The Okinawa Trough is a basin within the East China Sea, where maximum depth reaches 2300 m. There are two characteristic water masses in the Okinawa Trough. One is the high salinity water in the sub-surface layer shallower than 300 m and the other is the low salinity water in the intermediate layer from 400 m to 700 m. According to the previous studies, the former water is occupied by the South China Sea Tropical Water (SCSTW) and the Kuroshio Tropical Water (KTW), and the latter is dominated by modified water masses of the North Pacific Intermediate Water (NPIW) and the South China Sea Intermediate Water (SCSIW). However, in the previous studies, the southern part of the Okinawa Trough remains to be observed, and it should be confirmed whether the previous results can apply to the southern part.
In this study, water mass properties in the southern part of the Okinawa Trough are investigated in detail. We mainly used CTD data from T/V Kagoshima-maru cruises in Junes from 2013 to 2018. The high salinity waters in the sub-surface layer were classified into three groups: SCSTW, KTW and the tropical waters in the east of Ryukyu Islands chain. The low salinity water in the intermediate layer had a complicated distribution in which the low salinity water from the east of Taiwan and that from the Kerama Gap.

[A-OS08] ECS-Kuroshio and Ryukyu Current System -Observation, modeling and theory-

convener:Hirohiko Nakamura(Kagoshima University, Faculy of Fisheries), Xiao-Hua Zhu(Second Institute of Oceanography), Chairperson:Hirohiko Nakamura(Kagoshima University), Jae-Hun Park(Inha University)

The East China Sea (ECS) is separated from the North Pacific basin by the Ryukyu Islands. On each side of the Ryukyu Islands, there lies two western boundary currents -the Kuroshio on the northwest and the Ryukyu Current on the southeast. These two currents play an important role in the global substance cycle and have a remarkable impact on the climate and adjacent marginal seas. Our knowledge of the Kuroshio and the Ryukyu Current's dynamics, variability, and impact has advanced significantly over the last decade, because of recent international collaborative field programs, improvement in satellite measurements, and advancement in high-resolution numerical models. This session seeks contributions from ECS-Kuroshio and Ryukyu Current studies and will cover a wide range of topics of observation, modeling and theory. The dynamics of the Kuroshio and the Ryukyu Current's variability at all spatio-temporal scales, the influence of the Kuroshio on typhoons and climate, the interactions among the Kuroshio, Ryukyu Current and eddies, internal waves including near-internal waves and their interactions with background currents, and the water mass exchanges through the gaps between the Ryukyu Islands are welcome to be discussed in this session.

Discussion

Downstream Evolution of the Kuroshio Velocity Structure and Transport

*Magdalena Andres[1], Sen Jan[2]

1. Woods Hole Oceanographic Institution, 2. National Taiwan University

The Kuroshio flows along the North Pacific western boundary carrying heat, mass and momentum poleward. Along this route, the Kuroshio’ s strength and vertical structure undergo significant temporal and spatial variability. Recent observational studies have examined the Kuroshio between Luzon and Taiwan, just before the Kuroshio flows into the East China Sea and upstream of the beginning of the Ryukyu Current (a subsurface-intensified current that carries part of the total poleward western boundary current flow). These observations were part of the recent US Origins of the Kuroshio and Mindanao Currents (OKMC) and Taiwan Observations of Kuroshio Transport Variability (OKTV) and Study of the Kuroshio II (SK-II) observational programs. These studies, together with previous observational efforts, build a comprehensive picture of the Kuroshio on its route from its origins near Luzon to southeastern Japan, where the current finally transitions from a western boundary current into the Kuroshio Extension, a vigorously meandering free jet. Through the joint OKMC/OKTV efforts, Kuroshio strength and velocity structure were measured between June 2012 and November 2014 with pressure-sensor equipped inverted echo sounders (PIESs) and upward- looking acoustic Doppler current profilers (ADCPs) deployed across the current northeast of Luzon, Philippines, and east of Taiwan with an 8 month overlap in the two arrays’ deployment periods. The time-mean net (i.e., integrated from the surface to the bottom) absolute transport increases downstream and the observed downstream increase is consistent with the return flow predicted by the simple Sverdrup relation and the mean wind stress curl field over the North Pacific (despite the complicated bathymetry and gaps along the North Pacific western boundary). Northeast of Luzon, the Kuroshio is shallower than 750 dbar, while east of Taiwan areas of positive flow reach to the seafloor (3000 m). A similar deepening of the subtropical western boundary current is observed in the North Atlantic in the region where the Gulf Stream leaves Cape Hatteras. In addition, there is a deep counterflow beneath the poleward-flowing Kuroshio. Time-varying transports and velocities indicate the strong influence at both sections of westward propagating eddies from the ocean interior. Topography associated with the ridges east of Taiwan also influences the mean and time-varying velocity structure there. By comparison, in the North Atlantic there is also a deep counterflow beneath the Gulf Stream at Cape Hatteras, however, this is likely due to different processes than those at play in the North Pacific, due to the presence of the Deep Western Boundary Current there which carries equatorward flow in the Atlantic Meridional Overturning Circulation (AMOC) cold limb flow.

Non-seasonal variability of the Kuroshio shelf intrusion and its associated changes in the ocean environment over the East China Sea during 1993-2017

*Jiwon Kang[1], Hanna Na[1]

1. School of Earth and Environmental Sciences, Seoul National University, Republic of Korea

The Kuroshio in the East China Sea (ECS) exhibits strong variability over the northeast of Taiwan; weakening of the Kuroshio has been understood to be associated with shelf-ward shift of the Kuroshio axis, which induces shelf intrusion of the Kuroshio water. The Kuroshio intrusion plays an important role for understanding the characteristics of water masses over the shelf region that, in turn, influences ocean environment in the marginal seas. In this study, non-seasonal variability of the intrusion, which was reported to be more significant in comparison with its seasonal variability, is examined during 1993-2017.

The Kuroshio intrusion index was defined based on the Empirical Orthogonal Function analysis of satellite-altimetry-derived geostrophic velocity data. The composite analysis of oceanic and atmospheric variables according to the intrusion index reveals that strong Kuroshio intrusion is associated with increase of sea surface temperature and eddy kinetic energy, strengthening of northwesterly wind and upward surface heat flux in the continental shelf region. The strong Kuroshio intrusion would also be related to sub-mesoscale eddy variability inside the ECS, and its relationship is discussed by examining surface drifter data over the region.

The temporal and spatial variability of the Kuroshio in the East China Sea and its associated mechanisms

*Yanzhou Wei[1]

1. State Key Laboratory of Satellite Ocean Environment Dynamics, Second Institute of Oceanography, Ministry of Natural Resources, Hangzhou, China

The Kuroshio is a strong western boundary current of the North Pacific subtropical gyre. It transports huge amounts of heat and nutrients poleward, and has a profound effect on the hydrography, fisheries, and climate of countries surrounding the Northwestern Pacific. As such, the temporal and spatial variability of the Kuroshio on multiple scales is of wide interest to the oceanographic and climate communities. In this study, we examine the temporal and spatial variability of the Kuroshio based on long term hydrographic observation and satellite data, and discuss the associated mechanisms.

The Joint Kuroshio–Ryukyu Current System Study and a rapid report about mooring observations southeast of Miyakojima

*Xiao-Hua Zhu[1], Hirohiko Nakamura[2], Jae-Hun Park[3], Ruixiang Zhao[1], Ayako Nishina[2], Chuanzheng Zhang[1], Chanhyung Jeon[4], Hanna Na[5], Ze-Nan Zhu[1], Hong Sik Min[6]

1. State Key Laboratory of Satellite Ocean Environment Dynamics, Second Institute of Oceanography, Ministry of Natural Resources, Hangzhou, China, 2. Faculty of Fisheries, Kagoshima University, Kagoshima, Japan, 3. Department of Ocean Sciences, Inha University, Incheon, South Korea, 4. Department of Marine Science and Biological Engineering, Inha University, Incheon, Korea, 5. School of Earth and Environmental Sciences, Seoul National University, Seoul, Korea, 6. Ocean Circulation and Climate Research Center, Korea Institute of Ocean Science and Technology, Busan, Korea

From June 2015 to June 2017, an international cooperative research project called “Joint Kuroshio-Ryukyu Current System Study” (JKRYCSS) was conducted by scientists from Japan, China, and South Korea. Tall moorings with current meters (CMs) and upward-looking acoustic Doppler current profilers (ADCPs), and current and pressure-recording inverted echo sounders (CPIESs) were deployed on northwestern and southeastern sides of Miyakojima Island to observe the Kuroshio and the Ryukyu Current, simultaneously. These mooring sites lay along the altimeter track used by TOPEX/Poseidon and Jason-1/2/3, which is roughly perpendicular to the isobath of the continental shelf break.

In this talk, we will illustrate the velocity structure and variability of the Ryukyu Current by analyzing the 2-year record from a mooring array southeast of Miyakojima Island. The results showed that the shoreward intensified currents flowed northeastward. The subsurface core of the Ryukyu Current was located near the 1000 m isobath, with a maximum of 19.4 cm/s at 500 m. The observed velocity structure was reproduced well by the HYCOM reanalysis, except that the observed current core was stronger and shallower. The mean estimated volume transport across the observation section was 9.0 Sv with a standard deviation of 8.7 Sv, with a near 100-day variability dominant in the upper layer but absent in the deep layer.

Relationship of the Kuroshio with the current fields in the East China Sea from observations and model results

*Hong Sik Min[1], Chorong Hwang[1], Dong Guk Kim[1], Hirohiko Nakamura[2], Ayako Nishina[2], Xiao-Hua Zhu[3], Jae-Hun Park[4], Chanhyung Jeon[4], Hanna Na[5], Naoki Hirose[6]

1. Korea Institute of Ocean Science & Technology, 2. Kagoshima University, 3. Second Institute of Oceanography, 4. Inha University, 5. Seoul National University, 6. Kyushu University

We investigated relationship between variations of the Kuroshio in the southern East China Sea (ECS) and the current structure across the Korea/Tsushima Strait (KTS) using observational data and numerical simulation results. Variability of the Kuroshio in the southern ECS was obtained from moored current measurements located near the Kuroshio axis for 2 years (June 2015-June 2017), while current pattern across the KTS was obtained from acoustic Doppler current profiler (ADCP) measurements by a ferryboat between Hakata and Pusan. Comparisons between the two time series of observations reveal a significant relationship : when the Kuroshio in the southern ECS was strengthened the current in the western channel of KTS was also strengthened with a shift of the Tsushima Current (TC) to the coast. This correlated feature was also seen in the data-assimilated HYCOM, confirming that the HYCOM can reasonably reproduce the current field in the ECS. Further investigations using 25-year-long HYCOM outputs exhibit that the Kuroshio can vary the TC in the KTS. This presentation will show the connectivity of current fields in the northern ECS to the Kuroshio in the southern ECS.

Discussion

Separating Small-Scale Oceanic Internal Waves and Vortical Motions

*Ren-Chieh Lien[1]

1. University of Washington, Seattle, WA, USA

Internal waves and vortical motions coexist in the ocean, sometimes at same temporal and spatial scales. Observations taken by 20 EM-APEX floats in the upper ocean thermocline of the summer Sargasso Sea capture the temporal and vertical variations of Ertel potential vorticity (PV) in 7–70 m vertical scale, averaged over horizontal scales of O(4–8 km). PV is dominated by its linear components —vertical vorticity and vortex stretching, each with rms value of ~0.15 f. In the internal wave frequency band, they are coherent and in phase, expected for linear internal waves. Packets of strong vertical vorticity and vortex stretching, > 0.2 f, balance each other closely such that the rms PV ~0.03 f. PV is dominant at frequencies less than 1.4 f and peaks at vertical wavenumber $<$~0.1 cpm , our highest resolvable vertical wavenumber. PV frequency spectrum plateaus at subinertial frequencies and has a −1 spectral slope in the internal wave frequencies with a small peak at inertial frequency. The PV at near-inertial frequency is likely attributed to the differential advection of background PV by near inertial waves. Measurement errors might also contribute to PV in the internal wave frequency band. Vertical vorticity and vortex stretching are separated into linear vortical mode and internal wave components following the normal mode decomposition. The theoretical prediction of a negative correlation between vertical vorticity and vortex stretching for the linear vortical mode, i.e., reinforcing PV, is confirmed at subinertial frequencies. The Burger number of the vortical mode is ~0.84, implying HKE/APE of ~0.7. The vortical mode frequency and vertical wavenumber spectra are 1-2 decades less than internal wave components. A joint experiment will be conducted in Tokara Strait in the next 3 years to study Kuroshio interaction with seamounts in Tokara Strait. We will discuss the importance of separating internal lee waves and vortical motions behind the seamount on quantifying turbulence mixing and watermass transformation.

Structure and variability of the Kuroshio current in the Tokara Strait

*Zhao-Jun Liu[1], Hirohiko Nakamura[2], Xiao-Hua Zhu[1], Ayako Nishina[2], Xinyu Guo[3], Menghong Dong[1]

1. Second Institute of Oceanography, China, 2. Kagoshima University, Japan, 3. Ehime University, Japan

Transverse-vertical structure and temporal variability of the Kuroshio current across the Tokara Strait during 2003–2012 measured by ferryboat acoustic Doppler current profiler (ADCP) with a 2-km horizontal resolution and a 2-day interval are presented. The Kuroshio passing through the Tokara Strait exhibits a nearly permanent multicore velocity structure. The mean eastward Kuroshio transport is 25.84 Sv (1 Sv ≡10^6 m^3 s^{-1}) and the net baroclinic transport relative to 700 m is 19.57 Sv. The seasonal variation of the Kuroshio transport via the Tokara Strait is a “W”-shaped curve with a maximum in July and a second maximum in December–January. The baroclinic transport shows seasonal variation similar to that of the undecomposed transport, with a maximum in July. However, the barotropic transport displays a reversed seasonal variation—a “V”-shaped distribution—with a maximum in December. In the empirical orthogonal function (EOF) analyses of the cross-sectional velocity, with the exception of the well-known meander (EOF1: 41.1%) and transport (EOF2: 26.3%) modes, the third mode (EOF3: 19.2%) is first observed. The EOF3 mode exhibits a band-like structure, with a smaller horizontal scale than the first two EOF modes; such a band-like structure may be related to the wakes in the lee of the Tokara Islands. Additional analysis based on high-resolution JCOPE-T reanalysis data revealed that (1) many vortexes were generated around the Tokara Strait due to the strong flow-topography interaction; (2) the intensities of the island-induced wakes depend on the Kuroshio path position around the Tokara Strait.

Near-inertial waves advected by the Kuroshio from observation and simulation

*CHANHYUNG JEON[1], Jae-Hun Park[1], Hirohiko Nakamura[2], Ayako Nishina[2], Xiao-Hua Zhu[3], Dong Guk Kim[4], Hong Sik Min[4], Sok Kuh Kang[4], Hanna Na[5], Naoki Hirose[6], Youngseok Choi[1]

1. Inha University, 2. Kagoshima University, 3. Second Institute of Oceanography, 4. Korea Institute of Ocean Science and Technology, 5. Seoul National University, 6. Kyushu University

Advection of near-inertial waves (NIWs) by background currents has been predicted using numerical simulations, while supporting in-situ observations were rare. A pair of tall current moorings, deployed around 26˚N and 125˚E in Okinawa Trough from June 2015 to June 2016, provides a clear evidence exhibiting NIWs advected by the Kuroshio. Energetic NIWs are observed after two-typhoon passages in early August and late September 2015. Both typhoon passages occurred across the Kuroshio east of Taiwan upstream of the observation sites about 250-km southwest with a difference of about 2-degree in latitude. One site (KCM1), relatively close to the center of the Kuroshio axis, exhibits more energetic NIWs than near the edge of the Kuroshio (KCM2), ~32 km away from KCM1. The frequency of NIWs shifts to the lower band from the local inertial frequency (0.91*f*), inferring propagation from the south. The data-assimilative three-dimensional numerical model forced by 6-hourly atmospheric forcings including tides and oceanic circulation demonstrates local NIW generation is weak at observation sites during and after typhoon passages, while its generation upstream of observation sites is quite energetic. Current patterns and frequency shifts of NIWs between observation and simulation agree well at observation sites. Analyses of simulation provide that negative relative vorticity region works like a waveguide for NIW propagation, and the strong Kuroshio current advects the waves poleward with a speed ~85% of the local current.

Turbulent mixing and near-inertial internal waves induced by the Kuroshio over seamounts in the Tokara Strait

*Takeyoshi Nagai[1], Daisuke Hasegawa[2], Eisuke Tsutsumi[3], Hirohiko Nakamura[4], Ayako Nishina[4], Tomoharu Senjyu[3], Takahiro Endoh[3], Takeshi Matsuno[3], Ryuichiro Inoue[5], Amit Tandon[6]

Recent observations in the upstream side of the Tokara Strait during November 2016, where the Kuroshio south of Kyushu flows over a number of seamounts, show banded structures of large amplitude high vertical wavenumber shear roughly along isopycnal, which are suggestive of near-inertial internal waves. The measured vertical section of laterally high resolution (~1 km) tow-yo microstructure measurements show the banded layers of large turbulent kinetic energy dissipation rates clearly associated with the near inertial shear banding. In this study, the results from the similar tow-yo microstructure surveys during November 2017 and June 2018 cruise, which are extended further downstream side of the Tokara Strait in the Kuroshio are analyzed. It is found that the high vertical wavenumber near-inertial shear is amplified near the seamounts in the Kuroshio, and that turbulent kinetic energy dissipation rates are elevated near the seamounts over 100 km along the Kuroshio axis by a factor of 100-1000. This length scale, over 100 km, is much larger than that of the hydraulically controlled isopycnal displacements with large Froude number in close proximity to the seamounts ~5km. In the presentation, mechanisms of the amplified near-inertial shear and elevated turbulence over such a wide length scale are discussed with the results from June 2018 cruise and using numerical simulations with and without tide.

Microstructure and mooring observations of enhanced mixing in the Kerama Gap

*Ryuichiro Inoue[1], Hirohiko Nakamura[2], Takahiro Tanaka[3], Shinzou Fujio[4], Daigo Yanagimoto[4], Ichiro Yasuda[4]

1. Japan Agency for Marine-Earth Science and Technology, 2. Kagoshima University, Faculy of Fisheries, 3. Tohoku National Fisheries Research Institute, Japan Fisheries Research and Education Agency, 4. The University of Tokyo, Atmosphere and Ocean Research Institute

Microstructure and mooring observations were conducted around the Kerama Gap, near the midpoint of the Ryukyu Island chain, in December 2016. We observed the enhanced mixing near the topography, with vertical diffusivities of 10^{-2}~10^{-1} m^2 s^{-1} and found that tides are important to drive the enhanced mixing at the sill. To understand tidal processes, we conducted two-dimensional numerical simulations. The numerical simulation indicated that hydraulic jump or lee wave breaking are important for the enhanced mixing behind the sill. It also indicated that there are interferences between M2 internal tides radiated from entrance and exit of the Kerama Gap, which may correspond to observed enhanced vertical shear and mixing at a bottom of the North Pacific Intermediate Water in the Kerama Gap. These results suggest that enhanced mixing around Kerama Gap is important for ventilating deep water as well as renewal of the North Pacific Intermediate Water in the Okinawa Trough.

[A-OS11] Continental-Oceanic Mutual Interaction: Planetary scale Material Circulation

convener:Yosuke Alexandre Yamashiki(Earth & Planetary Water Resources Assessment Laboratory Graduate School of Advanced Integrated Studies in Human Survivability Kyoto University), Yukio Masumoto(Graduate School of Science, The University of Tokyo), Swadhin Behera(Climate Variation Predictability and Applicability Research Group, Application Laboratory, JAMSTEC, 3173-25 Showa-machi, Yokohama 236-0001), Takanori Sasaki(Department of Astronomy, Kyoto University), Chairperson:Yukio Masumoto, Behera Swadhin(JAMSTEC)

The main purpose of this session is to promote discussion on mutual interaction between Continental zone and Oceanic zone. The global-scale material circulation induced by River runoff through oceanic general circulation as major topic on Continental-Oceanic Interaction, where the ENSO / IOD influence into continental climate as major topics on Oceanic-Continental Interaction. Numerical simulation and field observation of radionuclide transport from continental zone into ocean and its potential impact is also important topics of this session. The session also extend discussion on planetary hydrology and oceanography focusing on subsurface ocean in Jupiter's moon & Ancient Martian Oceanography & Hydrology by possible application of terrestrial GCM into Ancient Mars.

Explorations and current understandings for subsurface ocean of icy bodies

*Jun Kimura[1]

1. Osaka University

Most of solid bodies in the outer solar system, around Jupiter's orbit and beyond, are covered with ice on its surface, which are called as "Icy bodies".
In these icy bodies, e.g., Jovian moon Europa and Saturnian moon Enceladus, existence of the global liquid water ocean under the icy crust, called as "subsurface ocean", has been strongly suggested through the past remote sensing (mainly by geodetic and electromagnetic measurement) and theoretical modelling.
In this talk, I introduce the results of previous observations and theoretical calculations, and summarize the current
understandings focusing on the geophysical knowledge about the subsurface ocean of icy bodies.

Climate predictability for societal applications including AI/ML

*Swadhin Behera[1], Manali Pal[2], J.V. Ratnam[1], Rajib Maity[2], Takeshi Doi[1], Yushi Morioka[1], Masami Nonaka[1]

1. Application Laboratory, JAMSTEC, 3173-25 Showa-machi, Yokohama 236-0001, 2. Indian Institute of Technology, Kharagpur, India

The tropical Indo-Pacific domain is important for global climate. Particularly, the warm pool region rooted in both basins plays an important role in the modulation of ocean and atmosphere variability on several spatio-temporal scales. While both basins share the extended warm pool, each of the two basins has its own modes of ocean and climate variations. Tropical Pacific Ocean is well-known for the El Niñ o/Southern Oscillation (ENSO) phenomenon, the influence of which is seen world-wide during ENSO occurrence years. Recently, another mode of climate variability called the ENSO Modoki is discovered in the tropical Pacific Ocean. The ENSO Modoki is distinct from ENSO in terms of its characteristics and global impacts. Therefore, predictability of ENSO and ENSO Modoki is important for reducing their impacts on the society. Coupled models like SINTEX-F has been predicting the ENSO Modokis quite well. Here an attempt is made to compare those predictabilities using predictions from an AI/ML based statistical approach.

Re-entry of giant-impact fragments and early evolution of the Earth's ocean

*Takanori Sasaki[1]

1. Department of Astronomy, Kyoto University

The late stages of Earth's formation remain a mystery. No building blocks remain in Earth's orbit and no geological evidence is available for the first 700 million years Earth's history. Herein we propose that protoplanetary fragments produced by the giant impacts during terrestrial planet formation may give some important clues to the era. Iron-bearing giant impact fragments provide significant reducing agent that could transform primitive CO2–H2O atmosphere and ocean into more reducing H2-bearing atmosphere. Re-entry of the giant-impact fragments into eary Earth would be important for the origin of Earth’ s life and its early evolution.

Modeling of Extreme Freshwater Discharge and influence from Japanese First-Class Rivers to Coastal zones

*Ryusuke Kuroki, Yosuke Alexandre Yamashiki[1], Sergey Varlamov[2], Yasumasa Miyazawa[2], Racault Fanny Marie[3], Hoshin Vijai Gupta[4]

1. Kyoto University, 2. Application Laboratory, Japan Agency for Marine-Earth Science and Technology, Japan, 3. Plymouth Marine Laboratory, Plymouth, United Kingdom, 4. University of Arizona

We estimated the effects of extreme fresh water discharge from Japanese first-class rivers to coastal zones of the Japanese coast. Our targeted event was a typhoon Etau from 06/09/2015 to 12/09/2015, a week, and we could success to optimize 5 parameters, soil roughness coefficient, river roughness coefficient, effective porosity, saturated hydraulic conductivity, and effective rainfall by using Shuffled Complex Evolution method developed by University of Arizona (SCE-UA method), that is one of the optimization method for hydrologic model during this week. In addition to this, we made a set of hourly simulated river outflow data of almost all of Japanese first-class rivers from these basins to the Pacific Ocean and the Sea of Japan during the period by using our model “Cell Distributed Runoff Model Version 3.1.1 (CDRMV3.1.1)”. After the simulation, we used these calculated discharge data with a coupled hydrological-oceanographic model JCOPE-T for estimation of sea surface salinity distribution (SSS) in Japanese coastal zones. And simulated SSS results were verified by comparison with Chlorophyll-a distribution, observed by satellite re-mote sensing. Therefore we successfully reproduced peak discharge prediction of extreme typhoon events on river mouth and the coastal oceanic circulation.

Establishment of new curriculum at Biosphere 2

*Kenji Miki[1], Takao Doi[2], Yosuke Yamashiki[3], Masahiro Terada[2]

1. Kyoto University Graduate School of Agriculture, 2. Kyoto University Unit of Synergetic Studies for Space, 3. Graduate School of Advanced Integrated Studies in Human Survivability

We are currently planning to start up a new practical training programme at Biosphere 2 under a contract between Kyoto University and Arizona State University.
Biosphere 2 was established in1991 and was designed to produce a closed-complete ecosystem in the institute. Although the ecosystem-establishment was not fully successful, the institute still has been used for various research such as ecology, terraforming, and closed-environental impact to human health.
Our practical training programme will include hands-on training for exoplanet observation, and lectures about water-cycle and atmospheric science.
Although the programme is going to be carried out in August 2019, the pilot programme were put into practice with ten participants including lecturers and students from the states and Japan.
At the conference, we would give a presentation about the detailed programme schedule and expected educational and academic results from this programme.

Development of the highly precise high-speed photometry technique with the photometer mounted with PIRKA telescope

*Nami Kimura[1]

1. Hokkaido University

There is a few striped pattern on Jupiter when we observe by visible light, and we can see white bands called " belt” and dark band called " zone". The cloud top altitude is high at zone, low at belt by infrared observation.Various models are proposed to figure out, but we cannot elucidate the mechanism of this large scale structure.The Galileo datas tell us that the zonal jets are located on boundaries between the belts and zones, with the westward jets on the poleward edges of belts and the eastward jets on the poleward edges of zones.It is still not clear that the wind occurs by sun light in atmospheric layer or internal heat source makes the global structure including the wind.One of the mechanism making zonal wind is that small eddies combine each other and make eddy flow, but it is not sufficiently to observe the cumulonimbus the source of small eddies. In the case of thunders of the earth, the study of the activity of cumulonimbus such a strong upward current and thunder storms makes progress. Upward current can help hydrologic cycle. There is a relationship of frequency of thunders and the altitude go the cumulonimbus on the earth, and the CMC is known to be proportion to brightness of the thunder, too. I developed a photometer equipped to PIRKA telescope to arrest the time change and the frequency of thunder lightning in the Jupiter.First I estimated the time of the duration and freqency and spatial distribution of lightnings of Jupiter by using parameters of lightnings on the earth and observation data of satellites.Then it is necessary to divide into 10 to observe lightning activity which continue 1ms and to focus on one cumulonimbus and to get high signal-noise ratio. I designed the equipment which can achieve these numerical goal and examined observation methods for example exposure time and field of view.

[E] Oral | A (Atmospheric and Hydrospheric Sciences)：A-OS Ocean Sciences & Ocean Environment

Wed. May 29, 2019 10:45 AM - 12:15 PM JST | Wed. May 29, 2019 1:45 AM - 3:15 AM UTC | 301A 3F

[A-OS11] Continental-Oceanic Mutual Interaction: Planetary scale Material Circulation

convener:Yosuke Alexandre Yamashiki(Earth & Planetary Water Resources Assessment Laboratory Graduate School of Advanced Integrated Studies in Human Survivability Kyoto University), Yukio Masumoto(Graduate School of Science, The University of Tokyo), Swadhin Behera(Climate Variation Predictability and Applicability Research Group, Application Laboratory, JAMSTEC, 3173-25 Showa-machi, Yokohama 236-0001), Takanori Sasaki(Department of Astronomy, Kyoto University), Chairperson:Yosuke Yamashiki(GSAIS Kyoto University), Takanori Sasaki(Department of Astronomy, Kyoto University)

The main purpose of this session is to promote discussion on mutual interaction between Continental zone and Oceanic zone. The global-scale material circulation induced by River runoff through oceanic general circulation as major topic on Continental-Oceanic Interaction, where the ENSO / IOD influence into continental climate as major topics on Oceanic-Continental Interaction. Numerical simulation and field observation of radionuclide transport from continental zone into ocean and its potential impact is also important topics of this session. The session also extend discussion on planetary hydrology and oceanography focusing on subsurface ocean in Jupiter's moon & Ancient Martian Oceanography & Hydrology by possible application of terrestrial GCM into Ancient Mars.

Understanding how the early Archean Earth supported standing bodies of liquid surface water under the faint young Sun is one of the greatest challenges of modern science. Can this problem be resolved as a part of the puzzle of understanding of the origin of building blocks of life on early Earth? Here, we present a new concept of how these two pieces of the mystery of life can be reconciled if we reconstruct the eruptive history of space weather from the young Sun at the time when life started on Earth. Our three-dimensional (3D) magnetohydrodynamic model of the young Sun suggests that energetic protons can be accelerated in shock waves driven by frequent and powerful Coronal Mass Ejection events and Corotating Interacting Regions produced by the young Sun's wind. Accelerated protons at energies > 300 MeV penetrated into the nitrogen-rich weakly reducing atmosphere and initiated the reactive chemistry by breaking molecular nitrogen, carbon dioxide, and methane, producing nitrous oxide, the potent greenhouse gas, and hydrogen cyanide, an essential feedstock molecule of life. Our Global Climate Model, ROCKE-3D, suggests that at 4(1000) ppmv of nitrous oxide produced in a 1(0.5) bar atmospheres outputs the mean annualized Earth’ s temperature of +16(5.2)C, and thus may provide a resolution of the FYS paradox and explain the presence of early oceans.

Experimental study on elementary hydrological process of rainfall in a forested continental hinterland

*Shigeki Murakami[1]

1. Kyushu Research Cente, Forestry and Forest Products Research Institute

There is an observational fact that a rainfall amount is constant or increases with increasing the distance from the coast (x) in a forest covered continent up to a few thousands kilometers, e.g. Amazon and Yenisei river basins. However, it contradicts the basic law of hydrology as shown in Fig 1a; rainfall (P) is partitioned into evapotranspiration (ET) and discharge (Q) that means P_0 at $x = x_0$ is larger than P_1 at $x = x_1$ ($x_0 < x_1$), because $P_0 = ET_0 + Q_0$ and $P_1 =< ET_0$. The contradiction is solved by Makarieva and Gorshkov (2007, hereafter refer to MG 2007) in which they proposed Biotic Pump of Atmospheric Moisture (BP) as illustrated in Fig. 1b. The principle of BP is that ET from forests (ET(F)) is greater than that from the ocean (ET(O)) that is the driving force to transport moisture from the ocean to a forested continental hinterland.

Nonetheless, MG (2007) and their series of studies did not explicitly mention the reason of large ET from forests. It is great in forests because evaporation of canopy interception (hereafter refer to interception; typically some 20% of rainfall) at the time of rainfall is larger than that from any other vegetative surfaces, though the amount of transpiration is similar independent of vegetation types under a certain climate condition.

Some studies showed that interception is proportional to the rainfall amount on an hourly basis. For example Hashino et al. (2012) observed evaporation rate of more than 10 mm/hour during rainfall that requires latent heat of five times as large as the solar constant. To explain such huge amount of evaporation during rainfall Murakami (2006) proposed splash droplet evaporation mechanism. I believe it is the only explanation of enormous evaporation because small droplets can evaporate and disappear quickly even under very high humidity based on the theory and experiments of cloud physics. On top of that, latent heat is supplied from clouds upon condensation of water vaper. However, splash droplet evaporation along with BP is still a hypothesis.

To prove the splash droplet evaporation hypothesis stable isotope of water is used. Over 1000 of rainwater samples were collected on an hourly basis both under the forest canopy and at the opening simultaneously (Fig. 2). The isotopic ratios are measured and are being analyzed in combine with the meteorological data. The outline of the methodology is presented at the meeting.

University of Bristol , 9. Kwasan Astronomical Observatory, Kyoto University

For a terrestrial planetary system, during the initiation period of planetary formation, the activity of a young Sun is extremely important in order to comprehend the atmospheric behavior of the planet. Relatively lower luminosity associated with lower surface temperature of the young Sun brings the planets a cooler surface environment. Terrestrial and Martian surfaces become icy cold in this environment without considering extensive GHG formation. Within such environments, the dose from SEP from a young Sun might play an important role in primordial atmospheric composition.

Here, we propose a reasonable radiological assssessment of the possible exposure intensity in SEP from a young Sun, by evaluating the possible magnitude and frequency of early solar flares by using possible star spot area, derived from their rotational period. We evaluated annual and maximum flare energy in different cases of solar spot areas for 3 %, 5 % ,and 10 % of solar surfaces. The maximum dose at the Martian TOA reaches 5.86 k Gy (265 Sv) when the solar spot area reaches 10 % of the solar surface. Such higher radiation dose may have influenced significantly atmospheric composition of Early Mars and Young Earth.

Evaluation of scintillator detection materials for application within environmental radiation monitoring

*Peter George Martin[1], D. Connor[1], M. Lowden[1], T. B. Scott[1]

1. School of Physics, University of Bristol, Bristol, UK

The last five years has seen the unabated growth in the number of airborne platforms performing radiation mapping –each using various iterations of low-altitude unmanned aerial vehicle (UAV). Alongside the associated advancements in the base airborne system transporting the radiation detection payload, from the earliest radiological analyses performed using gas-filled Geiger-Muller tube detectors, modern radiation mapping platforms are now based near-exclusively on solid-state scintillator (and to a lesser-extent semiconductor) detectors. With numerous types of these light-emitting crystalline materials now in existence, this combined desk and computational modelling study sought to evaluate the best-available detector material compatible with the requirements for low-altitude autonomous radiation mapping –of naturally-occurring but also anthropogenically-derived radionuclides.

Aside from ground-based radiation surveying undertaken by humans; environmental mapping of radiation distribution (resulting from both anthropogenic activities as well as from naturally-occurring radioactive material) has been performed historically using manned, fixed-wing aircraft. In contrast to the more limited detector volumes carried during on-ground operations (due to size and weight practicalities), the systems carried during these extensive spatial extent aerial surveys are typically not less than 33 litres in detector volume. For the gamma-ray measurements of naturally-occurring radionuclides, the key emission peaks are associated with the daughter products of the U (^{214}Bi) and Th (^{208}Tl) decay chains, alongside a strong contribution from radiogenic potassium (^{40}K). In contrast to the higher-energy (>1.0 MeV) gamma-ray emissions characteristic of the aforementioned naturally-occurring radionuclides, the primary anthropogenically-derived radionuclide released into the environment in extensive quantities during an emergency release event (such as at both Fukushima and Chernobyl) is radiocesium –specifically ^{137}Cs (half-life: 30.17 years), which emits a single gamma-ray photon at 0.662 MeV.

While the currently and widely-used NaI and CsI (both of which are Tl-doped) are the mainstays of radiation monitoring, during this study, LaBr scintillator detectors were determined to possess not only a greater sensitivity to incident gamma-radiation, but also a far superior spectral (energy) resolution over existing detector materials. Combined with their current competitive cost, an array of three such composition cylindrical detectors were determined to provide the best means of detecting and discriminating the various incident gamma-rays incident onto the detector owing to both naturally-occurring or anthropogenically-derived sources.
In this talk, we will present the results of multiple GEANT4 simulations that will inform the potential future development of the next generation of radiation detection materials and their optimal configurations for deployment.

The important factors for future human space activity in terms of space medicine

*Masahiro Terada[1], Yosuke Yamashiki[1], Kenji Miki[1], Satoko Tsujihiro[1], Takao Doi[1]

1. Kyoto University, Unit of Synergetic Studies for Space

When humans stay in space for long term, our body has various phyisiological effects by the specific space environments. Recently, space agency, such as NASA and JAXA, has the plan to send human to Moon or Mars. Therefore, it is very important to understand how we are effected during space staying. For example, our skeletal muscles on the leg become atrophy and bone volume decrease by spaceflight. And, astronauts must spend time in closed environment during human space mission. So, we need to know the mental or emotional changes during space mission.
Now, we have space camps which is simulated for future space misson. In this time, I will present the phyisiological data of mental factors in simulated space camps.

Storm Surge Response to Freshwater Outflow from Typhoons on the Ibaraki Coast

*Josko Troselj[1], Nobuhito Mori[1]

1. Coastal Engineering Laboratory, Disaster Prevention Research Institute, Kyoto University

Introduction and Objective

Collaborative results (Troselj et al., 2017) have permitted for the first time to quantitatively evaluate the influence of extreme freshwater outflow to the coastal ocean due to typhoon passage by combining river and ocean models using hourly time step data and remote-sensing technology. They found that projection of coastal Sea Surface Salinity was improved (up to 10 PSU difference) and became more realistic with included freshwater impact and concluded that extreme events freshwater outflows significantly decrease Sea Surface Salinity distribution in the coastal zone.

With the advance of weather forecasting systems and specific availability of forecasting typhoon trajectory and intensity, the research team aims to be able to apprehend freshwater impacts on the coastal marine environment in advance of typhoon events, and contribute to the comprehensive management and protection of coastal zones.

In our JpGU presentation (2018), we concluded that our findings that the freshwater outflow impact to the storm surge is negligible during the typhoon passage but is important to be considered in evaluating an after-runner storm surge mechanism should be further confirmed in future works by testing the applicability of using the same method with many other typhoon event cases.

A follow up of the previous studies is shown here. As parameters which affect the total sea level are storm surge, tides, waves and freshwater impact, the main objective of the study is to test dependence between storm surge heights and the freshwater impact before and after passing of several typhoons over the Ibaraki Coast, Japan.

Methods

We continued the study from Troselj et al. (2018) with improved downscaling model methodology and extended analyzed period into 7 years (2000-2006). We applied better vertical transformation equation (Vtransform=2, new formulation developed by A. Shchepetkin) and different vertical stretching function (Vstretching=4, where A. Shchepetkin improved double stretching) compared to Troselj et al. (2018). River forcing conditions were applied as observed river temperature and discharge (MLIT, 2017) with constant salinity of 0.5 PSU for Tone, Naka and Kuji rivers.

Discussions

We compared coastal storm surge heights for cases with and without freshwater outflow impact and discussed differences in results, for several typhoons passing over Ibaraki Coast during the analysed period. With new results, our conclusions from JpGU presentation (2018) cannot yet be certainly

©2019. Japan Geoscience Union. All Right Reserved.

confirmed. The mechanism which we found then, presence of so called after-runner storm surge occurring about 4 days after passage of the event, is occurring in some typhoon cases but not every time. Therefore, its occurrence is function of many parameters occurring simultaneously such as typhoon trajectory, intensity and central pressure, actual state of the ocean (tides, waves), river discharge magnitude and temporal distribution and model conditions.

Summary

Using dynamic downscaling for reanalysis of coastal current system in the Ibaraki Coast, our goal was to test dependence between storm surge heights and the freshwater impact before and after typhoon events. We found that the mechanism found in the previous study is not occurring every time on the same way but is rather function of many other dependent parameters.

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-OS Ocean Sciences & Ocean Environment

Wed. May 29, 2019 3:30 PM - 5:00 PM JST | Wed. May 29, 2019 6:30 AM - 8:00 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_7

[A-OS11] Continental-Oceanic Mutual Interaction: Planetary scale Material Circulation

convener:Yosuke Alexandre Yamashiki(Earth & Planetary Water Resources Assessment Laboratory Graduate School of Advanced Integrated Studies in Human Survivability Kyoto University), Yukio Masumoto(Graduate School of Science, The University of Tokyo), Swadhin Behera(Climate Variation Predictability and Applicability Research Group, Application Laboratory, JAMSTEC, 3173-25 Showa-machi, Yokohama 236-0001), Takanori Sasaki(Department of Astronomy, Kyoto University)

The main purpose of this session is to promote discussion on mutual interaction between Continental zone and Oceanic zone. The global-scale material circulation induced by River runoff through oceanic general circulation as major topic on Continental-Oceanic Interaction, where the ENSO / IOD influence into continental climate as major topics on Oceanic-Continental Interaction. Numerical simulation and field observation of radionuclide transport from continental zone into ocean and its potential impact is also important topics of this session. The session also extend discussion on planetary hydrology and oceanography focusing on subsurface ocean in Jupiter's moon & Ancient Martian Oceanography & Hydrology by possible application of terrestrial GCM into Ancient Mars.

Freshwater lakes, particularly shallow lakes often exhibit alternative vegetative states, a clear-water state dominated by submerged aquatic vegetation (SAV) and a turbid-water state dominated by phytoplankton. Phytoplankton and SAV constitute the base of the aquatic food web and are the primary driver of the biogeochemical process in both the freshwater and coastal water bodies. The abundance of phytoplankton biomass can potentially indicate the degree of eutrophication in a specific waterbody. On the other hand, the massive overgrowth of invasive SAV species can also pose a serious threat to the aquatic ecosystem. Conventional methods (eg. Site-specific Boat survey) used to monitor the large water bodies are often time-consuming and expensive. In this study, we used a remote sensing based approach to monitor SAV and phytoplankton of the Lake. A multi-spectral satellite image (Landsat-8 Operational Land Imager) was used to assess the phytoplankton concentration and SAV biomass. A spectral decomposing algorithm was used to estimate and quantify both phytoplankton and SAV. Based on the peak growth period of SAV in the lake, the estimations were limited to a certain period of the year (i.e. mainly August and September). The image was used to classify and map the SAV coverage area using the spectral mixture analysis. The SAV biomass estimation model was used to determine the biomass of the SAV classified pixels in the lake. The satellite-derived phytoplankton and SAV were validated using the in-situ measured data of the lake. The result indicates the time and location-specific variation in the dominance of the phytoplankton and SAV.

Hydrological and Debris-flow simulation of Martian Surface in Hesperian & early Amazonian epoch

*Hiroaki Sato[2], Yosuke Alexandre Yamashiki[1], Ryusuke Kuroki[1], Hideaki Miyamoto[3], Ryodo Hemmi[3]

1. Earth & Planetary Water Resources Assessment Laboratory Graduate School of Advanced Integrated Studies in Human Survivability Kyoto University, 2. Faculty of Engineering, Kyoto University, 3. Graduate School of Engineering, The University of Tokyo

It is considered that the Mars in Noachian ecoch to early Amazonian was much warmer temperature than current condition, with atmosphere and ocean supported by its magnetic activity. Several valley which seems to be developed by ancient hydrological processes are obsered in Martian surface, is being considered to be built long time before. Some fluvial fun was formed during the following Hesperian to early Amazonian epoch, which is considered as much cooler and drier than Noachian epoch. In this study, we applied Hydro-debris 2D model into Martian surface in Hesperian epoch in order to try develping surface vallay formation throughout hydrological processes.

Sediment transport and associated small-scale debris-flow occurrence may be the key for valley formation, where might be the micro-habitable zone in ancient period. At the same time it is still uncertain how much precipitation and erosion should have been required to formulate such topography. Following the last year’ s calculation we attempted to compare several cases of debris flow experiments by changing hypothetical precipitation rate and erosive coefficients in the initially distributed regolith.

Faculty of Agriculture, Kyoto University, 4. Educational Unit for Studies on Connectivity of Hills, Humans and Ocean, Kyoto University

Global Lakes & Reservoirs Repository (GLR) has been developed in order to list global scale freshwater storage focusing on Lakes & Reservoirs. In this presentation we'll introduce their application, combining this with the ecological model for lakes & reservoirs for their surface environmental assessment under different climatic conditions. A two-layer aquatic ecological model (consisted with three types of phytoplanktons & zooplankton) is linked for a number of global lakes for the evaluation of future trends of aquatic ecosystems, mainly focusing on phytoplankton growth. The application of the database, by coupling it with satellite remote sensing for monitoring aquatic environment, together with the three-dimensional lake & reservoir aquatic environment model, are also introduced in the database.

Numerical simulation of Tidal Heating using SPH and its application to inner sea formation

*keiya murashima[1], Yosuke Alexandre Yamashiki[1], Natsuki Hosono[2]

1. Kyoto University, 2. Japan Agency for Marine-Earth Science and Technology

There are some traces of liquid in icy moons, such as a plume of vapor of Europa acquired by Hubble Space Telescope and tiger stripes of Enceladus observed by Cassini. Since liquid water is essential for the origin of life, it can be important to understand the development of inner sea and also the temperature distribution inside of such icy moons.

It is considered that the tidal heating caused by tidal acceleration melts the inner icy layer which results in the presence of liquid water beneath its surface. Thus, we aim at simulating the tidal heating of an icy moon by 3-dimensional numerical fluid calculation in Smoothed Particle Hydrodynamics (SPH) method. As the tidal heating model, we apply the viscosity model which was used for numerical calculation of tidal stripping.

It is confirmed that this viscosity model lead to qualitatively correct result about tidal disruption, but the possibility of its application to tidal heating is not validiated. Therefore, as a first step, we tried to compare the result of this simulation with the result which is estimated theoretically. We made a rotation of a differentiated Titan-sized tidally locked object around a Saturn-mass material point with the radius of orbit being 1.1 times larger than its Roche limit. We also considered how to applicate this simulation to the calculation of actual icy moons. We will report the progress.

Wed. May 29, 2019 5:15 PM - 6:30 PM JST | Wed. May 29, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_12

[A-OS11] Continental-Oceanic Mutual Interaction: Planetary scale Material Circulation

convener:Yosuke Alexandre Yamashiki(Earth & Planetary Water Resources Assessment Laboratory Graduate School of Advanced Integrated Studies in Human Survivability Kyoto University), Yukio Masumoto(Graduate School of Science, The University of Tokyo), Swadhin Behera(Climate Variation Predictability and Applicability Research Group, Application Laboratory, JAMSTEC, 3173-25 Showa-machi, Yokohama 236-0001), Takanori Sasaki(Department of Astronomy, Kyoto University)

The main purpose of this session is to promote discussion on mutual interaction between Continental zone and Oceanic zone. The global-scale material circulation induced by River runoff through oceanic general circulation as major topic on Continental-Oceanic Interaction, where the ENSO / IOD influence into continental climate as major topics on Oceanic-Continental Interaction. Numerical simulation and field observation of radionuclide transport from continental zone into ocean and its potential impact is also important topics of this session. The session also extend discussion on planetary hydrology and oceanography focusing on subsurface ocean in Jupiter's moon & Ancient Martian Oceanography & Hydrology by possible application of terrestrial GCM into Ancient Mars.

[A-OS14] Coastal physical processes associated with mixing, eddies, internal waves

convener:Eiji Masunaga(Ibaraki University), Taira Nagai(Graduate School of Science, The University of Tokyo), TSUTSUMI EISUKE(Atmosphere and Ocean Research Institute, The University of Tokyo)

Recently developed observational and numerical approaches have revealed details of physical processes in coastal regions, which is a key to understanding global ocean circulations and ecosystems. This session aims to provide discussions of mixing, eddies, nonlinear internal waves in coastal and marginal oceans, estuaries and lakes. Observations, numerical modeling and laboratory experiments associated with these phenomena are encouraged to submit an abstract to this session. In addition, studies that consider linkages between coastal physical processes and large scale open ocean processes, e.g., the Kuroshio, global ocean circulations.

Observation of enhanced nonlinear interactions after the passage of typhoon in the western South China Sea

*gui ying Chen, chang rong Liang, xiao dong Shang

Typhoon Chanchu passed the subsurface mooring in the western South China Sea (SCS) in June 2004 and the effects of typhoon on the internal wave field and nonlinear interactions were examined. The internal wave field was characterized by diurnal (D_1) and semidiurnal (D_2) tides before typhoon. After the passage of typhoon, the internal wave field was characterized not only by diurnal and semidiurnal tides but also by near-inertial (f) waves, higher harmonic ($fD_2=f+D_2$ and $D_3=D_1+D_2$) frequency internal waves, and enhanced diurnal currents. Analysis on the rotary coefficient and bicoherence suggests that the observed fD_2 waves, D_3 waves, and enhanced diurnal currents were derived from nonlinear interactions of $f+D_2=fD_2$, $D_1+D_2=D_3$, and $f+f=2f$, respectively. Previous researches indicated that nonlinear interactions induced by typhoon mainly occur between near-inertial waves and internal tides ($f+D_1=fD_1$ or $f+D_2=fD_2$). Our observations first indicate that typhoon can also induce the self-interaction of near-inertial waves ($f+f=2f$) and enhance the nonlinear interaction between diurnal tides and semidiurnal tides ($D_1+D_2=D_3$). Critical diurnal latitudes (where $2f\approx D_1$) play an important role in the occurrence of these nonlinear interactions. Typhoon-induced near-inertial waves undergo self-interaction ($f+f=2f$) near the critical diurnal latitudes and transfer energy to diurnal waves. Enhanced diurnal waves further contribute to the nonlinear interaction of $D_1+D_2=D_3$. These nonlinear processes might promote the energy cascade of the typhoon-induced near-inertial waves near the critical diurnal latitudes and play an important role in ocean mixing.

Investigating vertical mixing in estuarine pycnocline: a case study in the Ariake Sea, Japan

*Takeshi Matsuno[1], Eisuke Tsutsumi[1]

1. Kyushu University

Turbulent mixing controls coastal environment and primary production through transportation of heat, freshwater, and various materials. Vertical mixing in pycnocline plays a key role in occurrence of major environmental problems in semi-enclosed seas and estuaries, such as bottom hypoxia and red tides, although it is not fully understood. For better understanding and prediction of coastal mixing processes, we investigate pycnocline mixing in a tidally-energetic shallow (~20 m) estuary, the Ariake Sea, Japan, where stratification is maintained almost throughout a year by large amounts of freshwater inputs from major rivers. We collected more than 5,000 microstructure turbulence profiles (~530-hour measurements) in several stations in the central area of the sea during 24-cruises conducted in various seasons over 2002-2012, and examined Turbulent kinetic energy (TKE) dissipation rate in the shear- and buoyancy-frequency space. TKE dissipation rates in pycnocline exhibited a broad variability, $O(10^{-9})$ - $O(10^{-5})$ W kg^{-1} , while most of them fell into a range where the gradient Richardson number is larger than a critical value, i.e., $Ri_g > 1/4$. In stratified seasons, we frequently observed high-vertical wavenumber internal tides in the pycnocline around the microstructure stations from separately-conducted mooring observations using acoustic Doppler current profilers. The large variability in the mixing around pycnocline is therefore likely to be originated from internal wave breaking and shear instability. We found an ordered structure of mean dissipation rate where it correlates positively with vertical shear, which gives a clue to improving a “background” vertical diffusion parameterization in numerical ocean models.

Possibility of interactions between the coastal and offshore branch of Tsushima Warm Current over the submarine canyon in the Sea of Japan.

*Yosuke Igeta[1], Alexander Yankovsky [2], Mizuki Kuga[1], Naoki Hirose[3], Kenichi Fukudome[4]

1. Japan Sea National Fishseries Research Institute, 2. University of South Carolina, 3. RIAM Kyushu Univ., 4. National Institute of Technology, Toyama College

Tsushima warm current (TWC) is known to flow northeastward over continental shelf off the northern coast of Japan. Coastal branch of TWC (CBTWC) is fundamentally current trapped by the coastline, whereas offshore branch of TWC (OBTWC) are interpreted as current steered by continental slope. The coastal line and continental shelf have alongshore discontinuity around the Toyama Trough (TT) which is a submarine canyon cutting across the continental shelf off the downstream side of the Noto Peninsula (NP) and almost reaching the coastline. The CBTWC is observed to change its path from coastal mode to offshore mode when encountering the TT (Igeta et al., 2017). This process results in transformation from the barotropic coastal current into baroclinic jet detached from the coast over the TT. On the other hand, the details of the OBTWC current path change are not well understood, as well as interaction between the CBTWC and OBTWC.
To clarify these, we analyzed re-analysis current data calculated by DR_C (Hirose et al., 2017) that is high resolution nested ocean model. Current paths of CBTWC around the TT were extracted by using current data from 2005 to 2014. The results showed that complete and incomplete current path transition of the CBTWC from coastal mode to offshore mode in 2013 and 2014, respectively. The OBTWC-like current was explicitly confirmed over continental slope just off the current path of the CBTWC over continental shelf around the northern off the NP in 2013, however such current was not able to be found out in 2014. These results suggest that interaction between the CBTWC and the OBTWC makes current path transition of the CBTWC fast.
To interpret these simply, we demonstrated numerical experiment using 2-layered ocean model with simplified continental shelf, continental slope and submarine canyon. Barotropic current trapped by continental slope, modeling the OBTWC, was applied from the upstream boundary. The OBTWC changed its current path from coast to offshore almost in the same manner as the CBTWC over the TT. The detached current over the submarine canyon was re-arrested by the continental slope on the opposite side of the submarine canyon. The OBTWC continued to take its current path in the offshore region after reaching steady state. Once the OBTWC has reached a steady state, the CBTWC was specified at the upstream boundary. The CBTWC flowed along the coast despite the existence of the OBTWC bridging over the TT. Although the CBTWC and OBTWC merged around the northern coast of the NP, they seemed to behave independently. Time scale of the CBTWC current path transition, however, was shorten in the presence of the OBTWC. This indicates the OBTWC let the current path transition of the CBTWC accelerate through vorticity generated around the upstream boundary of the TT. It is considered that vorticity supplied from the OBTWC accelerate eddy growth by the CBTWC that results in current path transition.

Observation of enhanced nonlinear interactions after the passage of typhoon in the western South China Sea

*gui ying Chen, chang rong Liang, xiao dong Shang

Typhoon Chanchu passed the subsurface mooring in the western South China Sea (SCS) in June 2004 and the effects of typhoon on the internal wave field and nonlinear interactions were examined. The internal wave field was characterized by diurnal (D_1) and semidiurnal (D_2) tides before typhoon. After the passage of typhoon, the internal wave field was characterized not only by diurnal and semidiurnal tides but also by near-inertial (f) waves, higher harmonic ($fD_2=f+D_2$ and $D_3=D_1+D_2$) frequency internal waves, and enhanced diurnal currents. Analysis on the rotary coefficient and bicoherence suggests that the observed fD_2 waves, D_3 waves, and enhanced diurnal currents were derived from nonlinear interactions of $f+D_2=fD_2$, $D_1+D_2=D_3$, and $f+f=2f$, respectively. Previous researches indicated that nonlinear interactions induced by typhoon mainly occur between near-inertial waves and internal tides ($f+D_1=fD_1$ or $f+D_2=fD_2$). Our observations first indicate that typhoon can also induce the self-interaction of near-inertial waves ($f+f=2f$) and enhance the nonlinear interaction between diurnal tides and semidiurnal tides ($D_1+D_2=D_3$). Critical diurnal latitudes (where $2f\approx D_1$) play an important role in the occurrence of these nonlinear interactions. Typhoon-induced near-inertial waves undergo self-interaction ($f+f=2f$) near the critical diurnal latitudes and transfer energy to diurnal waves. Enhanced diurnal waves further contribute to the nonlinear interaction of $D_1+D_2=D_3$. These nonlinear processes might promote the energy cascade of the typhoon-induced near-inertial waves near the critical diurnal latitudes and play an important role in ocean mixing.

Investigating vertical mixing in estuarine pycnocline: a case study in the Ariake Sea, Japan

*Takeshi Matsuno[1], Eisuke Tsutsumi[1]

1. Kyushu University

Turbulent mixing controls coastal environment and primary production through transportation of heat, freshwater, and various materials. Vertical mixing in pycnocline plays a key role in occurrence of major environmental problems in semi-enclosed seas and estuaries, such as bottom hypoxia and red tides, although it is not fully understood. For better understanding and prediction of coastal mixing processes, we investigate pycnocline mixing in a tidally-energetic shallow (~20 m) estuary, the Ariake Sea, Japan, where stratification is maintained almost throughout a year by large amounts of freshwater inputs from major rivers. We collected more than 5,000 microstructure turbulence profiles (~530-hour measurements) in several stations in the central area of the sea during 24-cruises conducted in various seasons over 2002-2012, and examined Turbulent kinetic energy (TKE) dissipation rate in the shear- and buoyancy-frequency space. TKE dissipation rates in pycnocline exhibited a broad variability, $O(10^{-9})$ - $O(10^{-5})$ W kg^{-1} , while most of them fell into a range where the gradient Richardson number is larger than a critical value, i.e., $Ri_g > 1/4$. In stratified seasons, we frequently observed high-vertical wavenumber internal tides in the pycnocline around the microstructure stations from separately-conducted mooring observations using acoustic Doppler current profilers. The large variability in the mixing around pycnocline is therefore likely to be originated from internal wave breaking and shear instability. We found an ordered structure of mean dissipation rate where it correlates positively with vertical shear, which gives a clue to improving a “background” vertical diffusion parameterization in numerical ocean models.

Keywords: turbulent mixing, stratification, vertical shear, parameterization

Possibility of interactions between the coastal and offshore branch of Tsushima Warm Current over the submarine canyon in the Sea of Japan.

*Yosuke Igeta[1], Alexander Yankovsky [2], Mizuki Kuga[1], Naoki Hirose[3], Kenichi Fukudome[4]

1. Japan Sea National Fishseries Research Institute, 2. University of South Carolina, 3. RIAM Kyushu Univ., 4. National Institute of Technology, Toyama College

Tsushima warm current (TWC) is known to flow northeastward over continental shelf off the northern coast of Japan. Coastal branch of TWC (CBTWC) is fundamentally current trapped by the coastline, whereas offshore branch of TWC (OBTWC) are interpreted as current steered by continental slope. The coastal line and continental shelf have alongshore discontinuity around the Toyama Trough (TT) which is a submarine canyon cutting across the continental shelf off the downstream side of the Noto Peninsula (NP) and almost reaching the coastline. The CBTWC is observed to change its path from coastal mode to offshore mode when encountering the TT (Igeta et al., 2017). This process results in transformation from the barotropic coastal current into baroclinic jet detached from the coast over the TT. On the other hand, the details of the OBTWC current path change are not well understood, as well as interaction between the CBTWC and OBTWC.
To clarify these, we analyzed re-analysis current data calculated by DR_C (Hirose et al., 2017) that is high resolution nested ocean model. Current paths of CBTWC around the TT were extracted by using current data from 2005 to 2014. The results showed that complete and incomplete current path transition of the CBTWC from coastal mode to offshore mode in 2013 and 2014, respectively. The OBTWC-like current was explicitly confirmed over continental slope just off the current path of the CBTWC over continental shelf around the northern off the NP in 2013, however such current was not able to be found out in 2014. These results suggest that interaction between the CBTWC and the OBTWC makes current path transition of the CBTWC fast.
To interpret these simply, we demonstrated numerical experiment using 2-layered ocean model with simplified continental shelf, continental slope and submarine canyon. Barotropic current trapped by continental slope, modeling the OBTWC, was applied from the upstream boundary. The OBTWC changed its current path from coast to offshore almost in the same manner as the CBTWC over the TT. The detached current over the submarine canyon was re-arrested by the continental slope on the opposite side of the submarine canyon. The OBTWC continued to take its current path in the offshore region after reaching steady state. Once the OBTWC has reached a steady state, the CBTWC was specified at the upstream boundary. The CBTWC flowed along the coast despite the existence of the OBTWC bridging over the TT. Although the CBTWC and OBTWC merged around the northern coast of the NP, they seemed to behave independently. Time scale of the CBTWC current path transition, however, was shorten in the presence of the OBTWC. This indicates the OBTWC let the current path transition of the CBTWC accelerate through vorticity generated around the upstream boundary of the TT. It is considered that vorticity supplied from the OBTWC accelerate eddy growth by the CBTWC that results in current path transition.

[A-OS14] Coastal physical processes associated with mixing, eddies, internal waves

convener:Eiji Masunaga(Ibaraki University), Taira Nagai(Graduate School of Science, The University of Tokyo), TSUTSUMI EISUKE(Atmosphere and Ocean Research Institute, The University of Tokyo), Chairperson:Eiji Masunaga, Eisuke Tsutsumi

Recently developed observational and numerical approaches have revealed details of physical processes in coastal regions, which is a key to understanding global ocean circulations and ecosystems. This session aims to provide discussions of mixing, eddies, nonlinear internal waves in coastal and marginal oceans, estuaries and lakes. Observations, numerical modeling and laboratory experiments associated with these phenomena are encouraged to submit an abstract to this session. In addition, studies that consider linkages between coastal physical processes and large scale open ocean processes, e.g., the Kuroshio, global ocean circulations.

The cooling of sea surface temperature in the southern Indonesian Seas due to a combination of the Ekman transport and tidal mixing in narrow straits

*Taira Nagai[1], Toshiyuki Hibiya[1]

1. Graduate School of Science, The University of Tokyo

The Indonesian archipelago is characterized by the warmest sea surface temperatures (SSTs) in the world and is a key region of the world climate system. Kida and Wijffels (2012) reported that SST cooling around the Nusa Tenggara Islands (NTIs) located at the southern Indonesia plays a crucial role in the seasonal variation of SST over a large area in the Indonesian Seas. Although they suggested that both the monsoonal winds and tidal mixing might significantly impact such SST cooling, their numerical model settings were somewhat idealized.

In this study, to investigate the mechanisms of SST cooling around the NTIs, we carry out a numerical simulation using a regional ocean model where the realistic distribution of vertical diffusivity estimated from a high resolution baroclinic tide model is incorporated. The simulated results show that significant mixing in the narrow tidal straits between the NTIs creates well-mixed waters, which spread out northward (southward) during Austral summer (winter) and finally causes significant SST cooling over a large area of southern Indonesian Seas.

We therefore carry out numerical experiments where either of the monsoonal wind or localized tidal mixing in the narrow straits is switched off. These numerical experiments show that well-mixed waters in the narrow straits are continuously advected by the northward (southward) flow driven by the western (eastern) monsoonal wind during Austral summer (winter) until the Indonesian Throughflow spreads them out over a large area of southern Indonesian Seas, demonstrating the importance of the combined effect of the Ekman transport and tidal mixing.

A reanalysis of regional circulations in the Southern South China Sea using a HYCOM-ROMS downscaling ocean model

*Naru Takaura[1], Yusuke Uchiyama[1], Nizamani Zafarullah[2], Akihiko Nakayama[2]

1. Kobe Univ, 2. Tunku Abdul Rahman University

A high-resolution, high-precision downscaling oceanic circulation model for the Southern China Sea (SCS) was developed based on the Regional Oceanic Modeling System (ROMS) at a lateral resolution of 5 km, initialized and forced by the Hybrid Coordinate Ocean Model (HYCOM) global reanalysis product. A multi-year reanalysis was conducted for the four-year period from 2012 to 2015 with the HYCOM-ROMS system that properly accounts for wind stress and heat budget at surface, freshwater influences from the atmosphere and major rivers, and tidal variability.
The model results were confirmed to agree well with satellite and in situ measurement, and generally consistent with the findings in previous studies. For instance, prevailing strong meridional currents are provoked along the continental shelves between China and the southern Vietnam, which are driven by seasonally varying monsoons dominated in the winter and summer, followed by current separation to the east off the southern Vietnam occurred in summer.
Prospective applications of the system include assessments of oceanic dispersal of wastewater, quantification of marine ecosystem network, analyses of micro plastic transport, its coastal accumulation and maintenance of offshore structure. In the present study, we utilized the model outcome to evaluate external forcing conditions on offshore oil platforms along the coast of the Malay Peninsular and Borneo Island by using extreme value statistics for surface currents and wind. The maximum surface velocity was found to occur off the coast of Borneo Island, which is influenced by the Mindanao Current. It was suggested that water mass exchange between the Pacific and the SCS is extremely significant as it subsequently controls regional circulations in the coastal margins in the SCS.

Nutrient and phytoplankton dynamics in the continental slope region of the East China Sea associated with the Kuroshio frontal eddy

*Naoki Yoshie[1], Anri Kabe[1], Kazuki Ohgi[1], Eisuke Tsutsumi[2], Shigenobu Takeda[3], Joji Ishizaka[4], Xinyu Guo[1]

1. Center for Marine Environmental Studies, Ehime University, 2. Research Institute for Applied Mechanics, Kyushu University, 3. Faculty of Fisheries, Nagasaki University, 4. Institute for Space-Earth Environmental Research, Nagoya University

The lower-trophic level ecosystem in the continental slope region of the East China Sea (ECS) during summer generally shows typical subtropical features, i.e., small size pico-phytoplankton such as cyanobacteria dominates in the euphotic layer under the oligotrophic condition due to the stable stratification. It is also known that such stable physical and chemical conditions are often disturbed by the Kuroshio frontal eddy. In this study, we investigated the phytoplankton dynamics associated with the passing of Kuroshio frontal eddies. We conducted comprehensive observations with the high horizontal resolution (7km) around the continental slope region in the ECS in the late-July, 2018. We observed drastic changes in the depth of subsurface chlorophyll maximum (SCM) and nitrate concentrations around the SCM, and micro-phytoplankton such as diatom mainly changed around SCM. We found cyclonic frontal eddies with 15-35 km diameter around the 40-80 m depth near the drastic change of the SCM. These changes were caused by the horizontal advection of nutrient-rich shelf water associated with the passing of the cyclonic frontal eddies.

Dissipation and transport due to internal tides generated by multiple submarine canyons

*Qiang Li[1], Xianzhong Mao[1], Ran Liao[1]

1. Tsinghua University

Rough seafloor is a major source to generate internal waves in the ocean. High-resolution multibeam survey reveals detailed seafloor with complicated features, however, some are not shown in commonly used topography datasets, such as Smith and Sandwell (1997). A group of canyons on the continental shelf of the northern South China Sea were recently discovered during a geographic survey. Interaction between barotropic tides and concave-shape canyons generates internal tides, showing complex interference patterns. A linear model, based on normal-mode decomposition, reveals complex beam generation and interaction inside and between the canyons. Then, a very high resolution and three dimensional numerical model is employed to validate the linear model result and estimate local energy dissipation for internal wave generation by a group of canyons. Instead of complicated turbulence models, constant viscosity coefficients are used. Nonlinear interaction or shear instability during internal tide generation and propagation causes local diapycnal mixing, which is one of the key processes to drive material transport in continental shelf. Transport due to internal tides in the canyon region is also calculated and its relationship with local internal tide generation and propagation is discussed.

Measurement of Physical structure in Kasumigaura using high resolution tow-yo instrument

*Daiki Asaoka[1], Eiji Masunaga[1], Shunsuke Komuro[2], Shunichi Matsumoto[2], Masahiko Ono[3], Hiroaki Banba[3]

1. Ibaraki University, 2. Ibaraki Kasumigaura Environmental Science Center, 3. Ministry of Land, Infrastructure, Transport and Tourism

This study shows physical processes in Lake Kitaura, Kasumigaura, using field observations by YODA Profiler and Mooring system. Hypoxia and eutrophication have a bad influence on ecosystems in the study area. Understanding physical processes is essential to understand ecosystems in lakes and oceans. Lake Kitaura is a long lake in the north-south direction with 25 km and 4 km in the east-west. The stratified layer is generated due to strong incoming heat flux during the summer season. Mooring observation results show that the thin mixed layer was gradually thickened due to the wind stress and disappeared within several hours. Details of this mixing processes were further investigated by making use of a high-resolution tow-yo instrument, the YODA Profiler. The warm surface water was transported toward on the downwind side due to the wind stress. Small scale K-H instability like motions were observed during this event. According to the data from the YODA Profiler, the Wedderburn number can roughly explain the baroclinic and mixing structures in the east-west direction. However, the Wedderburn number is not able to be used for explaining quantitative vertical displacements of the thermocline, because the complexity of the observed density distribution. The vertical isotherm displacements can be simply explained by wind stress. Time series of the mixed layer depth were calculated to evaluate mixing in the lake. The mixed layer reached the bottom when the daily-averaged wind speed exceeded 8 m/s, resulting in complete vertical mixing. Results from the north-south long transect survey show wavy like baroclinic (or stripe-shaped) temperature distribution with a horizontal scale of several km. In addition, three dimensional numerical simulations were conducted using the SUNTANS. Model results also show a wavy like baroclinic structure in the north-south direction caused by the complicated coastal shape and east-west wind stress. The wavy like baroclinic structure is generated by convergence of warm water into bay-shaped areas.

Mixing and baroclinic structure in a stratified shallow lake, Lake Kasumigaura, Japan

*Eiji Masunaga[1], Daiki Asaoka[1], Shunsuke Komuro[2], Shunichi Matsumoto[2], Masahiko Ono[3], Hiroaki Banba[3]

1. Ibaraki University, 2. Ibaraki Kasumigaura Environmental Science Center, 3. Ministry of Land, Infrastructure, Transport and Tourism

This study presents mixing and baroclinic structure associated with hypoxia in a shallow lake, Lake Kasumigaura, using field observations and numerical simulations. Hypoxia in stratified lakes is one of the pressing issues for maintaining water environment and ecosystems. Mooring observations show that hypoxia events occur when the stratification is enhanced by the surface heat flux. The stratification (N^2) is controlled by the ratio between the surface wind stress and surface heat (buoyanvy) flux. The strength of the stratification/mixing can be simply explained by the Monin-Obukov length scale, L_{MO}. N^2 is linearly related with L_{MO} in a log scale with a correlation coefficient of approximately 0.7. According to the heat budget analysis, the bottom sediment heat flux toward the bottom significantly contribute to the heat content as well as the surface heat flux. The heat flux toward the bottom is roughly an order of 100 W m^{-2} during the summer season, which suppresses mixing near the bottom. The internal wave-like baroclinic structure was observed by high resolution survey using the YODA Profiler. Baroclinic motions are enhanced by the surface wind stress, and they transport the hypoxic water, suspended sediments and phytoplanktons. In addition to field surveys, three-dimensional simulations were conducted with SUNTANS to further investigate physical processes in the lake. Numerical results well agree to observational results and show that baroclinic motions influence in the whole of the lake basin. The wind-induced baroclinic energy is generated in the middle of the lake basin and propagate to the onshore. This study suggests that mixing and baroclinic motions due to buoyancy and wind effects play an important role in the oxygen distribution in Lake Kasumigaura.

