Os isotopic values described above. In either case, the layer contains abundant volcanic fragments and clasts in which spherules tend to occur. This occurrence suggests that the spherules were likely reworked from the original site of deposition. A layer composed of carbonaceous grains including rip-up clasts that is found just below the spherule-rich layer (Fig. 1) indicates a steep high-energy depositional environment. This layer contrasts with the fine parallel lamination of carbonaceous chert layers seen at the other horizons, which indicates a quiet depositional environment. We infer that the original impact layer is present below the examined carbonaceous black chert layer and that a high-energy environment related to volcanic activity caused reworking of the spherule-rich deposits, which were transported to the present site of deposition. If this is the case, the high PGE concentrations and the significantly low $^{187}Os/^{188}Os$ initial ratios of the lower cherty samples could be explained as representing the aftermath of an impact event associated with precipitation of vaporized PGE from the atmosphere to the sediment.

Biogeochemical dynamics in during the Great Oxidation Event constrained by a biogeochemical cycle model

*Yuna Miura[1], Kazumi Ozaki[1]

1. Toho University

The accumulated geological and geochemical data indicate that Earth's ocean-atmosphere system has seen a fundamental increase in oxygen abundances from anoxic conditions (pO_2 <10^{-5} present atmospheric level (PAL)) to oxic conditions (pO_2 >10^{-2} PAL) during the Paleoproterozoic. This marked transition, known as the 'Great Oxidation Event (GOE)', may be accompanied by a transient time of relatively high oxygen levels in the atmosphere and ocean (called an 'oxygen overshoot'). However, the ultimate cause and biogeochemical consequences of the GOE remain unclear.
Harada et al. (2015) hypothesized the snowball Earth glaciation at 2.2 Ga as an ultimate cause of the GOE with a prolonged (~10^8 year) oxygen overshoot. Sedimentary record of iron and manganese oxides above the glacial deposit in the Transvaal Supergroup, South Africa, implies an oxygenation of Earth's surface environments just after the glaciation. The red beds and sulfate evaporites (gypsum, $CaSO_4$) also suggest a sustained oxygenation of the Earth surface environment. They constructed a biogeochemical cycle model of carbon, phosphorous and oxygen, and conducted sensitivity experiments to assess the biogeochemical dynamics after the snowball Earth glaciation. By assuming an atmospheric CO_2 level of 0.7 atm required to end the snowball Earth glaciation, they found that an extremely warm climate accelerates chemical weathering on land and phosphorus riverine input. This marked increase in phosphorus input results in a dramatic increase in biospheric oxygen production, with an oxygen overshoot lasting for ~10^8 years. However, it remains unclear whether their calculations are consistent with available geological constraints (e.g., sulfate evaporite depositions and sulfur isotope data), because they ignore the geochemical cycle of sulfur. A recent geochemical study suggests that concentration of sulfate ($[SO_4^{2-}]$) in the ocean may have been unusually high (>10 mM) during the gypsum formation. If correct, this provides a strong constraint on the biogeochemical conditions.
In this study we constructed a sulfur cycle model with a goal of finding the feasible conditions for the geochemical constraint ($[SO_4^{2-}]$ >10 mM). The model consists of three reservoirs—oceanic sulfate, crustal gypsum, and crustal pyrite. Sulfur enters the ocean through weathering of gypsum and pyrite. We assumed that the oxidative weathering of pyrite is a function of atmospheric O_2 levels and that the gypsum weathering is proportional to the global weathering rate. Sulfur is removed from the ocean via deposition of gypsum and pyrite. We assumed that sulfate burial in the ocean is proportional to seawater sulfate levels. Pyrite burial is assumed to be governed by microbial sulfate reduction dependent on marine sulfate content, biological production (i.e., the availability of organic matter), and oceanic O_2 levels. In this study, we performed a series of sensitivity experiment with a Harada et al.'s model, and obtained biogeochemical dynamics (e.g., atmospheric O_2 levels and weathering rates) were used as a forcing for our sulfur cycle model, enabling us to simulate the evolution of oceanic SO_4^{2-} levels after the glaciation. Our sensitivity experiments of a Harada et al.'s model demonstrate that the biogeochemical dynamics after the glaciation depend mainly on the initial value of atmospheric CO_2 levels: >0.2 bar and >0.25 bar of CO_2 are required for the GOE and the occurrence of an oxygen overshoot, respectively. Our sulfur cycle model, however, demonstrates that 0.25 bar of CO_2 is not sufficient to explain the unusually high levels of $[SO_4^{2-}]$ >10 mM during the overshoot. The systematic sensitivity experiments reveal that at least ~0.75 bar of CO_2 will be required. This result provides an additional support for the hypothesis that the severe glaciation was an ultimate cause of the GOE in the Paleoproterozoic.

Composition of seawater before the Sturtian Snowball Earth estimated by the occurrence of late Tonian evaporitic magnesite

*Aya Miyazaki[1], Akihiro Kano[1], Fumito Shiraishi[2]

1. Department of Earth and Planetary Science, The University of Tokyo, 2. Department of Earth and Planetary Systen Sciences, Hiroshima University

Neoproterozoic is an important period for biological evolution when the spread of algae, protozoan, and multicellular animal were radiated. Understanding of climate changes and fossil records after Ediacaran has been largely improved. But environmental background behind how the Earth’ s surface reached the Snowball Earth state has not been understood.
In Flinders Ranges, South Australia, thick shallow marine sequence preserves excellent geological records especially before and after Sturtian glaciation. This study targets Skillogalee Dolomite exposed at Leigh Creek, Northern Flinders Ranges (LC section) which was deposited around 788±7Ma(Late Tonian) before the Sturtian glaciation (Hood and Wallace 2018). The lithology of LC section contains a small amount of siliciclastics, but mainly consists of shallow water carbonate that exhibits various structures including intraformational conglomerate, stromatolite and tepee structure. However, the most remarkable feature is a large quantity of magnesite. Magnesite alternates with dolostone and occurs as layers of ~1m in thickness or crusts of intraformational conglomerate. The Tepee structure indicates an evaporative environment, and higher d13C and d18O of magnesite indicates that the magnesite deposited after the dolomite. These rocks lack gypsum pseudomorphs.
Evaportive mineral assemblage of the Skillogalee Dolomite can be recognized only in Proterozoic. While the Phanerozoic evaporate sequence starts from Ca carbonate-dolomite, follows to gypsum and halite, but does not include magnesite (Hardie and Eugster 1980). In order to explain this specific mineral assemblage, we made model calculations about the order of precipitated minerals, which expected by continuous evaporation of seawater. Then, we found the Skillogalee mineral sequence was achieved only from seawater of Mg/Ca > 10 and Mg > Alkalinity > Ca. We used sulfate concentration of the modern seawater, but it does no influence to the result. Alkalinity over 10 times higher than the modern level likely reflects from high partial pressure of carbon dioxide or low Ca concentration in seawater. Possible causes of high Mg/Ca ratio were inactive seawater circulation at low mid-ocean ridge, active carbonate sedimentation, or Ca depletion due to extensive evaporite formation including gypsum around 800 Ma. If pH of seawater has been controlled by the solubility equilibrium of CaCO3, the drastic decrease in Ca concentration would encouraged pH rise of sea water and lead to decline of atmospheric carbon dioxide.

Geochemical characteristics of black shales in the Japanese accretionary complex across the Permian-Triassic boundary extracted by independent component analysis

*Moei Yano[1], Kazutaka Yasukawa[1,3], Koichiro Fujinaga[3,2], Kentaro Nakamura[1], Yasuhiro Kato[2,1,3]

1. Department of Systems Innvation, School of Engineering, The University of Tokyo, 2. Frontier Research Center for Energy and Resources, School of Engineering, The University of Tokyo, 3. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology

The Permian-Triassic boundary (PTB) is characterized by an oxygen-depleted condition in the superocean Panthalassa. However, the degree of the oxygen depletion in deep-sea environments remains an open question.Deep-sea sediments that deposited from the latest Permian to early Triassic constitute black shale within the accretionary complexes of Japan, showing a distinct enrichment of redox sensitive trace metals (e.g., V, Mo, U) that precipitate under reducing conditions.In contrast to the Panthalassa at the PTB, the modern ocean is generally oxygenated from the surface to the bottom due to a sufficiently strong global ocean circulation. However, oxygen-depleted water masses can develop in some specific areas such as restricted basins and coastal upwelling areas, and blackish sediments in these areas show laminated facies and/or high total organic carbon contents reflecting oxygen-depleted conditions.Comparing the black shales at the PTB with the other sediments that deposited in oxygen-depleted conditions can characterize the Panthalassa across the PTB in a context of a broad spectrum of oceanic environmental changes throughout the Earth’ s history. To this end, clarifying geochemical features of multiple elements, especially of redox sensitive trace metals, is quite a useful approach to extract the information of the oceanic environments involving variations in redox conditions. Here we applied independent component analysis to the multi-elemental data set composed of major- and trace-element contents of the samples from the PTB sections within the accretionary complexes of Japan, and black mud and shale of other geological times obtained by scientific drillings in the modern oceans. We will discuss the geochemical characteristics of the PTB black shales and the other blackish sediments, and oceanic environmental conditions across the PTB.

The Distribution of the Ejecta Deposit derived from Australasian Tektite Event: Implication for the Location of the Impact

*Toshihiro Tada[1], Ryuji Tada[1,2], Paul Carling[3], Wickanet Songtham[4], Le Xuan Thuyen[5], Yu Chang, Eiichi Tajika[1]

1. Department of Earth and Planetary Science, 2. Yunnan University, 3. Geography and Environment, University of Southampton, 4. Northeastern Research institute of Petrified Wood and Mineral Resources, Nakhon Ratchasima Rajabhat University, 5. Ho Chi Minh City University of Science

Tektites are glass spherules formed by large extra-terrestrial impacts and so far reported from 4 strewn fields on the Earth (e.g, McCall, 2001). Australasian tektites—distributed widely from Southeast Asia to Antarctica—are considered to be formed by an impact event at ca. 0.79 Ma in Southeast Asia. This impact event is the youngest among large (diameter of a projectile larger than 1 km) impact events. Because of its young age, it is expected that evidence of the impact (impact crater and ejecta deposits) and the record of environmental perturbation by the impact are well preserved. Therefore, this impact event would serve as an important case study to understand the environmental effects of large impact events on the Earth.

Based on the wide distribution of the tektite—larger than 10% of the Earth’ s surface —the magnitude of the impact has been estimated as large enough to make 30–120 km sized impact crater (e.g., Prasad et al., 2007). The biggest mystery, however, is that no crater has been found and precise location and magnitude of the impact are not well understood.

The location of the impact has been estimated mainly based on the distribution of the tektites. The layered tektites, which are considered to be proximal to the source crater because of their large sizes (larger than 10 cm) and internal inhomogeneity, are distributed in the limited area in Thailand, Laos and Vietnam (Shnetzler, 1992). The number of microtektites per unit area in marine sediment cores decrease with the distance from Indochina peninsula (e.g., Prasad et al., 2007). Such distribution of tektites suggests that the location of the impact is somewhere in the eastern part of Indochina peninsula.

For more precisely constraining the location of the impact, the distribution of the ejecta deposit is important. The ejecta deposit, which is formed by deposition of materials ejected from the source crater, increases its thickness toward the location of the impact. It is also known that the abundance and size of shock-metamorphosed minerals in ejecta deposit increase towards the location of the impact (e.g., Morgan et al., 2006). The ejecta deposit of this impact event, however, has not been reported on the Indochina Peninsula.

In order to identify the ejecta deposit and clarify its distribution in the Indochina Peninsula, we have conducted field surveys in northeastern Thailand, central Vietnam, and southern Laos. We discovered shocked quartz grains—one of the most diagnostic evidence of impact—from the Quaternary sediment unconformably covering the basement rock, and identify the ejecta deposit at Huai Om section located near the border between northeastern Thailand and southern Laos. The ejecta deposit at Huai Om section can be divided into three units: silt–sand layers containing lip-up clasts of the basement rock (Unit 1, approximately 1 m in thickness), a tektite-bearing gravel layer (Unit 2, 20 cm–1 m in thickness), and a massive sand layer (Unit 3, approximately 3 m in thickness), in ascending order.

The tektite bearing gravel layer and the massive sand layer (corresponding to Units 2 and 3 at Huai Om

©2019. Japan Geoscience Union. All Right Reserved.

section) are distributed widely in the eastern part of Indochina Peninsula. Especially, the thickness of the tektite bearing gravel layer (Unit 2) increases toward the area around the southern part of the border between Thailand and Laos. We have measured abundance and size of shocked quartz grains at three sites in northeastern Thailand including Huai Om section. Although the size of shocked quartz grains is similar (approximately 200 μm) among these sites, its abundance varies between 5 and 10% and increases toward the area around the southern part of the border between Thailand and Laos. The distribution of the tektite-bearing gravel layer and abundance of shocked quartz grains indicate that the location of the impact is close to this area.
We are measuring the abundance and size of shocked quartz grains at additional sites in Thailand, Vietnam and Laos. In this presentation, we will report the distribution of the thickness of the ejecta deposit, abundance and size of shocked quartz in the eastern part of Indochina Peninsula to further constrain the location of the impact.

Tectonic-sedimentation reconstruction of Neoproterozoic metavolcanic sequences; the El-Dabbah area, Central Eastern Desert, Egypt

*Shoichi Kiyokawa[1], TAISHI SUZUKI[1], Maher Dawoud[3], El-Hasan Mohamed[3], Kenji Horie[2], Mami Takehara[2]

1. Department of Earth and Planetary Sciences Faculty of sciences, Kyuushu University, 2. National Institute of Polar Research, 3. Department of Geology, Faculty of Science, Menoufiya University,

In the Eastern Desert of Egypt, Neoproterozoic island arc sequence with Banded Iron Formations (BIFs) are reported within volcano-sedimentary sequence whose geological structure and stratigraphy are not well understood. In this study, the geological structure was established to reconstruct the stratigraphy in El Dabbah in the Central Eastern Desert.

It preserves a sequence of relatively undeformed lower greenschist-facies rocks, overlain by subaerial sedimentary strata deposited in strike-slip basins (the Atsham Formation and the Hammamat Group). Reconstructed a stratigraphic–tectonic history of this metavolcanic sequence is understand the Neoproterozoic iron formation stratigraphy and characteristics, which related snowball earth event or not. New geochronological data are used to date the crystallization of granite at *ca.*638.1±2.9 Ma and a rhyodacite at 659.6±3.0 Ma. Four generations of structural deformation have been identified in this area: accretional phase (D_1: 700–680 Ma); strike-slip deformation with transtension, normal faulting, and strong left-lateral shear after the Atsham Formation deposition (D_2: 650–640 Ma); and subaerial sedimentation of the Hammamat Group coincident with the activity of a strike-slip fault and formation of a pull-apart basin (D_3: 638–600 Ma) and followed by extensional deformation. Hear we show stratigraphic and structural interpretation in low grade metamorphosed sequence at the El-Dabbah area, in Central Eastern Desert in Arabian-Nubian Shield.

[M-IS07] Astrobiology

convener:Hikaru Yabuta(Hiroshima University, Department of Earth and Planetary Systems Science), Seiji Sugita(Department of Earth and Planetary Science, Graduate School of Science Sciece, The University of Tokyo), Misato Fukagawa(National Astronomical Observatory of Japan), Fujishima Kosuke(Tokyo Institute of Technology, Earth-Life Science Institute), Chairperson:Misato Fukagawa(名古屋大学大学院 理学研究科), Kosuke Fujishima(ELSI 地球生命研究所)

Twenty years have passed since when the field of Astrobiology, which aims to unveil the origins, evolution, and habitability of life by integrating multidisciplinary fields, was established. Individual themes related to Astrobiology, such as chemical evolution in the early Solar System, formation of planetary system, prebiotic chemistry in the early Earth, evolution of life in the Earth's history, extremophile, and habitable planetary environments, has been studied by the knowledge and methods from the multiple fields, which has enabled us to explain "Where we came from" in some ways. However, despite an overwhelming number of investigations and discussions through gathering of the scientists from different fields, there has remained the long-standing unsolved question: How did abiotic materials gain biological function in the Earth and elsewhere in universe? There is still a large gap between prebiotic organic chemistry and biochemistry toward Origins of Life and planetary habitability. Therefore, the JpGU Astrobiology session focuses on pathfinding of "integration of astronomy, geoscience, and biochemistry", which will face an increasing need for the future Astrobiology. In order to enhance our understanding of "What is life", we propose to discuss the biochemical events linked with planetary systems, which is beyond the knowledge in a test tube, by an integration of exoplanets and molecular biology, etc. Through this approach, we will lead the discussions and developments of life-detection strategies for the future exploration of life in universe.

Twenty-three pairs of silica aerogels and aluminum covers consisted of the Tanpopo capture panels were optically investigated and over 200 hypervelocity impacts signatures were identified and documented for further detailed analyses.
Among them, a low Ca-pyroxene micrometeoroid was captured intact inside the 10mg/cc density silica aerogel. In particular, we compared these data from both space and ram pointing faces of the Tanpopo panels exposed on the International Space Station for deducing meteoroid impact flux by taking into account of effects of local shielding and secondary ejecta impacts. This direct measurement showed that the micrometeoroid impact flux in low Earth orbit in 2015-7 are generally consistent with the previous post-retrieval measurements of LDEF, EuReCa, and SFU in 1980’s to 1990’s.

Growth and transport of dust, ice, and organics in the inner part of protoplanetary disks

*Satoshi Okuzumi[1]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology

Dust grains in protoplanetary disks are the fundamental building blocks of planets. Although recent radio interferometric observations have provided us with detailed images of gas and dust in the outer part of protoplanetary disks, it is still poorly understood how solids evolve in the warmer inner regions of the disks. Understanding the physics of gas and dust evolution in the inner part of disks is thus essential to address the question of how Earth-like planets form.

In this talk, I will discuss two topics on the growth and transport of solids (silicates, ices, and organics) in inner protoplanetary disks. The first topic is related to the water content of planets in the habitable zones. Models of protoplanetary disks suggest that the snow line in the dusty disks migrates with time. In the particular case of the solar nebula, the snow line could have moved to the current orbit of Venus in a late stage of its evolution. This raises the question of why the Earth today is so "dry" with the bulk water content of much less than 1 wt%. I will present simulations of ice pebble accretion by terrestrial planetary embryos, showing that Mars-sized rocky embryos would have grown into Neptune-sized waterworlds unless either the solar nebula was compact or a gas giant's core formed early and blocked the inward flux of the ice pebbles. I will also present the results of our latest MHD simulations of protoplanetary disks that imply that the snow line can migrate much faster than expected from the classical accretion model. These results indicate that Earth-like, modestly "water-poor" planets with both oceans and continents do not necessarily form easily in habitable zones.

The second topic is related to the role of organics in the formation of rocky planetesimals. It is widely accepted that silicate grains are poorly sticky and their growth into planetesimal-sized bodies is severely hindered by collisional fragmentation. Here I propose a scenario in which the seeds of rocky planetesimals form through direct coagulation of silicates coated by an organic mantle, like those found in interplanetary dust particles. Our adhesion model for core-mantle particles show that organic-mantled grains are much stickier than bare silicate grains, in particular in warm environments, thanks to the low elasticity of organic matter. I present simulations of the collisional evolution of organic-mantled grains in the inner part of protoplanetary disks, demonstrating that aggregates of organic-mantled grains are able to overcome the fragmentation barrier and directly form km-sized bodies. These organic-rich planetesimals may further evolve into carbon-poor rocky planetesimals by accreting carbon-poor chondrules.

Model Prediction of Complex Organic Molecules in Protoplanetary Disks

*Hideko Nomura[1], Catherine Walsh[2], Tom J. Millar[3]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. School of Physics and Astronomy, University of Leeds, 3. School of Mathematics and Physics, Queen’ s University Belfast

Protoplanetary disks are the natal place of planets. Understanding chemical components of gas, dust and ice in the disks is essential to investigate the origins of materials in our Solar system and other planetary systems. We investigate the synthesis of complex organic molecules (COMs) in protoplanetary disks using a large gas-grain chemical network including COMs together with a 2D steady-state physical model of a disk irradiated by UV and X-rays from the central star. COMs are efficiently formed on cold and warm grains in the disk midplane via hydrogen adding as well as radical-radical reactions on grain surface. Radiation processing on ice forms reactive radicals and helps build further complexity. Part of the icy molecules are photodesorbed into gas and their transition lines become observable. Actually, ALMA observations have detected CH3CN and CH3OH from protoplanetary disks. The line emitting region of these molecules are the outer relatively cold disk, which suggests that the molecules are non-thermally desorbed from grains following the formation on dust garains. Based on our model calculations, we perform ray-tracing calculations to predict line spectra of complex organic molecules observable with SPICA. Also, we discuss possible connection of COMs in protoplanetary disks to those in the Solar system objects, such as comets.

Abiotic synthesis of organic matters in environments simulating asteroids and the catalytic effect of minerals on amino acid formation

*Walaa Elmasry[1], Yoko Kebukawa[1], Kensei Kobayashi[1]

1. Yokohama National University

Solar system materials, such as comets, meteorites, and interplanetary dust particles are known to contain extraterrestrial molecules, which might have a heritage from interstellar, nebular, and/or parent body processing. Delivery of these molecules including amino acids to the early Earth may have been important for the origin of life as they are the building blocks of proteins and enzymes. It is suggested that chondritic organic matter was produced through condensation of interstellar formaldehyde, which is an abundant component of the interstellar medium (ISM) organic inventory and, presumably, the solar nebula followed by condensation and carbonization probably during hydrothermal alteration on chondritic asteroids (Cody et al 2011). According to Kebukawa et al. (2013, 2015), the presence of ammonia significantly enhances the formation of organic solids similar to chondritic insoluble organic matter (IOM) from formaldehyde via the formose reaction at 150˚C and could produce amino acids. Carbonaceous chondrites contain abundant clay minerals. Clays may act as absorbents and catalysts for the polymerization of organic interstellar precursor molecules in the early solar system (Pearson et.al 2002).

In this research, we are studying amino acid formation from formaldehyde and ammonia at 150˚C and reveal the expected effect of minerals, namely, montmorillonite clay, olivine and serpentine to simulate the processes of amino acid productions in water-bearing planetesimals.

We synthesized organic compounds using a mixture of water, formaldehyde and ammonia (H_2O, H_2 CO, NH_3) in a ratio of 100:7:1 (mol) with adding minerals (6 mg/ 0.6 mL solution) by simulating primordial materials in comets and asteroids. Aqueous solutions were heated at 150˚C for 24 hours. The resulted products were divided into two parts, the first analyzed using a FT/IR and the other part was acid hydrolyzed, desalted, and subjected to amino acid analysis using a HPLC.

FT/IR spectra indicated that the differences in the spectral intensities are due to synthesis of more organic compounds. In HPLC analysis, various amino acids including glycine and alanine were detected. Presence of non-protein amino acids (β-Ala, γ-ABA) is considered as evidence against terrestrial contamination. Our preliminary results showed that the obtained amount of amino acids was elevated with the presence of minerals. These results suggested that the associated minerals act as catalysts to produce amino acid precursors during aqueous activities in the planetesimals.

Peptide Formation from amino acid precursors under simulated submarine hydrothermal environments

*Kensei Kobayashi[1], Keisuke Naito[1], Koki Naito[1], Soushi Kuramoto[1], Ei-ichi Imai[2], MITA Hajime[3], Yoko Kebukawa[1]

1. Yokohama National University, 2. Nagaoka University of Technology, 3. Fukuoka Institute of Technology

Submarine hydrothermal systems have been recognized as one of most promising sites for chemical evolution toward the generation of the first life on the Earth [1]. In order to examine possible reactions in such environments, laboratory simulations by utilizing autoclaves and/or flow reactors have been conducted. Imai et al. reported that peptides were formed when glycine was subjected to heat-quench cycles in a flow reactor simulation submarine hydrothermal systems [2]. Amino acids have been detected in carbonaceous chondrites, and also in the products of experiments simulating interstellar environments. It should be noted that amino acid precursors rather than free amino acids were formed under extraterrestrial environments. Such exogenous amino acid precursors could have been delivered to the primitive Earth and processed in submarine hydrothermal systems. We studied possible reactions of amino acid precursors in simulated submarine hydrothermal environments.

Experimental: We chose the following compounds or materials for hydrothermal experiments: (i) Free glycine (Gly); (ii) aminoacetonitrile (AAN), a Strecker-type precursor; (iii) hydantoin (Hyd), a glycine precursor found in carbonaceous chondrites; (iv) CAW; complex organic molecules formed by proton irradiation of a mixture of CO, NH_3 and H_2O [3]. CAW gave various amino acids after acid hydrolysis, where glycine was predominant. The CAW stock solution used in this study yielded *ca.*10 mM glycine after acid hydrolysis.