Discussion

Turbulent mixing and vertical nitrate flux in the Bungo Channel, Japan

*TSUTSUMI EISUKE[1], Naoki Yoshie[2], Takashi Mano[3], Kanda Taisei[3], Naoki Fujii[4], Xinyu Guo[2]

1. Research Institute for Applied Mechanics, Kyushu University, 2. Center for Marine Environmental Studies, Ehime Univeristy, 3. Graduate School for Science and Engineering, Ehime University, 4. Faculty of Agriculture, Saga Univerisity

Turbulent mixing plays a key role in primary production in coastal seas through supplying nutrients to the euphotic zone from deeper layers and to the ocean from rivers. Understanding of turbulent dynamics in coastal seas is therefore essential for prediction, conservation and management of coastal ecosystems. Here, we studied turbulent mixing and the associated vertical nitrate transport in a tidally-energetic channel between the Kuroshio region and the Seto Inland Sea (Bungo Channel, Japan). Takeoka [1993] hypothesized that strong vertical mixing and the associated secondary circulation in the channel maintains primary production through supplying large amount of nutrients coming from the Kuroshio region. We conducted simultaneous measurements of turbulence and nitrate concentration along a section in the Bungo Channel using a microstructure turbulence profiler (TurboMAP-5, JFE Advantech) and optical nitrate sensor (SUNA-V2, Sea-Bird Scientific) on 27 August, 2017. We found nitrate-rich cold waters in the bottom of the southern part of the section, which coincide with a typical bottom intrusion from the Kuroshio region. Largest vertical eddy diffusivity of O(10^{-2}) m^2 s^{-1} and the associated upward nitrate flux of O(10) mmol m^{-2} day^{-1} were obtained at 20-30 m depth south of deep and narrow strait (Hoyo Strait). Also, subsurface maximum in chlorophyll fluorescence is observed just above the strong turbulence layer, possibly suggesting phytoplankton blooms in response to the high turbulent nitrate flux. The strong vertical turbulent diffusion was associated with density overturns and elevated vertical shear, indicating internal wave breaking. We hypothesis that internal tides generated in the Hoyo Strait is one of the key processes in enhancement of turbulent mixing and nutrient transport in the Bungo Channel.

Numerical Analysis of Submerged Turbulent Buoyant Jet in River Mouth

*Yen-Chen Mou[1], Gene You[1], Chih-Chieh Young[2]

1. National Taiwan University, 2. National Taiwan Ocean University

The purpose of this study is to investigate the characteristics of submerged turbulent buoyant jet in river mouth by simulating basic fluid mechanisms. The numerical model composes two-dimensional continuity equation, momentum equation, and advective diffusion equation. Since our model is building on basic fluid mechanics formulas, we can test the movement of buoyant jet in the river mouth depends on different parameters, such as environmental and geometrical factors. One of our focuses will be how the phenomena be influenced by inflow hydrograph and sediment concentration, as well as real events and analyze their effect submerged turbulent buoyant jet motion pattern.

Our model will be applied to simulated several characteristic behaviors that are consistent with prior knowledge, including: (1) the inflow concentration is higher at the fixed inflow rate and calculation time, the formed buoyant jet has a large influence range and higher concentration; (2) when the inflow rate is high in a fixed flow concentration and calculation time, the generated buoyant jet has a large influence range and that shape more bulging. Moreover, we will adjust the downstream boundary conditions. When the downstream water level is high, the range and the duration time of the buoyant jet are great. As expected, the concentration of the same location is also higher than other situation that has a lower downstream water level. So far, this model will progress to the extent that it can capture the overall trend of buoyant jet movements, and this simulation is based only on the physical mechanism of the sand-containing fluid itself.

Implementing regional downscaling capability in the STEAMER radionuclide dispersion prediction system based on multi-nested ROMS model

*Kamidaira Yuki[1], Hideyuki Kawamura[1], Takuya Kobayashi[1], Yusuke Uchiyama[2]

1. Japan Atomic Energy Agency, 2. Kobe University

Oceanic regional downscaling capability was implemented into Short-Term Emergency Assessment system of Marine Environmental Radioactivity (STEAMER) developed by Japan Atomic Energy Agency (JAEA) to enable us to predict more realistically the oceanic dispersion of radionuclides at higher spatiotemporal resolutions for broader applications. The system consisted of double-nested Regional Ocean Modeling System (ROMS) with tidal forcing embedded in the Multivariate Ocean Variational Estimation system for the Western North Pacific (MOVE-WNP), assimilative reanalysis/forecast product and an oceanic radionuclide dispersion model SEA-GEARN developed by JAEA. Surface wind stress was provided by the Grid Point Value of the Global Spectral Model (GPV-GSM) atmospheric reanalysis/forecast while surface heat and freshwater fluxes are from the Comprehensive Ocean-Atmosphere Data Set (COADS) monthly climatology. Ten principal tidal constituents from the TPXO 7.0 global tidal reanalysis were additionally imposed on the sea surface height as boundary condition along the perimeter to include barotropic tides and the resultant intrinsic baroclinic tides. The horizontal grid spacing was decreased from ~10 km in the outermost MOVE-WNP, to 3 km in the intermediate ROMS-L1 model, and further down to 1 km in the innermost ROMS-L2 model. The model results showed reasonable agreement with tidal observations. The system was used to comparatively examine downscaling and tidal effects on the dispersion of radionuclides hypothetically released from the Fukushima Daiichi Nuclear Power Plant. The simulated dissolved ^{137}Cs distribution had seasonal variability and was different from that obtained using coarser-resolution models because downscaling enhanced both horizontal and vertical mixing. Temporal ^{137}Cs fluctuations were slightly amplified as a result of the suppression of horizontal mixing and enhancement of vertical mixing by tides. In addition, the submesoscale effects strengthened the three-dimensional ^{137}Cs fluctuations by <10 times, while the tidal effects promoted slightly increased the intensity of three-dimensional ^{137}Cs fluctuations by approximately 3-30%. This indicated that the submesoscale effects substantially surpassed tidal forcing in oceanic mixing in the coastal margin off Fukushima.

Transport processes around the Izu-chain islands investigated with a Lagrangian particle tracking model

*Waku Kimura[1], Eiji Masunaga[1], Taichi Kosako[2], Yusuke Uchiyama[3]

1. Ibaraki University, 2. Port and Airport Research Institute, 3. Kobe University

This study investigated mass transport and dispersion around Izu-chain islands off the Japan mainland using with 3-D Lagrangian particle tracking simulations modeled in a high-resolution reginal ocean modeling system (ROMS). The Kuroshio and eddies, tides largely influence physical processes in the study area. Details of transport processes involving the Kuroshio, eddies and tides have not been understood well. However, these processes are important for understanding oceanic environments and ecosystems in the North Pacific Ocean. Particles were released from three regions: around the Izu-chain islands (north of the Kuroshio), in the Kuroshio, south of the Kuroshio. Model results show that the particle trajectory is different depends on the initial location of particles. Approximately 60% particles released from the Izu-chain islands were transported outside the model domain in 30 days. On the other hands, more than 90% particles released from the Kuroshio and south of the Kuroshio flew out from the domain in 30 days. The vorticity is enhanced by the tidal forcing in the whole study area. The tidal forcing enhances the horizontal diffusion of particles within 2 days scale. By contrast, in the longer time scale longer than 5 days, the dispersion of particles is suppressed by the tidal forcing, because large scale motions are suppressed by tides. The frequency spectrum of the particle velocity shows semi-diurnal peaks and high frequency (low frequency) is enhanced (decreased) by the tidal forcing.

Fates and dynamical roles of pinch-off mesoscale eddies originated from the Kuroshio Extension Jet

*Yusuke Uchiyama[1], Nobue Okada[1], Changming Dong[2]

1. Graduate School of Engineering, Kobe University, 2. Nanjing University of Information Science & Technology

Mesoscale eddies are ubiquitous in the world ocean that frequently collide with currents, leading to substantial alteration of the associated dynamics. For instance, the Kuroshio plays a major role in preconditioning the coastal environment around Japan through poleward heat and material transport from the subtropics, while its path is known to meander occasionally by eddy collisions. Pinch-off mesoscale eddies that detach intermittently from the Kuroshio tend to travel westward as Rossby waves and have been found to collide with the Kuroshio again to alter oceanic and coastal environment through alteration of the Kuroshio path.

For realization of such processes, we applied the eddy detection algorithm used in Liu et al. (2012) to ARMOR3D. The ARMOR3D dataset is a 3D global currents and density data set that is reconstructed from a combination of extensive satellite data and in situ observations based on the geostrophic thermal wind relation and statistical methods as described in Guinehut et al. (2012). By conducting several sensitivity tests, we introduced constraints on vorticity magnitude of detected mesoscale eddies and their relative positions to the Kuroshio path to determine pinch-off eddies near the Kuroshio Extension (KE) region. It was found that the constraint on vorticity magnitude of the detected individual eddies greater than $0.15f$, where f is the local Coriolis frequency, throughout eddy lifetime is significant to successfully isolate pinch-off eddies.

With this constraint, we discovered that most of the detected pinch-off eddies are cyclonic on the south side of the KE region, while anticyclonic eddies are predominant on the north side. The former occurred 2.5–3 times as often as the latter, although in the entire North Pacific, cyclonic eddies occurred only 12.1% more frequently than anticyclonic eddies. Hence, it is considered that this cyclone dominance in the pinch-off eddies from the Kuroshio is a unique feature. We also succeeded to determine pinch-off eddies that collide again with the Kuroshio by introducing another constraint, which is the threshold distance between the Kuroshio path and terminal positions of pinch-off eddies traveled westward. In several selected cases with these constraints, comparisons of the surface temperature and salinity before and after the eddy collisions clearly exhibit that the alteration of the Kuroshio path due to eddy collisions is quite influential in modifying the oceanic structures. It was also found that the pinch-off eddies occasionally interact with other mesoscale eddies to modify the upper-ocean structure pronouncedly.

The Kuroshio path in the KE region is known to vary on annual to decadal time scales, where it was rather stable for 1993-1995 and 2002-2005, whereas largely meandered unstably for 1996–2001 and 2006–2009. During the first unstable periods, the number of cyclonic pinch-off eddies were significantly increased in the area between 144 °E and 150 °E for 1996–2001. However, no significant increase was observed during the other unstable period for 2006–2009. More than 70% of the pinch-off eddies that collided with the Kuroshio appeared during the unstable periods, suggesting that the stability of the Kuroshio path in the KE region is a key influencer on vigorous generation of such colliding pinch-off eddies.

[A-HW22] Materials transport and nutrient cycles in watersheds; from headwaters to coastal seas

convener:Masahiro Kobayashi(Forestry and Forest Products Research Institute), Seiko Yoshikawa(Institute for Agro-environmental Sciences, National Agriculture and Food Research Organization), Jun Yasumoto(University of the Ryukyus, Faculty of Agriculuture), Adina Paytan(University of California Santa Cruz), Chairperson:Noboru Okuda(Research Institute for Humanity and Nature)

This session aims to synthetize watershed sciences in order to understand dynamical processes of materials transport and nutrient cycles in watersheds from headwaters to coastal seas. The session will be integrating a variety of research disciplines including limnology, ground water hydrology, coastal oceanography, meteorology, pedology, sedimentology, forestry, agriculture, fishery, ecology, social science and more. This session calls for ideas on new methods for the watershed sciences, such as tracer and molecular technique, hydrological modeling, paleontological approaches, laboratory and field experiments, social-scientific evaluation of ecosystem services and social-ecological systems, and so on, in order to elucidate physical, chemical and biological mechanisms for shedding light on natural phenomena and their changes over time in complex and dynamic watershed systems under human and climate impacts. Through this session, we would like to facilitate interdisciplinary collaboration among participants to create new knowledge on watershed sciences.

Coral Skeleton $\delta^{15}N$ as a Tracer of Historic Nutrient Loading to a Coral Reef in Maui, Hawaii

*Adina Paytan[1]

1. University of California Santa Cruz

Excess nutrient loading to nearshore environments has been linked to declining water quality and ecosystem health. Macro-algal blooms, eutrophication, and reduction in coral cover have been observed in West Maui, Hawaii, and linked to nutrient inputs from coastal submarine groundwater seeps. Here, we present a forty-year record of nitrogen isotopes ($\delta^{15}N$) of intra-crystalline coral skeletal organic matter in three coral cores collected at this site and evaluate the record in terms of changes in nitrogen sources. Our results show a dramatic increase in coral $\delta^{15}N$ values after 1995, corresponding with the implementation of biological nutrient removal at the nearby Lahaina Wastewater Reclamation Facility (LWRF). High $\delta^{15}N$ values are known to be strongly indicative of denitrification and sewage effluent, corroborating a previously suggested link between local wastewater injection and degradation of the reef environment. This record demonstrates the power of coral skeletal $\delta^{15}N$ as a tool for evaluating nutrient dynamics within coral reef environments.

Institute of Regional Innovation, Hirosaki University, Japan, 4. Research Center for Geotechnology, Indonesian Institute of Sciences, Indonesia

Reduction and oxidation (redox) conditions in the aquifer are essential factors; those can determine the behavior of chemicals in the groundwater system. Nowadays, researches concerning the low redox (reduction) environment are growing significantly since some pollutions occur under this condition. The study was taken place in Indramayu, Indonesia. The area is an alluvial plain located on the North Coast of West Java Island. The groundwater in the alluvial area is compelling to study because it has a large aquifer storage capacity but unfortunately vulnerable to contamination. Moreover, the contamination will get severe under reduction environment. The primary objective of this study is to understand groundwater vulnerability by identifying the reduction environmental zone in the study site.

In this research, we used combined chemical parameters: ammonium (NH_4^+-N), dissolve manganese (Mn^{2+}) and ferrous (Fe^{2+}), to trace reduction condition in the groundwater. NH_4^+-N is one form of nitrogen compound that usually arise under reduction condition. Other parameters that arise with the reduction process are Mn^{2+} and Fe^{2+}. Therefore, in this investigation, we assumed the use of NH_4^+-N, combined with the concentrations of Mn^{2+} and Fe^{2+} elements, are able to identify groundwater reduction environment.

Totally, there was ten soil taken from 2 boreholes located at the south and north of the research site and 20 water samples collected from groundwater (18) and river (2). The soil samples were analyzed for NH_4^+-N and C/N ratio parameters. These data were used to explain further about NH_4^+-N presence in groundwater. Additionally, the water samples were analyzed for NH_4^+-N, $Mn^{2+,}$ and Fe^{2+} concentrations. The aquifer materials consist of sandstone, claystone, and sandy claystone. The NH_4^+-N concentrations were ranged from 0.82 until 3.37 mg / L. However; there was no clear relationship between the soil’s depth and compositions with NH_4^+-N concentrations. The soil samples had low C/N ratios, with values of 8.00 to 12.19. This is indicating that N-organic in the soil potentially experiences mineralization, one that produces NH_4^+-N. Furthermore, NH_4^+-N in water samples were detected as the dominant nitrogen form at most sites. Similarly, Mn^{2+} was detected at almost all locations. Moreover, the concentrations of Mn^{2+} were high (> 0.05 mg / L), around 0.07 - 12.8 mg / L, at 16 locations. High concentrations of Fe^{2+} (> 0.3 mg/L), were found in groundwater at 6 locations. The concentrations were ranged from 1.39 to 9.91 mg/L. The presence of NH_4^+-N along with high Mn^{2+} contents indicated that almost all locations experienced reduction condition at a zone of manganese reduction. Moreover, at 6 locations, the reduction process was stronger and lead to becoming ferrous zone. This was shown by NH_4^+-N existence as dominant nitrogen form and high concentrations of Fe^{2+} as well as Mn^{2+}.

Spatial and temporal variation in submarine groundwater discharge (SGD) on a beach scale in a temperate coastal island: a multi-tracer approach

*Mitsuyo Saito[1], Shin-ichi Onodera[2], Yusuke Tomozawa[2], Kazuyoshi Asai[3]

1. Graduate School of Environmental and Life Science, Okayama University, 2. Graduate School of Integrated Arts and Sciences, Hiroshima University, 3. Geo Science Laboratory

Submarine groundwater discharge (SGD) is defined as subsurface water flow from the seabed to the coastal sea and ocean. Because groundwater often contains higher nutrients than river water, SGD delivers comparatively large quantities of nutrients to coastal ecosystems. However, there are few studies to examine the spatial relation between SGD and coastal ecosystem such as seagrasses and seaweeds. In the present research, we aimed to examine the spatial and temporal variation in SGD on a beach scale in a temperate coastal island.
The study areas are located on Ikuchijima Island in Seto Inland Sea, southern Japan. The regional climate is mild, with an annual mean precipitation of 1,100 mm and temperature of 15.6 ˚C. The whole island is characterized by steep slopes and is widely covered by citrus farms with more than 40% of the island. The previous researches confirmed that SGD can rival or even exceed surface runoff in this island. However, the spatial and temporal variation in SGD on a beach scale was not well examined. We installed piezometers in two beach sites (Gohonmatsu: IKG and Miyabara: IKM) and measured water pressure, water temperature, electric conductivity (EC), and radon (^{222}Rn) concentration in pore water in July and December 2018, and January 2019. In January 2019, SF6 (sulfur hexafluoride) concentration was measured to estimate residence time of pore water. Before the field campaign in July 2018, the study area had an extreme rainfall event. IKG has steeper backland topography than IKM. There is no surface water inflow to IKG, while a small channel inflow to IKM. Main bottom material is sand in both beaches, however, the western part of IKG is covered by coarse gravels. Large spatial variation in hydraulic potential, water temperature, EC and ^{222}Rn concentration in pore water were confirmed in both beaches, with larger variation range in IKG. EC was totally lower and ^{222}Rn was higher in IKG than IKM. These results suggest that higher rate in fresh-SGD in IKG than IKM. In addition, significant low EC and high ^{222}Rn concentration were confirmed in the western part of IKG in July 2018.

Phosphorus discharge via groundwater into the lake, based on lacustrine groundwater discharge (LGD) and alluvial plain sediment

*Shin-ichi Onodera[1], Mitsuyo Saito[2], Guangzhe Jin[3], Anna Fadliah Rusydi[1], Yusuke Tomozawa[1], Kunyang Wang[1], Syuhei Ban[4], Noboru Okuda[5]

1. Graduate School of Integrated and Arts Sciences, Hiroshima University, 2. Graduate School of Environmental and Life Science, Okayama University, 3. Guangdong Ocean University, 4. The University of Shiga Prefecture, 5. Research Institute for Humanity and Nature

Groundwater discharge and nutrient flux into a lake has not been confirmed enough in terms of spatial variation including those in deeper zone. Biwa Lake has different characteristics between in northern and southern. In northern, the water depth varies up to 100m, groundwater discharge is also expected not only in beach sides with shallower depth but in deeper zones. We examined to indicate spatial variation of Rn-222 and to compare with the results of seepage observations by Kobayashi (1993).

Radon radioisotope (Rn-222) concentrations were measured by a RAD7 at 500 m interval along the whole shoreline of the northern lake, and surface water samples were coincidently collected. Oxygen stable isotope ratio ($\delta^{18}O$), Chloride anion and nutrients (nitrogen, phosphorus, and silicon) concentrations were measured in the laboratory in order to evaluate inflow of the groundwater into the lake. Those dissolved materials were also measured from the groundwater samples were collected in ca. 20 wells situated along the shore of the lake as well as those in river waters. In the eastern coast (Hikone), artesian groundwater was also collected because of aquiclude at 10m deep under the ground. Lake waters at the surface, middle and bottom layers and interstitial waters in the bottom sediments were collected for measuring Rn-222 concentrations.

At the both sites of Yasu and Takashima, high pressures of groundwater indicated flow of the water to the lake under the ground. Spatial distributions in Rn-222, Cl^- and nutrient concentrations with those in $\delta^{18}O$ along the coasts also indicated discharges of groundwater into the lake. High concentrations of dissolved phosphorus phosphate (> 0.1ppm) were detected from several wells out of 15 ones investigated. Based on the comparative results with the seepage observations, we could confirm good correlation between Rn-222 concentration and seepage observation results.

In addition, Rn-222 concentrations in lake waters were measured in the surface and bottom layers at the 4 stations with different water depths (5m, 10m and 20m) in October 2015 and July 2016. The highest Rn-222 was observed in the bottom layer at 20m-deep site in both periods. The concentration was more than 2-fold of that in the littoral site. It suggests high possibility of deep-LGD from offshore lake floor.

Geochemical controls and health implications of water chemistry in Benoue River Basin, North Cameroon: Insights from Major ions

*Sharon Bih Kimbi[1,2], Wilson Y Fantong[3], Samuel N Ayonghe[2], Robert Kringel[4], Shin-ichi Onodera[1]

1. Graduate School of Integrate Arts and Sciences, Hiroshima University, 2. Department of Environmental Science, Faculty of science, University of Buea, 3. Institute of Mining and Geological Research (IRGM), 4. Federal Institute for Geoscience and Natural Resources Bundesanstalt fur Geowissenschaften und Rohstoffe (BGR) PRESS NO & SW

Increase population growth in the north region of Cameroon coupled with rapid urbanisation has led to the widespread of informal settlements in urban areas. Multivariate statistics and hydrochemical diagrams were used to investigate the groundwater chemistry, usability and the impact of urbanisation on water resource quality. The purposive random technique was used to sample and collect 86 water samples from 34 boreholes, 37 wells, 14 rivers and 1spring during the month of January, 2017. Major ions were analyzed using an Ion Chromatography. The results revealed that, water pH ranged from slightly acidic to basic meanwhile the water types varied from Ca-Cl in wells, Na-HCO_3 in springs and CaMg-HCO_3 in boreholes and rivers. Water sources did not meet WHO, 2006 quality standard with respect to pH (60.5% <7 & >8.5), EC (58.1%>250 μS/cm) and NO_3^-(60.5%>10mg/l). The Wilcox and USSL diagrams for irrigational uses showed that the water sources are of low to moderate salinity and low alkalinity hazard and thus excellent for use in irrigation. Increase concentrations of NO_3^- and Cl^- from 8.0mg/l to 198.4mg/l and from 2.0mg/l to 59.4mg/l in 1997 and 2017 (20yrs) respectively could be linked to increase population, poor waste disposal and pollution from agricultural fields. While anthropogenic activities are main provenance of NO_3^- and Cl^-, the population is equally affected by fluorosis from lithogenic fluoride and is at risk to nitrate. It is recommended that a monitoring and evaluation system for ground water sources with respect to their quantity and quality be put in place to ensure sustainable management by policy makers.

Drought Analysis based on Copulas and Poisson Process

*Pei-Yu Wu[1], Gene Jiing-yun You[1]

1. National Taiwan University, Department of Civil Engineering

Drought is a regular and recurring climatic phenomenon. Because of climate change and the increasing water demand, we have experienced higher drought deficit and severity in recent years. To evaluate the impact of the trend of drought, this study aims to develop an improved framework for streamflow drought analysis and simulation of the future conditions. Based on our proposed framework based on Copulas and Poisson process, this study firstly analyzes historical inflow data to estimate statistical parameters of drought. Secondly, we calculate three defined indices of the drought, drought duration, drought deficit, and interval time between droughts respectively. With statistical test, these three indices are found to be correlated. Following, the marginal distributions of these indices are estimated. Accordingly, this study constructs a stochastic model by three-dimensional Gaussian copulas to simulate the occurrence of drought events. In addition, to more appropriately simulate drought occurrences, a Poisson process is applied in this study to describe the occurrence between drought events. This simulation is based on the stationary assumption in current stage. In the future, we will consider the influence of climate change and simulate drought events under non-stationary condition. The results of this work can be utilized to support the decision or policy making processes in drought management.

Snow melt dynamics in snowfall dominated mountain regions in Shonai

*Alexander Brandt[1,3], Muhammad Fraz Ismail[2], Larry Maximo Lopez Caceres[1], Wolfgang Bogacki[2]

1. Yamagata University, 2. Hochschule Koblenz, 3. UGAS

With a total snowfall of 1500 mm, which is the half of the total annual precipitation, Shonai is one of the snowiest regions of the world (*Asaoka et al, 2013*). Snow depth can reach up to 5.2 meters in March before the snow melt finishes in May. The maximum snow depth as 50-year average is 2.7 m in the Yamagata University Research Forest (YURF), southern of the Shonai plains. The relatively warm air in winter (~ 0˚C) leads to several melting and refreezing processes within the snow column, increasing the snow density to 0.5 g/cm³. This huge amount of snow in Yamagata, Akita and Aomori prefecture is the dominating water source for plants in spring and a good thermal insulation for the soil, which is never freezing in YURF. A change of wind direction in winter is the reason for the high amount of snow. Cold air from Siberia is passing the warm Japanese Sea and faces the central mountains of Tohoku (*Asaoka et al., 2013*). These characteristics are very unique in the world leading to snow accumulations higher than in most areas of the world (*Krasting et al., 2013, Masiokas et al., 2006*).

The thick snow pack with high density results in a high Snow Water Equivalent (SWE). Monitoring and modelling of the snow melt period in spring is essential to confirm river discharges, water infiltration into the soil and to calculate the water balance of Japanese mountain forests. A modelling approach was done with the calculation of Degree-Day Factors (DDF) (*Ismail et al., 2015*). Measurements to determine the snow pack differences of forest covered sites and clear-cut sites are conducted this winter and will be intensified in the snow melting period. We expect results comparable to *Jost et al. (2009)* and *Schelker et al. (2013)*.

Automatic and manual measurements of snow density and snow depth were conducted intensively in the last 7 years in YURF. Together with the DDF we already discovered a significant trend of changing melt dynamics after half of the melting season. Results show furthermore, that the snow cover is not losing water, even in the warm periods during the winter. Soil moisture is measured to identify the start of the snow melt period, river flow discharge measurements will be introduced as soon as the snow melt starts. All these measurements together are parameters for the following calculations of snowmelt runoff. Melting dynamic related to temperature, snow cover and season was discovered and will be compared with river discharge measurements.

Study on transport of particulate organic matter in a small river with forest and paddy filed by using carbon isotopes ($\delta^{13}C$ and $\Delta^{14}C$)

*Seiya Nagao[1], Ryunosuke Tahara[2], Shinya Ochiai[1], Akiko Goto[3], Takashi Hasegawa[3]

1. Institute of Nature and Environmental Technology, Kanazawa University, 2. Graduate School of Natural Science and Technology, Kanazawa University, 3. Institute of Science and Engineering, Kanazawa University

Radioactive and stable isotopes of carbon (^{14}C and ^{13}C) can serve as powerful tools for identifying sources and estimating turnover times of organic matter in aquatic systems. The present study aims to investigate variations in the characteristics of riverine particulate organic matter running through forests and paddy fields, corresponding to a typical Japanese river system. We selected the Kumaki River located in the central part of the Noto Peninsula in Ishikawa Prefecture, Japan. The river research was conducted at a fixed site of the midstream Kumaki River from April 2016 to March 2018.

Total organic carbon and nitrogen content was measured using the elemental analyzer after the 0.1 M HCl treatment to remove inorganic carbonates. ^{14}C measurements were performed by accelerator mass spectrometry. Final ^{14}C activities are reported in $\Delta^{14}C$. $\delta^{13}C$ values were determined for sub-samples of the CO_2 gas generated during graphite production, using an isotope ratio mass spectrometer.

$\delta^{13}C$ and $\Delta^{14}C$ values of organic matter in the riverine POC of Kumaki River show the range of −27.2‰ to −25.1‰, and −130 to +3 ‰, respectively. There are two negative correlations (correlation factor of 0.78) between the $\delta^{13}C$ and $\Delta^{14}C$ values at winter and the other season except for summer in July and August in 2017. The results indicate that particulate organic matter is mixed with two end-members such as surface forest soil and paddy field soil.

Sources of Shallow Groundwater Salinity in the Ganges Delta of Bangladesh

*Masudur Rahman[1,2], Tomochika Tokunaga[1]

1. Department of Environment Systems, Graduate School of Frontier Sciences, The University of Tokyo, 5-1-5, Kashiwa-no-ha, Kashiwa-shi, Chiba 277-8563, Japan, 2. Environmental Science Discipline, Life Science School, Khulna University, Khulna 9208, Bangladesh

In Bangladesh, unconsolidated fluvio-deltaic sediments host highly productive aquifer systems that are generally classified as shallow aquifers (depth less than 150 m below ground level, mbgl) and deep aquifers (depth more than 150 mbgl). Elevated groundwater salinity in shallow aquifers underlying the southern deltaic areas, in addition to mass poisoning of arsenic, aggravates freshwater scarcity in the country. However, little is known about the origin of salinity and mechanisms of salinization. Therefore, we analyzed both measured and previously published data on pH (n=585), electrical conductivity (EC, n=737), chloride and bromide (n=120 each), stable isotopes of water (oxygen-18 & deuterium, n=175 each), and radiogenic isotopes (C-14, n=18 & tritium, n=29) to discuss these issues for the upper shallow groundwater (depth around 60 mbgl) in the Ganges delta covering much of the coastal areas of Bangladesh. Stable isotope data from two GNIP (Global Network of Isotopes in Precipitation) stations in the delta were incorporated in this study. A paleo-shoreline, representing the maximum extent of last marine transgression at around 7 ka, was retrieved from a previous study and incorporated as well.
The upper shallow groundwater shows slightly acidic to alkaline in nature (6.1-8.5) over the delta. EC ranges from 210-29,400 microsimens/cm with lower salinity in fluvial area (210-2,000 microsimens/cm) than those in tidal domain (383-29,400 microsimens/cm). Cl^-/Br^- molar ratios are higher in tidal area (160-540,000) than those in fluvial setting (42-2,800). The cross plot between oxygen-18 and deuterium isotopes shows that groundwater data fall on or slightly below the local meteoric water line (Figure 1). Most of the brackish groundwater (n=43, EC>2,000-10,000 microsimens/cm) contains depleted isotope signatures. In EC vs oxygen-18 cross plot, EC mostly increases with almost constant isotopic signatures and this trend does not follow seawater mixing. Tritium concentrations are either low (0.1-2.9 TU, n=6) or below detection limit (<0.3 TU, n=9) in tidal domain, whereas around 57% of data show 0.2-7.2 TU in fluvial area. Radiocarbon (C-14) signatures are also higher in fluvial area (around 50-88 pMC) than those in tidal domain (around 36-86 pMC).
These results indicate that present-day seawater intrusion or connate seawater/estuarine water entrapped within sediments is not a major source of elevated salinity in groundwater. Current seawater intrusion is being occurred probably only in limited areas, i.e., near the coast. Also, it is hypothesized that groundwater salinity was possibly provided through the dissolution of soluble salts in paleosols by paleo-precipitation and concurrent infiltration to aquifers. During the transgression, intertidal environment was dominated in the study area, where evaporites and mud-cracks were likely to be developed during prolonged dry season. Subsequently, the monsoonal precipitation dissolved these evaporite minerals and vertically infiltrated into aquifers through mud-cracks or sediments. The future tasks should concentrate on analyzing whether these processes are occurring currently in the delta as well as reconstruction of paleo-geography for validating the hypothesis.

Groundwater chemistry in the Gunii Khooloi basin, Southern Gobi Region of Mongolia using multivariate analysis

*Batdemberel BAYANZUL[1,2], Isao Machida[3], Kengo Nakamura[2], Noriaki Watanabe[2], Takeshi Komai[2]

1. School of Geology and Mining Engineering, Mongolian University of Science and Technology, 2. Graduate School of Environmental Studies, Tohoku University, 3. Groundwater research group, Advanced Industrial Science and Technology

Water plays a vital role in the southern part of Mongolia where is climatically classified as an arid and semi-arid region, so called Southern Gobi Region of Mongolia (SGR). Groundwater serves as the only source of water supply and is largely utilized by mining companies such as the Tavan Tolgoi and Oyu Tolgoi Mine located in the SGR. The area is expected to face severe water shortages of mining and drinking water, which may be related to changes in groundwater recharge due to climate change. Understanding the geochemical evolution of groundwater and recharge mechanisms in the Gunii Khooloi basin is thus paramount for water resource management in this region. However, chemical compositions of groundwater in the SGR has not been studied so far.

In this study, the hydrogeochemical approaches have been introduced to characterize hydrogeochemical characteristics and its associated recharge processes in the Gunii Khooloi basin. To investigate this hydrogeochemical study, springs, groundwater in shallow wells and deep wells in the study area were sampled twice (in September 2016, and in June 2017). A total of 95 groundwater samples were collected within these two years for major chemical analysis in order to understand the general hydrogeochemical conditions of the Gunii Khooloi basin.

Here, we will present the groundwater chemical properties and relationship between shallow and deep groundwater in the Gunii Khooloi basin clarified by multivariate statistical analysis, such as principal component analysis (PCA) and hierarchical cluster analysis (HCA).

Temporal observation of molybdenum concentrations in rivers from Erdenet mining area, Mongolia

*Solongo Tsetsgee[1], Keisuke Fukushi[1], Altansukh Ochir[2], Takahashi Yoshio[3], Ariuntungalag Yunden[2], Enkhjin Odgerel[2], Noriko Hasebe[1]

1. Kanazawa University, 2. National University of Mongolia, 3. The University of Toyko

Erdenet mine is one of the world’ s largest copper–molybdenum mine. This study is conducted the temporal observation of Mo concentrations in river waters. The waters were collected from three rivers, flowing thought Erdenet city, during 9 months in 2018 March to November.
During the summer Mo concentration was increasing with temperature and pH. On the other hand, When the winter was starting low concentration of Mo with low temperature and pH. The Mo concentration is positively correlated with pH and temperature. The tailing pond sample pH slightly lower than rivers due to it couldn’ t be increase of pH in river water. And also, sediment result showed that Mo concentration is lower than water. Therefore, another possibility of reason could be relating to the white dust and it can be increase pH of water.
A huge tailing pond is located in the north of the Erdenet area. It is recognized that the dried precipitates formed by the neutralization of the acidic mine water in the tailing ponds are dispersed widely in the Erdenet area by wind. The dried precipitates (so called white dust) are mainly composed with lime or carbonates containing high amount of Mo. It can be expected that the white dust may dissolve with rainwater. The increase of Mo concentrations associated with the increase of pH may be caused by the dissolution of the white dust at summer rainy season.

Discussion

Solid-water interaction of Mn and As near the bottom of Lake Biwa. –Implications for the spatio-temporal change of these elements for past 40 years-

*TAKAAKI ITAI[1], SACHIKA NATORI[1]

1. Department of Earth and Planetary Science, The University of Tokyo

Enrichment of Mn and As in the surface of sediment caused by diagenetic process has been reported from various lakes in the world. Lake Biwa is a typical example, in which clear enrichments of Mn (up to 5.7 wt%) and As (up to 900 mg/kg) within thin surface enriched layer (< 2 cm) of sediment were observed. This enrichment is caused by the accumulation of manganese oxide and arsenate both of which show lower mobility than these reducing chemical forms. However, decreasing trend of interannual minimum dissolved oxygen level reported from the lake-bottom can change redox behavior of these elements near the sediment-water interface (Itai et al. 2012, Sohrin et al. 2016, Fukushima et al. 2019). Through the geochemical survey after 2009, some specific scientific questions have been arisen.

(i) The degree of surface enrichment of Mn and As from 7 stations in northern lake were markedly increased in 2009 relative to 1977 (Itai et al., 2012). However, the source of them and process of this change are unclear.

(ii) The temporal increase of As in sediment is particularly significant in southern basin of northern lake (so called “first-basin”). The As accumulated on the surface of sediment is likely by scavenging from water column rather than upward diffusion from buried sediment. Nevertheless, difference between northern and southern basin (so called “second-basin”) is unclear.

(iii) Past study suggest that Mn and As level in sediment can be a unique indicator of palaeo water depth (Takamatsu, 1985). This is plausibly caused by higher enrichment of Mn and As toward deeper part of the lake. We confirmed this trend via measurement of 22 core sediments from northern lake. We hypothesize that this distribution is attributed to the geochemical focusing (Schaller et al., 1997), although scientific evidences are still not enough. Besides, there should be some specific mechanism to keep Mn and As enrichment after buried into deep sediment.

In order to answer these questions, we need comprehensive geochemical survey between water column and sediment with focusing speciation of these metals. In the presentation, we would like to present our dataset of lake water (3 stations, 10 m depth interval, 1 year), sediment core (30-40 cm depth, 22 stations), porewater (30 - 40 cm depth, 7 stations), filtered materials of 1, 3, 5, 7, 9 m from lake bottom (7 stations) characterized by X-ray absorption spectroscopy, micro beam chemical analysis, water chemistry analysis, porous diffusion model, and aqueous speciation calculation. Coupling with available monitoring data after 1950s, we make some constraints for the above questions.

Sources, pathways and treatment of contaminants in surface water: Applicability in developing countries

*Mst. Shamsun Nahar[1]

1. Earth Consultant Co. Ltd, Toyama, Japan

This report presents the contamination degree, occurrence, distribution characteristics in the surface water and sediments from Dhaka Rivers (Buriganga and Shitalakshya River) and the Bay of Bengal coast of Bangladesh. A model water treatment method is developing using Baburail Canal Water linked with Shitalakshya River, a World Bank supported project, under Narayanganj City Corporation, Bangladesh. By evaluating hypoxic to anoxic low dissolve oxygen (DO) (below the 0.85 mg/L critical level) associated with very high concentrations of biological oxygen demands (BOD) (5-10 mg/L) and toxic metals (Cr, As, Pb, Cd etc.) in surface water, a model treatment process is developing by using micro bubbling system for increasing the DO level, Neem leaves and bamboo powder are for heavy metals removal process and finally TiO_2 (P25)/ Fe^{+++} method is for the degradation and coagulation of organic content in treated water. The model method of this study should be applied to future water treatment focused on the potential to improve water quality in urban and surrounding areas in developing countries.

Numerical simulations (COMSOL) of γ-Fe_2O_3 nanohybrids for transport (3D) and arsenic removal in homogeneous porous media

*Ajay Kumar[1], Himanshu Joshi[1], Anil Kumar[1]

1. INDIAN INSTITUTE OF TECHNOLOGY ROORKEE, INDIA

Worldwide, arsenic is a menace among the living communities due to its contamination in groundwater. It leaches moderately into groundwater from earth crust and bedrocks enriched with its ores. The countries like India and Bangladesh are being critically affected due to their densely populated areas. Several nanomaterials have been developed and examined as adsorbents for its removal, which are being utilized in *ex-situ* remediation technique. This technique has the disadvantages in terms of generating highly toxic waste, causes due to its easy mobilization in the living ecosystems. Nowadays, *in-situ* (subterranean) sequestration of arsenic is gaining considerable attention in respect to reduce the chance of its mobilization in living environment.

To this aim, the γ-Fe_2O_3 nanohybrids are developed using a novel approach of synthesis which include the usage of industry waste as one of precursor material. These nanoparticles have been found significantly stable in aqueous solutions representing real world groundwater conditions. The measured zeta (ζ)-potential value of -31.6 mV, indicated their significant colloidal stability. In respect to *in-situ* application, the understanding of transport modeling and retardation of nanomaterials in aquifer systems by simulating through numerical models in complex 3-dimensional scenario are necessary. Therefore, a modeling approach based on modified advection-dispersion-retardation equations has been investigated, considering the coupled influence of head difference and reaction rate of particle transport.

All the experiments were performed in a sand-tank set up (0.6 x 0.3 x 0.50 m) having several injection ports at variable depths. The tank was packed with the porous media (medium size sand) having the grain size (mm), grain density (g cm^{-3}), bulk density (g cm^{-3}) and effective porosity (%) values of 0.5-1.0, 2.33 ± 0.2, 1.55 ±0.09 and 0.34 ±0.1, respectively. The longitudinal and traverse dispersivity of consolidated media were calculated using NaCl as a tracer. The COMSOL Multiphysics model (subsurface module) was investigated for simulation of γ-Fe_2O_3 nanohybrids injection and their transport through porous media. Transport of arsenic and as-synthesized nanomaterial were modelled by considering these as solute and colloid, respectively, under fully saturated homogenous porous media and variable flow rate conditions. After simulation, the colloidal solution of nanoparticles was allowed to inject at the concentration of 1.25 x 10^{-4} mol m^{-3} and flow rate of 1.2 L h^{-1}. The simulation results were matched with the experimental observations which provided estimates of transport parameters. The retardation efficiency utilized to predict the γ-Fe_2O_3 nanohybrids in similar porous media, although the extend of injection pressure, colloid concentration and pumping rate may be underpredicted which require further investigations.

Transport processes of suspended solids in the Kumaki River inferred from atmospheric radionuclides

*Shinya Ochiai[1], Ryunosuke Tahara[2], Tetsuya Matsunaka[1], Seiya Nagao[1]

1. Institute of Nature and Environmental Technology, Kanazawa University, 2. Graduate School of Natural Science and Technology, Kanazawa University

The Kumaki River, which drains into the Nanao Bay, is in the central part of the Noto Peninsula. Over recent years, the vegetation in the catchment area of the Kumaki River has changed, and the areas of unmanaged forest and cultivated areas have progressively increased because of plantation activities and decreasing and aging population. These anthropogenic catchment environmental changes may affect the erosion and transport of clastic materials and particulate organic matter to the lower reaches and coastal areas. It is therefore important to clarify the transport processes of these materials to achieve proper management and prediction of environmental changes in river watersheds and coastal areas.
To investigate the transport processes of suspended solids (SS) in the Kumaki River, the atmospheric radionuclides ($^{210}Pb_{ex}$, ^{7}Be, and ^{137}Cs) of SS samples were observed. The SS samples were obtained with a continuous centrifuge of the river water (100 L) collected at the three sampling points (upstream, midstream, and downstream) in Kumaki River every month since April 2016. The concentrations of atmospheric radionuclides in SS samples were measured with a Ge detector. The water discharge was also measured based on cross-sectional profiles of water depth and the flow velocity with a leveling rod and a flow meter at each sampling point.
The $^{7}Be/^{210}Pb_{ex}$ activity ratio of SS sample, which is related to the residence time of these radionuclides in the catchment area, showed clear positive correlation with the water discharge and it was high during winter season with higher precipitation in each sampling point. This result indicates that SS was transported in a shorter time scale during rainfall event and winter season. On the other hand, $^{7}Be/^{210}Pb_{ex}$ ratio exceptionally decreased during heavy rainfall events with the higher water discharge over the threshold value, implying that older stored sediment and subsurface soil were eroded and transported under these conditions. Temporal and spatial changes in ^{137}Cs concentration and $^{137}Cs/^{210}Pb_{ex}$ ratio of SS sample showed different fluctuation in each sampling point, suggesting that changes in discharge amount and source of SS were affected by the subcatchment-scale local hydrological environments and land use conditions.

Using tritium in Japanese precipitation for tritium-tracer transit time studies across Asia

*Maksym Gusyev[1], Yoshito Kikumori[1], Terumasa Nishihara[2], Takeshi Hayashi[3], Kimpei Ichiyanagi[4], Naofumi Akata[5], Tomoki Oda[6], Uwe Morgenstern[7], Michael Stewart[7]

Kumamoto University, 5. National Institute for Fusion Science (NIFS), 6. University of Tokyo, 7. GNS Science, New Zealand

In order to improve management of water resources, water circulation times are estimated with the use of tritium-tracer in catchments across Asia. As an environmental tracer generated in the upper atmosphere, tritium in precipitation is influenced by latitude, season and altitude, and understanding of tritium inputs in water cycle components is needed to estimate mean transit times (MTTs). For future studies, we established the latitude scaling factors to the north and south of the Tokyo area, which has the tritium measurements in monthly precipitation from 1961 to present, by investigating the latitude tritium effect at selected coastal stations in Asia (Gusyev et al., 2016; 2019). In Japan, higher spring tritium was confirmed with winter and spring precipitation samples in 2016 and we observed the altitude effect in March-April snowpack in Hokkaido. The importance of latitude and altitude effects is demonstrated with annual tritium in precipitation at Japanese meteorological stations compared to Tokyo tritium, and with estimated MTTs using 2016 tritium winter and summer baseflow samples at headwater catchments of the Tone and Ishikari River basins, Japan.

A multiobjective risk management model for real-time reservoir flood control operation

*Juan Chen[1,2], Ping-An Zhong[2], XinYu Wan[2], Yu Zhang[2]

1. College of Earth Sciences and Engineering, Hohai University, 2. College of Hydrology and Water Resources, Hohai University

Many uncertainties exit in the real-time reservoir flood control operation and bring risks to flood control decisions. A multiobjective optimization model is developed for the real-time risk management for the flood control operation of a reservoir system considering multiple uncertainties such as inflow forecast errors and outflow errors. The two competing objectives considered are: (1) minimizing the risk of reservoir upstream flooding and (2) minimizing the risk of downstream flooding. The optimization model seeks to find the operation schedules that satisfy the flood control objectives and simultaneously minimize the overall risks. The decision variables are the hourly reservoir releases. The formulated multiobjective optimization problem is nonlinear and non-convex, and is solved with an improved Non-dominated Sorting Genetic Algorithm-II (INSGA-II). We use a filtering algorithm to select representative non-dominated solutions from the Pareto front generated by INSGA-II to assist in real-time decision making. The proposed risk management model is applied to the Foziling reservoir in Huaihe river basin of China. The results show that the proposed method can provide a practical way to optimize the real-time flood control operation for risk management of a reservoir.

Assessment of the Flow Regime of Roanoke River due to Climatic and Anthropogenic Activities

*Rahul Kumar Singh[1], Dr. Manoj Kumar Jain[1]

1. Indian Institute of Technology, Roorkee, India

The natural flow regime of many rivers around the world has been significantly altered due to climatic and anthropogenic modifications such as the construction of dams and reservoirs. The natural flow regime plays an important role in the development of the riverine ecosystem. Therefore, quantification of the extent of the alterations in the natural flow regime would be helpful in the river’ s ecological assessment. The Roanoke River in southeastern United States had one of the biggest and least disturbed forest ecosystems but due to climatic changes and anthropogenic actions such as construction of dam, artificial regulations of the natural flow regime, the overall riverine ecosystem has severely impacted. In this study, SWAT (Soil Water Assessment Tool) has been used to reconstruct the long-term unaltered streamflow for a hypothetical no-dam scenario condition, in order to assess the impact of climate change as well as due to construction of the John H Kerr reservoir on Roanoke River streamflow from 1956-2012. In order to simulate the unaltered streamflow series post construction of John H Kerr reservoir, 32 years (1916-1948) of observed gauge inflow prior to anthropogenic disturbance (due to construction of John H Kerr Reservoir) was used for calibration and validation of the parameters of the SWAT model. Historical land use and land cover backcasting data for the year 1938 has been used in the hydrological model to simulate the flow regime prior to construction of the dam and it was kept same during the whole simulation period. The SWAT model simulated observed gauge data with Nash-Sutcliffe efficiency coefficient (NSE) = 0.70, Percent bias (PBIAS) = 0.00 and the determination coefficient (R^2) = 0.73 during the calibration period (1916 - 1936), and performed equally better during the validation period (1937-1948) with NSE = 0.72, PBIAS = 0.00 and R^2 = 0.74. The indicators of hydrologic alteration (IHA) methodology has been used to assess the natural flow regime (no dam or reservoir moderated flow regime) characteristics under a simulated no-reservoir scenario (scenario1) and compare with the IHA results obtained based on the gauged streamflow downstream of the dam (scenario2). Hence, in case of scenario 1, the post-impact period has been taken as the simulated flow series using SWAT model from 1956-2012 and in case of scenario 2 the post-impact period has been taken as the gauged observed streamflow from 1956-2012 at Roanoke Rapids gauging station downstream of the reservoir. The pre-impact period for both the scenario was kept the same i.e. from 1912 to 1949. The results reveal that in case of the IHA assessment based on scenario 1, significant alterations have been observed in 5 out of 32 indicators compared to 13 out 32 indicators in case of scenario 2. The overall hydrologic alteration in case of scenario 1 was 45.65% and it was 55.17% in the case of scenario 2. The alteration during the scenario 1 could be attributed to the overall natural climatic variability. The results also indicate that flow variability in terms of high and low flows were better in scenario 1 compared to scenario 2 where the high flows were completely absorbed including the low pulse count and duration due to regulation in the flow. However, the reservoir operations enhanced the monthly flows including the multiday minima low flows. Thus, the present method can be treated as an easy-to-implement comprehensive approach for designing natural flow regimes to mimic the pre-impact flow condition in order to restore the ecosystem of modified rivers due to anthropogenic interventions.

Predictive Analysis of Climate, Water, Health and the Environment Nexus

*Abhishek -[1], Deepika -[2]

1. Technical University Dresden, GERMANY, 2. BPS Government Medical College for Women, Sonepat, INDIA

Amid the major demographic transition of developing world from a rural, agrarian society to an urban, industrial one, there is a need for predictive analytics of impact of the major biotic and abiotic stressors on the environmental constituents. The current study emphasizes the connections between climate, water, environment, and health and their interdependency followed by an impact assessment focusing on an urban environment. A data-driven hybrid framework for water resources assessment and management based on machine learning techniques was developed, calibrated and validated with the ground data for the sub-region scale of North-East Indian regime (mean spatial coordinates: 28° 38' 41.2800" N and 77° 13' 0.1956" E). The remote sensing data for land cover and land change were coupled with the climate model simulations to formulate the health risk assessment framework. The large ensemble of downscaled scenario based outputs including the effects of anthropogenic factors was used to drive the hybrid model framework.

Multi-dimensional Random Walk Metropolis (RWM) algorithms used to optimize the sample observations converged with an RMSE error of 0.18 with a range of 0.006. Pearson Product Moment Correlation coefficient range of all the ensemble members was 0.886-0.904. The prediction accuracy construed from 95 % model uncertainty bounds was 89-91 % for the constituent parameters. The sensitivity analysis revealed that the climate is the key parameter and is the most sensitive for all other linkage units followed by water availability and health factors. Comparative analysis of the simulated- and experimental results enforced comprehensive clarification of the assumptions made therein. By real-time monitoring and forecasting the vital impacts, this research will serve and benefit local policymakers and in the decision-making process, particularly regarding water resources vulnerability and future availability with significant economic consequences. The upscaling of the model form sub-regional to regional scale is well underway.

Severe droughts provide huge fuel for widespread wildfires in California in USA

*Linghua Qiu[1], Ji Chen[1], Haiyun Shi[2], Liqun Sun[3], Jun Niu[4]

1. the University of Hong Kong, 2. Southern University of Science and Technology, 3. Shenzhen Institutes of Advanced Technology, Chinese Academy of Sciences, 4. China Agricultural University

The frequently occurred large wildfires in California caught the public’ s attention in recent years and the ability to identify and prevent such disasters is pressing. The study built the rational relationship between soil moisture and vegetation based on remote sensing, hydrology and wildfire data during 2001-2017 in California. The purpose is to estimate the effects of droughts on wildfires and to detect the valid fuel for wildfires. The study results reported that severe droughts could cause huge fuel for wildfires and made them even much more widespread and longer sustained. The consequences could provide significant information for identification and prevention of future wildfires in California and even other regions in the world.

A comprehensive evaluation of MODIS-based water use efficiency with global eddy covariance flux data and a process model

*Shanshan YANG[1,2], Jiahua ZHANG[1], Sha ZHANG[1,2], Jingwen WANG[1,2], Yun BAI[1,2], Fengmei YAO[2], Huadong GUO[1]

1. Institute of Remote Sensing and Digital Earth, Chinese Academy of Sciences, 2. University of Chinese Academy of Sciences, Beijing, China

Ecosystem water use efficiency (WUE), defined as the ratio of gross primary productivity (GPP) to evapotranspiration (ET), is an important indicator to investigate the interaction between the terrestrial carbon and water cycles. The spatiotemporal patterns of WUE inferred from MODIS GPP and ET products and its responses to environmental factors have been analyzed, however, the accuracy of MODIS-derived WUE (MODIS WUE) has not been well evaluated. In this study, we evaluated monthly and annual MODIS WUE using global covariance flux data (FLUXNET2015 dataset) during 2000-2014, and conducted global intercomparisons (2001-2011) among annual WUE from MODIS, gridded FLUXNET (MTE) and a process model (BESS). Site scale (53 sites) evaluation results revealed that MODIS gave reliable estimates for GPP and ET, however, the performances of MODIS WUE was poor for monthly WUE (R2=0.14) and even worse for annual WUE (R2=0.08). MODIS WUE was generally underestimated with a bias of -0.21 gC kg-1 H2O (-8.43%) and RMSE of 1.20 gC kg-1 H2O for monthly WUE, and a bias of -0.28 gC kg-1 H2O (-11.31%) and RMSE of 0.98 gC kg-1 H2O for annual WUE. Among all land cover types, MODIS WUE performed relatively better in savannas and woody savannas for monthly WUE and grasslands for annual WUE, but significantly overestimated WUE in open shrublands. Likewise, MODIS WUE was obviously overestimated in hot and cold semiarid and arid climate zones. The global intercomparison results demonstrated that the spatial pattern of MODIS WUE was broadly similar to that of MTE and BESS WUE, except for the tropical and subtropical arid and semiarid areas. In these regions MODIS WUE showed extremely high values with large uncertainty and different linear trends compared with MTE and BESS WUE. These disagreements were mainly caused by the discrepancies in MODIS ET. Therefore, the uncertainty of MODIS WUE in the tropical arid and semiarid areas should be taken with caution when using MODIS WUE to investigate and interpret how WUE varies spatially and its responses to climate change. Furthermore, the accuracy of MODIS GPP and ET datasets should be paid extra attention since the quality of both GPP and ET would directly affect the WUE accuracy.

Impact of variability and anisotropy in the correlation decay distance for precipitation spatial interpolation in China

*yingxian zhang[1]

1. National Climate Center, China Meteorological Administration

The correlation decay distance (CDD) plays a key role in the angular-distance weighting (ADW) interpolation technique, being used as the searching radius to select correlated neighbors and to calculate the relative weights. The CDD of daily precipitation in China varies spatially and seasonally, and it presents anisotropic behavior, as a result of topography and the predominant atmospheric circulation. In general, CDD is largest in winter and smallest in summer, except for limited regions such as the Tibetan plateau. From a cross validation analysis, it is found that taking account of spatial and seasonal variations in CDD generally improves the ADW interpolation. Utilization of anisotropic CDDs increases the interpolation skill scores in regions with a dense monitoring network, significant elevation variation (southwestern China) or strongly anisotropic CDDs (Tibetan plateau).

New Record-Breaking Frequency of Annual Maximum Daily Precipitation of 58 stations in the whole Japan, an increasing of extreme values.

*Chhay Ngorn SEANG[1], Tomohito YAMADA[1]

1. Hokkaido University

The changes in daily temperature extremes in global scale have affected the weather and climate extreme events when there is an increase of greenhouse gas GHG compare to the industrialization in the 19th century (IPCC, 2014). Yamada et al. (2014) illustrate that the water vapor and convective instability follow the Clausius-Clapeyron-like rate of change with 99th percentile hourly precipitation intensity. Lehmann, J. et al. (2015), on another hand, studied globally the characteristic of precipitation change anomaly using a relation of the Clausius-Clapeyron model. By the way, the climate change tends to include another factor, which is more statistical base. The theory of record values in independent and identically distributed (i.i.d) random variable is studied more extensively and is more applicable with an assumption of stationary climate. The Clausius-Clapeyron equation is then also applicable base on the thermodynamic term which illustrates the relation of the temperature, vapor pressure and precipitation formation characteristic which also mentioned in the above previous studies. At the first stage, 58 stations of AMeDAS data with 117-years period across Japan are used for this analysis. The result shows that mean long-term precipitation of these 58 stations is higher than the mean value from theory i.i.d random variable of stationary climate. From this result, it can be implied that the change of precipitation in Japan is influenced by the drift term either of climate change or the heat island. In this case, the Clausius-Clapeyron equation is applied to identify the temperature term of change. This study tries to formulate a theory which more statistical base of climate drifts, non-stationary and non-identically to extreme events in accordance with time series. Clausius-Clapeyron Model and the Linear Drift Model is considered to form an empirical stochastically based on climate trend.

Quantifying stemflow to better express its ecohydrological significance

*Shin'ichi Iida[1], Darryl E. Carlye-Moses[2], Sonja Germer[3], Pilar Llorens[4], Beate Michalzik[5], Kazuki Nanko[1], Alexander Tischer[5], Delphis F. Levia[6]

1. Department of Disaster Prevention, Meteorology and Hydrology, Forestry and Forest Products Research Institute, 2. Department of Bioengineering, Leibniz Institute for Agricultural Engineering and Bioeconomy, Potsdam, Germany, 4. Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Barcelona, Spain, 5. Soil Science, Institute of Geography, Friedrich Schiller University Jena, Jena, Germany, 6. Department of Geography and Department of Plant and Soil Sciences, University of Delaware, Newark, DE, USA

Stemflow is the flow of rainwater over the exterior of a tree stem to its base. Due to water balance calculations to obtain interception loss of forest stands, and the sometimes low percentage of stemflow as a function of rainfall, some literature ignores the ecohydrological significance of stemflow. However, stemflow is much more concentrated than throughfall per unit area. In recognition of the extreme amounts of water input to the small area around tree trunks, we advocate for two metrics to better express stemflow in relation to its ecohydrological importance: namely, the stand-scale funneling ratio and the stand-scale infiltration funneling ratio. We calculated these metrics based on measurements carried out in a tropical dry deciduous forest and a subpolar juvenile coniferous stand, and found that these are significantly larger than throughfall on both sites. The data cited from recent papers (n=34) showed that very small stand-scale amount of stemflow (approximately 0.5% on average) were necessary to make the stand-scale funneling ratio to be equal or more than unity. Moreover, the infiltration area of stemflow is generally < 0.2 m^2 due to the high infiltration capacity of top soil of forests, generally resulting in the stand-scale infiltration funneling ratio substantially greater than unity. Thus, stemflow is more effective for soil water recharge than throughfall. We recommend use of these metrics to better express ecohydrological importance of stemflow.

This presentation is based on the published paper as follows:
Carlye-Moses, D.E., Iida, S., Germer, S., Llorens, P., Michalzik, B., Nanko, K., Tischer, A., Levia, D.F. (2018): Expressing stemflow commensurate with its ecohydrological importance. Advances in Water Resources, 121, 472-479. Free open access article to: https://doi.org/10.1016/j.advwatres.2018.08.015

Hydraulic analysis of overland flow caused by temporally varying rainfall

*PING-CHENG HSIEH[1], Ming-Chang Wu[1]

1. National Chung Hsing University

With the development of human civilization and population migration, we use many different types of pervious or impervious materials to cover the original surface. As a result, the surface friction and water permeability are reduced, resulting in increased flow velocity and runoff, and thus increasing the frequency and scale of flood occurrence. Therefore, predicting changes in overland flow caused by rainfall has become an important issue.

This study intends to simulate the overland flow under different rainfall patterns by the theory of diffusion wave model. The diffusion wave equation was used as the governing equation, and an analytical solution of the water depth by the generalized integral transformation method was presented. Since the values of the parameters used in previous research for diffusion wave models vary in an extensive range. In this study, the parameters were adjusted for each location to ensure the rationality of the simulation results according to the law of mass conservation.
The results show that for the non-uniform rainfall, the peak water depth and peak flow due to the post-peak rainfall are the largest, followed by the third quarter peak rainfall; whereas the average flow velocity of the mid-peak rainfall is the largest, followed by the third quarter peak rainfall. The peak water depth, peak flow rate and average flow rate due to the double peak rainfall are the smallest among the six rainfall patterns in this study.

Keywords: overland flow, nonuniform rainfall, diffusion wave

A comparative Study on Water Environment of Isolated Islands - Focusing on Islands in Nagasaki Prefecture - (3)

*Go Yamaki[1], Koji Kodera[2], Kazuki Asami[1], Yoshihiro IGARI[1], Masaki Horiuchi[1]

1. Grad. Student, Hosei Univ., 2. Dep. of Geography, Hosei Univ.

1. Introduction Research on islands in Nagasaki prefecture has hardly been investigated and research has been promoted since 2014 from Goto Island Islands, Tsushima, Iki, Hirado. For this time, we will clarify the water environment in each area from the relationship with land use and climate, and make it a foothold to clarify the material cycle of each island.

2. Target area Iki is rugged with a maximum altitude of 213 m, and there are numerous reservoirs in various parts of the island. In Tsushima, the altitude of the entire island is relatively high, and the mountains occupy about 89%. The Goto Islands Island consists of about 140 large and small islands, with large geological differences on each island. The Hirado Islands have many mountains while the fields are also relatively large. The population penetration rate of wastewater treatment in both areas is as low as 20-40%.

3. Research method Field survey was conducted 2 to 4 times a year from 2014 after organizing and examining existing research. On the site, water temperature, temperature, electric conductivity (EC), pH and RpH, COD were measured, and water was taken to measure the total organic carbon and the main dissolved components.

4. Results and discussion In Iki, the influence of agriculture appears in EC and TOC, but it is interesting that there is almost no effect of nitric acid. On the other hand, although many nitric acid was detected in the Goto Islands, it is thought that factors are due to paddy fields in Iki and upland fields in Goto Islands. Tsushima showed relatively low concentrations of EC and dissolved components, and seasonal changes also appeared. In Hirado Island, especially in the southern part, the geological influence is large in many places, the impact of sea salt is strong in Ikitsuki island and Azuchi Oshima. EC tends to rise in rainwater from October to March, pH tends to decrease. From the above, it is considered that the difference in the quality of the islands is greatly influenced by the difference of geology, topography and agricultural form.

Water environment around Kusatsu-Shirane volcano and consideration of the effect of eruption in January 2018

*Igari Yoshihiro[1], Koji Kodera[2], Kazuki Asami[1]

1. Grad.Student,Hosei Univ., 2. Dep.of Geography Hosei Univ.

1. Introduction

The eruption (steam explosion) occurred in Mt.Motoshirane (One of Kusatsu-Shirane Volcano) on January 23, 2018. In this area, water quality survey of water environment began in May 2017 before the eruption. In addition to examining the influence on the water quality before and after the eruption, we studied the elution component of volcanic ash and the influence on the water environment. We also attempted to consider water quality forming factors in river water around Kusatsu-Shirane volcano.

2. Research method

We conducted about 21 field surveys from May 2017 to March 2019. The survey site is about 45 sites, centering on rivers flowing in the east and south of the mountain. Temperature, water temperature, pH, RpH, EC, and flow rate were measured locally, and the sampled sample was analyzed for the main dissolved components. In February 2018, we investigated the deposition situation and ash fall volume of volcanic ash and conducted sampling, and carried out dissolution experiment. In addition to rivers, field surveys and sampling of lakes and precipitation, snow cover, hot spring water were conducted.

3. Results and discussion

In Shirasuna River flowing to the east side of the mountain, groundwater and river water influenced by hot spring drainage and volcanic activity flow in from the tributary. There are points where the EC value fluctuates greatly, and it is influenced by the discharge and conduction of the dam which stores the neutralizing water of acidic rivers. In the Gando Swamp where the site of sulfur mine is located in the upstream part, the water quality is around pH:2.0, EC:6000 μS/cm. It is conceivable that the deposited volcanic ash affects the quality of the surrounding river due to snow melting water and precipitation.

Re-consideration of discharge rate of spring water in Lake Ezu, Kumamoto

*Kimpei Ichiyanagi[1], Kiyoshi Ide[1], Jun Shimada[1], Tsutomu Ichikawa[2]

1. Kumamoto University, 2. Tokai University

In Kumamoto area, 100% of tap water is sourced from abundant groundwater. Recently, there is a great fear of groundwater level decreasing. To estimate discharge rete of spring water in Lake Ezu, the flow rate at 13 sites has been observed every month since December 1991. In previous studies, the total discharge rate of spring water was calculated by flow rates only at the most downstream, the most upper-stream, and incoming streams. In this study, total discharge rate from December 1991 to December 2014 was re-considered as a sum of three zones, that is upper-stream area, Kami-Ezu Lake, and Shimo-Ezu lake. When the discharge rate in each zone became negative, the case 1 where calculation was carried out with minus and the case 2 where it assumed to 0m^3/day were compared. As a result, total discharge rate gradually declined from about 450,000m^3/day in 1992 to about 360,000m^3/day (case 1) and to about 410,000m^3/day (case 2) in 2005. In July 2006, total discharge rate rapidly increased with heavy rainfall. After that, it had fluctuated about 400,000 to 500,000m^3/day in both cases. The discharge rate of Shimo-Ezu Lake sometimes became negative after 2003, and that averaged after July 2006 in case 2 was about 90,000m^3/day more than the case 1. As a result of comparing seasonal variability of discharge rate, monthly mean values of total and Shimo-Ezu Lake are low in April-May and high in October-November. However, monthly mean values of upper-stream area and Kami-Ezu Lake show no significant seasonal fluctuation. Monthly mean values of Shimo-Ezu Lake in August averaged after 2006 was about -14,000m^3/day in case 1 and about 32,000 m^3/day in case 2. Since negative value is not suitable to represent seasonal fluctuation, case 2 is proper to represent the discharge rate of spring water.

Keywords: spring water, Lake Ezu, long-term trend, seasonal variability

Evaluating the efficacy of hydrologically and hydrodynamically driven methods of e-flow assessment for Upper Godavari River Basin, India

*GAURAV KALIDAS PAKHALE[1], Jyoti Punjahari Nale[2], Ashvin Kumar Gosain[3], Rakesh Khosa[3]

1. PhD Research Scholar, Civil Engineering Department, Indian Institute of Technology, Delhi, 2. Project Advisor, IEWP, GIZ India, New Delhi, India, 3. Professor, Civil Engineering Department, Indian Institute of Technology, Delhi

In Peninsular India, pronounced seasonality in the precipitation and tropical semi-arid climate have compelled the tremendous development in the water resources sector. The major proportion of this fertile plateau falls in the rainshadow region of Western Ghats and is rightfully supported through enormous irrigation schemes which include the operation of several large reservoirs. These developments have resulted in alteration of various components of a natural hydrological regime like low as well as high flows. Environmental flows (e-flows), though acknowledged widely for their benefits, have not been attempted vigorously for peninsular river basins due to the prioritised issues related to water scarcity and disputes over water sharing. Also, many of these river streams have historically been known as non-perennial, thus further weakening the case of e-flows. Effectively, many recent e-flow assessments, have been observed to be elementary, quick and based on methods that are less intensive in terms of data and time requirements. In this view, the present study attempts to verify the efficiency of various hydrology and hydrodynamics-based e-flow assessment methods in one of such river basins, Upper Godavari River Basin. For this, hydrological observations of 16 sites with long term record availability (20 years or more) have been used and latest cross section data for these sites have been used for hydrodynamic computations.

Hydrological indices based on concepts like Percentage of Flow (POF) and Range of Variability Approach (RVA) have been estimated using a natural flow regime obtained from SWAT rainfall-runoff modelling. POF approaches like Tennant Method, Tessman Method, Variable Monthly Flow Methods are analysed while RVA approach has been analysed using Indicators of Hydrological Alteration (IHA) platform. These indices have been analysed for their feasibility and acceptability under the natural flow regime to understand the efficacy of these indices in providing optimum e-flow suggestions. Present observed flow regime has been juxtaposed with these indices to assess the present flow health in their comparison.

Hydrodynamic computations have been performed in HEC-RAS using 1-dimensional steady state conditions. Flow discharge versus flow depth, wetted perimeter, etc. relationships obtained for these study sites have been utilised to understand the critical flow levels which ensure the maximum bed inundations preferable for ecological sustainability. Wetted perimeter method of e-flow assessment has been evaluated for its suitability to provide the optimum e-flow suggestions. It has been found that hydrology based simple and quick methods of e-flow assessment fail the basic criteria of feasibility even under natural flow regime while hydrodynamic approach gives site-specific solutions which may not be relatable in longitudinal e-flow implementation.

Keywords: environmental flows, Range of Variability Approach, Wetted perimeter method

Presence of pharmaceutical compounds in freshwater lakes and their impact on phytoplankton

*Nandakumar Kanavillil[1], Cassandra Fligg[1], Sreekumari Kurissery[1]

1. Lakehead University, Canada

Historically, microalgae have been used as bio-indicators of aquatic health and this can be seen in several studies across the world. Often, at the bottom of the food chain microalgae constitute the primary producer of energy of many freshwater ecosystems. Diatoms, a group of microalgae, have been shown to exhibit extreme sensitivity to varying environmental parameters thereby making themselves an excellent candidate for studying the impacts of pollutants such as Pharmaceuticals and Personal Care Products (PPCPs). The contamination by PPCPs is common in our inland water bodies with a potential to get into our drinking water supply. This study explores the presence of PPCPs (Ibuprofen, 17-β Estradiol, and Triclosan) in the nearshore waters of Lake Simcoe, Ontario, Canada and their impacts on microalgal community. The study involved assessment of several environmental and algal parameters in the surrounding freshwater systems of three Waste Water Treatment Plants (WWTPs) that discharge their effluents *via* a creek/water channel to Lake Simcoe. Water samples were also drawn from a control location located away from the WWTPs. The results indicated that 1) PPCPs contamination is prevalent in the water outside of WWTPs (as far as the point of confluence with Lake Simcoe), and 2) The algal parameters varied according to the presence of PPCPs in the surface waters. Thus the study supported the growing concern of pharmaceutical contamination in the freshwater systems and its impacts on primary producers.

Novel approximate solutions for solute transport due to injections: considering the scale-dependent dispersion and non-integer flow dimension

*Ye-Chen Lin[1], Hund-Der Yeh[1]

1. National Chiao Tung Univ.

Prior research indicated that the flow dimension in a fractured medium may be of non-integer. In this article, we aim at developing a mathematical model for solute transport problems due to continuous or pulse injection in a non-integer dimensional flow field. The model allows the flow dimension ranging from linear flow to spherical flow. Our model also considers the effect of scale-dependent dispersion. The approximate solutions of the model are derived by applying the arrival times of mean and variance and validated through the comparison with finite-difference solutions of the present model. The results show that the approximate solutions give reasonable predictions when the value of dispersion or flow dimension is not large.

Keywords: solute transport, non-integer flow dimension, approximate solution, scale-dependent dispersion

Experimemtal study on the residual saturation of Porous Media using Pore Doublets Micromodel

*Chun-Wei Peng[1]

1. Taiwan National Chiao Tung University

In this study, we use a micromodel of PDM with different channel diameter ratios to study the fluid entrapment and mobilization. This study focuses on the evolution of the trapping and the amount of residuals saturation in the porous media. We observed the movement of wetting and non-wet liquids during the imbibition and drainage processes.We found that, with the low injection flow rates, the residual amount was strongly related to the contact angle; with the high injection flow rates, viscous force was dominated the trapping process. The results also showed that the liquids were trapped in the small tube for low injection rate, and in the large tube for the high injection rate. Our findings can help to control the residual saturation during water-flooding oil recovery, groundwater remediation, and the storage of carbon dioxide in deep subsurface.