In order to simulate submarine hydrothermal reactions, we used a flow reactor, composed of a HPLC pump, an infrared gold image furnace, a cold bath and a backpressure regulator [4]. Injected aqueous samples could be heated up to 400˚C in the furnace, and then quenched in the ice bath (0 ˚C). Carrier used was purified water (neutral) or 1 mM HCl (acidic). In the present study, 0.25 mL of each sample was processed in the furnace at room temperature (reference) or 200-400˚C for 2 min, and then quenched. Amino acids in the effluent were determined by cation exchange HPLC (Shimadzu LC-20 amino acid analyzer with a fluorescence detector) before or after acid-hydrolysis. Peptides were determined by ion-pair HPLC (Shimadzu LC-20 HPLC system with a UV detector).

Results and Discussion: Stability of each material at 300˚C was examined by using 4 mM of Gly, AAN or Hyd, or 10-times diluted CAW. Hyd, AAN and CAW gave some glycine in unhydrolized products. Recovery was calculated by glycine amount after hydrolysis against the reference. Hyd and CAW were more stable than Gly and AAN.

Peptide formation experiments were performed by using 40 mM each of Gly, AAN or Hyd, or the CAW stock solution. Diketopiperazine (DKP; a cyclic dimer of Gly) and diglycine (Gly_2) were detected in the unhydrolized samples after Gly or Hyd was heat-processed. Hyd gave much more Gly_2 and DKP than Gly. The Best yield of Gly_2 was 1.3 %, which was observed when Hyd was processed at 200 or 250˚C under neutral conditions. CAW gave so many peaks in ion-pair chromatograms, so that we could not identify peptides there.

©2019. Japan Geoscience Union. All Right Reserved.

In order to examine possible catalytic abilities of CAW, 10-times diluted CAW was added to 40 mM Gly or 40 mM Hyd and then heat-processed. Yields of Gly_2 were increased when CAW was added to Gly or Hyd and heated at 200˚C under acidic conditions.

It was shown that amino acid precursors such as Hyd and CAW was more stable than free amino acids, and that amino acid precursors like Hyd could yield more peptides than free amino acids. It was also found that CAW (complex amino acid precursors) could facilitate peptide formation. It is known that CAW has amide bonds in its structure, which could be a reason why CAW could work as a condensing agent.

In summary, amino acid precursors were more plausible starting materials than free amino acids in prebiotic reactions in primordial terrestrial environments. Kurihara et al. [5] showed that organic aggregates could be formed from water-soluble organics in hydrothermal environments. It is of interest to examine whether CAW could give such aggregates after processed in the flow reactor.

This work was partly supported by JSPS KAKENHI Grant Number JP17H02991.

Development of Longitudinal dunes under the Pangean atmospheric circulation

*Hiroki Shozaki[1], Hitoshi Hasegawa[2]

1. Faculty of Science, Kochi University, 2. Faculty of Science and Technology, Kochi University

From the Permian into the Early Jurassic, the supercontinent Pangea dominated our planets. Because of its largest landmass in the Earth’ s history, atmospheric circulation at this period is thought to be significantly different from today. Modelling experiments have suggested cross-equatorial Hadley circulation and its seasonal overturning. However, there are large discrepancy between model-generated surface wind pattern and geological evidence of paleo-wind pattern recorded by eolian sandstones in the central-western U.S.A. Previous study suggested that its discrepancy can be caused by the wrong interpretation of how winds shaped the dune in Pangea. Here, we re-examined Lower Jurassic eolian sandstone records in U.S.A. and reconstructed paleo-wind pattern with focusing on its dune morphology and orientation. Based on the recently revised paleomagnetic reconstructions, sand dune sea was widespread at about 24˚–33˚N. Spatial pattern of paleo-wind directions suggests influence of multi-directed paleo-winds, with dominant westerly winds in northern area and northeasterly winds in southern area. The reconstructed paleo-wind pattern appears to be consistent with the modelling results of paleo-location of subtropical high-pressure belt in the boreal winter of the Early Jurassic. In addition, spatial pattern of eolian slipface orientations suggest that dunes are mainly consists of longitudinal dunes with NNW–SSE orientation in Pangean time, which are markedly different from orientation direction of longitudinal dunes in present desert. We proposed that the development of NNW-SSE oriented longitudinal dunes could be formed by orbitally-induced latitudinal shifts of subtropical high-pressure belt in Pangea supercontinent. Modeling experiments also generated large modulation of strength and location of subtropical high-pressure belt in response to orbital-scale insolation changes. Reconstructed surface wind pattern and different directions of longitudinal dune orientation recorded in Jurassic eolian sandstone records therefore represent a distinct pattern of Pangean atmospheric circulation.

Response of primary producers in the ocean anoxic events during the Cretaceous

*Haga Mayuko[1], Eiichi Tajika[1], Kazumi Ozaki[2]

1. The University of Tokyo, 2. Toho University

In the Cretaceous, it is known that the “Ocean Anoxic Events (OAEs)” occurred repeatedly. In the OAEs, marine biogeochemical cycles, biological activity, and process of sedimentation may have been different from those under the oxic condition like today. In fact, biomarkers of cyanobacteria and green sulfur bacteria have been found from the sediments during the OAEs. It is therefore suggested that the redox condition and the primary procedures were quite different at the time of the OAEs. If we regard OAE as a disturbance to the marine biogeochemical cycle system, it is important to understand the response of photosynthetic ecosystem that plays a key role in controlling the ocean redox condition during OAEs.

In the Cretaceous, the climate was warmer and the sea level were higher than today because seafloor spreading rate were very high, hence the shallow water area expanded due to the transgression. Under such conditions, the ocean tends to be oligotrophic and oxic because vast shelf area is locus for the deposition of organic matters and traps large amounts of phosphate and nitrogen (Ozaki et al, 2013). We, however, do not know the marine biogeochemical cycles of nutrients and the behaviors of primary procedures under such a condition in the Cretaceous. We therefore developed a marine biogeochemical cycle model coupled with a marine ecosystem model and investigated the condition of OAEs ,marine biogeochemical cycles of nutrients and the behaviors of primary producers in the Cretaceous.

We found that algae is the dominant primary procedure under the “normal” Cretaceous condition, but once the global surface temperature rises owing to, such as activities of large igneous provinces (LIPs), concentration of phosphate in the ocean increases owing to enhanced chemical weathering of land surface. This leads to increase in the marine primary production which, in turn, promotes anoxic conditions in the ocean because dissolved oxygen is consumed by organic matter decomposition, initiating OAE. In the anoxic ocean, nitrogen is limited because nitrate is consumed by organic matter decomposition and thiodenitrification, inhibiting photosynthetic activity of algae. Cyanobacteria becomes dominant primary procedure because some of them can fix nitrogen. In the upwelling regions, green sulfur bacteria becomes dominant because hydrogen sulfide produced by sulfate reducing bacteria upwells to the euphotic zone.

The linkage between desertification and tectonism inferred from the provenance change of the terrestrial sediments in the Tarim basin

*Aki Sakuma[1], Ryuji Tada[1], Tomohiro Yoshida[1], Hitoshi Hasegawa[2], Naomi Sugiura[1], Akinori Karasuda[1], Ke WANG[1], Hongbo Zheng[3]

1. Department of Earth and Planetary Science, School of Science, the University of Tokyo, 2. Faculty of Science and Technology, Kochi University, 3. School of Resource Environment and Earth Science, Yunnan University

The Tarim basin, which locates to the northwest from the Tibetan Plateau, is the area where the most significant aridification was expected as a result of the uplift of the Himalaya and the Tibetan plateau due to the collision between the Indian subcontinent and the Eurasia continent during Cenozoic (e.g. Kitoh, 2005). However, the geological evidence supporting the relationship between the aridification of the Tarim basin and the tectonism in its surrounding areas is not obtained sufficiently. The reason why the difficulty in examining the relationship between the timing of tectonism and aridification arises is that the timing of the onset of aeolian dune deposition in the Tarim basin, which is the good evidence of the aridification, depends on age models and, thus, there is uncertainty in the timing of the desertification. To solve this problem, it is effective to compare the timing of both tectonic and climatic events on the same section.

In this study, the provenance change of the upper Eocene to the middle Miocene fluvial sandstone deposited in the Aertashi section in the southwestern edge of the Tarim basin was examined using the Electron Spin Resonance (ESR) signal intensity and Crystallinity Index (CI) analyses of quartz in the 64-500 μm fraction and the thin section observation. The timing of the tectonic movement in the Pamir estimated from the provenance change is compared with the timing of the desertification implied by the lithology to examine the relationship between the tectonism and the desertification.

The result of the ESR signal intensity and the CI analyses indicates that the provenance changes of the fluvial sandstone in the Aertashi section are divided into six stages and the boundary between stages are ca. 35Ma, ca. 33Ma, ca. 26Ma, ca. 21Ma, and ca. 17Ma, respectively. Thin section observation shows that the composition of the fluvial sandstone changes significantly at ca. 17Ma with higher content of lithic fragments with wide variety of the types, and the relatively high content of biotite and mafic minerals after ca. 17Ma.
The significant provenance changes at ca. 33Ma, ca. 26Ma, and ca. 17Ma showen by the ESR signal and the CI data imply that the tectonic movement in the Pamir possibly occurred around these times. Since the onset of desertification in the Tarim basin is estimated around 35Ma based on the lithology, the uplift of the Pamir does not seem to have been the cause of the initial aridification in the Tarim basin.

Paleoceanographic reconstruction in the northwestern Pacific during MIS 19 using ultra-high temporal resolution oxygen isotope profiles and planktonic foraminiferal assemblage

*Yuki Haneda[1], Nanako Yokokawa[1], Makoto Okada[1], Hiroki Hayashi[2], Yoshimi Kubota[3], Yusuke Suganuma[4]

1. College of Science, Ibaraki University, 2. Interdisciplinary Factulty of Science and Engineering, Shimane University, 3. National Museum of Nature and Science, 4. National Institute of Polar Research

The orbital configuration during Marine Isotope Stage (MIS) 19 are characterized by a weak eccentricity-precession forcing and an obliquity maximum associated with a precession minimum as well as MIS 1, although the both absolute values of obliquity are different. Thus, MIS 19c, one of the sub-stages during MIS 19, is assumed as the best analogue for the present interglacial suggesting the timing of the next glacial inception in the future when the anthropogenic influences are excluded.

The Chiba composite section (CbCS) at east-central Japanese island faces the northwestern Pacific containing the Kuroshio Extension Front (KEF) which is north limit of the Kuroshio Current transporting amount of heat and water from the Equatorial to mid-latitude. Modern observation, climate model, and geologic records reveal that variations of the oceanic fronts in the northwestern Pacific (surface temperature and latitudinal position) and atmospheric circulation in the North Pacific interact. However, response of the KEF to external and internal forcings under the modern orbital configuration remain unclear.

Here, we reconstruct detailed paleoceanographic variations in the northwestern Pacific during MIS 19 using stable oxygen isotope ($\delta^{18}O$) and planktonic foraminiferal assemblage records form the CbCS. Spectral and wavelet analyses were conducted in order to assess periodicity of our new $\delta^{18}O$ records. Vertical water temperature structure and their gradient (ΔT), and relative abundance variation of warm-water species exhibit latitudinal displacements of the KEF on multi-millennial scale across the MIS 20–19 transition and during late MIS 19 (MIS 19b to 19a). Results of the spectral and wavelet analyses for the $\delta^{18}O$ records show periodicities of 2,300–6,000 year during late MIS 19. Similarities of timing and periodicity between paleoceanographic records from the CbCS and North Atlantic indicate that disruption of the Atlantic meridional overturning circulation due to freshwater discharge into the North Atlantic caused the southward displacements of the KEF via atmospheric dynamic. A power of the 9,700 year-periodicity in surface planktonic $\delta^{18}O$ and ΔT is stronger during MIS 19c, which probably originates from tropics caused by equatorial insolation at equinoxes with the orbital perihelion. This result indicates the seasonality of the insolation at low-latitudes paced the sea surface condition at the CbCS throughout MIS 19 and this low-latitude influence became larger especially when the North Atlantic forcing by freshwater discharges and AMOC variability was low. Our result suggests that millennial-scale stability and variation of oceanographic condition along the KEF under this orbital configuration depend on North Atlantic climate variability.

Paleoclimate reconstruction using fossil pollen analyses from a sedimentary sequence around the Matuyama-Brunhes polarity transition in the Chiba composite section

*Makoto Okada[1], Hitomi Takizawa[1], Yuki Haneda[2], Yusuke Suganuma[3,4], Quentin Simon[5]

1. Department of Earth Sciences, College of Science, Ibaraki University, 2. Graduate school of Science and Technology, Ibaraki University, 3. National Institute of Polar Research, 4. Graduate University for Advanced Studies, 5. Aix-Marseille University

To examine the “Svensmark effect”, linking climate cooling and geomagnetic field strength decrease, during the time of geomagnetic reversal, we have conducted a pollen analysis in the Chiba Composite Section including the Matuyama-Brunhes polarity reversal boundary, and correlated the quantitative paleoclimatic variation deduced by the modern analog method with the paleomagnetic and ^{10}Be records. The samples used in this study are from 33 horizons in a stratigraphic interval between 4-31 m above the Byk-E tephra bed where the sample density of pollen fossil data used in the previous study (Suganuma et al., 2018) is low. Samples were subjected to KOH-acetolysis treatment (Moore et al., 1991) and hydrofluoric acid treatment as pretreatment to extract pollen fossils. As a result of microscopic examination with an optical microscope, we identified 27 genera in total of 3 families, 24 genera of woody pollen, 2 genus pollen grasses and 2 spores. The abundant pollen fossils are Pinus, and some other genera distributed in the subarctic to cool temperate zones such as Picea, Tsuga, Fagus, etc.
Applying the modern analog method (Nakagawa et al., 2002) to the pollen assemblage data, the reconstructed paleoclimatic parameters show lower overall temperatures than the current study area. Comparing various climatic parameters from the modern analog method with the oxygen isotope records, insolation, ^{10}Be showing the penetration of galactic cosmic ray into the atmosphere and relative paleointensity, the reconstructed climatic parameters showed a variation consistent with paleoceanographic temperatures deduced from oxygen isotopes of planktonic foraminifera. Moreover, we do not recognize any trend of decreasing in air temperature corresponding to geomagnetic field strength collapse at the M-B boundary as reported by Kitaba et al. (2017).

Reconstruction of vertical thermal structure in the western Pacific warm pool over the last 1 Myr

*Fumito Mizuno[1], Takuya Sagawa[2], Keisuke Mukaida[3], Yoshimi Kubota[4], Toshitsugu Yamazaki[5], Junichiro Kuroda[5]

1. Graduate School of Natural Science and Technology. Kanazawa University, 2. Institute of Science & Engineering. Kanazawa University, 3. Collage of Science & Engineering. Kanazawa University, 4. National Museum of Nature & Science, 5. Atmosphere and Ocean Research Institute. The University of Tokyo

The zonal atmospheric circulation in the tropical Pacific, the Walker circulation, is closely related to the zonal gradients of sea surface temperature (SST) and thermocline through the ocean-atmosphere interaction. Variability of such an interaction in a couple of years timescale is known as El Niño Southern Oscillation (ENSO), which has a great influence on climate not only in the tropics but also in wide areas on the globe. Proxy SST records revealed that the zonal SST gradient has changed in various timescales, and it is interpreted that the ENSO-like ocean-atmosphere interaction also worked on the longer timescale. However, there is no definitive evidence that the change in the zonal SST gradient was accompanied by change of the Walker circulation. Here we reconstruct thermocline temperature variability, which is sensitive to the strength of the Walker circulation. By comparing the variations of zonal and vertical temperature gradients, we examined whether the ENSO-like ocean-atmosphere interaction was functioning on the tens of thousands to hundreds of thousands of years timescale. The sample used in this study is a piston core MR14-02 PC4 collected on the Ontong-Java Plateau located in the western Pacific warm pool (WPWP). Surface and thermocline temperatures were reconstructed by Mg/Ca analyses of planktonic foraminifera, *Globigerinoides ruber* and *Pulleniatina obliquiloculata*, respectively, for the last million years. We compared the vertical temperature gradient (difference between surface and thermocline temperature: ΔT_{WPWP}) and the zonal temperature gradient (difference between *G. ruber* SST in this study and alkenone SST in the East Equatorial Pacific ODP Site 846 : ΔSST_{W-E}). As a result, the relationship between ΔT_{WPWP} and ΔSST_{W-E} in the past was not similar to that of the modern ENSO variability. This result suggests that the change of temperature structure in longer timescale was caused by a mechanism different from today. Also, ΔT_{WPWP} and ΔSST_{W-E} showed a longer time scale change than the glacial-interglacial cycles, and the cycle is approximately 400 kyr. This implies that the thermocline variability in the equatorial Pacific might be related to the Milankovitch cycle. The results of this study suggest that it is necessary to discuss vertical and meridional thermal structures in addition to the zonal SST gradient in order to understand the dynamics of past ocean-atmosphere interaction.

[M-IS19] Paleoclimatology and paleoceanography

convener:Yusuke Okazaki(Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University), Akira Oka(Atmosphere and Ocean Research Institute, The University of Tokyo), Michinobu Kuwae(Center for Marine Environmental Studies), Hitoshi Hasegawa(Faculty of Science and Technology, Kochi University), Chairperson:Michinobu Kuwae(愛媛大学沿岸環境科学研究センター)

Past environmental changes and events at multi-decadal to tectonic timescale toward an understanding of Earth climate system by an integration of terrestrial and marine proxy studies and numerical modeling will be discussed. At JpGU2019, a series of presentations on present and future climate and environmental changes from paleo-perspective will be held. We welcome a variety of paleo-environmental studies from a wide range of background. We hope that this session will provide an opportunity to promote communication between participants from multidisciplinary field.

Future perspective on the response of marine calcifiers to “evil twins” of climate change due to increased PCO2

*Hodaka Kawahata[1]

1. Atmosphere Ocean Research Institute, the University of Tokyo

This talk is developed from our comprehensive review paper of PEPS: Kawahata, H., Fujita, K., Iguchi, A, Inoue, M., Iwasaki, S., Kuroyanagi, A., Maeda, A., Manaka, T., Moriya, K., Takagi, H., Toyofuku, T., Yoshimura, T., Suzuki, A. (2019) Perspective on the response of marine calcifiers to global warming and ocean acidification –Behavior of corals and foraminifera in a high CO2 world “hot house”. Progress in Earth and Planetary Science 6: 5 (p.1-37).

Our planet will experience global warming and ocean acidification due to increased partial pressure of CO2 in the atmosphere. They are often referred to as the “evil twins” of climate change, potentially inducing severe threats in the near future.

Generally, majority of marine calcifying organisms show decreases in calcification rates in response to acidified seawater by increased pCO2. However, the response often differs depending on situations, species, and life-cycle stage. Calcification of Calcarina gaudichaudii, generally increased with increased pCO2. As one possible cause of these different sensitivities, Calcarina hosts diatoms as its symbiotic algae. High-CO2 seawater is favorable to diatom growth.

X-ray micro-computed tomography will provide valuable information regarding biomineralization including calcification of planktic and benthic foraminifera in response to ocean acidification as well as regarding carbonate dissolution.

Based upon the analysis of the biogeochemical cycle (today, at P/E boundary and in Cretaceous), “high speed” and “high level” pCO2 are the primary and secondary factors, respectively, leading to acidification in the Earth surface’s system. Over the long-term, it is well known that alkalinity has fluctuated largely in the Earth’s surface environment. Therefore, it is important to quantitatively reconstruct alkalinity, which is another key factor determining the saturation state of carbonate minerals.

Reconstruction of seawater pH and atmospheric CO_2 concentration based on boron isotopic composition of biogenic calcium carbonate

*Kaoru Kubota[1]

1. Kochi Institute for Core Sample Research, JAMSTEC

A lot variety of environmental information is recorded in marine biogenic calcium carbonate that is represented by reef building coral skeletons and foraminifera shells. Among these, **boron isotope ($\delta^{11}B$)** proxy is of great importance in the realm of paleoclimatology and paleoceanography, since it can record seawater pH and CO_2 concentration of the overlying atmosphere. Along with the growing interest to recent environmental problems such as global warming and ocean acidification due to anthropogenic CO_2 emission, past carbon cycle research has been actively conducted, and boron isotope proxy is priceless tool to study it. In 1980s, applicability of this proxy was foreseen, but high precision boron isotope measurement with small sample requirement was difficult at that time. As boron exist abundantly around us (the most representative one is borosilicate grass), analytical technique has evolved as the boron-free clean environment improved. Thermal ionization mass spectrometry (**TIMS**) was first developed, and nowadays multi-collector inductively coupled plasma mass spectrometry (**MC-ICPMS**), secondary ionization mass spectrometry (SIMS), and laser-ablation inductively coupled plasma mass spectrometry (LA-ICPMS) (and others) is now available. Measurable minimum sample amount, achievable analytical precision, and spatial resolution of the analysis are largely different among methods, and efforts to measure boron isotope composition more precisely with smaller amount of samples has continued at research institutes around the world. In **Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology**, boron isotope measurements by using TIMS and MC-ICPMS are available: the former realizes the most precise measurement in the world, and the latter realizes analytical precision and required sample amount that is comparable with major overseas laboratory. In this presentation, I will explain theoretical background why boron isotope of marine biogenic calcium carbonate becomes seawater pH proxy and characteristics of two different mass spectrometry, and then overview already-done research and ongoing research topics. Recent development of visualization technology of pH of calcifying fluid of reef building coral and foraminifera has enabled deeper understandings of boron incorporation systematics. On the one hand, boron isotopes of reef building coral is most-likely a direct indicator of pH of calcifying fluid; on the other hand, those of foraminifera is likely influenced by microenvironment pH gradient surrounding foraminifera. Whatever the mechanism is, a clear relationship between boron isotopes and seawater pH is observed in various samples such as cultured, recently live-collected, and fossil samples, thus many studies use this proxy in paleoclimatology and paleoceanography by understanding empirical relationship collectly ("calibration").

A 70 years changes of the Java Sea surface condition based on geochemical analyses of a coral core

*Ai Genda[1], Atsushi Suzuki[2], Toyoho Ishimura[3], Minoru Ikehara[4], Mayuri Inoue[1]

1. Graduate School of National Science and Technology, Okayama University, 2. Geological Survey of Japan Natinal Institute of Advanced Industrial Science and Technology, 3. National Institute of Technology, Ibaraki College, 4. Center for Advanced Marine Core Research, Kochi University

At Indonesian Archipelago, observed and instrumental records have not been well recorded because of complex terrain. In this study, we have reconstructed sea surface condition of the Java Sea for past 70 years based on $\delta^{13}C$, Sr/Ca and U/Ca ratios in the coral skeleton.
A coral core (*Porites* sp.) was collected from the the Seribu Islands located at the Java Sea, Indonesia. Measurements of Sr/Ca, U/Ca ratios and $\delta^{13}C$ were performed by inductively coupled plasma (ICP)-optical emission spectrometer, ICP-mass spectrometer and stable isotope ratio mass spectrometer with about 2-month time resolution.
Although it has been reported that both coral Sr/Ca and U/Ca ratios can be used as paleothermometer [Beck et al., 1992; Min et al., 1995], coral U/Ca ratios also depends on seawater pH [Inoue et al., 2011] and carbonate ion concentration ($[CO_3^{2-}]$) [Anagnostou et al., 2011]. Furthermore, since coral $\delta^{13}C$ reflects DIC of ambient seawater, we will discuss about marine environments such as water temperature and seawater pH at the Java Sea for 70 years.

Reconstruction of paleoenvironments in the western Pacific for the last 220 years

Mutsumi Chihara[1], Ayaka Fukushima[2], Minoru Ikehara[3], Hodaka Kawahata[2], Atsushi Suzuki[4], *Mayuri Inoue[1]

1. Department of Earth Sciences, Okayama University, 2. Atmosphere and Ocean Research Institute, the University of Tokyo, 3. Center for Advanced Marine Core Research, Kochi University, 4. Geological Survey of Japan, AIST

In the tropics, *Porites* corals are recognized as the excellent archives of past climate and environmental and oceanic conditions because coral skeletal geochemistry, such as oxygen and carbon isotopes and Sr/Ca ratios, provides quantitative information on sea surface temperature (SST) and salinity. However, continuous long records more than 200 years based on coral records have been limited.

Here, we present a 224-year SST record with high time resolution (~2 month) derived from Sr/Ca ratios and stable isotopes ($\delta^{18}O$ and $\delta^{13}C$) from Philippines (13°N, 124°E), which located on the northern edge of the western pacific warm pool (WPWP).

Coral Sr/Ca was measured by an inductively coupled plasma optical/atomic emission spectrometer (ICP-OES/AES) with a precision was better than 0.6 % which is equivalent to 0.5 ℃. Analyses of $\delta^{18}O$ and $\delta^{13}C$ were measured by isotope ratio mass spectrometer (IR-MS). Precision was better than 0.05 ‰for $\delta^{13}C$ and 0.10 ‰for $\delta^{18}O$. In this study, spectral analysis was performed by using the kSpectra. Reconstructed SST varies from 25 to 32 ℃ and shows that there were multiple cold events during the last 224 years in the western tropical Pacific. A decreasing trend in $\delta^{13}C$ for the last 50 years was found which may reflect accelerated increase in the amount of anthropogenic CO_2 (Suess effect).The result of $\delta^{18}O$ analyses implies western pacific climate was cooler and drier in the early 19th century which is almost consistent with other coral records. In contrast, warmer and wetter conditions persist since 1950s.The spectral analysis of the annual SST and $\delta^{18}O$ anomaly for 224 years shows significant peaks at 3-8 years. These frequencies are considered to be related to the ENSO variability.

Keywords: the western Pacific, coral skeleton, paleoclimate

Ocean deoxygenation from the Last Glacial Maximum to the future global warming: inshight from model simulations

*Akitomo Yamamoto[1], Ayako Abe-Ouchi[2,1], Rumi Ohgaito[1], Akinori Ito[1], Masahito Shigemitsu[1], Yasuhiro Yamanaka[3], Akira Oka[2]

1. Japan Agency for Marine-Earth Science and TechnologyAtmosphere and Ocean Research Institute, 2. Atmosphere and Ocean Research Institute, The University of Tokyo, 3. Faculty of Environmental Earth Science, Hokkaido University

Global warming is expected to decrease ocean oxygen concentration by less solubility of surface ocean, reduced ventilation and enhanced stratification. The associated expansion of the oxygen minimum zone would have adverse impact on marine organisms and ocean biogeochemical cycles. Earth system models show a consistent deoxygenation trend over the twenty-first century; however, longer-term changes in ocean oxygen are still unclear due to the uncertain response of deep ocean circulation.

During the Last glacial maximum, recent proxy data show that, despite greater oxygen solubility due to sea surface cooling, the oxygen concentrations throughout the deep ocean were generally lower. These records provide the response of oxygen content to climate forcing that are comparable in magnitude to the expected future changes. Therefore, the understanding of glacial deoxygenation will help us to better understand and predict future oxygen changes. In addition, glacial deep-water deoxygenation is crucial to understand glacial-interglacial CO_2 change, since glacial deoxygenation reflects increased accumulation of respired carbon in the glacial deep ocean. However, the mechanisms of deep-water deoxygenation and contribution form the biological pump to glacial CO_2 drawdown are poorly understood due to the difficulties in reproducing glacial deoxygenation.

In this study, we report the importance of glaciogenic dust for the glacial deep-water deoxygenation from our numerical simulation which successfully reproduces the magnitude and large-scale pattern of the observed oxygen changes from the present to Last Glacial Maximum. Sensitivity experiments reveal that physical changes (e.g., more sluggish ocean circulation) contribute to only half of all glacial deep deoxygenation, whereas the other half is driven by enhanced efficiency of the biological pump. We found that iron input from the glaciogenic dust with higher iron solubility is the most significant factor for enhancement of the biological pump and global deep-water deoxygenation. The model-proxy agreement of oxygen change supports the simulated contribution of the enhanced biological pump to the decrease of more than 30 ppm of glacial CO_2.

On the other hand, our model underestimates deoxygenation in the deep Southern Ocean due to enhanced ventilation in the Southern Ocean. Our results suggest that the stratified Southern Ocean is required for reproducing glacial deoxygenation in the Southern Ocean. However, present climate models cannot reproduce the stratified Southern Ocean. A possible reason is that climate models are too coarse to capture the process of dense water formation on the Antarctic shelf and tend to underestimate the strength of stratified Southern Ocean. Similar to glacial oxygen changes, our global warming simulation show that changes in ocean circulation in the Southern Ocean are crucial for long-term projecting future oxygen changes associated with global warming. Therefore, the understanding of glacial oxygen changes will help us to better understand and predict future oxygen changes.

[M-IS19] Paleoclimatology and paleoceanography

convener:Yusuke Okazaki(Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University), Akira Oka(Atmosphere and Ocean Research Institute, The University of Tokyo), Michinobu Kuwae(Center for Marine Environmental Studies), Hitoshi Hasegawa(Faculty of Science and Technology, Kochi University), Chairperson:Akira Oka

Past environmental changes and events at multi-decadal to tectonic timescale toward an understanding of Earth climate system by an integration of terrestrial and marine proxy studies and numerical modeling will be discussed. At JpGU2019, a series of presentations on present and future climate and environmental changes from paleo-perspective will be held. We welcome a variety of paleo-environmental studies from a wide range of background. We hope that this session will provide an opportunity to promote communication between participants from multidisciplinary field.

Extraction of high-quality ^{14}C data from terrestrial sediments containing pollen fossils

*Takayuki Omori[1], Keitaro Yamada[2], Ikuko Kitaba[2], Takeshi Nakagawa[2]

1. The University Museum, The University of Tokyo, 2. Research Centre for Palaeoclimatology, Ritsumeikan University

Fossil pollen grains, which are commonly found in various types of sediments, have great potential for radiocarbon chronological research. If measurable amounts of fossil pollen grains can be extracted readily from sediment matrices, then ^{14}C age determination could be performed at any depositional depth, regardless of with or without plant macrofossils, and the quality of the deposition age model can be considerably increased. Thus far, several lake sediments have been tested for pollen ^{14}C. However, technical issues such as complex preparation procedures, collection rate, and purity of concentrated sample persisted and pollen ^{14}C analysis has not been applied routinely. A novel pollen concentration method is developed herein using a next-generation cell sorter to quickly prepare pure concentrates of fossil pollen grains suitable for ^{14}C dating, with a relatively simple preparation procedure.
Cell sorter was originally developed for biomedical researches to instantaneously identify and separate cells of specific fluorescence and shape. Some of the latest model machines can perform machine tuning and sample preparation semi-automatically, and it is designed to solve most issues via the exchange of replacement parts. In the proposed method of pollen purification, pollen-enriched suspension is introduced into cell sorter, which can separate more than a million grains of fossil pollen in half a day. The pollen ^{14}C analysis was conducted using a SG06 sediment core from Lake Suigetsu, which has one of the most reliable age models that we can use as reference. Pollen fossil samples equivalent to 50–100 μgC were extracted from ca. 25-30 g of wet sediment and were measured using a compact AMS system (NEC 0.5 MV 1.5SDH-1) of LRD.UMUT. The ^{14}C data of the pure pollen samples agreed well with the Suigetsu's ^{14}C dataset on terrestrial plant leaf fossils. This result shows that accurate ^{14}C data can be obtained from any depth of the core, even at depths at which plant remains are not present. Using the proposed method, the Suigetsu's ^{14}C data can be enhanced for data density and evenness of the data intervals, both of which would directly contribute to the accuracy of the age model. We also believe that the proposed method can be applied to various sediment types from both marine and terrestrial realms, and will assist high-precision chronological study as well as quantification of marine reservoir age.

Oxygen isotope fluctuations of pollen fossils from Lake Suigetsu, Japan

*Keitaro Yamada[1], Takayuki Omori[2], Ikuko Kitaba[1], Takeshi Nakagawa[1]

1. Research Organization of Science and Technology, Ritsumeikan University, 2. The University museum, The University of Tokyo

Interactions of atmospheric, marine, terrestrial, and cryospheric realms are important factors in considering mechanisms of climate change (Lowe et al., 2008). Pollen analysis widely used methods to reconstruct past climate changes. However, comparing pollen data with other geochemical proxies, especially stable isotope signals, is not straightforward due to the non-linearity included in the conventional pollen composition signals. On the other hand, pollen grains are composed of sporopollenin and potentially provide isotopic signals which can be more directly compared with key palaeoclimatic records from across the world (Loader and Hemming, 2004). In this study, we first established a method to extract fossil pollen grains from sediment matrix by “cell sorter”. Then we applied that new method to the varved sediments obtained from Lake Suigetsu, Japan (in particular, transition from the Lateglacial to the early Holocene) in order to test if the isotopic signals of pollen grains are keeping meaningful palaeoclimatic information or not.

Lake Suigetsu (35˚35'N, 135˚53'E, 0 m a.s.l.), Fukui prefecture, is one of the Mikata Five lakes, which measures 3 km east-west by 3 km north-south, with the maximum water depth of ca. 34 m. Lake Suigetsu preserves annually laminated sediments over the last ca.70 kyr with a significant number of event layers that allows precise correlation among parallel cores. Two long cores (SG93, SG06) have previously been recovered from the centre of the lake. An exceptionally precise age model has been established for the cores through a combination of over 800 radiocarbon (^{14}C) dates and high precision varve count (Staff et al., 2011; Marshall et al., 2012; Schlolaut et al., 2012; Bronk Ramsey et al., 2012). In this study, we used well-dated SG06 cores and extracted pollen fossils using cell sorter.

Cell sorter is able to characterise particles using optical parameters (mainly fluorescence), and separate specific particles using electrostatic deflection. Pollen fossils can be isolated by cell sorter without fluorescent dyes using cell sorter because sporopollenin constituting pollen grains is naturally auto-fluorescent (Tennant et al., 2013). After chemical and physical pre-treatments, pollen-enriched suspension was introduced into the cell sorter and extracted half a million pollen fossils from each sample. After drying and weighing, δ^{18}O value of the high-purity pollen pellets were determined using High Temperature Conversion Elemental Analyzer (TC/EA, Thermo Scientific) in the University of Tokyo.

The oscillation of the δ^{18}O value of the extracted pollen pellets roughly mirrored that of the NGRIP, showing typical climatic transitions that characterise the Late glacial period. Our results strongly imply that the stable isotope signal of fossil pollen grains is keeping record of past climate changes.

Reconstruction of lake-level changes during the last glaciation based on fossil diatom record in Lake Biwa

*Takashi Suzuki[1], Yoshio Inouchi[2], Keisuke Otsuka[1], Kaoru Kawakami[3]

1. Graduate School of Human Science, Waseda University, 2. Faculty of Human Sciences, Waseda University, 3. Graduate School of Environmental Science, Hokkaido University

This is a report of a research for reconstruction of lake-level change history of Lake Biwa based on the transfer function of diatom assemblage into water depth. We have analyzed diatom assemblages, sand content, and C/N ratio in drilling core sample from the lake bottom of 23.45 m in depth and surface sediment samples from the lake bottom from 5 m to 30 m in depth off estuary of Echi River, Lake Biwa. The relative abundance of planktonic species in diatom assemblage from surface sediments can be changed into water depth. The transfer function applied to fossil diatom record in drilling core sample into lake-level change history during the last 50 ka.
We compared the record with Sanbao & Hulu cave stalagmites $\delta^{18}O$ records in China and NGRIP $\delta^{18}O$ record in Greenland from 50 ka to 10 ka. The result shows that the lake-level change history in Lake Biwa reflects East Asian winter monsoon intensity. Lake-level rose under relatively cold conditions or abrupt cooling like Heinrich Events and lake-level fell under relatively warm conditions. The lake-level response to climate conditions suggests that snowfall in winter depending on East Asian winter monsoon intensity mainly contributed to water balance of Lake Biwa during the last glacial period.

An estimation of microplatcis sedimentation flux in a coastal sea

*Hirofumi Hinata[1], Michinobu Kuwae[1], Issei Masumoto[1], Hayato Kawamata[1]

1. Ehime University

Plastics production has been increasing each year. It is estimated that 4.8-12.7 million tons of plastics flowed out into the ocean in 2010. The plastics weathers due to UV degradation and fragmented into small pieces. Generally, the plastic particles of the 0.3-5mm in size are called microplastics. They are likely to be incorporated into the ecosystem and there is concern about bad influence on ecosystem. Recent studies have found that microplastics sink to the sea bottom. However, the sedimentation flux has not been clarified yet. In this study, the sedimentation flux of microplastics was estimated. We collected and analyzed the sediment cores from the bottom of Beppu Bay. Beppu Bay is suitable for the core sampling, because sediments have not been vertically disturbed.Five cores were taken using Gravity Corer. Four sediment cores were for microplastic analysis, and one for dating sediment layers. The sedimentary age was determined using the Pb-210 method. Microplastics extracted from the four core samples were analyzed by FT-IR to determine the polymer type. A total of 142 pieces of microplastic were detected. The most common polymer type among plastics was polyethylenewhich accounted for 55% of the total in number. The average sedimentary flux from 1998 to 2017 was calculated as 217 [pieces/m^2·y)].

Beppu Bay sediments: Potential palaeoenvironmental archives for a candidate auxiliary stratotype for Anthropocene-Holocene boundary

*Michinobu Kuwae[1], Yoshiaki Suzuki[2]

1. Center for Marine Environmental Studies, Ehime Univ., 2. Department of Eearth Scieces, Fuculty of Education and Integrated Arts and Sciences, Waseda Univ.

A markedly increasing influence of human activity on the Earth system since 1950s has gained attention as one of the notable turning points of Earth's history, which is noteworthy to propose the 'Anthropocene' as a potential new unit of the International Chronostratigraphic Chart which serves as the basis of the Geological Time Scale. Now is ongoing the definition and selection of the Global Boundary Stratotype Section and Point (GSSP) mainly by the Anthropocene Working Group (AWG), a working group of the Subcommission on Quaternary Stratigraphy (SQS) of the International Commission on Stratigraphy (ICS). There are several candidates of a suitable stratotype for hosting an Anthropocene GSSP, including ice core, tree-ring, and coral that record an increasing fallout signal of ^{14}C and ^{239}Pu as well as a rapid decrease in $\delta^{13}C$ during 1950s. However, since (1) radionuclide fallout did not have major biological or other widespread physical repercussions, (2) ice might disappear itself due to global warming, and (3) ^{14}C signal won't detect in 100, 000 years or more, other stable auxiliary stratotypes and markers may be needed for the establishment of GSSP.

GSSPs previously ratified have often been established in marine sediments; anoxic marine sediments emerges as one of the candidates for Anthropocene auxiliary stratotypes (Waters et al., 2018). In anoxic marine sediments, there are the potential Anthropocene boundary markers, including microplastics, diatom and foraminifer assemblages, metals, organic contaminations, and spheroidal carbonaceous particles, which can be used to correlate globally. Several marine anoxic basins have been addressed for a candidate of auxiliary stratotype, such as Santa Barbara Basin, etc., but, an existence of a Japanese marine anoxic basin has not been well-known. Here we introduce laminated sediments in the anoxic Beppu Bay basin for a potential auxiliary stratotype of Anthropocene and discuss its recent progress of stratigraphy and advantage to propose the candidate, and future tasks to acquire a comprehensive dataset for establishment of the boundary.

[M-IS22] Electromagnetic phenomena associated with seismic and volcanic activities

convener:Tetsuya Kodama(Research Unit I, Research and Development Directorate, Japan Space Exploration Agency), Toshiyasu Nagao(Institute of Oceanic Research and development, Tokai University)

This session deals with reviews and contributions on the recent studies of electromagnetic (EM) phenomena associated with earthquakes and volcanic eruptions. One of the main targets of the session is to clarify the mechanism of seismo-EM emission and Lithosphere-Atmosphere-Ionosphere (LAI) coupling. Recently, some scientists claim that seismic activities are the critical phenomena. These kinds of approach are also welcome.

Ionospheric TEC changes immediately before large earthquakes: Derivation of the standard curve and discussion on the physical mechanisms

*Yuki Takasaka [1], Kosuke Heki[1]

1. Department of Earth and Planetary Science, Faculty of Science, Hokkaido University

Shortly after the 2011 Tohoku-Oki Earthquake, Heki (2011) found that the ionospheric total electron content (TEC) started to change ~40 minutes before earthquake. Number of earthquakes showing similar immediate precursory TEC changes increased (e.g. He & Heki, 2017), but physical process behind the phenomenon has not been fully understood. Existence of such precursors suggest that the final size of an earthquake is largely prescribed when the fault rupture starts, which would be of sound seismological importance.

Why does the ionospheric TEC increase immediately before large earthquakes? We hypothesize that a certain process weakens the fault by sweeping the fault from one end to the other. It causes micro-scale cracks and dislocations, which cut peroxy bonds within rocks mobilizing positive holes. Electron movements let positive holes diffuse out of the rock and accumulate on the surface. They would make vertical electric fields (**E**) which may reach the ionosphere if the fault is large enough. High conductivity in ionosphere along geomagnetic fields (**B**) prohibits **E** along **B**. Thus, ionospheric electrons come down along **B** to cancel external **E**. This process would increase electron density at the bottom end of the geomagnetic field line and decrease electron density in higher regions. This hypothesis is supported by the 3-dimensional structure of the electron density anomalies just before the 2015 Illapel earthquake by He & Heki (2018).
In this study, we compare vertical TEC changes before and after the 18 earthquakes with Mw 7.3-9.2 that showed significant immediate preseismic TEC anomalies and explore scaling laws of various quantities. Then we derive the ‘standard curve’ of preseismic TEC changes by stacking the time series of individual cases after normalizing their horizontal and vertical axes. Comparing individual cases with the standard curve and highlighting their differences would help us characterize between-earthquake differences and get insight into their physical mechanisms. The current model suggests that the coseismic release of crustal stress would stop further generation of positive changes from faults and halt the TEC anomaly buildup. The derived standard curve suggested that the TEC does not show further increase after the earthquake occurrence time and remain almost constant until acoustic disturbances arrive. Also, the shapes of the pre-earthquake anomaly buildup curves may have regionality, reflecting e.g. the ocean-land proportion around the epicenter. Higher conductivity of the sea water will let electric charges diffuse rapidly and make the TEC anomaly reaches plateau earlier after its start. Comparison of the TEC change curves of individual earthquakes with the standard curve, however, showed that they are highly coincident in most cases with little significant differences in how the TEC anomaly builds up.

Examination of ionospheric disturbances at different altitudes associated with Tohoku earthquake using HF Doppler sounding

*Natsuki Ono[1], Hiroyuki Nakata[1], Hiroyo Ohya[1], Toshiaki Takano[1], Ichiro Tomizawa[2], Keisuke Hosokawa[2], Takuya Tsugawa[3], Michi Nishioka[3]

1. Department of Electrical and Electronic Engineering, Graduate School of Science and Engineering, Chiba University, 2. The University of Electro-Communications, 3. NICT

It is reported that ionospheric disturbances occur after giant earthquakes. One of the reasons for these disturbances are the infrasound wave excited by ground motions.
The infrasound wave propagates upward and produces perturbations of electron density in the ionosphere. Such perturbations are detected by a network of ground-based GPS receivers as TEC perturbations. Using these TEC perturbations, horizontally propagation of the ionospheric disturbances from the epicenter is examined. However, characteristics of vertical propagation of infrasound have been rarely reported. In this study, the coseismic ionospheric disturbances in the different altitudes are examined using HF Doppler (HFD) and GPS-TEC. The HF Doppler sounding system is enable to observe the vertical speed of the ionosphere in the midpoint between the transmitter and the receiver at the different altitudes.We observed fluctuations induced by Tohoku earthquake.The ionospheric disturbances determined by HFD and TEC data were observed about 9 and 10 minutes after the surface wave arrived below the observation point, respectively. Because it takes about 20 minutes for the acoustic wave to arrive directly from the tsunami to HFD observation point, the initial disturbances observed by HFD and TEC were excited by the ground motion. The frequencies of the disturbance. Obtained by the seismograph and HFD data (5.006, 6.055 MHz) were about 3 - 20 mHz, and those in the HFD data (8.006, 9.595 MHz) are 3 - 5 mHz.HFD data (8.006, 9.595 MHz) the frequencies of the disturbances obtained by, 3 - 5 mHz, were the same as those of TEC disturbances associated with earthquakes. In the lower frequency components with 7 - 20 mHz, the acoustic wave excited by the seismic wave tend to attenuate at a high altitudes. Therefore, it is considered that the variation attenuated with the data in HFD data (8.006, 9.595 MHz).

Electromagnetic observation addressed to the short-term earthquake prediction research in VLF band

*Toshiyasu Nagao[1], Jun Izutsu[2], Masashi Kamogawa[3], Yoshiaki Orihara[1], Shigeki Sugiura[4], Hitoshi Kondo[4]

1. Institute of Oceanic Research and development, Tokai University, 2. Intl. Digital Earth Applied Sci. Res. Ctr, Chubu Inst. for Advanced Studies, Chubu Univ., 3. Department of Physics, Tokyo Gakugei University, 4. Genesis Research Institute, Inc.

There have been many reports electromagnetic (EM) waves preceding earthquakes have existed since the 1980s. The late Professor Toshi Asada and his colleagues focused on the VLF band and developed devices and made observations at the Tokai University in the 1990s. As a result, in the apparent arrival direction analysis, the electromagnetic waves, which comes from the epicenter direction were observed. However, after that, the observation was interrupted due to the death of Professor Asada. It seemed promising results, therefore we resumed research from FY 2014. The feature of the present apparatus is that not only the apparent arrival direction analysis but also the wave source determination can be performed using the time difference of arrival (TDOA) of EM waves. Because the apparent arrival direction method can only apply when the observed EM wave has a linear polarization. In the wave source determination using TDOA, the arrival time of the EM wave was determined by using the autoregressive model and AIC. We observed EM waves coming from the epicentral region, two days before the earthquake, which occurred in the southern part of Nagano Prefecture on June 25, 2017 (M5.6). This earthquake was the largest one occurred in the vicinity of our observation network at this moment. In the presentation, we would like to present a detailed waveform analysis and future research plan.

Acknowledgments

ELF electric field intensity at the time of VLF precursor in the DEMETER data

*Masashi Kamogawa[1], Tetsuya Kodama[2], Toshiyasu Nagao[3]

1. Department of Physics, Tokyo Gakugei University, 2. Japan Space Exploration Agency, 3. Tokai University

A decrease of electric field at the 1.7 kHz, i.e., VLF electromagnetic waves, within 4 hours before neighboring earthquake (EQ) with the magnitude of more than 4.8 was statistically shown through the data set of in-situ DEMETER satellite measurement according to French groups (Nemec et al., GRL, 2008). In this study, we investigate the ELF intensity comparing with the pre-seismic VLF intensity decrease data.

Examination of ionospheric disturbances at different altitudes associated with Tohoku earthquake using HF Doppler sounding

*Natsuki Ono[1], Hiroyuki Nakata[1], Hiroyo Ohya[1], Toshiaki Takano[1], Ichiro Tomizawa[2], Keisuke Hosokawa[2], Takuya Tsugawa[3], Michi Nishioka[3]

1. Department of Electrical and Electronic Engineering, Graduate School of Science and Engineering, Chiba University, 2. The University of Electro-Communications, 3. NICT

It is reported that ionospheric disturbances occur after giant earthquakes. One of the reasons for these disturbances are the infrasound wave excited by ground motions.
The infrasound wave propagates upward and produces perturbations of electron density in the ionosphere. Such perturbations are detected by a network of ground-based GPS receivers as TEC perturbations. Using these TEC perturbations, horizontally propagation of the ionospheric disturbances from the epicenter is examined. However, characteristics of vertical propagation of infrasound have been rarely reported. In this study, the coseismic ionospheric disturbances in the different altitudes are examined using HF Doppler (HFD) and GPS-TEC. The HF Doppler sounding system is enable to observe the vertical speed of the ionosphere in the midpoint between the transmitter and the receiver at the different altitudes.We observed fluctuations induced by Tohoku earthquake.The ionospheric disturbances determined by HFD and TEC data were observed about 9 and 10 minutes after the surface wave arrived below the observation point, respectively. Because it takes about 20 minutes for the acoustic wave to arrive directly from the tsunami to HFD observation point, the initial disturbances observed by HFD and TEC were excited by the ground motion. The frequencies of the disturbance. Obtained by the seismograph and HFD data (5.006, 6.055 MHz) were about 3 - 20 mHz, and those in the HFD data (8.006, 9.595 MHz) are 3 - 5 mHz.HFD data (8.006, 9.595 MHz) the frequencies of the disturbances obtained by, 3 - 5 mHz, were the same as those of TEC disturbances associated with earthquakes. In the lower frequency components with 7 - 20 mHz, the acoustic wave excited by the seismic wave tend to attenuate at a high altitudes. Therefore, it is considered that the variation attenuated with the data in HFD data (8.006, 9.595 MHz).

Electromagnetic observation addressed to the short-term earthquake prediction research in VLF band

*Toshiyasu Nagao[1], Jun Izutsu[2], Masashi Kamogawa[3], Yoshiaki Orihara[1], Shigeki Sugiura[4], Hitoshi Kondo[4]

1. Institute of Oceanic Research and development, Tokai University, 2. Intl. Digital Earth Applied Sci. Res. Ctr, Chubu Inst. for Advanced Studies, Chubu Univ., 3. Department of Physics, Tokyo Gakugei University, 4. Genesis Research Institute, Inc.

There have been many reports electromagnetic (EM) waves preceding earthquakes have existed since the 1980s. The late Professor Toshi Asada and his colleagues focused on the VLF band and developed devices and made observations at the Tokai University in the 1990s. As a result, in the apparent arrival direction analysis, the electromagnetic waves, which comes from the epicenter direction were observed. However, after that, the observation was interrupted due to the death of Professor Asada. It seemed promising results, therefore we resumed research from FY 2014. The feature of the present apparatus is that not only the apparent arrival direction analysis but also the wave source determination can be performed using the time difference of arrival (TDOA) of EM waves. Because the apparent arrival direction method can only apply when the observed EM wave has a linear polarization. In the wave source determination using TDOA, the arrival time of the EM wave was determined by using the autoregressive model and AIC. We observed EM waves coming from the epicentral region, two days before the earthquake, which occurred in the southern part of Nagano Prefecture on June 25, 2017 (M5.6). This earthquake was the largest one occurred in the vicinity of our observation network at this moment. In the presentation, we would like to present a detailed waveform analysis and future research plan.