Assessment of Synergy between Biomedical Waste and Shallow Groundwater Pollution

*Deepika -[1], Abhishek -[2]

1. BPS Government Medical College for Women, Sonepat, INDIA, 2. Technical University Dresden, GERMANY

Rapid urbanization and increasing population growth rate followed by the high rates of resource consumption patterns and increased waste generation have had an unintended negative impact on the prevailing environment. In a developing country like India where 50.34 % groundwater resources are not suitable for drinking as per WHO standards (United Nations, 2016), scrutinizing the open dumping of pathogenic biomedical waste becomes of paramount importance. Poor waste management practices pose a huge risk to the health of the public, patients, professionals and contribute to environmental degradation (land, air, and water pollution) if dumped untreated on the open ground. To assess this nexus, a prevalence study of the patients affected with waterborne diseases was conducted in a total of 35 hospitals comprising of government-, government-aided- and private hospitals of Ambala city. With a pronounced steppe climate, Ambala is located in North-Eastern (mean spatial coordinates: 30˚ 22' 41.4480" N and 76˚ 46' 36.1020" E) edge of Haryana, India. The city is drained by non-perennial streams and therefore the inhabitants depend solely on shallow groundwater resources for meeting their domestic water demand.

Data about the sources, quantity produced, treatment facilities, and awareness of biomedical waste, collected by questionnaire method based survey revealed that the mean waste generation was 8.08 kg/day with SD 5.371 kg/day. The biomedical waste consisted of approximately 1.2 % of the total municipal waste generated by the city and the patients affected with waterborne diseases were about 36 % of the total patients recorded. A latin hypercube Pareto distribution coupled with AMALGAM algorithm was employed for the initial sampling states of the proposals from the observed data (no. of patients). Thereafter, posterior estimates were generated using the Markov Chain Monte Carlo (MCMC) methods which showed a close fit with the observed and simulated data with RMSE 0.158. Furthermore, regression analysis with R^2=0.868 construed strong positive linear correlation between two variables viz. the number of patients and biomedical waste generated (and dumped). Recommendations are made for prioritizing the waste segregation and employing the indispensable management processes including waste treatment to avoid the further deterioration of the drinking water quality. The hospital authorities are advised to conduct the periodic seminars for enhancing awareness among the workforce from present 93.3 % to a maximum possible level.

Erosion and transport processes of earth surface materials in a reservoir-catchment system inferred from atmospheric radionuclides ^{7}Be and ^{210}Pb

*Mikiya Tsuruoka[1], Shinya Ochiai[2], Atsushi Matsuki[2], Seiya Nagao[2]

1. Graduate School of Natural Science and Technology, Kanazawa University, 2. Institute of Nature and Environmental Technology, Kanazawa University

Erosion and transport processes of earth surface materials are related to landform development in river catchment area and material discharge from the land area to the ocean. It is necessary to understand erosion and transport processes of earth surface materials to achieve proper management and prediction of river watershed and coastal area. However, since discharge behavior of earth surface materials in a large-scale river system is complicated by various processes, it is difficult to trace individual processes. On the other hand, earth surface materials eroded from catchment is transported and accumulated in reservoir. Therefore, discharge behavior of earth surface materials from catchment can be observed by monitoring of reservoir sediment. In this study, erosion and transport processes of earth surface materials in catchment were investigated based on atmospheric deposition flux to the catchment and sedimentation flux in the reservoir of ^{7}Be (half-life: 53 days) and ^{210}Pb (half-life: 22.3 years). From July 2016, rain water sample was collected every month with a collecting pan installed on the roof of Noto Atmospheric Observatory in Suzu City. ^{7}Be and ^{210}Pb in rain water were collected on ion exchange resins and measured with a Ge semiconductor detector to obtain atmospheric deposition fluxes. Sediment samples were collected with two sediment traps installed on the bottom of the reservoir (Shin-ike Reservoir) near the Noto Atmospheric Observatory at the same interval with rain sampling. Another trap was also set up in the middle layer (1.5 m above the bottom) since May 2018. Sediment samples were freeze-dried and measured with a Ge semiconductor detector to obtain sedimentation fluxes of ^{7}Be and ^{210}Pb. The atmospheric deposition fluxes of ^{7}Be and ^{210}Pb ranged 1.06-30.7 and 0.334-7.68 Bq/m^{2}/day, respectively. It shows clear seasonal fluctuation with high deposition in winter. The sedimentation fluxes of ^{7}Be in the bottom and middle layers were same level with the deposition flux. This result indicates that the contribution of ^{7}Be from the catchment is small. On the other hand, the sedimentation flux of ^{210}Pb in the middle layer was about 1.7-7.3 times higher than the atmospheric deposition flux of ^{210}Pb. This result suggests that sedimentation flux of ^{210}Pb in the middle layer reflects the contribution of ^{210}Pb from the catchment. The sedimentation flux of ^{210}Pb in the bottom layer was much higher than the atmospheric deposition flux, implying that sedimentation flux in the bottom was largely affected by resuspension in addition to the contribution of ^{210}Pb from the catchment. Residence time of these radionuclides in the reservoir-catchment system was estimated from the ^{7}Be/^{210}Pb$_{ex}$ ratios of rain water and sediment samples. The average residence times of the bottom layer samples and middle layer sample were estimated at 278 days and 141 days, respectively. This difference in the residence time may result from resuspension effect in the reservoir bottom.

Fluctuation of groundwater level in a sloping unconfined aquifer due to time varying recharge

*Ming-Chang Wu[1], Ping-Cheng Hsieh[1]

1. National Chung Hsing University

When a water-permeable slope is recharged by rainfall, the variation of the groundwater level is usually observed by setting up observation wells. However, the point observations are not sufficient to represent the vast domain of an aquifer and are constrained by the high cost of instrumentation and excavated wells. Therefore, the development of mathematical models for groundwater simulations can help us to understand the change of groundwater level more easily.
This study considers the variation of the groundwater level in a sloping aquifer with an impervious bottom. We divided the aquifer into two areas with and without rainfall recharge, and then use the nonlinear Boussinesq equation with a source term derived from the law of mass conservation. Analytical solutions to the nonlinear equation was acquired by the perturbation method for a finite region and a semi-infinite domain. After the transformation of variables, the general integral transformation method was used. The groundwater level varying with time under different factors (such as the dip angle of impervious bed, hydraulic conductivity, storage coefficient and different recharge rates) was discussed.
The present results were compared with the observed data from an observation well, and the difference in between was discussed. It is expected that the research results can better understand the physical mechanism of groundwater level change, and help to manage the groundwater.

Effect of cutoff wall on recharge water storage volume

*Pei-hsun Tsai[1], Jung-hsing Tai[1]

1. Chaoyang University of Technology

Artificial groundwater recharge is used to increase groundwater in areas with water scarcity. Understanding the hydromechanical features of aquifers during groundwater withdrawal and recharge is necessary for managing groundwater resources effectively. In practice, an artificial pool can be used to collect surface runoff so that it infiltrates the aquifer and recharges groundwater. A cutoff wall can be constructed to seal recharge water and prevent it from flowing from the recharge area. Additional studies are required to understand the effect of the various parameters of cutoff walls on groundwater recharge. This study used the finite difference software FLAC 8.0 to examine the influence of the location and size of gaps of a cutoff wall on recharge water storage volume. Each aquifer was in an unsaturated state before groundwater recharging; therefore, groundwater recharge analyses were simulated by the two-phase flow in unsaturated porous media. The results revealed that when the groundwater layer was sand and the cutoff wall was not extended into the fully impermeable layer, the recharge water completely flowed from the gap between the bottom of the cutoff wall and the fully impermeable layer after stopping groundwater recharge. The recharge water volume related to the size of the gap at the bottom of the cutoff wall. When the cutoff wall was not extended into the groundwater layer, the cutoff wall did not intercept water. The gap at the top of the cutoff wall retained more recharge water compared with the gap at the bottom of the cutoff wall.

Studying Operation Parameters on Flat-Plate Membrane Bioreactor for Sewage Treatment

*Jen Hung Chiu[1], Wen Chin Chen[1]

1. Studying Operation Parameters on Flat-Plate Membrane Bioreactor for Sewage Treatment

The flat-plate membrane bioreactor is applied to the domestic sewage treatment, which has a high quality of effluent than the traditional activated sludge process, and decreasing the susceptible of hair entanglement with the hollow fiber membrane. It has become a priority for recent sewage treatment applications.

A flat-plate membrane bioreactor pilot plant with a reaction volume of 4 m^3 was installed in the existing sewage treatment plant. In this research, the parallel treatment of the same influent water quality and hydraulic retention time was carried out to compare the treatment efficiency between the MBR and traditional activated sludge process, and the operational effects of the membrane flux were discussed.

With one year of long-term research, the average removal efficiencies of MBR process, regardless of the COD, SS and E.coli were over 99%, wchih was better than the activated sludge process only 90~95%. Meanwhile, the optimal operation mode of the MBR was obtained in the study. The aeration flow rate in the system was adjusted to 10~13 NL/min per film, the effluent flux was controlled under 50% of the maximum recommended flux of membrane with 9-minute operation and 1 minute stop in a cycle, there is no significant change in operating flux and pressure. These operational mode of MBR can extend the life time of membrane and effectively improve the application of flat-plate MBR to domestic sewage treatment.It is suggested that, in view of water treatment and resource sustainability, the flat plate MBR technology is feasible, and can serve as a green guide to the sewage treatment.

Mine-water quality at a tertiary coalfield in India: Characterisation and treatment using novel polyvinyl alcohol (PVA) gel bioreactor

*Aparna Dutta[1], Sudipta Sarkar[1]

1. Indian Institute of Technology Roorkee

Nearly 78 percent of the total measured (proved) tertiary coal reserves of India is concentrated in the north-eastern state of Assam. The Tertiary coal of North–Eastern Coalfields (NEC) has been found to contain as high as 8% sulphur with varying percentage of pyrite, sulfate, organic and free sulphur. The pyrites are often associated with toxic heavy metals. Acid mine drainage (AMD) is generated when mining activities expose the pyrite and sulfides to atmospheric oxygen, moisture and micro-organisms that catalyse the oxidation process to release large amounts of sulfate into the mine water along with protons and dissolved metals. Microbial dissimilatory sulfate reduction (DSR) in the presence of a suitable organic carbon source can be engineered to treat such water. This study is significant because this region is rich in biodiversity and such mining impacted water may have adverse ecological impact, if discharged without appropriate treatment.The objective of the work is to characterise water samples collected from two open cast mines of Makum coalfield under NEC and evaluate the performance of a novel polyvinyl alcohol (PVA) gel packed bed bioreactor to treat the same. Sample collection, storage and physico-chemical analysis are carried out as per Standard methods of American Public Health Association. The biological treatment process is studied in a cylindrical continuous flow lab scale bioreactor under relevant acidic pH at different feed chemical oxygen demand (COD) to sulfate ratio and hydraulic retention time (HRT). Sludge from a lab scale anaerobic bioreactor treating very high sulfate industrial water is used as inoculum. The sulfate reducing microorganisms are enriched within the bioreactor in fed-batch mode using modified Postgate’ s medium for one month.Oxidation Reduction Potential (ORP), pH, sulfate removal, total inorganic carbon (TIC) and alkalinity produced are measured at the bioreactor outlet to evaluate the process performance. The mine water samples exhibit low pH, high sulfate, conductivity, dissolved solids, hardness, iron and manganese, which indicates the occurrence of AMD. The treatment process reduces the sulfate concentration and increases pH of the treated water. The use of highly porous PVA gel beads as packing material in the bioreactor treating sulfate rich acidic water imparts resilience to operational variation. The study evaluates the novel application of PVA gel beads to bioreactor for treating acidic mine waters from an ecologically important region. The research finding provides an understanding of the process for application to other biological AMD treatment configurations.

Keywords: acid mine drainage (AMD), polyvinyl alcohol (PVA), sulfate, sulfate reducing microorganism (SRM), dissimilatory sulfate reduction(DSR), pyrite

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-HW Hydrology & Water Environment

Wed. May 29, 2019 5:15 PM - 6:30 PM JST | Wed. May 29, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_14

[A-HW23] Hydrology & Water Environment

convener:Isao Machida(Geological Survey of Japan), Dai Yamazaki(Institute of Industrial Sciences, The University of Tokyo), Takeshi Hayashi(Faculty of Education and Human Studies, Akita University), Keisuke Fukushi(Institute of Nature & Environmental Technology, Kanazawa University)

We focus on various issues of water cycle and environment and aim to answer questions of hydrological and earth system sciences including 1) surface, subsurface and evapotranspiration processes of water cycle; 2) natural and anthropogenic hydrothermal systems, 3) environments issues and studies on a watershed or global scale, 4) water-related issues with ecological, environmental, and geochemical aspects, and 5) other issues in hydrological sciences. This session welcomes presentations regarding various kinds of approaches and techniques such as field survey, remote sensing, isotope tracers, numerical simulation, and theoretical analysis.

A multiobjective risk management model for real-time reservoir flood control operation

*Juan Chen[1,2], Ping-An Zhong[2], XinYu Wan[2], Yu Zhang[2]

1. College of Earth Sciences and Engineering, Hohai University, 2. College of Hydrology and Water Resources, Hohai University

Many uncertainties exit in the real-time reservoir flood control operation and bring risks to flood control decisions. A multiobjective optimization model is developed for the real-time risk management for the flood control operation of a reservoir system considering multiple uncertainties such as inflow forecast errors and outflow errors. The two competing objectives considered are: (1) minimizing the risk of reservoir upstream flooding and (2) minimizing the risk of downstream flooding. The optimization model seeks to find the operation schedules that satisfy the flood control objectives and simultaneously minimize the overall risks. The decision variables are the hourly reservoir releases. The formulated multiobjective optimization problem is nonlinear and non-convex, and is solved with an improved Non-dominated Sorting Genetic Algorithm-II (INSGA-II). We use a filtering algorithm to select representative non-dominated solutions from the Pareto front generated by INSGA-II to assist in real-time decision making. The proposed risk management model is applied to the Foziling reservoir in Huaihe river basin of China. The results show that the proposed method can provide a practical way to optimize the real-time flood control operation for risk management of a reservoir.

Assessment of the Flow Regime of Roanoke River due to Climatic and Anthropogenic Activities

*Rahul Kumar Singh[1], Dr. Manoj Kumar Jain[1]

1. Indian Institute of Technology, Roorkee, India

The natural flow regime of many rivers around the world has been significantly altered due to climatic and anthropogenic modifications such as the construction of dams and reservoirs. The natural flow regime plays an important role in the development of the riverine ecosystem. Therefore, quantification of the extent of the alterations in the natural flow regime would be helpful in the river’ s ecological assessment. The Roanoke River in southeastern United States had one of the biggest and least disturbed forest ecosystems but due to climatic changes and anthropogenic actions such as construction of dam, artificial regulations of the natural flow regime, the overall riverine ecosystem has severely impacted. In this study, SWAT (Soil Water Assessment Tool) has been used to reconstruct the long-term unaltered streamflow for a hypothetical no-dam scenario condition, in order to assess the impact of climate change as well as due to construction of the John H Kerr reservoir on Roanoke River streamflow from 1956-2012. In order to simulate the unaltered streamflow series post construction of John H Kerr reservoir, 32 years (1916-1948) of observed gauge inflow prior to anthropogenic disturbance (due to construction of John H Kerr Reservoir) was used for calibration and validation of the parameters of the SWAT model. Historical land use and land cover backcasting data for the year 1938 has been used in the hydrological model to simulate the flow regime prior to construction of the dam and it was kept same during the whole simulation period. The SWAT model simulated observed gauge data with Nash-Sutcliffe efficiency coefficient (NSE) = 0.70, Percent bias (PBIAS) = 0.00 and the determination coefficient (R^2) = 0.73 during the calibration period (1916 - 1936), and performed equally better during the validation period (1937-1948) with NSE = 0.72, PBIAS = 0.00 and R^2 = 0.74. The indicators of hydrologic alteration (IHA) methodology has been used to assess the natural flow regime (no dam or reservoir moderated flow regime) characteristics under a simulated no-reservoir scenario (scenario1) and compare with the IHA results obtained based on the gauged streamflow downstream of the dam (scenario2). Hence, in case of scenario 1, the post-impact period has been taken as the simulated flow series using SWAT model from 1956-2012 and in case of scenario 2 the post-impact period has been taken as the gauged observed streamflow from 1956-2012 at Roanoke Rapids gauging station downstream of the reservoir. The pre-impact period for both the scenario was kept the same i.e. from 1912 to 1949. The results reveal that in case of the IHA assessment based on scenario 1, significant alterations have been observed in 5 out of 32 indicators compared to 13 out 32 indicators in case of scenario 2. The overall hydrologic alteration in case of scenario 1 was 45.65% and it was 55.17% in the case of scenario 2. The alteration during the scenario 1 could be attributed to the overall natural climatic variability. The results also indicate that flow variability in terms of high and low flows were better in scenario 1 compared to scenario 2 where the high flows were completely absorbed including the low pulse count and duration due to regulation in the flow. However, the reservoir operations enhanced the monthly flows including the multiday minima low flows. Thus, the present method can be treated as an easy-to-implement comprehensive approach for designing natural flow regimes to mimic the pre-impact flow condition in order to restore the ecosystem of modified rivers due to anthropogenic interventions.

Predictive Analysis of Climate, Water, Health and the Environment Nexus

*Abhishek -[1], Deepika -[2]

1. Technical University Dresden, GERMANY, 2. BPS Government Medical College for Women, Sonepat, INDIA

Amid the major demographic transition of developing world from a rural, agrarian society to an urban, industrial one, there is a need for predictive analytics of impact of the major biotic and abiotic stressors on the environmental constituents. The current study emphasizes the connections between climate, water, environment, and health and their interdependency followed by an impact assessment focusing on an urban environment. A data-driven hybrid framework for water resources assessment and management based on machine learning techniques was developed, calibrated and validated with the ground data for the sub-region scale of North-East Indian regime (mean spatial coordinates: 28° 38' 41.2800" N and 77° 13' 0.1956" E). The remote sensing data for land cover and land change were coupled with the climate model simulations to formulate the health risk assessment framework. The large ensemble of downscaled scenario based outputs including the effects of anthropogenic factors was used to drive the hybrid model framework.

Multi-dimensional Random Walk Metropolis (RWM) algorithms used to optimize the sample observations converged with an RMSE error of 0.18 with a range of 0.006. Pearson Product Moment Correlation coefficient range of all the ensemble members was 0.886-0.904. The prediction accuracy construed from 95 % model uncertainty bounds was 89-91 % for the constituent parameters. The sensitivity analysis revealed that the climate is the key parameter and is the most sensitive for all other linkage units followed by water availability and health factors. Comparative analysis of the simulated- and experimental results enforced comprehensive clarification of the assumptions made therein. By real-time monitoring and forecasting the vital impacts, this research will serve and benefit local policymakers and in the decision-making process, particularly regarding water resources vulnerability and future availability with significant economic consequences. The upscaling of the model form sub-regional to regional scale is well underway.

Severe droughts provide huge fuel for widespread wildfires in California in USA

*Linghua Qiu[1], Ji Chen[1], Haiyun Shi[2], Liqun Sun[3], Jun Niu[4]

1. the University of Hong Kong, 2. Southern University of Science and Technology, 3. Shenzhen Institutes of Advanced Technology, Chinese Academy of Sciences, 4. China Agricultural University

The frequently occurred large wildfires in California caught the public’ s attention in recent years and the ability to identify and prevent such disasters is pressing. The study built the rational relationship between soil moisture and vegetation based on remote sensing, hydrology and wildfire data during 2001-2017 in California. The purpose is to estimate the effects of droughts on wildfires and to detect the valid fuel for wildfires. The study results reported that severe droughts could cause huge fuel for wildfires and made them even much more widespread and longer sustained. The consequences could provide significant information for identification and prevention of future wildfires in California and even other regions in the world.

A comprehensive evaluation of MODIS-based water use efficiency with global eddy covariance flux data and a process model

*Shanshan YANG[1,2], Jiahua ZHANG[1], Sha ZHANG[1,2], Jingwen WANG[1,2], Yun BAI[1,2], Fengmei YAO[2], Huadong GUO[1]

1. Institute of Remote Sensing and Digital Earth, Chinese Academy of Sciences, 2. University of Chinese Academy of Sciences, Beijing, China

Ecosystem water use efficiency (WUE), defined as the ratio of gross primary productivity (GPP) to evapotranspiration (ET), is an important indicator to investigate the interaction between the terrestrial carbon and water cycles. The spatiotemporal patterns of WUE inferred from MODIS GPP and ET products and its responses to environmental factors have been analyzed, however, the accuracy of MODIS-derived WUE (MODIS WUE) has not been well evaluated. In this study, we evaluated monthly and annual MODIS WUE using global covariance flux data (FLUXNET2015 dataset) during 2000-2014, and conducted global intercomparisons (2001-2011) among annual WUE from MODIS, gridded FLUXNET (MTE) and a process model (BESS). Site scale (53 sites) evaluation results revealed that MODIS gave reliable estimates for GPP and ET, however, the performances of MODIS WUE was poor for monthly WUE (R2=0.14) and even worse for annual WUE (R2=0.08). MODIS WUE was generally underestimated with a bias of -0.21 gC kg-1 H2O (-8.43%) and RMSE of 1.20 gC kg-1 H2O for monthly WUE, and a bias of -0.28 gC kg-1 H2O (-11.31%) and RMSE of 0.98 gC kg-1 H2O for annual WUE. Among all land cover types, MODIS WUE performed relatively better in savannas and woody savannas for monthly WUE and grasslands for annual WUE, but significantly overestimated WUE in open shrublands. Likewise, MODIS WUE was obviously overestimated in hot and cold semiarid and arid climate zones. The global intercomparison results demonstrated that the spatial pattern of MODIS WUE was broadly similar to that of MTE and BESS WUE, except for the tropical and subtropical arid and semiarid areas. In these regions MODIS WUE showed extremely high values with large uncertainty and different linear trends compared with MTE and BESS WUE. These disagreements were mainly caused by the discrepancies in MODIS ET. Therefore, the uncertainty of MODIS WUE in the tropical arid and semiarid areas should be taken with caution when using MODIS WUE to investigate and interpret how WUE varies spatially and its responses to climate change. Furthermore, the accuracy of MODIS GPP and ET datasets should be paid extra attention since the quality of both GPP and ET would directly affect the WUE accuracy.

Impact of variability and anisotropy in the correlation decay distance for precipitation spatial interpolation in China

*yingxian zhang[1]

1. National Climate Center, China Meteorological Administration

The correlation decay distance (CDD) plays a key role in the angular-distance weighting (ADW) interpolation technique, being used as the searching radius to select correlated neighbors and to calculate the relative weights. The CDD of daily precipitation in China varies spatially and seasonally, and it presents anisotropic behavior, as a result of topography and the predominant atmospheric circulation. In general, CDD is largest in winter and smallest in summer, except for limited regions such as the Tibetan plateau. From a cross validation analysis, it is found that taking account of spatial and seasonal variations in CDD generally improves the ADW interpolation. Utilization of anisotropic CDDs increases the interpolation skill scores in regions with a dense monitoring network, significant elevation variation (southwestern China) or strongly anisotropic CDDs (Tibetan plateau).

New Record-Breaking Frequency of Annual Maximum Daily Precipitation of 58 stations in the whole Japan, an increasing of extreme values.

*Chhay Ngorn SEANG[1], Tomohito YAMADA[1]

1. Hokkaido University

The changes in daily temperature extremes in global scale have affected the weather and climate extreme events when there is an increase of greenhouse gas GHG compare to the industrialization in the 19th century (IPCC, 2014). Yamada et al. (2014) illustrate that the water vapor and convective instability follow the Clausius-Clapeyron-like rate of change with 99th percentile hourly precipitation intensity. Lehmann, J. et al. (2015), on another hand, studied globally the characteristic of precipitation change anomaly using a relation of the Clausius-Clapeyron model. By the way, the climate change tends to include another factor, which is more statistical base. The theory of record values in independent and identically distributed (i.i.d) random variable is studied more extensively and is more applicable with an assumption of stationary climate. The Clausius-Clapeyron equation is then also applicable base on the thermodynamic term which illustrates the relation of the temperature, vapor pressure and precipitation formation characteristic which also mentioned in the above previous studies. At the first stage, 58 stations of AMeDAS data with 117-years period across Japan are used for this analysis. The result shows that mean long-term precipitation of these 58 stations is higher than the mean value from theory i.i.d random variable of stationary climate. From this result, it can be implied that the change of precipitation in Japan is influenced by the drift term either of climate change or the heat island. In this case, the Clausius-Clapeyron equation is applied to identify the temperature term of change. This study tries to formulate a theory which more statistical base of climate drifts, non-stationary and non-identically to extreme events in accordance with time series. Clausius-Clapeyron Model and the Linear Drift Model is considered to form an empirical stochastically based on climate trend.

Keywords: Clausius-Clapeyron, New record Breaking, i.i.d

Quantifying stemflow to better express its ecohydrological significance

*Shin'ichi Iida[1], Darryl E. Carlye-Moses[2], Sonja Germer[3], Pilar Llorens[4], Beate Michalzik[5], Kazuki Nanko[1], Alexander Tischer[5], Delphis F. Levia[6]

Department of Geography and Department of Plant and Soil Sciences, University of Delaware, Newark, DE, USA

Stemflow is the flow of rainwater over the exterior of a tree stem to its base. Due to water balance calculations to obtain interception loss of forest stands, and the sometimes low percentage of stemflow as a function of rainfall, some literature ignores the ecohydrological significance of stemflow. However, stemflow is much more concentrated than throughfall per unit area. In recognition of the extreme amounts of water input to the small area around tree trunks, we advocate for two metrics to better express stemflow in relation to its ecohydrological importance: namely, the stand-scale funneling ratio and the stand-scale infiltration funneling ratio. We calculated these metrics based on measurements carried out in a tropical dry deciduous forest and a subpolar juvenile coniferous stand, and found that these are significantly larger than throughfall on both sites. The data cited from recent papers (n=34) showed that very small stand-scale amount of stemflow (approximately 0.5% on average) were necessary to make the stand-scale funneling ratio to be equal or more than unity. Moreover, the infiltration area of stemflow is generally < 0.2 m^2 due to the high infiltration capacity of top soil of forests, generally resulting in the stand-scale infiltration funneling ratio substantially greater than unity. Thus, stemflow is more effective for soil water recharge than throughfall. We recommend use of these metrics to better express ecohydrological importance of stemflow.

This presentation is based on the published paper as follows:
Carlye-Moses, D.E., Iida, S., Germer, S., Llorens, P., Michalzik, B., Nanko, K., Tischer, A., Levia, D.F. (2018): Expressing stemflow commensurate with its ecohydrological importance. Hydraulic analysis of overland flow caused by temporally varying rainfall

*PING-CHENG HSIEH[1], Ming-Chang Wu[1]

1. National Chung Hsing University

With the development of human civilization and population migration, we use many different types of pervious or impervious materials to cover the original surface. As a result, the surface friction and water permeability are reduced, resulting in increased flow velocity and runoff, and thus increasing the frequency and scale of flood occurrence. Therefore, predicting changes in overland flow caused by rainfall has become an important issue.

This study intends to simulate the overland flow under different rainfall patterns by the theory of diffusion wave model. The diffusion wave equation was used as the governing equation, and an analytical solution of the water depth by the generalized integral transformation method was presented. Since the values of the parameters used in previous research for diffusion wave models vary in an extensive range. In this study, the parameters were adjusted for each location to ensure the rationality of the simulation results according to the law of mass conservation.
The results show that for the non-uniform rainfall, the peak water depth and peak flow due to the post-peak rainfall are the largest, followed by the third quarter peak rainfall; whereas the average flow velocity of the mid-peak rainfall is the largest, followed by the third quarter peak rainfall. The peak water depth, peak flow rate and average flow rate due to the double peak rainfall are the smallest among the six rainfall patterns in this study.

Keywords: overland flow, nonuniform rainfall, diffusion wave

A comparative Study on Water Environment of Isolated Islands - Focusing on Islands in Nagasaki Prefecture - (3)

*Go Yamaki[1], Koji Kodera[2], Kazuki Asami[1], Yoshihiro IGARI[1], Masaki Horiuchi[1]

1. Grad. Student, Hosei Univ., 2. Dep. of Geography, Hosei Univ.

1. Introduction Research on islands in Nagasaki prefecture has hardly been investigated and research has been promoted since 2014 from Goto Island Islands, Tsushima, Iki, Hirado. For this time, we will clarify the water environment in each area from the relationship with land use and climate, and make it a foothold to clarify the material cycle of each island.

2. Target area Iki is rugged with a maximum altitude of 213 m, and there are numerous reservoirs in various parts of the island. In Tsushima, the altitude of the entire island is relatively high, and the mountains occupy about 89%. The Goto Islands Island consists of about 140 large and small islands, with large geological differences on each island. The Hirado Islands have many mountains while the fields are also relatively large. The population penetration rate of wastewater treatment in both areas is as low as 20-40%.

3. Research method Field survey was conducted 2 to 4 times a year from 2014 after organizing and examining existing research. On the site, water temperature, temperature, electric conductivity (EC), pH and RpH, COD were measured, and water was taken to measure the total organic carbon and the main dissolved components.

4. Results and discussion In Iki, the influence of agriculture appears in EC and TOC, but it is interesting that there is almost no effect of nitric acid. On the other hand, although many nitric acid was detected in the Goto Islands, it is thought that factors are due to paddy fields in Iki and upland fields in Goto Islands. Tsushima showed relatively low concentrations of EC and dissolved components, and seasonal changes also appeared. In Hirado Island, especially in the southern part, the geological influence is large in many places, the impact of sea salt is strong in Ikitsuki island and Azuchi Oshima. EC tends to rise in rainwater from October to March, pH tends to decrease. From the above, it is considered that the difference in the quality of the islands is greatly influenced by the difference of geology, topography and agricultural form.

Water environment around Kusatsu-Shirane volcano and consideration of the effect of eruption in January 2018

*Igari Yoshihiro[1], Koji Kodera[2], Kazuki Asami[1]

1. Grad.Student,Hosei Univ., 2. Dep.of Geography Hosei Univ.

1. Introduction

The eruption (steam explosion) occurred in Mt.Motoshirane (One of Kusatsu-Shirane Volcano) on January 23, 2018. In this area, water quality survey of water environment began in May 2017 before the eruption. In addition to examining the influence on the water quality before and after the eruption, we studied the elution component of volcanic ash and the influence on the water environment. We also attempted to consider water quality forming factors in river water around Kusatsu-Shirane volcano.

2. Research method

We conducted about 21 field surveys from May 2017 to March 2019. The survey site is about 45 sites, centering on rivers flowing in the east and south of the mountain. Temperature, water temperature, pH, RpH, EC, and flow rate were measured locally, and the sampled sample was analyzed for the main dissolved components. In February 2018, we investigated the deposition situation and ash fall volume of volcanic ash and conducted sampling, and carried out dissolution experiment. In addition to rivers, field surveys and sampling of lakes and precipitation, snow cover, hot spring water were conducted.

3. Results and discussion

In Shirasuna River flowing to the east side of the mountain, groundwater and river water influenced by hot spring drainage and volcanic activity flow in from the tributary. There are points where the EC value fluctuates greatly, and it is influenced by the discharge and conduction of the dam which stores the neutralizing water of acidic rivers. In the Gando Swamp where the site of sulfur mine is located in the upstream part, the water quality is around pH:2.0, EC:6000 μS/cm. It is conceivable that the deposited volcanic ash affects the quality of the surrounding river due to snow melting water and precipitation.

Re-consideration of discharge rate of spring water in Lake Ezu, Kumamoto

*Kimpei Ichiyanagi[1], Kiyoshi Ide[1], Jun Shimada[1], Tsutomu Ichikawa[2]

1. Kumamoto University, 2. Tokai University

In Kumamoto area, 100% of tap water is sourced from abundant groundwater. Recently, there is a great fear of groundwater level decreasing. To estimate discharge rete of spring water in Lake Ezu, the flow rate at 13 sites has been observed every month since December 1991. In previous studies, the total discharge rate of spring water was calculated by flow rates only at the most downstream, the most upper-stream, and incoming streams. In this study, total discharge rate from December 1991 to December 2014 was re-considered as a sum of three zones, that is upper-stream area, Kami-Ezu Lake, and Shimo-Ezu lake. When the discharge rate in each zone became negative, the case 1 where calculation was carried out with minus and the case 2 where it assumed to 0m^3/day were compared. As a result, total discharge rate gradually declined from about 450,000m^3/day in 1992 to about 360,000m^3/day (case 1) and to about 410,000m^3/day (case 2) in 2005. In July 2006, total discharge rate rapidly increased with heavy rainfall. After that, it had fluctuated about 400,000 to 500,000m^3/day in both cases. The discharge rate of Shimo-Ezu Lake sometimes became negative after 2003, and that averaged after July 2006 in case 2 was about 90,000m^3/day more than the case 1. As a result of comparing seasonal variability of discharge rate, monthly mean values of total and Shimo-Ezu Lake are low in April-May and high in October-November. However, monthly mean values of upper-stream area and Kami-Ezu Lake show no significant seasonal fluctuation. Monthly mean values of Shimo-Ezu Lake in August averaged after 2006 was about -14,000m^3/day in case 1 and about 32,000 m^3/day in case 2. Since negative value is not suitable to represent seasonal fluctuation, case 2 is proper to represent the discharge rate of spring water.

Keywords: spring water, Lake Ezu, long-term trend, seasonal variability

Evaluating the efficacy of hydrologically and hydrodynamically driven methods of e-flow assessment for Upper Godavari River Basin, India

*GAURAV KALIDAS PAKHALE[1], Jyoti Punjahari Nale[2], Ashvin Kumar Gosain[3], Rakesh Khosa[3]

1. PhD Research Scholar, Civil Engineering Department, Indian Institute of Technology, Delhi, 2. Project Advisor, IEWP, GIZ India, New Delhi, India, 3. Professor, Civil Engineering Department, Indian Institute of Technology, Delhi

In Peninsular India, pronounced seasonality in the precipitation and tropical semi-arid climate have compelled the tremendous development in the water resources sector. The major proportion of this fertile plateau falls in the rainshadow region of Western Ghats and is rightfully supported through enormous irrigation schemes which include the operation of several large reservoirs. These developments have resulted in alteration of various components of a natural hydrological regime like low as well as high flows. Environmental flows (e-flows), though acknowledged widely for their benefits, have not been attempted vigorously for peninsular river basins due to the prioritised issues related to water scarcity and disputes over water sharing. Also, many of these river streams have historically been known as non-perennial, thus further weakening the case of e-flows. Effectively, many recent e-flow assessments, have been observed to be elementary, quick and based on methods that are less intensive in terms of data and time requirements. In this view, the present study attempts to verify the efficiency of various hydrology and hydrodynamics-based e-flow assessment methods in one of such river basins, Upper Godavari River Basin. For this, hydrological observations of 16 sites with long term record availability (20 years or more) have been used and latest cross section data for these sites have been used for hydrodynamic computations.

Hydrological indices based on concepts like Percentage of Flow (POF) and Range of Variability Approach (RVA) have been estimated using a natural flow regime obtained from SWAT rainfall-runoff modelling. POF approaches like Tennant Method, Tessman Method, Variable Monthly Flow Methods are analysed while RVA approach has been analysed using Indicators of Hydrological Alteration (IHA) platform. These indices have been analysed for their feasibility and acceptability under the natural flow regime to understand the efficacy of these indices in providing optimum e-flow suggestions. Present observed flow regime has been juxtaposed with these indices to assess the present flow health in their comparison.

Hydrodynamic computations have been performed in HEC-RAS using 1-dimensional steady state conditions. Flow discharge versus flow depth, wetted perimeter, etc. relationships obtained for these study sites have been utilised to understand the critical flow levels which ensure the maximum bed inundations preferable for ecological sustainability. Wetted perimeter method of e-flow assessment has been evaluated for its suitability to provide the optimum e-flow suggestions. It has been found that hydrology based simple and quick methods of e-flow assessment fail the basic criteria of feasibility even under natural flow regime while hydrodynamic approach gives site-specific solutions which may not be relatable in longitudinal e-flow implementation.

Presence of pharmaceutical compounds in freshwater lakes and their impact on phytoplankton

*Nandakumar Kanavillil[1], Cassandra Fligg[1], Sreekumari Kurissery[1]

1. Lakehead University, Canada

Historically, microalgae have been used as bio-indicators of aquatic health and this can be seen in several studies across the world. Often, at the bottom of the food chain microalgae constitute the primary producer of energy of many freshwater ecosystems. Diatoms, a group of microalgae, have been shown to exhibit extreme sensitivity to varying environmental parameters thereby making themselves an excellent candidate for studying the impacts of pollutants such as Pharmaceuticals and Personal Care Products (PPCPs). The contamination by PPCPs is common in our inland water bodies with a potential to get into our drinking water supply. This study explores the presence of PPCPs (Ibuprofen, 17-β Estradiol, and Triclosan) in the nearshore waters of Lake Simcoe, Ontario, Canada and their impacts on microalgal community. The study involved assessment of several environmental and algal parameters in the surrounding freshwater systems of three Waste Water Treatment Plants (WWTPs) that discharge their effluents *via* a creek/water channel to Lake Simcoe. Water samples were also drawn from a control location located away from the WWTPs. The results indicated that 1) PPCPs contamination is prevalent in the water outside of WWTPs (as far as the point of confluence with Lake Simcoe), and 2) The algal parameters varied according to the presence of PPCPs in the surface waters. Thus the study supported the growing concern of pharmaceutical contamination in the freshwater systems and its impacts on primary producers.

Novel approximate solutions for solute transport due to injections: considering the scale-dependent dispersion and non-integer flow dimension

*Ye-Chen Lin[1], Hund-Der Yeh[1]

1. National Chiao Tung Univ.

Prior research indicated that the flow dimension in a fractured medium may be of non-integer. In this article, we aim at developing a mathematical model for solute transport problems due to continuous or pulse injection in a non-integer dimensional flow field. The model allows the flow dimension ranging from linear flow to spherical flow. Our model also considers the effect of scale-dependent dispersion. The approximate solutions of the model are derived by applying the arrival times of mean and variance and validated through the comparison with finite-difference solutions of the present model. The results show that the approximate solutions give reasonable predictions when the value of dispersion or flow dimension is not large.

Keywords: solute transport, non-integer flow dimension, approximate solution, scale-dependent dispersion

Experimemtal study on the residual saturation of Porous Media using Pore Doublets Micromodel

*Chun-Wei Peng[1]

1. Taiwan National Chiao Tung University

In this study, we use a micromodel of PDM with different channel diameter ratios to study the fluid entrapment and mobilization. This study focuses on the evolution of the trapping and the amount of residuals saturation in the porous media. We observed the movement of wetting and non-wet liquids during the imbibition and drainage processes.We found that, with the low injection flow rates, the residual amount was strongly related to the contact angle; with the high injection flow rates, viscous force was dominated the trapping process. The results also showed that the liquids were trapped in the small tube for low injection rate, and in the large tube for the high injection rate. Our findings can help to control the residual saturation during water-flooding oil recovery, groundwater remediation, and the storage of carbon dioxide in deep subsurface.

Assessment of Synergy between Biomedical Waste and Shallow Groundwater Pollution

*Deepika -[1], Abhishek -[2]

1. BPS Government Medical College for Women, Sonepat, INDIA, 2. Technical University Dresden, GERMANY

Rapid urbanization and increasing population growth rate followed by the high rates of resource consumption patterns and increased waste generation have had an unintended negative impact on the prevailing environment. In a developing country like India where 50.34 % groundwater resources are not suitable for drinking as per WHO standards (United Nations, 2016), scrutinizing the open dumping of pathogenic biomedical waste becomes of paramount importance. Poor waste management practices pose a huge risk to the health of the public, patients, professionals and contribute to environmental degradation (land, air, and water pollution) if dumped untreated on the open ground. To assess this nexus, a prevalence study of the patients affected with waterborne diseases was conducted in a total of 35 hospitals comprising of government-, government-aided- and private hospitals of Ambala city. With a pronounced steppe climate, Ambala is located in North-Eastern (mean spatial coordinates: 30˚ 22' 41.4480" N and 76˚ 46' 36.1020" E) edge of Haryana, India. The city is drained by non-perennial streams and therefore the inhabitants depend solely on shallow groundwater resources for meeting their domestic water demand.

Data about the sources, quantity produced, treatment facilities, and awareness of biomedical waste, collected by questionnaire method based survey revealed that the mean waste generation was 8.08 kg/day with SD 5.371 kg/day. The biomedical waste consisted of approximately 1.2 % of the total municipal waste generated by the city and the patients affected with waterborne diseases were about 36 % of the total patients recorded. A latin hypercube Pareto distribution coupled with AMALGAM algorithm was employed for the initial sampling states of the proposals from the observed data (no. of patients). Thereafter, posterior estimates were generated using the Markov Chain Monte Carlo (MCMC) methods which showed a close fit with the observed and simulated data with RMSE 0.158. Furthermore, regression analysis with R^2=0.868 construed strong positive linear correlation between two variables viz. the number of patients and biomedical waste generated (and dumped). Recommendations are made for prioritizing the waste segregation and employing the indispensable management processes including waste treatment to avoid the further deterioration of the drinking water quality. The hospital authorities are advised to conduct the periodic seminars for enhancing awareness among the workforce from present 93.3 % to a maximum possible level.

Erosion and transport processes of earth surface materials in a reservoir-catchment system inferred from atmospheric radionuclides ^{7}Be and ^{210}Pb

*Mikiya Tsuruoka[1], Shinya Ochiai[2], Atsushi Matsuki[2], Seiya Nagao[2]

1. Graduate School of Natural Science and Technology, Kanazawa University, 2. Institute of Nature and Environmental Technology, Kanazawa University

Erosion and transport processes of earth surface materials are related to landform development in river catchment area and material discharge from the land area to the ocean. It is necessary to understand erosion and transport processes of earth surface materials to achieve proper management and prediction of river watershed and coastal area. However, since discharge behavior of earth surface materials in a large-scale river system is complicated by various processes, it is difficult to trace individual processes. On the other hand, earth surface materials eroded from catchment is transported and accumulated in reservoir. Therefore, discharge behavior of earth surface materials from catchment can be observed by monitoring of reservoir sediment. In this study, erosion and transport processes of earth surface materials in catchment were investigated based on atmospheric deposition flux to the catchment and sedimentation flux in the reservoir of ^{7}Be (half-life: 53 days) and ^{210}Pb (half-life: 22.3 years). From July 2016, rain water sample was collected every month with a collecting pan installed on the roof of Noto Atmospheric Observatory in Suzu City. ^{7}Be and ^{210}Pb in rain water were collected on ion exchange resins and measured with a Ge semiconductor detector to obtain atmospheric deposition fluxes. Sediment samples were collected with two sediment traps installed on the bottom of the reservoir (Shin-ike Reservoir) near the Noto Atmospheric Observatory at the same interval with rain sampling. Another trap was also set up in the middle layer (1.5 m above the bottom) since May 2018. Sediment samples were freeze-dried and measured with a Ge semiconductor detector to obtain sedimentation fluxes of ^{7}Be and ^{210}Pb. The atmospheric deposition fluxes of ^{7}Be and ^{210}Pb ranged 1.06-30.7 and 0.334-7.68 Bq/m^{2}/day, respectively. It shows clear seasonal fluctuation with high deposition in winter. The sedimentation fluxes of ^{7}Be in the bottom and middle layers were same level with the deposition flux. This result indicates that the contribution of ^{7}Be from the catchment is small. On the other hand, the sedimentation flux of ^{210}Pb in the middle layer was about 1.7-7.3 times higher than the atmospheric deposition flux of ^{210}Pb. This result suggests that sedimentation flux of ^{210}Pb in the middle layer reflects the contribution of ^{210}Pb from the catchment. The sedimentation flux of ^{210}Pb in the bottom layer was much higher than the atmospheric deposition flux, implying that sedimentation flux in the bottom was largely affected by resuspension in addition to the contribution of ^{210}Pb from the catchment. Residence time of these radionuclides in the reservoir-catchment system was estimated from the ^{7}Be/^{210}Pb$_{ex}$ ratios of rain water and sediment samples. The average residence times of the bottom layer samples and middle layer sample were estimated at 278 days and 141 days, respectively. This difference in the residence time may result from resuspension effect in the reservoir bottom.

Fluctuation of groundwater level in a sloping unconfined aquifer due to time varying recharge

*Ming-Chang Wu[1], Ping-Cheng Hsieh[1]

1. National Chung Hsing University

When a water-permeable slope is recharged by rainfall, the variation of the groundwater level is usually observed by setting up observation wells. However, the point observations are not sufficient to represent the vast domain of an aquifer and are constrained by the high cost of instrumentation and excavated wells. Therefore, the development of mathematical models for groundwater simulations can help us to understand the change of groundwater level more easily.
This study considers the variation of the groundwater level in a sloping aquifer with an impervious bottom. We divided the aquifer into two areas with and without rainfall recharge, and then use the nonlinear Boussinesq equation with a source term derived from the law of mass conservation. Analytical solutions to the nonlinear equation was acquired by the perturbation method for a finite region and a semi-infinite domain. After the transformation of variables, the general integral transformation method was used. The groundwater level varying with time under different factors (such as the dip angle of impervious bed, hydraulic conductivity, storage coefficient and different recharge rates) was discussed.
The present results were compared with the observed data from an observation well, and the difference in between was discussed. It is expected that the research results can better understand the physical mechanism of groundwater level change, and help to manage the groundwater.

Effect of cutoff wall on recharge water storage volume

*Pei-hsun Tsai[1], Jung-hsing Tai[1]

1. Chaoyang University of Technology

Artificial groundwater recharge is used to increase groundwater in areas with water scarcity. Understanding the hydromechanical features of aquifers during groundwater withdrawal and recharge is necessary for managing groundwater resources effectively. In practice, an artificial pool can be used to collect surface runoff so that it infiltrates the aquifer and recharges groundwater. A cutoff wall can be constructed to seal recharge water and prevent it from flowing from the recharge area. Additional studies are required to understand the effect of the various parameters of cutoff walls on groundwater recharge. This study used the finite difference software FLAC 8.0 to examine the influence of the location and size of gaps of a cutoff wall on recharge water storage volume. Each aquifer was in an unsaturated state before groundwater recharging; therefore, groundwater recharge analyses were simulated by the two-phase flow in unsaturated porous media. The results revealed that when the groundwater layer was sand and the cutoff wall was not extended into the fully impermeable layer, the recharge water completely flowed from the gap between the bottom of the cutoff wall and the fully impermeable layer after stopping groundwater recharge. The recharge water volume related to the size of the gap at the bottom of the cutoff wall. When the cutoff wall was not extended into the groundwater layer, the cutoff wall did not intercept water. The gap at the top of the cutoff wall retained more recharge water compared with the gap at the bottom of the cutoff wall.

Studying Operation Parameters on Flat-Plate Membrane Bioreactor for Sewage Treatment

*Jen Hung Chiu[1], Wen Chin Chen[1]

1. Studying Operation Parameters on Flat-Plate Membrane Bioreactor for Sewage Treatment

The flat-plate membrane bioreactor is applied to the domestic sewage treatment, which has a high quality of effluent than the traditional activated sludge process, and decreasing the susceptible of hair entanglement with the hollow fiber membrane. It has become a priority for recent sewage treatment applications.

A flat-plate membrane bioreactor pilot plant with a reaction volume of 4 m^3 was installed in the existing sewage treatment plant. In this research, the parallel treatment of the same influent water quality and hydraulic retention time was carried out to compare the treatment efficiency between the MBR and traditional activated sludge process, and the operational effects of the membrane flux were discussed.

With one year of long-term research, the average removal efficiencies of MBR process, regardless of the COD, SS and E.coli were over 99%, wchih was better than the activated sludge process only 90~95%. Meanwhile, the optimal operation mode of the MBR was obtained in the study. The aeration flow rate in the system was adjusted to 10~13 NL/min per film, the effluent flux was controlled under 50% of the maximum recommended flux of membrane with 9-minute operation and 1 minute stop in a cycle, there is no significant change in operating flux and pressure. These operational mode of MBR can extend the life time of membrane and effectively improve the application of flat-plate MBR to domestic sewage treatment.It is suggested that, in view of water treatment and resource sustainability, the flat plate MBR technology is feasible, and can serve as a green guide to the sewage treatment.

Mine-water quality at a tertiary coalfield in India: Characterisation and treatment using novel polyvinyl alcohol (PVA) gel bioreactor

*Aparna Dutta[1], Sudipta Sarkar[1]

1. Indian Institute of Technology Roorkee

Nearly 78 percent of the total measured (proved) tertiary coal reserves of India is concentrated in the north-eastern state of Assam. The Tertiary coal of North–Eastern Coalfields (NEC) has been found to contain as high as 8% sulphur with varying percentage of pyrite, sulfate, organic and free sulphur. The pyrites are often associated with toxic heavy metals. Acid mine drainage (AMD) is generated when mining activities expose the pyrite and sulfides to atmospheric oxygen, moisture and micro-organisms that catalyse the oxidation process to release large amounts of sulfate into the mine water along with protons and dissolved metals. Microbial dissimilatory sulfate reduction (DSR) in the presence of a suitable organic carbon source can be engineered to treat such water. This study is significant because this region is rich in biodiversity and such mining impacted water may have adverse ecological impact, if discharged without appropriate treatment.The objective of the work is to characterise water samples collected from two open cast mines of Makum coalfield under NEC and evaluate the performance of a novel polyvinyl alcohol (PVA) gel packed bed bioreactor to treat the same. Sample collection, storage and physico-chemical analysis are carried out as per Standard methods of American Public Health Association. The biological treatment process is studied in a cylindrical continuous flow lab scale bioreactor under relevant acidic pH at different feed chemical oxygen demand (COD) to sulfate ratio and hydraulic retention time (HRT). Sludge from a lab scale anaerobic bioreactor treating very high sulfate industrial water is used as inoculum. The sulfate reducing microorganisms are enriched within the bioreactor in fed-batch mode using modified Postgate’ s medium for one month.Oxidation Reduction Potential (ORP), pH, sulfate removal, total inorganic carbon (TIC) and alkalinity produced are measured at the bioreactor outlet to evaluate the process performance. The mine water samples exhibit low pH, high sulfate, conductivity, dissolved solids, hardness, iron and manganese, which indicates the occurrence of AMD. The treatment process reduces the sulfate concentration and increases pH of the treated water. The use of highly porous PVA gel beads as packing material in the bioreactor treating sulfate rich acidic water imparts resilience to operational variation. The study evaluates the novel application of PVA gel beads to bioreactor for treating acidic mine waters from an ecologically important region. The research finding provides an understanding of the process for application to other biological AMD treatment configurations.

Keywords: acid mine drainage (AMD), polyvinyl alcohol (PVA), sulfate, sulfate reducing microorganism (SRM), dissimilatory sulfate reduction(DSR), pyrite

The cryosphere is a fundamental component of the earth system. It is a region where snow and ice exist in the form of glacier/ice sheet, snow cover and snowfall, frozen ground, sea ice and fresh water ice, and they play a critical role in the global environment under the interactions with atmosphere, ocean, ecosystem and others. In this session, research results on physical and chemical characteristics of snow and ice, variations and dynamics of cryospheric environment, roles of the cryosphere on the earth and other planets will be discussed broadly, regardless of the research method.

Japan Aerospace Exploration Agency (JAXA) polar-orbit satellite, Global Change Observation Mission for Climate (GCOM-C) has been launched on 23 December 2017. The Second-generation Global Imager (SGLI) which is carried on GCOM-C observes various geophysical variables in the Atmosphere, Ocean, Land and Cryosphere for long-term monitoring of earth environment using multi wavelength, high resolution and multi angles. When focusing on the cryosphere: snow, sea-ice, glacier and ice sheet, their high albedo affect the cooling mechanism of the radiative balance. The GCOM-C/SGLI regularly creates cryosphere standard products including C1: snow, ice and cloud classification product and C2: snow grain size and snow surface temperature product. We validated these products by comparison with other satellite products and in-situ observation data. C1 product was validated by comparing other similar satellite product (e.g. Terra/MODIS) focusing on the snow and ice extent. C2 product was validated by match-up comparison with in-situ data and satellite retrieval results. Snow grain size of shallow layer was measured at the in-situ observation carried out at the East GRIP site on the North-eastern Greenland Ice Sheet in July 2018. Snow and ice surface temperature was derived from automatic weather station (AWS). From these validation results, all standard product was achieved the release threshold and JAXA decided to release the GCOM-C/SGLI product. In the presentation, some examples and case study of the GCOM-C/SGLI observation results will be shown.

The “Global Change Observation Mission-Climate” (GCOM-C) is an Earth observing satellite of Japan Aerospace Exploration Agency (JAXA) for the global observation of the Earth environment. GCOM-C carries a multi-spectral optical radiometer named Second Generation Global Imager (SGLI), which has special features of wide spectral coverage from 380 nm to 12 μm, a high spatial resolution of 250 m, a field of view exceeding 1000 km, two-direction simultaneous observation, and polarization observation. The GCOM-C satellite was successfully launched from the Tanegashima Space Center in Japan on December 23, 2017 and SGLI started the Earth observations on January 1st, 2018. From the SGLI observations snow-related variables such as snow and ice cover extent, snow grain size, and snow surface temperature are being retrieved and the products of those variables have been released to the public from the JAXA’s satellite data providing service “G-Portal” (https://gportal.jaxa.jp/gpr/index/index) since December 20th 2018. These snow physical variables are important for determining spectral albedo and radiation budget at the snow surface. In this presentation, the first-year results of SGLI snow observations are presented as well as the introduction of the SGLI products with the special attention to the thermal infrared observations at 250-m spatial resolution.

Relationships between PASAR-2 backscatter amplitude changes and snow depths

For local governments heavy snowfall gives a very big economic burden. A large amount of tax will be put into operation of the snow removal vehicle, for example. The snow removal expenses of Niigata prefecture approaches 10 billion yen annually, but the operation plan (route selection and operation count) of the snow removal vehicle is not based on objective awareness of snow depth which can vary year by year.
In order to solve this problem, it is important to grasp the snow depth deep space distribution. The estimation of snow accumulation by the conventional satellite-mounted synthetic aperture radar (SAR) was mostly based on the C-band, and adaptation to the snow layer including liquid moisture have difficulty due to the short wavelength (Bernier et al., 1999; Li et al., 2017; Rignot et al., 2001; Shi et al., 1993; Shi and Dozier, 1995). However, in the L-band SAR, the correlation between the snow depth and the backscattering intensity was confirmed to be wet snow, which was a negative correlation (the snow is deeper the reflected intensity decreases) in the night observation assumed to be dry snow It was shown that positive correlation was obtained by day observation (Nagai et al., 2018a, 2018b).
In this research, we examined the image processing algorithm suitable for snow depth estimation for PALSAR-2 which is the L-band SAR equipped with "Daichi-2". First of all, the night observation data was used to minimize the influence of liquid moisture. Obtain data of the observation as 2015/11/22, 2016/11/20 as the no-snow period and 2018/01/28 as the snowy season, convert the backscattering intensity (dB). A series of moving average filter of 0, 5, 10, 15...55 pixels were carried out for each. Then statistical comparison of the ground measurement value compiled by Niigata University (Iyobe and Kawashima, 2016) and the SAR-derived backscatter amplitude changes was carried out.
As a result, the moving average filter with 10 pixels or more shows a negative correlation of $r < -0.3$, $p < 0.1\%$ in all cases, and the correlation coefficient decreased as the number of pixels of the filter increased. There was no significant difference between the November average image and the single scene image. For the linear approximation between the intensity difference and the measured value, the slope was almost constant with the moving average filter of 10 pixels or more.
By using data at night during the winter season, we can estimate snow depth from SAR with high negative correlation. In order to create a snow depth map with a better correlation coefficient, it is necessary to apply a stronger moving average filter, but since it becomes a coarse and smooth snow depth map according to it, it is necessary to consider a filter according to the application.
In addition to this, statistical analysis is also presented in this presentation on other seasons as the standard as well as for snow melting daytime observations presumed to contain a large amount of snow in the snow, and a snow depth estimation method using SAR deepens in the discussion.

On 25 April 2015, an earthquake (M7.8) occurred at Gurkha region located northwest of Kathmandu, the capital of Nepal. On 12 May, an earthquake of M 7.3 occurred at 80 km northeast from Kathmandu. Due to this series of large earthquakes, slope failure events (ice avalanche, snow avalanche, snow-rock avalanche, rock avalanche) occurred frequently in snow mountain area of the Himalaya. In Langtang valley, a huge snow-rock avalanche caused more than 100 victims in Langtang village. We investigated the characteristics of bereaking-off from hunging glaciers around Mt. Langtang-Lirung using satellite data and digital aerial images in 2015 and 2018.

Glaciers in High Mountain Asia are valuable indicator of climate change, and its melt water have an important role for the regional water resources (e.g. Immerzeel et al., 2010). We thus need to estimate Himalayan glacier melting amount. However, the lower part of large Himalayan glaciers is generally covered with debris mantle, which makes the melting process complicated. Several previous works pointed out a role of ice cliffs that promote local enhancement of the ice melting (e.g. Brun et al., 2018). In previous studies, digital elevation models (DEMs) based on satellite imageries have been analyzed to estimate glacier mass change. However, it is difficult to extract ice cliffs due to their low resolution. Recently, Structure from Motion (SfM), image analysis technology, has been dramatically developed. This method enables to obtain high resolution glacial terrain data and identify the small features on glacier surface such as ice cliffs.
In this study, we generated high resolution DEMs and orthomosaic images from aerial photographs taken at three different times at the Trakarding glacier, Rolwaling region, Nepal Himalaya in order to evaluate area and aspect of ice cliffs, and analyzed the relation between cliff distribution and glacier surface elevation change. We carried out field observations and conducted aerial photogrammetry by fixed wing UAV in 2017 and helicopter in 2018 at the entire debris-covered area (3.1 km^2). We also analyzed photographs taken in 2007, and then created high resolution (0.2~2.0 m/pix) DEMs and orthomosaic images, from which about 500 ice cliffs were extracted.
DEMs shows that the surface elevation of the Trakarding Glacier declined between 2007 and 2017 by -1.65 m w.e. yr^{-1} while it lifted up between 2017 and 2018 by +1.25 m w.e. yr^{-1}. We find that the surface elevation changes are spatially heterogeneous. The more significant surface lowering happens, the higher cliff density is observed, suggesting that the ice cliff locally enhances glacier melting. In addition, the ice cliff length density was 7.9×10^{-3} m m^{-2} in 2017, which remarks the highest density comparing to a previous study in the Khumbu region (Watson et al., 2017). Further, we find significant correlation between ice cliff length and its slope area, which means that it is possible to estimate the slope area of cliff from the cliff length, which can be obtained from satellite images.

Quantify the range of projections of future changes in glacier mass caused by differences among observed past climate datasets

*Megumi Watanabe[1], Aki Yanagawa[2], Yukiko Hirabayashi[3], Satoshi Watanabe[4], Shinjiro Kanae[1]

1. Tokyo Institute of Technology, 2. Meisei University, 3. Shibaura Institute of Technology, 4. The University of Tokyo

Observed climate data used as input in glacier models are expected to differ among datasets particularly at high elevations. Differences among datasets have not yet been described as a cause of uncertainty in projections of future changes in glacier mass, although uncertainty caused by varying future climate projections among general circulation models (GCMs) has often been discussed. Differences among climate datasets are expected to propagate as uncertainty in future changes in glacier mass due to bias correction of GCMs and calibration of glacier models. We project ensemble future changes in the mass of glaciers in Asia through the year 2100 using a glacier model. A set of 18 combinations of inputs, including two observed past air temperature datasets, three observed past precipitation datasets, and future air temperature and precipitation projections from three GCMs were used. The uncertainty in projected changes in glacier mass was partitioned into three distinct sources: GCM uncertainty, observed past air temperature uncertainty, and observed past precipitation uncertainty. Our findings indicate that, in addition to the differences in climate projections among GCMs, differences among climate datasets can propagate uncertainty into projected changes in glacier mass. Significant differences in observed precipitation did not cause major uncertainty in projected changes in glacier mass.

Snow grain size is one of the most important factors as a snow physical parameter expressing the snow metamorphism as well as controlling the albedo. As snow grains are generally non-spherical and complicated shapes, the optically-equivalent grain size is not a common glaciological grain size[1)]. Thus, various techniques to measure the specific surface area (SSA) as an optically-equivalent grain size have been developed[2-5)]. It is known from intercomparisons of those techniques so far that one of the most accurate field instruments is IceCube (A2 Photonics Sensor, France)[2)]. The IceCube measures a reflectance of snow sample at the wavelength of 1,310 nm using an integrating sphere and a laser light source. The value of SSA is transformed from the reflectance. A weight of the IceCube is as much as about 20 kg and the snow sampling into a sampling case is needed. These impose not only a workload to the observer but also a certain observation time. We therefore developed a small and light-weight (1/10) instrument, the Handheld Integrating Sphere Snow Grain Sizer (HISSGraS), which operates on the same principle as the IceCube and can measure snow pit face or snow surface directly. This direct measurement enables us to measure the SSA of snow of natural condition in a short time. We measured the SSAs with HISSGraS and IceCube for several snow samples in a cold laboratory and for natural snow pit face in Japan and Greenland. When the SSAs were measured for the same snow samples with both HISSGraS and IceCube, the those SSAs agreed well with each other. When HISSGraS measured snow pit face directly and IceCube measured snow samples collected from the same snow pit, the SSAs by HISSGraS were somewhat larger than those by IceCube. This is because the snow crystals in a sampling case would be compressed at the sampling and the snow grain size could differ from that under natural snow condition.

Experimental study on compaction process of highly porous ice: Implications for density change of icy regolith layer on icy bodies

Minami Yabe[1], *Minami Yasui[1], Masahiko Arakawa[1]

1. Department of Planetology, Graduate School of Science, Kobe University

Ice sheets are found on the polar regions of Earth and Mars. Ice sheets were formed as snow was piled up and compacted into ice. Icy satellites are covered with ice regolith layer which is generated from impact craters by collisions of small bodies. It is supposed that this regolith layer is compacted by self-gravity, but the gravity of small icy satellites is very small and also the surface temperature is quite low, compared with that on the surfaces of Earth and Mars, so the compaction rate of ice regolith layer could be very low, then the deep icy regolith layer might be kept at high porosity on their surfaces. This icy regolith layer could be attributed to the evolution of the surface geology on icy satellites such as topographic relaxation and impact cratering. In this study, we focused on the compaction process of icy regolith layer on icy satellites and conducted compression experiments for highly porous ice under low stresses to examine the relationship between the compaction rate and the porosity.

Snow samples were prepared by filling ice particles with the diameter of ~20 μm into the cylinder mold and by compressing them by a piston into the cylinder with the diameter of 20 mm and the height of 40 mm. The initial porosity was 0.5-0.65. In order to examine the effect of sintering among ice particles on the compression rate, the sintering duration was changed from 0 to 200 hours. We conducted creep tests under constant stresses from 21 to 42 kPa. The displacement of the sample height was measured by a laser or a contact-typed displacement sensors while the diameter change was measured by using images take by a time lapse camera. The temperature was set to be -9and -11 ˚C.

First, we examined the relationship between the strain in a height direction, dh/h, and that in a horizontal direction (diameter change), dr/r, and found to be (dr/r)=-0.11(dh/h). Thus, the compaction rate, $(1/\rho \cdot d\rho/dt)$, was found to be obtained to be -0.78 times the strain rate in a height direction (we call this rate as “compression rate” hereafter), $1/h \cdot dh/h$.

Next, we examined the effect of sintering duration on the compression rate. Under same stress condition, the compression rate was smaller as the sintering duration was longer. However, when the sintering duration passed the critical period, the compression rate was nearly constant even if the sintering duration passed longer. This critical period became shorter as the initial porosity was larger. In this study, to exclude the effect of sintering duration on the compression rate, we examined the effects of porosity, stress, and temperature on the compression rate that was expected for the sample sintering at the period loger than the critical period.

We examined the relationship between the compression rate and the porosity, ϕ, and found that the compression rate could be fitted by the following power equation under a constant stress, irrespective of the initial porosity, $1/h \cdot dh/dt = B\exp(C\phi)$, where B and C are constants. The constant increased exponentially with the increase of the stress, σ, that is, $B \propto \sigma^n$, where n is constant. The constants, C, and n, did not depend on the stress and obtained to be C=24, and n=1.8.

Finally, we evaluated the compaction processes due to self-gravity on the Antarctica and a saturnian icy satellite, Enceladus, by using our obtained empirical equation. We calculated the density and the elevation change of the snow layer on the Antarctica and the icy regolith layer on Enceladus. In this calculation, we assumed that the initial density was homogeneous, 180 kg/m^3, in the whole layer and the stress on the ground surface was 100 kPa. In the case of the Antarctica (a layer thickness of 10 m), the density just above the ground surface increased about three times and the thickness was changed to be a half after 100 years. In the case of Enceladus (a layer thickness of 5 km), the thickness was changed to be

©2019. Japan Geoscience Union. All Right Reserved.

a half after 100 years, as same as the case of the Antarctica, but the density just above the ground surface increased about only twice and the density in the layer on Enceladus was smaller than that on the Antarctica on the whole.

Effect of snow impurities on the radiation budget and snow melting observed at Sapporo during 10 winter seasons

*Yoichiro Hirozawa[1], Teruo Aoki[1,2], Masashi Niwano[2], Sumito Matoba[3], Yuji Kodama[4], Tomonori Tanikawa[2]

1. Okayama University, Graduate School of Natural Science and Technology, 2. Meteorological Research Institute, 3. Institute of Low Temperature Science, Hokkaido University, 4. National Institute of Polar Research

Snow impurities originated from light-absorbing aerosols in the atmosphere have an effect to accelerate the cryospheric warming by reducing the albedo. According to IPCC AR5, black carbon (BC) on snow and ice was assessed to have a global and annual mean radiative forcing (RF) of +0.04 Wm^{-2}. However, the larger effect on the radiation budget and snow melting could be expected in urban area where the snow impurity concentrations are high. In this study, we investigated the effect of snow impurity (BC and mineral dust) concentration on albedo and snow melting from snow and meteorological data observed at Sapporo using physical based snow albedo model (PBSAM) (Aoki et al., 2011). The observation site is the meteorological observation field (43° 04' 56"N, 141° 20' 30"E, 15 m a.s.l) of the Institute of Low Temperature Science of Hokkaido University and the observation period analyzed is 10 winter seasons from 2007 to 2017. The observed broadband albedos were compared with the theoretical values calculated with the PBSAM to which the observed data of snow grain size, impurity concentrations, and downward radiation were input. In addition, we conducted numerical sensitivity experiments on the albedo change due to snow impurities and calculated their RFs. We also estimated a contribution of snow impurities to snow melting from the energy balance analysis.
Comparing the time series of the observed broadband albedos with the theoretically calculated values, the calculated albedo variations due to the change in snow grain size and impurity concentration agreed well with the observations in each year of the analysis period. The determination coefficient (R^2) and the root mean square error (RMSE) for the whole period obtained from the albedo comparison in the shortwave (SW) spectral region were 0.847 and 0.046, respectively, confirming the high accuracy of PBSAM. Next, sensitivity experiments were conducted on the albedo changes in the visible (VIS), near-infrared (NIR), and SW regions depending on the presence and absence of snow impurities. The albedo change and RF due to snow impurities (BC + mineral dust) in the whole period were -0.053 and +6.7 Wm^{-2}, respectively for the SW region. In addition, we estimated total snowmelt amount from the surface energy balance calculation and measured energy flux between the bottom of the snowpack and the underlying ground. The total estimated amount of snow melt for the whole period was 398 mm w. e..The contributions from surface melting and melting at the ground were 76% and 24%, respectively. The melting energy due to snow impurity-induced albedo reduction is equivalent to 28% of total amount of snow melting, which is larger than the melting at the ground and is not negligible. Furthermore, the contributions from BC and dust to this value are 21% and 7%, respectively.

The cryosphere is a fundamental component of the earth system. It is a region where snow and ice exist in the form of glacier/ice sheet, snow cover and snowfall, frozen ground, sea ice and fresh water ice, and they play a critical role in the global environment under the interactions with atmosphere, ocean, ecosystem and others. In this session, research results on physical and chemical characteristics of snow and ice, variations and dynamics of cryospheric environment, roles of the cryosphere on the earth and other planets will be discussed broadly, regardless of the research method.

The rock glacier which composed of ice (permafrost) and debris is one of topographies to confirm periglacial area. It normally moves down at about 0.1-1m/yr by ice creeping, but the velocity of rock glacier in the study area is more faster than any other mountain regions. It has come to understand that the rock glacier is significantly accelerated in the Alps recently, and it is attributed to increasing temperature. But as for the rock glacier in the Tien Shan, it does not have sufficient data to know how fast it moves in the present and past. In this study, we tried to investigate the surface changes of rock glaciers in the Tien Shan Mountains at various time interval using DInSAR analysis. In addition, we observed the surface motion using GNSS measurement, and air and ground surface temperatures.

Keywords: rock glacier, DInSAR, Tien Shan

Verification of AMSR-2 sea ice concentration and utilization of ship navigation in the Arctic Ocean

*Nodoka Ono[1]

1. Earth Observation Research Center, Japan Aerospace Exploration Agency

Mitsui O.S.K. Lines, Ltd. (MOL) plans to transport LNG produced in Yamaru through the Arctic Ocean for 28 years from 2018 using the Northern Sea Route.

JAXA offers sea ice products (sea ice concentration, etc.) from the Advanced Microwave Scanning Radiometer-2 (AMSR-2) carried by the Global Change Observation Mission-Water (GCOM-W) via the ship navigation support service 'VENUS' developed by the National Institute of Polar Research and verifies the availability of AMSR2 products for ship navigation.

In addition, JAXA has installed interval cameras developed by Weathernews Inc. on the LNG ship, which enables the acquisition of sea ice information in the Arctic Ocean for long periods.

Based on these field data, sea ice concentrations are calculated using the image analysis system developed by Tanaka et al. (2015), which are then verified against products from the AMSR-2 and the MODerate resolution Imaging Spectroradiometer (MODIS) carried by Terra/Aqua satellite.

In this study, the result of verification are reported.

Understanding Antarctic ice sheet dynamics related to global climate change is of scientific and societal interest as the future behavior of the ice sheets under currently changing climate is unknown. We present beryllium-10 analysis of a high-resolution marine sediment core from Adélie Basin near the Wilkes Land ice sheet, which is susceptible to retreat due to the low-lying nature and down-sloping trough of the Wilkes Basin. Combined with a newly constructed age model using compound specific radiocarbon dates, the data reveal three ice sheet meltwater discharge events at ca. ~10 ka, ca. ~6.5 ka and ca. ~4 ka. The earlier events correspond to the disappearance of Northern Hemisphere ice sheets and interglacial level atmospheric CO_2. The timing of the latest meltwater influx complements the 4.2 ka event, a period of abrupt global climatic change and the beginning of the Meghalayan Age.

Keywords: Holocene, East Antarctica, Adelie Basin, 4.2 ka event, Beryllium-10

In the eastern Himalayas and Karakoram, sudden large-scale drainage and flooding can occur from debris-covered glaciers that lack a large proglacial lake.This type of glacial lake outburst flood (GLOF) differs clearly from large proglacial lakes. Thus, these studies indicate that debris-covered glaciers that lack a large proglacial lake can have one or more supraglacial lakes vanish when a sudden, large drainage occurs through englacial/subglacial channels, sometime leading to dangerous flooding.

It has been clarified that seasonal variation of supraglacial lakes exist as variation of supraglacial lakes, but shorter period variation are not disclosed. Therefore, in this research it is to elucidate the daily variation of supraglacial lakes.

Using field survey in 2017 and 2018 plus satellite data from the 2014-2018 period, we analyze the daily variation of supraglacial lakes on the Southern Inylchek Glacier in the central Tien Shan.

Keywords: supragracial lake, drainage, debris-covered glacier , englacial channel

Historical development of Spillway Lake on Ngozompa Glacier, Nepal

*Mohan Bahadur Chand[1], Teiji Watanabe[2], Yusuki Kobayashi[1]

1. Graduate School of Environmental Science, Hokkaido University, 2. Faculty of Environmental Earth Science, Hokkaido University

Continuous loss of glacier mass in the recent period resulted the growth of several moraine-dammed glacial lakes at the terminus of the glaciers in the Himalayan region. It increases the risk of glacier lake outburst floods with the increase in size and volume of lakes. The loss of glacier mass decreases the elevation of the glacier surface and leads to the formation of elevated moraine dam which increase the possibility for developing new glacial lakes. In this study, we document the historical development of the spillway lake on Ngozompa Glacier, Nepal using a combination of Unmanned Aerial Vehicle (UAV) photos, WorldView imageries (0.5 –2 m), and Landsat imageries. We used Landsat imageries from 1989-2018 to prepare the long-term development of the lakes. High-resolution WorldView images and UAV photos were used for accuracy assessment. We also processed the UAV photos to prepare the Digital Elevation Model to understand the possibility of future development of the lakes. We observed the three small supraglacial ponds (0.03 km^2) near the terminus of the glacier in 1989 and they have undergone rapid change in their area till 2018 (0.32 km^2), increased by more than ten times. Several supraglacial ponds are merging together to become a large lake and it will be likely to continue in the future. The further growth of the lake is dependent largely on the subaqueous melting and calving of glacier ice, and on undercutting action of lake water. Subaqueous melting of the glacier ice leads to increase of lake depth and volume of water. However, future development of the lake depends largely on the level of the outlet channel. Presence of glacier ice under the channel may continuously lower its level and drain the water from lake. Geophysical studies are needed to understand the condition of the outlet channel.

Feature analysis of the spectral of snow, ice, and water in Lake Suwa using MODIS data

*Tomohiro Nakazawa[1], Takashi Nonaka[2], Keishi Iwashita[2]

1. Department of Civil Engineering, College of Industrial Technology, Nihon University , 2. College of Industrial Technology, Nihon University

The freezing and breakup dates of the lake are important as an index of climate change. There is not enough record of freezing and breakup dates of the lakes in Japan though various publication reports are available in Europe and United States. Estimating freezing and breakup dates in Japanese lakes contributes to grasp the trend of climate change in Japan. Satellite data is expected to complement the dates of such lakes without in-situ observations.
Therefore, our study team has developed the methodology to classify the lake surface on Lake Suwa using optical satellite data. Currently, we tried to classify the lake surface into snow, ice, and water and estimate the temporal surface changes of the lake using the spectral reflectance data and the surface temperature acquired by MODIS on daily observed Terra satellite. However, we found the difficulty to distinguish thin ice and water by the difference of the surface reflectance.
The purpose of this study was to grasp the feature of reflectance of the Lake Suwa, and we used the surface reflectance data derived by MODIS in winter season mainly in 2014 and 2018. This study acquired the lake surface status referring to the newspaper articles.
From the analysis of the reflectance of each band, it showed that the variation of the reflectance between snow, ice, and water was different depending on the wavelength. The ice showed the relatively high reflectance on band 3 (visible blue) and 4 (visible green), while snow had high reflectance on band 1 (visible red) and 2 (near infrared). The water also showed the high reflectance on band 3 and 4, and classification between ice and water was difficult only by the reflectance data. This study also compared the observations derived by the spectral band values of Landsat-8, and confirmed the validity of the result.

[A-CG34] Satellite Earth Environment Observation

convener:Riko Oki(Japan Aerospace Exploration Agency), Yoshiaki HONDA(Center for Environmental Remote Sensing, Chiba University), Yukari Takayabu(Atmosphere and Ocean Research Institute, the University of Tokyo), Tsuneo Matsunaga(Center for Global Environmental Research and Satellite Observation Center, National Institute for Environmental Studies), Chairperson:Misako Kachi(Earth Observation Research Center, Japan Aerospace Exploration Agency)

In recent years, we cannot avoid facing issues on global environmental changes that occur in various spatiotemporal scales. The earth environmental observation data by satellites became the necessary basic data to tackle and solve those issues. Due to the recent advancement in the observation sensor technique and the data processing technique, the satellite observation has been showing rapid progress, and the time is changing from examining the accuracy of the observation sensor data to the advancement of the data application, leading to broaden potential users. In these days application became synergetic, so we comprehensively pick
up this topic in the Atmospheric and Hydrospheric Sciences Session of this Union Meeting that enables to comprise the atmospheric, oceanic and land sciences; by combining the intelligence and the knowledge of the party, we propose a session that aims to prompt further studies towards the issues on earth environmental change, the advancement in the data application and future plans of Earth Observation missions.

3:30 PM - 3:45 PM JST | 6:30 AM - 6:45 AM UTC

[ACG34-01] Current Status and Future Plan of the Global Change Observation Mission - Water (GCOM-W) and Advanced Microwave Scanning Radiometer 2 (AMSR2)

*Misako Kachi[1], Takashi Maeda[1], Nodoka Ono[1], Hideyuki Fujii[1], Marehito Kasahara[1], Naoto Ebuchi[1,2] (1.Earth Observation Research Center, Japan Aerospace Exploration Agency, 2.Institute of Low Temperature Science, Hokkaido University)

3:45 PM - 4:00 PM JST | 6:45 AM - 7:00 AM UTC

[ACG34-02] Testing and Evaluation for JPSS-1 Algorithms using Algorithm Development Library Block 2.1

*Bigyani Das[1,2], Weizhong Chen[1,2], Thomas S King[1,2], Walter Wolf[2] (1.IMSG, 2.STAR/NESDIS/NOAA)

4:00 PM - 4:15 PM JST | 7:00 AM - 7:15 AM UTC

*Haruhisa Shimoda[1], Toshiyoshi Kimura[2], Rei Mituhashi [2], Junpei Muruoka [2], Daisuke Sakaizawa[2], Tadashi Imai [2], Kazuhiro Asai[3] (1.Tokai University, 2.JAXA, 3.Tohoku Institute of Technology)

Current Status and Future Plan of the Global Change Observation Mission - Water (GCOM-W) and Advanced Microwave Scanning Radiometer 2 (AMSR2)

*Misako Kachi[1], Takashi Maeda[1], Nodoka Ono[1], Hideyuki Fujii[1], Marehito Kasahara[1], Naoto Ebuchi[1,2]

1. Earth Observation Research Center, Japan Aerospace Exploration Agency, 2. Institute of Low Temperature Science, Hokkaido University

The Global Change Observation Mission (GCOM) –Water (GCOM-W) is one of two medium sized satellites to provide comprehensive information of the Essential Climate Variables (ECV) of atmosphere, ocean, land, cryosphere, and ecosystem. The GCOM-W (Water) or “SHIZUKU” satellite that carries the Advanced Microwave Scanning Radiometer 2 (AMSR2), which was launched on May 2012; and GCOM-C (Climate) or “SHIKISAI” satellite that carries the Second-generation Global Imager (SGLI) and launched in December 2017. Both satellites are currently operating, and their data are distributed through the JAXA G-Portal (https://gportal.jaxa.jp/gpr/).

AMSR2 is multi-frequency, total-power microwave radiometer system with dual polarization channels for all frequency bands, and a successor of JAXA’s Advanced Microwave Scanning Radiometer for EOS (AMSR-E) on the NASA's Aqua satellite. Sensor specification of AMSR2 is almost identical to that of AMSR-E, except larger (2.0 m) antenna, additional 7.3 GHz channels to mitigate Radio Frequency Interference (RFI) and improved internal calibration. Due to its higher spatial resolution, all-weather capability, near-real-time availability and observation stability, AMSR2 data is routinely used in many operational and science applications. To provide consistent dataset between AMSR2 and AMSR-E for long-term water cycle monitoring and climate studies, we applied the latest AMSR2 algorithms and formats to AMSR-E data and have provided products through the G-Portal system. Level 1B and 1R (resampled L1B) products have been released since April 2018, and Level 2 products will be released early summer in 2019. We have also released new AMSR2 research products, Thin Ice Detection (sea ice thinner than 30 cm) and Total Precipitable Water over Land, since January 2019 through the GCOM-W Research Product Data Providing Service (https://suzaku.eorc.jaxa.jp/GCOM_W/research/resdist.html).

The GCOM-W satellite has been in extended mission phase since 2017, and we expect to operate satellite and instrument as long as possible to reduce observation gaps between AMSR2 follow-on mission, which has been in Pre-project Phase (Phase A) since September 2018.

Testing and Evaluation for JPSS-1 Algorithms using Algorithm Development Library Block 2.1

*Bigyani Das[1,2], Weizhong Chen[1,2], Thomas S King[1,2], Walter Wolf[2]

1. IMSG, 2. STAR/NESDIS/NOAA

The Joint Polar Satellite System 1 (JPSS-1) is the next generation polar-orbiting operational environmental satellite which was launched on November 18, 2017. It carries advanced versions of the instruments Advanced Technology Microwave Sounder (ATMS), Cross-track Infrared Sounder (CrIS), Ozone Mapping and Profiler Suite (OMPS) and Visible Infrared Imaging Radiometer Suite (VIIRS) that are on board of Suomi National Polar-Orbiting Partnership (S-NPP) satellite which was launched on October 28, 2011. All the Sensor Data Record (SDR) algorithms for the instruments are processed in the Interactive Data Processing Segment (IDPS) system designed and maintained by Raytheon. The Algorithm Development Library (ADL) Block 2.1 is an updated offline test system developed by Raytheon to mimic the operational system. Current version of the algorithm has gone through many recent code updates as well as Look-up-Table (LUT) updates for improving product quality. The center for Satellite Applications and Research (STAR) Algorithm Scientific Software Integration and System Transition Team (ASSISTT) uses ADL Block 2.1 to test and integrate updates to JPSS-1 algorithms, both code and the Lookup Tables (LUTs). Weekly updates are made to Dark tables for both OMPS Nadir Mapper (NM) and Nadir Profiler (NP) instruments and for both SNPP and JPSS-1 (J01) satellites. These are tested, integrated and submitted as packages with inputs, outputs and guide documents for further verification by the Data Products Engineering and Services (DPES) team and final integration by Raytheon in the operational system IDPS. Updates are also made to bi-weekly Wavelength and Solar tables for OMPS NP for SNPP satellite. They are tested and submitted in the package for operational implementation. We have created scripts to automate the staging and processing of weekly and bi-weekly updated LUTs in ADL Block 2.1. Details of the process of integration and application of the scripts for testing and integration of LUTs for OMPS as well as other instruments will be discussed.

Remote Sensing of Atmospheric and Surface Properties using Hyperspectral satellite Sensors

*Xu Liu[1]

1. NASA Langley Research Center

Hyperspectral remote sensors from satellite platforms provide high information content on clouds, atmospheric temperatures, moisture, and trace gases profiles. They also provide surface information. In order to retrieve these information from hyperspectral remote sensing data, a fast and accurate radiative transfer model and a robust inversion algorithm are needed. We will describe a Principal Component-based Radiative Transfer Model (PCRTM) and an associated non-linear inversion algorithm. The PCRTM model can provide fast and accurate top of atmosphere high spectral resolution radiance or reflectance spectra from far infrared spectral region to UV-VIS spectral region. The forward model has been used to analyse hyperspectral data such as AIRS, CrIS, IASI, and SCIAMACHY. Examples of retrieval results from some of these satellite sensors will be given.

Keywords: remote sensing, atmospheric profiles, radiative transfer

RADIOMETRIC UNIFORMITY AND STABILITY OF GROUND SITE CHARACTERIZATION FOR INSAT-3D

*Shailesh Parihar[1], R. Bhatla[1], A. K. Mitra[2]

1. Banaras Hindu University, Varanasi, India, 2. India Meteorological Department, New Delhi, India

Radiometric phenomena of Earth Observation Satellite sensors vary between ground pre-launch calibration campaign, after launch and over satellite lifetime due to launching vibration, eventual optical element misalignments, generally space harsh environment. One of vicarious calibration methods is the reflectance-based approach that is applied here to radiometric calibration of INSAT-3D visible channel. In-situ vicarious calibration method for radiometric calibration of visible (VIS 550–750 nm) sensor onboard geostationary satellite INSAT-3D has been carried out for characterizing the radiometric uniformity of the site at Bhuj, Gujarat. The measurements of ground reflectance (spectral range of 350–2500 nm), aerosol optical depth (AOD), total column ozone from Spectroradiometer (spectral range of 350–2500 nm), Sunphotometer, Ozonometer respectively and other meteorological variables were obtained from site during the field campaigns and calibration coefficients with bias and relative error for optical sensor of the INSAT-3D satellite is presented. Based on these measurements, simulations of radiance reaching at top of the atmosphere (TOA) were carried out using radiative transfer model 6S (Second Simulation of the Satellite Signal in the Solar Spectrum). The computed TOA radiances when compared with the sensor measured radiances for various dates and sites show an over-estimation of TOA radiance. The analysis suggested that Bhuj site has been preferred for post launch vicarious calibration of optical sensor of INSAT-3D satellite as well as upcoming geostationary INSAT satellite series.

Vicarious calibration activities of ASTER Thermal Infrared Radiometer (TIR) for Earth environmental observation

*Satoru Yamamoto[1], Hideyuki Tonooka[2], Soushi Kato[3], Kazuki Ayuzawa[2], Tsuneo Matsunaga[4]

1. Japan Space Systems, 2. Ibaraki University, 3. Remote Sensing Technology Center of Japan, 4. National Institute for Environmental Studies

The Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) instrument on the Terra satellite has been retrieving multiband images with 14 spectral bands from the visible through thermal infrared and stereo images over the Earth's surface since 2000. The data set by ASTER has provided the composition and distribution of materials, temperature/emissivity map, and digital elevation topography models (DEM), contributing to a variety of Earth's science applications, i.e., natural resources, agricultural applications, natural disasters, geology, and urban development as well as monitoring global environmental change. In addition, the data of ASTER is being used for space business involved in space-enabled economic activity and service.

In order to establish the ASTER data for high-accuracy applications, radiometric calibration and atmospheric correction are highly important. Since any optical sensor is expected to degrade in space, we need to monitor the performance of the sensor over time based on onboard and vicarious calibrations. One of vicarious calibration approaches characterizes instrument performance based on comparison with the data measured by field campaigns at homogeneous ground areas such as lake and desert sites. The field campaigns for ASTER took place at various test sites such as Railroad Valley Playa, Lunar Lake, and Alkali Lake in Nevada and water sites such as Lake Kasumigaura in Japan during about two decades.

On 30 August through 1 September 2018, as part of annual vicarious calibrations for ASTER Thermal Infrared Radiometer (TIR), we conducted the field campaigns at Railroad Valley playa and Alkali Lake in Nevada. We also made the vicarious calibration at Lone Mountain playa in Nevada, which is a new test site discovered during this campaign. In this presentation, we will report the activity of the 2018's field campaigns at Nevada, and discuss how important the radiometric calibration after launch is to Earth's science applications including assessment of global environmental change based on satellites.

Overview of Vegetation Lidar MOLI

*Haruhisa Shimoda[1], Toshiyoshi Kimura[2], Rei Mituhashi [2], Junpei Muruoka [2], Daisuke Sakaizawa[2], Tadashi Imai [2], Kazuhiro Asai[3]

1. Tokai University, 2. JAXA, 3. Tohoku Institute of Technology

Under the PARIS AGREEMENT (Adopted at COP 21 in 2015), each country, including developing countries, is obliged to declare its emissions, but an objective verification method was considered necessary from the perspective of credibility and accuracy. It is said that one of the largest errors today is in the evaluation of CO_2 absorption by forests. Regarding the assessment of forests as a CO_2 absorption source, biomass and the change of biomass observed. We propose the use of airborne and satellite-mounted LIDAR as an effective method of directly measuring tree height. JAXA has begun studying the space vegetation LIDAR mission using the Multi-footprint Observation Lidar and Imager (MOLI) in collaboration with scientists. The main objective of this mission is to globally and precisely measure canopy height from space for improving biomass estimation. MOLI is designed to be mounted on the Exposed Facility (EF) of the Japanese Experiment Module on the International Space Station (ISS). The mission requirements for MOLI were set through discussions with scientists, and are listed as follows:

1. MOLI measures canopy height globally with accuracy of ±2 m (for canopy height less than 20 m) or ± 10% (for canopy height above 20 m) so as to generate map data of canopy heights and biomass, combined with imagery data from other satellites. The measurement data are also used as inputs or for validation in carbon cycle models.

2. Simultaneously, MOLI also measures the vegetation index and vegetation phenology for generating more accurate map data of canopy height and biomass.

3. MOLI measures the average amount of carbon per sub-national-scale area (80 km grid) to an uncertainty level of 20% or less (95% confidence interval).

The system requirements for MOLI are set based on the mission requirements. Regarding the waveform generated by the Geoscience Laser Altimeter System (GLAS) installed in the ICESat. However, waveforms with a lower S/N (less than 10) were excluded from analysis, as it greatly reduced the accuracy of canopy height measurement. Based on this result, the S/N requirement of MOLI was set to 10 or more, and the measurement precision of canopy height reached ±2 m or 10 %.

The tilted ground causes significant errors in measuring the canopy height due to the difference in height of the ground in the footprint. MOLI must be able to detect the inclination of the ground in order to estimate the difference in height of the footprint ground. Thus, MOLI must have a multi-footprint to estimate the tilt of the ground surface by detecting the time lag of each footprint.

Since MOLI needs to acquire data on vegetation phenology and vegetation index at the same time as the LIDAR observation to generate map data, it also has an optical imager with multiple bands. Using the imager, MOLI also measures the canopy height to identify the trees observed by MOLI for ground verification. The imager GSD is 5m. The imager also has green, red and NIR bands for measuring vegetation phenology and vegetation index.

©2019. Japan Geoscience Union. All Right Reserved.

To realize the sampling design, it is necessary to irradiate two laser beams and receive two reflection signals with the array detector. We considered dividing the laser beam into two laser beams by using an optical system. Based on this method, one laser transmitter is attached and the pulse energy is 40 mJ

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-CG Complex & General

Wed. May 29, 2019 10:45 AM - 12:15 PM JST | Wed. May 29, 2019 1:45 AM - 3:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_6

[A-CG35] Projection and detection of global environmental change

convener:Michio Kawamiya(Japan Agency for Marine-Earth Science and Technology), Hiroaki Tatebe(Japan Agency for Marine-Earth Science and Technology), Kaoru Tachiiri(Japan Agency for Marine-Earth Science and Technology)

Anthropogenic forcings on global environment are expected to cause intensification of extreme events, sea level rise, ocean acidification and deoxygenation, as well as large-scale ecosystem changes. The CMIP6 experimental protocol has been established based on which modeling groups across the world are starting to provide environmental projection data toward 6th IPCC assessment report due in 2021. Various new types of studies, such as event attribution and coupling of socio-economic processes and Earth system dynamics, are also emerging in the field of global change projection. In addition, observational studies are becoming increasingly more important for grasping changes in the global environment and evaluating model projections. Interactions and collaborations beyond boundaries of conventional scientific disciplines are desired for dealing with the issue of global changes. This session thus aims to deepen our understanding on global change, from both disciplinary and interdisciplinary viewpoints. This session is co-organized by AIMES - Future Earth project "Analysis, Integration and Modelling of the Earth System" (https://aimesproject.org/).

World Regionalization of Climate Change (1961–2010)

*Shao Sun[1,2], Peijun Shi[2,3,4], Daoyi Gong[2], Tao Zhou[2]

1. National Climate Center, China Meteorological Administration, Beijing 100081, China, 2. State Key Laboratory of Earth Surface Processes and Resource Ecology, Beijing Normal University, Beijing 100875, China, 3. Key Laboratory of Environmental Change and Natural Disaster of Ministry of Education, Beijing Normal University, Beijing 100875, China, 4. Academy of Disaster Reduction and Emergency Management, Ministry of Civil Affairs & Ministry of Education, Beijing 100875, China

Existing climate regionalization aims to characterize the regional differences in climate based on years of the mean values of climate indices. However, with the accelerating climate change nowadays, existing climate regionalization cannot represent the regional difference of climate change, nor can it reflect the extreme weather and climate disasters and environmental risks incurred from climate changes. This paper utilizes the tendency value and fluctuation value of temperature and precipitation from 1961 to 2010 to identify the climate change quantitatively, and completes world regionalization of climate change (1961–2010) with administrative subdivisions of countries as the basic unit in combination with world's terrain feature. Level-I regionalization divides world's climate change (1961–2010) into twelve tendency zones based on the tendency of temperature and precipitation; level-II regionalization refers to twenty-eight fluctuation regions based on level-I regionalization according to the fluctuation of temperature and precipitation. Climate change regionalization provides a basis for countries and regions in the world to develop plans for adapting to climate change, especially for managing extreme weather and climate disasters and environmental risks.

Quantifying and identifying future climate signal, noise, and internal variability at finer temporal scales

*Jongho Kim[1], Manh Van Doi[1]

1. University of Ulsan

Quantifying and identifying climate internal variability (CIV) plays an important role in climate change studies because of its irreducible and unpredictable characteristics. A large number of studies have addressed such an issue; however, the issue was only resolved at coarser resolution on the first order moments of few climate variables. Our recent study has estimated CIV of climate variables for a “current” period at finer spatial and temporal scales; however, whether CIV will change or remain constant in the future under the impact of representative concentration pathways (RCP45 and RCP85) is still questionable. To investigate how CIV will change in the future in both spatial pattern and magnitude, CIV is assessed over 30-year periods in both current and future periods with two scenarios in Korea by analyzing an ensemble of 100 simulations generated by an hourly weather generator. In this study, signal to noise ratio (SNR) used to evaluate the model performance will be applied to simulating ensemble for different periods. CIV is then estimated by two methods: “detrended” and “differenced”; SNR is estimated by “analysis of variance” and “trend analysis” methods. Both SNR and CIV are evaluated with four proposed matrices signifying rainfall volume, extremes and occurrence of rainfall. To consider the change of CIV in the future periods, t-test (test for mean difference) and f-test (test for variance difference) are applied to the ensemble of CIV. In this study, analyzing SNR’s values shows that the four proposed matrices are controlled by non-linear stochastic process and the change tend to increase in the future with increase of CO2 concentration. CIV is proved to change in the future periods under impact of CO2 scenarios. Spatial distribution of CIV’s change over future periods of which locations provides the important and useful information for decision making of water resources planning and proposing mitigation measures of disaster protection.

Basic evaluation of MIROC6 and current status of CMIP6 experiments

*Hiroaki Tatebe[1]

1. Japan Agency for Marine-Earth Science and Technology

The sixth version of the Model for Interdisciplinary Research on Climate (MIROC), called MIROC6, was cooperatively developed by a Japanese climate modeling community. Overall reproducibility of mean climate and internal climate variability in MIROC6 is better than that in the previous version (MIROC5). The tropical climate systems (e.g., summertime precipitation in the western Pacific and the eastward propagating Madden-Julian Oscillation) and the mid-latitude atmospheric circulations (e.g., the westerlies, the polar night jet, and troposphere-stratosphere interactions) are significantly improved in MIROC6. These improvements can be attributed to the newly implemented parameterization for shallow convective processes and to the directly resolved stratosphere. In the present study, simulated mean climate, internal climate variability in MIROC6 are evaluated and briefly summarized in comparison with MIROC5 and observations. Using MIROC6, designated simulations tackling a wide range of climate science issues, as well as seasonal-to-decadal climate predictions and future climate projections, are currently ongoing with an aim towards contributing to the sixth phase of the Coupled Model Intercomparison Project (CMIP6). Preliminary results of historical climate simulations from the middle of the 19th century, climate projections from the present to the end of the 21th century based on future scenarios of the Shared Socio-economic Pathways, and initialized climate predictions on seasonal-to-decadal timescales will be given in this talk.

Synchronized increase of extreme cold and warm events in China during the recent global warming slowdown

*Xiubao Sun[1,3], Chunzai Wang[1], Guoyu Ren[2,3], Panfeng Zhang[2]

1. State Key Laboratory of Tropical Oceanography (LTO), South China Sea Institute of Oceanology(SCSIO), Chinese Academy of Sciences (CAS), 2. Department of Atmospheric Science, School of Environmental Studies, China University of Geosciences (CUG), 3. Laboratory for Climate Studies, National Climate Center (NCC), China Meteorological Administration (CMA)

From the end of 1990s to the middle of 2010s, global mean temperature experienced a process of warming slowdown. However, global warm extremes did not show the slowdown phenomenon during the recent global warming slowdown. Based on the observation data of 2362 land surface stations in China, we analyzed the cold and warm extremes changes over mainland China between global warming period (1961-1999) and warming slowdown period (2000-2014). Results indicate that the warming trend in the cold season (MAM and DJF) is significantly higher than that in the warm season (JJA and SON) in the period of global warming (1961-1999), while the warming trend in the warm season is significantly higher than that in the cold season in the period of global warming slowdown. That is, the trend of warm season and the cool season in China have reversed. At the same time, we also found that the synchronous increase occurrence of extreme warm events in summer (JJA) and extreme cold events in winter (DJF) leads to the seasonal trend reverse phenomenon, but there are differences in the spatial variation characteristics between cold and warm extremes. The increase of warm extremes in summer is mainly due to the strong increase of warm events in south China, while the increase of cold events in winter is due to the increase of cold events over China. Further, we also found that the variability of extreme temperature has increased more significantly in the warming slowdown period than that in global warming period. East Asian winter monsoon and summer monsoon both show enhanced characteristics during the global warming slowdown period, which indicates that the increase of sea-land temperature difference in summer and winter results in the synchronous increase of extreme cold and warm events by increasing the climate variability in China.

Quantification of thermodynamical and dynamical contributions to the anthropogenic influences on tropical cyclone rainfall extremes

*Cheng-Ta Chen[1], Shih-How Lo[1], Chung-Chieh Wang[1], Kazuhisa Tsuboki[2]

1. Department of Earth Sciences, National Taiwan Normal University, 2. Hydrospheric-Atmospheric Research Center, Nagoya University

The rainfall extremes and strong winds associated with tropical cyclones lead to significant damages and lost to where they make landfalling. Upward trend in term of financial lost was indicated for the past few decades from the report of major reinsurance firms. Whether the past anthropogenic warming played a significant role in such extreme event and their changes remained very controversial. On one hand, people argue it’s nearly impossible to attribute an individual extreme event to global warming. On the other hand, the increase of heavy rainfall is consistent with the expected effects of climate change on tropical cyclone. To diagnose possible anthropogenic contributions to the odds of heavy rainfall associated with tropical cyclone, we adapt an existing event attribution framework of modeling a ‘world that was’ and comparing it to a modeled ‘world that might have been’ for that same time but for the absence of historical anthropogenic drivers of climate. One limitation for applying such approach to high-impact weather system is that it will require models capable of capturing the essential processes lead to the studied extremes. Using a cloud system resolving model that can properly simulate the complicated interactions between tropical cyclone, large-scale background, topography, we first perform the ensemble ‘world that was’ simulations forced by the high resolution ECMWF YOTC analysis. We then re-simulate with the adjusted ‘world that might have been conditions’ by removing the regional atmospheric and oceanic forcing due to human influences estimated from the CMIP5 model ensemble mean conditions between all forcing and natural forcing only historical runs. Thus our findings are highly conditional on the driving analysis and adjustments therein, but the setup allows us to elucidate possible contribution of anthropogenic forcing to changes in the likelihood of heavy rainfall associated tropical cyclone. With only less than half of degree anthropogenic warming over the study area, we found that this forcing very likely (9 out of 10 cases) increase the risk of heavy rainfall event (grid rainfall greater than 33 mm per hour) by at least 16%. The role of dynamical processes that leads to precipitation extreme increases beyond the moisture content increase will be further analyzed and discussed.

Temporal Evolution of the Long-Term Distributional Biases of Climate Models as a Parameter for the Regional Evaluation of the Simulation of Climate Change

*Martin Gomez-Garcia[1], Akiko Matsumura[1], Shiro Hishinuma[1], Daikichi Ogawada[1]

1. Nippon Koei Co. Ltd., Reasearch and Development Center

Owing to the climate variability of the General Circulation Models (GCM), the discrepancy between their outputs and observational datasets at scales that range from hours to years is practically random. Thus, the associated errors need to be evaluated in terms of the long-term (multidecadal) distributional properties of the atmospheric variables. A recently developed bias-correction method corrects the systematic errors (i.e., biases) in the climate mean state and in three distributional measures of the daily and the interannual variability (namely the frequency of extremes, the skewness, and the scale of the variable at each timescale). The adjustment of these biases is done in such a way that the corrections at one timescale do not affect the probability distribution at another. Therefore, this bias-correction method is able to preserve the GCM-simulated climate trends and extensively reproduce the long-term frequency of the observed extreme weather (e.g. 98th percentile of wet days, maximum seasonal mean of surface temperature).

Generally, the bias-correction of GCMs faces the challenge of including the simulated changes of climate, which supposes alterations in not only the mean but also other aspects like the skewness and the frequency of extremes. The abovementioned bias-correction method includes the effect of the simulated climate change in the correction of the distributional biases. However, considering the coarse resolution of the GCMs and the imperfections in the parameterizations of the subgrid physical processes, the fundamental assumption that the distributional biases are predictable (i.e., stationary) is made.

In this study, we explored the possibility of evaluating the sensibility with which GCMs simulate the response of the earth-system components to external forcing (i.e., climate change) by comparing the temporal evolution of the distributional biases at different timescales over specific regions. For the short period in which the observed data was available, our results revealed that many CMIP5 GCMs are indeed able to simulate with a quasi-stationary bias the changes caused by climate change. Moreover, being able to identify the regions in which certain models do not show the errors with a systematic behavior in either the climate mean state, the daily variability or the interannual variability can be useful for the further development of climate models. We expect that with the data of the GCM outputs of the future phases of the CMIP project, the period in which the observed and the modeled data coincide becomes longer and, thus, our conclusions can be supported by more robust evidence.

A global simulation of bioenergy crop yield

*Zhipin Ai[1], Naota Hanasaki[1]

1. National Institute for Environmental Studies

Large-scale development of bioenergy is considered as an effective pathway to achieve the 2 degrees target of the Paris Agreement. To avoid the competition with food crops, so-called the second-generation bioenergy crops such as miscanthus and switchgrass are regarded as potential dedicated biomass crop. However, the models to estimate the yield of miscanthus and switchgrass at a global scale which enable analyzing the effects of irrigation water application are seldom seen as of today. Here, we firstly updated the crop module in the global hydrological model H08 for miscanthus and switchgrass. Then, we conducted a global simulation and validation of the yield for miscanthus and switchgrass at 0.5 degree. The results indicated that the updated H08 have a good ability in simulating the yield of perennial bioenergy crops, which provides a good foundation for further integrated assessment of the impacts of bioenergy crop production on water sector.

Integrated Research Program for Advancing Climate Models - Theme B: national research program in Japan on earth system modeling

*Michio Kawamiya[1], Tomohiro Hajima[1], Kaoru Tachiiri[1], Jun'ichi Tsutsui[2], Tokuta Yokohata[3], Takashi Arakawa[4], Takahiro Inoue[4]

1. Japan Agency for Marine-Earth Science and Technology, 2. Central Research Institute of Electric Power Industry, 3. National Institute for Environmental Studies, 4. Research Organization for Information Science and Technology

The Integrated Research Program for Advancing Climate Models, or TOUGOU (abbreviation taken from its Japanese name), is a national project for projection of global change. Its aim to provide information for adaptation and mitigation, based on scientific evaluation of changes including those in extreme events and carbon cycle. The project was launched in April, 2017. While the entire program deals with a wide range of physical aspects and consequent impacts of climate change, Theme B (TOUGOU-B) focuses on the development of a state-of-the-art Earth system model (ESM) incorporating biogeochemical processes, such as sophisticated carbon and nitrogen cycles, as well as its application to exploring future socio-economic pathways of climate change mitigation. MIROC-ESM, an ESM developed under TOUGOU-B (and the previous SOUSEI-B) has been significantly improved since the 5th phase of coupled model intercomparison project (CMIP5), and has started to be run for CMIP6. During the three years since TOUGOU was launched, results have been obtained that may contribute to 6th Assessment Report (AR6) of Intergovernmental Panel on Climate Change (IPCC) including those on impacts of pyrogenic iron on oceanic ecosystem, assessment of the outcome of labor productivity change due to warming, and effects of high dust amount on surface temperature during the Last Glacial Maximum. Besides, efforts to secure ways to disseminate projection data are ongoing under TOUGOU-B. Specifically, collaboration has been established between climate modeling community in Japan and Data Integration and Analysis System (DIAS), a national IT project for environmental data, have been continuing, in order for Japan to participate in Earth System Grid Federation (ESGF). ESGF is an international cooperative activity to construct a data distributing system for climate related data such as CMIP6 outputs. Some of the details of these results will be explained in the presentation.

Towards probabilistic climate projections based on the CMIP6 multi-model ensemble

*Junichi Tsutsui[1]

1. Central Research Institute of Electric Power Industry

Research on climate change mitigation uses a climate model emulator that represents the average and range over a specific multi-model ensemble of complex climate simulations. The Coupled Model Intercomparison Project (CMIP) has provided such multi-model ensembles, and its latest Phase 6 (CMIP6) results are being revealed. As a first step to applying the CMIP6 results to probabilistic climate projections, we focus on the distribution of key parameters representing atmospheric CO_2-induced forcing and transient temperature responses.

In this study, we develop a procedure to determine the forcing-response parameters of a complex climate model. We simultaneously fit a curve built on an impulse response function to the global mean time series of the model's surface temperature anomaly and top-of-atmosphere energy imbalance from two basic CO_2 -forced experiments, i.e., an abrupt quadrupling and a 1%-per-year increase in atmospheric CO_2 concentration. This scheme serves as an improved alternative to the widely-used regression method of Gregory et al. (2004). Furthermore, it makes a complete set of parameters to emulate the target model from which equilibrium climate sensitivity (ECS) and transient climate response (TCR) are derived. The properties of a multi-model ensemble are quantified through a statistical approach including a principal component analysis for the parameters.

The two CO_2-forced experiments are included in the set of common experiments which is designed to maintain continuity across different CMIP phases. Here, we compare the parameters of individual CMIP6 models with those of the previous-phase CMIP5 models. The parameters of the CMIP5 ensemble have several features. The ratio of TCR to ECS is distributed in the range of approximately 0.5 to 0.7, and for models with large ECS, the ratio tends to decrease. The scaling parameter for the effective radiative forcing of CO_2 varies from model to model and tends to be less than a reference value used in a conventional formula of CO_2 radiative forcing. Although the number of CMIP6 models is currently limited, their parameters show similar distributions within the CMIP5 ranges.

Effect on the earth system of realizing 1.5 degree climate target by overshooting after reaching 2 degree level

*Kaoru Tachiiri[1], Herran Diego Silva[2], Xuanming Su[1], Michio Kawamiya[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Institute for Global Environmental Strategies

By using an Earth system model (ESM) with emissions and land use scenarios consistent with socio-economic projections from an integrated assessment model, the effect of overshooting to 1.5 degree target (in Celsius from pre-industrial periods) after reaching 2 degree level is investigated in selected indicators of the global environment. Unlike the internationally coordinated model intercomparison project, the scenario is developed for a specific climatic model. The ESM output results in delayed achievements for both of 1.5 and 2 degree targets in terms of global surface mean air temperature, but achieved before or around 2100 as expected when we use global mean surface temperature (for which sea surface temperature and surface air temperature are used for ocean and land, respectively) masked with observation areas. In the overshooting scenario more heat is absorbed by the ocean compared to a case without overshooting, but still we found significant difference between the two scenarios in Arctic sea ice, while in both scenarios corals seem difficult to survive the 21st century (when no thermal adaptation is assumed) . The difference in steric sea level rise between the scenarios is only below 2 cm in 2100. In addition, vegetation productivity in broad regions shows slight (~5%) increase. Emission pathways in the scenarios rely on a large amount of carbon sequestration. In the 2 degree scenario CO2 emissions in 2100 are slightly below zero, while for 1.5 degree scenario they are below -20 GtCO2.. When the Earth system has high climate sensitivity and TCRE, to reach the 1.5 degree target we need to take an overshooting temperature pathway, but in case the overshooting is large, difference in some indicators between 1.5 degree and 2 degree scenarios can be non-significant, which is an important indication in implementing adaptive mitigation in the coming decades.

Historical regional and sectoral contributions to climate change

*Xuanming Su[1], Kaoru Tachiiri[1], Katsumasa TANAKA[2], Michio Watanabe[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Institute for Environmental Studies

Regional or sectoral contributions to climate change are important in the formulation of climate change policy. After the industrial revolution, developed countries emit CO_2 and non-CO_2 greenhouse gases (GHGs), and the historical emissions are large; while developing countries contribute relative fewer emissions in historical period but increase significantly in recent years or visible future. To assess the contributions to climate change, using cumulative emissions is a general and direct method. However, such method may ignore the lifetime of GHGs since part of the GHGs sink into the biosphere, ocean, soil or diminish during biogeochemical cycles. In this study, we evaluate the historical regional and sectoral contributions to climate change by using an improved version of Simple Climate Model for OPTimization (SCM4OPT) with a normalized marginal method. Based on the results, we analyze ten major GHG emitting countries and 12 sectors.

First, current emissions with relative long lifetime like CO_2 and N_2O, from developing countries increase significantly, like China, India, Mexico and Brazil, however, their contributions to climate change are still relatively smaller, compared with the developed countries such as USA, Japan, Germany, Canada and UK, of which countries the cumulative emissions are in relatively larger scale and current emissions are already under controlled. We can conclude here that the GHGs with relatively long lifetime need to be controlled stringently to reduce the long-term effects on climate change. For CH_4, which has a relatively shorter lifetime, the contributions to climate change are closely related to emissions within recent decades. These imply that reductions on short lifetime emissions can make immediate alleviation regarding climate change.

Second, energy sector contributes most of the CO_2 emissions, and therefore contribute almost half to the climate change among all the sectors. However, for CH_4 and N_2O, agriculture sector contributes most of the emissions and therefore their contributions to climate change are remarkable. Reduction policiesneed to targetthesesectors. In addition, CO_2 from land transportation and CH_4 from waste treatment increase rapidly in recent years, attention also needs to be paid to these sectors for making climate change policies.

Future projection of global climate, water, food, bio-energy, and land investigated with MIROC-INTEG: a global bio-geophysical land surface model with human components

*Tokuta Yokohata[1], Yusuke Satoh[1], Tsuguki Kinoshita[2], Gen Sakurai[3], Yadu Pokhrel[4], Akihiko Ito[1], Etsushi Kato[5], Masashi Okada[1], Naota Hanasaki[1], Tomoko Nitta[6], Seita Emori[1]

1. National Institute for Environmental Studies, 2. Ibaraki University, 3. National Agriculture and Food Research Organization, 4. Michigan State University, 5. The Institute of Applied Energy, 6. University of Tokyo

Future climate changes possibly affect water resources, food production, energy supply, and ecosystem services. It is critical to better understand the interactions between the changes in these complicated factors. While earth system models and integrated assessment models are applicable to explore this topic, parts of their natural and/or human processes tend to be simplified depending on their scope. As such, it still remains a challenge to realistically model the human-natural interface. In this context, the MIROC integrated terrestrial model (MIROC-INTEG) was developed. One of the features of MIROC-INTEG is that the natural ecosystem and human activity models are coupled to a global land surface model MATSIRO (Nitta et al. 2014, Journal of Climate), which is a component of a state-of-the-art global climate model, MIROC (Watanabe et al. 2010, Journal of Climate). As a natural ecosystem model, we use a global vegetation model, VISIT (Ito and Inatomi 2012, Biogeosciences). As human activity models, we use a global land-surface model with anthropogenic water regulation modules, HiGW-MAT (Pokhrel et al, 2012, Journal of Hydrometeorology), and a global crop model, PRYSBI2 (Sakurai et al, 2014, Scientific Reports). In HiGW-MAT, models of human water regulations such as water withdrawal from river, dam operation, and irrigation (Hanasaki et al. 2008, Hydrol. Earth Syst. Sci.) are incorporated to the above-mentioned global land surface model, MATSIRO. In PRYSBI2, the growth and yield of four crops (wheat, maize, soybean, rice) are calculated. In addition to these models, a global land use model (Terrestrial Land-use Model, TeLMO) is newly developed in the present study. TeLMO calculate the grid ratio of cropland (food and bio-energy crops), pasture, forest (managed and un-managed), as well as their transition. Output variables of each sub-model are passed to other sub-models during the time integration.
We will present an analysis of historical and future simulations with a focus on the interactions between water, food, energy, and land. In the historical simulations, we validated the model output such as irrigated water, crop yield, ecosystem productions, and cropland area by comparing to the observed or reanalysis data. In the future simulations, we investigated the role of uncertainties in climate (Representative Concentration Pathways) and socio-economic (Shared Socio-economic Pathways) scenarios. We also investigate the role of uncertainties in model parameters, and found that an uncertainty in the fertilization effect of crop growth model PRYSBI2 strongly affect uncertainty in future projection of crop yield and land use change in TeLMO. We found that future changes in precipitation and/or temperature possibly cause decrease in soil moisture, leading to decreases in crop yield (especially in high emission scenario such as RCP8.5). Decrease in crop yield bring about increase in crop land area, which also causes the increase in irrigation demands. Interaction between water, crop yield, and land use, as well as possible impacts on ecosystem service will be discussed in the presentation.

Downscaling a global agricultural land use model to country level for national SSP analysis

*Wenchao Wu[1], Tomoko Hasegawa[1], Kiyoshi Takahashi[1], Shinichiro Fujimori[2]

1. National Institute for Environmental Studies, 2. Kyoto Univ.

The Shared Socioeconomic Pathways (SSPs) has been part of latest scenario framework developed by the climate change research society in the recent decade, serving the integrated analysis of future climate impacts, vulnerabilities, adaptation, and mitigation, in which the agriculture, food system and land use are important components. Multiple integrated assessment models (IAMs) have been used for the quantitative projections of future agriculture, food system and land use in the global scale. However, the tool and application of IAMs to the quantification of SSPs on regional or national level is limited. Meanwhile, there are growing needs for the quantification of SSPs on regional or national level for a more detailed understanding of agriculture, food, and land use, and their interactions with other nexus, such as energy, water, and biodiversity. One obstacle for such application is the coarse spatial resolution of global IAMs for land use module. This study aims to apply the Asian-Pacific Integrated Model/Platform for Land-Use and Environmental Model (AIM/PLUM) for the quantification of agriculture, food system, and land use in Japan under its national-specific SSPs narratives. To achieve this, a regional land use model, AIM/PLUM-Japan, was developed, by improving the spatial resolution to 0.05˚ (targeting 1km) from global model of 0.5˚. We combined the statistical production area data and spatial land use data to produce a refined base crop map. Agricultural land use could be downscaled to 0.05˚ resolution and gridded agricultural land use information could be generated using this model. Aside from providing quantitative land use information for Japan’ s SSPs, this study also contributes to the IAMs and SSPs societies by testing the applicability and feasibility of global IAMs, especially land use models, to the regional or national extension. For example, regional (national) SSPs quantifications for other regions could be easily implemented by a similar paradigm using AIM/PLUM.

Extreme Events and Emergent Trends in Marine Ecosystem Stressors under a historical/RCP8.5 Climate Change Pathway

*Keith Bradley Rodgers[1,2], Sarah Schlunegger[3], Richard Slater[3], Burke Hales[4], Axel Timmermann[1,2]

1. IBS Center for Climate Physics, Busan, South Korea, 2. Pusan National University, Busan, South Korea, 3. AOS Program, Princeton University, Princeton NJ, USA, 4. College of Ocean and Atmospheric Sciences, Oregon State Universitym, Corvallis, OR, USA

It is important to identify the degree to which climate change will impact ocean ecosystems over the 21st century. Over the last decade there has been increasing application of Earth System Models (ESMs) to project changes in ecosystem stressors (acidification, warming, and de-oxygenation) with a focus on surface and/or thermocline-integrated conditions. Recent efforts have made combined use of CMIP5 models, large ensemble simulations, and/or scenario sensitivity experiments to estimate uncertainties in future projections. Nevertheless very little to date has been done to evaluate how the frequency of extreme events with ecosystem stressors will respond to future climate perturbations. Here we consider for an ensemble suite of simulations with GFDL's ESM2M changes in the frequency of marine ecosystem extreme events over the 21stcentury. We focus on the contrast between the behavior at the ocean's surface vs. base of the ocean's euphotic zone, as these are both important horizons for ocean ecosystems, and on the contrast between the Time of Emergence of decadal trends vs. frequency changes of extreme events, as these are both important ecological timescales. Particular attention is devoted to acidification at the base of the euphotic zone, as this pertains to the life cycle of pteropods. Preliminary results indicate that in addition to the subpolar Northern Oceans and the Southern Ocean, the Large Marine Ecosystems (LME) regions of the eastern Pacific become increasingly exposed to corrosive waters over the 21stcentury.

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-CG Complex & General

Wed. May 29, 2019 5:15 PM - 6:30 PM JST | Wed. May 29, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_16

[A-CG35] Projection and detection of global environmental change

convener:Michio Kawamiya(Japan Agency for Marine-Earth Science and Technology), Hiroaki Tatebe(Japan Agency for Marine-Earth Science and Technology), Kaoru Tachiiri(Japan Agency for Marine-Earth Science and Technology)

Anthropogenic forcings on global environment are expected to cause intensification of extreme events, sea level rise, ocean acidification and deoxygenation, as well as large-scale ecosystem changes. The CMIP6 experimental protocol has been established based on which modeling groups across the world are starting to provide environmental projection data toward 6th IPCC assessment report due in 2021. Various new types of studies, such as event attribution and coupling of socio-economic processes and Earth system dynamics, are also emerging in the field of global change projection. In addition, observational studies are becoming increasingly more important for grasping changes in the global environment and evaluating model projections. Interactions and collaborations beyond boundaries of conventional scientific disciplines are desired for dealing with the issue of global changes. This session thus aims to deepen our understanding on global change, from both disciplinary and interdisciplinary viewpoints. This session is co-organized by AIMES - Future Earth project "Analysis, Integration and Modelling of the Earth System" (https://aimesproject.org/).

World Regionalization of Climate Change (1961–2010)

*Shao Sun[1,2], Peijun Shi[2,3,4], Daoyi Gong[2], Tao Zhou[2]

1. National Climate Center, China Meteorological Administration, Beijing 100081, China, 2. State Key Laboratory of Earth Surface Processes and Resource Ecology, Beijing Normal University, Beijing 100875, China, 3. Key Laboratory of Environmental Change and Natural Disaster of Ministry of Education, Beijing Normal University, Beijing 100875, China, 4. Academy of Disaster Reduction and Emergency Management, Ministry of Civil Affairs & Ministry of Education, Beijing 100875, China

Existing climate regionalization aims to characterize the regional differences in climate based on years of the mean values of climate indices. However, with the accelerating climate change nowadays, existing climate regionalization cannot represent the regional difference of climate change, nor can it reflect the extreme weather and climate disasters and environmental risks incurred from climate changes. This paper utilizes the tendency value and fluctuation value of temperature and precipitation from 1961 to 2010 to identify the climate change quantitatively, and completes world regionalization of climate change (1961–2010) with administrative subdivisions of countries as the basic unit in combination with world's terrain feature. Level-I regionalization divides world's climate change (1961–2010) into twelve tendency zones based on the tendency of temperature and precipitation; level-II regionalization refers to twenty-eight fluctuation regions based on level-I regionalization according to the fluctuation of temperature and precipitation. Climate change regionalization provides a basis for countries and regions in the world to develop plans for adapting to climate change, especially for managing extreme weather and climate disasters and environmental risks.

Quantifying and identifying future climate signal, noise, and internal variability at finer temporal scales

*Jongho Kim[1], Manh Van Doi[1]

1. University of Ulsan

Quantifying and identifying climate internal variability (CIV) plays an important role in climate change studies because of its irreducible and unpredictable characteristics. A large number of studies have addressed such an issue; however, the issue was only resolved at coarser resolution on the first order moments of few climate variables. Our recent study has estimated CIV of climate variables for a “current” period at finer spatial and temporal scales; however, whether CIV will change or remain constant in the future under the impact of representative concentration pathways (RCP45 and RCP85) is still questionable. To investigate how CIV will change in the future in both spatial pattern and magnitude, CIV is assessed over 30-year periods in both current and future periods with two scenarios in Korea by analyzing an ensemble of 100 simulations generated by an hourly weather generator. In this study, signal to noise ratio (SNR) used to evaluate the model performance will be applied to simulating ensemble for different periods. CIV is then estimated by two methods: “detrended” and “differenced”; SNR is estimated by “analysis of variance” and “trend analysis” methods. Both SNR and CIV are evaluated with four proposed matrices signifying rainfall volume, extremes and occurrence of rainfall. To consider the change of CIV in the future periods, t-test (test for mean difference) and f-test (test for variance difference) are applied to the ensemble of CIV. In this study, analyzing SNR’s values shows that the four proposed matrices are controlled by non-linear stochastic process and the change tend to increase in the future with increase of CO2 concentration. CIV is proved to change in the future periods under impact of CO2 scenarios. Spatial distribution of CIV’s change over future periods of which locations provides the important and useful information for decision making of water resources planning and proposing mitigation measures of disaster protection.

Basic evaluation of MIROC6 and current status of CMIP6 experiments

*Hiroaki Tatebe[1]

1. Japan Agency for Marine-Earth Science and Technology

The sixth version of the Model for Interdisciplinary Research on Climate (MIROC), called MIROC6, was cooperatively developed by a Japanese climate modeling community. Overall reproducibility of mean climate and internal climate variability in MIROC6 is better than that in the previous version (MIROC5). The tropical climate systems (e.g., summertime precipitation in the western Pacific and the eastward propagating Madden-Julian Oscillation) and the mid-latitude atmospheric circulations (e.g., the westerlies, the polar night jet, and troposphere-stratosphere interactions) are significantly improved in MIROC6. These improvements can be attributed to the newly implemented parameterization for shallow convective processes and to the directly resolved stratosphere. In the present study, simulated mean climate, internal climate variability in MIROC6 are evaluated and briefly summarized in comparison with MIROC5 and observations. Using MIROC6, designated simulations tackling a wide range of climate science issues, as well as seasonal-to-decadal climate predictions and future climate projections, are currently ongoing with an aim towards contributing to the sixth phase of the Coupled Model Intercomparison Project (CMIP6). Preliminary results of historical climate simulations from the middle of the 19th century, climate projections from the present to the end of the 21th century based on future scenarios of the Shared Socio-economic Pathways, and initialized climate predictions on seasonal-to-decadal timescales will be given in this talk.

Synchronized increase of extreme cold and warm events in China during the recent global warming slowdown

*Xiubao Sun[1,3], Chunzai Wang[1], Guoyu Ren[2,3], Panfeng Zhang[2]

1. State Key Laboratory of Tropical Oceanography (LTO), South China Sea Institute of Oceanology(SCSIO), Chinese Academy of Sciences (CAS), 2. Department of Atmospheric Science, School of Environmental Studies, China University of Geosciences (CUG), 3. Laboratory for Climate Studies, National Climate Center (NCC), China Meteorological Administration (CMA)

From the end of 1990s to the middle of 2010s, global mean temperature experienced a process of warming slowdown. However, global warm extremes did not show the slowdown phenomenon during the recent global warming slowdown. Based on the observation data of 2362 land surface stations in China, we analyzed the cold and warm extremes changes over mainland China between global warming period (1961-1999) and warming slowdown period (2000-2014). Results indicate that the warming trend in the cold season (MAM and DJF) is significantly higher than that in the warm season (JJA and SON) in the period of global warming (1961-1999), while the warming trend in the warm season is significantly higher than that in the cold season in the period of global warming slowdown. That is, the trend of warm season and the cool season in China have reversed. At the same time, we also found that the synchronous increase occurrence of extreme warm events in summer (JJA) and extreme cold events in winter (DJF) leads to the seasonal trend reverse phenomenon, but there are differences in the spatial variation characteristics between cold and warm extremes. The increase of warm extremes in summer is mainly due to the strong increase of warm events in south China, while the increase of cold events in winter is due to the increase of cold events over China. Further, we also found that the variability of extreme temperature has increased more significantly in the warming slowdown period than that in global warming period. East Asian winter monsoon and summer monsoon both show enhanced characteristics during the global warming slowdown period, which indicates that the increase of sea-land temperature difference in summer and winter results in the synchronous increase of extreme cold and warm events by increasing the climate variability in China.

Quantification of thermodynamical and dynamical contributions to the anthropogenic influences on tropical cyclone rainfall extremes

*Cheng-Ta Chen[1], Shih-How Lo[1], Chung-Chieh Wang[1], Kazuhisa Tsuboki[2]

1. Department of Earth Sciences, National Taiwan Normal University, 2. Hydrospheric-Atmospheric Research Center, Nagoya University

The rainfall extremes and strong winds associated with tropical cyclones lead to significant damages and lost to where they make landfalling. Upward trend in term of financial lost was indicated for the past few decades from the report of major reinsurance firms. Whether the past anthropogenic warming played a significant role in such extreme event and their changes remained very controversial. On one hand, people argue it’s nearly impossible to attribute an individual extreme event to global warming. On the other hand, the increase of heavy rainfall is consistent with the expected effects of climate change on tropical cyclone. To diagnose possible anthropogenic contributions to the odds of heavy rainfall associated with tropical cyclone, we adapt an existing event attribution framework of modeling a ‘world that was’ and comparing it to a modeled ‘world that might have been’ for that same time but for the absence of historical anthropogenic drivers of climate. One limitation for applying such approach to high-impact weather system is that it will require models capable of capturing the essential processes lead to the studied extremes. Using a cloud system resolving model that can properly simulate the complicated interactions between tropical cyclone, large-scale background, topography, we first perform the ensemble ‘world that was’ simulations forced by the high resolution ECMWF YOTC analysis. We then re-simulate with the adjusted ‘world that might have been conditions’ by removing the regional atmospheric and oceanic forcing due to human influences estimated from the CMIP5 model ensemble mean conditions between all forcing and natural forcing only historical runs. Thus our findings are highly conditional on the driving analysis and adjustments therein, but the setup allows us to elucidate possible contribution of anthropogenic forcing to changes in the likelihood of heavy rainfall associated tropical cyclone. With only less than half of degree anthropogenic warming over the study area, we found that this forcing very likely (9 out of 10 cases) increase the risk of heavy rainfall event (grid rainfall greater than 33 mm per hour) by at least 16%. The role of dynamical processes that leads to precipitation extreme increases beyond the moisture content increase will be further analyzed and discussed.

Temporal Evolution of the Long-Term Distributional Biases of Climate Models as a Parameter for the Regional Evaluation of the Simulation of Climate Change

*Martin Gomez-Garcia[1], Akiko Matsumura[1], Shiro Hishinuma[1], Daikichi Ogawada[1]

1. Nippon Koei Co. Ltd., Reasearch and Development Center

Owing to the climate variability of the General Circulation Models (GCM), the discrepancy between their outputs and observational datasets at scales that range from hours to years is practically random. Thus, the associated errors need to be evaluated in terms of the long-term (multidecadal) distributional properties of the atmospheric variables. A recently developed bias-correction method corrects the systematic errors (i.e., biases) in the climate mean state and in three distributional measures of the daily and the interannual variability (namely the frequency of extremes, the skewness, and the scale of the variable at each timescale). The adjustment of these biases is done in such a way that the corrections at one timescale do not affect the probability distribution at another. Therefore, this bias-correction method is able to preserve the GCM-simulated climate trends and extensively reproduce the long-term frequency of the observed extreme weather (e.g. 98th percentile of wet days, maximum seasonal mean of surface temperature).

Generally, the bias-correction of GCMs faces the challenge of including the simulated changes of climate, which supposes alterations in not only the mean but also other aspects like the skewness and the frequency of extremes. The abovementioned bias-correction method includes the effect of the simulated climate change in the correction of the distributional biases. However, considering the coarse resolution of the GCMs and the imperfections in the parameterizations of the subgrid physical processes, the fundamental assumption that the distributional biases are predictable (i.e., stationary) is made.

In this study, we explored the possibility of evaluating the sensibility with which GCMs simulate the response of the earth-system components to external forcing (i.e., climate change) by comparing the temporal evolution of the distributional biases at different timescales over specific regions. For the short period in which the observed data was available, our results revealed that many CMIP5 GCMs are indeed able to simulate with a quasi-stationary bias the changes caused by climate change. Moreover, being able to identify the regions in which certain models do not show the errors with a systematic behavior in either the climate mean state, the daily variability or the interannual variability can be useful for the further development of climate models. We expect that with the data of the GCM outputs of the future phases of the CMIP project, the period in which the observed and the modeled data coincide becomes longer and, thus, our conclusions can be supported by more robust evidence.

A global simulation of bioenergy crop yield

*Zhipin Ai[1], Naota Hanasaki[1]

1. National Institute for Environmental Studies

Large-scale development of bioenergy is considered as an effective pathway to achieve the 2 degrees target of the Paris Agreement. To avoid the competition with food crops, so-called the second-generation bioenergy crops such as miscanthus and switchgrass are regarded as potential dedicated biomass crop. However, the models to estimate the yield of miscanthus and switchgrass at a global scale which enable analyzing the effects of irrigation water application are seldom seen as of today. Here, we firstly updated the crop module in the global hydrological model H08 for miscanthus and switchgrass. Then, we conducted a global simulation and validation of the yield for miscanthus and switchgrass at 0.5 degree. The results indicated that the updated H08 have a good ability in simulating the yield of perennial bioenergy crops, which provides a good foundation for further integrated assessment of the impacts of bioenergy crop production on water sector.

Integrated Research Program for Advancing Climate Models - Theme B: national research program in Japan on earth system modeling

*Michio Kawamiya[1], Tomohiro Hajima[1], Kaoru Tachiiri[1], Jun'ichi Tsutsui[2], Tokuta Yokohata[3], Takashi Arakawa[4], Takahiro Inoue[4]

1. Japan Agency for Marine-Earth Science and Technology, 2. Central Research Institute of Electric Power Industry, 3. National Institute for Environmental Studies, 4. Research Organization for Information Science and Technology

The Integrated Research Program for Advancing Climate Models, or TOUGOU (abbreviation taken from its Japanese name), is a national project for projection of global change. Its aim to provide information for adaptation and mitigation, based on scientific evaluation of changes including those in extreme events and carbon cycle. The project was launched in April, 2017. While the entire program deals with a wide range of physical aspects and consequent impacts of climate change, Theme B (TOUGOU-B) focuses on the development of a state-of-the-art Earth system model (ESM) incorporating biogeochemical processes, such as sophisticated carbon and nitrogen cycles, as well as its application to exploring future socio-economic pathways of climate change mitigation. MIROC-ESM, an ESM developed under TOUGOU-B (and the previous SOUSEI-B) has been significantly improved since the 5th phase of coupled model intercomparison project (CMIP5), and has started to be run for CMIP6. During the three years since TOUGOU was launched, results have been obtained that may contribute to 6th Assessment Report (AR6) of Intergovernmental Panel on Climate Change (IPCC) including those on impacts of pyrogenic iron on oceanic ecosystem, assessment of the outcome of labor productivity change due to warming, and effects of high dust amount on surface temperature during the Last Glacial Maximum. Besides, efforts to secure ways to disseminate projection data are ongoing under TOUGOU-B. Specifically, collaboration has been established between climate modeling community in Japan and Data Integration and Analysis System (DIAS), a national IT project for environmental data, have been continuing, in order for Japan to participate in Earth System Grid Federation (ESGF). ESGF is an international cooperative activity to construct a data distributing system for climate related data such as CMIP6 outputs. Some of the details of these results will be explained in the presentation.

Towards probabilistic climate projections based on the CMIP6 multi-model ensemble

*Junichi Tsutsui[1]

1. Central Research Institute of Electric Power Industry

Research on climate change mitigation uses a climate model emulator that represents the average and range over a specific multi-model ensemble of complex climate simulations. The Coupled Model Intercomparison Project (CMIP) has provided such multi-model ensembles, and its latest Phase 6 (CMIP6) results are being revealed. As a first step to applying the CMIP6 results to probabilistic climate projections, we focus on the distribution of key parameters representing atmospheric CO_2-induced forcing and transient temperature responses.

In this study, we develop a procedure to determine the forcing-response parameters of a complex climate model. We simultaneously fit a curve built on an impulse response function to the global mean time series of the model's surface temperature anomaly and top-of-atmosphere energy imbalance from two basic CO_2 -forced experiments, i.e., an abrupt quadrupling and a 1%-per-year increase in atmospheric CO_2 concentration. This scheme serves as an improved alternative to the widely-used regression method of Gregory et al. (2004). Furthermore, it makes a complete set of parameters to emulate the target model from which equilibrium climate sensitivity (ECS) and transient climate response (TCR) are derived. The properties of a multi-model ensemble are quantified through a statistical approach including a principal component analysis for the parameters.

The two CO_2-forced experiments are included in the set of common experiments which is designed to maintain continuity across different CMIP phases. Here, we compare the parameters of individual CMIP6 models with those of the previous-phase CMIP5 models. The parameters of the CMIP5 ensemble have several features. The ratio of TCR to ECS is distributed in the range of approximately 0.5 to 0.7, and for models with large ECS, the ratio tends to decrease. The scaling parameter for the effective radiative forcing of CO_2 varies from model to model and tends to be less than a reference value used in a conventional formula of CO_2 radiative forcing. Although the number of CMIP6 models is currently limited, their parameters show similar distributions within the CMIP5 ranges.

Effect on the earth system of realizing 1.5 degree climate target by overshooting after reaching 2 degree level

*Kaoru Tachiiri[1], Herran Diego Silva[2], Xuanming Su[1], Michio Kawamiya[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Institute for Global Environmental Strategies

By using an Earth system model (ESM) with emissions and land use scenarios consistent with socio-economic projections from an integrated assessment model, the effect of overshooting to 1.5 degree target (in Celsius from pre-industrial periods) after reaching 2 degree level is investigated in selected indicators of the global environment. Unlike the internationally coordinated model intercomparison project, the scenario is developed for a specific climatic model. The ESM output results in delayed achievements for both of 1.5 and 2 degree targets in terms of global surface mean air temperature, but achieved before or around 2100 as expected when we use global mean surface temperature (for which sea surface temperature and surface air temperature are used for ocean and land, respectively) masked with observation areas. In the overshooting scenario more heat is absorbed by the ocean compared to a case without overshooting, but still we found significant difference between the two scenarios in Arctic sea ice, while in both scenarios corals seem difficult to survive the 21st century (when no thermal adaptation is assumed) . The difference in steric sea level rise between the scenarios is only below 2 cm in 2100. In addition, vegetation productivity in broad regions shows slight (~5%) increase. Emission pathways in the scenarios rely on a large amount of carbon sequestration. In the 2 degree scenario CO2 emissions in 2100 are slightly below zero, while for 1.5 degree scenario they are below -20 GtCO2.. When the Earth system has high climate sensitivity and TCRE, to reach the 1.5 degree target we need to take an overshooting temperature pathway, but in case the overshooting is large, difference in some indicators between 1.5 degree and 2 degree scenarios can be non-significant, which is an important indication in implementing adaptive mitigation in the coming decades.

Historical regional and sectoral contributions to climate change

*Xuanming Su[1], Kaoru Tachiiri[1], Katsumasa TANAKA[2], Michio Watanabe[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Institute for Environmental Studies

Regional or sectoral contributions to climate change are important in the formulation of climate change policy. After the industrial revolution, developed countries emit CO_2 and non-CO_2 greenhouse gases (GHGs), and the historical emissions are large; while developing countries contribute relative fewer emissions in historical period but increase significantly in recent years or visible future. To assess the contributions to climate change, using cumulative emissions is a general and direct method. However, such method may ignore the lifetime of GHGs since part of the GHGs sink into the biosphere, ocean, soil or diminish during biogeochemical cycles. In this study, we evaluate the historical regional and sectoral contributions to climate change by using an improved version of Simple Climate Model for OPTimization (SCM4OPT) with a normalized marginal method. Based on the results, we analyze ten major GHG emitting countries and 12 sectors.

First, current emissions with relative long lifetime like CO_2 and N_2O, from developing countries increase significantly, like China, India, Mexico and Brazil, however, their contributions to climate change are still relatively smaller, compared with the developed countries such as USA, Japan, Germany, Canada and UK, of which countries the cumulative emissions are in relatively larger scale and current emissions are already under controlled. We can conclude here that the GHGs with relatively long lifetime need to be controlled stringently to reduce the long-term effects on climate change. For CH_4, which has a relatively shorter lifetime, the contributions to climate change are closely related to emissions within recent decades. These imply that reductions on short lifetime emissions can make immediate alleviation regarding climate change.

Second, energy sector contributes most of the CO_2 emissions, and therefore contribute almost half to the climate change among all the sectors. However, for CH_4 and N_2O, agriculture sector contributes most of the emissions and therefore their contributions to climate change are remarkable. Reduction policiesneed to targetthesesectors. In addition, CO_2 from land transportation and CH_4 from waste treatment increase rapidly in recent years, attention also needs to be paid to these sectors for making climate change policies.

Future projection of global climate, water, food, bio-energy, and land investigated with MIROC-INTEG: a global bio-geophysical land surface model with human components

*Tokuta Yokohata[1], Yusuke Satoh[1], Tsuguki Kinoshita[2], Gen Sakurai[3], Yadu Pokhrel[4], Akihiko Ito[1], Etsushi Kato[5], Masashi Okada[1], Naota Hanasaki[1], Tomoko Nitta[6], Seita Emori[1]

1. National Institute for Environmental Studies, 2. Ibaraki University, 3. National Agriculture and Food Research Organization, 4. Michigan State University, 5. The Institute of Applied Energy, 6. University of Tokyo

Future climate changes possibly affect water resources, food production, energy supply, and ecosystem services. It is critical to better understand the interactions between the changes in these complicated factors. While earth system models and integrated assessment models are applicable to explore this topic, parts of their natural and/or human processes tend to be simplified depending on their scope. As such, it still remains a challenge to realistically model the human-natural interface. In this context, the MIROC integrated terrestrial model (MIROC-INTEG) was developed. One of the features of MIROC-INTEG is that the natural ecosystem and human activity models are coupled to a global land surface model MATSIRO (Nitta et al. 2014, Journal of Climate), which is a component of a state-of-the-art global climate model, MIROC (Watanabe et al. 2010, Journal of Climate). As a natural ecosystem model, we use a global vegetation model, VISIT (Ito and Inatomi 2012, Biogeosciences). As human activity models, we use a global land-surface model with anthropogenic water regulation modules, HiGW-MAT (Pokhrel et al, 2012, Journal of Hydrometeorology), and a global crop model, PRYSBI2 (Sakurai et al, 2014, Scientific Reports). In HiGW-MAT, models of human water regulations such as water withdrawal from river, dam operation, and irrigation (Hanasaki et al. 2008, Hydrol. Earth Syst. Sci.) are incorporated to the above-mentioned global land surface model, MATSIRO. In PRYSBI2, the growth and yield of four crops (wheat, maize, soybean, rice) are calculated. In addition to these models, a global land use model (Terrestrial Land-use Model, TeLMO) is newly developed in the present study. TeLMO calculate the grid ratio of cropland (food and bio-energy crops), pasture, forest (managed and un-managed), as well as their transition. Output variables of each sub-model are passed to other sub-models during the time integration.
We will present an analysis of historical and future simulations with a focus on the interactions between water, food, energy, and land. In the historical simulations, we validated the model output such as irrigated water, crop yield, ecosystem productions, and cropland area by comparing to the observed or reanalysis data. In the future simulations, we investigated the role of uncertainties in climate (Representative Concentration Pathways) and socio-economic (Shared Socio-economic Pathways) scenarios. We also investigate the role of uncertainties in model parameters, and found that an uncertainty in the fertilization effect of crop growth model PRYSBI2 strongly affect uncertainty in future projection of crop yield and land use change in TeLMO. We found that future changes in precipitation and/or temperature possibly cause decrease in soil moisture, leading to decreases in crop yield (especially in high emission scenario such as RCP8.5). Decrease in crop yield bring about increase in crop land area, which also causes the increase in irrigation demands. Interaction between water, crop yield, and land use, as well as possible impacts on ecosystem service will be discussed in the presentation.

Downscaling a global agricultural land use model to country level for national SSP analysis

*Wenchao Wu[1], Tomoko Hasegawa[1], Kiyoshi Takahashi[1], Shinichiro Fujimori[2]

1. National Institute for Environmental Studies, 2. Kyoto Univ.

The Shared Socioeconomic Pathways (SSPs) has been part of latest scenario framework developed by the climate change research society in the recent decade, serving the integrated analysis of future climate impacts, vulnerabilities, adaptation, and mitigation, in which the agriculture, food system and land use are important components. Multiple integrated assessment models (IAMs) have been used for the quantitative projections of future agriculture, food system and land use in the global scale. However, the tool and application of IAMs to the quantification of SSPs on regional or national level is limited. Meanwhile, there are growing needs for the quantification of SSPs on regional or national level for a more detailed understanding of agriculture, food, and land use, and their interactions with other nexus, such as energy, water, and biodiversity. One obstacle for such application is the coarse spatial resolution of global IAMs for land use module. This study aims to apply the Asian-Pacific Integrated Model/Platform for Land-Use and Environmental Model (AIM/PLUM) for the quantification of agriculture, food system, and land use in Japan under its national-specific SSPs narratives. To achieve this, a regional land use model, AIM/PLUM-Japan, was developed, by improving the spatial resolution to 0.05˚ (targeting 1km) from global model of 0.5˚. We combined the statistical production area data and spatial land use data to produce a refined base crop map. Agricultural land use could be downscaled to 0.05˚ resolution and gridded agricultural land use information could be generated using this model. Aside from providing quantitative land use information for Japan’ s SSPs, this study also contributes to the IAMs and SSPs societies by testing the applicability and feasibility of global IAMs, especially land use models, to the regional or national extension. For example, regional (national) SSPs quantifications for other regions could be easily implemented by a similar paradigm using AIM/PLUM.