Acknowledgments

This study was partly supported by the Ministry of Education, Culture, Sports, Science and Technology (MEXT) of Japan, under its Earthquake and Volcano Hazards Observation and Research Program, research fund of the core-project of Institute of Oceanic Research and Development (IORD), Tokai University and Genesis Research Institute, Inc.

ELF electric field intensity at the time of VLF precursor in the DEMETER data

*Masashi Kamogawa[1], Tetsuya Kodama[2], Toshiyasu Nagao[3]

1. Department of Physics, Tokyo Gakugei University, 2. Japan Space Exploration Agency, 3. Tokai University

A decrease of electric field at the 1.7 kHz, i.e., VLF electromagnetic waves, within 4 hours before neighboring earthquake (EQ) with the magnitude of more than 4.8 was statistically shown through the data set of in-situ DEMETER satellite measurement according to French groups (Nemec et al., GRL, 2008). In this study, we investigate the ELF intensity comparing with the pre-seismic VLF intensity decrease data.

[M-IS22] Electromagnetic phenomena associated with seismic and volcanic activities

convener:Tetsuya Kodama(Research Unit I, Research and Development Directorate, Japan Space Exploration Agency), Toshiyasu Nagao(Institute of Oceanic Research and development, Tokai University), Chairperson:Tetsuya Kodama, Toshiyasu Nagao

This session deals with reviews and contributions on the recent studies of electromagnetic (EM) phenomena associated with earthquakes and volcanic eruptions. One of the main targets of the session is to clarify the mechanism of seismo-EM emission and Lithosphere-Atmosphere-Ionosphere (LAI) coupling. Recently, some scientists claim that seismic activities are the critical phenomena. These kinds of approach are also welcome.

Stress-induced charges in gabbro at high temperature

*Chihiro Yamanaka[1], Daiki Maezono[1]

1. Graduate School of Science, Osaka University

Preseismic ionospheric disturbance just before large earthquakes was found at the 2011 off the Pacific coast of Tohoku Earthquake (Heki,2011). Similar phenomena up to 18 cases (Heki's TEC anomaly) were found in earthquakes of M 7-9 since 1994. It should be noted all the earthquakes larger than M 8.5 during that duration were 5 times and Heki's TEC anomaly was observed for all of them.
Assuming the phenomena were drived by surface electromagnetic field due to stress induced charges distributed thinly around focal or nucleation zone, we have been studying stress-induced charges from silicate rocks. A dried gabbro sample (10×10×3 cm) was heated up to 350℃, then stress-induced current under uniaxial stress of 10 MPa was observed with the variation of temperature.
Experimental results showed that stress-induced charges increased from room temperature to 200℃ but then decreased at higher temperature. We would like to discuss the mechanism of Heki's TEC anomaly based on the experimental results and computer simulation.

Evaluation of ULF seismo-magnetic precursor phenomena at Kakioka, Japan over 1983 –2018 by using SEA and Molchan’ s error diagram

*Katsumi Hattori[1], Kei Takahashi[2], Peng Han[3]

1. Department of Earth Sciences, Graduate School of Science, Chiba University, 2. Department of Earth Sciences, Faculty of Science, Chiba University, 3. Southern University of Science and Technology, China

To clarify and verify the ultralow frequency (ULF) seismo-magnetic phenomena, we have performed statistical studies on the geomagnetic data observed at the Kakioka (KAK) station, Japan, during 1983-2017. We investigated the energy of ULF geomagnetic signals of the frequency around 0.01 Hz using wavelet transform analysis. To minimize the influences of artificial noises and global magnetic perturbations, we used only the geomagnetic data observed at midnight time (LT 2:30 AM to 4:00 AM).We define the geomagnetic anomalies when the Z components of geomagnetic data exceeds median +1.5 IQR, where IQR is the interquartile range. Considering that ionospheric disturbances may also lead to enhancements in the Z component, we exclude the anomaly when the energy of H component exceeds median +3.0 IQR. Statistical analysis of superposed epoch analysis have indicated that ULF magnetic anomalies are more likely to appear before sizable isolated earthquake events rather than after them, especially 6-10 days before the events. Finally, we have evaluated the precursory information of ULF geomagnetic signals for local sizable earthquakes using Molchan’ s error diagram. The results show that the ULF seismo-magnetic phenomena at Kakioka clearly contain precursory information and have a possibility of improving forecasting of large earthquakes. The details will be given in the presentation.

On the tsunami and electromagnetic pulses appeared abound 10min. after the 2011 Tohoku earthquake

*Yuji Enomoto[1], Tsuneaki Yamabe[1], Shigeki Sugiura[2], Hitoshi Kondo[2]

1. Shinshu Univeristy, Ueda Campus Fii, 2. Genesis Reserach Institute, Inc.

Tsunami and electromagnetic pulses have appeared about 10 min. after the 2011 Tohoku-Oki earthquake(Heki, GRL, 2011; Utada et al. EPS Lett., 2011; Tsunagawa et al. EPS Lett., 2011). The disturbance to the ionosphere is thought to have been influenced by the atmospheric gravity wave caused by the tsunami. But this model could not explain the variation of geomagnetism, observed at Esahi site. In order to explain geomagnetic variation, we present a model that positively charged mists flied up with the atmospheric gravity wave along with the atmospheric electric field as the tsunami pulse was generated.

Reinvestigation of correlation between groundwater anomalies and earthquakes carried out by an amateur network in Japan

*Yoshiaki Orihara[1], Masashi Kamogawa[2], Toshiyasu Nagao[1]

1. Institute of Oceanic Research and Development, Tokai University, 2. Dpt. of Phys., Tokyo Gakugei Univ.

An amateur volunteer group for an earthquake prediction, “the catfish club”, had monitored groundwater levels and the temperature of thermal water to detect earthquake precursor signals since 1976. More than 200 participants in Kanagawa, Tokyo, Shizuoka, and some prefectures monitored them. Their sampled data are sent to the office of the catfish club, and the summarized reports were published every month. Oki and Hiraga (1988) reported the probably predicted events such as the 1978 Izu-Ohshima kinkai earthquake (M 7.0) and the 1978 Miyagiken-Oki earthquake (M 7.4). In this study, we statistically evaluate the anomaly appearance rate, the earthquake occurrence rate, and the probability gain using the data from 1977 to 1987.

The future direction of EMSEV, IUGG International Working Group

*Toshiyasu Nagao[1]

1. Institute of Oceanic Research and development, Tokai University

EMSEV (Electromagnetic Studies of Earthquakes and Volcanoes) was established in 2001 as a mother foundation of IAGA, IAVCEI, and IASPEI under IUGG (International Union of Geodesy and Geophysics). At that time, many studies of electromagnetic precursory phenomena were reported in earthquake prediction research but never seemed to be recognized by the traditional seismology community. For this reason, the grassroots movement had been expanded for the necessity of promoting international research.

Therefore we urged the establishment of an organization to study earthquake prediction and volcanic eruption prediction based on the electromagnetics in IUGG. It was officially launched in 2001 and the first meeting was made during the IUGG Sapporo in 2003.

Professor emeritus of the University of Tokyo, Seiya Uyeda served as the first chair of EMSEV, then Dr. Jacques Zlotnicki of the French National Science Research Center took the chair till 2018. EMSEV meeting was held, which organizes every two years, in Potenza in Italy in 2018. During the meeting, Professor Toshiyasu Nagao was proposed to serve as the next chair. This proposal was approved through the discussion of the mailing list.

In the future EMSEV, we must show the statistical correlation between the ionospheric anomaly and the earthquake first, then we have to prove why the earthquake precursors phenomena appear in the ionosphere based on the lithosphere - atmosphere - ionosphere coupling hypothesis. In particular, from satellite observations, France launched the DEMETER satellite in 2004, showing the statistical significance of VLF band anomalies just before the earthquake. Inspired by this result, China launched the CSES (Chinese Seismo-Electromagnetic Satellite) in 2018.

We decided that the next meeting of EMSEV will be held in Taiwan in the fall of 2020.

[M-GI30] Data assimilation: A fundamental approach in geosciences

convener:Shin ya Nakano(The Institute of Statistical Mathematics), Yosuke Fujii(Meteorological Research Institute, Japan Meteorological Agency), SHINICHI MIYAZAKI(Graduate School of Science, Kyoto University), Takemasa Miyoshi(RIKEN)

Data assimilation is an inversion approach to estimate the evolution of a system by utilizing a constraint given by a dynamical simulation model. Data assimilation is now widely used not only in meteorology and oceanography but also other fields of geosciences such as hydrology, solid earth science, and space science. This session aims at providing an opportunity for discussion on data assimilation studies among researchers of various field of geosciences. We encourage contributions addressing novel methods and theoretical developments of data assimilation. Contributions dealing with useful applications of data assimilation are also welcome.

Superposition of atmospheric states using information redundancy for Numerical Weather Prediction

*Toshiyuki Ishibashi[1]

1. Meteorological Research Institute/Japan Meteorological Agency

Atmospheric state analysis is a difficult scientific problem due to our limited ability in computation and observation, and analysed atmospheric states are fluctuating around the true state. The purpose of this paper is to analyse atmospheric state as a superposition of possible atmospheric states using information redundancy, and evaluate its accuracy in the context of numerical weather prediction (NWP). This atmospheric state analysis approach has two novel aspects. First, it uses only real atmospheric information, and no-artificial perturbations unlike existing ensemble based methods. Second, it does not require specific error structures of our knowledge of the atmosphere. We performed this method on a global numerical weather prediction system of Japan Meteorological Agency. The experimental results show the method can clearly reduce forecast root means square errors about 3-5% in average within 2 day forecast compared to existing methods (CNTL). Furthermore, forecast RMSEs of ensemble means of ensemble forecasts using only a few members generated by this method are significantly smaller than CNTL from the forecast initial time.

Numerical Weather Prediction Experiments using a Coupled Atmosphere-Ocean Data Assimilation System in JMA/MRI (3)

*Toshiyuki Ishibashi[1], Takeshi Iriguchi[1], Yosuke Fujii[1], Tamaki Yasuda[1], Yuhei Takaya[1], Naoki Saito[1], Toshikazu Onogi[1]

1. Meteorological Research Institute/Japan Meteorological Agency

An atmosphere-ocean coupled data assimilation system (CDAS) has been developed at the JMA/MRI to investigate feasibility of a CDAS as a future DAS for seamless numerical prediction including both numerical weather prediction (NWP) and numerical seasonal climate prediction (NCP), and for reanalysis of the atmosphere-ocean. Our CDAS (**MRI-CDA1**) has two features. 1) It composed of the JMA operational systems, the global atmospheric DAS (MRI-NAPEX) based on 4D-Var, the global ocean DAS (MOVE-G2) based on 3D-Var, and the atmosphere- ocean coupled global forecast model (CGCM: JMA/MRI-CGCM2). 2) Coupling strategy is “weak coupling” with two different data assimilation window lengths for the atmosphere and ocean. Here, “weak coupling” denotes the approximation that ignores correlations of atmosphere and ocean background forecast errors. Following the previous reports in JpGU2018 and JpGU-AGU joint meeting 2017 (Ishibashi et al. 2018; 2017), we will report basic property of MRI-CDA1 in NWP.

Accurate estimation of posterior error covariance in a 4D-Var inverse analysis

*Yosuke Niwa[1,2], Yosuke Fujii[2,3]

1. National Institute for Environmental Studies, 2. Meteorological Research Institute, Japan Meteorological Agency, 3. The Institute of Statistical Mathematics

The four-dimensional variational method (4D-Var) is one prominent data assimilation/inversion method. However, it is a non-trivial task for a conventional 4D-Var to estimate a posterior error variance-covariance matrix. This study developed a method to estimate a posterior error variance-covariance matrix especially focusing on its off-diagonal elements, i.e., covariance. Off-diagonal elements are usually difficult to be estimated but provide error correlations that are beneficial for interpreting optimized parameter variations. The method was developed within a 4D-Var framework using a quasi-Newton method with the Broyden–Fletcher–Goldfarb–Shanno (BFGS) formula. This study newly introduces numerical techniques that ensure conjugacy among the set of increment vector pairs in the BFGS formula. Through application to an inverse problem of atmospheric CO_2, the developed method was evaluated with three diagnostic measures and compared against existing methods. The evaluation revealed that the developed method could provide accurate estimates of the posterior variance-covariance matrix, in terms not only of the diagonal but also of the off-diagonal elements. Although far more expensive than optimal state estimation, the computational efficiency was found reasonable for practical use, especially in conjunction with an ensemble approach.

Keywords: inversion, data assimilation, posterior error covariance

Assimilation CO_2 concentration data in the Kanto region using AIST-MM model and for the estimation of CO_2 emissions

*Yutaka Arai[1], Ryoichi Imasu[1], Hiroaki Kondo[2], Yosuke Niwa[3]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. National Institute of Advanced Industrial Science and Technology, 3. National Institute for Environmental Studies, Independent Administrative Institutions

Atmospheric carbon dioxide (CO_2) known as greenhouse gas is the most important gas for global warming. For the reason, there have been many researches about CO_2 such as model calculations, satellite observations and direct observations recently. As computer spec get higher, the CO_2 model has been more improved and 3D distributions of CO_2 has been calculated in more detail. In Japan, the satellite observation has been high resolution by satellite, Greenhouse Observing SATellite-2 (GOSAT-2). But in urban area, CO_2 distributions are complicated because of complexed CO_2 emission source and sink around the area. Especially, in the Kanto district mega city, Tokyo is located, CO_2 emissions from power plants and human activities are very huge. Furthermore, around the city there are forests and mountains which strongly affect to CO_2 concentrations in the atmosphere through their respiration and photosynthesis. In case to calculate such the district with high spatial resolutions, the models are required to be able to represent the temporal and spatial variations of the respiration and photosynthesis of the plants precisely. It has been also pointed out that representativeness of the vertical transport of CO_2 in the models is a key subject. About satellite observations, it is not always possible to observe CO2 distributions because of to be influenced by the weather and the frequencies of them are limited, and what ca be observed are not 3 dimensional but 2 dimensional namely vertical column densities of CO_2. On the other hand, the accuracy of the in-situ observations, is best, but there are very limited observation points. These are obstacles to grasping the detailed behavior of CO_2 concentration.

In this study, a regional transport model, AIST-MM has been used to investigate the behavior of CO_2 concentrations in Kanto district (Kondo et al., 2001). Firstly, AIST-MM computes CO_2 concentrations in the outer area (630 km×550 km), and then calculates CO_2 concentrations in the inner area (216 km×216 km) using the results from the former.
Firstly, the model was improved to be able to calculate the CO_2 seasonal variations through a year in order to estimate CO_2 emission source which contained large error. It was found that AIST-MM had uncertainty in the part of plant activities especially respiration in summer. As the calculation of plant respiration strongly depends on the temperature, when the temperature becomes high, the respiration of plants unrealistically increases. So the plant respiration parameter was tuned.
In order to compensate for the CO_2 influx from outside of the calculation region, the result of a global model, NICAM-TM (GL5) were used as the boundary conditions when calculating outer region. This modification led to improve the calculation of the vertical transport.
Furthermore, constant sea surface temperature was replaced with the satellite observation data derived from AVHRR-AMSR. In order to improve the simulating performance, we adjusted many detailed emission information by distinguishing between holidays and weekdays.
Secondly, Local Ensemble Transform Kalman Filter (LETKF) which is one of data assimilation methods is adapted to the adjusted AIST-MM and try to calculate CO_2 concentrations using in-situ observations, satellite observations, and ground remote sensing observations. In the near future, the CO_2 emissions will be estimated using Kalman smoother method.

Application of data assimilation method on parameter estimation of flow and nutrient behavior in watershed model

*Yosuke Horie[1]

1. Nippon Koei Co., Ltd.

In schemes for nutrient reduction from watershed such as Japanese total volume control framework on nutrient or master plan for sewerage system propagation, hydrologic and nutrient behavior in watershed is critical to make an effective plan to fulfill environmental standard of water body. However, there are many uncertainties in constructing a watershed model as follows. First, observation frequency of concentration of water quality, which is a target of such scheme on nutrient reduction, is not enough because they can be obtained in public water quality observation system only about once a month. Second, pollutant load unit, which is used for quantifying pollutant load from watershed, can be fluctuated from place to place. Third, there are many parameters of watershed models which should be calibrated. To resolve these problems, this study applied EnKF, one of data assimilation method, to SWAT (Soil and Water Assessment Tools) model, which can simulate hydrologic and nutrient cycle in watershed, and conducted parameter estimation to achieve more robust result from watershed model under the uncertainties above.

Bayesian inference of grain growth prediction via multi-phase-field models

*Shin-ichi Ito[1], Hiromichi Nagao[1], Takashi Kurokawa[1], Tadashi Kasuya[1], Junya Inoue[1]

1. The University of Tokyo

We propose a Bayesian inference methodology to evaluate unobservable parameters involved in multi-phase-field models with the aim of accurately predicting the observed grain growth, such as in metals and rocks. This approach integrates models and a set of observational image data of grain structures. Since the set of image data is not a time series, directly applying conventional inference techniques that require time series as the input data is difficult. The key idea in our methodology to overcome this difficulty is to construct a time series with an appropriate statistic that characterizes static image data of grain structures. Our methodology implements the empirical Bayes method. It can estimate not only a probability density function of the parameters but also an initial phase-field, which is generally unobservable in real experiments. After validating the proposed method through numerical tests using synthetic data, we apply it to real experimental images of grain structures in a steel alloy. The proposed method properly estimates unobservable parameters together with their uncertainties, and successfully selects the initial phase-field that best explains the experimental data from among candidate initial phase-fields.

GNSS data assimilation for the Bungo channel Long-term SSEs using Ensemble Kalman Filter (EnKF)

*Megumi Fujita[1], Takuya NISHIMURA[2], Kazuro Hirahara[3], SHINICHI MIYAZAKI[1]

1. Graduate School of Science , Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University, 3. Institute of Education, Research and Regional Cooperation for crisis Management Shikoku, Kagawa University

Long-term Slow Slip Events (L-SSEs) in the Bungo channel, southwest Japan occur in the down-dip side of the seismogenic zones on the megathrust plate interface. Although L-SSEs release accumulated strain in the L-SSE zones, they can increase strain in the up-dip seismogenic locked zones. Therefore, better understanding of the temporal evolution of L-SSEs is very important for earthquake hazard assessment. Hirahara, and Nishikiori (JpGU, 2018) developed a method for estimating slip evolution and frictional properties on L-SSE area in the Bungo channel, by applying a data assimilation method EnKF (Ensemble Kalman Filter), which has been developed in meteorology and oceanology, to the synthetic GNSS data. Although they used the surface velocity data as GNSS data, the actual data which we can observe at GNSS station is the surface displacement data, not surface velocity data. In order to apply EnKF to the actual GNSS observational data, we conducted two numerical experiments, as follows.

i)We used the surface velocity data converted from the synthetic surface displacement data as observational data.

ii) We used the surface displacement data, not the surface velocity data as observational data.

We used the same model settings in above two numerical experiments as Hirahara and Nishikiori (2018) did. Firstly, we set a plane fault in homogeneous isotropic elastic body, whose angle of dip is 15 degrees. The frictional force on the plane fault follows a Rate and State Friction (RSF) law with an aging law [Dieterich,1979; Ruina,1983]. We set a velocity weakening (A-B<0) circular patch, whose radius R is 35 km, in the velocity strengthen (A-B>0) fault plane. We reproduced the observed L-SSEs in the Bungo Channel, using the frictional parameters in such a way that R is smaller than the critical nucleation size R_c [Rubin and Ampuero (2005), Chen and Lapusta (2009)]. Secondly, we considered the effect the seismogenic locked zones in the up-dip side of the L-SSEs zone. We set a locked zone at the up-dip of the L-SSE fault, whose back-slip rate is 6.0 cm/yr.

As the common analysis settings, we selected several pairs of frictional parameters in a wide range of parameter space which reproduce L-SSEs for the initial ensemble members of frictional parameters. We made the daily synthetic GNSS surface displacement data for 93 GEONET stations around the Bungo channel by calculating the surface displacements using true synthetic frictional parameters and adding random Gaussian noise. We set the assimilation interval to 10 days.

In experiment i), we calculated 31 day moving averages of the synthetic GNSS displacement data, and we obtained the surface velocities at GNSS stations from the derivatives of a 150-day cubic spline function fitting the moving averaged surface displacements. Then we applied EnKF to the obtained surface velocities and we successfully estimated slip evolution and frictional parameters. This result suggests this method for converting the surface displacement data into the surface velocity data at GNSS stations might be applicable.

©2019. Japan Geoscience Union. All Right Reserved.

In experiment ii), we applied EnKF to the synthetic GNSS displacement data directly. When we conducted experiment ii), we changed some analysis settings for stabilizing the assimilation. Firstly, when the slip velocity at the center of fault plane is low, we added larger random noise to the innovations artificially. Secondly, when the slip velocity at the center of fault plane is high, we reduced the assimilation interval to 1 day and introduced additive inflation to prevent the prediction errors from being too small. As a result, we also successfully estimated slip evolution and frictional parameters using the surface displacements, although the experiment sometime fails depending on the start timing of the analysis. Therefore, this method has not been fully stabilized yet, and we need to improve it for robust estimation.

Finally, we applied EnKF to the real GNSS data before the 2011 Tohoku-oki earthquake in the same settings as experiment i) and ii) respectively. We corrected offsets of major earthquakes and antenna changes in the GNSS data. However, both experiments stopped during the assimilation due to negative slip velocities. It manifests an importance of correction of GNSS data including removing annual and semiannual components for a stable assimilation of real GNSS data. Furthermore, we need to consider the realistic model settings including the geometry of the subducting Philippine Sea plate interface and distribution of both L-SSE and locked zones.

A data assimilation library with Python for parallel computing

*Shin ya Nakano[1], Yuya Ariyoshi[2], Tomoyuki Higuchi[1]

1. The Institute of Statistical Mathematics, 2. Faculty of Engineering, Nippon Bunri University

Parallel computing is essential to reduce the computational time in the ensemble-based data assimilation. However, it requires skills in parallel programming. It is sometimes a hard task to attain high computational efficiency with ensemble-based data assimilation. In particular, the particle filter (PF) algorithm, which is applicable to nonlinear and/or non-Gaussian problems, contains a procedure difficult to parallelize.
It is thus challenging to achieve high computational efficiency with the PF even for experienced users.

We have developed a Python library named P-cubed (Python Parallelized Particle Filter Library), that enables us to use parallel-ready PF algorithms with high parallel efficiency. Now we are also planning to attach a module of other data assimilation algorithms such as the ensemble Kalman filter to this library. In this presentation, we introduce the parallelized PF algorithms which are already available in P-cubed and explain the design and characteristics of the library. Future prospects of this library will also be discussed.

[M-GI30] Data assimilation: A fundamental approach in geosciences

convener:Shin ya Nakano(The Institute of Statistical Mathematics), Yosuke Fujii(Meteorological Research Institute, Japan Meteorological Agency), SHINICHI MIYAZAKI(Graduate School of Science, Kyoto University), Takemasa Miyoshi(RIKEN)

Data assimilation is an inversion approach to estimate the evolution of a system by utilizing a constraint given by a dynamical simulation model. Data assimilation is now widely used not only in meteorology and oceanography but also other fields of geosciences such as hydrology, solid earth science, and space science. This session aims at providing an opportunity for discussion on data assimilation studies among researchers of various field of geosciences. We encourage contributions addressing novel methods and theoretical developments of data assimilation. Contributions dealing with useful applications of data assimilation are also welcome.

Superposition of atmospheric states using information redundancy for Numerical Weather Prediction

*Toshiyuki Ishibashi[1]

1. Meteorological Research Institute/Japan Meteorological Agency

Atmospheric state analysis is a difficult scientific problem due to our limited ability in computation and observation, and analysed atmospheric states are fluctuating around the true state. The purpose of this paper is to analyse atmospheric state as a superposition of possible atmospheric states using information redundancy, and evaluate its accuracy in the context of numerical weather prediction (NWP). This atmospheric state analysis approach has two novel aspects. First, it uses only real atmospheric information, and no-artificial perturbations unlike existing ensemble based methods. Second, it does not require specific error structures of our knowledge of the atmosphere. We performed this method on a global numerical weather prediction system of Japan Meteorological Agency. The experimental results show the method can clearly reduce forecast root means square errors about 3-5% in average within 2 day forecast compared to existing methods (CNTL). Furthermore, forecast RMSEs of ensemble means of ensemble forecasts using only a few members generated by this method are significantly smaller than CNTL from the forecast initial time.