Extreme Events and Emergent Trends in Marine Ecosystem Stressors under a historical/RCP8.5 Climate Change Pathway

*Keith Bradley Rodgers[1,2], Sarah Schlunegger[3], Richard Slater[3], Burke Hales[4], Axel Timmermann[1,2]

1. IBS Center for Climate Physics, Busan, South Korea, 2. Pusan National University, Busan, South Korea, 3. AOS Program, Princeton University, Princeton NJ, USA, 4. College of Ocean and Atmospheric Sciences, Oregon State Universitym, Corvallis, OR, USA

It is important to identify the degree to which climate change will impact ocean ecosystems over the 21st century. Over the last decade there has been increasing application of Earth System Models (ESMs) to project changes in ecosystem stressors (acidification, warming, and de-oxygenation) with a focus on surface and/or thermocline-integrated conditions. Recent efforts have made combined use of CMIP5 models, large ensemble simulations, and/or scenario sensitivity experiments to estimate uncertainties in future projections. Nevertheless very little to date has been done to evaluate how the frequency of extreme events with ecosystem stressors will respond to future climate perturbations. Here we consider for an ensemble suite of simulations with GFDL's ESM2M changes in the frequency of marine ecosystem extreme events over the 21stcentury. We focus on the contrast between the behavior at the ocean's surface vs. base of the ocean's euphotic zone, as these are both important horizons for ocean ecosystems, and on the contrast between the Time of Emergence of decadal trends vs. frequency changes of extreme events, as these are both important ecological timescales. Particular attention is devoted to acidification at the base of the euphotic zone, as this pertains to the life cycle of pteropods. Preliminary results indicate that in addition to the subpolar Northern Oceans and the Southern Ocean, the Large Marine Ecosystems (LME) regions of the eastern Pacific become increasingly exposed to corrosive waters over the 21stcentury.

[A-CG35] Projection and detection of global environmental change

convener:Michio Kawamiya(Japan Agency for Marine-Earth Science and Technology), Hiroaki Tatebe(Japan Agency for Marine-Earth Science and Technology), Kaoru Tachiiri(Japan Agency for Marine-Earth Science and Technology), Chairperson:Hiroaki Tatebe

Anthropogenic forcings on global environment are expected to cause intensification of extreme events, sea level rise, ocean acidification and deoxygenation, as well as large-scale ecosystem changes. The CMIP6 experimental protocol has been established based on which modeling groups across the world are starting to provide environmental projection data toward 6th IPCC assessment report due in 2021. Various new types of studies, such as event attribution and coupling of socio-economic processes and Earth system dynamics, are also emerging in the field of global change projection. In addition, observational studies are becoming increasingly more important for grasping changes in the global environment and evaluating model projections. Interactions and collaborations beyond boundaries of conventional scientific disciplines are desired for dealing with the issue of global changes. This session thus aims to deepen our understanding on global change, from both disciplinary and interdisciplinary viewpoints. This session is co-organized by AIMES - Future Earth project "Analysis, Integration and Modelling of the Earth System" (https://aimesproject.org/).

Sour and anoxic Sea of Japan in the near future

*Chen-Tung Arthur Chen[1], Hon-Kit Lui[1], Masao Ishii[2]

1. National Sun Yat Sen University, 2. Japan Meteorological Agency

The ocean acidification is frequently related to hypoxia. In the paper "An anoxic Sea of Japan in 2200?" (Chen, Marine Chemistry, 1999) it was suggested that the sea is undergoing rapid de-oxygenation, and that the sea may become anoxic by the year 2200. But, a question mark was used in the title because of large uncertainties. In a recent Nature Climate Change paper (Chen et al., 2017), however, it was further concluded that the deep Sea of Japan has acidified at a faster rate than anywhere else in the world oceans. The conclusion of rapid acidification is in line with the conclusion of de-oxygenation. In addition, adding 20 years of new data confirms that the assessment of 1999 was correct. Likely the Sea of Japan would become sour and anoxic within the next two hundred years, if not sooner, based on nutrients, oxygen and pH data.

1. Max Planck Institute for Meteorology, Bundesstraße 53, 20146 Hamburg, Germany, 2. Deutscher Wetterdienst, Bernhard-Nocht-Straße 76, 20359 Hamburg, Germany

The global ocean, as a major carbon sink, absorbs about 25% of the contemporary anthropogenic CO_2 emissions; hence the carbon uptake by the ocean largely mitigates the CO_2concentration increase in the atmosphere and hence the global warming. Moreover, the strength of the carbon flux into the ocean, varies substantially from annual to decadal time-scale. Therefore, predicting the variable ocean carbon uptake and global carbon cycle is of essential value of tracing the fate of carbon and the corresponding climate and ecosystem changes.

By assimilating atmosphere and ocean physical observations into the decadal prediction system based on the Max Planck Institute Earth System Model (MPI-ESM), we reproduce the ocean carbon uptake variations in consistent with the data-based estimates. The retrospective predictions starting from the assimilation states show a predictive skill of 2 years in the ocean carbon uptake globally. Regionally the predictive skill is up to 5 years in the Southern Ocean and the North Pacific. To understand the mechanisms in maintaining the predictability of the ocean carbon uptake, we separate the ocean surface pCO_2, which is the main driver of the variability in carbon fluxes, into thermal and non-thermal components. The thermal component is affected by the solubility of CO_2via temperature variations, and the non-thermal component is affected by the ocean circulation and biology, i.e., is not first order affected by the temperature. We find that the thermal component contributes mainly to shorter-term (of <3 years) of predictive skill of the ocean carbon uptake, while the non-thermal component is responsible for longer-term (of >3 years) of predictive skill of the ocean carbon uptake.

Decadal prediction study of the global carbon cycle and corresponding ecosystem based on the ESMs is still at its early stage and facing a number of challenges arising from limited ocean biogeochemical observations and lack of proper initialization strategies. An extension of our predictions in the context of multi-model framework is in progress and this will facilitate deeper understanding of the mechanisms and further improvement of the predictive skill in the global carbon cycle.

Air-sea CO_2 flux variations in the tropical Pacific simulated with two ESMs embedded an ocean data assimilation system

*Michio Watanabe[1], Hiroaki Tatebe[1], Hiroshi Koyama[1], Tomohiro Hajima[1], Masahiro Watanabe[2], Michio Kawamiya[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Atmosphere and Ocean Research Institute, the University of Tokyo

Interannual-to-decadal fluctuations of the global-mean atmospheric CO_2 concentration are observed associated with internal climate variations, and these fluctuations sometimes cancel out and at other times support the centennial increasing trend of the global-mean atmospheric CO_2 concentration due to accumulation of anthropogenic CO_2 emissions. One direct cause of the fluctuations is the oceanic absorption or release of CO_2 through the global air-sea CO_2 flux variations which are mainly dominated by the tropical Pacific. Therefore, deeper understanding of the tropical oceanic processes and properly initializing oceanic states including marine ecosystem are of importance in future predictions of the global CO_2 concentration together with quantification of human-influences. In the present study, we examined the simulated air-sea CO_2 flux variations in the tropical Pacific in two ESMs (MIROC-ES2L and MIROC-ESM) with the same ocean data assimilation system. Although the assimilation procedures are the same, observed anti-correlated relationship between interannual variations of the upward air-sea CO_2 flux and the sea surface temperature (SST) in the tropical Pacific are well captured in MIROC-ES2L, but the relationship is reversed in MIROC-ESM. Tropical climatic-mean state of MIROC-ESM shows significant biases of weaker trade winds as well as more diffuse equatorial thermocline than observations, and simulated amplitude of interannual variations of NINO3-SST is about half as large as observations. When observations are assimilated into the model, these biases lead to non-negligible correction terms on the governing equations of ocean temperature and salinity, which induces an anomalous spurious equatorial upwelling during El-Niño events. The spurious upwelling brings dissolved inorganic carbon rich water in the subsurface layer to the surface mixed layer. Consequently, an anomalous upward air-sea CO_2 flux is occurred during El-Niño, as opposed to observations and MIROC-ES2L. Better modeling physical processes in the tropical climate system is suggested to be essential for better marine ecosystem modeling and reanalysis.

A Study of Decadal Ocean Deoxygenation and Heat Uptake from a suite of OMIP Simulations

*Yohei Takano[1], Jerry Tjiputra[2], Jörg Schwinger[2], Matthias Gröger[3], Sarah Berthet[4], Roland Séférian[4], Andrew Yool[5], Julien Palmieri[5], Michio Watanabe[6], Irene Stemmler[1], Tatiana Ilyina[1]

1. Max Planck Institute for Meteorology, 2. Norwegian Research Centre, 3. Swedish Meteorological and Hydrological Institute, 4. Centre National de Recherche Météorologique, Unite mixte de recherche 3589 Météo-France/CNRS, 5. National Oceanography Centre, 6. Japan Agency for Marine-Earth Science and Technology

Observational studies reveal substantial ocean deoxygenation and increased heat uptake in the past decades. These two properties are known to be tightly connected. The Earth System Models (ESMs) struggle to simulate the observed trends in oxygen inventory (O_2-Inv) and the tight global O_2-heat relationship. One possible reason is the role of decadal climate variability.

The past decadal changes in oxygen inventory and tight global O_2-heat relationship cannot be fully explained by changes in solubility alone, indicating the important role of changes in ocean circulation and biology. Climate variability could modulate O_2-Inv and heat uptake on decadal timescales but the observed climate variability is not necessarily simulated in the ESMs historical simulations due to the fact that the models have their own internal climate variability, which vary in magnitude and phase, in the coupled climate system. Here we address the question how the observed decadal climate variability modulates O_2-Inv and heat uptake using a suite of OMIP simulations.

We will present results from the comparison of state-of-the-art ocean model simulations driven by the atmospheric reanalysis forcing. The main focus is to understand decadal changes in global and regional upper ocean O_2-Inv and OHC based on the results from six different model simulations (NorESM-OC, EC-EARTH3.3.0, CNRM-ESM2-1, UKESM1, MIROC-ES2L, and MPI-OM-HAMOCC), and observations. The model structural differences result in different physical and biogeochemical mean states, which lead to different decadal variability of O_2-Inv and OHC. The regional O_2-heat relationship among the models and observations would be presented to discern the biases in the simulated ocean circulations and biological processes. Our study will provide first indications of the importance of decadal climate variability on determining changes in O_2-Inv and OHC. Hence, it will also provide guidance on accuracy and uncertainty of future deoxygenation and warming projected in the ESMs. We aim on stimulating the discussion on near term strategy of how we analyze upcoming OMIP simulations within the context of climate variability and changes in ocean physics and biogeochemistry based on our multi-model analysis.

Role of large-scale environmental variability in changing storm climate

*Nilima Aditya Natoo[1]

1. University of Bremen, Germany

This paper focusses sequentially on two different aspects: (a) recent changes in observed storms, and (b) its linkages to the changes in large-scale environmental (LSE) variability. The analysis of observed storm show that in spite of an overall reduction in the Southwest Pacific (SWP) storminess over the past four decades, the number of extreme storms corresponding to the mean maximum sustained storm wind speed, has increased. At the same time, a slight reduction in the corresponding mean minimum central pressure is observed. The transition time from category 1 to 3 has also reduced substantially (by ~12 hours). Possible conditions for some of these observed behavioural change in terms of quick intensification and traveling longer distance towards south pole will be discussed.
The second aspect explores the linkages between above changes in storm indices and corresponding variability in LSE variability. The methodology uses multiple linear regression analysis to establish their relationship. This relationship is used to construct scenarios of likely change in future storminess using simulated (RCP8.5 minus historical) differences. The analysis will show how the role of some of the environmental indices when in combination can aid in modulating the Southwest Pacific change in storminess.

The forced response of the climate system: The case of climatic teleconnections

*Tamas Bodai[1], Matyas Herein[2], Gabor Drotos[3]

1. University of Reading, 2. Eotvos University Budapest, 3. Universitat de les Illes Balears

We frame the forced response of the climate system in terms of an ensemble that represents the so-called snapshot/pullback attractor, and explore the implications and power of this approach. Teleconnections as cross-correlations can be defined in the ensemble-based framework by evaluating the correlations over ensemble members. As a specific example, we studied the teleconnection between the El Niño–Southern Oscillation (ENSO) and the Indian summer monsoon in ensemble simulations from state-of-the-art climate models, the Max Planck Institute Earth System Model (MPI-ESM) and the Community Earth System Model (CESM). We detect an increase in the strength of the teleconnection in the MPI-ESM under historical forcing between 1890 and 2005, which is in contrast with scientific consensus. In the MPI-ESM no similar increase is present between 2006 and 2099 under the Representative Concentration Pathway 8.5 (RCP8.5), and in a 110-year-long 1-percent pure CO2 scenario; neither is in the CESM between 1960 and 2100 with historical forcing and RCP8.5. This is also a puzzling result inasmuch as the historical forcing is the weakest. Accordingly, we evaluated that the static susceptibility of the strength of the teleconnection with respect to radiative forcing (assuming an instantaneous and linear response) is at least three times larger in the historical MPI-ESM ensemble than in the others.

[A-CG35] Projection and detection of global environmental change

convener:Michio Kawamiya(Japan Agency for Marine-Earth Science and Technology), Hiroaki Tatebe(Japan Agency for Marine-Earth Science and Technology), Kaoru Tachiiri(Japan Agency for Marine-Earth Science and Technology), Chairperson:Kaoru Tachiiri(Japan Agency for Marine-Earth Science and Technology), Michio Kawamiya(JAMSTEC)

Anthropogenic forcings on global environment are expected to cause intensification of extreme events, sea level rise, ocean acidification and deoxygenation, as well as large-scale ecosystem changes. The CMIP6 experimental protocol has been established based on which modeling groups across the world are starting to provide environmental projection data toward 6th IPCC assessment report due in 2021. Various new types of studies, such as event attribution and coupling of socio-economic processes and Earth system dynamics, are also emerging in the field of global change projection. In addition, observational studies are becoming increasingly more important for grasping changes in the global environment and evaluating model projections. Interactions and collaborations beyond boundaries of conventional scientific disciplines are desired for dealing with the issue of global changes. This session thus aims to deepen our understanding on global change, from both disciplinary and interdisciplinary viewpoints. This session is co-organized by AIMES - Future Earth project "Analysis, Integration and Modelling of the Earth System" (https://aimesproject.org/).

Guiding Mother Earth: taking stock of progress to a long-term temperature goal

*Myles Robert Allen[1]

1. Environmental Change Institute, School of Geography and the Environment and Department of Physics, University of Oxford

The IPCC Special Report on 1.5˚C found that human-induced global warming had reached 1˚C ±0.2˚C, increasing at 0.2˚C per decade, leaving only a few decades for emissions to be reduced to net zero to limit warming to 1.5˚C. The Paris Climate Agreement introduced a regime of periodic stocktakes of progress to the long-term temperature goal of limiting warming to well below 2˚C, pursuing efforts to 1.5˚C. While there is general agreement that these stocktakes are to be informed by science, these is less consensus on how this will be done. I will explain how we can robustly estimate the level of human-induced warming to date, and how this information was used to support a revision in the remaining carbon budget for cumulative future CO_2 emissions consistent with limiting warming to 1.5˚C. CO_2 budgets in the IPCC Special Report were contingent on scenarios for non-CO_2 forcing, but the concept of a carbon budget can be generalised if we recognise how other anthropogenic forcing agents affect climate on different timescales, either expressing them as CO_2-forcing-equivalent emissions, or applying the traditional GWP_{100} metric in a new way. Taken together, these insights provide a simple, transparent, scenario-independent and model-independent method of assessing the implications of current and future emissions for progress towards a long-term temperature goal.

Uneven distributions of four hazard indicators of climate change with the Paris Agreement's goals

*Hideo Shiogama[1]

1. Center for Global Environmental Research, National Institute for Environmental Studies

Clarifying characteristics of hazards and risks of climate change at 2ºC and 1.5ºC global warming is important for understanding the implications of the Paris Agreement. We perform and analyse large ensembles of 2ºC and 1.5ºC warming simulations. In the 2ºC runs, we find substantial increases in extreme hot days, heavy rainfalls, high streamflow and labor capacity reduction related to heat stress. For example, about half of the world's population will experience a present day 1-in-10 year hot day event every other year at 2ºC warming. The regions with largely increases of these four hazard indicators coincide with countries characterized by small CO_2 emissions, low-income and high vulnerability. Limiting global warming to 1.5ºC, compared to 2ºC, will lower increases in the four hazard indicators especially in those regions.

Understanding the centennial-scale human-natural interactions using an integrated terrestrial model MIROC-INTEG under ISIMIP2 project

*Yusuke Satoh[1], Julien Boulange[1], Naota Hanasaki[1], Kumiko Takata[1], Yadu Pokhrel[3], Ted Veldkamp[2,4], Peter Burek[2], Tokuta Yokohata[1]

1. National Institute for Environmental Studies, 2. International Institute for Applied Systems Analysis, 3. Department of Civil and Environmental Engineering, Michigan State University, 4. Institute for Environmental Studies (IVM), VU Amsterdam

Within the earth system, changing-climate, -human society, and -ecosystems interact mutually. It is crucial to better understand the interconnectedness among such human-natural systems in order to assess the potential impacts of climate and socioeconomic changes on each system and identify sustainable pathways. Although existing earth system models and integrated assessment models are applicable to explore this field, parts of their natural and/or human processes tend to be simplified depending on their scope. Therefore, it still remains a challenge to improve integrated modeling frameworks. For these reasons, a process-based integrated terrestrial model, MIROC INTEGrated terrestrial model (MIROC-INTEG), was developed. The modeling framework is composed of five natural/human subcomponents. At its core is a land surface model (MATSIRO), which is coupled to three human modules; water use (H08), food and biofuel crop production(PRYSBI2) and land use change (TELMO). An ecosystem model (VISIT) calculates the C and N cycles among atmosphere-vegetation-soil. While each sub-model can run independently, MIROC-INTEG dynamically simulates their interactions, embracing the water-food-energy nexus within a system.

The goal of this study is to improve our quantitative understanding on coupled terrestrial systems at the global scale for past and future time-scales. Hence, we have run MIROC-INTEG following the Inter-Sectoral Impact Model Inter-comparison Project phase 2a (ISIMIP2a) and 2b (ISIMIP2b) simulation protocols. Using 3 hourly climate forcing data and considering anthropogenic activities, MIROC-INTEG simulated agro-hydrological condition at a spatial resolution of 0.5˚, globally. As its inputs, ISIMIP2a makes use of three reanalysis-base metrological data for historical periods, and ISIMIP2b employs an ensemble of bias-corrected forcing data set of four general circulation models covering preindustrial, historical, and future time-periods under four representative concentration pathways. Furthermore, ISIMIP provides a unique opportunity for validation of simulation skill in comparison with other models' under consistent protocols.
Within this contribution we present the first results of MIROC-INTEG looking specifically at the centennial-scale human-natural interactions over the period 1851-2099 and its consequences for long-term changes in fundamental hydrological variables. The results are presented at global, regional and large-basin scale and are compared against existing ISIMIP runs of other hydrological and land surface models.

Radiative forcing of the physiological CO_2 response

*Victor Brovkin[1], Veronika Gayler[1], Sonia I Seneviratne[2], Pierre Gentine[3]

1. Max Planck Institute for Meteorology, Hamburg, Germany, 2. ETH, Institute for Atmospheric and Climate Science, Zurich, Switzerland, 3. Columbia University, Earth and Environmental Engineering, New York, USA

Theory and observations indicate that plant stomatal conductance decreases in response to increase in the atmospheric CO_2. This physiological CO_2 response causes reduction in the evapotranspiration and modification of the global hydrological cycle, affecting the global radiative fluxes and climate sensitivity. While this biogeophysical mechanism is included into all comprehensive Earth System Models, its radiative forcing has not been isolated from the other biospheric feedbacks. To evaluate the scale of its radiative forcing, we performed two sensitivity experiments with the CMIP6 version of the MPI Earth system model (MPI-ESM1.2-LR). In addition to the standard 4xCO_2 simulation, in which both climate and carbon cycle respond to an instantaneous 4-fold increase in CO_2, we performed the 4xCO_2rad simulation in which biogeochemistry and plants were not affected by elevated CO_2. We analyse changes in outgoing radiation and surface temperature using the Gregory et al. (2004) approach for radiative forcing, and compare results with- and without physiological CO_2 response. Rescaling to the doubling of the CO_2 concentration, stomatal conductance response increases equilibrium climate sensitivity of the model by ca. 10%, and its radiative feedback is estimated at 0.14 W/m^2/K. This suggest that the magnitude of this positive biogeophysical feedback is comparable with the magnitude of biogeochemical (climate-carbon) feedback.

Progress of MIROC-ES2 simulations in CMIP6 and the analysis of the biogeochemical feedbacks

*Tomohiro Hajima[1], Shingo Watanabe[1], Michio Kawamiya[1], Kaoru Tachiiri[1], Hiroaki Tatebe[1], Akihiko Ito[2], Kumiko TAKATA[2], Michio Watanabe[1], Maki Noguchi[1], Akitomo Yamamoto[1], Akinori Ito[1], Manabu Abe[1], Rumi Ohgaito[1], Dai Yamazaki[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Institute for Environmental Studies, 3. Institute of Industrial Science, the University of Tokyo

In order to reveal how climate-biogeochemical system responds to anthropogenic forcing, a new Earth system model “MIROC-ES2L” has been developed for CMIP6. The physical core of the model is “MIROC5.2”, and the biogeochemical component are updated from that used for CMIP5: the new model has explicit CN interaction in land ecosystem, and ocean component has been improved to include P, Fe, and O in addition to C and N cycles that were already incorporated into that of CMIP5 ver. In the new model, ocean N cycle is opened to other subsystems: N input via biological fixation, deposition and riverine transport are considered, and denitrification process controls N loss from the ocean. This model is used for CMIP6 runs, by participating in endorsed MIPs such as C4MIP, PMIP, OMIP, LUMIP, CDRMIP, ScenarioMIP, VolMIP, etc.
A provisional historical simulation by MIROC-ES2L with CMIP6 official forcing (v6.2.1) clearly showed a global warming trend from 1970’s, which is consistent with observation (HadCRU4). Carbon stored in land ecosystem decreased by responding to the land-use change forcing, and started to increase around 1960 by responding to CO2 increase and increased N input into land (N deposition and fertilizer), in addition to the response to LUC. Ocean continuously store the anthropogenic CO2: the increase during 1850-2005 is about 150PgC, which is almost similar level to the number reported in Global Carbon Budget 2017. In addition to C cycle, the historical simulation showed drastic changes in global N budget, by directly responding to the anthropogenic forcing (LUC and agriculture), and indirectly affected by climate–carbon cycle change. Agriculture increased both land N2O emission (diagnosed) and N leaching, the latter of which impacted on ocean biogeochemistry near river mouths.

The impact of long-term historical warming on the global terrestrial gross primary production

*Irina Melnikova[1], Takahiro Sasai[1]

1. Tohoku University

The recent increase of carbon dioxide in the atmosphere from anthropogenic emissions resulted in the increase of carbon uptake by the global biosphere. The most uncertain contributor to the interannual global uptake variability is land, and the largest and primary land carbon flux is gross primary production (GPP). In this study, we aim to estimate the impact of the long-term (1951–2010) historical warming on the global terrestrial GPP. We use the Biosphere model integrating Eco-physiological And Mechanistic approaches using Satellite data (BEAMS ver.1.3) [*Sasai et al.*, 2016] forced by historical and nonwarming simulation climates of the Database for Policy Decision making for Future climate change (d4PDF) [*Mizuta et al.*, 2017]. This is a pioneer study to apply a diagnostic GPP estimation approach on the large-size ensembles climate data to simulate the long-term global GPP.

First, we evaluated the surface d4PDF climatology in comparison with existing modern datasets, including reanalyses, and discussed the benefits and limitations of the database in the studies of the terrestrial carbon fluxes. Second, we validated the BEAMS GPP forced by d4PDF data against observations and evaluated the BEAMS performance against existing GPP grid-datasets by other approaches (data-driven datasets and process-driven models). Finally, we discussed the impact of the long-term historical warming on the global GPP in terms of decadal trends and density histograms.

We confirmed that d4PDF surface climatology is appropriate for use in the studies of the terrestrial carbon fluxes, and d4PDF historical climate data is comparable to existing modern datasets. BEAMS estimated both the magnitude and decadal trends of the global terrestrial GPP realistically by using the benefits of the diagnostic approach. The global long-term (1951–2010) mean GPP equaled 144.0 ±2.3 GtC $year^{-1}$ for historical and 140.3 ±1.3 GtC $year^{-1}$ for nonwarming climates. The accumulated increase of the historical warming-induced GPP equaled 184.8 ±5.8 GtC for the period of 1951–2010 and accounted for nearly half of all anthropogenic emissions. The GPP increase intensified over time. The density histogram analyses showed that the global GPP distribution in the present (2001–2010) share neither the mean nor spread of GPP in the nonwarming climate.
This study provides the evidence of the impact of long-term historical warming on the global GPP by a novel approach using the benefits of the diagnostic model and large-size ensemble climate data.

[A-CG42] Biogeochemical linkages between the surface ocean and atmosphere

convener:Yuzo Miyazaki(Institute of Low Temperature Science, Hokkaido University), Jun Nishioka(Hokkaido University, Institute of low temperature sciences), Koji Suzuki(Hokkaido University), Yoko Iwamoto(Graduate School of Biosphere Science, Hiroshima University), Chairperson:Yuzo Miyazaki(Institute of low temperature science, Hokkaido University), Jun Nishioka(Institute of low temperature science, Hokkaido University)

Multi-scale vertical and horizontal ocean mixing processes can strongly influence the distribution of dissolved and suspended substances including macro- and micro-nutrients, and may impact on phytoplankton bloom formation. The changes in nutrient dynamics generally affect the abundance, composition and metabolic activity of marine organisms such as phytoplankton and bacteria during the bloom. Marine phytoplankton can produce volatile organic compounds (VOCs) and marine atmospheric aerosols, which strongly influence on atmospheric chemistry. Primary and secondary organic and inorganic components produced via marine phytoplankton activity can contribute to the Earth's radiative forcing, and in turn marine ecosystems including biogeochemical processes directly or indirectly. Therefore, the biogeochemical cycles have a tight linkage between the ocean and the atmosphere. In order to understand physical, chemical and biological processes relevant to phytoplankton bloom formation in the ocean, dynamics of VOCs and marine aerosols in the atmosphere, and the biogeochemical linkage between the ocean and the atmosphere, we welcome new interdisciplinary presentations and active discussions on physical, chemical, and biological sciences both from ocean and atmospheric fields in this session. Studies linked to the Surface Ocean-Lower Atmosphere Study (SOLAS) project are good examples, but other related studies are also invited.

Bromoform ($CHBr_3$) is one of the important bromine containing volatile halocarbons that are involved in ozone depletion in the atmosphere. Although the possible source of reactive bromine species from snow and sea ice has been discussed, mechanisms that control $CHBr_3$ production within sea ice and emission to the atmosphere remain unclear. Here, we show evidence of massive $CHBr_3$ production at sea ice surface-snow interfaces and its strong emission to the atmosphere from five field-campaigns to the Arctic Ocean, the Southern Ocean, and the Sea of Okhotsk in the winter and spring, in addition to supporting laboratory experiments. We found that the ice-related strong $CHBr_3$ emission was linked to the production of the $CHBr_3$ at the snow-sea ice interface through the haloform reaction. Our results suggest that sea ice acts as a strong $CHBr_3$ source for the atmosphere, indicating a significant contribution to the atmospheric bromine cycle.

Accumulation processes of trace metals into arctic sea ice: distribution of Fe, Mn and Cd associated with ice structure

*La Kenya Evans[1], Jun Nishioka[1]

1. Institute of Low Temperature Sciences, Hokkaido University

Increased loss of Arctic summer sea ice can influence the cycling of biogeochemical materials (trace metals, nutrients, etc.), affecting seawater’ s biology and chemistry. Sea ice is important for the supply of biogeochemical materials, especially trace metals, to the surface waters of the polar oceans; but its role is not clear. Understanding the accumulation and release mechanisms into Arctic sea ice will clarify the geochemical behaviour of trace metals. This study compared dissolved (D) and labile particulate (LP) Fe, Mn, and Cd to the observed sea ice structure from a single Arctic sea ice core. The structure of sea ice reflects the process of ice formation, which may aid in the determination of accumulation processes. Using photographic analysis for the percentage of pore microstructure and $\delta^{18}O$ analysis, sea ice structure was observed as: snow, granular (frazil), mixed (granular and columnar) and columnar ice. Salinity and nutrients were low, indicating brine drainage and multi-year ice. High trace metal concentrations in snow ice indicated meteoric snow as a source and accumulation during snow ice formation. High concentrations of LPFe in granular ice indicated accumulation via suspension freezing by frazil ice followed by entrainment. Dissolved Mn and Cd accumulated in snow and granular ice through chemical transformation processes. Elevated DMn and DCd in granular ice resulted from the reduction and release from accumulated Fe and Mn oxides. Elevated DMn and DCd in snow ice may have been due to the photochemical reduction of LPFe and LPMn. Low trace metal concentrations in mixed and columnar ice indicated trace metal release due to brine drainage. Our study clearly indicated that the differences observed in trace metals, within sea ice structure, showed that sea ice formation, chemical reduction and brine release were the processes behind trace metal accumulation and release in this Arctic sea ice.

Is halogen chemistry responsible for low ozone levels observed over western Pacific equatorial region? - From observations on R/V Mirai

*Yugo Kanaya[1], Kazuyuki Miyazaki[1], Fumikazu Taketani[1], Takuma Miyakawa[1], Hisahiro Takashima[1,2], Yuichi Komazaki[1], Xiaole PAN[3,1], Saki Kato[2], Kengo Sudo[4,1]

Constraints from ozone (O_3) observations over oceans are needed in addition to those from terrestrial regions to fully understand global tropospheric chemistry and its impact on the climate. Here, we provide a large data set of ozone and carbon monoxide (CO) levels observed (for 11666 and 10681 h, respectively) over oceans. The data set is derived from observations made during 24 research cruise legs of R/V *Mirai* during 2012 to 2017, in the Southern, Indian, Pacific, and Arctic Oceans, covering the region from 67˚S to 75˚N. The data are suitable for critical evaluation of the over-ocean distribution of ozone derived from chemical transport models. We first give an overview of the statistics in the data set and highlight key features in terms of geographical distribution and air mass type. We then use the data set to evaluate ozone concentration fields from Tropospheric Chemistry Reanalysis version 2 (TCR-2), produced by assimilating a suite of satellite observations of multiple species into a chemical transport model, namely CHASER. Over the western Pacific equatorial region (125-165˚E, 10˚S to 25˚N), the observed O_3 level frequently decreased to less than 10 ppb in comparison to that obtained with TCR-2, and also those obtained in most of the Atmospheric Chemistry Climate Model Intercomparison Project (ACCMIP) model runs for the decade from 2000. These results imply loss processes that are unaccounted for in the models. We found that the model's positive bias positively correlated with the daytime residence times of air masses over a particular grid, namely 165-180˚E and 15-30˚N; an additional loss rate of 0.25 ppb h^{-1} in the grid best explained the gap. Halogen chemistry, which is commonly omitted from currently used models, might be active in this region and could have contributed to additional losses. Our open data set covering wide ocean regions is complementary to the Tropospheric Ozone Assessment Report data set, which basically comprises ground-based observations, and enables a fully global study of the behavior of O_3.

Very low $\delta^{15}N$ of atmospheric nitrate found in the earstern equatorial Pacific and its implication to dynamic nitrogen recycle between ocean and lower atmosphere

*Shohei Hattori[1], Kazuki Kamezaki[1], Yoko Iwamoto[2], Sakiko Ishino[1], Mitsuo Uematsu[3], Kazuhiko Miura[4], Naohiro Yoshida[1]

Atmospheric nitrogen sources in the marine boundary layer of the remote ocean have been known to include long-range transport (LRT) of anthropogenic pollutants, and the LRT of anthropogenic atmospheric particulate nitrate ($p\text{-}NO_3^-$) within the free troposphere has been observed in regions influenced by westerlies from the Asian continent over Pacific Ocean. This traditional paradigm that the ocean is considered a passive recipient of anthropogenic N deposition can be applied western north Pacific regions. However, for the equatorial Pacific under the influence of pristine air, the sources of such $p\text{-}NO_3^-$ remain unresolved. To address this, we present $\delta^{15}N$ of $p\text{-}NO_3^-$ collected over the Pacific Ocean between 40˚S and 68˚N on two cruises, carried out by the Research Vessel *Hakuho Maru*, and estimated $\delta^{15}N$ of source NO_x of each sample. We categorized six marine regions within the Pacific Ocean, based on backward trajectory analysis to determine their source regions and various ion concentrations to assess whether anthropogenic or non-anthropogenic sources were dominant.

We found remarkably low $\delta^{15}N(NO_x)$ values for the equatorial Pacific regions compared to those in other regions over Pacific Ocean. These low source $\delta^{15}N(NO_x)$ values cannot be explained using conventional NO_x apportionment. Given that the eastern equatorial Pacific is one of the biologically active ocean regions resulted from upwelling water, here we postulate the alternative biogenic nitrogen source (NH_3 or alkyl nitrate) in this region. In the presentation, we will discuss important feature of self-recycle process of nitrogen between ocean and lower atmosphere in the eastern equatorial Pacific. We will also discuss its implication to nitrogen deposition for this region, which may contribute to new marine biological production and/or nitrous oxide emissions.

Origin of water-soluble organic nitrogen in marine atmospheric aerosols in the subtropical North Pacific

*Tsukasa Dobashi[1,2], Yuzo Miyazaki[1], Eri Tachibana[1], Yoko Iwamoto[3], Kazutaka Takahashi[4], Sachiko Horii[4], Shu-Kuan Wong[5], Koji Hamasaki[5]

1. Institute of Low Temperature Science, Hokkaido Univ., 2. Graduate School of Env. Sci., Hokkaido Univ., 3. Graduate School of Biosphere Science, Hiroshima Univ., 4. Graduate School of Agricultural and Life Sciences, Univ. of Tokyo, 5. Atmosphere and Ocean Research Institute, Univ. of Tokyo

Marine atmospheric aerosol is one of the most important factors that determine the climate change, because it absorbs and reflects the sunlight which affects radiative balance of the atmosphere. In particular, water-soluble organic nitrogen (WSON) in aerosol affect physicochemical properties of aerosol such as water-solubility characteristics, acidity, light-absorption properties of the particles. However, little is known about the origin of WSON in marine atmospheric aerosols. The purpose of this study is to elucidate the origin of WSON by cruise observation in subtropical North Pacific where very limited data are available.

Size-segregated aerosol samples were collected on board the R/V *Hakuho Maru* (KH-17-4) over the subtropical North Pacific, mainly along 23ºN, during August–October in 2017. Water-soluble organic carbon (WSOC) and water-soluble total nitrogen (WSTN) were measured by a total organic carbon analyzer with a TN unit. The concentrations of inorganic nitrogen (IN) were measured by ion chromatograph. The WSON concentration was derived from the difference between WSTN and IN. The stable carbon isotope ratio ($\delta^{13}C$) was measured by elemental analyzer-isotope ratio mass spectrometer (EA-IRMS). Longitudinal distributions of WSON at 23ºN showed that the submicrometer WSON concentration (av. 5.9 ±6.0 ng N m^{-3}) to the east of 160ºW was significantly larger than that to the west (av. 2.2 ±2.0 ng N m^{-3}). Additionally, the mass fraction of WSON to WSTN in the eastern oceanic region reached as large as 40% with an average of 14.1%, suggesting the importance of WSON in this oceanic region. Backward trajectory, the chlorophyll *a* concentration in seawater, and the $\delta^{13}C$ value suggested that the majority of the observed WSON was derived from microbial activity in the sea surface. WSON did not show any significant correlation with a tracer of primary emission (i.e., Na^{+}), indicating that the majority of WSON were not directly emitted as aerosol particles from the ocean surface, but were produced from N-containing gas species released into the atmosphere. Furthermore, a significant correlation between the concentrations of WSON and the nitrogen fixation rate in the sea surface indicates that reactive nitrogen, produced by nitrogen fixing organisms (e.g., cyanobacteria), are emitted from sea surface to the atmosphere, which significantly contributed to the formation of aerosol WSON.

Atmospheric NH_3 plays a vital role not only in the environmental ecosystem but also in atmosphere chemistry. To fully understand the effects of NH_3 on the formation of haze pollution in Beijing, ambient NH_3 and related species were measured at high resolutions during the wintertime Air Pollution and Human Health-Beijing (APHH-Beijing) campaign in 2016. Simulations were made to gain insights into impacts of NH_3 on the formation of secondary inorganic aerosols (SIAs) and regional fine particle pollution. We found that the total NH_x (gaseous NH_3+particle NH_4^+) was mostly in excess of the SO_4^{2-}-NO_3^--NH_4^+-water equilibrium system during our campaign. This NH_x excess made medium aerosol acidity, with the median pH value being 3.6 and 4.5 for polluted and non-polluted conditions, respectively, and enhanced the formation of particle phase nitrate. During polluted periods, SIAs contributed most to $PM_{2.5}$ and were highly correlated with aerosol water content (AWC), indicating the importance of heterogeneous reactions in haze formation. Our analysis suggests that NH_4NO_3 is the most important factor driving the formation of AWC, with NO_3^- controlling the prior pollution stage and NH_4^+ the most polluted stage. Increased formation of NH_4NO_3 under excess NH_x, especially during the nighttime, may trigger the decreasing of aerosol DRH and hence lead to hygroscopic growth even under lower RH conditions and the wet aerosol particles become better medium for rapid heterogeneous reactions. A further increase of RH promotes the positive feedback "AWC-heterogeneous reactions" and ultimately leads to the formation of severe haze. Both our observational and modelling results suggest that the control of NH_3 may be more effective in reducing $PM_{2.5}$ under current emissions conditions in the North China Plain (NCP).

[A-CG42] Biogeochemical linkages between the surface ocean and atmosphere

convener:Yuzo Miyazaki(Institute of Low Temperature Science, Hokkaido University), Jun Nishioka(Hokkaido University, Institute of low temperature sciences), Koji Suzuki(Hokkaido University), Yoko Iwamoto(Graduate School of Biosphere Science, Hiroshima University)

Multi-scale vertical and horizontal ocean mixing processes can strongly influence the distribution of dissolved and suspended substances including macro- and micro-nutrients, and may impact on phytoplankton bloom formation. The changes in nutrient dynamics generally affect the abundance, composition and metabolic activity of marine organisms such as phytoplankton and bacteria during the bloom. Marine phytoplankton can produce volatile organic compounds (VOCs) and marine atmospheric aerosols, which strongly influence on atmospheric chemistry. Primary and secondary organic and inorganic components produced via marine phytoplankton activity can contribute to the Earth's radiative forcing, and in turn marine ecosystems including biogeochemical processes directly or indirectly. Therefore, the biogeochemical cycles have a tight linkage between the ocean and the atmosphere. In order to understand physical, chemical and biological processes relevant to phytoplankton bloom formation in the ocean, dynamics of VOCs and marine aerosols in the atmosphere, and the biogeochemical linkage between the ocean and the atmosphere, we welcome new interdisciplinary presentations and active discussions on physical, chemical, and biological sciences both from ocean and atmospheric fields in this session. Studies linked to the Surface Ocean-Lower Atmosphere Study (SOLAS) project are good examples, but other related studies are also invited.

Atmospheric aerosol particles can play a vital role in the climate change because they influence the radiative forcing on the Earth through absorbing and scattering of solar radiation. Especially, black carbon (BC) is known to a strong absorber of visible spectrum solar radiation in the atmosphere. However, its radiative forcing changes variably depending on its microphysical properties (e.g. mixing state, compositions, and shape). Therefore, it is important to accurately measure their parameters, especially, over the ocean because the observation is limited. In this study, the morphology and chemical compositions of marine aerosol particles including BC over the western north Pacific Ocean were analyzed by the individual particle analyses.

Measurement and samplings of atmospheric aerosol particles were carried out during the R/V Hakuho-Maru cruise (14-30/11/2017). The ambient BC mass concentrations were measured by a particle soot/absorption photometer (PSAP). In this study, we focused on relatively high BC mass concentration events over the western north Pacific Ocean at 26.62˚N, 137.93˚E and at 25.51˚N, 135.77˚E on 19/11/2017. The aerosols collected in both events were analyzed using a transmission electron microscope and an energy dispersive X-ray spectrometer.

In both samples, most BCs were embedded in sulfate particles that have organic coatings. Only a few BCs were attached to sea-salt particles. The backward trajectory analyses suggested that the air masses of both events passed through the land of China and Japan. These results indicate that BCs were emitted in or around the land, and then SO_2 condensed on their surface before organic carbon condensed during transportation. Our result is useful to understand the aging process of BC over the ocean.

To investigate the influence for the deposition of inorganic nitrogen compounds derived from the continent on the marine ecosystem at Bay of Bengal (BOB) in the North East Indian Ocean, we performed numerical simulations with and without atmospheric deposition of inorganic nitrogen compounds, using a 3-D lower trophic-marine ecosystem model (COCO-NEMURO), coupled with an atmospheric regional chemical transport model (WRF-CMAQ). The monthly mean data of wet and dry deposition of inorganic nitrogen compounds consisted of gases (HNO_3 and NH_3) and aerosol particles (NO_3^- and NH_4^+) at BOB region in 2009 –2016 produced by WRF-CMAQ were inputted to the COCO-NEMURO as a new nitrogen nutrient supplying process from the atmosphere. The results indicated that monthly average chlorophyll mass concentration at the surface in BOB was significant increase. This study indicates that the supply of atmospheric inorganic nitrogen compounds from continent to the BOB could lead to a high nutrient impact on the marine ecosystem within the subtropical region.

Carbon isotopic characterization of organic aerosols in tropical marine atmosphere at the Maïdo high-altitude observatory, Reunion Island

Sharmine Akter Simu[1], *Yuzo Miyazaki[1], OCTAVE Science Team

1. Institute of Low Temperature Science, Hokkaido University

Ocean-derived atmospheric aerosols can affect radiative forcing via formation of cloud droplets and ice nuclei as well as biogeochemical cycle of bioelements. Moreover, oxygenated volatile organic compounds (OVOCs) give significant impact on the atmospheric oxidative capacity and climate, which serve as key precursors of climatically active secondary organic aerosol (SOA) in the marine boundary layer. Atmospheric reactions of OVOCs and aerosols are closely linked to those of halogens, emissions of which are significant in the tropical oceans. However, current atmospheric models significantly underestimate the budget of OVOCs as well as SOA especially over tropical oceans, primarily due to poor knowledge of sources and paucity of observations of these parameters in tropical remote regions.
To improve our knowledge on the role of tropical oceans in the formation of atmospheric organic aerosols, size-segregated aerosol sampling was conducted for the first time at the Maïdo observatory (2,200m a.s.l) in Reunion Island in the Indian Ocean. The aerosol measurements were made during the Oxygenated Compounds in the Tropical Atmosphere–Variability and Exchanges (OCTAVE) project in March-June 2018, with integrated approach combining in situ/off-line measurements, satellite retrievals, and modelling. Stable carbon isotopic compositions together with molecular characterization of organic aerosols showed clear seasonal changes with significant contribution of marine sources to the observed aerosols in March when the microbial activity in sea surface was most active in that oceanic region. The effect of the changes in conditions of marine boundary layer and free troposphere on the observed organic aerosols are also discussed.

Carbon isotopic characterization of organic aerosols in tropical marine atmosphere at the Maïdo high-altitude observatory, Reunion Island

Sharmine Akter Simu[1], *Yuzo Miyazaki[1], OCTAVE Science Team

1. Institute of Low Temperature Science, Hokkaido University

Ocean-derived atmospheric aerosols can affect radiative forcing via formation of cloud droplets and ice nuclei as well as biogeochemical cycle of bioelements. Moreover, oxygenated volatile organic compounds (OVOCs) give significant impact on the atmospheric oxidative capacity and climate, which serve as key precursors of climatically active secondary organic aerosol (SOA) in the marine boundary layer. Atmospheric reactions of OVOCs and aerosols are closely linked to those of halogens, emissions of which are significant in the tropical oceans. However, current atmospheric models significantly underestimate the budget of OVOCs as well as SOA especially over tropical oceans, primarily due to poor knowledge of sources and paucity of observations of these parameters in tropical remote regions.
To improve our knowledge on the role of tropical oceans in the formation of atmospheric organic aerosols, size-segregated aerosol sampling was conducted for the first time at the Maïdo observatory (2,200m a.s.l) in Reunion Island in the Indian Ocean. The aerosol measurements were made during the Oxygenated Compounds in the Tropical Atmosphere–Variability and Exchanges (OCTAVE) project in March-June 2018, with integrated approach combining in situ/off-line measurements, satellite retrievals, and modelling. Stable carbon isotopic compositions together with molecular characterization of organic aerosols showed clear seasonal changes with significant contribution of marine sources to the observed aerosols in March when the microbial activity in sea surface was most active in that oceanic region. The effect of the changes in conditions of marine boundary layer and free troposphere on the observed organic aerosols are also discussed.

Surface structure as a control for gully complex development in the Mackey`s block, North Island, New Zealand

*Thomas Parkner[1]

1. University of Tsukuba, Graduate School of Life and Environmental Sciences

Gully erosion occurs on many steep, erosion-prone slopes. While most research focusses on gully formation by water erosion, gullies can also enlarge by mass movement processes. In New Zealand, such process combinations are named gully complexes. While concepts on gully complex development are available, material variability - other than lithology –is not included. In this study, development of gullies and gully complexes is analyzed by focusing on properties of the initial surface into with gullies and gully complexes erode to relate gully orientation and erosion intensity to surface structure.

The study area consists of 12 headwater catchments in the Mackey`s Block, North Island, New Zealand. Bedrock consists of Cretaceous-aged, highly crushed and sheared mudstones and sandstones. Deforestation by European settlers at the beginning of the 20th century for pastoral farming was followed by reforestation for wood production from the 1980s. Sequential aerial photographs from 1939 to 2005 were interpreted to map mass movements and the development of gullies. Digital elevation models were extracted from aerial photography from 1957 to 2002 using ERDAS to relate surface structure to gully orientation and erosion intensity.

Mapping results indicate that prior to a severe gully erosion phase, which started shortly before the first aerial photography in 1939, the surface structure is charaterized by (revegetated) small gullies, deep-seated landsliding with double ridges, and shallow flows. Deep (few meters to 15m) gullies complexes incised at the toe of mass movement bodies and eroded upslope. Such gullies developed oversteepened sidewalls, which in turn initiate extensive mass movements at the gully walls. Erosion intensity increased suddenly, where gullies destabilized mass movement deposits. Above the deep gully complexes, shallow (about 1 -2m deep), hundreds of meter long gully arms extended along boundaries of mass movements. These results indicate that next to morphometric parameters (slope, catchment size), material type, vegetation change, and moisture conditions, the development of gully complexes is also controlled by surface structure.

Keywords: gully, mass movement

Model Linking Landslides and River Evolution of Incisional Channel Created by River Erosion

*Chia-Ting Kao[1], Gene Jiing-yun You[1]

1. National Taiwan University

Landslides produce enormous volumes of sediment in mountainous watersheds. However, quantifying landslide-derived sediment transported downstream remains a challenge. This study makes effort in determine the amount of landslide-derived sediment that eroded by the water and the ratio of sediment yield of this problem. We try to use a coupled two-dimensional model to investigate the evolution of landslide aggregation influenced by the channel flow.In this study, the shallow water equations consider the two-dimensional distribution flow velocity to estimate the shear stress. In addition, the Exner equation is applied to calculate the sediment transport the landslide aggregation evolution. By assuming constant inflow, the Exner equation can be derived as a diffusion equation. Besides, both of the two equations under a horizontal 2D straight, non-erodible banks, and no secondary flow channel can be derived as our governing equation which has the nonlinear terms, and the analytical method may not work to solve the two equations under the 2D condition. As a result, this study adopts the finite volume method to proceed this work. This proposed model will be able to have a better presentation in estimating the landslide-derived sediment in channel, and these sequences are expected to be useful indicators in the watershed management according to the predicted the upstream of watershed sediment yield .

A semi-automated method for extracting channels and channel profiles from LiDAR-derived digital elevation models

*Pinliang Dong[1]

1. University of North Texas

Stream channels are an integral part of hydrology, alluvial geomorphology and tectonic geomorphology, and have long been studied qualitatively and quantitatively. With the advent of digital elevation models (DEMs) and geographic information systems (GIS), several methods have been proposed to extract channels from raster DEMs. This presentation introduces a semi-automated method for extracting stream channels from high resolution DEMs. The methodology flowchart includes the following major steps: (1) channel detection, (2) mathematical morphological operation, (3) vectorization, (4) profile generation, and (5) accuracy assessment. The method is implemented as an ArcGIS Python add-in toolbar. The application of the toolbar is demonstrated using a LiDAR-derived DEM in a study area along the San Andreas Fault in California, USA.

Laboratory experiments on the landform development

*Shunji Ouchi[1]

1. Faculty of Science and Engineering, Chuo University

Geomorphic experiments with uplift and rainfall erosion are expected to provide some important knowledge to interpret the development of landform, which has left only scarce and hard-to-find evidence. This type of experiments had not been conducted so often, probably because no one had a good idea to scale down the processes of landform development. In recent years, however, laboratory experiments on the development of landform were increasingly conducted for the purpose to verify numerical/analytical models, which have been promoted by the development of computer technology and the spread of DEM, while the fundamental problems of huge scale difference have not been solved yet. Some of these recent experiments demonstrated a certain mechanism or a law governing the experimental landform development, such as the self-organized criticality or the competition between diffusive hill slope transport and advective transport in channels, which was suggested by numerical analyses. This indicates the applicability of numerical models to the experimental landform, but not to the real landform yet, although the authors believed it. Real landforms we see today have developed in the geographical space through the historical time, and inevitably have infinite varieties. We can find landscapes similar to the experimentally formed landscapes somewhere in the world, but this does not mean that mechanisms or laws dominated in the experiment also work on the real landform. The experimental landform develops within a certain setting, which is restricted by the facilities and arranged for the purpose. We still have a lot to do before taking the experiments as a bridge between numerical models and natural landscapes. I have been conducting a series of geomorphic experiments with changing experimental settings (40 runs by now), and I here try to make clear the significance of experiments in the study of geomorphology on the basis of these experiments.
A mixture of fine sand and kaolinite (10:1 by weight) compacted in a square prism-shaped stainless container (ca. 60×60×40cm) is pushed up by the uplift-generating device put under the bottom plate of container. Mist-type rainfall is generated by a pump through spray nozzles. The results of experiments suggested the existence of two thresholds of uplift rate, which is the most important independent controlling factor. Below the lower threshold, fluvial erosion offsets the surface rising by slow uplift, and gentle landforms reflecting the mound erodibility and rainfall intensity appear (Characteristic relief phase). Above the upper threshold, uplift overwhelms and a massive mountain grows until it hits the limit of experimental facilities (Mountain building phase). When the uplift rate is between the lower and upper thresholds, average surface height stops increasing and changes around a certain height depending on the uplift rate, after valley systems develop and slopes grow enough to cause landslides (Steady state phase). This steady state phase is the most common condition through the series of experiments. Rainfall intensity is expected to affect the amount of surface flow; and therefore, the rate of erosion. Low rainfall generates less surface flow, and this reduces erosion and make the surface grow higher. Permeability of the sand mound is considered to have a similar effect concerning the surface flow. However, more permeable material, associated with lower sear strength, promotes slope failures even in the earlier stage. The surface, therefore, becomes lower even with less rainfall. These factors, which relate each other themselves, apparently have complex effects on the development of experimental landform. The relationships among these controlling factors can be compared to those concerning real landform. Revealing these relationships and their effects on the experimental landform is probably the key to make geomorphic experiments meaningful in the study of geomorphology.

Characteristics of lake sediment from southern part of Mongolia and comparison to meteorological data

*Uyangaa Udaanjargal[1], Noriko Hasebe[1], Keisuke Fukushi[1], Tanaka Yukiya[2], Davaadorj Davaasuren[4], Makoto Sambo[1], Baasansuren Gankhurel[1], Nagayoshi Katsuta[3], Shinya Ochiai[1], Tuvshin Gerelmaa[4]

1. Kanazawa University, 2. Kyunghee University, 3. Gifu University, 4. National University of Mongolia

Mongolia is located in center of the Central Asia and it provides an important key archive for the research of climate characteristics inside continents. Lake sediments are an excellent archive to study long-term fluctuations of environmental conditions (Gunten et al. 2009). Lake is the subject to a variety of extrinsic and intrinsic forcing variables that regulate the subsequent history of the lake, such as climate, watershed bedrock composition, tectonic and volcanic activity, vegetation, aquatic biota, and human activities (Gierlowski-Kordesch, 2004). To understand how climate system works in Mongolia and how we can extract information from the lake sediments, sediment cores of about 30 cm long from Boontsagaan, Orog and Olgoy lakes are analyzed and compared to the meteorological data (air temperature, precipitation and wind) of Galuut and Baatsagaan stations, Bayanhongor Province. The sedimentary features include whole and mineral grain size, grain density, water, organic matter, carbonate, and amorphous silica contents. Sedimentary ages were estimated by excess 210Pb measurement. According to the comparison between sediment characteristics and climate condition, temperature is correlated to whole grain size in three of lakes.

Further comparison reveals that calcium carbonate concentration, amorphous silica concentration, and mineral grain size correlate to temperature in Boontsagaan and Olgoy lakes. In Orog lake, wetter years with high wind and much rainfall result in fine grain size, while the high amount of $CaCO_3$and organic flux is found during the low precipitation. Some of the major fluctuations may indicate indirect consequence of climate change, for instance, some events such as the earthquake or a permafrost degradation.

Evaluation of geomorphological changes on Kujukuri beach based on UAV SfM

*Mergen Kungaa[1], Toshihiko Sugai[1], Natsuki Sasaki[1], Taiga Kimori[1], Taro Funatsu

1. Tokyo University, Graduate School of Frontier Sciences, Department of Natural Environmental Studies

Nowadays, structure from motion (SfM) photogrammetry became a powerful tool in the hands of coastal researchers. During 2018-2019 we conducted 4 aerial survey by UAV on the 4 km long stretch on Kujukuri beach between Nabakigawa and Horikawa rivers, Chiba Prefecture. These 2 rivers separate research area from rest of 60-km long Kujukuri beach, forming separate morpho- and lithodynamical unit. The results of the research were high-resolution digital elevation models (DEM) and orthomosaics for February 2018, June 2018, September 2018 and February 2019. Based on DEM and orhomosaics we were able evaluate geomorphological changes throughout the year. From February 2018 to September 2018 we recorded active accumulation along the entire length of the beach. But accumulation intensity varied in different zones of beach as if foreshore, backshore or dunes. Also, the accumulation processes did not occur evenly for 7 months, but mostly intensified in the summer. From September 2018 to February 2019 erosional processes prevailed having different intensity at various sites. Thus, we were able to record in high resolution the process of transition from the winter profile of the beach to the summer profile and back.

Honeycomb Weathering (Tafoni) of Sandstone and Environmental Factors in Yonaguni Island, Okinawa Prefecture, Japan

*Takayuki Ogata[1]

1. Disaster Prevention Research Center for Island Regions, University of the Ryukyus

Sandstone surfaces of Yonaguni Island (westernmost of the Ryukyu Arc) often show a honeycomb structure (tafoni) derived from physical disintegration in relation to salt weathering. Miocene sandstone (Yaeyama Group) is extensively exposed on the island surface, and forms sea cliffs along rocky coasts. The honeycomb structure is especially observed along the coasts where wave splashes produce wetting and drying processes assisted by strong wind and active evaporation. The geometry and density of tafoni seem to be controlled by vertical height from the sea level and horizontal distance of the coast line. Field observations at the rocky coasts of Yonaguni Island suggest that larger holes are developed along the north-faced coasts than the south-faced coasts, which depends mainly on the northeastern monsoon during the winter period.

Colluvial deposits in first-order streams and channel head migration by shallow landslides: Case study in granitic basins, Asaminami, Hiroshima, Japan

*Tsuyoshi Hattanji[1], Ryuya Kodama[2], Takahisa Furuichi[3], Shoji Doshida[4], Yasushi Tanaka[5]

1. Faculty of Life and Environmental Sciences, University of Tsukuba, 2. former College of Geoscience, University of Tsukuba, 3. Hokkaido University, 4. National Research Institute of Fire and Disaster, 5. Komazawa University

Relationship between dates of colluvial deposits and channel-head migration was examined in granitic mountains where a debris-flow disaster occurred in 2014. Topographic analysis using 1-m grid DEMs before and after the disaster indicates that post-event channel heads were located upslope from pre-event channel heads due to landslide or erosion by debris flow. Post-event channel heads with shallow landslides had strong inverse correlations between local slope and drainage area. Charcoal samples were collected in colluvial deposits of two post-event channel heads (A and B) where the channel heads migrated more than 50 m upslope with shallow landslides. The radiocarbon dates of the samples were 1162–1194 y BP for channel head A and 786 y BP for channel head B. Another sample was collected in colluvial deposits of a post-event channel head (C) with shallow landslide but no migration. The radiocarbon date of the sample at the channel head C was 670 y BP. These radiocarbon data explain contrasting intervals of landslide events in hollows. The channel head A with older radiocarbon dates has the longer interval of landslide events and therefore the valley head has been buried in longer distance (more than 50 m) along the channel since the last landslide event to 2014.

Rock restrictions on topographical features of rivers: model experiment

*Yuta Takase[1], Noritaka Endo[1]

1. Kanazawa University

Landforms of mountainous areas is developed by both downcutting and lateral erosion of rivers. For example, ingrown meanders develop when the lateral erosion is predominant, while entrenched meanders form when the downcutting is dominant. It is a generally accepted understanding that the relative superiority or inferiority between the downcutting and lateral erosion is determined by the uplift rate of the land, rock strength difference, riverbed gradient, deflection of flow in a channel, but the systematic discussion remains insufficient. In this study, we conducted flume experiments to investigate the relationship between bedrock strength and sinuosity, and the relationship between time series pattern of uplift and meandering development. We prepared a single channel that cut a uniform substrate in a two-dimensional flume. The substrates were made of the mixture of fine sand and clay, and we examined two types of substrate, hard and soft ones, which can be formed by changing the ratio of sand and clay (the mixure including more clay is harder). Uplift of the experimental land was realized by lowering a weir set at the downstream end of the channel, i.e. the base-level lowering.

Knickpoints were observed more frequently in the case of hard substrate, which is consistent with previous study (Grimaud, 2016). Sinuosity of the channel tended to be higher for the hard substrate than the soft substrate, which is seemingly opposite the conventional understanding, but can be attributed to sustainability of the channel shape due to erosion resistance of the hard substrate. In all the experiments, the sinuosity tended to be higher after the uplift ceased rather than during the period of uplift.

Stream power incision model and the stage of topographic equilibrium, using physical experiments

*Imamura Akihiro[1], Noritaka Endo[1]

1. Kanazawa University

Bedrock rivers develop their landforms very slowly, compared with alluvial river, thus bedrock rivers and their surrounding topographies are expected to record long-term environmental changes such as tectonics and climate. The stream power incision model (SPIM) is an empirical model that expresses the erosion rate due to rivers by the product of two power functions of the contributing area and river bed slope. Using this equation with an uplift term, the differential equation of the temporal change in the altitude of riverbed is constituted. When applying the model to a natural drainage basin, the equilibrium state between erosion and uplift is often assumed, partially because the uplift rate is usually unknown. Under the assumption of equilibrium state, SPIM is reduced to the relationship in which the riverbed slope is a power function of the contributing area, known as Flint’s law, which is the basis of “slope-area analysis” to determine the concavity (equivalent to the ratio of two power exponents in SPIM). Usually the two power exponents in SPIM are presumed to be constant if lithology, climate, and other factors are the same. This postulation, however, is difficult to verify for natural landforms, because of heterogeneity of various kind of property within a single drainage basin and difficulty in evaluation of the incision rate.

This study investigates the relation between the incision rate and topographic properties in river basins, through the observation of small-sized physical experiments under well-controlled conditions. A flume used was 90×180 cm, and the substrate to be dissected composed of the uniform mixture of sand and clay was installed. Rainfall was simulated by supplying mist from 10 nozzles. Uplift was realized by lowering a weir that was installed at the downstream end of the flume and determined the base level. The landform was measured by photogrammetry using several hundred photos taken during intermission from rainfall for photographing.

We compared the results of (1) this and (2) the previous studies (Imamura and Endo, 2018) realizing different kinds of uplift: (1) sudden base level lowering from a stable state of basin, to observe the response processes of the landforms until the basin became stable again (about 5 hours); (2) Sudden change in the uplift rate, to observe the change from a stable state under constant uplift of 4.5 mm/h to a new stable state under faster uplift rate of 6.0 mm/h (about 6 hours).

The results of Experiment (1) showed that the incision rate decreased with time (presumably asymptotic to zero), while Experiment (2) always displayed a certain finite value of the incision rate. The power exponents in SPIM, m (for the contributing area) and n (for the slope) did not seem to be constant in both experiments. The ratio m/n also changed, but seemed to converge to a certain value in each experiment.

We evaluated the correlation of the incision rate with the fitted function for each measurement time. In Experiment (1), although the denudation rate decreased with time, the first half of the run time showed good correlations but the latter half showed the worse. By contrast, Experiment (2) exhibited increasing correlations in the latter half of the run. These results suggests that SPIM holds for dynamic equilibrium (tectonic steady state (Montgomery, 2001)) or the early stage of static quasi-equilibrium (erosional stead state (Montgomery, 2001)), but fails for mature or later stages in which a landform proceeds to a

Downstream variation in gravel size of the Tenjin River system

*Kazuaki Hori[1], Kazuya Yonehara[1]

1. Department of Geography, Graduate School of Environmental Studies, Nagoya University

Many researchers have studied downstream variation in river-bed material size and its controlling factors, because they are important to understand the evolution of fluvial landforms and drainage basin. Many of these studies have focused only on rivers flowing through mountains or alluvial plains. Thus, it is desirable to examine a much broader range, i.e. from head to mouth of a river. We investigated the downstream variation of gravel size and channel gradient in the Tenjin River system (Tenjin, Ogamo, and Mitoku rivers) located in the central part of Tottori prefecture, Japan. The Tenjin River is approximately 34 km in length and major tributaries, the Ogamo and Mitoku rivers, join the Tenjin River at approximately 7 km and 12 km upstream from the mouth, respectively. Mean gravel size tends to decrease toward the downstream between 5 and 23 km upstream from the Tenjin River mouth where exposed gravel bars are easily found. Channel gradient is usually less than 0.03 and its variation is relatively small in this range. On the other hand, exposed gravel bars are uncommon between 23 and 34 km upstream from the mouth. The channel gradient become larger (> 0.06) and shows large variation. Large boulders (> 500 mm) are distributed in the channel. The number of boulders, especially > 1000 mm, seems to be inversely proportional to the distance from the valley wall. Buffers along the rivers regulate the supply of boulders from the valley wall in the upper reaches and reduce the connectivity of sediment supply from the tributaries in the middle and lower reaches. Barriers typified by weirs reduce the connectivity in the longitudinal direction throughout the basin.

Keywords: sediment connectivity, grain size, channel gradient

Talus slope development in the time of deglaciation: a case study of the Rev Valley, SW Spitsbergen

*Krzysztof Senderak[1], Marta Kondracka[1], Bogdan Gądek[1]

1. Faculty of Earth Sciences, University of Silesia

Every high-mountain area is characterized by the occurrence of talus slopes. A process of development this kind of forms depends on among other things climatic conditions. Currently in Spitsbergen, we observe the deglaciation process caused climate changes. This causes that the evolution’ s tempo of all environments linked with glaciers is very high. It also concerns the talus slopes, which, in the last time, are more often used as key element to paleo-environmental reconstructions for last thousands. In this paper, we present the geophysical surveys of talus slopes conducted in the Rev Valley (SW Spitsbergen). The valley was shaped by glacier, which left behind among other things glacial lake and buried glacial ice in mixed slope-moraine material. Nowadays, the talus slopes in this valley develop under the typical conditions of periglacial environment. In the studies of 15 talus slopes we used the ground-penetrating radar (GPR) and electrical resistivity tomography method (ERT). The studies allowed to recognize the internal structure of talus slopes and to determine a character of their elements, such as thickness of slopes, permafrost table and a depth of active layer, present of buried glacial ice, sediementological structures caused by various deposition of material on the slope surface, and finally a shape of bedrock. A comparison obtained results indicates on relevant regularity in the development of internal structure of talus slopes. These are for example visible differences in the terms of present of permafrost, which is located from a depth 2-3 m in the oldest slopes to a depth 4-5 m in the youngest. On the other hands, the studies discovers the deviations from the typical evolution models. The buried glacial ice has not been survived in a younger forms, whereas it is present in these older slopes. Based on the results we created the proposition of model of talus slope evolution developing in a periglacial period. In this time the development of slopes characterize a very high variability, not much lower than in previous paraglacial period. This work was financed from the funds of the National Science Centre in Poland received by Krzysztof Senderak in the Preludium 12 project: Determination of the evolution of slopes of southern Spitsbergen on the background of climate changes (2016/23/N/ST10/00162).

Distribution of Large Benthic Foraminifers in one of Majuro's Conservation Areas –Drenmeo Island

*Benedict Yamamura[1], Kazuhiko Fujita[2], Melba White[3], Kyotak Ishiguro[3], Hironobu Kan[1]

1. Kyushu University, Integrated Sciences for Global Society - Research Center for Coastal Seafloor , 2. Department of Physics and Earth Sciences, University of the Ryukyus, 3. Marshall Islands Marine Resources Authority

Climate change is having a huge impact on the island formation. In this study, we examined the composition and distribution of large benthic foraminifers (LBF) from 12 chosen sample sites (see map) within and outside of Drenmeo islet, one of the designated conservation areas in Majuro atoll. Samples were collected from the area to further investigate the sand built-up between the conservation area and the adjacent islet. The preliminary findings showed that the area is predominantly composed of two island-building LBF, namely *Calcarina sp.* and *Amphistegina sp.* The final results from this study will help stakeholders to amend the management plan to include the adjacent islet under the current management plan.

Luminescence chronology of fluvial and marine records from subsurface sediment cores: An insight into the geomorphic evolution of Kaveri delta, India

*kartika goswami[1], Anbarasu Kumaresan[2], Sivakumar Krishnan[2], Senthil K. Sadasivam[2], Manoj Kumar Jaiswal[1]

1. Department of Earth Sciences, Indian Institute of Science Education and Reserach Kolkata, 2. National College Tiruchirappalli, India

Long-term evolution of river deltas is a result of forcings (tectonics, climate, sea level, avulsion, compaction etc). We present the results of luminescence dating of sediments from four sediment cores (VKI, TNR, SY and KKI) of 25 m depth each, retrieved from the Kaveri delta in south India. The coring sites are ~2.5 km, ~11 km, ~17 km and ~20 km away from the present coastline respectively. The cores were analysed for OSL dating, 14C dating, lithology and microfossils and represent various stages of fluvial and marine activity in the region over the last ~150 ka. The chronology of the core closet to the coast (VKI) reflects eight major phases of increased sea level during the late quaternary period (142-140 ka, 104-100 ka, ~121 ka, 87-81 ka, 60-57 ka, 9-6 ka, ~5 ka and ~3 ka) partly coinciding with the global climate cycles MIS 6, MIS 5, MIS 3, MIS 1 respectively. During ~121 ka and 9-6 ka, marine transgression reached the core location to leave marine signatures in the forms of foraminifera. VKI core replicates the quaternary sea level curve, showing strong control of the sea in coastal deposition.

The oldest age of VKI is ~140 ka. The three cores situated further inland give oldest/bottom most ages of~120 ka. This indicates the coastal land has uplifted in the recent years with deeper sediments being encountered at relative shallower depth. The uplift is expected to occur around post 50 ka, creating a basin fill situation for riverine sediments to accumulate and restricting the delta to prograde. This is observed from the sedimentation pattern and robust chronology of the other three inland cores. Analysis of DEM also supported the occurrence of uplift. Thus, the present work examines the geomorphic evolution of Kaveri delta, an archive of fluvial, shoreline and tectonic activities.

[E] Poster | H (Human Geosciences)：H-GM Geomorphology

Wed. May 29, 2019 5:15 PM - 6:30 PM JST | Wed. May 29, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_18

[H-GM03] Geomorphology

convener:Tsuyoshi Hattanji(Faculty of Life and Environmental Sciences, University of Tsukuba), Masayuki Seto(Fukushima Future Center for Regional Revitalization, Fukushima University)

The main subject of this session is interdisciplinary discussion on the whole range of themes relating to geomorphology, especially geomorphic processes, landform development and its relation to environmental changes, geomorphological hazards and their mitigation, relationships among geomorphic processes, other natural phenomena and human activities, and various techniques of geomorphological measurements and landform classification. All presentations and discussion of this session are made in English.

Honeycomb Weathering (Tafoni) of Sandstone and Environmental Factors in Yonaguni Island, Okinawa Prefecture, Japan

*Takayuki Ogata[1]

1. Disaster Prevention Research Center for Island Regions, University of the Ryukyus

Sandstone surfaces of Yonaguni Island (westernmost of the Ryukyu Arc) often show a honeycomb structure (tafoni) derived from physical disintegration in relation to salt weathering. Miocene sandstone (Yaeyama Group) is extensively exposed on the island surface, and forms sea cliffs along rocky coasts. The honeycomb structure is especially observed along the coasts where wave splashes produce wetting and drying processes assisted by strong wind and active evaporation. The geometry and density of tafoni seem to be controlled by vertical height from the sea level and horizontal distance of the coast line. Field observations at the rocky coasts of Yonaguni Island suggest that larger holes are developed along the north-faced coasts than the south-faced coasts, which depends mainly on the northeastern monsoon during the winter period.