1. Meteorological Research Institute/Japan Meteorological Agency

An atmosphere-ocean coupled data assimilation system (CDAS) has been developed at the JMA/MRI to investigate feasibility of a CDAS as a future DAS for seamless numerical prediction including both numerical weather prediction (NWP) and numerical seasonal climate prediction (NCP), and for reanalysis of the atmosphere-ocean. Our CDAS (**MRI-CDA1**) has two features. 1) It composed of the JMA operational systems, the global atmospheric DAS (MRI-NAPEX) based on 4D-Var, the global ocean DAS (MOVE-G2) based on 3D-Var, and the atmosphere- ocean coupled global forecast model (CGCM: JMA/MRI-CGCM2). 2) Coupling strategy is “weak coupling” with two different data assimilation window lengths for the atmosphere and ocean. Here, “weak coupling” denotes the approximation that ignores correlations of atmosphere and ocean background forecast errors. Following the previous reports in JpGU2018 and JpGU-AGU joint meeting 2017 (Ishibashi et al. 2018; 2017), we will report basic property of MRI-CDA1 in NWP.

Accurate estimation of posterior error covariance in a 4D-Var inverse analysis

*Yosuke Niwa[1,2], Yosuke Fujii[2,3]

1. National Institute for Environmental Studies, 2. Meteorological Research Institute, Japan Meteorological Agency, 3. The Institute of Statistical Mathematics

The four-dimensional variational method (4D-Var) is one prominent data assimilation/inversion method. However, it is a non-trivial task for a conventional 4D-Var to estimate a posterior error variance-covariance matrix. This study developed a method to estimate a posterior error variance-covariance matrix especially focusing on its off-diagonal elements, i.e., covariance. Off-diagonal elements are usually difficult to be estimated but provide error correlations that are beneficial for interpreting optimized parameter variations. The method was developed within a 4D-Var framework using a quasi-Newton method with the Broyden–Fletcher–Goldfarb–Shanno (BFGS) formula. This study newly introduces numerical techniques that ensure conjugacy among the set of increment vector pairs in the BFGS formula. Through application to an inverse problem of atmospheric CO_2, the developed method was evaluated with three diagnostic measures and compared against existing methods. The evaluation revealed that the developed method could provide accurate estimates of the posterior variance-covariance matrix, in terms not only of the diagonal but also of the off-diagonal elements. Although far more expensive than optimal state estimation, the computational efficiency was found reasonable for practical use, especially in conjunction with an ensemble approach.

Keywords: inversion, data assimilation, posterior error covariance

Assimilation CO_2 concentration data in the Kanto region using AIST-MM model and for the estimation of CO_2 emissions

*Yutaka Arai[1], Ryoichi Imasu[1], Hiroaki Kondo[2], Yosuke Niwa[3]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. National Institute of Advanced Industrial Science and Technology, 3. National Institute for Environmental Studies, Independent Administrative Institutions

Atmospheric carbon dioxide (CO_2) known as greenhouse gas is the most important gas for global warming. For the reason, there have been many researches about CO_2 such as model calculations, satellite observations and direct observations recently. As computer spec get higher, the CO_2 model has been more improved and 3D distributions of CO_2 has been calculated in more detail. In Japan, the satellite observation has been high resolution by satellite, Greenhouse Observing SATellite-2 (GOSAT-2). But in urban area, CO_2 distributions are complicated because of complexed CO_2 emission source and sink around the area. Especially, in the Kanto district mega city, Tokyo is located, CO_2 emissions from power plants and human activities are very huge. Furthermore, around the city there are forests and mountains which strongly affect to CO_2 concentrations in the atmosphere through their respiration and photosynthesis. In case to calculate such the district with high spatial resolutions, the models are required to be able to represent the temporal and spatial variations of the respiration and photosynthesis of the plants precisely. It has been also pointed out that representativeness of the vertical transport of CO_2 in the models is a key subject. About satellite observations, it is not always possible to observe CO2 distributions because of to be influenced by the weather and the frequencies of them are limited, and what ca be observed are not 3 dimensional but 2 dimensional namely vertical column densities of CO_2. On the other hand, the accuracy of the in-situ observations, is best, but there are very limited observation points. These are obstacles to grasping the detailed behavior of CO_2 concentration.

In this study, a regional transport model, AIST-MM has been used to investigate the behavior of CO_2 concentrations in Kanto district (Kondo et al., 2001). Firstly, AIST-MM computes CO_2 concentrations in the outer area (630 km×550 km), and then calculates CO_2 concentrations in the inner area (216 km×216 km) using the results from the former.
Firstly, the model was improved to be able to calculate the CO_2 seasonal variations through a year in order to estimate CO_2 emission source which contained large error. It was found that AIST-MM had uncertainty in the part of plant activities especially respiration in summer. As the calculation of plant respiration strongly depends on the temperature, when the temperature becomes high, the respiration of plants unrealistically increases. So the plant respiration parameter was tuned.
In order to compensate for the CO_2 influx from outside of the calculation region, the result of a global model, NICAM-TM (GL5) were used as the boundary conditions when calculating outer region. This modification led to improve the calculation of the vertical transport.
Furthermore, constant sea surface temperature was replaced with the satellite observation data derived from AVHRR-AMSR. In order to improve the simulating performance, we adjusted many detailed emission information by distinguishing between holidays and weekdays.
Secondly, Local Ensemble Transform Kalman Filter (LETKF) which is one of data assimilation methods is adapted to the adjusted AIST-MM and try to calculate CO_2 concentrations using in-situ observations, satellite observations, and ground remote sensing observations. In the near future, the CO_2 emissions will be estimated using Kalman smoother method.

Application of data assimilation method on parameter estimation of flow and nutrient behavior in watershed model

*Yosuke Horie[1]

1. Nippon Koei Co., Ltd.

In schemes for nutrient reduction from watershed such as Japanese total volume control framework on nutrient or master plan for sewerage system propagation, hydrologic and nutrient behavior in watershed is critical to make an effective plan to fulfill environmental standard of water body. However, there are many uncertainties in constructing a watershed model as follows. First, observation frequency of concentration of water quality, which is a target of such scheme on nutrient reduction, is not enough because they can be obtained in public water quality observation system only about once a month. Second, pollutant load unit, which is used for quantifying pollutant load from watershed, can be fluctuated from place to place. Third, there are many parameters of watershed models which should be calibrated. To resolve these problems, this study applied EnKF, one of data assimilation method, to SWAT (Soil and Water Assessment Tools) model, which can simulate hydrologic and nutrient cycle in watershed, and conducted parameter estimation to achieve more robust result from watershed model under the uncertainties above.

Bayesian inference of grain growth prediction via multi-phase-field models

*Shin-ichi Ito[1], Hiromichi Nagao[1], Takashi Kurokawa[1], Tadashi Kasuya[1], Junya Inoue[1]

1. The University of Tokyo

We propose a Bayesian inference methodology to evaluate unobservable parameters involved in multi-phase-field models with the aim of accurately predicting the observed grain growth, such as in metals and rocks. This approach integrates models and a set of observational image data of grain structures. Since the set of image data is not a time series, directly applying conventional inference techniques that require time series as the input data is difficult. The key idea in our methodology to overcome this difficulty is to construct a time series with an appropriate statistic that characterizes static image data of grain structures. Our methodology implements the empirical Bayes method. It can estimate not only a probability density function of the parameters but also an initial phase-field, which is generally unobservable in real experiments. After validating the proposed method through numerical tests using synthetic data, we apply it to real experimental images of grain structures in a steel alloy. The proposed method properly estimates unobservable parameters together with their uncertainties, and successfully selects the initial phase-field that best explains the experimental data from among candidate initial phase-fields.

GNSS data assimilation for the Bungo channel Long-term SSEs using Ensemble Kalman Filter (EnKF)

*Megumi Fujita[1], Takuya NISHIMURA[2], Kazuro Hirahara[3], SHINICHI MIYAZAKI[1]

1. Graduate School of Science , Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University, 3. Institute of Education, Research and Regional Cooperation for crisis Management Shikoku, Kagawa University

Long-term Slow Slip Events (L-SSEs) in the Bungo channel, southwest Japan occur in the down-dip side of the seismogenic zones on the megathrust plate interface. Although L-SSEs release accumulated strain in the L-SSE zones, they can increase strain in the up-dip seismogenic locked zones. Therefore, better understanding of the temporal evolution of L-SSEs is very important for earthquake hazard assessment. Hirahara, and Nishikiori (JpGU, 2018) developed a method for estimating slip evolution and frictional properties on L-SSE area in the Bungo channel, by applying a data assimilation method EnKF (Ensemble Kalman Filter), which has been developed in meteorology and oceanology, to the synthetic GNSS data. Although they used the surface velocity data as GNSS data, the actual data which we can observe at GNSS station is the surface displacement data, not surface velocity data. In order to apply EnKF to the actual GNSS observational data, we conducted two numerical experiments, as follows.

i)We used the surface velocity data converted from the synthetic surface displacement data as observational data.

ii) We used the surface displacement data, not the surface velocity data as observational data.

We used the same model settings in above two numerical experiments as Hirahara and Nishikiori (2018) did. Firstly, we set a plane fault in homogeneous isotropic elastic body, whose angle of dip is 15 degrees. The frictional force on the plane fault follows a Rate and State Friction (RSF) law with an aging law [Dieterich,1979; Ruina,1983]. We set a velocity weakening (A-B<0) circular patch, whose radius R is 35 km, in the velocity strengthen (A-B>0) fault plane. We reproduced the observed L-SSEs in the Bungo Channel, using the frictional parameters in such a way that R is smaller than the critical nucleation size R_c [Rubin and Ampuero (2005), Chen and Lapusta (2009)]. Secondly, we considered the effect the seismogenic locked zones in the up-dip side of the L-SSEs zone. We set a locked zone at the up-dip of the L-SSE fault, whose back-slip rate is 6.0 cm/yr.

As the common analysis settings, we selected several pairs of frictional parameters in a wide range of parameter space which reproduce L-SSEs for the initial ensemble members of frictional parameters. We made the daily synthetic GNSS surface displacement data for 93 GEONET stations around the Bungo channel by calculating the surface displacements using true synthetic frictional parameters and adding random Gaussian noise. We set the assimilation interval to 10 days.

In experiment i), we calculated 31 day moving averages of the synthetic GNSS displacement data, and we obtained the surface velocities at GNSS stations from the derivatives of a 150-day cubic spline function fitting the moving averaged surface displacements. Then we applied EnKF to the obtained surface velocities and we successfully estimated slip evolution and frictional parameters. This result suggests this method for converting the surface displacement data into the surface velocity data at GNSS stations might be applicable.

©2019. Japan Geoscience Union. All Right Reserved.

In experiment ii), we applied EnKF to the synthetic GNSS displacement data directly. When we conducted experiment ii), we changed some analysis settings for stabilizing the assimilation. Firstly, when the slip velocity at the center of fault plane is low, we added larger random noise to the innovations artificially. Secondly, when the slip velocity at the center of fault plane is high, we reduced the assimilation interval to 1 day and introduced additive inflation to prevent the prediction errors from being too small. As a result, we also successfully estimated slip evolution and frictional parameters using the surface displacements, although the experiment sometime fails depending on the start timing of the analysis. Therefore, this method has not been fully stabilized yet, and we need to improve it for robust estimation.

Finally, we applied EnKF to the real GNSS data before the 2011 Tohoku-oki earthquake in the same settings as experiment i) and ii) respectively. We corrected offsets of major earthquakes and antenna changes in the GNSS data. However, both experiments stopped during the assimilation due to negative slip velocities. It manifests an importance of correction of GNSS data including removing annual and semiannual components for a stable assimilation of real GNSS data. Furthermore, we need to consider the realistic model settings including the geometry of the subducting Philippine Sea plate interface and distribution of both L-SSE and locked zones.

Recent progresses and applications of geomagnetic data assimilation

*Julien Aubert[1], Vincent Lesur[1], Alexandre Fournier[1], Gauthier Hulot[1]

1. Institut de Physique du Globe de Paris, France

Over the past ten years, numerical simulations of Earth’ s core magnetohydrodynamics have advanced to a point where their output can be compared in detail to the geomagnetic field behaviour over time scales ranging from a few years to centuries. Motivated by this progress, geomagnetic data assimilation is an emerging discipline that aims at optimally combining the statistical output of such simulations with geomagnetic data. Among the many possible outcomes of this approach, the main goals are to infer the hidden dynamical properties of Earth’ s core from the surface observations, forecast the future evolution of the geomagnetic field in a dynamically consistent way and at horizons of a few years to a century, and improve the quality of source separation in analyses of the geomagnetic field. We will present a few examples to emphasize the value added by statistics extracted from Earth-like geodynamo simulations when attempting to tackle these underdetermined geophysical inverse problems. We will also put these works in context of forthcoming contributions to the 13th iteration of the International Reference Geomagnetic Field (IGRF 2020).

Accounting for non-locality of vertical error correlation within ETKF through eigen-spectral localization

*Daisuke Hotta[1]

1. Meteorological Research Institute, Japan Meteorological Agency

Covariance localization is an indispensable component of any EnKF and it is most straightforwardly formulated as tapering of the sampled background error covariance matrix by means of Schur product (B-loc). However, within most (L)ETKF implementations, this operation is substituted by artificial inflation of R-matrix for observations distant from the analyzed grid-point (R-loc) due to the computational the difficulty of B-loc approach. Recently studies (Bocquet et al. 2016; Bishop et al. 2017) have derived an efficient way to implement B-loc within an ETKF, so that B-loc within ETKF is now a feasible option.

The author's recent work has focused on clarifying the differences between B-loc and R-loc, and showed with idealized 1D models that B-loc can increase the effective rank of the background covariance while R-loc cannot and that B-loc can more faithfully reproduce canonical KF analysis than R-loc does when the observation operator is non-local, suggesting that B-loc is particularly advantageous in cases where the desired amount of assimilated observations are much larger than the affordable ensemble size and/or the observation operator is highly non-local.

This work extends the B-loc approach to accommodate situations where the true background error covariance is not well localized (i.e., the correlation between two grid-points is not given in terms of the physical distance between them). In the proposed scheme, the state vector of each background ensemble is first linearly transformed into the space spanned by the (truncated) eigenbasis of the climatological background error covariance prior to performing data assimilation. The transformed ensemble is then used to form sample covariance to which we apply localization (i.e., control on sampling noises) by neglecting all the off-diagonal components. This method reposes on two assumptions: (1) the true covariance, when expressed in its eigen-space, is diagonal, so that, in this space, any off-diagonal component present in the sample covariance from ensemble is a sign of sampling error, and (2) the eigenstructure of the true covariance is close to its climatological expectation.

In this presentation, I will show several preliminary verifications of this approach using an idealized 1-dimensional system and discuss its promise and limitations.

Data assimilation experiments with MODIS LAI observations and the dynamic global vegetation model SEIB-DGVM over Siberia

*Hazuki Arakida[1], Shunji Kotsuki[1], Shigenori Otsuka[1], Yohei Sawada[1,2], Takemasa Miyoshi[1]

1. RIKEN Center for Computational Science, 2. Meteorological Research Institute

In the previous study, Arakida et al. (2017) developed a data assimilation system with the SEIB-DGVM (Spatially Explicit Individual-Based Dynamic Global Vegetation Model, Sato et al. 2007) and assimilated satellite-observed Leaf Area Index (LAI) successfully at a flux measurement site in Siberia. In this study, we extend the experiment to a large domain in Siberia and estimate the vegetation functions and structures, and model parameters related to the phenology of the deciduous needle-leaved tree and the undergrowth. At the annual meeting in 2017, we presented the results of total LAI, tree LAI, above ground biomass, carbon flux, and the model parameters. This year, we present further comparisons with the previous studies: carbon flux (FLUXCOM: Tramontana et al., 2016, Jung et al., 2017) estimated by a machine learning method using in-situ flux measurements and various explanatory data, tree LAI (Delbart et al., 2005, Kobayashi et al., 2010) estimated by a radiative transfer model and satellite observations, and above ground biomass (Liu et al., 2015) estimated by satellite observations. The results showed high correlations between this study and the previous studies except for above ground biomass. This is probably because above ground biomass of Liu et al. [2015] is estimated from microwave-based observations, different from optical-based observations in this study, Kobayashi et al. [2010], and FLUXCOM. The results suggest that the type of the satellite sensor affect the estimation results. Most of the estimated variables by DA were highly correlated with the observed LAI and the previous studies, indicating that the DA system generally performed well over Siberia.

Inversion of the ocean vertical diffusivity from steady-state tracer distributions by using an adjoint method

*Akira Oka[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

The ocean vertical diffusivity is important for controlling the distribution of various ocean tracer including the temperature and salinity. Recent studies clarified that its spatial distribution is very inhomogeneous but the global coverage of its direct measurements from turbulent mixing observations are not enough and its quantification is still difficult. On the other hand, recent observational data about the ocean tracer including temperature and salinity are increasing significantly and dataset covering the global ocean is available. The inversion of ocean velocity distribution from ocean tracer has been reported in the previous studies (e.g. Wunsch, 1996). In the same way as this velocity inversion, some studies tried the inversion of the ocean vertical diffusivity (e.g. Ganachaud and Wunsch, 2000) but there are few studies which discuss its detail 3-dimmensional distribution. In this presentation, I would like to report some attempts about the inversion of the ocean vertical diffusivity from the ocean tracer distribution; we focus on the temperature, salinity, and carbon isotope (C14) and discuss how their steady-state distribution is useful for obtaining the 3-dimmensional distribution of the ocean vertical diffusivity.

Nonlinear data assimilation with 4DEnVar using iterative weather forecast model

*Sho Yokota[1], Ko Koizumi[1], Masaru Kunii[2,1], Kosuke Ito[3,1]

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Numerical Prediction Division, Forecast Department, Japan Meteorological Agency, 3. University of the Ryukyus

En4DVar and 4DEnVar are two popular ensemble-based variational data assimilation methods for the numerical weather prediction. Although the ensemble-based forecast error covariance can be reflected in the analyses of both methods, En4DVar calculates the gradient of the cost function with the adjoint of tangent linear forecast model, which requires large development and computational costs. Such costs are generally not required in 4DEnVar because 4DEnVar does not use the tangent linear forecast model. However, 4DEnVar analyses are generally worse than those of adjoint-based En4DVar probably because 4DEnVar does not iteratively calculate the nonlinear forecast model. In this study, therefore, we developed 4DEnVar with iterative nonlinear forecast model (hereafter, 4DEnVar-IF). In 4DEnVar-IF, the nonlinear forecast model is iteratively calculated to gain the non-quadratic cost function and its gradient in each iteration. The 4DEnVar-IF applied to the Lorenz63 model showed that the 4DEnVar-IF analysis can be better than those of En4DVar and general 4DEnVar when nonlinearity is strong and ensemble perturbations are appropriate. Moreover, we also applied 4DEnVar-IF to JMA nonhydrostatic model-based 4DVar data assimilation (JNoVA) system. The single-observation assimilation experiments with JNoVA showed that 4DEnVar-IF can make the cost function smaller than En4DVar when the assimilated observation has the strong nonlinearity as like potential temperature associated with cloud microphysics. In the assimilation experiment of multiple real observations with 4DEnVar-IF of the small localization scale, however, the minimization of the cost function was not sufficiently succeeded. As a next step, we will develop the localization and hybrid of forecast error covariance matrix.

Development of Data Assimilation System for Atmospheric Density to Improve Satellite's Orbit Prediction Accuracy

*Hiroshi Kato[1], Hideaki Hinagawa[1], Kyohei Akiyama[1], Yuki Akiyama[1], Masaya Nakano[2], Daichi Obinata[2], Shinichi Nakamura[1]

1. Japan Aerospace Exploration Agency, 2. FUJITSU LIMITED

Satellite's orbit prediction with high accuracy requires atmospheric drag prediction with high accuracy, because there is a slight atmosphere in a low-orbital environment. The atmospheric drag can be calculated from the atmospheric density, the ballistic coefficient (mass, cross-sectional area, drag coefficient) of each satellite, but the uncertainty of the atmospheric density is considered to occupy most of the uncertainty of atmospheric drag prediction.
Several atmospheric density models have been proposed so far. Although observation information in low orbit environments is very limited, the models are based on slight satellite observation information. However, it is difficult to predict the atmospheric density with high accuracy, and the satellite operator improves the accuracy of orbit prediction by estimating correction amount based on the orbit determination value.
Since 2018, JAXA has started to develop the atmospheric density reanalysis system (data assimilation system). This system realizes the reanalysis of the atmospheric density from the atmospheric density observation, which is averaged atmospheric density on the satellite locus, and atmospheric density models. The averaged atmospheric density on the satellite locus can be estimated based on orbit information of TLE (two-line element) of each satellite provided by NORAD in the United States. The atmospheric density model uses the NRLMSIS-00 model and the Jacchia-Bowman 2008 model usually used in the orbit field. As data assimilation methods, the ensemble Kalman filter and the ensemble transformed Kalman filter are implemented.
In this presentation, we introduce the details of the atmospheric density reanalysis system and show the results of the twin experiment (numerical experiment) being advanced as system verification.

[M-GI30] Data assimilation: A fundamental approach in geosciences

convener:Shin ya Nakano(The Institute of Statistical Mathematics), Yosuke Fujii(Meteorological Research Institute, Japan Meteorological Agency), SHINICHI MIYAZAKI(Graduate School of Science, Kyoto University), Takemasa Miyoshi(RIKEN), Chairperson:Shinichi Miyazaki(Kyoto University), Yosuke Fujii

Data assimilation is an inversion approach to estimate the evolution of a system by utilizing a constraint given by a dynamical simulation model. Data assimilation is now widely used not only in meteorology and oceanography but also other fields of geosciences such as hydrology, solid earth science, and space science. This session aims at providing an opportunity for discussion on data assimilation studies among researchers of various field of geosciences. We encourage contributions addressing novel methods and theoretical developments of data assimilation. Contributions dealing with useful applications of data assimilation are also welcome.

An LETKF-based ocean reanalysis for the Asia-Oceania region using Himawari-8 SSTs and SMOS/SMAP SSS

*Shun Ohishi[1], Tsutomu Hihara[2], Hidenori AIKI[1], Joji Ishizaka[1], Yasumasa Miyazawa[2], Misako Kachi[3]

1. Nagoya University, 2. JAMSTEC, 3. JAXA

With the global spread of the Argo floats and development of high-resolution ocean models, global ocean reanalysis datasets have been released. Although regional high-resolution ocean reanalysis datasets also have been established around the North Pacific, most of their coverage area is limited to regions north of 10˚N. We suggest that reanalysis datasets for tropical-subtropical oceans are yet to be constructed for coastal environmental monitoring and typhoon researches around the Asia-Oceania region.
Since July 2015, a geostationary satellite “Himawari-8” has been measuring sea surface temperatures (SSTs) with a high spatial and temporal resolution of 2 km and 10 min. in the western Pacific region using an infrared sensor. Because of the high temporal resolution, daily composite map shows that coverage area of Himawari-8 exceeds that of an orbital satellite “GCOM-W” with a microwave sensor. The infrared sensor enables us to capture fine nearshore SST structure, such as localized cool SSTs induced by Ekman upwelling along the Vietnam coast during the southwesterly summer monsoon.
We have established a one-way nest high-resolution ocean data assimilation system based on LETKF (Hunt et al. 2007) with 20 ensemble members at 1-day interval. The southeast Asia coastal region [98˚–115˚E, 0˚–22˚N] has been modeled at a spatial resolution of 1/36˚ and 47 layers with an intent to be applied for fishery and marine environmental monitoring, while the large-scale western Pacific region [95˚E–165˚W, 50˚S–50˚N] has been constructed at a spatial resolution of 1/12˚ and 47 layers to make contributions to tropical cyclone studies. Himawari-8 SSTs and sea surface salinity (SSS) derived from SMOS and SMAP satellites as well as sea surface height, and temperature/salinity derived from GTSPP and AQC Argo dataset have been assimilated. To improve the salinity field, freshwater fluxes also have been incorporated. To avoid generation of spurious gravity waves, the Incremental analysis Update (IAU) filter (Bloom et al. 1996) have been implemented. We will introduce low salinity water transport from the Mekong river in the southeast Asia system and the SST cooling with the passage of tropical cyclones in the western Pacific system.

Validation of JCOPE-T DA ocean assimilation product

*Tsutomu Hihara[1], Sergey Varlamov[1], Yasumasa Miyazawa[1], Toru Miyama[1], Misako Kachi[2], Hiroshi Murakami[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Japan Aerospace Exploration Agency

We constructed the high resolution (3km, 1hour) ocean data assimilation system named as JCOPE-T DA which targets around Japan. This system is running operationally and that’ s outputs have been provided by JAXA through the Himawari Monitor website and P-Tree System since November 2018. One of the aims in this system is to make the useful ocean analysis and forecast data by assimilating satellite SST data provided by JAXA directly. We assimilate the satellite SST data observed by Himawari/AHI, GCOM-W/AMSR2, GPM main satellite/GMI, and Coriolis/WindSAT. Multi-3DVAR (Miyazawa et al. 2017) and IAU are applied in this system.