Colluvial deposits in first-order streams and channel head migration by shallow landslides: Case study in granitic basins, Asaminami, Hiroshima, Japan

*Tsuyoshi Hattanji[1], Ryuya Kodama[2], Takahisa Furuichi[3], Shoji Doshida[4], Yasushi Tanaka[5]

1. Faculty of Life and Environmental Sciences, University of Tsukuba, 2. former College of Geoscience, University of Tsukuba, 3. Hokkaido University, 4. National Research Institute of Fire and Disaster, 5. Komazawa University

Relationship between dates of colluvial deposits and channel-head migration was examined in granitic mountains where a debris-flow disaster occurred in 2014. Topographic analysis using 1-m grid DEMs before and after the disaster indicates that post-event channel heads were located upslope from pre-event channel heads due to landslide or erosion by debris flow. Post-event channel heads with shallow landslides had strong inverse correlations between local slope and drainage area. Charcoal samples were collected in colluvial deposits of two post-event channel heads (A and B) where the channel heads migrated more than 50 m upslope with shallow landslides. The radiocarbon dates of the samples were 1162–1194 y BP for channel head A and 786 y BP for channel head B. Another sample was collected in colluvial deposits of a post-event channel head (C) with shallow landslide but no migration. The radiocarbon date of the sample at the channel head C was 670 y BP. These radiocarbon data explain contrasting intervals of landslide events in hollows. The channel head A with older radiocarbon dates has the longer interval of landslide events and therefore the valley head has been buried in longer distance (more than 50 m) along the channel since the last landslide event to 2014.

Rock restrictions on topographical features of rivers: model experiment

*Yuta Takase[1], Noritaka Endo[1]

1. Kanazawa University

Landforms of mountainous areas is developed by both downcutting and lateral erosion of rivers. For example, ingrown meanders develop when the lateral erosion is predominant, while entrenched meanders form when the downcutting is dominant. It is a generally accepted understanding that the relative superiority or inferiority between the downcutting and lateral erosion is determined by the uplift rate of the land, rock strength difference, riverbed gradient, deflection of flow in a channel, but the systematic discussion remains insufficient. In this study, we conducted flume experiments to investigate the relationship between bedrock strength and sinuosity, and the relationship between time series pattern of uplift and meandering development. We prepared a single channel that cut a uniform substrate in a two-dimensional flume. The substrates were made of the mixture of fine sand and clay, and we examined two types of substrate, hard and soft ones, which can be formed by changing the ratio of sand and clay (the mixure including more clay is harder). Uplift of the experimental land was realized by lowering a weir set at the downstream end of the channel, i.e. the base-level lowering.

Knickpoints were observed more frequently in the case of hard substrate, which is consistent with previous study (Grimaud, 2016). Sinuosity of the channel tended to be higher for the hard substrate than the soft substrate, which is seemingly opposite the conventional understanding, but can be attributed to sustainability of the channel shape due to erosion resistance of the hard substrate. In all the experiments, the sinuosity tended to be higher after the uplift ceased rather than during the period of uplift.

Stream power incision model and the stage of topographic equilibrium, using physical experiments

*Imamura Akihiro[1], Noritaka Endo[1]

1. Kanazawa University

Bedrock rivers develop their landforms very slowly, compared with alluvial river, thus bedrock rivers and their surrounding topographies are expected to record long-term environmental changes such as tectonics and climate. The stream power incision model (SPIM) is an empirical model that expresses the erosion rate due to rivers by the product of two power functions of the contributing area and river bed slope. Using this equation with an uplift term, the differential equation of the temporal change in the altitude of riverbed is constituted. When applying the model to a natural drainage basin, the equilibrium state between erosion and uplift is often assumed, partially because the uplift rate is usually unknown. Under the assumption of equilibrium state, SPIM is reduced to the relationship in which the riverbed slope is a power function of the contributing area, known as Flint’s law, which is the basis of “slope-area analysis” to determine the concavity (equivalent to the ratio of two power exponents in SPIM). Usually the two power exponents in SPIM are presumed to be constant if lithology, climate, and other factors are the same. This postulation, however, is difficult to verify for natural landforms, because of heterogeneity of various kind of property within a single drainage basin and difficulty in evaluation of the incision rate.

This study investigates the relation between the incision rate and topographic properties in river basins, through the observation of small-sized physical experiments under well-controlled conditions. A flume used was 90×180 cm, and the substrate to be dissected composed of the uniform mixture of sand and clay was installed. Rainfall was simulated by supplying mist from 10 nozzles. Uplift was realized by lowering a weir that was installed at the downstream end of the flume and determined the base level. The landform was measured by photogrammetry using several hundred photos taken during intermission from rainfall for photographing.

We compared the results of (1) this and (2) the previous studies (Imamura and Endo, 2018) realizing different kinds of uplift: (1) sudden base level lowering from a stable state of basin, to observe the response processes of the landforms until the basin became stable again (about 5 hours); (2) Sudden change in the uplift rate, to observe the change from a stable state under constant uplift of 4.5 mm/h to a new stable state under faster uplift rate of 6.0 mm/h (about 6 hours).

The results of Experiment (1) showed that the incision rate decreased with time (presumably asymptotic to zero), while Experiment (2) always displayed a certain finite value of the incision rate. The power exponents in SPIM, m (for the contributing area) and n (for the slope) did not seem to be constant in both experiments. The ratio m/n also changed, but seemed to converge to a certain value in each experiment.

We evaluated the correlation of the incision rate with the fitted function for each measurement time. In Experiment (1), although the denudation rate decreased with time, the first half of the run time showed good correlations but the latter half showed the worse. By contrast, Experiment (2) exhibited increasing correlations in the latter half of the run. These results suggests that SPIM holds for dynamic equilibrium (tectonic steady state (Montgomery, 2001)) or the early stage of static quasi-equilibrium (erosional stead state (Montgomery, 2001)), but fails for mature or later stages in which a landform proceeds to a

Downstream variation in gravel size of the Tenjin River system

*Kazuaki Hori[1], Kazuya Yonehara[1]

1. Department of Geography, Graduate School of Environmental Studies, Nagoya University

Many researchers have studied downstream variation in river-bed material size and its controlling factors, because they are important to understand the evolution of fluvial landforms and drainage basin. Many of these studies have focused only on rivers flowing through mountains or alluvial plains. Thus, it is desirable to examine a much broader range, i.e. from head to mouth of a river. We investigated the downstream variation of gravel size and channel gradient in the Tenjin River system (Tenjin, Ogamo, and Mitoku rivers) located in the central part of Tottori prefecture, Japan. The Tenjin River is approximately 34 km in length and major tributaries, the Ogamo and Mitoku rivers, join the Tenjin River at approximately 7 km and 12 km upstream from the mouth, respectively. Mean gravel size tends to decrease toward the downstream between 5 and 23 km upstream from the Tenjin River mouth where exposed gravel bars are easily found. Channel gradient is usually less than 0.03 and its variation is relatively small in this range. On the other hand, exposed gravel bars are uncommon between 23 and 34 km upstream from the mouth. The channel gradient become larger (> 0.06) and shows large variation. Large boulders (> 500 mm) are distributed in the channel. The number of boulders, especially > 1000 mm, seems to be inversely proportional to the distance from the valley wall. Buffers along the rivers regulate the supply of boulders from the valley wall in the upper reaches and reduce the connectivity of sediment supply from the tributaries in the middle and lower reaches. Barriers typified by weirs reduce the connectivity in the longitudinal direction throughout the basin.

Talus slope development in the time of deglaciation: a case study of the Rev Valley, SW Spitsbergen

*Krzysztof Senderak[1], Marta Kondracka[1], Bogdan Gądek[1]

1. Faculty of Earth Sciences, University of Silesia

Every high-mountain area is characterized by the occurrence of talus slopes. A process of development this kind of forms depends on among other things climatic conditions. Currently in Spitsbergen, we observe the deglaciation process caused climate changes. This causes that the evolution’ s tempo of all environments linked with glaciers is very high. It also concerns the talus slopes, which, in the last time, are more often used as key element to paleo-environmental reconstructions for last thousands. In this paper, we present the geophysical surveys of talus slopes conducted in the Rev Valley (SW Spitsbergen). The valley was shaped by glacier, which left behind among other things glacial lake and buried glacial ice in mixed slope-moraine material. Nowadays, the talus slopes in this valley develop under the typical conditions of periglacial environment. In the studies of 15 talus slopes we used the ground-penetrating radar (GPR) and electrical resistivity tomography method (ERT). The studies allowed to recognize the internal structure of talus slopes and to determine a character of their elements, such as thickness of slopes, permafrost table and a depth of active layer, present of buried glacial ice, sediementological structures caused by various deposition of material on the slope surface, and finally a shape of bedrock. A comparison obtained results indicates on relevant regularity in the development of internal structure of talus slopes. These are for example visible differences in the terms of present of permafrost, which is located from a depth 2-3 m in the oldest slopes to a depth 4-5 m in the youngest. On the other hands, the studies discovers the deviations from the typical evolution models. The buried glacial ice has not been survived in a younger forms, whereas it is present in these older slopes. Based on the results we created the proposition of model of talus slope evolution developing in a periglacial period. In this time the development of slopes characterize a very high variability, not much lower than in previous paraglacial period. This work was financed from the funds of the National Science Centre in Poland received by Krzysztof Senderak in the Preludium 12 project: Determination of the evolution of slopes of southern Spitsbergen on the background of climate changes (2016/23/N/ST10/00162).

Luminescence chronology of fluvial and marine records from subsurface sediment cores: An insight into the geomorphic evolution of Kaveri delta, India

*kartika goswami[1], Anbarasu Kumaresan[2], Sivakumar Krishnan[2], Senthil K. Sadasivam[2], Manoj Kumar Jaiswal[1]

1. Department of Earth Sciences, Indian Institute of Science Education and Reserach Kolkata, 2. National College Tiruchirappalli, India

Long-term evolution of river deltas is a result of forcings (tectonics, climate, sea level, avulsion, compaction etc). We present the results of luminescence dating of sediments from four sediment cores (VKI, TNR, SY and KKI) of 25 m depth each, retrieved from the Kaveri delta in south India. The coring sites are ~2.5 km, ~11 km, ~17 km and ~20 km away from the present coastline respectively. The cores were analysed for OSL dating, 14C dating, lithology and microfossils and represent various stages of fluvial and marine activity in the region over the last ~150 ka. The chronology of the core closet to the coast (VKI) reflects eight major phases of increased sea level during the late quaternary period (142-140 ka, 104-100 ka, ~121 ka, 87-81 ka, 60-57 ka, 9-6 ka, ~5 ka and ~3 ka) partly coinciding with the global climate cycles MIS 6, MIS 5, MIS 3, MIS 1 respectively. During ~121 ka and 9-6 ka, marine transgression reached the core location to leave marine signatures in the forms of foraminifera. VKI core replicates the quaternary sea level curve, showing strong control of the sea in coastal deposition.

The oldest age of VKI is ~140 ka. The three cores situated further inland give oldest/bottom most ages of~120 ka. This indicates the coastal land has uplifted in the recent years with deeper sediments being encountered at relative shallower depth. The uplift is expected to occur around post 50 ka, creating a basin fill situation for riverine sediments to accumulate and restricting the delta to prograde. This is observed from the sedimentation pattern and robust chronology of the other three inland cores. Analysis of DEM also supported the occurrence of uplift. Thus, the present work examines the geomorphic evolution of Kaveri delta, an archive of fluvial, shoreline and tectonic activities.

Discussion

Salt weathering in humidity-change environments: a laboratory experiment

*Masato Sato[1], Tsuyoshi Hattanji[2]

1. Graduate School of Life and environmental Sciences, University of Tsukuba, 2. Faculty of Life and Environmental Sciences, University of Tsukuba

A laboratory weathering experiment simulating under changing humidity conditions were carried out using five types of rocks (porous tuff, porous sandstone, dense sandstone, and two porous mudstones) with three types of salts (sodium chloride, sodium sulfate, or magnesium sulfate). The rock specimens were subjected to humidity oscillations in a climatic cabinet where air humidity ranged from 20%RH to 98%RH during 6-hour periods 20˚C. Prior to the weathering experiment, the specimens were oven-dried, and the water supply was restricted only from air humidity during the experiment.
Humidity oscillation induced cycles of repeated of salt deliquescence-recrystallization and hydration-dehydration. Salts on rock surface deliquesced and hydrated in a high-humidity period, while they crystallized in a low-humidity period. The degrees of damage were correlated with moisture amounts absorbed to the rock specimens in the high-humidity period.
Sodium chloride which deliquesces at humidity of more than 80%RH caused the most intensive weathering. Porous sandstone with sodium chloride was completely broken down after 100 cycles of humidity changes. Dense sandstone and porous tuff showed flaking or swelling on their surfaces. Equotip surface hardness of dense sandstone with sodium chloride decreased with increasing number of humidity cycles. Sodium chloride can easily induce salt weathering by salt deliquesce and recrystallize in environment where air humidity fluctuates in a short time interval, such as the surfaces of rock cliff in coastal spray zones.
Magnesium sulfate induced a weight loss in porous sandstone, through flaking from the surface of porous tuff, and through swelling and cracking on the surface of dense sandstone. Sodium sulfate was not effective in the humidity-change experiment, although salt efflorescence was extensively produced. Slow hydration rate of sodium sulfate can cause the ineffectiveness of sodium sulfate. In addition, volumetric expansion with hydration of sodium sulfate may result in pore clogging, and hinder infiltration of moisture into the rock specimens. The restricted activity of sodium sulfate suggests that sodium sulfate rarely induces salt weathering by daily humidity fluctuation. Magnesium sulfate might influence rock decay more than sodium sulfate when air humidity fluctuates in a short period.

Verification a new control device of blown sand transport rate by wind tunnel experiments

*Yoshinori Kodama[1], Riko Saikusa[2]

1. Faculty of Agriculture, 2. Faculty of Regional Sciences

A new water-pool device for reducing blown sand transport rate was proposed from a view point of saltating particle motion. Wind duct experiments were conducted to check sediment trap efficiencies of a proposed device. In our experimental conditions, maximum wind velocity: 12.9 m/s, it worked well: reducing blown sand transport rate less than 6 % within 4.55 m distance. We estimated that the least length of the device is 11.3 m at 18.0 m/s wind condition, which is almost maximum in Tottori Sand Dunes.

Bedrock landslides, river blockage, and barrier-lake outburst as general geomorphic processes in high-relief mountainous landscape: an example from the Marshyangdi River, central Nepal

*Yuki Matsushi[1], Hiroshi YAGI[2], Hiroyuki Matsuzaki[3]

1. Disaster Prevention Research Institute, Kyoto University, 2. Department of Education, Art and Science, Yamagata University, 3. icro Analysis Laboratory, Tandem Accelerator, The University of Tokyo

This study demonstrates generality of large-scale bedrock landslides, river blockage by the slid mass, and debris flow by the barrier-lake outburst in landscape evolution of high-relief mountainous watersheds. We focused on the Marshyangdi River, south-eastern range of the Annapurna massif, central Nepal, to conduct ground-based surveys and geo-spatial analyses. Geology along the river consists mainly of Paleozoic and Mesozoic sedimentary rocks, gneiss, phyllite, schist, and shale from the upper to lower reach. Deeply-incised gorge develops in the area of massive gneiss, while fill terraces occupy the wide area of valley floor downstream from the Main Central Thrust. The lower- to mid-level terraces exhibit characteristic morphology with hummocky mounds with gneiss boulders settled on the surface, indicating their origin that may be relevant to large scale debris flow events by deep-seated bedrock landslide and subsequent barrier lake breach. Exposure ages of the boulders ranges from 2 to 4 ka, indicating repeated occurrence of such events under the Holocene climate. On the upstream area, several sets of lacustrine deposits remain along the main channel. The sequence and distribution indicate that the paleo landslide-dammed lakes expanded few-kilometers in length and few hundreds meters in depth before breaching. The debris flow ran through the river for tens of kilometers, spreading out over the downstream valley. Results of evidence mapping and topographic analysis indicate that these kind of large-scale sequential phenomena play a general function in landscape evolution of a high-relief steep mountainous watershed in tectonically-active settings. Disaster mitigation for such possible event requires enhancement of preparedness through prediction and risk assessment for conceivable hillslope and/or fluvial processes.

We measured rates of soil production and transport using cosmogenic ^{10}Be and measured characteristics of soil properties in hillslopes underlain by granite and hornfels in Shirakawa watershed, eastern Kyoto City. Rates of soil production and transport of the granite hillslope were faster than those of the hornfels hillslope. Soil on the granite hillslope was incohesive sand with large saturated hydraulic conductivity and low water retention ability. In contrast, soil on the hornfels hillslope was cohesive sand with low saturated hydraulic conductivity and high water retention ability. Characteristics of the granite soil promote wet–dry weathering effect in the shallow subsurface materials of the granite hillslope. Thus, physical, mechanical, and hydrological properties of soils on each bedrock control the rates of soil production and transport.

Characterization of the vertical unsaturated flow for an integrated prediction of the storm runoff response and landslide initiation on a hillslope

*Makoto Tani[1], Yuki Matsushi[2], Takahiro Sayama[2], Nagahiro Kojima[3]

1. University of Human Environments, 2. Disaster Prevention Research Institute, Kyoto University, 3. Lake Biwa Environmental Research Institute

Studies on hillslope hydrology have demonstrated storm runoff responses are generated mainly through subsurface flow instead of overland flow, and studies on erosion control have empirically revealed landslides usually occur at the time of intense rainfall after a large cumulative rainfall. based on these findings, we have to explain with consistency that the flow generation mechanism for large magnitude storms on hillslope can produce both hydrograph responses below a threshold condition of rainfall and a landslide initiation above the threshold. Recent observational studies have shown vertical unsaturated flow within a hillslope soil layer may dominantly control the responses of ephemeral groundwater table to storm rainfall through the pressure-head propagation and that the responses are rather transmitted to the stream runoff with little modification. The present study discusses the reason why the vertical unsaturated flow can produce the runoff responses during large magnitude storms and provides a perspective on an integrative prediction of the storm runoff response and landslide initiation

Discussion

The landform and flood characteristics of the Iron Gate on the ancient road from Samarkand to Bamian, south Uzbekistan

*Hiroshi Shimazu[1]

1. Department of Geography, Faculty of Geo-Environmental Science, Rissho University

“The Iron Gate” is located on the ancient road from Samarkand, which has been one of the largest cities in the central Asia from ancient times, via Termes, where is the crossing point of the Amudarya, to Bamian, which has been one of the important cities as Buddhism. The Iron Gate is a narrow gorge located several kilometers east of the main mountain ridge of the Hissar Mountains. Its length is 2 kilometers and its width of the narrowest part is 10 meters. Both valley side slopes are very steep and their relative height is about 200 meters. Genjo, who is one of the most famous Buddhism priest of 7th century walked through the gorge on the way to India.

Debris flow deposits, whose maximum diameter in b-axis is over 50cm, and sorted and clear laminated flood sediments, which are more rounded and smaller sandy gravels are distributed in the canyon. The relative height between these surface top and valley bottom is several meters. Present valley floor is buried valley bottom, whose surface is flat or covered with lobate large gravel deposits. Although there is poor vegetation on the both valley side slopes and surface of the sediments, only sporadic shrubs are on the valley bottom and both side of the eroded cliff of the sediments Heavy flood event frequent occurred in this region and debris flow and sediment flow buried the Iron Gate canyon section. After the event the buried valley bottom was dissected by water flow. Sediment transport events repeated more than once in a year and heavy flood event repeated once in several years. Samarkand and Termes have precipitation between October and April. The temperature in cold season of the city is below zero and this region has some snow. Snow melt is accelerated by rain in March and April and flood events are caused in this region.

The reason why this important road was constructed in the area of such higher risk of flood is that this place was the important checkpoint of this road. The forts of this region, located the ridge of hill, were favorable to watch passers pass through the canyon road, where sometimes closed by flood.

OSL dating of sediment core in Olgoi lake, Mongolia

*Yudai Igarashi[1], Noriko Hasebe[1], Nagayoshi Katsuta[2], Hitoshi Hasegawa[3], Davaadorj Davaasuren[4], Yukiya Tanaka[5], Uyangaa Udaanjargal[1], Keisuke Fukushi[1], Ichinnorov Niiden[6]

In the southern part of Mongolia, there are many lakes in the basin between mountain ranges, which is called “Valley of the Lakes”. These lakes experienced lake level fluctuations during the Quaternary period. This lake level variation is considered important information to understand climate change. The influx from the Khangai Mountains is a major source of water for the Valley of the Gobi lakes, a large southern basin. Olgoi lake is the research target of this study and locates closer to the summit of the Khangai mountain range than other lakes of Valley of the Gobi lakes, so it is highly likely that it reflects influx sensitively. A sediment core was collected from Olgoi lake to investigate the environmental change of the region. In this study, OSL dating of quartz was carried out to date core samples from Olgoi lake. This Core sample showed the age value of 0.7 to 10 ka covering the Holocene. In addition, it is suggested that the sedimentation of gravels, which is the most characteristic feature of the lower part of the Olgoi lake core sample, was related to the Holocene rapid temperature change events. There is a large gap in age values in this core sample at 7.5-9.0m. There is a high possibility that it reflects past sedimentary environment and even the climate, but I could not reach the final argument by the ages obtained in this research. To understand the complex transition of sedimentary environment of Olgoi lake, high resolution analyses of sediment characteristics and precise age control would be necessary.

Paleo Lake level change in southern part of Mongolia

*Noriko Hasebe[1], Makoto Sambo[2], Uyangaa Udaanjargal[2,3], Shuukaaz Ganbat[3], Keisuke Fukushi[1], Yukiya Tanaka[4], Davaadorj Davaasuren[3]

Lake Boontsagaan, Orog and Olgoy are located in the Valley of the Lakes, Gobi-Altai transition zone, which stretches from central to western Mongolia. This area suffers desertification probably due to the ongoing global worming and dried up lake sediments are worried as a source of contaminated sand storm. The flat surface in Valley of Lakes is covered with Quaternary lake sediments. Paleoshorelines are identified near the lakes. This study observed the sedimentary structures of the outcrops on the paleoshoreline and samples were collected to estimate the time when lake level was high by Quartz OSL dating method. The outcrop near the Ology, Boontsagaan, and Orog lakes are higher than the present lake level by 8 m, 15 m and 3 m, respectively.
The history of lake level change is proposed based on the age, altitude of the localities, and sedimentary structure of the outcrops. Data from Boontsagaan lake, for which coarse grains were analysed, scatter, therefore the youngest age component is extracted by plotting the data on the radial plot (Galbraith, 1988, Vermeesch, 2009). Ages from Boontsagaan Lake are around ~4-9 ka, while ages from Olgoy and Orog lakes are around ~1-2 ka. Because Boontsagaan Lake is larger and deeper than other lakes, its lake level change would be less active. Besides, relative height of the locality to the current lake level is higher then other two lakes. Therefore, the lake level was very high before ~5 ka, and relatively high at ~1-2 ka. The obtained results are consistent with previously reported data from the nearby sites (Lehmkuhl et al., 2018).

Coral reefs commonly act as natural barrier against swell wave impact. Conventionally, reefs efficiently attenuate storm waves. However, recent studies have indicated that during energetic typhoon swells, generation of infragravity waves can lead to hazardous conditions where the reef does not act like a protecting barrier anymore. In order to know the wave behavior near and over the reef, high-resolution 3D topographic data is required for the numerical calculation. However, most of the previous studies result from one- or two-dimensional numerical calculations based on low-resolution topographic data. This is mainly due to the challenging environment for conducting bathymetry/topography surveys in the vicinity of the reef. Hence, it was difficult to discuss the wave processes under the influence of the microtopography. In this study, we developed high resolution and complete set of the 3D topographic data (girid size: 1 m) from land to about 95 m water depth at the east coast of Kudaka Island, Okinawa Prefecture (an area of approximately 3 ×5 km) by UAV topographic and multibeam bathymetric surveys. Based on the terrain data with 5 m mesh size, we conducted two-dimensional wave-by-wave calculations with the Boussinesq-type wave model, BOSZ. The results show that the deformation and propagation mechanisms of the waves near the reef are highly controlled by microtopography features such as the differences in slope angles and the presence of spurs and grooves.

The coastal seafloor at depths shallower than ~130 m was subjected to alternating subaerial erosion and sedimentation during Quaternary sea-level change. However, the coastal seafloor is rarely discussed in conventional geomorphology. Recently, the development of exploration technology such as multibeam echo sounder survey enables us to observe the accurate and detailed coastal seafloor geomorphology. In this presentation, we discuss the novelty and possibilities of coastal seafloor geomorphology based on case studies from around the world and research materials of our group.

Keywords: multibeam bathymetry, echo sounder, sea level change, shelf

Automatic landform classification using Self-Organizing Map (SOM) by geomorphological features calculated from DEM

*Ito Yoshiki[1], Yoshiya Oda[1], Toshifumi Matsuoka[2]

1. Tokyo Metropolitan University, 2. Fukada Geological Institute

The landform classification map based on the various geomorphological features which calculated from DEM data is adopted in many scenes of the modern society. As is well known, Iwahashi and Pike (2007) had proposed a classification method of terrain by using slope gradient, local convexity, and surface texture. In this research, we tried to automate landform classification by using Self-Organizing Map (SOM) which is an unsupervised neural network. It is aimed at grasping the influence on the classification result depending on the combination of the geomorphological features used. The target area in this preliminary study is the same area as Iwahashi and Pike (2007); the southern part of Yatsugatake located at the prefecture boundary between Yamanashi prefecture and Nagano prefectures (about 22.5 km east-west, about 20.0 km north and south).

The SOM was carried out by the following procedure. Calculate the amount of slope gradient, surface texture, local convexity, direction of dip, the ridge valley degree, surface curvature, and the hill figure from DEM data. ② These geomorphological features were combined and adopted as input data to SOM. Totally seven patterns of geomorphological features were selected. ③ For these data, learning by SOM was conducted, and seven landform classification maps were obtained. Also, in order to visualize the features of classification by SOM, a histogram of each feature was also calculated. (4) The classification results were compared based on the landform classification maps and histograms, and the influence of the classification result by combination of the geomorphological features used was examined. We also compared SOM results with the classification results by Iwahashi and Pike (2007) method. In concludingly, it was found that in the automatic landform classification by SOM using multiple geomorphological features, the relatively uniformly distributed topographical feature quantities greatly affect classification compared to biased terrain feature. We also found that the topographic features with histograms with symmetric distribution and narrow histograms do not have a significant effect on topographic classification results by SOM. We would like to consider an application of supervised neural network and to obtain a landform

Keywords: digital elevation model(DEM), Self-Organizing Maps(SOM), landform classifications

Functionalization of the Average Erosion of Drainage Basin Using DEM

*Rei Yamanaka[1], Tatsuto Aoki[1]

1. Kanazawa University

1.First.

Geomorphic development model of tectonically active and intensive denuded regions in japan has been discussed.
Yoshikawa (1985) showed the need to discuss as a geomorphic development model considering the changing terrain in the wet variation zone in Japan.
Ohmori (1978), using a 50mDEM, to determine the dispersion of altitude. Moreover, he will evaluate the stages in the geomorphic development of the mountains.
In this study, 10 m DEM available nationwide was used.
The average amount of erosion per basin was obtained by ArcGIS and compared with the data of the dispersion of altitude of Ohmori (1978).

2.Target area

Soya Hill, Taihei Mountain, Abukuma Plateau, Shirakami Mountains, Mikawa Plateau, Hakusan Mountains, Kanto Mountains, Akaishan Mountains, Hida Mountain Range with different stages in geomorphic development is Target areas. Selected from the mountains that are analyzed by Ohmori (1978).

3.Analysis method

This is a procedure with ArcGIS, calculation of average erosion amount per watershed.
First, I made summit level map with grid sizes 3 to 301. The summit level map can be regarded as a virtual ground surface before erosion. For this reason, I set "summit level map - DEM" as the depth of erosion.

4.Functionalization of average erosion amount

We made a function of the relationship between grid size and erosion amount. At that time, graph fitting to the linear function, power function, exponential function, logarithmic function, approximate curve and its error were obtained. As a result, the most fitted function was logarithmic function "y = alog (1 + bx)", and the error was the smallest. a is considered to represent the depth of the valley and b is the width of the valley.

5.Evaluation of average erosion amount by mountain area

A scatter diagram based on the coefficients was prepared from the average erosion amount by mountainous area which was functionalized. According to Ohmori (1978), Mikawa Plateau is topography development more advanced than Shirakami mountain range. However, it was found that the Shirakami mountain area is deep in the valley, and the Shirakami mountain area was found to have a steep valley.

6.Evaluation

Functionalization of the average erosion amount has made it possible to identify eroded parts within the same mountainous region. Also, together with ohmori's topography development classification, you can also grasp the place of erosion from now. Furthermore, it is possible to consider the expansion of the mountainous area, it is possible to estimate the developmental stage, to narrow down the scale to the contrary, also to consider in the catchment area unit, so it is thought that it is possible to evaluate the future topography change.

The Movement of Sediment and Development of Gullies Inside of Landslide area

*Yasuhiro Horikawa[1], Tatsuto Aoki[2]

1. Tsukuba University, 2. Kanazawa University

There are many researches focusing on gully network. Distinguishing these researches into some groups, two major approaches are found. One is inductive approach. This approach of study makes the theory based on the specific observation of current terrains. From this approach, some famous theories, such as Horton’s Law, are led and discussions based on natural condition are realized. However this type of survey has a limitation in researching the formation of gully network in short time scale. Other one is deductive approach. This approach researches the formation of gully network by doing slope experiments. This kind of research invokes some theories led by inductive approach. By doing experiments, the formation of gull network in short time scale is discussed. But because the experiments have to equalize conditions of soil, rainfall, slope angle, etc. The result based on natural conditions cannot be observed. For these reasons the researches connecting two approaches are required.
To meet this condition, researching formation of gully network in short time scale, analyze based on the real terrain is ideal. One of the study areas meeting the condition is a landslide area. This study researched newly formed landslide area located in Kanazawa city, Japan. This landslide had few gullies when the observation was begun. Research was done for five months, from July 2018 to November 2018.In this research, by using an Unmanned Ariel Vehicle (UAV), observation of gully network was done. From the images taken by the UAV, Digital Surface Models (DSMs) are made. Comparing these DSMs, in drainage systems expansion of gully network was measured. At the same time, to understand the movement of sediment was measured by using pins and bricks. Also the profile of each gully was taken.

In five months, gully network extended to the top of the landslide. Analyzing the gully network, the tendency of network matched Horton’s 1stlaw. But the gully network’s tendency did not match Horton’s 2ndlaw. On the landslide surface and inside of gullies, erosion and sedimentation occurred. This can be said to the small gravels to big ones. The erosion and sedimentation occurs intermittently not continuity. Gullies became deeper by downward erosion, and they became wider by lateral erosion. However sedimentation inside of gullies was also observed. By sedimentation, small scale of channel changes happened. Small scale of sedimentation is ignored or omitted in experiments of gully network. But in reality, small-scale sedimentation can play an important role in forming gully network. Small sedimentation can interrupt the formation of gully network. Adding to this, landslide’ original terrains controlled the gully formation. For these reasons, to gully network in landslide area it can be said that the gullies adopted Horton’s 1st law but by the small sedimentation and the terrain of landslide, gully network did not adopt Horton’s 2ndlaw. From the result of the observation, slope experiment and the real terrain have both common points and different points. This survey is primitive research of gully network in real terrain. To make the data for sure, more researches are required.

Detailed topographic survey of valley head in hill by terrestrial laser scanning

*KIYOSHI SAIJO[1], Takahisa Furuichi[2], Asaka Konno[3]

1. Miyagi University of Education, 2. Graduate School of Agriculture, Hokkaido University, 3. Tokoha University

Detailed contour map 0.5 m of a valley head in the Ohmatsuzawa Hills in Miyagi Prefecture, northeast Japan was produced based on the topographic survey by terrestrial laser scanning. As the results, we could make more accurate geomorphic map, and recognize some micro landforms which suggest tiny slope processes and artificial landforms related to human activity such as charcoal burning.

Preliminary application of electrical resistivity tomography to estimate subsurface structure of unchanneled valley: A case at granitic hillslope near Mt. Tsukuba, Japan

*Naoyuki Yoshihara[1], Tsuyoshi Hattanji[2]

1. Graduate School of Life and Environmental Sciences, University of Tsukuba, 2. Faculty of Life and Environmental Sciences, University of Tsukuba

Subsurface structure, for example, depth of soil-bedrock interface, is one of the important factors for shallow landslide. Estimating spatially continuous subsurface structure requires an enormous amount of work and time, and more efficient survey method improves our understanding as well as the work time. Electrical resistivity tomography (ERT), which has conventionally been used for groundwater survey, is potentially useful for visualization of shallow subsurface structure. Therefore, we conducted ERT, cone penetration test and some soil tests at an unchanneled valley underlain by weathered granite near Mt. Tsukuba, Japan, and discussed the applicability of ERT imaging for estimation of shallow subsurface structure.
Little antecedent precipitation was observed before the ERT survey. Distribution of resistivity obtained from ERT with 0.5-m electrode spacing visualized the depth of loose soil (N_c = 3) as a band of a specific resistivity range (4000–10000 Ωm). However, the depth of soil-bedrock boundary (N_c = 30) did not correspond to any specific resistivity range. The resistivity distribution and the result of some soil tests indicate that surface layer was dry at the survey, and the deeper layer was wet because of bedrock groundwater. Thus, we presumed that surface electrical conductivity of the slope materials affected the resistivity value in the shallower layer, and that liquid electrical conductivity affected the resistivity value in the deeper layer that contain bedrock groundwater.

Estimating distribution of soil thickness in doline from electrical resistivity tomography: A case study in the Akiyoshi-dai Karst Plateau, Japan

*Naoya Hiramoto[1], Tsuyoshi Hattanji[2]

1. Graduate School of Life and Environmental Sciences, University of Tsukuba, 2. Faculty of Life and Environmental Sciences, University of Tsukuba

Distribution of soil thickness in doline was estimated based on 2-D electrical resistivity tomography in ten dolines on Akiyoshi-dai Karst Plateau in Yamaguchi Prefecture, western Japan. Relationship between topographic parameters and soil thickness was examined based on topographic analysis using GIS software. The 2-D electrical resistivity tomography revealed a clear transition zone of resistivity in subsurface doline. The resistivity ranging from 280 Ω·m to 400 Ω·m represents transition layer of soil and bedrock. The layers above (< 280 Ω·m) and below (> 400 Ω·m) the transition layer were identified as soil and bedrock, respectively. Electrical resistivity survey for each doline revealed that (1) soil at the upper slope of doline (max. 6.5 m) was thinner than that at the lower slope (max. 9 m), and (2) soil at doline bottom (max. 11 m) was thicker than that of slope (max. 9 m). For doline bottom, mean soil thickness increased with increasing catchment area, and catchment area is one of the main factors determining soil thickness on doline bottom.

Occurrence and origin of potholes developed on the eastern slope of Miharayama in Hachijojima, Izu Islands, Tokyo Prefecture, Japan

*Takashi Ishibashi[1], Tomoaki Mastumi[2], Ren Higuchi[2], Yuki Yamatmoto[2], Keigo Shimada[2], Hirotomo Morimoto[2], Tsutomu Shimada[3], Kenji Asakura[4]

1. Masutomi Museum of Geocience, 2. Ritsumeikan University Explorers Club, 3. Pothole Survey Team, 4. Kyoto University Graduate School of Science

Introduction

In Hachijojima (Hachijo Town, Tokyo), a lot of potholes are seen along swamps on the eastern slope of Miharayama. The finding of the potholes was in recent years, and they were designed as cultural property by Hachijo Town in 2016. But the distribution and its origin had not been elucidated enough, the potholes had surveyed in many aspects of geography four times over from 2014 to 2016. We will report the knowledge obtained from the survey and discuss the origin of the potholes. The study area is the special area of Fuji Hakone Izu National Park. The sampling of study specimens approved by the permission of the Minister of the Environment specified by Natural Park Act (No.1509143).

Definition of pothole

"Cyclopedia of Earth Science" (The Association for the Geological Collaboration in Japan, 1996) defines pothole as ‘a round shape structural failure developed on the surface of riverbed by erosion’, but the definition of pothole is not strict in general. So, in the case of Hachijojima potholes, we measured the size of pothole as follows. 1. The depth of pothole is the vertical distance from the surface of bedrock to the bottom of pothole. 2. The width of pothole is average of the major axis and the minor axis, which are the horizonal distance at the attitude of the surface of pothole. We accept the hole whose depth and width are bigger than 10 cm and 30 cm, respectively. Furthermore, the holes developed on the soil made by water current are excluded.

Potholes developed on the eastern slope of Miharayam

Potholes occur in Sueyoshi district, eastern Miharayama. On the eastern slope of Miharayama, some small valleys are lined in the WNW-ESE direction. Potholes are formed on the waterway of the valleys continuously. Over 700 potholes are found in 9 valleys. Among them, the “main” valley is the biggest one. In addition, schematic occurrence of potholes is recognized in the main valley. So, we will report the survey of the main valley chiefly. The types of the potholes are divided into two types. 1. Pothole type : a typical pothole removed by pebbles deeply. 2. Spoon type : a pothole whose depth is small as compared with its width. In the main valley, we found 19 pothole type potholes and 122 spoon type potholes. Some potholes had captured pebbles. The waterways are commonly step-wise. The steps of the waterway are several meters away from each other. Waterfalls are common on the step. The bedrock of the potholes is basaltic lava, which has 1-2 cm euhedral anorthite crystals. Under the microscope, the lava shows intersertal texture, and plagioclase, clinopyroxene and orthopyroxene (up to 1 mm) were recognized. Intergranular basaltic xenoliths usually occur in the lava. They seem to be crusts of volcanic vent when the lavas erupted. Potholes exist only in the area the basaltic lavas occur. The lavas must be a part of the main volcanic body of Miharayama, whose age is estimated to be 26-30 ka (Suga, 1998).

©2019. Japan Geoscience Union. All Right Reserved.

Origin of potholes
It is necessary to form potholes that water flow and pebbles which remove the bedrock exist. Over and under the basaltic lavas, scoriaceous beds are recognized. Waterfalls are formed usually on the scoriaceous beds because they are weak and water-permeable layer although the basaltic lavas are impermeable layer. Basaltic rocks over the waterfall turn to pebbles when the waterfall goes back. The occurrence of pebbles is a factor of formation of potholes as described above. In addition, sands which are formed by boll mill crushing accelerate erosion of the bedrocks. They must be a factor of spoon type pothole.

Temporal and spatial changes of sediment supply processes from tributaries since the last glacial period in the upper valleys of the Tama and Ara rivers, central Japan

*Takayuki Takahashi[1], Toshihiko Sugai[1]

1. Graduate School of Frontier Sciences, The University of Tokyo

To understand the sediment routing systems in the long-term, it is important to reveal the temporal and spatial changes of sediment supply processes from tributaries to the trunk river in upper reaches. Although Shimazu (1990; 1991) discuss the relationship between the longitudinal changes of the gravel size on the trunk riverbed and the tributary slope based on the slope 8% (the slope which debris flow deposition occurs), few studies discuss the temporal changes of the sediment supply processes of tributaries. Fill terrace formed in the last glacial period are developed in the upper reaches of the rivers in the Hokkaido, northeastern and central Japan. In the upper valley of the Tama and Ara rivers, most fill terraces are toe-cut terraces formed by tributaries (e.g. Takahashi and Sugai, 2018). The slope of their tread (Sg) indicates the tributary slope in the last glacial period. This study compares Sg and the present tributary slope (Sp) and discusses the temporal and spatial changes of the tributary slope and the sediment supply process from tributaries based on the slope 8%.

Sg is greater than Sp at the same tributary. This indicates that the tributary channels have been steepened because of the incision of the trunk river in the postglacial. Based on 8%, the tributaries can be classified as the three types (Type-A, B and C). Type-A tributaries (Sg and Sp > 8%) have been able to supply the sediment the debris flow to trunk river since the last glacial period. Type-B tributaries (Sg is less than 8%, Sp > 8%) supply the sediment by debris flow in the post glacial and by traction in the postglacial. Type-C tributaries (Sg and Sp are less than 8%) have supplied the sediment the traction to trunk river since the last glacial period. Based on the tributary Types above, the upper valleys of the Tama and Ara rivers were classified as three segment types (Seg. A, B and C). Seg. A is the segment that Type-A tributaries frequently join and appears in the upper part of the Tama and Ara river valleys. Seg. B is the segment that Type-B tributaries frequently join and appears in the lower part of the Tama River valley, and the upper part of the Chichibu Basin and the gorge of the Ara River valley. Seg. C is the segment that Type-C tributaries frequently join and appears in the lower part of the Chichibu Basin and gorge of the Ara River valley.

Seg. A appears the upper part of Tama and Ara river valleys, the sorting of the trunk river was dominated in their downstream in the last glacial period. The reason why Seg. C appears in the lower part of the Chichibu Basin is that the tributaries from the hills composed of the Neogene sedimentary rocks join. In contrast steep tributaries join in the gorge mainly because metamorphic rocks partly appear along the gorge of the Ara River and because the valley width are narrow by rock control. Sp and Sg are positively correlated with the relief ratio (Rr) of the tributary catchment. Sp, Sg and Rr decrease toward downstream (the east) in the Tama River valley. In the Ara River valley, these values decrease downstream from the headwaters to the Chichibu Basin, and increase in the gorge. The tendency for Sp, Sg and Rr to decrease downstream reflects the lowering of mountain ridges toward the east. It is suggested that the changes of tributary slope and the sediment supply process from tributaries are affected by the distribution of lithology and mountain relief along with the elevation changes of the trunk riverbed.

Landform evolution and active tectonics in the eastern part of Oiso Hills inferred by characteristics of gravels composing Kissawa Formation, Japan

*Masahiro Muraki[1], Toshihiko Sugai[1]

1. Graduate School of Frontier Science, The University of Tokyo

Introduction

Oiso Hills are uplift blocks bounded by active faults and uplifted rapidly in the late Quaternary period (Fig. 1: Active Fault Research Group, 1991). In the eastern part of Oiso Hills, however, the relationships between the landform development and active tectonics have not been clarified. The aim of this study is to clarify the landform evolution and the active tectonics in the eastern part of Oiso Hills based on the paleo-geography inferred from the depositional environments of gravel layers of the Pleistocene Kissawa Formation (KF: Machida and Moriyama, 1968), marine deposits of the last interglacial period (125 ka). The study area is divided into Mt. Koma area and Hinataoka area. Furthermore, Mt. Koma area can be subdivided into four blocks of OSA, OSB, OSC and OSD bounded with the active faults defined by Active Fault Research Group (1991) (Fig. 2).

Methods

In order to compare the present fluvial and beach gravels with gravels of KF, we established a frame of 1 m ×1 m at each gravel sampling site along the Kaname River, the Sagami bay beach, and at the outcrop of gravel layers of KF to collect 100 gravels from the largest size. The size, lithology, roundness and degree of weathering of the gravels were measured. Also, the matrix was analyzed with a sieve. And besides, chemical composition of tephras intervening or covering KF was analyzed.
Terrace surfaces were identified by aerial photo interpretation and field observation.

Results

The average middle diameter of the Kaname River gravels decreased downstream from 7 to 3 cm, and the average roundness increased from 0.3 to 0.6. Average flatness was 0.3 ~ 0.4. As the lithologic composition of sampled gravels, pyroclastic rocks occupied the majority upstream, and the ratio of sandstone, mudstone, and conglomerate increased to downstream. The average middle diameter of the Sagami Bay beach gravels was about 3 cm, roundness was about 0.7 and flatness was about 0.6. As the lithologic composition of sampled gravels, pyroclastic rocks, sandstone and mudstone occupied the majority. The average middle diameter of the sampled gravels of KF was about 2 cm, roundness was 0.6 ~ 0.7 and flatness was 0.3 ~ 0.4. As the lithologic composition of the gravels, pyroclastic rocks, sandstone and chart occupied the majority.
Kissawa Terrace (KT) I, II and Nanakuni-touge Terrace (230 ~ 250 ka) were identified in the study area. KT I (Shonan daira surface) develop in OSB and KT II in OSA, OSC and OSD. Eastern Takatori Terrace (ETT) formed around 30 ka by tributaries was also identified along the Fudou River.

Discussion

The flatness of the Kaname River bed gravel did not increase to downstream, while the roundness increased associated with the decrease of the particle size. Lithologic composition of the lowest reach of the Kaname River bed gravels was similar with that of the Sagami River, suggesting that the Sagami River flowed to the west side of the Sagami plain in the late Holocene, depositing gravel of the Sagami River

©2019. Japan Geoscience Union. All Right Reserved.

system at around the lowest reach of the present Kaname River. Sagami Bay beach gravels were characterized by well-rounded flat shape influenced by coastal current. Kaname River gravels and Sagami Bay beach gravels were distinguished from roundness 0.6, lower was the former and higher was the latter. Spatial variation of characteristics of the KF gravels implies that KT I is older than the last interglacial period and OSB may be a hilly island during the last interglacial period while the Kaname River flowed into the present Fudou River and formed KT II. This interpretation suggests that the Hinataoka and Komukai fault activities triggered the change of the river course in the last glacial period. After that ETT was probably formed by tributaries flowed into the present Fudou River.

Sediment movement and collapse of bank protections by a series of large flood events at the Sendai River, Tottori, southwest Japan

*Yoshinori Kodama[1], Kento Takemoto[2]

1. Faculty of Agriculture, 2. Hyogo Prefecture

In recent two years, large flood events more than 15 year-occurrence interval happened in a row at the Sendai River (Ad=1,190 km^2, L=52 km), southwest Japan. We surveyed recording artificial bank damages and sediment movements to build bars. We also analyzed satellite images for pre-events, middle, post events. The results show that the Sendai River could be divided into three sections, except uppermost 6.6 km reach: i) 6.6-11.8 km: river bed sediments were washed away to be bedrock exposure, ii) 11.8-31.0 km: alternate bars with small wavelength (less than 1000 m) were formed and iii) 31.0-48.4 km: alternate or multiple bars with larger wavelength (less than 4000 m) were formed, some of them were covered by vegetation. Many sites of artificial bank protection collapse were observed in bedrock exposure reach, where basement of artificial bank protection lost support by removing sediments. The other many sites of bank collapse were in adjacent points of small wavelength (less than 800 m) and high in relief (c.a. 2m) alternate bars, where convergent flood flow occurred scouring of river bed material.

Channel incision history with knickpoint retreat in the Kushira River after the deposition of Ata pyroclastic flow, Osumi Peninsula, Kyushu, Japan

*Shintaro Takanami[1]

1. Meiji University

The Ata welded ignimbrite (110 ka B.P.) lies concealed in the Osumi pumice fall deposits and the Ito pyroclastic flow deposits (non-welded, 30 ka B. P.), having been exposed along the Kushira River valley in the northern margin of Kasanohara ignimbrite plateau, southern Kyushu of Japan (Aramaki and Ui 1966). The Kushira River has a number of knickpoints along its course. Riverbed of Kushira River is composed of the Ata ignimbrite in the upstream reach after the Tanida waterfall. The preceding research by Yokoyama (2000) revealed rapid erosion processes on the Ito non-welded ignimbrite plateau. By contrast, almost no studies reported on the processes of the Ata ignimbrite exposed along Kushira River. Here, to gain a better understanding of this topic, the present study estimated the recession rates of knickpoints in various duration (i.e., from 110 ka to 30 ka, from 30 ka to present and during 110 kyrs), by restoring and comparing the three longitudinal profiles based on field observation and existing borehole data.

In this study, the bottom elevation of Osumi pumice fall deposits in the Kushira River valley was identified as the maximum elevation of riverbed just before the deposition of Osumi pumice. And the elevation of riverbed immediately after the Ata pyroclastic flow was also provided by the distributional top of the Ata ignimbrite. At 11 outcrops, unconfined compressive strength of the Ata ignimbrite was evaluated by KS-type Schmidt rock hammer.

Restored longitudinal profile of 110 ka indicates that the Kushira River had a marked knickpoint at the edge of Ata ignimbrite plateau that was 16 km away from present river mouth. The recession rate of this knickpoint is estimated to 5.4 cm/yr considering that it has retreated to the present position of Tanida waterfall. Estimated unconfined compressive strength of the Ata ignimbrite is gradually decreasing toward its upper part, and showing the exceptionally highest value at the “lower-positioned” Tanida waterfall ($421\times10^6 N/m^2$). Taking this into consideration, another knickpoint located now observed at 26 km from the present river mouth is also candidate for the original knickpoint at 110 ka and had retreated from the edge of Ata ignimbrite plateau to such above position (26 km inland). In this latter case, the recession rate of the knickpoint in the past 110,000 years is calculated as 8.6 cm/yr. The maximum elevation of estimated riverbed at 30 ka indicates that the Kushira River had a steeper gradient than any other timing (probably except for LGM) and incised deeper into the Ata ignimbrite plateau along the downstream side. At that time, the former Tanida waterfall was likely situated in the downstream side of 19 km from the present river mouth. Therefore, its recession rates were estimated more than 2.6 cm/yr during the period from 110 ka to 30 ka, and less than 10 cm/yr in the last 30,000 years. Based on these, this study concludes that continuous bedrock incision might have been occurred with knickpoint retreat since the formation of Ata welded ignimbrite until the deposition of Osumi pumice fall. And it is highly probable that this incision in the Kushira River valley was definitely controlled by the sea level lowering during the period of LGM.

This work was financially supported by the School of Arts and Letters, Meiji University.

Implications of the distribution of marine terraces and submerged terraces in Japanese Island

*Tetsuya Komatsu[1], Hiura Yuki[1], Takayuki Takahashi[2], Taro Funatsu[2], Masahiro Muraki[2], Taiga Kimori[2], Toshihiko Sugai[2]

1. Japan Atomic Energy Agency, 2. Graduate School of Frontier Sciences, The University of Tokyo

One of the primary issues of the geological disposal technology is to advance the techniques associated with investigation/assessment for long-term uplift and erosion in terrestrial-marine transitional zone in Japan. To examine this issue, it is inevitable to understand the geomorphic features indicating uplift and erosion in the continental shelf, which widely emerged during glacial periods. Submerged terraces defined as step-like and lobate seabed features can be identified along the continental shelfs. These landforms morphologically mimic marine terraces in terrestrial areas. This study compared the distribution of submerged terraces and MIS 5e terraces in Japan. As a result, the trends of the depth change of submerged terraces in some areas appear to be consistent with the trends of the elevation change of MIS 5e terraces. Furthermore, some cases show the depth of submerged terraces changes abruptly at the seaward extension of terrestrial active fault. These results imply submerged terraces in Japan can be an indicator of regional tectonics in the seafloor.

This study was carried out under a contract with METI (Ministry of Economy, Trade and Industry) as part of its R&D supporting program for developing geological disposal technology.

Marine erosional landforms along the southern coast of Yonaguni Island, Ryukyus

*Hayate Kimura[1], Kensaku Urata[2], HASEGAWA Hitoshi[3], Toshihiko Ichihara[4], Atsushi Suzuki[5], Nobuyuki Hori[6], Hironobu Kan[2]

1. Graduate school of integrated sciences for global society, 2. Graduate School of Integrated Sciences for Global Society, Kyushu University, 3. Kokushikan University, 4. Sedimentary Environments Research, 5. Geological Survey of Japan National Institute of Advanced Industrial Science and Technology (AIST), 6. Department of Geography, Nara University

Yonaguni Island is located at the westernmost of Japan, where marine erosional landform is widely seen. However, high sea cliffs refuse the investigator’ s approach. We created three-dimensional models by taking photographs from drone. The coastal area of Yonaguni Island is composed of the Middle Miocene sedimentary rocks of the Yaeyama Group and Pleistocene limestone of the Ryukyu Group. We observed characteristic erosional landforms which varies depending on geology along the southern coast of Yonaguni Island.
We surveyed 6 areas where locate the east and south coasts in Yonaguni Island. Photogrammetric surveys were carried out using DJI Phantom 4 Pro. We installed a GCP at accessible places. PhotoScan Professional was used as SfM-MVS software to create terrain models.
Coastal landforms are largely different depending on geological structure. In the limestone coast, collapsed areas of several hundred meters wide are formed. These collapses seem to originate from the unconsolidated layer of unconformity below the limestone or the detrital layer in the limestone. In the coast of sedimentary rocks, coastal landform varies with sedimentary facies. Shore platform is formed at the base of cliff which composed of layers of sandstone and shale. On the other hand, large boulders are distributed at the base of cliff composed of massive sandstone without layers.

Seafloor topography of Amami Sumiyo Bay -Visualization of Seafloor derived from multibeam bathymetric survey-

*Miho Tanaka[1], Ken Toguchi[2], Nobuyuki Hori[3], Hayate Kimura[4], Yukihiko Imai[5], Yosuke Nakashima[6], Yayoi Najima[7], Hironobu Kan[8]

1. Graduate School of Integrated Sciences for Global Society, 2. University of the Ryukyus, 3. Tokyo Metropolitan University, 4. School of Engineering, Kyushu University, 5. Faculty of science, Okayama University, 6. National Institute of Technology, Ariake College, 7. The Graduate University for Advanced Studies, 8. Kyushu University

The shallow water area is a very important area to reveal the sea level change during the last glacial period. In this study, we conducted multibeam bathymetric survey at Amami Sumiyo Bay and created a seafloor topographic map with high accuracy of 1 m grid.
Sumiyo Bay is located on the eastern coast of Amami Island. The Kawauchi River and the Sumiyo River are flowing into that bay. Multibeam bathymetric survey was conducted from August 20th to September 2nd, 2018 by using R2SONIC 2022 Broadband Multibeam Echosounder. Also, we measured the reflection intensity to discriminate sediment by using the side scan sonar function (TruePix / Snippets) installed in that device.
As a result of this survey, the topography distribution of the seafloor was revealed. Terrace scarp can be confirmed near the water depth of 100m in the central part of Sumiyo Bay, and it is thought that it was formed by erosion at the low sea level of the glacial period.
In this study, I integrated 10m DEM data of terrestrial area provided by Geographical Survey Institute to the highly accurate seafloor topographic map created by us and consider about geomorphology.

Automatic landform classification using Self-Organizing Map (SOM) by geomorphological features calculated from DEM

*Ito Yoshiki[1], Yoshiya Oda[1], Toshifumi Matsuoka[2]

1. Tokyo Metropolitan University, 2. Fukada Geological Institute

The landform classification map based on the various geomorphological features which calculated from DEM data is adopted in many scenes of the modern society. As is well known, Iwahashi and Pike (2007) had proposed a classification method of terrain by using slope gradient, local convexity, and surface texture. In this research, we tried to automate landform classification by using Self-Organizing Map (SOM) which is an unsupervised neural network. It is aimed at grasping the influence on the classification result depending on the combination of the geomorphological features used. The target area in this preliminary study is the same area as Iwahashi and Pike (2007); the southern part of Yatsugatake located at the prefecture boundary between Yamanashi prefecture and Nagano prefectures (about 22.5 km east-west, about 20.0 km north and south).

The SOM was carried out by the following procedure. Calculate the amount of slope gradient, surface texture, local convexity, direction of dip, the ridge valley degree, surface curvature, and the hill figure from DEM data. ② These geomorphological features were combined and adopted as input data to SOM. Totally seven patterns of geomorphological features were selected. ③ For these data, learning by SOM was conducted, and seven landform classification maps were obtained. Also, in order to visualize the features of classification by SOM, a histogram of each feature was also calculated. (4) The classification results were compared based on the landform classification maps and histograms, and the influence of the classification result by combination of the geomorphological features used was examined. We also compared SOM results with the classification results by Iwahashi and Pike (2007) method. In concludingly, it was found that in the automatic landform classification by SOM using multiple geomorphological features, the relatively uniformly distributed topographical feature quantities greatly affect classification compared to biased terrain feature. We also found that the topographic features with histograms with symmetric distribution and narrow histograms do not have a significant effect on topographic classification results by SOM. We would like to consider an application of supervised neural network and to obtain a landform

Functionalization of the Average Erosion of Drainage Basin Using DEM

*Rei Yamanaka[1], Tatsuto Aoki[1]

1. Kanazawa University

1.First.

Geomorphic development model of tectonically active and intensive denuded regions in japan has been discussed.
Yoshikawa (1985) showed the need to discuss as a geomorphic development model considering the changing terrain in the wet variation zone in Japan.
Ohmori (1978), using a 50mDEM, to determine the dispersion of altitude. Moreover, he will evaluate the stages in the geomorphic development of the mountains.
In this study, 10 m DEM available nationwide was used.
The average amount of erosion per basin was obtained by ArcGIS and compared with the data of the dispersion of altitude of Ohmori (1978).

2.Target area

Soya Hill, Taihei Mountain, Abukuma Plateau, Shirakami Mountains, Mikawa Plateau, Hakusan Mountains, Kanto Mountains, Akaishan Mountains, Hida Mountain Range with different stages in geomorphic development is Target areas. Selected from the mountains that are analyzed by Ohmori (1978).

3.Analysis method

This is a procedure with ArcGIS, calculation of average erosion amount per watershed.
First, I made summit level map with grid sizes 3 to 301. The summit level map can be regarded as a virtual ground surface before erosion. For this reason, I set "summit level map - DEM" as the depth of erosion.

4.Functionalization of average erosion amount

We made a function of the relationship between grid size and erosion amount. At that time, graph fitting to the linear function, power function, exponential function, logarithmic function, approximate curve and its error were obtained. As a result, the most fitted function was logarithmic function "y = alog (1 + bx)", and the error was the smallest. a is considered to represent the depth of the valley and b is the width of the valley.

5.Evaluation of average erosion amount by mountain area

A scatter diagram based on the coefficients was prepared from the average erosion amount by mountainous area which was functionalized. According to Ohmori (1978), Mikawa Plateau is topography development more advanced than Shirakami mountain range. However, it was found that the Shirakami mountain area is deep in the valley, and the Shirakami mountain area was found to have a steep valley.

6.Evaluation

Functionalization of the average erosion amount has made it possible to identify eroded parts within the same mountainous region. Also, together with ohmori's topography development classification, you can also grasp the place of erosion from now. Furthermore, it is possible to consider the expansion of the mountainous area, it is possible to estimate the developmental stage, to narrow down the scale to the contrary, also to consider in the catchment area unit, so it is thought that it is possible to evaluate the future topography change.

The Movement of Sediment and Development of Gullies Inside of Landslide area

*Yasuhiro Horikawa[1], Tatsuto Aoki[2]

1. Tsukuba University, 2. Kanazawa University

There are many researches focusing on gully network. Distinguishing these researches into some groups, two major approaches are found. One is inductive approach. This approach of study makes the theory based on the specific observation of current terrains. From this approach, some famous theories, such as Horton’s Law, are led and discussions based on natural condition are realized. However this type of survey has a limitation in researching the formation of gully network in short time scale. Other one is deductive approach. This approach researches the formation of gully network by doing slope experiments. This kind of research invokes some theories led by inductive approach. By doing experiments, the formation of gull network in short time scale is discussed. But because the experiments have to equalize conditions of soil, rainfall, slope angle, etc. The result based on natural conditions cannot be observed. For these reasons the researches connecting two approaches are required.
To meet this condition, researching formation of gully network in short time scale, analyze based on the real terrain is ideal. One of the study areas meeting the condition is a landslide area. This study researched newly formed landslide area located in Kanazawa city, Japan. This landslide had few gullies when the observation was begun. Research was done for five months, from July 2018 to November 2018.In this research, by using an Unmanned Ariel Vehicle (UAV), observation of gully network was done. From the images taken by the UAV, Digital Surface Models (DSMs) are made. Comparing these DSMs, in drainage systems expansion of gully network was measured. At the same time, to understand the movement of sediment was measured by using pins and bricks. Also the profile of each gully was taken.

In five months, gully network extended to the top of the landslide. Analyzing the gully network, the tendency of network matched Horton’s 1stlaw. But the gully network’s tendency did not match Horton’s 2ndlaw. On the landslide surface and inside of gullies, erosion and sedimentation occurred. This can be said to the small gravels to big ones. The erosion and sedimentation occurs intermittently not continuity. Gullies became deeper by downward erosion, and they became wider by lateral erosion. However sedimentation inside of gullies was also observed. By sedimentation, small scale of channel changes happened. Small scale of sedimentation is ignored or omitted in experiments of gully network. But in reality, small-scale sedimentation can play an important role in forming gully network. Small sedimentation can interrupt the formation of gully network. Adding to this, landslide’ original terrains controlled the gully formation. For these reasons, to gully network in landslide area it can be said that the gullies adopted Horton’s 1st law but by the small sedimentation and the terrain of landslide, gully network did not adopt Horton’s 2ndlaw. From the result of the observation, slope experiment and the real terrain have both common points and different points. This survey is primitive research of gully network in real terrain. To make the data for sure, more researches are required.

Detailed topographic survey of valley head in hill by terrestrial laser scanning

*KIYOSHI SAIJO[1], Takahisa Furuichi[2], Asaka Konno[3]

1. Miyagi University of Education, 2. Graduate School of Agriculture, Hokkaido University, 3. Tokoha University

Detailed contour map 0.5 m of a valley head in the Ohmatsuzawa Hills in Miyagi Prefecture, northeast Japan was produced based on the topographic survey by terrestrial laser scanning. As the results, we could make more accurate geomorphic map, and recognize some micro landforms which suggest tiny slope processes and artificial landforms related to human activity such as charcoal burning.

Preliminary application of electrical resistivity tomography to estimate subsurface structure of unchanneled valley: A case at granitic hillslope near Mt. Tsukuba, Japan

*Naoyuki Yoshihara[1], Tsuyoshi Hattanji[2]

1. Graduate School of Life and Environmental Sciences, University of Tsukuba, 2. Faculty of Life and Environmental Sciences, University of Tsukuba

Subsurface structure, for example, depth of soil-bedrock interface, is one of the important factors for shallow landslide. Estimating spatially continuous subsurface structure requires an enormous amount of work and time, and more efficient survey method improves our understanding as well as the work time. Electrical resistivity tomography (ERT), which has conventionally been used for groundwater survey, is potentially useful for visualization of shallow subsurface structure. Therefore, we conducted ERT, cone penetration test and some soil tests at an unchanneled valley underlain by weathered granite near Mt. Tsukuba, Japan, and discussed the applicability of ERT imaging for estimation of shallow subsurface structure.
Little antecedent precipitation was observed before the ERT survey. Distribution of resistivity obtained from ERT with 0.5-m electrode spacing visualized the depth of loose soil (N_c = 3) as a band of a specific resistivity range (4000–10000 Ωm). However, the depth of soil-bedrock boundary (N_c = 30) did not correspond to any specific resistivity range. The resistivity distribution and the result of some soil tests indicate that surface layer was dry at the survey, and the deeper layer was wet because of bedrock groundwater. Thus, we presumed that surface electrical conductivity of the slope materials affected the resistivity value in the shallower layer, and that liquid electrical conductivity affected the resistivity value in the deeper layer that contain bedrock groundwater.

Estimating distribution of soil thickness in doline from electrical resistivity tomography: A case study in the Akiyoshi-dai Karst Plateau, Japan

*Naoya Hiramoto[1], Tsuyoshi Hattanji[2]

1. Graduate School of Life and Environmental Sciences, University of Tsukuba, 2. Faculty of Life and Environmental Sciences, University of Tsukuba

Distribution of soil thickness in doline was estimated based on 2-D electrical resistivity tomography in ten dolines on Akiyoshi-dai Karst Plateau in Yamaguchi Prefecture, western Japan. Relationship between topographic parameters and soil thickness was examined based on topographic analysis using GIS software. The 2-D electrical resistivity tomography revealed a clear transition zone of resistivity in subsurface doline. The resistivity ranging from 280 Ω·m to 400 Ω·m represents transition layer of soil and bedrock. The layers above (< 280 Ω·m) and below (> 400 Ω·m) the transition layer were identified as soil and bedrock, respectively. Electrical resistivity survey for each doline revealed that (1) soil at the upper slope of doline (max. 6.5 m) was thinner than that at the lower slope (max. 9 m), and (2) soil at doline bottom (max. 11 m) was thicker than that of slope (max. 9 m). For doline bottom, mean soil thickness increased with increasing catchment area, and catchment area is one of the main factors determining soil thickness on doline bottom.

Occurrence and origin of potholes developed on the eastern slope of Miharayama in Hachijojima, Izu Islands, Tokyo Prefecture, Japan

*Takashi Ishibashi[1], Tomoaki Mastumi[2], Ren Higuchi[2], Yuki Yamatmoto[2], Keigo Shimada[2], Hirotomo Morimoto[2], Tsutomu Shimada[3], Kenji Asakura[4]

1. Masutomi Museum of Geocience, 2. Ritsumeikan University Explorers Club, 3. Pothole Survey Team, 4. Kyoto University Graduate School of Science

Introduction

In Hachijojima (Hachijo Town, Tokyo), a lot of potholes are seen along swamps on the eastern slope of Miharayama. The finding of the potholes was in recent years, and they were designed as cultural property by Hachijo Town in 2016. But the distribution and its origin had not been elucidated enough, the potholes had surveyed in many aspects of geography four times over from 2014 to 2016. We will report the knowledge obtained from the survey and discuss the origin of the potholes. The study area is the special area of Fuji Hakone Izu National Park. The sampling of study specimens approved by the permission of the Minister of the Environment specified by Natural Park Act (No.1509143).

Definition of pothole

"Cyclopedia of Earth Science" (The Association for the Geological Collaboration in Japan, 1996) defines pothole as ‘a round shape structural failure developed on the surface of riverbed by erosion’, but the definition of pothole is not strict in general. So, in the case of Hachijojima potholes, we measured the size of pothole as follows. 1. The depth of pothole is the vertical distance from the surface of bedrock to the bottom of pothole. 2. The width of pothole is average of the major axis and the minor axis, which are the horizonal distance at the attitude of the surface of pothole. We accept the hole whose depth and width are bigger than 10 cm and 30 cm, respectively. Furthermore, the holes developed on the soil made by water current are excluded.

Potholes developed on the eastern slope of Miharayam

Potholes occur in Sueyoshi district, eastern Miharayama. On the eastern slope of Miharayama, some small valleys are lined in the WNW-ESE direction. Potholes are formed on the waterway of the valleys continuously. Over 700 potholes are found in 9 valleys. Among them, the “main” valley is the biggest one. In addition, schematic occurrence of potholes is recognized in the main valley. So, we will report the survey of the main valley chiefly. The types of the potholes are divided into two types. 1. Pothole type : a typical pothole removed by pebbles deeply. 2. Spoon type : a pothole whose depth is small as compared with its width. In the main valley, we found 19 pothole type potholes and 122 spoon type potholes. Some potholes had captured pebbles. The waterways are commonly step-wise. The steps of the waterway are several meters away from each other. Waterfalls are common on the step. The bedrock of the potholes is basaltic lava, which has 1-2 cm euhedral anorthite crystals. Under the microscope, the lava shows intersertal texture, and plagioclase, clinopyroxene and orthopyroxene (up to 1 mm) were recognized. Intergranular basaltic xenoliths usually occur in the lava. They seem to be crusts of volcanic vent when the lavas erupted. Potholes exist only in the area the basaltic lavas occur. The lavas must be a part of the main volcanic body of Miharayama, whose age is estimated to be 26-30 ka (Suga, 1998).

©2019. Japan Geoscience Union. All Right Reserved.

Origin of potholes
It is necessary to form potholes that water flow and pebbles which remove the bedrock exist. Over and under the basaltic lavas, scoriaceous beds are recognized. Waterfalls are formed usually on the scoriaceous beds because they are weak and water-permeable layer although the basaltic lavas are impermeable layer. Basaltic rocks over the waterfall turn to pebbles when the waterfall goes back. The occurrence of pebbles is a factor of formation of potholes as described above. In addition, sands which are formed by boll mill crushing accelerate erosion of the bedrocks. They must be a factor of spoon type pothole.

Temporal and spatial changes of sediment supply processes from tributaries since the last glacial period in the upper valleys of the Tama and Ara rivers, central Japan

*Takayuki Takahashi[1], Toshihiko Sugai[1]

1. Graduate School of Frontier Sciences, The University of Tokyo

To understand the sediment routing systems in the long-term, it is important to reveal the temporal and spatial changes of sediment supply processes from tributaries to the trunk river in upper reaches. Although Shimazu (1990; 1991) discuss the relationship between the longitudinal changes of the gravel size on the trunk riverbed and the tributary slope based on the slope 8% (the slope which debris flow deposition occurs), few studies discuss the temporal changes of the sediment supply processes of tributaries. Fill terrace formed in the last glacial period are developed in the upper reaches of the rivers in the Hokkaido, northeastern and central Japan. In the upper valley of the Tama and Ara rivers, most fill terraces are toe-cut terraces formed by tributaries (e.g. Takahashi and Sugai, 2018). The slope of their tread (Sg) indicates the tributary slope in the last glacial period. This study compares Sg and the present tributary slope (Sp) and discusses the temporal and spatial changes of the tributary slope and the sediment supply process from tributaries based on the slope 8%.

Sg is greater than Sp at the same tributary. This indicates that the tributary channels have been steepened because of the incision of the trunk river in the postglacial. Based on 8%, the tributaries can be classified as the three types (Type-A, B and C). Type-A tributaries (Sg and Sp > 8%) have been able to supply the sediment the debris flow to trunk river since the last glacial period. Type-B tributaries (Sg is less than 8%, Sp > 8%) supply the sediment by debris flow in the post glacial and by traction in the postglacial. Type-C tributaries (Sg and Sp are less than 8%) have supplied the sediment the traction to trunk river since the last glacial period. Based on the tributary Types above, the upper valleys of the Tama and Ara rivers were classified as three segment types (Seg. A, B and C). Seg. A is the segment that Type-A tributaries frequently join and appears in the upper part of the Tama and Ara river valleys. Seg. B is the segment that Type-B tributaries frequently join and appears in the lower part of the Tama River valley, and the upper part of the Chichibu Basin and the gorge of the Ara River valley. Seg. C is the segment that Type-C tributaries frequently join and appears in the lower part of the Chichibu Basin and gorge of the Ara River valley.