We will show the results of validation of JCOPE-T DA using independent in situ data observed by buoys and ship in this presentation. The results of comparison with CTD data observed by SHINSEI-MARU off the Kii Channel show that JCOPE-T DA ocean temperature data are good estimate in upper layer (Figure 1). Biases and RMS error are lower than ±0.2 deg.C and 0.7 deg.C in 2 –40m depth respectively. On the other hand, there are negative bias and large RMS difference (over 1 deg.C) in thermocline (5 –200 m depth). These mean that mixed layer of JCOPE-T DA is deeper than that of observation.
JCOPE-T DA clearly show the internal tide because the ocean model of JCOPE-T DA considers the tide effects. Especially, we find that the channel between Taiwan and Philippines causes strong internal tide which is made change of several degree Celsius at 500m depth in a day.

In the future plan, we are going to construct the higher resolution (1km grid) ocean model with CaMa-Flood river flow data. And also, we are going to assimilate the GCOM-C/SGLI SST data which have 250m resolution. Furthermore, we will construct a nest model for coastal area.

Do surface lateral flows matter for land data assimilation?: Implication for hyper-resolution land modeling and observation

*Yohei Sawada[1]

1. Meteorological Research Institute

Hyper-resolution land modeling is expected to innovate the simulation of terrestrial water, energy, and carbon cycles. One of the major advantages of existing hyper-resolution land models against conventional 1-demensional land surface models is that surface and subsurface lateral water flows can be explicitly simulated. Despite a lot of efforts on assimilating hydrological observations into the hyper-resolution integrated surface-groundwater land models, how and in what case topography-driven surface water flows matter for data assimilation of soil moisture observations has yet to be clarified. In this study, I perform a minimalist synthetic numerical experiment, in which shallow soil moisture observations are assimilated into an integrated surface-groundwater land model by an ensemble Kalman filter. Propagation of a background error due to surface lateral water flows is crucially important to adjust the unobserved model state and parameter variables by horizontally propagating the information of soil moisture observations. However, the non-Gaussianity of the background error induced by the nonlinear dynamics of topography-driven surface flows harms the performance of an ensemble Kalman filter and the efficiency of data assimilation strongly depends on soil characteristics. The new capability of data assimilation with the hyper-resolution land models found in this study may improve the monitoring and prediction of flash floods caused by local severe rainfalls.

Sawada, Y. (2018), Do surface lateral flows matter for data assimilation of soil moisture observations into hyperresolution land models?, *EarthArXiv,* https://doi.org/10.31223/osf.io/byguf

Geodynamo data assimilation for candidate models of IGRF13-SV from Japan team

*Takuto Minami[1], Shin ya Nakano[2], Futoshi Takahashi[3], Masaki Matsushima[4], Hisayoshi Shimizu[1], Hiroaki TOH[5]

1. Ocean Hemisphere Research Institute, Earthquake Research Institute,The University of Tokyo, 2. The Institute of Statistical Mathematics, 3. Faculty of Science, Kyushu University, 4. School of Science, Tokyo Institute of Technology, 5. Graduate School of Science, Kyoto University

International Geomagnetic Reference Field (IGRF) is a series of standard global geomagnetic field models that consist of Gauss coefficients to represent spatial distribution. International Association of Geomagnetism and Aeronomy (IAGA) produces IGRF every five years, the last version of which, the 12th generation of IGRF (IGRF-12), was released in December 2014 (Thebault et al., 2015). Each generation of IGRF comprises not only the main field part but secular variation (SV) part (first time derivative of the main field) to forecast evolution of the geomagnetic field for the next five years to come. The next generation, IGRF-13, will be published around December 2019, comprising the spatial distribution of the field at epoch 2020.0 and its secular variation in the period from 2020.0 to 2025.0. We plan to submit a candidate SV model to contribute for determining IGRF13-SV.
We employ data assimilation with geodynamo calculations to generate a SV candidate model for the period from 2020.0 to 2025.0. Although the two standard approaches, (1) adoption of SV at the IGRF release time and (2) spline extrapolation of the main field in the future, are common for generating SV candidates, they are not “physics-based” forecasts, and, intrinsically, cannot alleviate the effect of sudden changes in the SV field called “geomagnetic jerks” (Mandea et al., 2010). In this context, data assimilation is one of novel approach to obtain an appropriate initial condition for geodynamo calculations at the time of IGRF release time. Since the parameters used in geodynamo calculations are apart by some orders of magnitude from those for the Earth's core, it is not appropriate to take geodynamo solutions as they are for the predictions. Nevertheless, it is possible to rescale the time-axis of geodynamo calculations using the ratio of the so-called “secular-variation time-scale” (Chlistensen and Tilgner, 2004) between the geomagnetic field and geodynamo calculations. In this presentation, we are going to show candidate models of secular variation obtained by geodynamo data assimilation with discussions on the time-scales, the method of assimilation, and data-set employed for the assimilation.

A pilot study of geomagnetic data assimilation into a geodynamo model

*Shin ya Nakano[1], Takuto Minami[2], Futoshi Takahashi[3], Masaki Matsushima[4], Hiroaki TOH[5], Hisayoshi Shimizu[2]

1. The Institute of Statistical Mathematics, 2. Earthquake Research Institute, the University of Tokyo, 3. Faculty of Science, Kyushu University, 4. School of Science, Tokyo Institute of Technology, 5. Data Analysis Center for Geomagnetism and Space Magnetism, Graduate School of Science, Kyoto University

Geomagnetic secular variation is a long-term variation of the Earth's magnetic field. The magnetic field of the Earth is originated from a dynamo in the outer core. Modeling of geodynamo process is thus a straightforward approach for predicting geomagnetic secular variations. However, it is intrinsically difficult to resolve the current state of the geodynamo from observable magnetic field and to predict future evolution of geodynamo. We are developing a framework for estimating the current state of the geodynamo by using a data assimilation approach. As a preliminary study, we performed data assimilation experiments using synthetic geomagnetic data in order to evaluate if data assimilation methods are effective for estimating the state of the geodynamo. Some data assimilation schemes based on ensemble-based variational method were applied and compared. Preliminary results of the experiments will be demonstrated.

Keywords: ensemble-based data assimilation, geodynamo model, secular variation

Bayesian parameter estimation of a physics-based model of postseismic crustal deformation

*Jun'ichi Fukuda[1], Kaj Johnson[2]

1. Earthquake Research Institute, University of Tokyo, 2. Department of Earth and Atmospheric Sciences, Indiana University

Recent development GPS and other geodetic networks makes it possible to capture transient crustal deformation at high resolution in both space and time. A primary example of geodetically observed transient deformation in plate boundary zones is postseismic deformation following large earthquakes. Two primary processes that are responsible for observed postseismic deformation are viscoelastic relaxation of in the asthenosphere and afterslip on the plate interface surrounding the coseismic rupture. Both of the processes are triggered by stress changes induced by an earthquake and the evolution of the two processes is governed by rheological properties of the asthenosphere and frictional properties of the plate interface as well as coseismic stress perturbations.

In this study, we develop a physics-based model of postseismic deformation following the 2011 Mw9.0 Tohoku-oki earthquake that incorporates stress-driven afterslip and viscoelastic relaxation. In this model, the evolution of afterslip is assumed to be governed by a velocity-strengthening friction law that is characterized with a friction parameter. Viscoelastic relaxation of the asthenosphere is modeled with a biviscous Burgers rheology that is characterized with steady-state and transient viscosities. The evolution of afterslip and viscoelastic relaxation is calculated using coseismic slip distribution as an initial condition. We treat the friction parameters, viscosity parameters, coseismic slip distribution, and a smoothing parameter for coseismic slip distribution as unknown parameters and estimate them using coseismic and postseismic GPS and seafloor geodetic data.

In order to quantify uncertainties of the model, we adopt a Bayesian approach and estimate the posterior probability density function (PDF) of the model parameters. In principle, the Markov chain Monte Carlo (MCMC) methods can be used for this purpose. However, the MCMC methods require many forward calculations and the forward model employed in this study is computationally intensive. Therefore, it is difficult to sample the posterior PDF within a realistic computation time. We thus combine a surrogate modeling approach with the MCMC methods to efficiently sample the posterior PDF. In this approach, we first obtain a function approximation to the posterior PDF by fitting a surrogate function to the posterior probability densities calculated for sample points in the model parameter space. Then a MCMC method is used to sample the surrogate posterior PDF. By using this approach, we obtain the posterior PDFs of the model parameters that successfully reproduce the observed coseismic and time-dependent postseismic displacement fields. Our results suggest that such approaches may be useful for parameter estimation and uncertainty quantification of computationally intensive forward models.

Disaster response agencies always suffer from the human resource shortage under the disaster situation. To solve the problem, efficient disaster response applying ICT technology to the social media has been required. In this study, we are developing two systems helping disaster responses. The first system automatically collects and summarizes disaster damage reports through the interactions between a chatbot and a victim. The second system provides optimized information for each victim based on each situation estimated via the interaction. In this presentation, we introduce this study as a case study of social implementation of the social media with technical background.

第2期SIP「国家レジリエンス（防災・減災）の強化」

共同研究開発機関：株式会社ウェザーニューズ
国立研究開発法人情報通信研究機構

対話型災害情報流通基盤の研究開発

2018年度～ 防災チャットボットをつくっています。

【研究の概要】
●個人が避難や活動に必要な情報をスマホ等での対話システムを介して入手・提供できるようにすることで、迅速・確実な避難を実現するとともに、その情報に基づいて災害対応機関の業務を効率化する情報流通基盤を研究開発する。
●①個人の状況・要望に応じて情報提供する技術（個人適応型対話技術）、②社会動態を観測する情報収集・要約技術（対話からの社会動態抽出技術）を開発し、個人との自動対話システムとして確立する。

●各種災害情報と発話情報の融合処理と、対話を介することで誤情報等を排除しながら効果的に情報収集を行い、社会動態として抽出

●LINE等、普段使いのメッセージングアプリ等で数十万人規模で実現

防災チャットボットはどんな課題を解決するの？

こんなことを実現する予定です。

- 国民一人ひとりに最適化された避難等の支援
- 逐次変化する状況/要望に合わせた最適な情報提供
- 従来のセンサーでは得られなかった情報の取得
- 大量の個別要望等を短時間に自動処理し、人的資源が不足する災害対応機関の業務効率化を支援

すでに始まっている取り組みを教えて

神戸市での実証実験（2018.12.21）をおこないました。

- SIP第2期で開発中の防災チャットボットのプロトタイプを用いてコンセプトを実証しました
- 防災チャットボットの有用性を確認しました
- 神戸の震災で救援の対応をされた経験のある危機管理室長から、「大変わかりやすく、阪神淡路大震災の時とは隔世の感がある」とコメントをいただきました

Collaboration between NIPR image platform service and social media

*Takeshi Terui[1], Yasuyuki Minamiyama[2], Masaki Hidano[3]

1. National Institute of Polar Research, 2. Tokyo Foundation for Policy Research, 3. Info Lounge Corporation

NIPR is developing an open image archive platform with metadata that recorded the history of Antarctic / Arctic observation. This platform is now experimentally openned as NIPR Image Archive Web service as a following link.

https://image.nipr.ac.jp

Images to release on this platform are recorded pictures and videos in the Antarctic / Arctic. These images are data that recorded Japanese public activity in polar regions. In order to efficiently utilize data and distribute metadata, we are considering cooperation with various external Web services. For this reason, we are dealing with IIIF, Web API, JSON-LD, and we are testing the distribution on the Web. In the future we plan to respond to image retrieval and distribution enhancement on social media and various cloud services through image search engines. In this study, we will introduce the effect on data distribution expected to promote publication of image data by research institutions, and expectation to strengthen cooperation with social media and search engines.

Twitter account of the Association of Japanese Geographers: History of establishment and operation

*Takashi Oguchi[1], Yuichiro Nishimura[2], Daichi Kohmoto[3], Atsuko Niina[4], Hitoshi Saito[5]

1. Center for Spatial Information Science, The University of Tokyo, 2. Division of Humanities and Social Sciences, Nara Women's University, 3. Nara University of Education, 4. Izu Peninsula Geopark Promotion Council, 5. College of Economics, Kanto Gakuin University

The Twitter account of the Association of Japanese Geographers (AJG) with some 15,000 followers (@ajgeog) is widely recognized and has a certain level of social influence. Unlike most other accounts of academic societies, the AJG account often retweets geography-related tweets posted by various people, and refollows the majority of the followers. The account has been operated by the Public Relations Committee of the AJG for more than five years, to transfer information related to geography. This paper is presented by five AJG members who played a major role in creating the account and its operation at the early stage, to introduce background history.

Disaster response agencies always suffer from the human resource shortage under the disaster situation. To solve the problem, efficient disaster response applying ICT technology to the social media has been required. In this study, we are developing two systems helping disaster responses. The first system automatically collects and summarizes disaster damage reports through the interactions between a chatbot and a victim. The second system provides optimized information for each victim based on each situation estimated via the interaction. In this presentation, we introduce this study as a case study of social implementation of the social media with technical background.

第2期SIP「国家レジリエンス（防災・減災）の強化」

共同研究開発機関：株式会社ウェザーニューズ
国立研究開発法人情報通信研究機構

対話型災害情報流通基盤の研究開発

2018年度～ 防災チャットボットをつくっています。

【研究の概要】
●個人が避難や活動に必要な情報をスマホ等での対話システムを介して入手・提供できるようにすることで、迅速・確実な避難を実現するとともに、その情報に基づいて災害対応機関の業務を効率化する情報流通基盤を研究開発する。
●①個人の状況・要望に応じて情報提供する技術（個人適応型対話技術）、②社会動態を観測する情報収集・要約技術（対話からの社会動態抽出技術）を開発し、個人との自動対話システムとして確立する。

●各種災害情報と発話情報の融合処理と、対話を介することで誤情報等を排除しながら効果的に情報収集を行い、社会動態として抽出

●LINE等、普段使いのメッセージングアプリ等で数十万人規模で実現

防災チャットボットはどんな課題を解決するの？

こんなことを実現する予定です。

- 国民一人ひとりに最適化された避難等の支援
- 逐次変化する状況/要望に合わせた最適な情報提供
- 従来のセンサーでは得られなかった情報の取得
- 大量の個別要望等を短時間に自動処理し、人的資源が不足する災害対応機関の業務効率化を支援

すでに始まっている取り組みを教えて

神戸市での実証実験（2018.12.21）をおこないました。

- SIP第2期で開発中の防災チャットボットのプロトタイプを用いてコンセプトを実証しました
- 防災チャットボットの有用性を確認しました
- 神戸の震災で救援の対応をされた経験のある危機管理室長から、「大変わかりやすく、阪神淡路大震災の時とは隔世の感がある」とコメントをいただきました

Discussion

Experimental platform for design and advance evaluation of frequent satellite observations to innovate weather, ocean and land surface predictions

*Takemasa Miyoshi[1], Shunji Kotsuki[1], Koji Terasaki[1], Shigenori Otsuka[1], Takumi Honda[1], Atsushi Okazaki[1], Kohei Takatama[1]

1. RIKEN

We propose to develop a unique platform with an advanced data assimilation technology, realizing numerical simulation experiments for advance evaluation of future satellite missions in their design phase. This will provide a scientific, objective approach to an effective design of future satellite missions to maximize the benefit to practical applications such as hydrometeorological prediction and resource control of fisheries. The authors have been leading data assimilation research to explore the best mix of computer model simulations and real-world data for weather forecasting, taking advantage of new-generation technologies such as the K computer and Himawari-8 satellite. The authors' previous research revealed that every-10-minute Himawari-8 observations could lead to a large improvement of typhoon and heavy rainfall predictions, though every-30-minute observation was insufficient. We would expect that frequent observations would also be beneficial for ocean and land surface prediction. Therefore, we aim to develop a platform for numerical experimentation to evaluate potential future satellite missions such as quasi-zenith orbiters and small cube-sat constellations for frequent observation over Japan and its surrounding area. This platform will be useful for designing future satellite missions with high cost-benefit performance.

Technology demonstration mission for next generation precipitation observation radars

*Tomoo Ushio[1], Toshio Iguchi[2], Kenji Nakamura[4], Kinji Furukawa[3], Riko Oki[3], Daisuke Jodoi[3]

1. Tokyo Metropolitan University, 2. NICT, 3. JAXA, 4. Dokkyo University

We have studied doppler velocity measurement for precipitation particles using a precipitation observation radar in a low Earth orbit as a post-mission of Dual-frequency Precipitation Radar (DPR) on the Global Precipitation Measurement (GPM) core satellite. Also, we have studied Geostationary Precipitation Radar (GPR) which can observe precipitation continuously and flexibly from a geostationary orbit as a future mission. In this study, we have studied the method which can separate precipitation echoes from ground/sea clutters by the doppler velocities in order to observe high latitude areas. Therefore, we need to verify the feasibility of the doppler velocity measurement for precipitation particles. Additionally, we need to improve antenna performance drastically in order to observe precipitation from a geostationary orbit which is far away from a low Earth orbit. Therefore, we need to verify the feasibility of upsizing an antenna for the GPR.

Based on the above background, the purpose of the proposed mission is to demonstrate that it is possible to measure the doppler velocity of precipitation particles from an orbit by a pulse compression radar using a planar antenna and to operate antenna deployment and connection mechanisms normally in an orbit. Also, we aim to get data regarding antenna deployment behavior and structural characteristics.

We consider the value of the proposed mission as follows. Firstly, the value of the doppler velocity measurement demonstration is as follows.
This demonstration contributes to realize post-GPM/DPR mission. If the doppler velocity measurement becomes possible in the mission, it is expected to understand the mechanical structure of a precipitation system globally and to improve the accuracy of weather and flood forecasts. This demonstration contributes to realize the GPR mission. If the GPR becomes possible, it is expected to identify the forming process of a typhoon and to improve the accuracy of weather and flood forecasts.
Next, the value of the antenna deployment and connection demonstration is as follows.
This demonstration contributes to improve the performance of satellite antennas for earth observation, communication, radio astronomy, disaster monitoring, national security, etc. because the deployment and connection mechanisms make it possible to enlarge planar antennas. This demonstration contributes to realize innovative missions like the GPR because the deployment and connection mechanisms make it possible to construct a 30-m-class large planar antenna. The deployment and connection mechanisms have the potential to construct super large space structures like Space Solar Power Systems (SSPS).
We consider the feasibility of the proposed mission as follows. When we assume that the size of a demonstration system is 1.2m x 2.2m x 0.7m in storage state and 1.2m x 2.2m x 4.4m in deployment state, we expect that the system meets the installation condition for HTV-X which has been developed as a post-KOUNOTORI (HTV) by JAXA. Also, as a result of thermal analysis for the system, we expect that the system meets the thermal condition for HTV-X. Furthermore, we demonstrated that it is possible to operate the half size deployment and connection mechanisms of the system normally by a ground experiment in FY2017.
As future works, we will study the feasibility of the doppler velocity measurement from the aspect of HTV-X attitude control performance. Also, we will improve the function and performance of the deployment and connection mechanisms.

Mission of creating base maps as public infrastructures for disaster and monitoring

*ISHITSUKA Naoki[1]

1. The Remote Sensing Society of Japan

As a satellite earth observation mission to be realized as Japan, we propose a mission of creating base maps as public infrastructures for disaster and monitoring.

The purpose of the proposed mission, is the observation and the base map prepared, as well as the monitoring and elucidation of global resources from long-term and continuous quantitative monitoring of large-scale disasters. Optical and SAR sensors, which are the genealogy of ALOS, observe with high spatial resolution, so that it can be applied to basic information (land cover, topography), disaster prevention / reduction (change detection, flooding, illegal dumping) Actual utilization such as agriculture(precision farming, food security), forestry, fishery, energy (geology, reserves, resource management, pollution monitoring), climate change (glacier, drift ice, flood), environment (coastal environment, carbon stock) , To earth science, and so on.

High resolution earth observation data with a wide swath is necessary for detailed map creation which is limited in medium resolution satellite. The high-resolution base map created from the satellite data covering the whole earth will be developed as public infrastructures and become a data access hub and can contribute to social implementation of satellite images such as disaster and agriculture. Then, it will serve as a basis for use in policies to solve international and regional issues, and for use in providing services enriching our lives. In particular, agriculture, forestry and fisheries industry and land management, disaster prevention, social infrastructure is a leading application area. For example, it is difficult to predict when and where a disaster occurs, so it is necessary to maintain wide-area high-resolution images as a base map. In SIP the second phase by the Japanese Cabinet Office, "strengthening national resilience (disaster prevention and reduction)" is started, high-resolution satellite as public infrastructure, supposed to be the supply of data and information There. Also, for use in the map creation field, there are cases where ALOS data was used for updating maps at the Geographical Survey Institute, etc. and for field polygon production work at Ministry of Agriculture and Fisheries. Underlying data of these G space is necessary essential to the realization of data society called “Society 5.0” promoted by the government. In SAR, it is required to make observation of the ground change due to forest monitoring and interferometric SAR, making full use of the achievement of Japan 's L band. In addition, there is great expectation for high resolution monitoring of polar sea ice and glacier utilizing observational weatherability. It is desirable for both sensors to operate at the same time, since various effects such as complementation and improvement in accuracy can be obtained by using the optical sensor and the SAR sensor in an integrated fashion.

Thus, for optical, it is necessary capability to observe a wide range of several tens of km high resolution image having m ~ sub meter. In addition, it is regrettable that ALOS-3 could not install the all-time stereoscopic observation that was an advantage over other countries in ALOS, and it is desirable to have a resurrection by successor satellite. With regard to SAR, it is considered to adopt a new method by DBF in ALOS - 4, and it is considered that wide range high resolution observation such as several hundred kilometers at several m resolution by DBF technology can be continued for succeeding machines depending on the result.

©2019. Japan Geoscience Union. All Right Reserved.

However, since the data becomes extremely large in both optical and SAR, the part of downlinking this data becomes a bottleneck. It is important to continue to cooperate with the development of other data downlink environments including data transmission speed, data on board processing, data relay satellite, ground station and communication, basic research on data compression technology.

In addition, the observed frequency secure has become a real operational issues, this is a need for a solution to break, the number of satellites increases or the constellation, a wide swath, the study of technologies, such as the attitude maneuver. In addition, as an innovative solution, it is necessary to consider the high resolution observation from the geostationary orbiting satellite, etc.

Environmental changes caused by global warming, earth resources from the viewpoint of long-term monitoring of (mineral resources, biological resources, water resources, etc.), and continues without interrupted the ALOS Series with high resolution sensor is desired. We believe it will lead to a worldwide presence improvement of the ALOS series.

Aerosol monitoring, forecasting and estimate of its impacts with multispectral imager data

*Keiya Yumimoto[1,2], Takashi Maki[2], Taichu Y Tanaka[2], Thomas Sekiyama[2], Toshihiko Takemura[1]

1. Kyushu University, 2. Meteorological Research Institute

Airborne aerosols are tiny particles that are globally distributed in the atmosphere from the troposphere to the stratosphere and that affect various aspects of human society and health and the Earth system including ocean biogeochemistry and climate. Our understanding of the aerosol lifecycle and aerosol impacts has been advanced by the following activities: (1) aerosol monitoring: observations of distributions of aerosol components and their radiative impacts, (2) assimilation/forecasting: aerosol (PM2.5) numerical prediction and early warning system to reduce effects on human society and health, and (3) climate data: long-term records including aerosol reanalysis product contributing climate and epidemiology studies. Multispectral imagers (from near UV to near infrared) onboard polar-orbiting and geostationary satellites have been providing essential data to those activities. In this presentation, we will make a brief review of those activities to show how multispectral imagers play the important role in aerosol studies and to provide an opportunity to consider their future plan.

Global aerosol and cloud observation by space-borne multi-wavelength polarization high-spectral-resolution lidar

*Tomoaki Nishizawa[1], Hajime Okamoto[2], Syoken Ishii[3], Yoshitaka Jin[1]

1. National Institute for Environmental Studies, 2. Kyushu University, 3. National Institute of Information and Communication Technology

We propose global satellite measurements of vertical distributions of aerosols and clouds (particles) by multi-wavelength polarization high-spectral-resolution lidar (HSRL) using both HSRL and polarization measurement techniques. This proposal realizes polarization HSRL measurements in ultraviolet, visible, and near-infrared spectral regions (355, 532, and 1064nm) and conducts multi-wavelength and multi-parameter measurements of particles simultaneously.
The proposed lidar, which has twice or larger measurement channels than the previous space lidars, measures global, three-dimensional (vertical and horizontal) distributions of particles; this enables to observe various optical and microphysical properties (e.g., extinction, size distribution, chemical components) simultaneously and to obtain more reliable particle information in quantitative and qualitative than the past. Observational studies using both these global, three-dimensional data of particles and numerical models (e.g., aerosol chemical transport model, and cloud resolving model) will lead to understating preprocess on aerosol-cloud interaction better, reducing uncertainties on evaluation the particle effects on climate change, and improving prediction accuracy of the climate change. Furthermore, this space lidar observation can be used to monitor and forecast transport and diffusion of aerosols getting air quality worse (e.g., volcanic ash, mineral dust, smoke, and air pollution) and to evaluate the aerosol effects on atmospheric environment (e.g., human health, vegetation, and air quality). These improvements of the scientific knowledges contribute to internationally consensus building to solve global warming issues and improving environmental measures both within and outside Japan.
The proposed lidar should have a role to be a succession sensor of space lidar mission to observe global particle distributions such as CALIPSO satellite lidar (CALIOP) launched in 2006 and EarthCARE satellite lidar (ATLID) launched in 2021 and lead internationally particle observation mission by space lidar after EarthCARE mission. More advanced techniques on laser and lidar in space by improving the laser and lidar techniques established in vegetation lidar mission MOLI as well as HSRL techniques developed for ground-based lidars are established in this proposal. The developed techniques are also key techniques for lidars to measure meteorological parameters such as temperature, wind speed, and water vapor. Thus, this proposal is also a bridge for the technical development of the space lidar to measure meteorological parameters.

Dual-Doppler-velocity-mission using cloud radar and lidar

*Okamoto Hajime[1], Kentaroh Suzuki[2], Tomoaki Nishizawa[3], Shoken Ishii[4]

1. Kyushu University, 2. The university of Tokyo, 3. National Instuitute for Environmental Studies, 4. National Institute of Information and Communications Technology

Dual-Doppler velocity measuring mission from space-borne cloud radar and lidar is proposed. 94GHz cloud radar and lidar with Doppler function will measure three-dimensional air motion in clouds as well as in clear sky, respectively. High spectral resolution functions at 355nm and 532nm with polarization are planned to distinguish cloud particle type and aerosols. The lidar will have multiple field of views in order to penetrate relatively thick clouds. Since the radar will have capability to observe clouds and lidar will measure aerosols, it will be a successor mission to CloudSat and CALIPSO launched in 2006 and EarthCARE satellite in 2021. The mission will also serve to construct continuous records of clouds and aerosols for climate change studies.

Wind is one of key meteorological elements describing the atmospheric state as well as pressure, temperature, and humidity. Global wind profile observation is important to significantly improve the initial conditions essential for numerical weather prediction (NWP) and other meteorological studies. Although space-based observation system is a very important role in NWP, current space-based wind observing system has a problem that it is biased to observation related to temperature and water vapor compared with wind observation. The World Meteorological Organization wants to develop a global wind profiling system. Space-based Doppler Wind Lidar (DWL) can provide global wind profiles, which is a promising technique to fill the current gap. Under the circumstance, ESA launched the first space-based DWL Aeolus in August 2018. Since target mission period of Aeolus is three years, many NWP and science communities want continuous global wind profile observation. The working group on Japanese space-based DWL has made feasibility study for the space-based DWL for future global wind profiling since 2011. In 2017, ANA Holdings Inc. proposed to apply for optimizing aviation route using wind data improved by the future space-based DWL wind measurement at the space business promotion event S-Booster 2017. The proposal won the grand prize at S-Booster 2017, and the space-based DWL for the space business has been spotlighted since the event. The proposal is based on the global wind profile observation with the space-based DWL. The purposes of the global wind profile observation are to improve the precision of NWP and to contribute to understandings of mechanism of natural disasters and climate change and to new applications of wind data use.

Technology demonstration of space-borne water vapor DIAL

*Makoto Abo[1], Chikao Nagasawa[1], Yasukuni Shibata[1], Osamu Uchino[2], Takashi Shibata[3]

1. Graduate School of System Design, Tokyo Metropolitan University, 2. National Institute for Environmental Studies, 3. Nagoya University

We propose technology demonstration of space-borne water vapor differential absorption lidar (DIAL) for global high-resolution water vapor observations in the troposphere and lower stratosphere, to improve the understanding about the role of water in the global water and energy cycles and main physical processes (e.g., convection, emission, rainfall, the troposphere-stratosphere exchange of chemical species).

[J] Oral | M (Multidisciplinary and Interdisciplinary)：M-SD Space Development & Earth Observation from Space

Wed. May 29, 2019 1:45 PM - 3:15 PM JST | Wed. May 29, 2019 4:45 AM - 6:15 AM UTC | 302 3F

[M-SD44] Future Missions of Satellite Earth Observation

convener:Yoshiaki HONDA(Center for Environmental Remote Sensing, Chiba University), Yukari Takayabu(Atmosphere and Ocean Research Institute, the University of Tokyo), Shinichi Sobue(Japan Aerospace Exploration Agency), Yuki Kaneko(Japan Aerospace Exploration Agency), Chairperson:Riko Oki(宇宙航空研究開発機構)

Satellite observation can be an effective tool in science and can be applied to the rapid global environmental change. Monitoring for a long term, advancing new ideas and developing technologies to support them are needed to solve social and scientific problems.
The Task Force on Future Space R&D System of the Subcommittee on Remote Sensing (TF) supported by 25 academic societies and affiliated organizations has formulated the ''Grand Design of Earth Observation'' in FY2017. From the academic point of view, it suggests earth observation missions that Japan should conduct within a decade. From September 2018 to December 2018, the TF calls for proposals of earth observation missions as a trial that aims to discover new ideas from the scientific and practical domains and refine those ideas through multidisciplinary discussion. The adopted proposals will be mentioned in the revised Grand Design, and the TF will work with the government on using it as a reference in updating the Implementation Plan of the Committee on National Space Policy. This session consists of oral presentations of the proposals that passed the preliminary examination of documents and active discussions to expand and deepen the study. We welcome attendees from various backgrounds who are interested in earth observation.

Impact assessment of hyperspectral infrared sounders toward Himawari-8/9 follow-on satellites

*Kozo OKAMOTO[1], Hiromi Owada[2], Masahiro Kazumori[2], Michiko Otsuka[1], Yoshifumi Ota[2], Naotaka Uekiyo[1], Hiromu Seko[1], Akiyoshi Ando[2], Ryo Yoshida[2], Hiroshi Ishimoto[1], Masahiro Hayashi[1], Haruma Ishida[3], Yoshiaki Sato[2], Hiroshi Kunimatsu[2], Kotaro Bessho[2], Hironobu Yokota[2]

1. Meteorological Research Institute, 2. Japan Meteolological Agency, 3. Meteorological Satellite Center

Japan Meteorological Agency has started the discussion on Himawari-8/9 follow-on satellites to be launched in 2028. We are investigating impacts on numerical weather prediction of a hyperspectral infrared sounder on the follow-on satellites using an observing system simulation experiment (OSSE) approach. We will present preliminary results of simulation and global and regional data assimilation experiments of the sounder.

Observation system simulation experiments for a hyperspectral infrared sounder onboard geostationary satellite

*HIROMI OWADA[1], Kozo OKAMOTO[2], Masahiro Kazumori[1], NAOTAKA UEKIYO[2], Hiroshi Ishimoto[2], Masahiro Hayashi[2]

1. Japan Meteorological Agency, 2. Meteorological Research Institute

At the Japan Meteorological Agency, we started preparation for the Himawari-8/9 follow-on satellites. Hyperspectral infrared sounder (HSS) is one of the instruments to consider to be installed in the follow-on satellites. By installing HSS on a new geostationary satellite, it is possible to acquire information on highly accurate profiles of temperature and water vapor at high frequency, and it is expected that accuracy of numerical weather prediction is greatly improved by using this new data in data assimilation system. In order to confirm this assumption, we evaluate the impact on numerical weather prediction when we install HSS on the follow-on satellites and assimilate their data with observation system simulation experiment (OSSE).

In this presentation, we report on the generation of HSS pseudo observation data and the initial results of OSSE in JMA's current global data assimilation system.

Realization of pseudo high frequency high resolution observation by geostationary satellite and orbiting satellite combined observation

*Yoshiaki HONDA[1]

1. Center for Environmental Remote Sensing, Chiba University

Observation data of the earth observation optical sensor data from both the earth science and the actual utilization is required more frequently and higher resolution. However, in order to realize this high frequency observation and high resolution observation at the same time, it is impossible with one satellite, and it is being realized by many operations of micro satellite. However, in general, micro satellites have problems such as short design life and no calibration system. On the other hand, satellites of medium size or more including geostationary satellites have a long design life and have a calibration system. However, in order to realize high frequency and high resolution with satellites of medium size or larger, if we try to secure the number of satellites, its budget is enormous and not realistic. This proposal is based on high frequency observation of geosynchronous satellites with relatively low resolution among satellites launched by Japan (assumed to be successors such as Himawari, GCOM - C, ALOS etc), and high resolution but low frequency orbiting satellite observations We aim to manufacture pseudo high frequency high resolution observation data through a model that adjusts part of sensor specifications of each satellite and adjusts the difference between observation geometries, and provides such a high quality long-term framework . This aims to expand the use of satellite optical sensor data in earth science and practical use fields, and to expand scientific progress and practical use. This framework is a planned budget size, one step to get bigger results, and expansion of the actual field of use will also contribute to the continuity of the Earth observation in Japan. Furthermore, by incorporating newly planned satellites of other countries into this framework, we aim to increase the presence of our Earth observation in the field of earth science and practical use.

Geostationary Optical Earth Observation Satellite

*Kazuo Oki[1], Toshiyoshi Kimura[2], Tadahito Mizutani[2], Takeo Tadono[2]

1. The University of Tokyo, 2. JAXA

Geostationary satellite is the most practical Earth Observation for its instantaneous observation and ability to choose target area on demand. Some kind of users, especially disaster monitoring, agriculture and national security users are demanding such unique character crucially. However, technical difficulties prevent from realization of the system, so far. Practical observation needs a certain fine ground resolution. But it means necessity for huge main mirror for the satellite optics. For an example, 5~7m resolution at Nadir position needs 3.6m diameter mirror. So far, 1~2m diameter one-piece mirrors were studied, in contrast. Recent optical technologies make it possible to have an extra large telescope using segmented mirrors for astronomical telescope on the ground, like Keck astronomy or TMT project. Using such technologies, we studied geostationary satellite telescope system with 3.6m diameter segmented telescope to materialize 7m ground resolution at Nadir position. Observation bands should have good correlation with ALOS-3 satellite on low Earth orbit, i.e. panchromatic, RGB, NIR and additional bands. To ensure the night observation, IR band is under consideration in addition. Such new Earth observation scheme improves time resolution dramatically, and it will make possible to observe movement of target like video camera. It will reveal many motile phenomena including Tsunami, Typhoon and human activities like car traffics. Also, it is expected that various social services unprecedented in cities, forests, agriculture, water (rivers and oceans), etc. are expected to be offered, and we believe that many users will appear in the field of science and practical use. The study started in 2018 and will end in 2020 to confirm the technical readiness level of required technologies, observation plan and algorithms for new earth observation data products.

Precipitation Measuring Mission by Active Sensors

*Nobuhiro Takahashi[1], Yukari Takayabu[2], Kinji Furukawa[3], Riko Oki[3], Kosuke Yamamoto[3], Yuki Kaneko[3]

1. Institute for Space-Earth Environmental Research, Nagoya University, 2. The Atmosphere and Ocean Research Institute (AORI) , 3. The Japan Aerospace Exploration Agency (JAXA)

We propose precipitation observation mission with DPR2, which is greatly improved performance of the dual-frequency precipitation radar (DPR) onboard the core satellite of Global Precipitation Measurement (GPM) mission in order to improve the understanding of cloud-precipitation mechanism and to monitor global precipitation. Based on the global precipitation observation heritages of more than 20 years by the precipitation radar (PR) onboard the tropical rainfall measuring mission (TRMM) satellite and GPM/DPR and new mission concept has been discussed by considering the current scientific issues regarding precipitation.

One of the urgent issues is the climate change (the global warming) issue. It is necessary to grasp phenomena of various scales to solve this issue, because it is necessary to evaluate not only the global climate (temperature) change but also the impact on the precipitation systems by global warming and it turns out the necessity of the accurate understanding of the earth's water circulation covering from the microphysical processes, cloud scale phenomena to the global scale precipitation and interactions among them. Considering the precipitation observation, we need better understanding of the cloud-precipitation processes, the global distribution of solid and liquid precipitation and the intense precipitation that affects the soil recharge and flooding. To implement these scientific purposes, observation (system) including cloud observation as well as observation specialized in precipitation in TRMM and GPM is necessary. Furthermore, in order to accurately grasp the precipitation formation mechanism from clouds, it is necessary to acquire dynamic information in the cloud. On the other hand, acquiring climatological information of global precipitation continued from TRMM and GPM is important as the long term record of precipitation. The improvement of the global precipitation map such as GSMaP are also necessary for practical use of precipitation information.

We need to consider the international cooperation such as the framework of TRMM and GPM that is Japan-US cooperative mission. In the United States, Cloud, Convection and Precipitation (CCP) and Aerosol (A) observations are listed as high priority observation in Decadal Survey report. The mission architecture study has been started focusing on aerosol, cloud and precipitation observation. The observation method exemplified in Decadal Survey is high sensitivity observation of cloud by scanning W-band cloud radar and Ka-band radar and Doppler velocity measurement with these radars. This observation concept is complementary to DPR2 concept.

DPR2 plans to improve the sensitivity from 10 times to 100 times (10 to 20 dB) of DPR by using advanced semiconductor devices such as GaN and introducing pulse compression technology, and also plans to introduce Doppler velocity measurement. Improvement in sensitivity is necessary to resolve that DPR has insufficient sensitivity to weak snowfall, as well as to sufficiently overlap the sensitivity range of cloud radar. Resources for improving the sensitivity can be utilized to the expansion of the scan width (but the sensitivity gets worse accordingly), for example, the data of the DPR2 observation can be directly input to the GSMaP to improve the accuracy. Regarding the utilization of this sensitivity resource as maximum, it is also consider the flexible radar operation. Theoretically, it is necessary to maintain correlation between

©2019. Japan Geoscience Union. All Right Reserved.

radar pulses for Doppler velocity measurement. Because of the very fast movement of satellite, sufficient correlation cannot be obtained with the antenna size of DPR, and at least double sized antenna is necessary. Technically, a deployable antenna should be introduced to realize the large antenna and it is a large development item for DPR2, the heritages from EarthCARE can be used for radar control and signal processing system on the Doppler velocity measurement.

Asian Small Precipitation Radar Constellation (ASPRC)

*Kinji Furukawa[1], Toshiaki Ogawa[2], Riko Oki[1], Takuji Kubota[1], Moeka Yamaji[1]

1. Japan Aerospace Exploration Agency, 2. NEC Corporation

The Japan Aerospace Exploration Agency (JAXA) and NEC Corporation (NEC) have developed a Dual-frequency Precipitation Radar (DPR) equipped with a main satellite for the Global Precipitation Measurement (GPM) core observatory. GPM/DPR was launched in 2014, and its observation data is utilized in various ways such as being incorporated into the Global Satellite Mapping of Precipitation (GSMaP) provided by JAXA. GPM/DPR is superior to precipitation observation by microwave radiometer in that it can observe highly accurately without distinguishing between ocean and land, and it is possible to acquire vertical profile of rainfall etc. Meanwhile, GPM/DPR has a relatively narrow observation width and only one observatory is operated, so the problem is that the observation frequency at the same spot is small. In order to solve this problem, we propose Small Precipitation Radar Constellation based on the Ku band precipitation radar (KuPR) which constitutes GPM/DPR. It will decrease observation interval of the same spot about 6 hours. Note that this precipitation radar is supposed to be mounted on the small satellite bus NEXTAR-300L developed by NEC.
With the proposed Small Precipitation Radar Constellation, it is possible to greatly improve the observation frequency of the same spot with respect to GPM/DPR. Although the number of satellites will increase, both the precipitation radar and the satellite bus will utilize already developed products and it will be mounted on relatively inexpensive small satellite to reduce the cost of the overall system. Assuming that both the precipitation radar and the satellite bus utilize already developed products, we aim to target the development cost of the first observatory to 10 billion yen or less (excluding ground equipment, launch, operation cost).
As the application of the small precipitation radar constellation, it is assumed that utilization in disaster prevention such as improving the accuracy of weather forecast, predicting the occurrence of flood caused by typhoon and severe rainfall. Scientifically, it is useful for the study of the diurnal change of precipitation by high frequency observation in tropical zone. Observation data of this precipitation radar can also be used in Southeast Asian countries (Indonesia, the Philippines, Vietnam, etc.), and it is assumed that a satellite constellation will be constructed by countries which are interested in development and launch (Realized by ODA). As a technical development, we aim increase the number of constellation satellite for further high frequent precipitation obseravtion through further size down and cost reduction.

In-orbit Payload Demonstration of Circularly Polarized SAR

*Josaphat Tetuko Sri Sumantyo[1], Kuze Hiroaki[1], Nobuyoshi Imura[1]

1. Center for Environmental Remote Sensing, Chiba University

Recently, we develop small circularly polarized SAR satellite, where the flight test of airborne circularly polarized SAR was success, and we plan to do the in-orbit payload demonstration of this circularly polarized SAR in the next step. Small circularly polarized SAR satellite is 100 kg microsatellite with circularly polarized synthetic aperture radar (CP-SAR) sensor onboard that is originally developed by Chiba University. This in-orbit satellite system has the objective to realize high level education and research on global environmental and disaster monitoring, i.e. active fault, landslide, earthquake, volcanic eruption etc, and data analysis.

Global wind measurement system using Doppler Wind Lidar and Imaging FTS

*Okamoto Hajime[1], Toshiyoshi Kimura[2], Daisuke Sakaizawa[2], Shoken Ishii[3]

1. Kyushu University, 2. Japan Aerospace Exploration Agency, 3. National Institute of Information and Communications Technology

We propose global wind measurement system by using Doppler Wind Lidar (DWL) and FTS on Geostationary satellites. Wind as atmospheric circulation is the most important element in climate and weather studies. Air- and ship-traffic are also using wind information as most prioritized one to ensure their safe operation. Current systems cannot measure global distribution of winds. Recent progress of DWL technology made precise wind measurement possible in three-dimensional manner, limited to narrow swarth over its orbit. A DWL-satellite was already launched by European Space Agency, and NASA is also planning to launch. In Japan, NICT and JAXA are studying DWL. Also, recent geostationary weather satellite made possible to distinguish wind distribution by altitude using water vapor band imagery. Measurement error is still large. The basic concept is to combine DWL and FTS on Geostationary satellites to complement each other. To cover the globe using geostationary orbit, we need about four satellites at each region. Using current weather satellite network is the most demanded approach. NASA, ESA and JAXA/NICT can make a strong network to maintain data from spaceborne DWLs to calibrate the results of retrieved wind from imaging FTS on Geostationary satellite. The requirement of spacial resolution for the system is 1km horizontal resolution, 300m height distribution, <1m/s windspeed accuracy and wind vector.

Mission regarding monitoring and elucidation of global environmental change (global radiation forcing and ecological change that affect global warming)

*Yoshiaki HONDA[1], Teruo AOKI[2], Takashi NAKAJIMA[3], Mitsuhiro TORATANI[4]

1. Center for Environmental Remote Sensing, Chiba University, 2. Graduate School of Natural Science and Technology, Okayama University, 3. Tokai University, Research & Information Center, 4. Tokai University, Earth and Environmental Systems

The purpose of this proposal is to monitor and clarify global environmental change (long-term and ongoing quantitative monitoring) global environment change (global radiation forcing and global ecological change affecting global warming). The technology of optical (near ultraviolet to thermal infrared) imager is a fundamental technology that can develop into new optical sensors of the future and it is necessary to continue to maintain the world advantage.
Optical imagers, which are the genealogy of SGLI, can be monitored by a wide range of wavelengths, including current unexpected changes in climate system fluctuations that change with global warming. In addition, by being able to accurately grasp the predicted progress of climate change, it is possible to evaluate the effect of global warming control policy, and to develop adaptation measures for the future and to make a diagnostic orbit correction . By having its own information source as a sensor of its own country, it is possible to have Japan's unique judgment materials for grasping the situation of climate change and to disseminate it to the world as global standard information. And we can have an international strategy on climate change.

Proposal of satellite for observing large point sources of carbon dioxide

*Hirofumi Ohyama[1], Tsuneo Matsunaga[1], Isamu Morino[1], Yukio Yoshida[1], Makoto Saito[1]

1. National Institute for Environmental Studies

We propose an earth-observing satellite that aims to quantify amounts of atmospheric carbon dioxide (CO_2) emitted from large point sources (LPSs) such as thermal power plants and steel plants, which account for approximately 40% of energy-related CO_2 emissions in the world. In the Global Stocktake Process under the Paris Agreement, each country is required to report sources and sinks of greenhouse gases (inventory) with sufficient accuracy. However, there are large uncertainties in the CO_2 and methane (CH_4) emissions from the LPSs, especially for the developing countries. Space-borne observation could be useful for quantifying and verifying the emissions from the LPSs, given that it provides column abundances in and out a plume with high spatial resolution. With regard to the LPS observation of CH_4, several satellites with a footprint size of less than 1 km^2 are developed recently: GHGSat series (2016 and 2019, GHGSat Inc. in Canada), COOL (2020, Bluefield Technologies Inc. in the U.S.), and MethaneSAT (2021, Environmental Defense Fund in the U.S.). That kind of CO_2 satellite is, however, not planed. Our proposed satellite has an ability of measuring back-scattered solar spectra in the near-infrared region with a footprint size of less than 1 km x 1 km (if feasible, hundreds of meters by hundreds of meters) using an imaging grating spectrometer. Additionally, to increase the signal to noise ratio of the spectrum, the satellite is dedicated to a target observation mode that observe an area of ~50 km x ~50 km including the LPSs more than 2 min continuously by using a pointing mechanism as adopted for the Greenhouse gases Observing SATellite (GOSAT) series.

Earth's health diagnosis - Imaging spectrometer of SLCP for early verification of global warming countermeasure effect, and understanding of status of air pollution -

*YASUKO KASAI[1], Yugo Kanaya[2], Hiroshi Tanimoto[3], JSAC Satellite team[4]

1. NICT, 2. JAMSTEC, 3. NIES, 4. JSAC

We propose a satellite constellation observation plan that understanting of inventory of short-lived climate pollutants (SLCP*) emitted by human activities. SLCP is related to both air pollution and climate change. As the reduction effect of SLCP is obtained in the short term compared with CO2, ministerial-level international efforts began in 2012 as a new method of countermeasures against global warming (CCAC). In addition, the number of deaths due to air pollution is around 3.7 million people worldwide (WHO Report 2012), which is about three times the number of traffic fatalities. Especially, the rate of early death in Japan is at the highest level in OECD countries and the situation is serious.
Also, the impact on agricultural crops can not be ignored. SLCP has local sources of emissions, and observation with a spatial resolution of 1 km class is necessary for grasping actual conditions, but it has not existed so far due to technical difficulties. The proposed SLCP imaging spectrometer (UV / VIS / SWIR) is installed in the low orbit satellite asynchronously realizing the world's first high horizontal resolution (target: horizontal resolution 1 to 2 km), day change observation. We propose detection of SLCP substances in the vicinity of the ground (especially oxidants affecting health damage) by MIR + MW spectroscopic observation synergy as an optional function. From the spatial resolution and observation local time (LT), this sensor has the function as "standard machine" for air pollution satellite observation around the world, and the existence of this machine enables constellation connecting world satellites. This will integrate satellite data around the world, obtain the highest standards of scientific knowledge and encourage evidence-based measures.

The Remote Sensing Technology Center of Japan, 7. National Institute for Environmental Research, 8. National Institute of Information and Communications Technology, 9. Kyoto University, 10. Japan Aerospace Exploration Agency

A lidar is a generic term for light wave radar using pulse laser for transmitter. The lidar on board satellite can precisely measure the ground level and the forest canopy height and three-dimensional forest structure by analyzing round trip time until a light pulse irradiated from orbit to the ground is reflected at the ground surface and returned to the lidar on orbit. This paper propose the Japan’ s first satellite-borne vegetation lidar (MOLI: Multi-footprint Observation Lidar and Imager) mission to investigate the above-ground ground forest biomass (AGB) on a global scale, which plays an important role for carbon cycle and climate change mechanism.
The main purpose of the MOLI mission on board ISS (International Space Station) -JEM (Japanese Experiment Module) is to successfully demonstrate the functional performance of the lidar in space for establishing a vegetation lidar that can acquire canopy height / three-dimensional forest structure information necessary for AGB evaluation with high accuracy. The second objective is to ultimately develop algorithms for highly accurate AGB estimation in high dense tropical forest zone that is inferior in reliability at the present time by merging MOLI data into L-band SAR (ALOS-2 / PALSAR-2 etc.) data and passive spectroscopic data such as GCOM-C / SGLI, and to obtain design guidelines for the practical space-borne lidar in future.
The MOLI proposed here has the function of self-determining the inclination angle and the azimuth angle for reducing the error in the canopy height measurement induced by the ground surface inclination. The output light of the pulse laser is split into two beams and then irradiated as a pair of foot prints on the ground surface. Each footprint diameter on the ground is 25 m, the footprint interval is about 50 m @ along - track, about 43 m @ cross - track. The inclination angle and the azimuth angle are determined from the difference between the trajectory-ground reciprocating time for three closest footprints among a large number of pairs of footprints appearing continuously in the along-track direction on each laser shot and on the ground. Transmission output is 20 mJ / pulse / foot print, repetition frequency 150 Hz, pulse width 7 nsec. The aperture diameter of the receiving optical system is 0.45 m, the detector is two-dimensional Si-APD, the A / D converter is bandwidth 500 MHz, 12 bit resolution. High resolution imager consists of R/G/NIR band, swath width 1000 m, ground resolution 5 m, and acquires information on the size, height, and field data of the canopy. Measurement accuracy of canopy height is <±3 m (<15 m forest height) or <±25% (> 15 m forest height) at ground level inclination angle <30 degrees. The target of AGB observation accuracy is <±20 t / ha (AGB<100 t / ha), <±25% (AGB> 100 t / ha) ,respectively. Field survey is an important work for forest management (forest register), but it comes across many difficulties especially in tropical forest areas. According to our estimate, by implementing MOLI data, a number of AGB field survey and survey costs are able to be reduced by 1/2 (ρ^2: coefficient of determination in two phase regression from ground survey to MOLI estimation) to 1/5 ($\rho^2 = 0.8$), there is a possibility of drastically reducing the maximum by 1/10 ($\rho^2 = 0.9$). A disadvantage of MOLI is strongly affected by weather conditions.