Seg. A appears the upper part of Tama and Ara river valleys, the sorting of the trunk river was dominated in their downstream in the last glacial period. The reason why Seg. C appears in the lower part of the Chichibu Basin is that the tributaries from the hills composed of the Neogene sedimentary rocks join. In contrast steep tributaries join in the gorge mainly because metamorphic rocks partly appear along the gorge of the Ara River and because the valley width are narrow by rock control. Sp and Sg are positively correlated with the relief ratio (Rr) of the tributary catchment. Sp, Sg and Rr decrease toward downstream (the east) in the Tama River valley. In the Ara River valley, these values decrease downstream from the headwaters to the Chichibu Basin, and increase in the gorge. The tendency for Sp, Sg and Rr to decrease downstream reflects the lowering of mountain ridges toward the east. It is suggested that the changes of tributary slope and the sediment supply process from tributaries are affected by the distribution of lithology and mountain relief along with the elevation changes of the trunk riverbed.

Landform evolution and active tectonics in the eastern part of Oiso Hills inferred by characteristics of gravels composing Kissawa Formation, Japan

*Masahiro Muraki[1], Toshihiko Sugai[1]

1. Graduate School of Frontier Science, The University of Tokyo

Introduction

Oiso Hills are uplift blocks bounded by active faults and uplifted rapidly in the late Quaternary period (Fig. 1: Active Fault Research Group, 1991). In the eastern part of Oiso Hills, however, the relationships between the landform development and active tectonics have not been clarified. The aim of this study is to clarify the landform evolution and the active tectonics in the eastern part of Oiso Hills based on the paleo-geography inferred from the depositional environments of gravel layers of the Pleistocene Kissawa Formation (KF: Machida and Moriyama, 1968), marine deposits of the last interglacial period (125 ka). The study area is divided into Mt. Koma area and Hinataoka area. Furthermore, Mt. Koma area can be subdivided into four blocks of OSA, OSB, OSC and OSD bounded with the active faults defined by Active Fault Research Group (1991) (Fig. 2).

Methods

In order to compare the present fluvial and beach gravels with gravels of KF, we established a frame of 1 m ×1 m at each gravel sampling site along the Kaname River, the Sagami bay beach, and at the outcrop of gravel layers of KF to collect 100 gravels from the largest size. The size, lithology, roundness and degree of weathering of the gravels were measured. Also, the matrix was analyzed with a sieve. And besides, chemical composition of tephras intervening or covering KF was analyzed.
Terrace surfaces were identified by aerial photo interpretation and field observation.

Results

The average middle diameter of the Kaname River gravels decreased downstream from 7 to 3 cm, and the average roundness increased from 0.3 to 0.6. Average flatness was 0.3 ~ 0.4. As the lithologic composition of sampled gravels, pyroclastic rocks occupied the majority upstream, and the ratio of sandstone, mudstone, and conglomerate increased to downstream. The average middle diameter of the Sagami Bay beach gravels was about 3 cm, roundness was about 0.7 and flatness was about 0.6. As the lithologic composition of sampled gravels, pyroclastic rocks, sandstone and mudstone occupied the majority. The average middle diameter of the sampled gravels of KF was about 2 cm, roundness was 0.6 ~ 0.7 and flatness was 0.3 ~ 0.4. As the lithologic composition of the gravels, pyroclastic rocks, sandstone and chart occupied the majority.
Kissawa Terrace (KT) I, II and Nanakuni-touge Terrace (230 ~ 250 ka) were identified in the study area. KT I (Shonan daira surface) develop in OSB and KT II in OSA, OSC and OSD. Eastern Takatori Terrace (ETT) formed around 30 ka by tributaries was also identified along the Fudou River.

Discussion

The flatness of the Kaname River bed gravel did not increase to downstream, while the roundness increased associated with the decrease of the particle size. Lithologic composition of the lowest reach of the Kaname River bed gravels was similar with that of the Sagami River, suggesting that the Sagami River flowed to the west side of the Sagami plain in the late Holocene, depositing gravel of the Sagami River

©2019. Japan Geoscience Union. All Right Reserved.

system at around the lowest reach of the present Kaname River. Sagami Bay beach gravels were characterized by well-rounded flat shape influenced by coastal current. Kaname River gravels and Sagami Bay beach gravels were distinguished from roundness 0.6, lower was the former and higher was the latter. Spatial variation of characteristics of the KF gravels implies that KT I is older than the last interglacial period and OSB may be a hilly island during the last interglacial period while the Kaname River flowed into the present Fudou River and formed KT II. This interpretation suggests that the Hinataoka and Komukai fault activities triggered the change of the river course in the last glacial period. After that ETT was probably formed by tributaries flowed into the present Fudou River.

Sediment movement and collapse of bank protections by a series of large flood events at the Sendai River, Tottori, southwest Japan

*Yoshinori Kodama[1], Kento Takemoto[2]

1. Faculty of Agriculture, 2. Hyogo Prefecture

In recent two years, large flood events more than 15 year-occurrence interval happened in a row at the Sendai River (Ad=1,190 km^2, L=52 km), southwest Japan. We surveyed recording artificial bank damages and sediment movements to build bars. We also analyzed satellite images for pre-events, middle, post events. The results show that the Sendai River could be divided into three sections, except uppermost 6.6 km reach: i) 6.6-11.8 km: river bed sediments were washed away to be bedrock exposure, ii) 11.8-31.0 km: alternate bars with small wavelength (less than 1000 m) were formed and iii) 31.0-48.4 km: alternate or multiple bars with larger wavelength (less than 4000 m) were formed, some of them were covered by vegetation. Many sites of artificial bank protection collapse were observed in bedrock exposure reach, where basement of artificial bank protection lost support by removing sediments. The other many sites of bank collapse were in adjacent points of small wavelength (less than 800 m) and high in relief (c.a. 2m) alternate bars, where convergent flood flow occurred scouring of river bed material.

Channel incision history with knickpoint retreat in the Kushira River after the deposition of Ata pyroclastic flow, Osumi Peninsula, Kyushu, Japan

*Shintaro Takanami[1]

1. Meiji University

The Ata welded ignimbrite (110 ka B.P.) lies concealed in the Osumi pumice fall deposits and the Ito pyroclastic flow deposits (non-welded, 30 ka B. P.), having been exposed along the Kushira River valley in the northern margin of Kasanohara ignimbrite plateau, southern Kyushu of Japan (Aramaki and Ui 1966). The Kushira River has a number of knickpoints along its course. Riverbed of Kushira River is composed of the Ata ignimbrite in the upstream reach after the Tanida waterfall. The preceding research by Yokoyama (2000) revealed rapid erosion processes on the Ito non-welded ignimbrite plateau. By contrast, almost no studies reported on the processes of the Ata ignimbrite exposed along Kushira River. Here, to gain a better understanding of this topic, the present study estimated the recession rates of knickpoints in various duration (i.e., from 110 ka to 30 ka, from 30 ka to present and during 110 kyrs), by restoring and comparing the three longitudinal profiles based on field observation and existing borehole data.

In this study, the bottom elevation of Osumi pumice fall deposits in the Kushira River valley was identified as the maximum elevation of riverbed just before the deposition of Osumi pumice. And the elevation of riverbed immediately after the Ata pyroclastic flow was also provided by the distributional top of the Ata ignimbrite. At 11 outcrops, unconfined compressive strength of the Ata ignimbrite was evaluated by KS-type Schmidt rock hammer.

Restored longitudinal profile of 110 ka indicates that the Kushira River had a marked knickpoint at the edge of Ata ignimbrite plateau that was 16 km away from present river mouth. The recession rate of this knickpoint is estimated to 5.4 cm/yr considering that it has retreated to the present position of Tanida waterfall. Estimated unconfined compressive strength of the Ata ignimbrite is gradually decreasing toward its upper part, and showing the exceptionally highest value at the “lower-positioned” Tanida waterfall ($421\times10^6 N/m^2$). Taking this into consideration, another knickpoint located now observed at 26 km from the present river mouth is also candidate for the original knickpoint at 110 ka and had retreated from the edge of Ata ignimbrite plateau to such above position (26 km inland). In this latter case, the recession rate of the knickpoint in the past 110,000 years is calculated as 8.6 cm/yr. The maximum elevation of estimated riverbed at 30 ka indicates that the Kushira River had a steeper gradient than any other timing (probably except for LGM) and incised deeper into the Ata ignimbrite plateau along the downstream side. At that time, the former Tanida waterfall was likely situated in the downstream side of 19 km from the present river mouth. Therefore, its recession rates were estimated more than 2.6 cm/yr during the period from 110 ka to 30 ka, and less than 10 cm/yr in the last 30,000 years. Based on these, this study concludes that continuous bedrock incision might have been occurred with knickpoint retreat since the formation of Ata welded ignimbrite until the deposition of Osumi pumice fall. And it is highly probable that this incision in the Kushira River valley was definitely controlled by the sea level lowering during the period of LGM.

This work was financially supported by the School of Arts and Letters, Meiji University.

Implications of the distribution of marine terraces and submerged terraces in Japanese Island

*Tetsuya Komatsu[1], Hiura Yuki[1], Takayuki Takahashi[2], Taro Funatsu[2], Masahiro Muraki[2], Taiga Kimori[2], Toshihiko Sugai[2]

1. Japan Atomic Energy Agency, 2. Graduate School of Frontier Sciences, The University of Tokyo

One of the primary issues of the geological disposal technology is to advance the techniques associated with investigation/assessment for long-term uplift and erosion in terrestrial-marine transitional zone in Japan. To examine this issue, it is inevitable to understand the geomorphic features indicating uplift and erosion in the continental shelf, which widely emerged during glacial periods. Submerged terraces defined as step-like and lobate seabed features can be identified along the continental shelfs. These landforms morphologically mimic marine terraces in terrestrial areas. This study compared the distribution of submerged terraces and MIS 5e terraces in Japan. As a result, the trends of the depth change of submerged terraces in some areas appear to be consistent with the trends of the elevation change of MIS 5e terraces. Furthermore, some cases show the depth of submerged terraces changes abruptly at the seaward extension of terrestrial active fault. These results imply submerged terraces in Japan can be an indicator of regional tectonics in the seafloor.

This study was carried out under a contract with METI (Ministry of Economy, Trade and Industry) as part of its R&D supporting program for developing geological disposal technology.

Marine erosional landforms along the southern coast of Yonaguni Island, Ryukyus

*Hayate Kimura[1], Kensaku Urata[2], HASEGAWA Hitoshi[3], Toshihiko Ichihara[4], Atsushi Suzuki[5], Nobuyuki Hori[6], Hironobu Kan[2]

1. Graduate school of integrated sciences for global society, 2. Graduate School of Integrated Sciences for Global Society, Kyushu University, 3. Kokushikan University, 4. Sedimentary Environments Research, 5. Geological Survey of Japan National Institute of Advanced Industrial Science and Technology (AIST), 6. Department of Geography, Nara University

Yonaguni Island is located at the westernmost of Japan, where marine erosional landform is widely seen. However, high sea cliffs refuse the investigator’ s approach. We created three-dimensional models by taking photographs from drone. The coastal area of Yonaguni Island is composed of the Middle Miocene sedimentary rocks of the Yaeyama Group and Pleistocene limestone of the Ryukyu Group. We observed characteristic erosional landforms which varies depending on geology along the southern coast of Yonaguni Island.
We surveyed 6 areas where locate the east and south coasts in Yonaguni Island. Photogrammetric surveys were carried out using DJI Phantom 4 Pro. We installed a GCP at accessible places. PhotoScan Professional was used as SfM-MVS software to create terrain models.
Coastal landforms are largely different depending on geological structure. In the limestone coast, collapsed areas of several hundred meters wide are formed. These collapses seem to originate from the unconsolidated layer of unconformity below the limestone or the detrital layer in the limestone. In the coast of sedimentary rocks, coastal landform varies with sedimentary facies. Shore platform is formed at the base of cliff which composed of layers of sandstone and shale. On the other hand, large boulders are distributed at the base of cliff composed of massive sandstone without layers.

Seafloor topography of Amami Sumiyo Bay -Visualization of Seafloor derived from multibeam bathymetric survey-

*Miho Tanaka[1], Ken Toguchi[2], Nobuyuki Hori[3], Hayate Kimura[4], Yukihiko Imai[5], Yosuke Nakashima[6], Yayoi Najima[7], Hironobu Kan[8]

1. Graduate School of Integrated Sciences for Global Society, 2. University of the Ryukyus, 3. Tokyo Metropolitan University, 4. School of Engineering, Kyushu University, 5. Faculty of science, Okayama University, 6. National Institute of Technology, Ariake College, 7. The Graduate University for Advanced Studies, 8. Kyushu University

The shallow water area is a very important area to reveal the sea level change during the last glacial period. In this study, we conducted multibeam bathymetric survey at Amami Sumiyo Bay and created a seafloor topographic map with high accuracy of 1 m grid.
Sumiyo Bay is located on the eastern coast of Amami Island. The Kawauchi River and the Sumiyo River are flowing into that bay. Multibeam bathymetric survey was conducted from August 20th to September 2nd, 2018 by using R2SONIC 2022 Broadband Multibeam Echosounder. Also, we measured the reflection intensity to discriminate sediment by using the side scan sonar function (TruePix / Snippets) installed in that device.
As a result of this survey, the topography distribution of the seafloor was revealed. Terrace scarp can be confirmed near the water depth of 100m in the central part of Sumiyo Bay, and it is thought that it was formed by erosion at the low sea level of the glacial period.
In this study, I integrated 10m DEM data of terrestrial area provided by Geographical Survey Institute to the highly accurate seafloor topographic map created by us and consider about geomorphology.

[H-SC07] CCUS (Carbon Dioxide Capture, Utilization, and Storage) for Climate Mitigation

convener:Masao Sorai(Institute for Geo-Resources and Environment, National Institute of Advanced Industrial Science and Technology), Ziqiu Xue(Research Institute of Innovative Tech for the Earth), Masaatsu Aichi(Graduate School of Frontier Sciences, University of Tokyo), Chairperson:Masao Sorai(National Institute of Advanced Industrial Science and Technology)

The prevention of the global warming, which is the urgent challenge facing the world, requires the full-out efforts of science and technology. This session focuses on the CCUS (Carbon Dioxide Capture, Utilization, and Storage) as one of the useful countermeasures for the CO2 emission reduction. It not only targets various scientific phenomenon caused by the capture and storage of CO2, CO2 utilization, and CO2-EOR/EGR, but also discusses the latest R&D developments of each method for the environmental impact assessment, safety assessment, the measuring, monitoring and verification (MMV), and public acceptance. The main theme is the recognition of key issues toward the practical use of CCUS, in addition to the deepening of our knowledge about the CO2 behavior on the underground.

Numerical simulation of variational pore pressure response to ocean tidal loading during CO2 injection

*Toshifumi Akaki[1], Hajime Yamamoto[1]

1. Taisei Corporation

As a promising measure against global warming, CCS (Carbon dioxide capture and storage) has been extensively studied over recent decades and some large-scale projects are currently in operation worldwide. Carbon dioxide is captured from flue gases emitted from large sources such as coal-fired power plant, and injected and kept stored in a deep geologic formation for long-term. In the geologic CO2 storage, reliable and cost-effective monitoring techniques of the injected CO2 need to be established. It is well known that the pore-pressure of groundwater is affected by the earth and ocean tides. Recently, at a geologic CO2 storage project, it has been reported that the pore-pressure fluctuation at a monitoring well is explained by diurnal earth tides, and the amplitude of the pressure fluctuation significantly attenuated when the carbon dioxide arrived at the well due to the changes in compressibility of pore fluid around the well (i.e. the compressibility of CO2 is much smaller than that of water). This suggests a potential low-cost CO2 monitoring technique through monitoring and analyzing tidal responses of pore pressure during geologic CO2 storage. The tidal response of pressure is understood as a hydro-geomechanical coupled phenomena in deformable porous media containing water and CO2. Previous studies indicated that the changes in amplitude of pore-pressure before and after CO2 arrival at a monitoring well can be simply explained by poroelasticity theory. However, numerical simulations are required to further quantitatively investigate the tidal effects on pressure fluctuation at monitoring wells during CO2 injection. For example, the pressure response is possibly affected by many geometrical and geological settings in three-dimensional space, such as distance between the monitoring wells and CO2 plume, geometry of CO2 plume, and pressure dissipation induced by fluid flow. In this study, we developed a numerical simulator in the framework of poromechanics to simulate three-dimensional deformations and stress changes of geological formations under two-phase flow conditions of water-CO2, which was enhanced to be adoptive to cyclic loading by diurnal and semi-diurnal tide. Using this simulator, we investigate variation of responses of pore water pressure to the ocean tide loading during CO2 injection. Amplitude of the response at injection well decrease during CO2 injection, and somewhat recovered due to upward movement of CO2 plume after injection. The final amplitude in this simulation is smaller than initial amplitude under water saturated condition due to an effect of CO2 plume staying top of the reservoir.

Relationship between rock deformation and permeability evolution during fracturing in rocks for CCUS technology

*Takashi Fujii[1], Xinglin Lei[1], Masao Sorai[1]

1. National Institute of Advanced Industrial Science and Technology

An understanding of relationship between fluid flow transport and geo-mechanical response within geological reservoirs is of a fundamental concept for a suitable utilization of deep underground repositories (e.g., Carbon Capture and Storage (CCS), Carbon Capture Utilization and Storage (CCUS), shale gas exploration). Particularly, fracture permeability within caprocks plays an important role in producing hydrocarbon during the trapping of buoyant gas fluids in reservoirs for CCUS projects. Wide variations of permeability value depending on rock deformation (including fracturing process) for several types of rocks has been determined using the coupled fluid flow transport (TOUGH2) and geo-mechanical response (FLAC3D) simulator (e.g., Rutqvist et al., 2002) so far. However, the evolution of permeability during fracturing in such rocks is very complex, and there now are being reported few constitute law for the linked deformation and fracture permeability. Furthermore, few laboratory studies have experimentally been conducted so as to replicate this process by simultaneously fracturing specimens and measuring permeability at in situ fracturing stress states (Carey et al., 2015; Fujii et al., 2015; Frash et al., 2016).
The purpose of this study is to investigate experimentally permeability change during fracturing in (i) caprocks (shale, mudstone, slate) and (ii) reservoir rock (sandstone, tuff), the conditions of which assumes that CO_2 is injected into geological media. We attempt to fit a model to obtained experimental data (i.e., permeability: K, volumetric strain: e_v) in order to develop suitable constitute law for the optimize use of coupled geo-mechanics and fluid flow simulator.
Our results demonstrate that there could mainly be classified into the two patterns of relationship between e_v and K of all materials tested. Particularly, it is apparent that the permeability behavior throughout fracturing and slipping processes are quite different between rock groups of (i) and (ii). Caprocks have a sharp-jumped increase of permeability during fracturing in the rock matrix, but reservoir rocks have significantly smaller permeability change, compared to the caprocks in post-failure regime. Furthermore, model fitting results suggest that the relationship between e_v and K of all materials tested could be explained fully by modification of conventional model (e.g., Cappa et al., 2009)
In light of findings of our study, it can be concluded that the propsed constitute law might be contributed to the simplification and optimization of the coupled fluid flow and geomechanical simulator.

Comparison of Optical Fiber Sensing Technique and Strain Gauge in a Measurement of Rock Deformation Caused by Chemical Osmosis

*Shogo Hirota[1], Tomochika Tokunaga[1], Ziqiu Xue[2], Hyuck Park[2]

1. Department of Environmental Systems, Graduate School of Frontier Science, the University of Tokyo, 2. Research Institute of Innovative Technology for the Earth

Mass transport and water flow in subsurface are generally considered to be much smaller than those on surface environment. Stability of subsurface environment is useful to isolate specific substances (e.g. CO_2 or high-level radioactive wastes) from human societies for a long time. For these purposes, argillaceous formations perform as effective seal layer because of its low permeability and smaller diffusion coefficient.

It is known that some argillaceous rocks show semipermeable membrane behavior, i.e., the process called chemical osmosis. Chemical osmosis causes water flow across semipermeable membrane driven by the gradient of osmotic pressure between two solutions (Marine and Fritz, 1981). Previous research showed that the pressure change caused by chemical osmosis can reach to about 20 MPa (Neuzil, 2000). Osmosis-induced pore pressure change can cause deformation of porous medium (Greenberg et al., 1973: Noy et al., 2004), however, the detailed discussion on the osmosis-induced deformation behavior of argillaceous rocks is still premature because of the difficulty for measuring multiple strain in the sample.

Generally, normal strain gauges by measuring the changes of the electrical resistance are used for laboratory-scale rock deformation experiments. Experiments for measuring deformation caused by chemical osmosis take a long time and drifts caused by water intrusion and/or delayed heat dissipation is considered to be the issue for the accurate measurements. Distributed optical fiber sensing (DOFS) is a technique for possibly avoiding the measurement drift. In DOFS measurement, the backscattering light is used to measure strains along the fiber, and DOFS can use entire optical fiber as a sensor, thus, strain behavior at multiple points along the optical fiber can be obtained.

The purpose of this study is to investigate the applicability of both strain gauges and DOFS to the laboratory-scale chemical osmosis experiments through the comparison of both results, and to discuss the strain behavior of argillaceous rocks by chemical osmosis. In this experiment, core samples with the height of about 30mm and diameter of about 50mm made from mudstones collected from the Wakkanai Formation in Hokkaido prefecture and the Oganocho Formation in the Chichibu Basin, Saitama prefecture, were used. Strain gauges were attached to the sample, and axial and circumstantial strains near the both edges were measured. Optical fiber was attached helically to the sample, and the strains along the direction of the fiber were measured. The lateral and top surfaces of the specimen were sealed by silicon rubber to prevent water flow through these surfaces. In the experiment, the bottom surface of the sample was contacted to NaCl solution with 10g/L higher concentration than that of pore water, and osmotic flow was induced by the concentration gradient. The strains of the specimen caused by osmotic flow were measured by both DOFS and strain gauges. Temperature was kept almost constant throughout 240 hours by putting the apparatus into a box made with heat insulating material and the experimental room was controlled by air conditioner.

In the initial phase of the experiments, the strain behaviors measured by both strain gauges and DOFS showed a good agreement. Initial strain behavior characteristic to the poroelastic effect was found only in the measurement by strain gauges because of the much shorter sampling interval compared with that in

©2019. Japan Geoscience Union. All Right Reserved.

DOFS. On the other hand, after 20 hours, strains measured by the strain gauges near the bottom of the sample, i.e., high-concentration side, started to increase while those measured by DOFS not. It is considered to be caused by the unstable behavior of strain gauges.

Experiment of precipitation of salt for dry-out condition caused by CO_2 storage in saline aquifer

*Hayato Morigaki[1,2], Masaatsu Aichi[1]

1. University of Tokyo, 2. Toshiba Energy Systems & Solution Corporation

Since CO_2 is transported in dry condition to prevent corrosion of the press-in pipe, CO_2 injected into the saline aquifer may evaporate water and dry the formation. In this case, there is concern that the porosity and permeability of the reservoir will decrease due to salt precipitation and clogging. On the other hand, the influence of cap rock on the sealing ability has not been considered sufficiently.
In this study, in order to observe the state of salt precipitation while controlling the degree of drying, the experiment was carried out with humidity control to generate a suction of about 100 MPa using a thermo-hygrostat. In the experiment, the core sample with the side sealed and the brine reservoir attached at the bottom was placed in the humidity control space, and the water evaporation from the top of the core sample was measured and the precipitation of salt was observed. In addition, in the comparison between before and after this experiment, we also tried to evaluate the influence of semipermeable membrane performance of mudstone on the presence or absence of precipitation and change in salt concentration of brine in the reservoir. The salt concentration of the reservoir, which was assumed to be the saline aquifer, was set at 0.6 mol / L as seawater, and when experiments were conducted assuming that the brine saturated rock was exposed to dryness, it was confirmed that the flux of moisture did not change remarkably before and after salt precipitation on the muddy sandstone of the Otadai Formation, the mudstone of the Otadai Formation and the mudstone of Wakkanai Formation. Also, the salt transport inhibition due to the semipermeable membrane effect was not noticeable. This suggests it is not necessarily expected that the precipitation of salt by drying improves CO_2 shielding performance of cap rock.

Thermodynamic Approach to Wettability of CO_2/Brine/Mineral System by Augmented Young Laplace Equation

*Masashige Shiga[1,2], Masao Sorai[1], Masaatsu Aichi[2], Hiromi Honda[2]

1. AIST, 2. The University of Tokyo

CO_2 Geo-Sequestration (CGS)has been regarded as one of the most significant technologies to reduce the amount of CO_2 emissions into the atmosphere.

Sealing performance of the caprock in the geological formation is largely influenced by wettability which is evaluated by the contact angle of the CO_2/Brine/Mineral system.

A lot of researchers have measured the angles in various conditions (e.g. pressure, temperature, salinity, or types of minerals) by various methods.

However, the value and the trend of the contact angle have not been confirmed yet.

This is mainly because there are a lot of inconsistencies in the experimental data due to the difficulties of controlling the surface roughness or impurities.

In order to tackle this problem,we calculated the contact angle and studied the key factor to affect its value by using augmented Young Laplace equation in which a thickness of the film on the mineral substrate is considered as a thermodynamic variable.

Parameters of the interfacial properties were calculated by PhreeqC, which is a simulator performing a wide variety of aqueous geochemical calculations.

A proposal of CO2 underground storage using hydrate

*Takaomi Tobase[1]

1. Electric Power Development Co., Ltd.

There is a fact that methane exists naturally and stably in the form of hydrate (solid).
As natural analog with methane hydrate, form CO2 hydrate using gas hydrate mechanism based on temperature and pressure, propose that could also be applied to underground storage of CO2. The concepts of the CO2 hydrate storage are as follows.
(1) Injection liquid or supercritical CO2 in the storage layer.
(2) Injected CO2 moves above by a density difference, when temperature and pressure condition reached the domain that formed hydrate, make clogging in a pore (come to have seal function).
(3) CO2 becomes able to storage under layer of CO2 hydrate having seal function. (not need the cap rock as geological structure)
As a result of investigating the temperature in the surrounding sea area of Japan, we confirm that temperature and pressure condition to form CO2 hydrate in the underground of sea bottom. It is thought that very likely to be the CO2 hydrate storage.
Aquifer storage (including CO2-EOR) to have the cap rock as a method of the CO2 storage is popular. But if CO2 hydrate storage is realized, we can hope that contribute to right lot expansion of the CO2 storage.

Carbon Capture and Storage (CCS) is expected as a mitigation measure of climate change and global warming causing by the rise in atmospheric carbon dioxide (CO_2) concentration. CCS is a technology that can reduce the amount of CO_2 emissions from large point sources, such as electricity power plant, by separating and recovering CO_2 from atmosphere-releasing gas and storing it in the basement. Main items of reservoir evaluation are (1) evaluation of injection performance and (2) evaluation of storage capacity. In this research, the above two evaluation items were investigated by numerical analysis. Analysis module, TOUGH2-ECO2N which deals with multicomponent and multiphase fluid was used.

(1) Evaluation of injection performance
The influence of basic physical parameter (permeability and porosity) on the CO_2 injection performance of the reservoir layer was investigated. As a result, it has been found that permeability affects whole pressure level of the reservoir layer and porosity affects the slope of pressure rise. Furthermore, their influence on the long-term distribution range of pressure and CO_2 plume has been revealed clearly.

(2) Evaluation of storage capacity
The basic physical parameter of analysis model for the evaluation of the storage capacity was determined with history matching based on the monitoring and the prediction simulation of the pressure, which was conducted in the CCS project in Canada Quest. In order to reveal the factors affecting the storage capacity evaluation were carried out, case studies such as changing placement of injection wells, etc. It is expected that the findings from this study can contribute to the evaluation of the storage capacity, such as predicting pressure rise in the reservoir layer and distribution of CO_2 plume, and the helpful for enabling "reservoir management", such as arrangement of injection wells, number of wells, injection rate and time, and installation of a pressure relief well.

Monitoring hydromechanical responses in aquifer by distributed fiber-optic strain sensing: From lab to field

*Yi Zhang[1,2], Ziqiu Xue[1,2], Tsutomu Hashimoto[1,2], Hyuck Park[1,2]

1. Geological Carbon dioxide Storage Technology Research Association, 2. Research Institute of Innovative Tech for the Earth

Pore fluids control deformation of porous media by the fluid-to-solid hydromechanical (HM) coupling in which a change in fluid pressure can modify the effective stress and deform the porous medium (Wang, 2000). The HM coupling mechanism provides a possibility that to understand aquifer characteristics and fluid activities during fluid extraction and/or injection operations, e.g., in geological CO_2 storage (GCS), by monitoring rock strain changes. We successfully measured such HM deformations using a high-resolution distributed fiber optic strain sensing (DFOSS) tool in both laboratory and field scale studies. From the DFOSS-obtained HM information, we are able to track the pressure impact zone, understand the permeability structure of the aquifer formation and identify the preferential flow layers. Moreover, we can track the fluid migration front during CO_2 displacing water and the mechanical response of CO_2 breaking through to a low-permeability layer or caprock. The application of DFOSS would be beneficial to guide the aquifer pressure management for safe GCS with prior or simultaneous water extraction (Buscheck et al., 2012).

Field Testing of Hybrid Brillouin-Rayleigh Distributed Sensing System for Subsurface Water Injection Monitoring

*Yankun Sun[1,2], Ziqiu Xue[1,2], Tsutomu Hashimoto[1,2], Xinglin Lei[3], Yi Zhang[1,2]

1. Geological Carbon Dioxide Storage Technology Research Association, 2. Research Institute of Innovative Technology for the Earth, 3. National Institute of Advanced Industrial Science and Technology

Massive fluid injections into underground formations inevitably alter stress state and even induce damaging earthquakes, so robust high-resolution monitoring technologies are urgent to track geomechanical behaviors of injected fluids. Here we present one of the first case studies demonstrating the use of distributed fiber optic sensing (DFOS) technique based on hybrid Brillouin-Rayleigh backscattering for well-based monitoring of geomechanical deformations induced by field water injection. Injection tests were conducted with different injection scenarios between injection well (230 m, IW #2) and 5.5 m away from fibered monitoring well (300 m, MW #1) deployed cable behind casing in Mobara, Japan. Geomechanical responses were real- time recorded using DFOS approach; the resulting strain profiles were used to capture fluid evolution behaviors; thus evidencing that induced strains significantly depend on injection rate, injection pressure and lithological heterogeneity using this approach. Concurrent borehole logging was utilized to detect injection-induced variation of near- wellbore formations, which results agreed reasonably well with DFOS readings. This field application of hybrid DFOS technology conclusively enables speedy improvement of finely monitoring subsurface geoscience engineering activities, such as CO_2 storage.

Based on this methodology, some conclusions in this study can be drawn below:
1. An advanced DFOS system based hybrid Brillouin-Rayleigh backscattering is successfully applied to real-time monitor water injection tests between two adjacent wells. Two different injection formations ① and ② are investigated.
2. Field testing demonstrates that induced geomechanical deformation (i.e., strain) is mainly dependent on injection volume rather than injection temperature, which has no significant effect on the strain changes.
3. Geomechanical deformations harmoniously emerge and eliminate with injection schemes, although the effect of packers on the strain profile results in slight emergency of strain leaps. The impacted zones expand along vertical direction beyond corresponding injection sections.
4. Formation heterogeneity results in lateral transport of injected water and its pressure propagation in the pore space. Compared with *V*sh -GR and BH, the lower *V*sh related to formation is easier for strain accumulation. In addition, although the impact acting on clay-rich formations is relatively small, the existence of shale just weakens the induced deformation intensity rather than completely stops the strain expansion.
5. According to open-hole resistively logs of IW and MW, simplified simulation result further confirms strong small-scale formation heterogeneity and discontinuities of shale-sand distribution in the injection formations.
6. Testing results also reveal that there are two main reasons accounting for vertical expansion of impacted zones during water injections. First reason is formation heterogeneity, which is quantified by open-hole resistivity logging and GR data, largely affecting fluid behaviors, including migration, evolution and diffusion in subsurface. Second reason is that due to poroelastic deformation, different injection scenarios can generate different injection pressure, which will ultimately lead to different geomechanical deformation responses and first-arrival pressure front patterns of injected water propagating to the

Monitoring the distribution and migration of CO_2 injected into geological formations is needed for management of geological storage of CO_2. Superconducting gravimeters (SG’s) potentially enable monitoring of offshore CO_2 storage at ground-based stations because of its high precision. We conducted continuous gravity observations using SG’s near the seashore at the Tomakomai CCS (carbon dioxide capture and storage) demonstration site, Japan to study variation in the observed gravity near the seashore. The gravity data after correcting for tides, polar motion, and barometric pressure changes was strongly affected by shallow groundwater level changes but it was corrected by expressing their effects as a summation of linear functions of groundwater level changes. The standard deviation of the gravity residuals was reduced to less than 1 μGal after correcting for the groundwater effects. The small variation in the observed gravity residuals suggests that the ground-based gravity monitoring using SG's can be useful in long-term monitoring of offshore CO_2 storage.

Pilot test for microbubble CO_2 injection to reservoir in oil field - Test planning and preparation -

*Kazunori Nakagawa[1], Ryo Ueda[1], Masanori Nakano[1], Ziqiu Xue[2]

1. Japan Petroleum Exploration Co., Ltd., 2. Research Institute of Innovative Technology for the Earth

In this study we have studied to evaluate the effect of microbubble CO_2 injection to CO_2 storage by core flooding test in laboratory and develop the tools for microbubble CO_2 injection in reservoir and we reached at the step which we plan to conduct the field pilot test in 2019.

We provide an introduction to the planning and preparation to the field pilot test for microbubble injection technology.
Summary of the pilot test
We plan to conduct this test at a part of oil field in Japan. This oil reservoir is consisted of the alternate layers of sand and mud and has high hetrogeneity which the advantage in the microbubble injection technology is expected. Huff' n Puff method will be applied in this test and pressure and flow rate at CO_2 injection and reproduction (flow back) from reservoir after CO_2 injection are measured as field test data. Two CO_2 injection tests, microbubble and normal injection are planned to estimate the effect of microbubble injection technology and behavior. Injected CO_2 volume is 100t at each test, microbubble and normal injection. Moreover, we construct the flow simulation model and estimate the microbubble CO_2 injection before and after field test.
preparation
We produced the tools for microbubble CO_2 injection in well based on prototype tools developed in this study and constructed facility which consisted of CO2 storage tank, CO2 injection pump and warming apparatus in test field.

Acknowledgements

This presentation is based on results obtained from a project commissioned by the New Energy and Industrial Technology Development Organization (NEDO) and the New Energy the Ministry of Economy, Trade and Industry (METI) and attributed to basic study for micro bubble CO_2 injection technology by Tokyo-gas Co., Ltd. and RITE. We deeply appreciate them.

1. Geological CO2 Storage Technology Research Association, 2. RITE

When CO_2 is stored in sub-seabed geological formations in Japan, marine monitoring is mandatory to detect CO_2 leakage as soon as possible should it occur. In the Tomakomai CCS Demonstration Project, a threshold line based on a negative correlation between partial pressure of CO_2 (pCO_2) and dissolved Oxygen saturation in seawater is used to detect an anomalously high value of pCO_2, which is suspected to be a sign of CO_2 leakage. Although CO_2 leakage has never occurred in Tomakomai, pCO_2 values obtained in the monitoring have frequently exceeded the threshold line; that is, many false-positives have been produced. It is important to consider what can be causes of the false-positives. To discuss the causes, we analyzed data observed in the marine monitoring of the Tomakomai project, and meteorological data at Tomakomai. It is implied that weather conditions, such as wind speeds and precipitation, were related with false-positives. Also, we found that total alkalinity was remarkably low at a monitoring survey where many false-positives were observed. The low values of total alkalinity make pCO_2 values higher than usual, and consequently they might produce many false-positives. Based on the results, we are going to present how to avoid or reduce false-positives.

Evaluation of seismic event location accuracy of Tomakomai CO2 injection site: a numerical simulation case study

*Luchen Wang[1], Takahiro Nakajima[1], Ziqiu Xue[1]

1. RITE, Research Institute of Innovative Technology for the Earth

For CO2 injection monitoring in many CCS project, the most basic monitoring information is the seismic events. The seismic event location is the first step to understanding the causal process of a natural or induced fracture. In the case of CO2 geological storage, the location of an event is of special importance. The events in the reservoir may affect the storage capability. The events in the cap-rock may indicate the CO2 leakage. However, the location of the seismic event is probably to contain bias, especially for the limited seismic observation system. Therefore, the operator should understand that there is uncertainty in the location estimation of a detected event. In this study, we use the Tomakomai (Ocean Bottom Cable) OBC and borehole system (OB1 well) to study the seismic location accuracy in Tomakomai site. We believe that it can help to evaluate the event location effect with different azimuths and different depths. Moreover, this study may also be applied to the optimization of the seismic observation system.

At Tomakomai site, the permanent OBC is arranged as a line (length 3.6 km, containing 55 available sensors), deployed 2 m under the seabed. It is located above the CO2 reservoir and the center point is 3 km from the coast. The OB1 contains 4 sensors in the well with depths ranging from 2 km to 2.2 km. All sensors of OBC and OB1 contain a three-component geophone. Therefore, we can use only detected P phase signal for seismic location. We assume that the velocity model is layered and homogeneous, so that a simple model can be built based on the logging result. The ray-tracing method is employed in the seismic simulation and location process.

We compared the modelling event location accuracy for different azimuths and different depths. All events were distributed around Tomakomai site. The results showed that as the epicenter distance increases, the location errors increases. For the events which the epicenter is far away from the area enclosed by OBC and OB1, the locating effect is significantly worse. In addition, as the event depth increases, the location error also increases. The location error of shallow (0-1 km) events can be maintained within 1 m, while the location error of deep (8 km) events can reach the scale of several hundred meters. Ignoring the effects of the simulation method, it is obviously affected by the geometric distribution of the observation system.

Secondly, we also compared different observation system optimization strategies. The result indicated that, based on the Tomakomai seismic monitoring system, if the number of sensor is fixed, the longer OBC line can provide a better location result. Based on these analyses, future seismic monitoring system designs can be optimized for specific purposes (number of sensors, expected depth of monitoring, etc.).

Technical Challenges of Machine Learning Approach for Porosity Estimation in Nagaoka CCS site

*Takayuki Miyoshi[1], Takahiro Nakajima[1], Ziqiu Xue[1]

1. Research Institute of Innovative Technology for the Earth

In CCS, the distribution of hydraulic parameters such as porosity and permeability is one of the key parameters for evaluation of CO_2 storage capacity and CO_2 saturations. These parameters are measured as 1D profiles through well-logging. CCS projects, in general, have only a few wells available in the area of target. The 3D seismic data which covers the three dimensional space does not represent the hydraulic features directly. A technique to integrate these different types of data is required to estimate appropriate geological models.
Machine learning (ML) is a technique for predicting a target property from unknown input data by learning the relationship between known input data and prediction target. In this research, we apply ML approaches to Nagaoka CCS site data for predicting porosity distribution from seismic attributes created from the 3D seismic data. Determination of hyper-parameters of the ML model is often site-specific in predicting geological models. We present the technical challenges when using multiple attributes as input data.

Utilization of wave attenuation in time-lapse sonic logging data to evaluate the effect of super-critical CO_2 in the reservoir

*Takahiro Nakajima[2,1], Luchen Wang[2,1], Ziqiu Xue[2,1]

1. Research Institute of Innovative Technology for the Earth, 2. Geological Carbon Dioxide Storage Technology Research Association

This paper discusses seismic wave attenuation by injected CO_2 in the formation. Seismic methods have been broadly used for the monitoring of injected CO_2 at many CCS sites. Concerning the velocity change by the existence of CO_2, the relationship between P-wave velocity and CO_2 saturation in rock samples and formation have been studied well. Some laboratory experiments studied amplitude of P-wave as well as the velocity change by the invasion of CO_2, and the change in amplitude was larger than that of time delay (e.g. Muller et al., 2010). Meanwhile investigations on amplitude attenuation were rather limited. In this paper, we investigated P-wave data in the results of time-lapse sonic logging at the Nagaoka site.
At the Nagaoka site, time-lapse well loggings have been conducted during the injection period and post injection period at observation wells, which are 40 m and 60 m apart from the injection well. The sonic logging was conducted 45 times during 12 years using Halliburton’ s LFDL (Low Frequency Dipole-Sonic Logging Tool). Since it is not ascertain that the monopole transmitter has emitted the same energy at every logging, we chose a reference point in the cap rock 10 m above the target zone. At this depth, the formation was highly cemented with very small slowness, so the position was easily recognized in wave data and its wave field would not change during the CO_2 injection. We took the amplitude of the first P-wave arrival as the reference. We also assume that the emitted energy from the transmitter would not change at the reservoir within 15 m interval from the reference point.
Firstly, we compared the wave data at the depth where the largest change observed by CO_2 injected. We can see that the first arrival of P-wave at the nearest observation logging was shifted from 1.64 to 1.8 micro-sec at 14-th run. Amplitude of the peak was also gradually decreased after the CO_2 breakthrough, and the amplitude at 21-st run was clearly small. Next we calculated spectrum around the first P-wave arrivals, and found that high frequency components decreased much than the lower frequency components. This frequency shift looked like to be recovered during the imbibition process. These could be an evidence of wave-induced flow of two phase liquid.
From these analyses, amplitude attenuation can be observed in the sonic logging at geological storage site. The combination of seismic wave amplitude and time-delay could be applied for more reliable evaluation of CO_2 saturation as Azuma et al. (2014) pointed out. The amplitude change might be effective in the early detection of CO_2 leakage along the well, if results as the laboratory experiments were obtained in the field. An effective measurement for this purpose could be realized with the use of DAS-VSP.

Geological sequestration in saline carbonate formations: CO_2 -brine-rock interaction

*Shachi Shachi[1], Brijesh Kumar Yadav[1], Mohammad Azizur Rahman[2], Mayur Pal[3]

1. Indian Institute of Technology Roorkee, 2. Texas A&M University Qatar, 3. North Oil Company, Qatar

To reduce unequivocal global warming due to continuous emission of greenhouse gas CO_2 into atmosphere, geo-sequestration is one such emerging technology. For geologic sequestration, CO_2 is injected into suitable deep subsurface formations at supercritical temperature and pressure conditions. Saline carbonate formations are one such promising sink due to its wide spread availability and enormous storage potential. In this study, a series of experiments have been performed on carbonate cores for finding out the effect of injected supercritical CO_2 in subsurface formations. The laboratory study reported here investigated the cyclic injection of $scCO_2$ and brine on two types (Edward White and Edward Yellow) of core samples under reservoir conditions. Further, the pre and post flooded carbonate core samples are analysed for mineralogical changes of CO_2-brine-rock interaction using image analysis techniques such as FeSEM and EDX. The cyclic injection provides the differential pressure (DP) profile of the two samples with time, and is found to have increased with successive injection cycles. The FeSEM images showed that there was some dissolution and precipitation of minerals after the CO_2 flooding emphasizing on solubility trapping and EDX provides the quantitative information about mineral compositions. The results are also compared for both porosity and permeability changes which are found to have decreased post $scCO_2$ flooding. The results of this study provide vital information about mineralogical changes and thus will enhance the knowledge of implementing full scale CO_2 sequestration in subsurface carbonate formations.

Changes in sealing performance of artificial caprocks caused by carbonate reactions

*Masao Sorai[1]

1. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

Geological CO_2 storage assumes that a caprock retains injected CO_2 stably within a reservoir. However, there is little knowledge whether the caprock geochemically-reacted over a long time keep equal sealing performance. This study aims to quantify the change of the rock's sealing performance caused by geochemical reactions.

To understand the rock reaction and the resultant changes in pore structure, it is reasonable to perform experiments under the system with clear reaction process and of controlled pore structures. I used sintered compacts comprising of differently packed uniform silica beads, whose particle size were respectively 0.5, 1 and 10 μm. Here, attention was focused on reactions of carbonate minerals because carbonates have the highest reactivity of usual aquifer minerals. Therefore, products were immersed into the calcium acetate solution and heated up to 700˚C, which resulted in the precipitation of carbonates within their pore space. In the current experiment, samples were reacted in a supercritical CO_2-water system at 10 MPa and 40ºC, which corresponds to the condition of 1000 m depth. The reaction was performed separately setting the reaction time to 1, 2, and 4 weeks. Each sample after reactions was made available for the measurement of permeability *k*.

It is generally expected that the dissolution of carbonates in rock's pore space causes an increase in *k*, whereas that the precipitation of carbonates results in a decrease in *k*. Applying this presumption to experimental results, the *k* change caused by carbonate reactions was considered. On high density samples, carbonates dissolve from the sample surface by the CO_2-dissolved water, but once the surrounding water reaches a concentration saturated to carbonates, no more dissolution occurs. In addition, even if the water does not reach a saturating concentration, most of leaching components have no way out. Therefore, they are concentrated and re-precipitated in the central part of a sample. This scenario expects that the permeability is initially increased and then maintained constant or decreased to a prior level. In contrast, low density samples dissolve more carbonates because of the penetration of CO_2 -dissolved water deep into a sample and of active material transport between surface and interior. This results in an increase in *k*. Hereafter, we should quantify the leakage risk through a caprock based on both penetration rate within a rock and the carbonates content.

CO_2 migration characteristics of microbubble and conventional sequestration in Berea sandstone revealed by X-ray CT imaging

*Hongyu Zhai[1,2], Yi Zhang[1,2], Hyuck Park[1,2], Ziqiu Xue[1,2]

1. Geological Carbon dioxide Storage Technology Research Association,9-2, Kizugawadai, Kizugawa Shi, Kyoto, 6190292 Japan, 2. Research Institute of Innovative Technology for the Earth (RITE),9-2, Kizugawadai, Kizugawa Shi, Kyoto, 6190292 Japan

CO_2 geological sequestration is an effective technique to mitigate the increase of global CO_2 emission and warming effect. To improve CO_2 storage capacity in porous sediments, we applied a new technology, of which a particular filter is utilized to generate supercritical CO_2 (SC) microbubble, for the SC injection. A Berea sandstone sample was used for the tests: the microbubble injection (MBI) and conventional injection (CI). By X-ray CT imaging, we find that the MBI can enhance the SC migration and sweep efficiency, and finally result in a higher SC saturation. To quantify the difference in SC saturation variation for MBI and CI, we classify the porous space (as imaged volume) into three subsets (low-porosity: $\Phi_L \leqq$ 19%; medium-porosity: 19%$<\Phi_M \leqq$22%; and high-porosity: 22%$<\Phi_H$). We identify that there are different SC migration patterns (P1: rapid and high-massed SC flow occupied large-sized porosity sites with an apparent migration trace; P2: slow and low-massed SC flow diffused into small-sized porosity sites; and P3: a mixed migration pattern of P1 and P2) dominated by the porosity distribution and sediment layers. The main differences in the flow characteristics of MBI and CI for the three groups of porosity sites are outlined as follows.

(1)-Φ_H: At the beginning, the MBI formed a step-increased SC saturation gradient in the Φ_H sites along the axial direction. Subsequently, several times of SC saturation accumulation occurred before the injected SC reached 0.15 PV. In contrast, in the CI, there was a continuous SC flow migrated in the high-porosity sites from the inlet side to the outlet side before the injected SC reached 0.1 PV. After the SC flow transported to the left part (with a distance >150 mm from inlet side), the SC sweep efficiency became weakened. When the injected SC was greater than 0.08 PV, the increase of SC saturation propagated simultaneously from the central position towards inlet and outlet sides.

(2)-Φ_M: In the Φ_M sites, before the injected SC smaller than 0.9 PV, the P1 model controlled the flow migration for MBI. Then the P3 model dominated the SC flow migration. In the CI, similar SC flow transport features also occurred, however, with a lower SC sweep efficiency, and the P3 model commenced until the injected SC approximated 0.15 PV.

(3)-Φ_L: In the Φ_L sites, both the MBI and CI produced only the P1-type SC transport pattern. But the MBI had an earlier trigger time and higher SC saturation than CI.

These analyses demonstrate that the SC flow in the MBI can permeate into more porous space and build a higher CO_2 saturation than CI. The MBI has the potential to provide a more efficient and lower cost choice for the CO_2 geological storage.

Strain detection by optical fiber for CO_2 injected core specimen

*Hyuck Park[1], Yankun Sun[1], Ziqiu Xue[1]

1. Research Institute of Innovative Technology for the Earth

In order to detect strain of rock specimen during CO_2 injection using optical fiber, a laboratory experiment was carried out using porous sandstone. Spiral direction strain of core specimen was detected by optical fiber. We compared the strain profiles in the case of one-phase flow (water only) and the case of two-phase flow (CO_2 in water saturated specimen). CT image analysis was also used to determine the internal state of the specimen. Sarukawa sandstone (diameter: 34.83mm, length: 179.50mm) was used in this study. Porosity of the specimen determined by X-ray CT imaging is 23.38%. This specimen is homogeneous overall, but there are some gravels in some places. The permeability is about 7 mDarcy. The experiment was conducted under the pressure and temperature conditions that simulate underground environments; pore pressure: 10MPa, temperature: 40 degrees Celsius. The confining pressure selected in this study is 12MPa. The specimen was first saturated with KI aqueous solution (11.5 wt%). The permeability was confirmed using the KI aqueous solution. The upstream pump was prepared at 10.5 MPa for differential pressure of 0.5MPa. The CO_2 flooding was carried out until the total fluid injection reaches about 7.6PV (pore volume). Optical fiber measurement and X-ray CT imaging were performed in all experimental steps. In the case of one-phase flow (water only), as soon as the water injection started, the strain profile was completed. And the strain profile was almost constant until the test ended. In the case of two-phase flow (CO_2 flooding in water saturated specimen), there was a small strain increase up to CO_2 breakthrough and there was a sudden strain increase after the breakthrough. In this study, it was possible to measure the spiral direction strain of 180mm long core specimen. At the same time, we could visualize the process of CO_2 flooding by X-ray CT image analysis. It has become possible to measure distortion of a long distance under the ground with a single optical fiber. It reveals that the optical fiber sensing is a potential tool for future CO_2 storage industries.

Bed deformation measured by distributed optical fiber and its sedimentological interpretation: alternated sandstone and mudstone aquifer, Boso Peninsula, Japan

*Takuma Ito[1,2], Tsutomu Hashimoto[1,2], Ziqiu Xue[1,2]

1. Research Institute of Innovative Technology for the Earth, 2. Geological Carbon Dioxide Storage Technology Research Association

We have been developing a technology to monitor real-time bed deformation by utilizing the distributed fiber optic sensing. Pumping test results illustrated that uneven bed deformation in an aquifer during pumping groundwater. This uneven bed deformation may be related to geological heterogeneity. For investigating geological heterogeneity, sediment cores were taken from the target aquifer, however detailed sedimentological features are less studied. Purposes of this study are to clarify sedimentary environment and grain size features on the basis of core analysis, and to compare core analysis results with bed deformation signature during the pumping test.

Sediment cores were taken from a Middle Pleistocene alternated sandstone and mudstone aquifer on Boso Peninsula, Japan. Facies analysis indicates that 3 types of sand layers were recognized in the cores: type 1 is single normally graded bed, type 2 is inversely-to-normally graded bed, and type3 is deformed beds in association with rip-up clasts. These features indicate that these sand layers are event deposits. This interpretation supports the view from the previous study that sandstone beds in the target aquifer are interpreted as event deposits in front of a shelf-margin delta. Grain-size analysis of the cores indicates that three depositional cycles were recognized at the depth between 164 and 230 m. Depositional cycles are the origin of the geological heterogeneity in the aquifer, which appears to be related to transgressive-regressive cycles.

Pumping test results showed four intervals with no bed deformation at the depth between 164 and 230 m. These intervals with no bed deformation appear to be related to the geological feature of the aquifer. Comparison between strain measured by optical fiber and depositional cycles identified by detailed core analysis indicates that depths with compressive strain correspond to that composing of coarse-grained sand beds. This pumping test result suggests that compressive strain, which can be used as an indicator of the groundwater pathway in the aquifer, largely depends on the lithology and grain size features. The field experimental results demonstrated that the bed deformation monitoring using distributed fiber optic sensing is useful for as indirect evaluation of the hydraulic properties of aquifer, which is closely linked to geological heterogeneity.

How many data are necessary to make a suitable threshold for anomalous pCO_2 owing to CO_2 leakage?

*Keisuke Uchimoto[1,2], Yuji Watanabe[1,2], Makoto Nishimura[1,2], Ziqiu Xue[1,2]

1. Geological Carbon dioxide Storage Technology Research Association , 2. Research Institute of Innovative Technology for the Earth

In Japan, the offshore storage of CO_2 is regulated by Act on Prevention of Marine Pollution and Maritime Disaster, which requires monitoring to be able to detect CO_2 leakage should it occur. If CO_2 stored in deep geological formations leaks into the sea, carbonate variables in seawater such as pH, dissolved inorganic carbon, and partial pressure of CO_2 (pCO_2) would change. Hence, to find anomalous values of the carbonate variables can be a method of the marine monitoring. It is, however, difficult to judge whether an observed carbonate value is anomalous, because the natural variability of carbonate variables is relatively great. Actually, many data were judged as anomalous at Tomakomai CCS Demonstration Project, where pCO_2 have been monitored, although CO_2 leakage has never occurred. Although false-positives (natural variability misjudged as anomalous) themselves are unavoidable, there are also avoidable false-positives, some of which are caused by an unsuitable threshold based on insufficient baseline data. In this study, we studied how many data are necessary to make a suitable threshold. For this purpose, we analyzed quarterly data observed in a semi-enclosed bay, Osaka Bay, from 2002 to 2010. Using N ($1 \leqq N \leqq 9$) years' data out of them, we calculated a threshold line based on a correlation between pCO_2 and dissolved oxygen saturation, applied all the 9 years' data to the threshold line, and counted the number of data exceeding the threshold line, i.e. false-positives. We suggest that at least around 5 years' data are necessary to make a reasonable threshold line based on quarterly data.

Evaluation of seismic event location accuracy of Tomakomai CO2 injection site: a numerical simulation case study

*Luchen Wang[1], Takahiro Nakajima[1], Ziqiu Xue[1]

1. RITE, Research Institute of Innovative Technology for the Earth

For CO2 injection monitoring in many CCS project, the most basic monitoring information is the seismic events. The seismic event location is the first step to understanding the causal process of a natural or induced fracture. In the case of CO2 geological storage, the location of an event is of special importance. The events in the reservoir may affect the storage capability. The events in the cap-rock may indicate the CO2 leakage. However, the location of the seismic event is probably to contain bias, especially for the limited seismic observation system. Therefore, the operator should understand that there is uncertainty in the location estimation of a detected event. In this study, we use the Tomakomai (Ocean Bottom Cable) OBC and borehole system (OB1 well) to study the seismic location accuracy in Tomakomai site. We believe that it can help to evaluate the event location effect with different azimuths and different depths. Moreover, this study may also be applied to the optimization of the seismic observation system.

At Tomakomai site, the permanent OBC is arranged as a line (length 3.6 km, containing 55 available sensors), deployed 2 m under the seabed. It is located above the CO2 reservoir and the center point is 3 km from the coast. The OB1 contains 4 sensors in the well with depths ranging from 2 km to 2.2 km. All sensors of OBC and OB1 contain a three-component geophone. Therefore, we can use only detected P phase signal for seismic location. We assume that the velocity model is layered and homogeneous, so that a simple model can be built based on the logging result. The ray-tracing method is employed in the seismic simulation and location process.

We compared the modelling event location accuracy for different azimuths and different depths. All events were distributed around Tomakomai site. The results showed that as the epicenter distance increases, the location errors increases. For the events which the epicenter is far away from the area enclosed by OBC and OB1, the locating effect is significantly worse. In addition, as the event depth increases, the location error also increases. The location error of shallow (0-1 km) events can be maintained within 1 m, while the location error of deep (8 km) events can reach the scale of several hundred meters. Ignoring the effects of the simulation method, it is obviously affected by the geometric distribution of the observation system.

Secondly, we also compared different observation system optimization strategies. The result indicated that, based on the Tomakomai seismic monitoring system, if the number of sensor is fixed, the longer OBC line can provide a better location result. Based on these analyses, future seismic monitoring system designs can be optimized for specific purposes (number of sensors, expected depth of monitoring, etc.).

Technical Challenges of Machine Learning Approach for Porosity Estimation in Nagaoka CCS site

*Takayuki Miyoshi[1], Takahiro Nakajima[1], Ziqiu Xue[1]

1. Research Institute of Innovative Technology for the Earth

In CCS, the distribution of hydraulic parameters such as porosity and permeability is one of the key parameters for evaluation of CO_2 storage capacity and CO_2 saturations. These parameters are measured as 1D profiles through well-logging. CCS projects, in general, have only a few wells available in the area of target. The 3D seismic data which covers the three dimensional space does not represent the hydraulic features directly. A technique to integrate these different types of data is required to estimate appropriate geological models.
Machine learning (ML) is a technique for predicting a target property from unknown input data by learning the relationship between known input data and prediction target. In this research, we apply ML approaches to Nagaoka CCS site data for predicting porosity distribution from seismic attributes created from the 3D seismic data. Determination of hyper-parameters of the ML model is often site-specific in predicting geological models. We present the technical challenges when using multiple attributes as input data.

Utilization of wave attenuation in time-lapse sonic logging data to evaluate the effect of super-critical CO_2 in the reservoir

*Takahiro Nakajima[2,1], Luchen Wang[2,1], Ziqiu Xue[2,1]

1. Research Institute of Innovative Technology for the Earth, 2. Geological Carbon Dioxide Storage Technology Research Association

This paper discusses seismic wave attenuation by injected CO_2 in the formation. Seismic methods have been broadly used for the monitoring of injected CO_2 at many CCS sites. Concerning the velocity change by the existence of CO_2, the relationship between P-wave velocity and CO_2 saturation in rock samples and formation have been studied well. Some laboratory experiments studied amplitude of P-wave as well as the velocity change by the invasion of CO_2, and the change in amplitude was larger than that of time delay (e.g. Muller et al., 2010). Meanwhile investigations on amplitude attenuation were rather limited. In this paper, we investigated P-wave data in the results of time-lapse sonic logging at the Nagaoka site.
At the Nagaoka site, time-lapse well loggings have been conducted during the injection period and post injection period at observation wells, which are 40 m and 60 m apart from the injection well. The sonic logging was conducted 45 times during 12 years using Halliburton’ s LFDL (Low Frequency Dipole-Sonic Logging Tool). Since it is not ascertain that the monopole transmitter has emitted the same energy at every logging, we chose a reference point in the cap rock 10 m above the target zone. At this depth, the formation was highly cemented with very small slowness, so the position was easily recognized in wave data and its wave field would not change during the CO_2 injection. We took the amplitude of the first P-wave arrival as the reference. We also assume that the emitted energy from the transmitter would not change at the reservoir within 15 m interval from the reference point.
Firstly, we compared the wave data at the depth where the largest change observed by CO_2 injected. We can see that the first arrival of P-wave at the nearest observation logging was shifted from 1.64 to 1.8 micro-sec at 14-th run. Amplitude of the peak was also gradually decreased after the CO_2 breakthrough, and the amplitude at 21-st run was clearly small. Next we calculated spectrum around the first P-wave arrivals, and found that high frequency components decreased much than the lower frequency components. This frequency shift looked like to be recovered during the imbibition process. These could be an evidence of wave-induced flow of two phase liquid.
From these analyses, amplitude attenuation can be observed in the sonic logging at geological storage site. The combination of seismic wave amplitude and time-delay could be applied for more reliable evaluation of CO_2 saturation as Azuma et al. (2014) pointed out. The amplitude change might be effective in the early detection of CO_2 leakage along the well, if results as the laboratory experiments were obtained in the field. An effective measurement for this purpose could be realized with the use of DAS-VSP.

Geological sequestration in saline carbonate formations: CO_2 -brine-rock interaction

*Shachi Shachi[1], Brijesh Kumar Yadav[1], Mohammad Azizur Rahman[2], Mayur Pal[3]

1. Indian Institute of Technology Roorkee, 2. Texas A&M University Qatar, 3. North Oil Company, Qatar

To reduce unequivocal global warming due to continuous emission of greenhouse gas CO_2 into atmosphere, geo-sequestration is one such emerging technology. For geologic sequestration, CO_2 is injected into suitable deep subsurface formations at supercritical temperature and pressure conditions. Saline carbonate formations are one such promising sink due to its wide spread availability and enormous storage potential. In this study, a series of experiments have been performed on carbonate cores for finding out the effect of injected supercritical CO_2 in subsurface formations. The laboratory study reported here investigated the cyclic injection of $scCO_2$ and brine on two types (Edward White and Edward Yellow) of core samples under reservoir conditions. Further, the pre and post flooded carbonate core samples are analysed for mineralogical changes of CO_2-brine-rock interaction using image analysis techniques such as FeSEM and EDX. The cyclic injection provides the differential pressure (DP) profile of the two samples with time, and is found to have increased with successive injection cycles. The FeSEM images showed that there was some dissolution and precipitation of minerals after the CO_2 flooding emphasizing on solubility trapping and EDX provides the quantitative information about mineral compositions. The results are also compared for both porosity and permeability changes which are found to have decreased post $scCO_2$ flooding. The results of this study provide vital information about mineralogical changes and thus will enhance the knowledge of implementing full scale CO_2 sequestration in subsurface carbonate formations.

Changes in sealing performance of artificial caprocks caused by carbonate reactions

*Masao Sorai[1]

1. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

Geological CO_2 storage assumes that a caprock retains injected CO_2 stably within a reservoir. However, there is little knowledge whether the caprock geochemically-reacted over a long time keep equal sealing performance. This study aims to quantify the change of the rock's sealing performance caused by geochemical reactions.

To understand the rock reaction and the resultant changes in pore structure, it is reasonable to perform experiments under the system with clear reaction process and of controlled pore structures. I used sintered compacts comprising of differently packed uniform silica beads, whose particle size were respectively 0.5, 1 and 10 μm. Here, attention was focused on reactions of carbonate minerals because carbonates have the highest reactivity of usual aquifer minerals. Therefore, products were immersed into the calcium acetate solution and heated up to 700˚C, which resulted in the precipitation of carbonates within their pore space. In the current experiment, samples were reacted in a supercritical CO_2-water system at 10 MPa and 40ºC, which corresponds to the condition of 1000 m depth. The reaction was performed separately setting the reaction time to 1, 2, and 4 weeks. Each sample after reactions was made available for the measurement of permeability *k*.

It is generally expected that the dissolution of carbonates in rock's pore space causes an increase in *k*, whereas that the precipitation of carbonates results in a decrease in *k*. Applying this presumption to experimental results, the *k* change caused by carbonate reactions was considered. On high density samples, carbonates dissolve from the sample surface by the CO_2-dissolved water, but once the surrounding water reaches a concentration saturated to carbonates, no more dissolution occurs. In addition, even if the water does not reach a saturating concentration, most of leaching components have no way out. Therefore, they are concentrated and re-precipitated in the central part of a sample. This scenario expects that the permeability is initially increased and then maintained constant or decreased to a prior level. In contrast, low density samples dissolve more carbonates because of the penetration of CO_2 -dissolved water deep into a sample and of active material transport between surface and interior. This results in an increase in *k*. Hereafter, we should quantify the leakage risk through a caprock based on both penetration rate within a rock and the carbonates content.

CO_2 migration characteristics of microbubble and conventional sequestration in Berea sandstone revealed by X-ray CT imaging

*Hongyu Zhai[1,2], Yi Zhang[1,2], Hyuck Park[1,2], Ziqiu Xue[1,2]

1. Geological Carbon dioxide Storage Technology Research Association,9-2, Kizugawadai, Kizugawa Shi, Kyoto, 6190292 Japan, 2. Research Institute of Innovative Technology for the Earth (RITE),9-2, Kizugawadai, Kizugawa Shi, Kyoto, 6190292 Japan

CO_2 geological sequestration is an effective technique to mitigate the increase of global CO_2 emission and warming effect. To improve CO_2 storage capacity in porous sediments, we applied a new technology, of which a particular filter is utilized to generate supercritical CO_2 (SC) microbubble, for the SC injection. A Berea sandstone sample was used for the tests: the microbubble injection (MBI) and conventional injection (CI). By X-ray CT imaging, we find that the MBI can enhance the SC migration and sweep efficiency, and finally result in a higher SC saturation. To quantify the difference in SC saturation variation for MBI and CI, we classify the porous space (as imaged volume) into three subsets (low-porosity: $\Phi_L \leqq$ 19%; medium-porosity: 19%$<\Phi_M \leqq$22%; and high-porosity: 22%$<\Phi_H$). We identify that there are different SC migration patterns (P1: rapid and high-massed SC flow occupied large-sized porosity sites with an apparent migration trace; P2: slow and low-massed SC flow diffused into small-sized porosity sites; and P3: a mixed migration pattern of P1 and P2) dominated by the porosity distribution and sediment layers. The main differences in the flow characteristics of MBI and CI for the three groups of porosity sites are outlined as follows.

(1)-Φ_H: At the beginning, the MBI formed a step-increased SC saturation gradient in the Φ_H sites along the axial direction. Subsequently, several times of SC saturation accumulation occurred before the injected SC reached 0.15 PV. In contrast, in the CI, there was a continuous SC flow migrated in the high-porosity sites from the inlet side to the outlet side before the injected SC reached 0.1 PV. After the SC flow transported to the left part (with a distance >150 mm from inlet side), the SC sweep efficiency became weakened. When the injected SC was greater than 0.08 PV, the increase of SC saturation propagated simultaneously from the central position towards inlet and outlet sides.

(2)-Φ_M: In the Φ_M sites, before the injected SC smaller than 0.9 PV, the P1 model controlled the flow migration for MBI. Then the P3 model dominated the SC flow migration. In the CI, similar SC flow transport features also occurred, however, with a lower SC sweep efficiency, and the P3 model commenced until the injected SC approximated 0.15 PV.

(3)-Φ_L: In the Φ_L sites, both the MBI and CI produced only the P1-type SC transport pattern. But the MBI had an earlier trigger time and higher SC saturation than CI.

These analyses demonstrate that the SC flow in the MBI can permeate into more porous space and build a higher CO_2 saturation than CI. The MBI has the potential to provide a more efficient and lower cost choice for the CO_2 geological storage.

Strain detection by optical fiber for CO_2 injected core specimen

*Hyuck Park[1], Yankun Sun[1], Ziqiu Xue[1]

1. Research Institute of Innovative Technology for the Earth

In order to detect strain of rock specimen during CO_2 injection using optical fiber, a laboratory experiment was carried out using porous sandstone. Spiral direction strain of core specimen was detected by optical fiber. We compared the strain profiles in the case of one-phase flow (water only) and the case of two-phase flow (CO_2 in water saturated specimen). CT image analysis was also used to determine the internal state of the specimen. Sarukawa sandstone (diameter: 34.83mm, length: 179.50mm) was used in this study. Porosity of the specimen determined by X-ray CT imaging is 23.38%. This specimen is homogeneous overall, but there are some gravels in some places. The permeability is about 7 mDarcy. The experiment was conducted under the pressure and temperature conditions that simulate underground environments; pore pressure: 10MPa, temperature: 40 degrees Celsius. The confining pressure selected in this study is 12MPa. The specimen was first saturated with KI aqueous solution (11.5 wt%). The permeability was confirmed using the KI aqueous solution. The upstream pump was prepared at 10.5 MPa for differential pressure of 0.5MPa. The CO_2 flooding was carried out until the total fluid injection reaches about 7.6PV (pore volume). Optical fiber measurement and X-ray CT imaging were performed in all experimental steps. In the case of one-phase flow (water only), as soon as the water injection started, the strain profile was completed. And the strain profile was almost constant until the test ended. In the case of two-phase flow (CO_2 flooding in water saturated specimen), there was a small strain increase up to CO_2 breakthrough and there was a sudden strain increase after the breakthrough. In this study, it was possible to measure the spiral direction strain of 180mm long core specimen. At the same time, we could visualize the process of CO_2 flooding by X-ray CT image analysis. It has become possible to measure distortion of a long distance under the ground with a single optical fiber. It reveals that the optical fiber sensing is a potential tool for future CO_2 storage industries.

Bed deformation measured by distributed optical fiber and its sedimentological interpretation: alternated sandstone and mudstone aquifer, Boso Peninsula, Japan

*Takuma Ito[1,2], Tsutomu Hashimoto[1,2], Ziqiu Xue[1,2]

1. Research Institute of Innovative Technology for the Earth, 2. Geological Carbon Dioxide Storage Technology Research Association

We have been developing a technology to monitor real-time bed deformation by utilizing the distributed fiber optic sensing. Pumping test results illustrated that uneven bed deformation in an aquifer during pumping groundwater. This uneven bed deformation may be related to geological heterogeneity. For investigating geological heterogeneity, sediment cores were taken from the target aquifer, however detailed sedimentological features are less studied. Purposes of this study are to clarify sedimentary environment and grain size features on the basis of core analysis, and to compare core analysis results with bed deformation signature during the pumping test.

Sediment cores were taken from a Middle Pleistocene alternated sandstone and mudstone aquifer on Boso Peninsula, Japan. Facies analysis indicates that 3 types of sand layers were recognized in the cores: type 1 is single normally graded bed, type 2 is inversely-to-normally graded bed, and type3 is deformed beds in association with rip-up clasts. These features indicate that these sand layers are event deposits. This interpretation supports the view from the previous study that sandstone beds in the target aquifer are interpreted as event deposits in front of a shelf-margin delta. Grain-size analysis of the cores indicates that three depositional cycles were recognized at the depth between 164 and 230 m. Depositional cycles are the origin of the geological heterogeneity in the aquifer, which appears to be related to transgressive-regressive cycles.

Pumping test results showed four intervals with no bed deformation at the depth between 164 and 230 m. These intervals with no bed deformation appear to be related to the geological feature of the aquifer. Comparison between strain measured by optical fiber and depositional cycles identified by detailed core analysis indicates that depths with compressive strain correspond to that composing of coarse-grained sand beds. This pumping test result suggests that compressive strain, which can be used as an indicator of the groundwater pathway in the aquifer, largely depends on the lithology and grain size features. The field experimental results demonstrated that the bed deformation monitoring using distributed fiber optic sensing is useful for as indirect evaluation of the hydraulic properties of aquifer, which is closely linked to geological heterogeneity.

How many data are necessary to make a suitable threshold for anomalous pCO_2 owing to CO_2 leakage?