©2019. Japan Geoscience Union. All Right Reserved.

On the other hand, L-band SAR (ALOS-2 / PALSAR-2 etc.) is excellent not only for changes of AGB in real time because it can observe all weather, but also for measuring AGB even in steep mountain area because the method of correcting the distortion of data was recently improved very much. Since then, SAR observation is greatly been demanded. However, there is a big disadvantage for L-band SAR observation. Its backscattering signals easily saturate above AGB of 150 t/h in highly dense tropical forests, that is, in the South American Amazon basin, African Congo region, and Southeast Asia region. It will be able, therefore, to be achieved to improve the accuracy of AGB observation in the high dense rainforest region by complementing each other's advantage and disadvantage for MOLI and SAR with each other. Furthermore, realization of MOLI can be expected to work very effectively for JJ-FAST which is early warning system of deforestation using ALOS-2 / PALSAR-2. This logging detection system focuses on the measurement of deforestation area and does not have the function of AGB measurement. The fusion with MOLI data will also be able to precisely calculate the amount of carbon released at the logged place.

Estimation of forest resources by a dual-wavelength imaging LiDAR system

*Ryuichi Hirata[1], Yoshito Sawada[1], Masato Hayashi[2], Hideki Saito[3], Tomoaki Takahashi[3], Tsuneo Matsunaga[1]

1. National Institute for Environmental Studies, 2. Japan Aerospace eXploration Agency, 3. Forestry and Forest Products Research Institute

We propose a mission of a dual-wavelength imaging LiDAR system, which measure global forest resources such as canopy heights and forest biomass with high accuracy. The purpose of the mission is to clarify global carbon cycle, countermeasure climate change, and to protect biodiversity. They are useful to evaluate forest resources for REDD+ and MRV.

This system includes two new technologies. One is imaging LiDAR with modulating Laser light to measure spatial distribution of forest resource in a footprint. Another is dual-wavelength to detect ground surface with high accuracy. Measuring spatial distribution of forest in a footprint by modulating Laser Light gives us information about canopy height and biomass with high accuracy compared with the former sensor such as ICESat/GLAS. A dual-wavelength is able to detect forest surface and ground surface more correctly than the former sensor. This system can increase measurement accuracy for canopy height on a slope, which is difficult situation for evaluating canopy height by the former systems because the system is able to measure a shape of ground surface in the area of Laser irradiation. One of the objective of this mission is to evaluate canopy height with 1 m accuracy; the accuracy of canopy heitht of ICESat/GLAS was 5 m and that of MOLI will be 3 m.

Development of new satellite to monitor SIF and PRI of terrestrial vegetation with high spatial and wavelength resolutions

*Hibiki M Noda[1], Kenji Omasa[2], Kouki Hikosaka[3], Kazuhito Ichii[4], Hideki Kobayashi[5], Tomomichi Kato[6], Hiroyuki Muraoka[7]

1. NIES National Institute of Environmental Studies, 2. University of Tokyo, 3. Tohoku University, 4. Chiba University, 5. JAMSTEC, 6. Hokkaido University, 7. Gifu University

To deal effectively with global warming by mitigation and adaptation, it is necessary to monitor emission and sequestration of greenhouse gases with their underlying mechanisms including biogeochemical processes. The Earth-observation satellite is powerful tool to observe temporal and spatial variations in structure and function on ecosystem in regional to global scale. It has been conducted to estimate GPP (gross primary production) by using satellite-measured optical properties of vegetation canopy such as NDVI (normalized vegetation index). Those vegetation indices are related to greenness of the canopy but not reflect the photosynthetic activity, that are quite sensitive to climatic conditions. Thus, there are still large uncertainty in the estimation of GPP.
In recent years, advent of the Earth-observation satellite with high wavelength-resolution sensors enable us to observe SIF (Solar-Induced chlorophyll Fluorescence) emitted from terrestrial vegetation. Since the chlorophyll fluorescence is emitted in photochemical reaction, which is a part of photosynthetic process, SIF would be good indicator of photosynthetic activity. In the photochemical reaction, xanthophyll cycle is also play important roll to release extra energy and it is able to monitor its condition by using PRI (Photochemical Reflectance Index). In the recent study in single-leaf scale, it has been shown that simultaneously measured SIF and PRI help us to estimate accurate photosynthetic rate based on ecophysiological model (Hikosaka and Noda 2019). Similarly, simultaneous measurement of SIF and PRI with the Earth-observation satellite would be helpful to estimate GPP and understand the in regional to global scale. However, there are no satellite to measure SIF and PRI simultaneously to date. FLEX, which will be launched in 2022 is the only satellite mission to measure them.
In this talk, we will propose development of new satellite to observe SIF, PRI and other vegetation indices such as NDVI with high spatial and wavelength resolutions. This satellite would contribute accurate estimation of GPP and effective policy making against global warming.
In this talk we will suggest to develop new Earth-obsevation satellite to monitor SIF and PRI of terrestrail vegetation with high spatial and wavelength resolutions.

Satellite Observation of the Whole Atmosphere - Superconducting Submillimeter-Wave Limb-Emission Sounder (SMILES-2)

*Masato Shiotani[1], Akinori Saito[1], Takatoshi Sakazaki[1], Satoshi Ochiai[2], Philippe Baron[2], Toshiyuki Nishibori[3], Makoto Suzuki[3], Takumi Abe[3], Hiroyuki Maezawa[4], Shin-ichiro Oyama[5,6,7]

1. Kyoto University, 2. National Institute of Information and Communications Technology, 3. Japan Aerospace Exploration Agency, 4. Osaka Prefecture University, 5. Nagoya University, 6. University of Oulu, 7. National Institute of Polar Research

The Superconducting Submillimeter-Wave Limb-Emission Sounder (SMILES) launched by an H-IIB rocket with the H-II Transfer Vehicle (HTV) in September 2009 and attached to the Japanese Experiment Module (JEM) on the International Space Station (ISS) demonstrated high-sensitivity submillimeter limb-emission sounding of atmospheric observations. Though the observation period is limited to about 6 months (October 12, 2009- April 21, 2010) owing to the failure of a critical component, outstanding results have been achieved such as an identification of diurnal cycle of the stratospheric ozone, which had not been examined yet because of poor data quality in the previous satellite measurements. In addition by comparing SMILES data with existing observation data and results from the chemistry climate models, it has been recognized that we need a reference data for temperature, wind, and minor species with high precision to constrain the models. After the launch there has been discussions about the possibility to derive wind information from the Doppler shift of observed lines, and the necessity to have temperature information from adequate line selection. Thus we now recognize the potential of high-sensitivity observations about temperature and wind fields up to 150 km.

Based on the SMILES heritage, we propose a satellite mission to observe temperature and wind fields, and distributions of atmospheric minor species for the full diurnal cycle from the middle atmosphere (stratosphere and mesosphere) to the upper atmosphere (thermosphere and ionosphere) for a period of five years. SMILES-2 observations will enable us to obtain global information with unprecedented accuracy on the whole atmosphere including upper mesosphere and lower thermosphere where observation data have been lacking.

This mission has four science objectives:
(MO.1) To investigate the 4-D space-time structure of the diurnal variations (atmospheric tides) in view of dynamics, chemistry, and electromagnetic processes
(MO.2) To unveil the vertical propagation of synoptic-to-planetary scale disturbances from the middle atmosphere (non-migrating tides and stratospheric sudden warming events) to the upper atmosphere
(MO.3) To understand atmospheric variations due to energy inputs from the magnetosphere (particle precipitation and magnetic storm)
(MO.4) To provide benchmarks for whole atmosphere models and climate models with detailed description of the background thermal structure and distribution of minor species

Using observation data from the middle atmosphere to the upper atmosphere as a whole, we will be able to grasp the 4-D dynamical structure of diurnal variations (atmospheric tides) which are one of the most essential variabilities in the earth’ s atmosphere. For understanding climate change in view of chemical processes affecting the ozone layer, we will be able to utilize high-sensitivity measurements of the atmospheric minor species in a quantitative manner. In the upper atmosphere, a transition layer between the atmosphere and the outer space, we will be able to clarify a role of energy inputs from the

©2019. Japan Geoscience Union. All Right Reserved.

magnetosphere from the temperature and wind observations. These outcomes including the atmospheric trace gas data will greatly contribute to improvement in reliability of chemistry climate models for future projection and accuracy of prediction models for space weather.

Keywords: middle atmosphere, upper atmosphere, satellite observations, temperature, wind

SMILES-2 is a mission prepared for the next call-for-proposals for JAXA/ISAS M-class scientific satellite mission. It aims at scanning the atmospheric limb from 20 to 160 km above the surface at frequencies near 700 GHz and 2 THz. It could provide the temperature and composition as well as, for the first time, the horizontal wind vector above 30 km, the atomic oxygen in its ground state above 90 km, and the atmospheric density and the geomagnetic field vector near the mesopause. The measurement performances have been assessed from numerical simulations. We will present the results obtained for the 3 radiometers.

Feasibility of Superconducting Submillimeter-Wave Limb-Emission Sounder (SMILES-2) on an M-class satellite

*Satoshi Ochiai[1], Philippe Baron[1], Yoshihisa Irimajiri[1], Toshiyuki Nishibori[2], Makoto Suzuki[2], Yoshinori Uzawa[3], Hiroyuki Maezawa[4], Takeshi Manabe[4], Akinori Saito[5], Masato Shiotani[5]

1. National Institute of Information and Communications Technology, 2. Japan Aerospace Exploration Agency, 3. National Astronomical Observatory of Japan, 4. Osaka Prefecture University, 5. Kyoto University

The Superconducting Submillimeter-Wave Limb-Emission Sounder-2 (SMILES-2) is a proposed mission for comprehensive observation of temperature, wind, and atmospheric compositions in the middle and upper atmospheres using limb observation technique at submillimeter-wave from an satellite on a non-sunsynchronous low Earth orbit. The proposal of SMILES-2 is assumed to be one of M-class missions of the Japan Aerospace Exploration Agency / the Institute of Space and Astronautical Science (JAXA/ISAS). SMILES-2 will enable us to observe temperature profile between the tropopause and the lower thermosphere below an altitude of 150 km, horizontal wind profile between the upper stratosphere above 30 km and the lower thermosphere, and atmospheric compositions including water vapor, ozone, and other minor species in the stratosphere and mesosphere and atomic oxygen in the lower thermosphere with a vertical resolution of 2.5 km or 5 km. Those observation will be daily and sampled at numerous positions spread in global scale. Diurnal cycles can be estimated. The local time of observing point will be shifted by 24 hours in about 3 months.
The observation of the diurnal cycles is one of the most important targets for the SMILES-2 science. To meet the scientific requirements, SMILES-2 shall have the superconducting receivers at bands of 638 GHz, 763 GHz, and 2 THz, and observe limb atmosphere from a satellite on an orbit at an altitude of 550 km and an inclination of 66 degree. Atmospheric vertical profiles are observed at every 690 km on the sun-shade side along the orbit. Each vertical profile is observed two times from different directions with a time interval of about 8 minutes so that horizontal wind vector can be retrieved. Approximately 830 vertical profiles will be observed in one day.Estimated precision of those measurements is summarized in another paper of this meeting. The wind measurement precision is estimated to be comparable or slightly better than a typical amplitude of diurnal cycle of the wind variation. The measurement precision depends on the receiver sensitivity and the spatial and time resolution of measurements. Because the average number of the wind observation can hardly increase, the receiver sensitivity is extremely important to keep a good measurement precision. Superconducting devices, which show the best performance among heterodyne receivers in the frequency range, are essential for the SMILES-2 receiver.
SMILES-2 will use a technological heritage of JEM/SMILES, which is a mission operated on the Japanese Experiment Module in the International Space Station for a half year from 2009 to 2010. JEM/SMILES successfully demonstrated submillimeter limb observation for the first time with superconducting heterodyne receivers cooled by spaceborne cryocooler. Although no cryocooler in Japan was demonstrated in space for much longer lifetime, an improved model of 4-K cryocooler for space has been tested on the ground and showed a lifetime of more than 4 years. The power consumption of the cryocooler for JEM/SMILES was measured about 153 W on the ground, and that of the JEM/SMILES payload was about 320 W. The power resource of an M-class satellite is very limited comparing to that of JEM missions. The available power for the mission is estimated about 323 W when the orbit comes at the maximum sun-shading ratio. That seems larger than the required power, but it is not enough because the SMILES-2 mission includes telecommunication systems and data recorders that are not in the JEM/SMILES payload. Moreover, the power consumption by the SMILES-2 cryocooler may be larger by increasing the number of frequency bands and requiring power margin for compensating the decrease of

©2019. Japan Geoscience Union. All Right Reserved.

cooling efficiency of the cryocooler for 3 or 5 year operation.
The design of power balance, as well as the cost evaluation, is the largest issue in judging the feasibility of SMILES-2 on M-class satellite. We are studying measures of reducing the cryocooler power consumption. For example, we are estimating power consumption with a detailed design of the cryostat for the receivers and cooling system. We are also developing a new receiver configuration that saves heat flow into the cooling stage, and designing the radiation cooling system to reduce the base temperature of cryocooling system. With additional reductions of the power consumption by the other mission components, we believe that the power consumption of the SMILES-2 mission can be kept within the available power.
The SMILES-2 mission will be proposed to JAXA/ISAS for the next opportunity of M-class mission, which is targeting a launch in 2026 or later.

[M-TT45] Cryoseismology - a new proxy for detecting surface environmental variations of the Earth -

convener:Genti Toyokuni(Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University), Masaki Kanao(National Institute of Polar Research), Seiji Tsuboi(JAMSTEC, Center for Earth Information Science and Technology)

Several kinds of environmental signals associated with ocean - cryosphere - solid earth systems have recently been detected in bi-polar regions. Ice-related seismic motions for small magnitude events are generally named ice-quakes (ice-shocks) and can be generated by glacially related dynamics. Such kinds of cryoseismic sources are classified into the movements of ice sheets, sea-ice, oceanic tide-cracks, icebergs and the calving fronts of ice caps. Cryoseismic waves are likely to be influenced by variations in environmental conditions, and the continuous study of their time-space variability provides indirect evidence of climate change. As glacial earthquakes are the most prominent phenomena found recently in polar regions, in particular on the Greenland in this 21st century, the new innovative studies from seismology are expected by long-term monitoring under extreme conditions in the Earth's environment.

Taking these issues into account, the conveners are willing to invite many contributions to a special session on "Cryoseismology", which will cover the recent achievements on glacial related seismic events and associated phenomenon observed in polar regions. It is particularly encouraged to have contributions based on seismic signals involving the dynamics of ice sheets, sea-ice, and icebergs and glaciers. Although the glacial earthquakes are the most prominent evidence found recently in polar regions, all related topics involving polar seismology are welcome, such as studies of crust and mantle structure in the area, comparison of tectonic and glacier-related seismicity, recent triggered earthquakes and active volcanoes, glacial isostatic adjustment (GIA), harmonic tremor associated with cryoseismic events, etc. This session has been held every year since 2015, and was held as Union Session last year.

Application of neural network and theoretical seismograms as training data to locate ice quakes

*Seiji Tsuboi[1], DAISUKE SUGIYAMA[1]

1. JAMSTEC, Center for Earth Information Science and Technology

We have applied numerically computed theoretical seismograms and deep machine learning to locate earthquakes. We calculate theoretical seismograms for realistic three-dimensional Earth model and use these seismograms to create seismic wave propagation images at the surface of the Earth. Then we use these images as training dataset of convolutional neural network. We build neural networks for determination of hypocentral parameters, such as epicenter, depth, origin time and magnitude, and applied these networks to actual seismograms to examine if this procedure works to locate earthquake and determine magnitude. Although the number of earthquakes is small and the regional extent is quite limited, the results demonstrate that it is feasible to locate earthquakes by using this approach. Advantages of using this approach to locate earthquakes and determine magnitude are; accuracy of hypocenter parameters can be increased by accumulating theoretical seismograms for various earthquake location and size as learning dataset of deep machine learning; three dimensional Earth structure can be included without additional computational cost to locate earthquakes. Here we will discuss a possibility of applying this methodology to locate ice quakes, which happen in and near the ice sheet.

P-wave tomography beneath Greenland

*Takaya Matsuno[1], Genti Toyokuni[1], Dapeng Zhao[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

The Greenland landmass has a long and complex tectonic history (~4 billion years). However, most of the continent is covered by the extensive inland ice cap, so it was hard to access its geology and the underlying tectonics. The Greenland Ice Sheet Monitoring Network (GLISN) is an international project by 11 countries to establish a seismic network in and around Greenland (Toyokuni et al., 2014). The project was initiated in 2009, and now it provides broadband, continuous, and real-time seismic data recorded at 33 stations. In this study we aim to investigate the 3-D upper mantle structure beneath Greenland by using the GLISN data.

We inverted a number of P-wave arrival-time data of both local and teleseismic events, observed at 30 GLISN stations, to estimate a 3-D P-wave velocity (Vp) model beneath Greenland and surrounding regions. All of the GLISN arrival-time data are downloaded from the Bulletins of the International Seismological Centre. We used the seismic tomography method by Zhao et al. (2012).

In the polar region, if grid nodes are arranged on the basis of equatorial coordinates, distance between two adjacent nodes in the same latitude decreases as it gets closer to the pole. To overcome this problem, we converted our study region from the equatorial coordinates to the ecliptic coordinates. This scheme enables us to solve tomographic equations in quasi-Cartesian coordinates (e.g., Kobayashi & Zhao, 2004; Gupta et al., 2009; Takenaka et al., 2017). We set up a 3-D grid with a horizontal grid interval of 2° and a vertical grid interval of 15–30 km (at depths of 5–700 km).

The results of this study are summarized as follows.
(1) There is a prominent low-Vp anomaly beneath Iceland (depth < 500 km), which is related to the current Iceland plume.
(2) In the shallow mantle (40-250 km depths) beneath central and offshore eastern Greenland, Vp is relatively lower than those in the other inland areas of Greenland in the depth range, which may reflect the ancient motion path of the Iceland plume. This feature coincides with known basalt areas at central western and eastern coasts of Greenland.

The Greenland Ice Sheet (GrIS) is a huge storehouse of water on Earth, and has the potential to raise the global sea level by approximately 7 m if completely melted. Although researchers have been mainly studying the GrIS surface snowmelt as a response to climate warming, recent progress in ice-core drilling, remote sensing, and theoretical analyses has turned a spotlight on its basal conditions. However, the traditional observation techniques, such as ice-core drilling and ice-penetrating radar, provide only discontinuous information in both time and space.

Seismic observation is now drawing widespread attention as an alternative method for monitoring the GrIS. The Greenland Ice Sheet Monitoring Network (GLISN), an international project between 11 countries that began in 2009, now provides broadband, continuous, and real-time seismic data from 33 stations in and around Greenland. Japan is a partner country from when the GLISN project was launched, and has been sending an expedition team every year since 2011. In 2011, a joint USA and Japanese GLISN team installed the dual seismic–GPS station ICESG-GLS2 in the middle of the GrIS. During 2012–2018, we conducted maintenance of three stations on the GrIS (station codes: ICESG-GLS2, DY2G-GLS1, and NEEM-GLS3), and three stations on bedrock in coastal areas (NUUK, DBG, and SOEG). We had succeeded in real-time transmission of broad-band and continuous seismic waveform data from the three ice stations. It was the first time in the world that the seismic data with such a high sampling rate are transferred from the ice sheet. The data is now open to public and available from the IRIS Data Management Center (http://www.iris.edu/ds/nodes/dmc/). This presentation will summarize our field activities for 2011–2018, and introduce the future field plans.

Acknowledgments: The Japanese GLISN team has been supported by research grants from JSPS (24403006).

[M-TT45] Cryoseismology - a new proxy for detecting surface environmental variations of the Earth -

convener:Genti Toyokuni(Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University), Masaki Kanao(National Institute of Polar Research), Seiji Tsuboi(JAMSTEC, Center for Earth Information Science and Technology)

Several kinds of environmental signals associated with ocean - cryosphere - solid earth systems have recently been detected in bi-polar regions. Ice-related seismic motions for small magnitude events are generally named ice-quakes (ice-shocks) and can be generated by glacially related dynamics. Such kinds of cryoseismic sources are classified into the movements of ice sheets, sea-ice, oceanic tide-cracks, icebergs and the calving fronts of ice caps. Cryoseismic waves are likely to be influenced by variations in environmental conditions, and the continuous study of their time-space variability provides indirect evidence of climate change. As glacial earthquakes are the most prominent phenomena found recently in polar regions, in particular on the Greenland in this 21st century, the new innovative studies from seismology are expected by long-term monitoring under extreme conditions in the Earth's environment.

Taking these issues into account, the conveners are willing to invite many contributions to a special session on "Cryoseismology", which will cover the recent achievements on glacial related seismic events and associated phenomenon observed in polar regions. It is particularly encouraged to have contributions based on seismic signals involving the dynamics of ice sheets, sea-ice, and icebergs and glaciers. Although the glacial earthquakes are the most prominent evidence found recently in polar regions, all related topics involving polar seismology are welcome, such as studies of crust and mantle structure in the area, comparison of tectonic and glacier-related seismicity, recent triggered earthquakes and active volcanoes, glacial isostatic adjustment (GIA), harmonic tremor associated with cryoseismic events, etc. This session has been held every year since 2015, and was held as Union Session last year.

Application of neural network and theoretical seismograms as training data to locate ice quakes

We have applied numerically computed theoretical seismograms and deep machine learning to locate earthquakes. We calculate theoretical seismograms for realistic three-dimensional Earth model and use these seismograms to create seismic wave propagation images at the surface of the Earth. Then we use these images as training dataset of convolutional neural network. We build neural networks for determination of hypocentral parameters, such as epicenter, depth, origin time and magnitude, and applied these networks to actual seismograms to examine if this procedure works to locate earthquake and determine magnitude. Although the number of earthquakes is small and the regional extent is quite limited, the results demonstrate that it is feasible to locate earthquakes by using this approach. Advantages of using this approach to locate earthquakes and determine magnitude are; accuracy of hypocenter parameters can be increased by accumulating theoretical seismograms for various earthquake location and size as learning dataset of deep machine learning; three dimensional Earth structure can be included without additional computational cost to locate earthquakes. Here we will discuss a possibility of applying this methodology to locate ice quakes, which happen in and near the ice sheet.

P-wave tomography beneath Greenland

The Greenland landmass has a long and complex tectonic history (~4 billion years). However, most of the continent is covered by the extensive inland ice cap, so it was hard to access its geology and the underlying tectonics. The Greenland Ice Sheet Monitoring Network (GLISN) is an international project by 11 countries to establish a seismic network in and around Greenland (Toyokuni et al., 2014). The project was initiated in 2009, and now it provides broadband, continuous, and real-time seismic data recorded at 33 stations. In this study we aim to investigate the 3-D upper mantle structure beneath Greenland by using the GLISN data.

We inverted a number of P-wave arrival-time data of both local and teleseismic events, observed at 30 GLISN stations, to estimate a 3-D P-wave velocity (Vp) model beneath Greenland and surrounding regions. All of the GLISN arrival-time data are downloaded from the Bulletins of the International Seismological Centre. We used the seismic tomography method by Zhao et al. (2012).

In the polar region, if grid nodes are arranged on the basis of equatorial coordinates, distance between two adjacent nodes in the same latitude decreases as it gets closer to the pole. To overcome this problem, we converted our study region from the equatorial coordinates to the ecliptic coordinates. This scheme enables us to solve tomographic equations in quasi-Cartesian coordinates (e.g., Kobayashi & Zhao, 2004; Gupta et al., 2009; Takenaka et al., 2017). We set up a 3-D grid with a horizontal grid interval of 2° and a vertical grid interval of 15–30 km (at depths of 5–700 km).

The results of this study are summarized as follows.
(1) There is a prominent low-Vp anomaly beneath Iceland (depth < 500 km), which is related to the current Iceland plume.
(2) In the shallow mantle (40-250 km depths) beneath central and offshore eastern Greenland, Vp is relatively lower than those in the other inland areas of Greenland in the depth range, which may reflect the ancient motion path of the Iceland plume. This feature coincides with known basalt areas at central western and eastern coasts of Greenland.