*Keisuke Uchimoto[1,2], Yuji Watanabe[1,2], Makoto Nishimura[1,2], Ziqiu Xue[1,2]

1. Geological Carbon dioxide Storage Technology Research Association , 2. Research Institute of Innovative Technology for the Earth

In Japan, the offshore storage of CO_2 is regulated by Act on Prevention of Marine Pollution and Maritime Disaster, which requires monitoring to be able to detect CO_2 leakage should it occur. If CO_2 stored in deep geological formations leaks into the sea, carbonate variables in seawater such as pH, dissolved inorganic carbon, and partial pressure of CO_2 (pCO_2) would change. Hence, to find anomalous values of the carbonate variables can be a method of the marine monitoring. It is, however, difficult to judge whether an observed carbonate value is anomalous, because the natural variability of carbonate variables is relatively great. Actually, many data were judged as anomalous at Tomakomai CCS Demonstration Project, where pCO_2 have been monitored, although CO_2 leakage has never occurred. Although false-positives (natural variability misjudged as anomalous) themselves are unavoidable, there are also avoidable false-positives, some of which are caused by an unsuitable threshold based on insufficient baseline data. In this study, we studied how many data are necessary to make a suitable threshold. For this purpose, we analyzed quarterly data observed in a semi-enclosed bay, Osaka Bay, from 2002 to 2010. Using N ($1 \leqq N \leqq 9$) years' data out of them, we calculated a threshold line based on a correlation between pCO_2 and dissolved oxygen saturation, applied all the 9 years' data to the threshold line, and counted the number of data exceeding the threshold line, i.e. false-positives. We suggest that at least around 5 years' data are necessary to make a reasonable threshold line based on quarterly data.

[H-DS10] Natural hazards impacts on human society, economics and technological systems

convener:ELENA PETROVA(Lomonosov Moscow State University, Faculty of Geography), Hajime Matsushima(Research Faculty of Agriculture, Hokkaido University), Chairperson:Elena Petrova, Hajime Matsushima

The last decade set a record for the number and scale of natural disasters and demonstrates high vulnerability of human society and technosphere to their impacts. The most serious consequences have the so-called natural-technological disasters in which natural hazards trigger accidents at technology and infrastructure such as nuclear power and chemical plants, oil refineries and pipelines, power supply systems, buildings, and roads. A distinctive feature of natural-technological events, such as of the 2011 Tohoku earthquake, is their multi-hazard and synergistic nature, which creates cascading impacts, resulting in simultaneous occurrences of myriad catastrophes. The main goal of this multidisciplinary session is to summarize case studies of relationships between natural hazards and technological disasters, their social and economic consequences; and to encourage a discussion about tools and methods to prevent disasters and to minimize their consequences, disaster reconstruction, and tourism for reconstruction, Eco-DRR, and green infrastructure.

People's lives utilizing coastal dunes ecosystem service

*Kaneko Korehisa[1]

1. Hokuso Creature Association

1. Introduction

The coastal sand system is a buffer zone between the sea and the land, and originally, it has a function to mitigate the natural disasters such as tsunamis and the formation of biodiversity. People form a settlement "town" in the coastal sand dunes for a long time. However, because natural coastal sand dunes have been destroyed due to the progress of development, opportunities to receive the benefits of nature have decreased since the period of high economic growth.
In this research, I evaluate the functions and ecosystem services from people's living in the coastal sand dunes before large-scale coastal development, we will also discuss about the regeneration of the coastal sand dunes in regard to social changes.

2. Method

The study sites are coastal cities in the coastal areas of Chiba Prefecture. In coastal area of Tokyo Bay side, large scale development has been conducted since the 1960’ s. Therefore, I judged it to be an effective place for evaluating coastal sand dunes before development. We investigated the environment of study sites, including the soil and groundwater. There were supported as necessities and luxury items in the area.

3. Results

In distance ratio of coastal type in Chiba Prefecture in 1993, natural coast was 23.5%, the artificial coast was 70.0%. The coastal cities of study site existed brewing industry such as soy sauce, miso, sake brewery. It was an industry that utilized ecosystem services such as the freshwater layer of the coastal dunes and the sea creatures. As a result investigated the location environment of the main coastal cities (soil, groundwater level, water quality), the coastal cities were often located on the geographical features consisting of sand, sandbanks and natural levees. The surface geology consisted of sand-rich sediments, including sand 1(i.e., exceedingly soft), the depth of the groundwater was 3-10 m. I believe that the coastal cities benefited from the proximity of the coast.

4. Themes for the future

The future prediction in Japanese society are ①progress of population decline, declining birthrate and aging population, ②economic decline, financial tightening, ③infrastructure (roads, railroads etc.) aging and the maintenance problem, the social situation change drastically. Moreover, in the coastal industrial area, the number of companies that suspended or stopped production facilities and the expansion of idle land have increased due to the shift of major manufacturing to overseas due to the shrinking domestic

©2019. Japan Geoscience Union. All Right Reserved.

demand over the medium to long term and intensified global competition. As a future task, it is important to work on the regeneration (green infrastructure) of the natural coast sand dune utilizing idle land while cooperating with the government, enterprises, local residents, and academics.

Survey on the Impact of Sea wall on the Vegetation of Coastal sand dune

*XIANGMEI ZHONG[1], Hajime Matsushima[2], Akira Suzuki[3], Yoshihiko Hirabuki[4], Kouji Kimura[5]

1. Graduate school of Agriculture, Hokkaido University, 2. Research Faculty of Agriculture, Hokkaido University, 3. Kita-no-satohama Hana-no-kanehashi Network, 4. Faculty of Liberal Arts, Tohoku Gakuin University, 5. Snow Brand Seed Co., Ltd.

[Introduction]

In recent years, many extreme events have come out due to climate change such as heavy rain, typhoon, etc. Large amounts of expenses are required for disaster-management measures. However, with the declining of population, the government budget is gradually lessening. On the other hand, people’s interests about disasters risk reduction are increasing. Before the disaster in 2011, at Yuriage district in Miyagi prefecture, coastal sand dune, pine forest and backward wetlands can be seen from the shoreline to the landward. In 2011, it is clear that the tsunami disturbed the organisms that support the coastal ecosystem and the environment which is the foundation of its habitat on a large scale. Since the coastal sand dune ecosystem here was disturbed, it has been restored naturally over time and then as a tsunami protection measure, a large seawall was built. Later, on the land side of the Sea wall was reclaimed by the mountain soil. However, the impact of them on the coastal dune ecosystem is unclear. This study clarifies the ecological impact on coastal sand dune vegetation of the Sea wall and mountain soil. And if there is a negative effect, how can we reduce that effect? This study records it as a reference for future solutions.

Three sites at the Yuriage district were selected as survey targets(figure 1.). From the north to the south: the Yuriage area 1(Y1), the Yuriage area 2(Y2), and the Yuriage area 3(Y3). In Y1, the Sea wall was built about 2 years ago and the coastal ecology recovered in nature. In August 2017, plants (*Ixeris repens*) were planted on both sides of the Sea wall in Y2. In Y3, the Sea wall was built about 5 years ago, and the coastal ecology recovered naturally. Additionally, the land sides of the three survey areas were reclaimed with mountain soil.

[Methods]

A belt was set up from the coastal forest to the shoreline. Then, the terrain was recorded with Unmanned aerial vehicle(UAV). Vegetation surveys were conducted at 5m intervals and Plant species / Coverage(%) / Grass height(cm) were investigated. Furthermore, samples of sand were collected at intervals of 10m, and the particle diameter composition(mm) as well as Electrical Conductivity(mS / m)(EC) of each sample were measured. After that, the average plant volume(mm^3) was calculated. Based on the above data, the current status of the plants on both sides of the Sea wall and the physical environment were analyzed.

[Results&Discussion]

About the result of vegetation, there are three plant species on both sides of the Sea wall: *Imperata cylindrica, Digitaria ciliaris* and *Artemisia capillaris*. On the land side, *Artemisia capillaris,* and *Setaria viridis* are the dominant species. On the sea side, *Carex kobomugi, Glehnia littoralis, Calystegia soldanella* and *Ixeris repens* are the dominant species. It is obvious that the plant species on land side and sea side are different because of the separation by the sea wall. It can be seen that the distribution of plants on the

©2019. Japan Geoscience Union. All Right Reserved.

land side is significantly affected by the mountain soils, resulting in an increase in the number of inland plants, such as *Setaria viridis* and *Trifolium repens.* From the EC value, it is evident that the trend from the shoreline to the sea wall is gradually decreasing, and the trend from the sea wall to the inland is increasing. The phenomenon that the EC value increases inland can be considered as the impact of artificial coverage of mountain soil. About the result of particle diameter composition, it is obvious that the medium sand has a decreasing trend from the shoreline to the inland side. Closer to the shoreline, the proportion of the very fine sand is increasing. The closer to the inland, the greater the proportion of the very coarse sand and the coarse sand.

In general, the composition of particle diameter on both sides of the sea and land of the sea wall is of difference, and this phenomenon may be caused by the barrier effect of the sea wall. This phenomenon may become larger as time goes by.

After the Tsunami disaster in March 11th, 2011 at east Japan area, especially on the pacific side of Tohoku region, our government built huge seawalls along the coastline about 400 km long to protect inland area from Tsunami disaster. We aimed to regenerate the ecotone of coastal ecosystem using the dune plants by greening the seawall. We were planting the seven species of dune plants on the seawall in 2017. On this presentation we report the survival rate for a year of planted dune plants on the seawall.
As a result, most dune plants were survived around 80% or more on the seaside seawall. But the survival rates were decreased around 70% on the landside seawall because of dried out by soil loss. Comparison between natural recovered seaside seawall and planted seaside seawall, the dominant species *Ischaemum anthephoroides* were similar. But *Ixeris repens* were less survived on the planted seaside seawall, in spite of one of the dominant species on the natural recovered seaside seawall. On the other hand, species of landside seawall were completely different with natural recovered landside seawall. This results shows that the greening on the seawall, especially on the landside seawall, were important for regeneration of coastal dune ecotone.

Distribution Characteristics of Informal Green Space and Its Extension of perspective into Green Infrastructure

*minseo kim[1], Katsunori Furuya[1]

1. Chiba University Graduate School of Horticulture

1. introduction

The issues of Green Infrastructure (GI) and urban natural disasters are being addressed around the world, not only in North America and Europe, where the discussion first began, but throughout Asia. GI is a planned network strategically between natural and semi-natural areas, along with environmental factors designed for overall ecosystem services. A well-connected network provides positive benefits for quality of life and biodiversity and can receive ecosystem services such as reduction of disaster risk, water purification, air quality, recreational space, and climate change mitigation and adaptation. GI is a widely applicable element that can effectively respond to the various damage caused by climate change. Examples include efficient use of water resources, water restoration, protection of plant species susceptible to disasters, implementation of water conservation measures, reduction of heat island phenomena. In the case of the U.S. and Europe, a network of natural or semi-natural spaces with multidisciplinary functions is defined with the aim of restoring the functions of the ecosystem, and the policy is to utilize the combined spatial plan of domestic or countries. However, in recent years, the decline of cities has increased and limitations have been considered to create new urban green space as GI. Accordingly, the interest in informal green space such as vacant lots, street verges, water verges, and brownfields is increasing as an open space that is abandoned or overlooked in interstices in a city. In particular, interest is growing in strategies to enhance the urban environment and the vitality of residents by converting the value of vacant properties in urban areas to GI. Therefore, this study aims to examine the potential of informal green space as GI, and to suggests a connection with natural disaster prevention.

2. method

Since informal green spaces do not have an officially documented database, fieldwork on the site should be involved to derive the implications of this study. Therefore, in this study, Ichikawa City was analyzed as a study site, and informal green space and urban structures were analyzed using the spatial information collected from the field and the official open data sources. The sampling strategy used in this study was to set a square sample site of 50 meters at the intersection of a grid 500m and collect site information in focusing on the sample site. The total number of sample sites set up is 229 and the total area is about 1% of the entire city area.

3. results

Informal green space was found on 106 sample sites out of 229 sample sites in this study area. The total area of collected informal green space is 26,458 m^2 and consists of 229 patches. The total area of the informal green space found accounts for about 4.62% of the entire sample sites area, with an average area of about 115 m^2. Informal green space was distributed 123 patches and 67.6 m^2 mean size in residential areas, 15 patches and 48 m^2 mean size in commercial area, 16 patches and 230 m^2 mean size in industrial area, and 75 patches and 183 m^2 mean size in the urbanization control area. In the residential and commercial area, where are population density, informal green spaces are frequently distributed with a small scale. On the other hand, the informal green space of the urbanization control area with low population density and high elderly density is relatively large scale compared to residential and commercial area.

©2019. Japan Geoscience Union. All Right Reserved.

4. discussion and conclusion

Informal green space is a secondary green space created by human activities. Therefore, the distribution characteristics of informal green space differ according to the land use patterns that are related to human activities. Given the accessibility according to the distribution characteristics of informal green space and the linkage with the surrounding natural environment, a supplementary system of urban green infrastructure can be proposed.

DISASTER ANALYSIS OF LIGHTNING STRIKE DENSITY BASED ON LANDFORM FOR REDUCING VICTIMS IN WONOSOBO, INDONESIA

*Astry Zulky Permatasari[1], Gagad Nur Ridho[1], Yan Abdi Rahmanu[1], Emilya Nurjani[1]

1. Gadjah Mada University

Wonosobo regency is a region with diverse configuration landforms. The morphological and material aspects of the landform different responses to the lightning strike density. The incident of lightning strikes in Wonosobo Regency has negative impacts on people, buildings, and environment. Therefore, a lightning strike density analysis is important to minimize the negative impact of lightning strikes. This study aims to determine the condition of landform, analyze the relationship of lightning strike density and the landform, to know the risk of a lightning strike and give a recommendation of mitigation to reduce the negative impacts caused lightning strike. The research was conducted in Wonosobo Regency, Central Java Province. The data used are lightning strike type Cloud to Ground (CG) on 2015 - 2017 obtained from BMKG Yogyakarta station. Data is processed using ArcGIS 10.3 software with Kernel Density modeling and analyzed quantitatively-qualitative. Lightning strike density in Wonosobo shows a lower pattern from the southeast to the northwest. Wonosobo's landforms are volcanic and structural. Structural landform in Wonosobo Regency is anticlinal mountains with a strong or moderate incision that has the highest lightning strike density. The condition of the lithology of Wonosobo Regency dominated by Breccia, Lava and Tuff rocks that effect on the number of lightning strikes, because it has a low resistivity value (conductor). Kepil District and Wonosobo District are areas that have the highest risk of lightning strikes. Some mitigation activities that can be applied to reduce the risk of losses and death are installing a lightning rod, unplug the cable of electronic device inside the house during a lightning strike and immediately ending the outdoor activities when Cumulonimbus clouds begin to appear, and protect yourself by going into permanent buildings.

Development of Cost Competitive Unmanned Aerial Vehicle for Search and Rescue

*Aditya Keshav Natoo

UAV Technology is progressing at a rapid pace around the world. Some organizations have tried to develop Enterprise class UAVs which aim to cater to large section of users.
A dedicated cost competitive UAV to be used during and after disaster and for search and rescue missions is currently not available.

An effort is made to develop quad/hexa copter based UAVs with thermal and/or regular video cameras alongwith a servo controlled arm for transporting objects during search and rescue mission.

The thermal camera can transmit video images to the UAV operator to check for presence of victims during floods, earthquakes, forest fires, landslides, avalanches, tsunamis and cyclones.
During the search and rescue operations, items like inflatable lifejackets, harness, food and water supply etc can be dropped to the victims as well as rescue teams.

[H-DS10] Natural hazards impacts on human society, economics and technological systems

convener:ELENA PETROVA(Lomonosov Moscow State University, Faculty of Geography), Hajime Matsushima(Research Faculty of Agriculture, Hokkaido University)

The last decade set a record for the number and scale of natural disasters and demonstrates high vulnerability of human society and technosphere to their impacts. The most serious consequences have the so-called natural-technological disasters in which natural hazards trigger accidents at technology and infrastructure such as nuclear power and chemical plants, oil refineries and pipelines, power supply systems, buildings, and roads. A distinctive feature of natural-technological events, such as of the 2011 Tohoku earthquake, is their multi-hazard and synergistic nature, which creates cascading impacts, resulting in simultaneous occurrences of myriad catastrophes. The main goal of this multidisciplinary session is to summarize case studies of relationships between natural hazards and technological disasters, their social and economic consequences; and to encourage a discussion about tools and methods to prevent disasters and to minimize their consequences, disaster reconstruction, and tourism for reconstruction, Eco-DRR, and green infrastructure.

The 2018 Activity of Kamchatka Volcanoes and Danger to Aviation

*Olga Girina[1], Dmitry Melnikov[1], Alexander Manevich[1], Anton Nuzhdaev[1], Elena Petrova[2]

1. Institute of Volcanology and Seismology, Far East Division, Russian Academy of Sciences, 2. M.V. Lomonosov Moscow State University

Strong explosive eruptions of volcanoes are the most dangerous for aircraft because they can produce in a few hours or days to the atmosphere and the stratosphere till several cubic kilometers of volcanic ash and aerosols. Ash plumes and the clouds, depending on the power of the eruption, the strength and wind speed, can travel thousands of kilometers from the volcano for several days, remaining hazardous to aircraft, as the melting temperature of small particles of ash below the operating temperature of jet engines.

There are 30 active volcanoes in the Kamchatka, and several of them are continuously active. Scientists of KVERT monitor Kamchatkan volcanoes since 1993. In 2018, three of these volcanoes (Sheveluch, Klyuchevskoy, Karymsky) had strong and moderate explosive eruptions.
The eruptive activity of Sheveluch volcano began since 1980 (growth of the lava dome) and is continuing at present. In 2018, strong explosions sent ash up to 10-11 km a.s.l. on 09 January, 26 and 30 December; and up to 6-7 km a.s.l. –on 09 November, and 12, 14, 26-27 and 29 December; ash plumes extended more 2000 km to the different directions of the volcano. Satellite data by KVERT showed a thermal anomaly over the volcano all year. Activity of the volcano was dangerous to international and local aviation.

The moderate explosive events (ash up to 5-6 km a.s.l.) of Klyuchevskoy volcano were observing from 01 till 18 January, on 08 May, and 06 and 15 June. Strong explosions sent ash up to 10.5 km a.s.l. on 14 May. Ash plumes extended more 350 km to the eastern and south-western directions from the volcano. Satellite data by KVERT showed a thermal anomaly over the volcano all year. Activity of the volcano was dangerous to international and local aviation.

The thermal anomaly over Karymsky volcano was recorded on satellite images from time to time, most brightly it manifested in January, May, June-August, September and December. According to visual and satellite data, at this time explosions rose ash up to 6.5 km a.s.l., ash plumes drifted for about 860 km to the different directions from the volcano. The most intense eruptive activity of the volcano was observed on 10, 14-20 and 26-31 July, besides, isolated strong explosive events were observed on 07 and 25 August, on 10-11, 22-23 and 30 September, and 01 December. The size of the ash clouds varied from 5-6 to 240 km. Activity of the volcano was dangerous to local aviation.
This work was supported by the Russian Science Foundation, project No. 16-17-00042.

Keywords: volcano, eruption, Kamchatka, danger to Aviation

Planning Methodology on the Effective Use of Green Infrastructure for Disaster Risk Reduction

*Keita Aragane[1], Satoshi Funakubo[1]

1. National Institute for Land Infrastructure Management

Green Infrastructure (GI) is a concept based on infrastructure development and land utilization that take advantage of natural environments' various functions for creating sustainable and attractive national land or regions. In Japan, since 2015, the concept of GI has been include in National Spatial Strategy, National Land Use Plan, and Priority Plan for Infrastructure Development, etc. Also, lessons learned from the Great East Japan Earthquake raised awareness of the need for more-comprehensive disaster risk reduction strategies in preparing for disasters that surpass worst-case scenarios. Additionally, there is concern over anticipated the Nankai Trough Earthquakes that might cause greater damage in near future, and increasingly frequent urban flooding owing to climate change. Thus, initiative for disaster risks reduction by utilizing GI's multiple functions in addition to approaches focusing on artificial infrastructure has become increasingly important.

This study aims to discuss planning methodology regarding the effective use of GI for disaster risk reduction in urban area by examining the “Green Master Plan (GMP)” through 72 case studies. In Japan, 680 municipal governments have developed GMPs as their basic policy for green space planning, management, and greening. These municipal governments in Japan are recommended to emphasize the viewpoint of disaster risk reduction in their GMPs, and to implement disaster risk reduction systematically through effective use of green spaces such as parks, roadside trees, waterways, private domestic gardens, agricultural land, and woodlands. Result from the case studies revealed that almost all GMPs designated green spaces such as parks as evacuation sites for mega-earthquakes or large-scale fires. Several GMPs were also found to present countermeasures that make effective use of GI for tsunami-related disasters and urban flooding.

Through these findings and through discussions with scholars at a workshop, we published “Technical Note on Green Infrastructure Planning for Urban Resilience” in June 2018. In this technical note, we explain six key points for developing GMPs that enhance the role of GI in disaster risk reduction: (1) combining various measures for disaster risk reduction by utilizing GI from a comprehensive perspective, (2) examining the role and combination of GI and other artificial infrastructure in urban disaster risk reduction, (3) building cooperative relationships with various stakeholders and citizens, (4) taking advantage of multiple functions of GI not only during disasters but also in normal times, (5) establishing a mechanism for maintaining and using GI from a long-term perspective, and (6) considering regional conditions and social situations.

EMERGENCY CALL PATTERN IN PETROZAVODSK

*Boris Zalmanovich Belashev[1], Natalia Vladimirovna Krutskikh[1], Anna Aleksandrovna Gerasimova[1]

1. Karelian research center of Russian academy of science

The aim of the study is to analyze the emergency call distribution for Petrozavodsk, Russia, to obtain quantitative disease estimates and to assess the effect of environmental factors on them.

The study was based on medical statistical data and geophysical and geochemical monitoring. Environmental factors, such as magnetic storms and air and urban soil pollution, were assessed. The impersonified catalogue of emergency calls of Petrozavodsk Ambulance from 2015.1.1 to 2017.12.19, database of geomagnetic field variations at Petrozavodsk Geophysical Observatory, data on Kp index monitoring at the Laboratory of Tesis X-ray Astronomy at Lebedev Physical Institute, and the results of geochemical soil sampling in Petrozavodsk were used. Emergency call and geomagnetic activity distributions were constructed and processed in MATLAB computer mathematics system and Qgis software package. Analytical results were demonstrated on cardiovascular diseases.

The number of emergency call for patients with cardiac diseases in 2015-2017 is at about the same level. Seasonal factors affect the time distribution trends of calls for patients with essential hypertension, stenocardia and ischemic cardiac disease and do not affect the distribution trends of myocardial infarction and cerebral crisis. Time distribution spectra display a 25.6 day cycle similar to a geomagnetic activity period, two- and one-week cycles and cycles with periods of about 6, 4 and 3 days. Emergency calls for patients with myocardial infarction reflect the gender and age of the patients. The number of calls on weekends is typically low. On week-days, the number of calls at rush hours is maximum. The number of calls on days close to magnetic storms is not necessarily great. An elevated number of calls on these days for patients with stenocardia and myocardial infarction is observed.

The spatial distribution of the number of emergency calls were obtained using the Ambulance Geoinformation System. The system constructs the spatial distributions of the number of emergency team calls with known diagnoses for the streets and blocks of the city and is used to compare call frequency with district factors. With its help the link of distribution of quantity of calls of ambulance with diagnoses of cardiovascular diseases, bronchial asthma, vegeto-vascular dystonia, new growths, other diseases on districts of the city with the soils contamination indicated by the environmental hazard index –a total of the weighted average concentration values of As, Pb, Zn, Cd, Co, Cu, V, W is studied. No significant correlations between these values have been revealed.

3, 6-daily cycles in the analyzed ranges can be connected to thyroid gland hormone activity and a 4-day cycle to glucocorticoid hormone activity. Circadian rhythms are either thought to be general or to be due to the unwillingness of people to be sent to hospital or call for a doctor on weekends. In case of myocardial infarction, when help is needed urgently, the latter factor does not work, and a one-week cycle in the spectrum, showing the time dependence of the number of calls, is displayed.

This fact and the weekend effect can be understood, based on the properties of hydrocortisone. Stress from production activity stimulates the supply of the hormone into the blood, which rushes to the heart and muscles. When the heart fails to cope with the rush of blood, a cardiac disease becomes more acute.

©2019. Japan Geoscience Union. All Right Reserved.

As the hydrocortisone level in the blood on weekends and holidays declines, the number of emergency calls for patients with cardiovascular diseases decreases.

Peaks in the daily emergency call dynamics distribution on week-days are interpreted to be due to air pollution with car gases at rush hours (9-10 a.m., 1-2 and 6-7 p.m.) and an approximately one-hour delay caused by progress in disease and the need to apply for a doctor.
The emergency call distributions analyzed are highly informative, showing the complete dynamic disease pattern of the urban population.

Keywords: diseases, emergency call, patient, diagnose, magnetic storms, contamination

IDENTIFYING “REGIMES” IN THE TIME SEQUENCES OF PROCESSES

*Boris Zalmanovich Belashev[1]

1. Karelian research center of Russian academy of science

A process is represented as a sequence of “regimes” when describing climatic variations and complex systems, detecting the malfunctioning of instruments and illegal interference in computer and hardware networks. For natural, technological and social processes such representation is comfortable to detect precursors of disastrous events.
The shifts of “regimes” in the sequences are commonly detected by checking statistical hypotheses by Student’s test and tests of non-parametric statistics when comparing the characteristics of the sequence at one or another site. Algorithms often use a priori information, work in unstable fashion over short intervals and at sequences boundaries, find it hard to recognize the shifts and trends of “regimes”.
Widespread R-algorithm [1] analyze data consecutively in a sliding window, operate with a small number of parameters and filter off “red” noise. The boundary regimes it detect may reflect distortions characteristic of the beginning and end of measurements.
The goal of the present study is to develop B-algorithm which automatically recognizes stable “regimes” in time data sequences.
The main stages of the algorithm are clusterization, comparison and optimization. Clusterization preliminary divides a normalized time sequence into “regimes”. While comparing the characteristics of the “regimes”, the division obtained is re-estimated. The final model of division is formed during optimization, which minimizes the variance of deviations from the trends of the “regimes” by varying the internal boundaries of the sites.
The algorithm, developed as a software in the MATLAB computer mathematics system, fulfils procedures automatically, decreases the amount of a priori data, increases operation speed and brings solutions closer to optima.
The operation of B- and R-algorithms is exemplified by the PDO (Pacific Decade Oscillation) sequence of mean January temperatures [2].
In both algorithms the number of “regimes” and their approximate positions coincide. The delay of part of R-“regimes” emphasize the sensitivity of B-algorithm to new “regimes”. Discrepancies are connected with the last “regime” identified by R- and B-algorithms on 2 and 15 members of sequence, respectively.
B- algorithm can operate with constant, linear and complex trends.
B- and R-algorithms, applied to the time sequences of river runoff, solar and seismic activity and the sequences of the annual rings of trees, have provided new information on the stages of processes.
The simplified schematic “regime” representation of a process reveals trends commonly obscured by the abundance of details. B- algorithm identifies stable “regimes” and recognizes the shifts and trends of “regimes”. The use of MATLAB functions increases the potential of the algorithm, admits the fulfilment of procedures by various methods, brings solutions closer to optimum solutions and ensures high operation speed. The ability of the algorithm to automatically process data makes it suitable for working with extensive data in various earth sciences.

Investigation of status and demand on public service of earthquake disaster mitigation in China

*Lina Dong[1], Weiping Lian[1], Weitao Chen[1]

1. Development Research Center, China Earthquake Administration

In order to make a comprehensive and systematic evaluation of the status and demands of public service of earthquake disaster mitigation, we launched an investigation with National Bureau of Statistics on the current situation of public service of earthquake disaster mitigation and the demands for it in 2018. The investigation was conducted in 31 provinces of China mainland using the Computer Assisted Telephone Interview(CATI) method and received 20078 valid samples in total.

The results indicate that 52.2% of the population have received the scientific knowledge education for earthquake disaster mitigation in Different levels. It shows that the public still possesses a high expectation of earthquake prediction and farmers have a low level of scientific knowledge of earthquake disaster mitigation. And TV, network, and the new media app such as wechat and weibo become the most important information channels for the public to obtain the earthquake related information. Furthermore, the degree of satisfaction evaluation of public service of earthquake disaster mitigation is marked on 81.22 points (the full mark is 100 points). And the most expectative services for the public are reconstruction, earthquake warning, and house earthquake resilience test. The results of the investigation have provided a scientific evidence for the government to provide better services of earthquake disaster mitigation and to make scientific knowledge popularization in a more scientific way.

Analysis of Eco-DRR and Ecological Services using InVEST at the Disaster Areas of Kumamoto Earthquake

*Minghui Tang[1], Naoko Fujita[1]

1. Kyushu University

When compared with other countries in a global point of view, Japan is a country with high number of natural calamities, significant causalities, economic loss and damages by earthquakes, typhoons, and eruption. The damage is especially big when a hazard comes right after another one.

Complex disaster refers to the occurrence of multiple disasters instead of one. Such as, in 2016, Kumamoto prefecture was hit by earthquakes with magnitude as large as 7 and within another 2 months, by heavy rain and the damage was tremendous.

There is a huge number of researches on the eco-application of proceeding in various countries and it is vitally important to verify their validity. Here, InVEST refers to the ArcGIS tool for the integrated review for ecological services and its compensation.

This research focuses on the analysis of the changes of the land cover as reflected in satellite pictures of the whole Kumamoto prefecture taken after the complex disaster, the earthquake in April 2016 and heavy rain in June 2016. Also, it’ s a review on the ecological services with the use of InVEST. A special focus is paid on the review of the soil retention and the quality changes of the eco-habitant as reflection of the disaster damage reduction measures.

In addition, there is an analysis on the change of land coverage on area-unit level with Mashiki-machi, the epicenter, as the target. Furthermore, projection was plotted for the ecological services implemented as the reconstruction plan.

Transformation as praxis: Exploring socially just and transdisciplinary pathways to sustainability in marginal environments (TAPESTRY)

*Nobuhito Ohte[1], Lyla Mehta[2], Synne Movik[3], Devanathan Parthasarathy[4]

1. Department of Social Informatics, Graduate School of Informatics, Kyoto University, 2. Institute of Development Studies at the University of Sussex, 3. Department of Urban and Regional Planning, Norwegian University of Life Sciences, 4. Department of Humanities and Social Sciences, Indian Institute of Technology

Climate change related uncertainties are the main threats to the sustainability of societies and their environments. To tackle these challenges, systemic transformations are required. Our project focuses on three cases of transformation in marginal environments in India and Bangladesh, and is concerned with: How transformation happens through bottom up processes in these sites; and how they can be scaled up and facilitate wider societal changes. Both require transdisciplinary co-production and the praxis of transformation which presupposes change in social arrangements and reconstruction by individuals. Our project addresses issues concerning governance, wellbeing, identity and quality of life in relation to transformations to sustainability in a lower middle income country (India) and a least developed country (Bangladesh). Our results should help inform processes that ultimately improve the quality of life in marginal environments, and build action and capacity among all partners.

Keywords: Transformation, Sustainability, Marginal environment, Transdisciplinary study, India, Bangladesh

Study for the Establishment of the Design for Disaster prevention through the survey of Recognition of tsunami disaster prevention from the viewpoint of green infrastructure in the coastal area of Kyushu-Pacific region.

*Shanshan Xu[1], Naoko Fujita[1], Minghui Tang[1]

1. Kyushu University

Considering the possibility of Nankai Trough large-scale earthquake predicted to occur in the nearest future, the issue of the tsunami in the coastal area of Kyushu-Pacific region is becoming extremely important. Efforts to utilize the various functions of the ecosystem internationally for the society creation are expanding in recent years, and even in the situation of toughening of the land in Japan, the initiative to incorporate Green Infrastructure (GI) which utilizes the disaster prevention and reduction functions of the natural ecosystem are being observed. Also, during the process of self-help/mutual assistance action and disaster reconstruction at the time of disaster, attention is paid as regional ties are affected, which are being considered as Social capital (SC).

The purpose of this study is to clarify the actual situation of tsunami disaster prevention of Nankai Trough earthquake based on the viewpoint of GI. We conducted a questionnaire survey on tsunami disaster prevention and GI at local governments and local communities. After analyzing the questionnaire, we analyzed the needs of the self-governing president's disaster prevention measures, the problems of the area, and the deviation of the improved situation of municipalities' disaster prevention measures. A correlation analysis was conducted to grasp the relationship between the consciousness concerning GI utilization, the strength of regional linkage SC and the recognition of evacuation.

1. Misalignment between demand and maintenance situation desired by the region

Policy regarding the issue of disaster helpers was extracted as a gap between needs and maintenance situation. Regarding the needs of the soft pattern in disaster prevention, a lot of measures were taken by disaster support supporters, however as it comes from the municipality questionnaire results, the measures related to the introduction of the barrier-free system and evacuation action supporters were introduced only partially. Further improvement is necessary for welfare evacuation sites, measures against supporters requiring evacuation actions, barrier-free formation.

2. SC regarded from the viewpoint of the relationship between intentions to utilize GI and recognition on disaster.

©2019. Japan Geoscience Union. All Right Reserved.

Especially, the correlation coefficient was 0.701 between No.7 and No.6. This shows that those who responded that disaster can happen among residents can respond that regional ties are stronger. For items with a high correlation coefficient between No.3 and No.8, the correlation became 0.437. This means the respondents who answered that evacuation is possible for all area inhabitants including elderly people in case of disaster (flooding, earthquakes, and tsunami) are able to use local well water and spring water in the event of a disaster.

Between No.2 and No.4, the correlation coefficient became 3.380. This is because those who respond that they think they can fully utilize the resources of the area (resources such as firewood, foods that can be harvested in mountains) even in the event of disasters will escape by utilizing the nearby natural landforms such as plateaus and mountains for tsunami evacuation. Between No.2 and No.8, the correlation coefficient became 0.351. This is because it shows those who responded that they thought that they could escape by utilizing nearby plateau and mountains such as mountains during the tsunami evacuation, even if disasters (flood, earthquake, tsunami) occurred, everyone including the elderly in the area evacuated. Between No.2 and No.6, the correlation coefficient became 0.343. This indicates that those who responded that they believe that they can escape by utilizing nearby plateaus and mountains when evacuating the tsunami think that the connection of the community people is strong. Between No.3 and No.6, the correlation coefficient became 0.287. This indicates that those who responded as they thought they could use local well water and spring water at the time of a disaster replied that they think that the regional connection is stronger.

Based on the above, we clarified the SC from the viewpoint of the gap between the request and the maintenance situation the region desires and the relationship between the intention to utilize GI and the perception of disaster. The fact that utilization of natural resources such as well water and spring water and understanding that natural topography can be utilized for evacuation leads to a positive feeling making people believe it is possible for everyone to evacuate even if the tsunami comes, can be suggested from this study.

Design for Green Infrastructure: Analysis of Landscape change in the Kumamoto earthquake area

*Naoko Fujita[1]

1. Kyushu University

The concept of “Green Infrastructure” and “Eco-DRR” is developed in Europe and North America lately, and it started to spread around in Japan after the Tohoku earthquake and tsunami in 2011. Landscape ecology is parallel with this conceptually, as well as in terms of spatial scale. Its successful focused researches and social implementation are becoming pervasive.

The new concept is to solve various problems by local resources and pearls of wisdom, it connects local communities to the world while it’s mainly led by front liners and researchers in engineering and ecological fields that little attention is paid to the aspects of arts and designs. It’s still not well-penetrated despite the validity and functions of the concept are well verified. Thus, it’s vitally important to work on the insufficient.

The purpose of this research is to analyze the reconstruction plan prepared by the affected municipalities of the Kumamoto earthquake and compare the landscape change read from the plan and the actual landscape change actually occurred and make clear how the cities and nature have changed during the reconstruction process.

In this research, we firstly gathered and analyzed the earthquake reconstruction plans created by each local government for all 45 municipalities in Kumamoto prefecture. In this analysis, while studying each municipal original plan, we primarily focused on the background, features, and landscape references of the plan formulation. During this analysis, we grasped the relations between the reconstruction plan and the landscape change, and also clarified what exactly each local government emphasizes independently. As the next step, basing on the field survey, we analyzed the actual state of the landscape changes described in the plan. As a method, we took the photographs at places where the plans adopted by each municipality in Kumamoto prefecture were scheduled or executed, and after recording the current situation and the surrounding landscape, we made a comparison with the photographs taken at the same place in the past. By doing this, we revealed what kind of changes have occurred between the past and the present due to the disaster, and how they affected the surrounding landscape.

Among the 45 municipalities in downtown Kumamoto Prefecture, we found that earthquake reconstruction plan was formulated in 16 municipalities, and 5 municipalities planned to formulate. There were references that "consideration of the landscape when promoting housing improvement and infrastructure development" and "to consider the landscape from the tourism viewpoint". Also, there were plans to utilize the process of reconstruction itself as a resource for tourist attraction. Furthermore, as a result of analyzing the individual plans described in the reconstruction plan, the reference to landscape,

©2019. Japan Geoscience Union. All Right Reserved.

reference to the prediction of landscape change, reference to landscape protection exists in all 16 cities, towns, and villages. Totally 117 relevant plans have been found. Although many of them were intended to cope with the damage at the time of the disaster, there were several plans originally adopted by the local governments to make necessary improvements of the problems they had from the past by conducting disaster recovery.

The field survey was conducted for 16 municipalities in total in Kumamoto Prefecture. One year has passed since the earthquake disaster, and recovery works progressed in a wide range in Kumamoto Prefecture. In the recovery sites in various places, a secondary change of the landscape, which caused the recovery activity aimed at improving the convenience of life and safety, has already been taking place. Moreover, recovery works progressed also in Kumamoto castle which is also cultural asset and tourist attraction, as well as the station and the government office which are the center of town. As a result, we could confirm the change of landscape.

In this research, through the analysis of the reconstruction plan created by the municipalities affected by the Kumamoto earthquake and the field survey, from the viewpoint of Green Infrastructure, we could make clear the process of the landscape change occurred during the process of recovery/reconstruction of the living base, the tourist resources, the natural environment in the affected areas and its influence respectively. Although few local governments have formulated landscape-friendly reconstruction plans, to gain medium- and long-term benefits, we should make landscape-friendly reconstructions from the original planning stage. This is because it is the factor determining the richness of living base, tourism resources, and natural environment.

[H-DS10] Natural hazards impacts on human society, economics and technological systems

convener:ELENA PETROVA(Lomonosov Moscow State University, Faculty of Geography), Hajime Matsushima(Research Faculty of Agriculture, Hokkaido University)

The last decade set a record for the number and scale of natural disasters and demonstrates high vulnerability of human society and technosphere to their impacts. The most serious consequences have the so-called natural-technological disasters in which natural hazards trigger accidents at technology and infrastructure such as nuclear power and chemical plants, oil refineries and pipelines, power supply systems, buildings, and roads. A distinctive feature of natural-technological events, such as of the 2011 Tohoku earthquake, is their multi-hazard and synergistic nature, which creates cascading impacts, resulting in simultaneous occurrences of myriad catastrophes. The main goal of this multidisciplinary session is to summarize case studies of relationships between natural hazards and technological disasters, their social and economic consequences; and to encourage a discussion about tools and methods to prevent disasters and to minimize their consequences, disaster reconstruction, and tourism for reconstruction, Eco-DRR, and green infrastructure.

The 2018 Activity of Kamchatka Volcanoes and Danger to Aviation

*Olga Girina[1], Dmitry Melnikov[1], Alexander Manevich[1], Anton Nuzhdaev[1], Elena Petrova[2]

1. Institute of Volcanology and Seismology, Far East Division, Russian Academy of Sciences, 2. M.V. Lomonosov Moscow State University

Strong explosive eruptions of volcanoes are the most dangerous for aircraft because they can produce in a few hours or days to the atmosphere and the stratosphere till several cubic kilometers of volcanic ash and aerosols. Ash plumes and the clouds, depending on the power of the eruption, the strength and wind speed, can travel thousands of kilometers from the volcano for several days, remaining hazardous to aircraft, as the melting temperature of small particles of ash below the operating temperature of jet engines.

There are 30 active volcanoes in the Kamchatka, and several of them are continuously active. Scientists of KVERT monitor Kamchatkan volcanoes since 1993. In 2018, three of these volcanoes (Sheveluch, Klyuchevskoy, Karymsky) had strong and moderate explosive eruptions.
The eruptive activity of Sheveluch volcano began since 1980 (growth of the lava dome) and is continuing at present. In 2018, strong explosions sent ash up to 10-11 km a.s.l. on 09 January, 26 and 30 December; and up to 6-7 km a.s.l. –on 09 November, and 12, 14, 26-27 and 29 December; ash plumes extended more 2000 km to the different directions of the volcano. Satellite data by KVERT showed a thermal anomaly over the volcano all year. Activity of the volcano was dangerous to international and local aviation.

The moderate explosive events (ash up to 5-6 km a.s.l.) of Klyuchevskoy volcano were observing from 01 till 18 January, on 08 May, and 06 and 15 June. Strong explosions sent ash up to 10.5 km a.s.l. on 14 May. Ash plumes extended more 350 km to the eastern and south-western directions from the volcano. Satellite data by KVERT showed a thermal anomaly over the volcano all year. Activity of the volcano was dangerous to international and local aviation.

The thermal anomaly over Karymsky volcano was recorded on satellite images from time to time, most brightly it manifested in January, May, June-August, September and December. According to visual and satellite data, at this time explosions rose ash up to 6.5 km a.s.l., ash plumes drifted for about 860 km to the different directions from the volcano. The most intense eruptive activity of the volcano was observed on 10, 14-20 and 26-31 July, besides, isolated strong explosive events were observed on 07 and 25 August, on 10-11, 22-23 and 30 September, and 01 December. The size of the ash clouds varied from 5-6 to 240 km. Activity of the volcano was dangerous to local aviation.
This work was supported by the Russian Science Foundation, project No. 16-17-00042.

Planning Methodology on the Effective Use of Green Infrastructure for Disaster Risk Reduction

*Keita Aragane[1], Satoshi Funakubo[1]

1. National Institute for Land Infrastructure Management

Green Infrastructure (GI) is a concept based on infrastructure development and land utilization that take advantage of natural environments' various functions for creating sustainable and attractive national land or regions. In Japan, since 2015, the concept of GI has been include in National Spatial Strategy, National Land Use Plan, and Priority Plan for Infrastructure Development, etc. Also, lessons learned from the Great East Japan Earthquake raised awareness of the need for more-comprehensive disaster risk reduction strategies in preparing for disasters that surpass worst-case scenarios. Additionally, there is concern over anticipated the Nankai Trough Earthquakes that might cause greater damage in near future, and increasingly frequent urban flooding owing to climate change. Thus, initiative for disaster risks reduction by utilizing GI's multiple functions in addition to approaches focusing on artificial infrastructure has become increasingly important.

This study aims to discuss planning methodology regarding the effective use of GI for disaster risk reduction in urban area by examining the “Green Master Plan (GMP)” through 72 case studies. In Japan, 680 municipal governments have developed GMPs as their basic policy for green space planning, management, and greening. These municipal governments in Japan are recommended to emphasize the viewpoint of disaster risk reduction in their GMPs, and to implement disaster risk reduction systematically through effective use of green spaces such as parks, roadside trees, waterways, private domestic gardens, agricultural land, and woodlands. Result from the case studies revealed that almost all GMPs designated green spaces such as parks as evacuation sites for mega-earthquakes or large-scale fires. Several GMPs were also found to present countermeasures that make effective use of GI for tsunami-related disasters and urban flooding.

Through these findings and through discussions with scholars at a workshop, we published “Technical Note on Green Infrastructure Planning for Urban Resilience” in June 2018. In this technical note, we explain six key points for developing GMPs that enhance the role of GI in disaster risk reduction: (1) combining various measures for disaster risk reduction by utilizing GI from a comprehensive perspective, (2) examining the role and combination of GI and other artificial infrastructure in urban disaster risk reduction, (3) building cooperative relationships with various stakeholders and citizens, (4) taking advantage of multiple functions of GI not only during disasters but also in normal times, (5) establishing a mechanism for maintaining and using GI from a long-term perspective, and (6) considering regional conditions and social situations.

EMERGENCY CALL PATTERN IN PETROZAVODSK

*Boris Zalmanovich Belashev[1], Natalia Vladimirovna Krutskikh[1], Anna Aleksandrovna Gerasimova[1]

1. Karelian research center of Russian academy of science

The aim of the study is to analyze the emergency call distribution for Petrozavodsk, Russia, to obtain quantitative disease estimates and to assess the effect of environmental factors on them.

The study was based on medical statistical data and geophysical and geochemical monitoring. Environmental factors, such as magnetic storms and air and urban soil pollution, were assessed. The impersonified catalogue of emergency calls of Petrozavodsk Ambulance from 2015.1.1 to 2017.12.19, database of geomagnetic field variations at Petrozavodsk Geophysical Observatory, data on Kp index monitoring at the Laboratory of Tesis X-ray Astronomy at Lebedev Physical Institute, and the results of geochemical soil sampling in Petrozavodsk were used. Emergency call and geomagnetic activity distributions were constructed and processed in MATLAB computer mathematics system and Qgis software package. Analytical results were demonstrated on cardiovascular diseases.

The number of emergency call for patients with cardiac diseases in 2015-2017 is at about the same level. Seasonal factors affect the time distribution trends of calls for patients with essential hypertension, stenocardia and ischemic cardiac disease and do not affect the distribution trends of myocardial infarction and cerebral crisis. Time distribution spectra display a 25.6 day cycle similar to a geomagnetic activity period, two- and one-week cycles and cycles with periods of about 6, 4 and 3 days. Emergency calls for patients with myocardial infarction reflect the gender and age of the patients. The number of calls on weekends is typically low. On week-days, the number of calls at rush hours is maximum. The number of calls on days close to magnetic storms is not necessarily great. An elevated number of calls on these days for patients with stenocardia and myocardial infarction is observed.

The spatial distribution of the number of emergency calls were obtained using the Ambulance Geoinformation System. The system constructs the spatial distributions of the number of emergency team calls with known diagnoses for the streets and blocks of the city and is used to compare call frequency with district factors. With its help the link of distribution of quantity of calls of ambulance with diagnoses of cardiovascular diseases, bronchial asthma, vegeto-vascular dystonia, new growths, other diseases on districts of the city with the soils contamination indicated by the environmental hazard index –a total of the weighted average concentration values of As, Pb, Zn, Cd, Co, Cu, V, W is studied. No significant correlations between these values have been revealed.

3, 6-daily cycles in the analyzed ranges can be connected to thyroid gland hormone activity and a 4-day cycle to glucocorticoid hormone activity. Circadian rhythms are either thought to be general or to be due to the unwillingness of people to be sent to hospital or call for a doctor on weekends. In case of myocardial infarction, when help is needed urgently, the latter factor does not work, and a one-week cycle in the spectrum, showing the time dependence of the number of calls, is displayed.

This fact and the weekend effect can be understood, based on the properties of hydrocortisone. Stress from production activity stimulates the supply of the hormone into the blood, which rushes to the heart and muscles. When the heart fails to cope with the rush of blood, a cardiac disease becomes more acute.

©2019. Japan Geoscience Union. All Right Reserved.

As the hydrocortisone level in the blood on weekends and holidays declines, the number of emergency calls for patients with cardiovascular diseases decreases.

Peaks in the daily emergency call dynamics distribution on week-days are interpreted to be due to air pollution with car gases at rush hours (9-10 a.m., 1-2 and 6-7 p.m.) and an approximately one-hour delay caused by progress in disease and the need to apply for a doctor.
The emergency call distributions analyzed are highly informative, showing the complete dynamic disease pattern of the urban population.

Keywords: diseases, emergency call, patient, diagnose, magnetic storms, contamination

IDENTIFYING “REGIMES” IN THE TIME SEQUENCES OF PROCESSES

*Boris Zalmanovich Belashev[1]

1. Karelian research center of Russian academy of science

A process is represented as a sequence of “regimes” when describing climatic variations and complex systems, detecting the malfunctioning of instruments and illegal interference in computer and hardware networks. For natural, technological and social processes such representation is comfortable to detect precursors of disastrous events.
The shifts of “regimes” in the sequences are commonly detected by checking statistical hypotheses by Student’s test and tests of non-parametric statistics when comparing the characteristics of the sequence at one or another site. Algorithms often use a priori information, work in unstable fashion over short intervals and at sequences boundaries, find it hard to recognize the shifts and trends of “regimes”.
Widespread R-algorithm [1] analyze data consecutively in a sliding window, operate with a small number of parameters and filter off “red” noise. The boundary regimes it detect may reflect distortions characteristic of the beginning and end of measurements.
The goal of the present study is to develop B-algorithm which automatically recognizes stable “regimes” in time data sequences.
The main stages of the algorithm are clusterization, comparison and optimization. Clusterization preliminary divides a normalized time sequence into “regimes”. While comparing the characteristics of the “regimes”, the division obtained is re-estimated. The final model of division is formed during optimization, which minimizes the variance of deviations from the trends of the “regimes” by varying the internal boundaries of the sites.
The algorithm, developed as a software in the MATLAB computer mathematics system, fulfils procedures automatically, decreases the amount of a priori data, increases operation speed and brings solutions closer to optima.
The operation of B- and R-algorithms is exemplified by the PDO (Pacific Decade Oscillation) sequence of mean January temperatures [2].
In both algorithms the number of “regimes” and their approximate positions coincide. The delay of part of R-“regimes” emphasize the sensitivity of B-algorithm to new “regimes”. Discrepancies are connected with the last “regime” identified by R- and B-algorithms on 2 and 15 members of sequence, respectively.
B- algorithm can operate with constant, linear and complex trends.
B- and R-algorithms, applied to the time sequences of river runoff, solar and seismic activity and the sequences of the annual rings of trees, have provided new information on the stages of processes.
The simplified schematic “regime” representation of a process reveals trends commonly obscured by the abundance of details. B- algorithm identifies stable “regimes” and recognizes the shifts and trends of “regimes”. The use of MATLAB functions increases the potential of the algorithm, admits the fulfilment of procedures by various methods, brings solutions closer to optimum solutions and ensures high operation speed. The ability of the algorithm to automatically process data makes it suitable for working with extensive data in various earth sciences.

Investigation of status and demand on public service of earthquake disaster mitigation in China

*Lina Dong[1], Weiping Lian[1], Weitao Chen[1]

1. Development Research Center, China Earthquake Administration

In order to make a comprehensive and systematic evaluation of the status and demands of public service of earthquake disaster mitigation, we launched an investigation with National Bureau of Statistics on the current situation of public service of earthquake disaster mitigation and the demands for it in 2018. The investigation was conducted in 31 provinces of China mainland using the Computer Assisted Telephone Interview(CATI) method and received 20078 valid samples in total.

The results indicate that 52.2% of the population have received the scientific knowledge education for earthquake disaster mitigation in Different levels. It shows that the public still possesses a high expectation of earthquake prediction and farmers have a low level of scientific knowledge of earthquake disaster mitigation. And TV, network, and the new media app such as wechat and weibo become the most important information channels for the public to obtain the earthquake related information. Furthermore, the degree of satisfaction evaluation of public service of earthquake disaster mitigation is marked on 81.22 points (the full mark is 100 points). And the most expectative services for the public are reconstruction, earthquake warning, and house earthquake resilience test. The results of the investigation have provided a scientific evidence for the government to provide better services of earthquake disaster mitigation and to make scientific knowledge popularization in a more scientific way.

Analysis of Eco-DRR and Ecological Services using InVEST at the Disaster Areas of Kumamoto Earthquake

*Minghui Tang[1], Naoko Fujita[1]

1. Kyushu University

When compared with other countries in a global point of view, Japan is a country with high number of natural calamities, significant causalities, economic loss and damages by earthquakes, typhoons, and eruption. The damage is especially big when a hazard comes right after another one.

Complex disaster refers to the occurrence of multiple disasters instead of one. Such as, in 2016, Kumamoto prefecture was hit by earthquakes with magnitude as large as 7 and within another 2 months, by heavy rain and the damage was tremendous.

There is a huge number of researches on the eco-application of proceeding in various countries and it is vitally important to verify their validity. Here, InVEST refers to the ArcGIS tool for the integrated review for ecological services and its compensation.

This research focuses on the analysis of the changes of the land cover as reflected in satellite pictures of the whole Kumamoto prefecture taken after the complex disaster, the earthquake in April 2016 and heavy rain in June 2016. Also, it’ s a review on the ecological services with the use of InVEST. A special focus is paid on the review of the soil retention and the quality changes of the eco-habitant as reflection of the disaster damage reduction measures.

In addition, there is an analysis on the change of land coverage on area-unit level with Mashiki-machi, the epicenter, as the target. Furthermore, projection was plotted for the ecological services implemented as the reconstruction plan.

Transformation as praxis: Exploring socially just and transdisciplinary pathways to sustainability in marginal environments (TAPESTRY)

*Nobuhito Ohte[1], Lyla Mehta[2], Synne Movik[3], Devanathan Parthasarathy[4]

1. Department of Social Informatics, Graduate School of Informatics, Kyoto University, 2. Institute of Development Studies at the University of Sussex, 3. Department of Urban and Regional Planning, Norwegian University of Life Sciences, 4. Department of Humanities and Social Sciences, Indian Institute of Technology

Climate change related uncertainties are the main threats to the sustainability of societies and their environments. To tackle these challenges, systemic transformations are required. Our project focuses on three cases of transformation in marginal environments in India and Bangladesh, and is concerned with: How transformation happens through bottom up processes in these sites; and how they can be scaled up and facilitate wider societal changes. Both require transdisciplinary co-production and the praxis of transformation which presupposes change in social arrangements and reconstruction by individuals. Our project addresses issues concerning governance, wellbeing, identity and quality of life in relation to transformations to sustainability in a lower middle income country (India) and a least developed country (Bangladesh). Our results should help inform processes that ultimately improve the quality of life in marginal environments, and build action and capacity among all partners.

Keywords: Transformation, Sustainability, Marginal environment, Transdisciplinary study, India, Bangladesh

Study for the Establishment of the Design for Disaster prevention through the survey of Recognition of tsunami disaster prevention from the viewpoint of green infrastructure in the coastal area of Kyushu-Pacific region.

*Shanshan Xu[1], Naoko Fujita[1], Minghui Tang[1]

1. Kyushu University

Considering the possibility of Nankai Trough large-scale earthquake predicted to occur in the nearest future, the issue of the tsunami in the coastal area of Kyushu-Pacific region is becoming extremely important. Efforts to utilize the various functions of the ecosystem internationally for the society creation are expanding in recent years, and even in the situation of toughening of the land in Japan, the initiative to incorporate Green Infrastructure (GI) which utilizes the disaster prevention and reduction functions of the natural ecosystem are being observed. Also, during the process of self-help/mutual assistance action and disaster reconstruction at the time of disaster, attention is paid as regional ties are affected, which are being considered as Social capital (SC).

The purpose of this study is to clarify the actual situation of tsunami disaster prevention of Nankai Trough earthquake based on the viewpoint of GI. We conducted a questionnaire survey on tsunami disaster prevention and GI at local governments and local communities. After analyzing the questionnaire, we analyzed the needs of the self-governing president's disaster prevention measures, the problems of the area, and the deviation of the improved situation of municipalities' disaster prevention measures. A correlation analysis was conducted to grasp the relationship between the consciousness concerning GI utilization, the strength of regional linkage SC and the recognition of evacuation.

1. Misalignment between demand and maintenance situation desired by the region

Policy regarding the issue of disaster helpers was extracted as a gap between needs and maintenance situation. Regarding the needs of the soft pattern in disaster prevention, a lot of measures were taken by disaster support supporters, however as it comes from the municipality questionnaire results, the measures related to the introduction of the barrier-free system and evacuation action supporters were introduced only partially. Further improvement is necessary for welfare evacuation sites, measures against supporters requiring evacuation actions, barrier-free formation.

2. SC regarded from the viewpoint of the relationship between intentions to utilize GI and recognition on disaster.

©2019. Japan Geoscience Union. All Right Reserved.

Especially, the correlation coefficient was 0.701 between No.7 and No.6. This shows that those who responded that disaster can happen among residents can respond that regional ties are stronger. For items with a high correlation coefficient between No.3 and No.8, the correlation became 0.437. This means the respondents who answered that evacuation is possible for all area inhabitants including elderly people in case of disaster (flooding, earthquakes, and tsunami) are able to use local well water and spring water in the event of a disaster.

Between No.2 and No.4, the correlation coefficient became 3.380. This is because those who respond that they think they can fully utilize the resources of the area (resources such as firewood, foods that can be harvested in mountains) even in the event of disasters will escape by utilizing the nearby natural landforms such as plateaus and mountains for tsunami evacuation. Between No.2 and No.8, the correlation coefficient became 0.351. This is because it shows those who responded that they thought that they could escape by utilizing nearby plateau and mountains such as mountains during the tsunami evacuation, even if disasters (flood, earthquake, tsunami) occurred, everyone including the elderly in the area evacuated. Between No.2 and No.6, the correlation coefficient became 0.343. This indicates that those who responded that they believe that they can escape by utilizing nearby plateaus and mountains when evacuating the tsunami think that the connection of the community people is strong. Between No.3 and No.6, the correlation coefficient became 0.287. This indicates that those who responded as they thought they could use local well water and spring water at the time of a disaster replied that they think that the regional connection is stronger.

Based on the above, we clarified the SC from the viewpoint of the gap between the request and the maintenance situation the region desires and the relationship between the intention to utilize GI and the perception of disaster. The fact that utilization of natural resources such as well water and spring water and understanding that natural topography can be utilized for evacuation leads to a positive feeling making people believe it is possible for everyone to evacuate even if the tsunami comes, can be suggested from this study.

Design for Green Infrastructure: Analysis of Landscape change in the Kumamoto earthquake area

*Naoko Fujita[1]

1. Kyushu University

The concept of “Green Infrastructure” and “Eco-DRR” is developed in Europe and North America lately, and it started to spread around in Japan after the Tohoku earthquake and tsunami in 2011. Landscape ecology is parallel with this conceptually, as well as in terms of spatial scale. Its successful focused researches and social implementation are becoming pervasive.

The new concept is to solve various problems by local resources and pearls of wisdom, it connects local communities to the world while it’s mainly led by front liners and researchers in engineering and ecological fields that little attention is paid to the aspects of arts and designs. It’s still not well-penetrated despite the validity and functions of the concept are well verified. Thus, it’s vitally important to work on the insufficient.

The purpose of this research is to analyze the reconstruction plan prepared by the affected municipalities of the Kumamoto earthquake and compare the landscape change read from the plan and the actual landscape change actually occurred and make clear how the cities and nature have changed during the reconstruction process.

In this research, we firstly gathered and analyzed the earthquake reconstruction plans created by each local government for all 45 municipalities in Kumamoto prefecture. In this analysis, while studying each municipal original plan, we primarily focused on the background, features, and landscape references of the plan formulation. During this analysis, we grasped the relations between the reconstruction plan and the landscape change, and also clarified what exactly each local government emphasizes independently. As the next step, basing on the field survey, we analyzed the actual state of the landscape changes described in the plan. As a method, we took the photographs at places where the plans adopted by each municipality in Kumamoto prefecture were scheduled or executed, and after recording the current situation and the surrounding landscape, we made a comparison with the photographs taken at the same place in the past. By doing this, we revealed what kind of changes have occurred between the past and the present due to the disaster, and how they affected the surrounding landscape.

Among the 45 municipalities in downtown Kumamoto Prefecture, we found that earthquake reconstruction plan was formulated in 16 municipalities, and 5 municipalities planned to formulate. There were references that "consideration of the landscape when promoting housing improvement and infrastructure development" and "to consider the landscape from the tourism viewpoint". Also, there were plans to utilize the process of reconstruction itself as a resource for tourist attraction. Furthermore, as a result of analyzing the individual plans described in the reconstruction plan, the reference to landscape,

©2019. Japan Geoscience Union. All Right Reserved.

reference to the prediction of landscape change, reference to landscape protection exists in all 16 cities, towns, and villages. Totally 117 relevant plans have been found. Although many of them were intended to cope with the damage at the time of the disaster, there were several plans originally adopted by the local governments to make necessary improvements of the problems they had from the past by conducting disaster recovery.

The field survey was conducted for 16 municipalities in total in Kumamoto Prefecture. One year has passed since the earthquake disaster, and recovery works progressed in a wide range in Kumamoto Prefecture. In the recovery sites in various places, a secondary change of the landscape, which caused the recovery activity aimed at improving the convenience of life and safety, has already been taking place. Moreover, recovery works progressed also in Kumamoto castle which is also cultural asset and tourist attraction, as well as the station and the government office which are the center of town. As a result, we could confirm the change of landscape.

In this research, through the analysis of the reconstruction plan created by the municipalities affected by the Kumamoto earthquake and the field survey, from the viewpoint of Green Infrastructure, we could make clear the process of the landscape change occurred during the process of recovery/reconstruction of the living base, the tourist resources, the natural environment in the affected areas and its influence respectively. Although few local governments have formulated landscape-friendly reconstruction plans, to gain medium- and long-term benefits, we should make landscape-friendly reconstructions from the original planning stage. This is because it is the factor determining the richness of living base, tourism resources, and natural environment.

[H-DS10] Natural hazards impacts on human society, economics and technological systems

convener:ELENA PETROVA(Lomonosov Moscow State University, Faculty of Geography), Hajime Matsushima(Research Faculty of Agriculture, Hokkaido University), Chairperson:Hajime Matsushima, Elena Petrova

The last decade set a record for the number and scale of natural disasters and demonstrates high vulnerability of human society and technosphere to their impacts. The most serious consequences have the so-called natural-technological disasters in which natural hazards trigger accidents at technology and infrastructure such as nuclear power and chemical plants, oil refineries and pipelines, power supply systems, buildings, and roads. A distinctive feature of natural-technological events, such as of the 2011 Tohoku earthquake, is their multi-hazard and synergistic nature, which creates cascading impacts, resulting in simultaneous occurrences of myriad catastrophes. The main goal of this multidisciplinary session is to summarize case studies of relationships between natural hazards and technological disasters, their social and economic consequences; and to encourage a discussion about tools and methods to prevent disasters and to minimize their consequences, disaster reconstruction, and tourism for reconstruction, Eco-DRR, and green infrastructure.

Seasonal variations of atmospheric hazard impacts on infrastructure

*ELENA PETROVA[1]

1. Lomonosov Moscow State University, Faculty of Geography

Infrastructure facilities consist of power, heat and water supply systems, communication lines, transport infrastructure including roads and bridges, railways, airports, oil and gas pipelines, etc. Above-ground and ground infrastructure facilities are most affected by impacts of various natural hazards, especially those of atmospheric origin. More than 90% of all natural-technological accidents in infrastructure facilities of Russia are triggered by atmospheric hazards such as strong winds, heavy snowfalls and rainfalls, snowdrifts, torrents, thunderstorms and lightning, hailstorms, hard frost, icing, etc. Natural factors cause about 70 percent of “blackouts”, more than 10 percent of accidents at heat and water supply systems as well as water accidents; about four percent of air crashes, automobile and railway accidents, and about two percent of pipeline ruptures. Various atmospheric hazards can also cause long delays in automobile, railway and air transportation of passengers and goods. The majorities of these events are triggered by windstorms and hurricanes (37 percent), snowfalls and snowstorms (27 percent), rainfalls (16 percent), hard frost and icing (12 percent), thunderstorms and lightning (nearly 4 percent). All of these weather conditions are subject to seasonal variations. During the cold season, there are much more weather events influencing the growth in the number of accidents than in the warm season. The author created a database of natural-technological accidents occurring in Russia, including those in infrastructure facilities. More than 18.5 thousands events are registered in the database between 1991 and 2018. The collected information allows analyzing the main causes and triggers of accidents, their distribution within area of Russia, temporal variations, and revealing “weak spots” to cope with. The risk of natural-technological accidents in infrastructure facilities was assessed for Russian federal regions. The Far Eastern, South and North-Western parts of Russia are at the most risk of atmospheric hazard impacts. The risk of natural-technological accidents is highest in Sakhalin region, Krasnodarsky and Primorsky territories.

Assessment of water supply function and measures for chemical release accidents triggered by major earthquakes

*Lisa Ito[1], Toyohiko Nakakubo[2], Naoya Kojima[1], Akihiro Tokai[1]

1. Graduate School of Engineering, Osaka University, 2. Faculty of Core Research, Ochanomizu University

In recent years, natural disasters called Natech (Natural hazard triggered technological accident) has become a big issue around Europe. Also, in Japan, Natech becomes social issues by the recent major earthquake such as the Great East Japan Earthquake, in which highly concentrated toxic chemical substances was released due to tsunami or fire. Such an accident causes risks related to serious environmental contamination. However, chemical behaviors in the environments and degrees of the impact on the infrastructure after the accident have not been clarified especially under the unstable situation. In this research, we aimed i) to clarify the influence of toxic chemicals released into the environment due to the major earthquake and ii) to evaluate the efficiency of the countermeasure option, focusing on unintended releases of chemicals from manufacturing or on-site storage facilities to water. As the research area, we selected Yodo River in Osaka, which is an essential water source that supports the infrastructure of Kansai area. On the other hand, there are growing concerns for the risks caused by seismic motion and liquefaction as there are many chemical factories with drainage pouring into Yodo River.

We selected 38 chemical substances with high risk such as acrylonitrile in addition to toluene and xylene that are used in large quantities. These chemicals are also included in Pollutant Release and Transfer Register (PRTR) which make it possible to grasp more actual discharge status. Among PRTR, these 38 substances have especially high toxicity for human (LD_{50} ≦300 mg/kg) (UN, 2015), and have difficulty to remove even in the water treatment process because of its high solubility in water (≧10,000 mg/L) and hydrophilic properties (octanol/water partition coefficients (Log Kow)≦ 1.5) (Ito et al., 2014). The prediction occurrence of chemical release accident caused by the earthquake was calculated as the expected value (Y) based on the statistical data in the world (Santella et al., 2011). Probability (P_n) of occurrence of the accident in Yodo basin area caused by Hanaore fault was calculated by the Poisson distribution. Subsequently, we calculated the maximum expected concentration of chemical substances at the water-intake points in the river after the accident using the hydrology-exposure analysis model (AIST-SHANEL ver. 3)(AIST, 2015). The accident date on the model was set for winter season since the streamflow is relatively low throughout the year from a factory which has the largest storage of target chemicals. Emergency shut-off valve was adopted as a countermeasure in this scenario. As judgement criteria for suspension of water supply, we evaluated subacute toxicity as a criterion ($JC_i^{subacute}$).

As a result of the model calculation, the concentration of acrylonitrile in the purified water was calculated to be 2.19×10^{-1} mg/L for a maximum. In this case, water supply system would stop, since it exceeds $JC_i^{subacute}$ ($=6.25\times10^{-2}$ mg/L) based on the no observable adverse effect level (NOAEL) (Ministry of the Environment, 2003) obtained from rats. Furthermore, as it exceeds the predicted no effect concentration (PNEC) of aquatic organisms, 7.6×10^{-3} mg/L (Ministry of the Environment, 2003), intake of the water would also stop. On the other hand, if the Emergency shut-off valve works properly, the outflow rate is 2% or less of the storage tank, calculating from the length of pipe and tube diameter outside the valve (Osaka, 2013). In that condition, the concentration of acrylonitrile in the river is less than $JC_i^{subacute}$ and PNEC, which suggested that outage of water supply function can be avoided. According to these analyses, we found that an emergency shut-off valve is a useful option as a countermeasure for an earthquake. Furthermore, it would be possible to implement more quick and proper responses applying the method of this study, even in the case that the released chemicals are not included in the criteria for tap water.

Development of disaster risk management plan of a thermal power plant: Spearheading the paradigm shift from disaster management to disaster risk management of NATECH in India

*Repaul Kanji[1], Madan Mohan Rout[2], Ankur Srivastava[3]

1. Gujarat Institute of Disaster Management, Gandhinagar, Gujarat, India, 2. Institute of Seismological Research, Gandhinagar, India, 3. Indian Institute of Technology Delhi, India

With global phenomenon like climate change looming large on the horizon, occurrences of extreme events are expected to rise eventually. Rapid urbanisation and the powerful want of globalisation does little to control the exposure of our ‘assets’ to such events, thereby increasing the disaster risks. The quantum of risk rises exponentially if the exposed asset is a critical infrastructure like a nuclear power plant or a thermal power plant which might lead to ‘natural hazard triggered technological disasters’ like that of Fukushima. The damage and loss in such cases is borne not only by the infrastructure in question but also by the community in its immediate surrounding. Management of disasters, which has long been the usual trend, has a very little effectiveness in such tragic scenarios, thus rather than managing disasters, one should manage the disaster risks. Even the Sendai Framework for Disaster Risk Reduction (SFDRR) talks about reduction of the acceptable risks and management of the residual risks. However, for all this to be implemented, one needs to understand and anticipate risks, which is way more than the current practice of risk identification.

The researchers, when provided with the opportunity to develop a disaster management plan for a thermal power plant in India, took cognisance of the priorities of SFDRR embarked on a strategy of disaster risk management and disaster risk reduction rather than mere disaster management. This study elaborates on the strategy adopted during the development of the plan. The first step was to conduct field survey and collect primary geo-technical and meteorological data. Content analysis of hazard maps were done to identify the possible hazards which can affect the critical infrastructure. Earthquake, cyclone and technological hazards were identified as the main probable hazards. The methodology developed by Cornell (1968) for Probabilistic Seismic Hazard Assessment (PSHA) was applied for the estimation of seismic hazard for 10% and 2% probability of exceedence in 50 years. In this method, seismogenic zones were delineated and then seismicity parameters were estimated using the decluttered earthquake catalog and finally the ground motion was estimated using different ground motion prediction equations (GMPE). In addition to this, probable intensities of earthquakes were evaluated according to the seismic zonation and the corresponding grade of damage was estimated, taking into account the typology of building construction. To elucidate assessment of cyclonic winds and rainfall over the critical infrastructure an experiment was designed in which 9 major cyclonic systems occurring in the region in last ten years were considered. These cyclonic events were numerically simulated around the geographical location of the infrastructure. Weather Research Forecasting (WRF) model was used to carry out the simulations. As a result, the maximum windspeed and the maximum rainfall was obtained. In addition to these natural hazards, content analysis was done to enumerate all the possible technological hazards and Maximum Credible Accident Analysis (MCAA) was performed. These steps were integral in assessing the hazards and the outputs of these simulations were fed as inputs of the Quick Risk Estimation (QRE) tool developed by UNISDR. Based on the outputs of the QRE tool, the disaster risk management plan was developed.

This particular study tries to identify and assess the hazards, vulnerabilities and capacities and estimates

©2019. Japan Geoscience Union. All Right Reserved.

the risks which is then used to develop risk management plans. Offcourse, management of extreme events through institutionalisation of Incident Response System (IRS) is a part of the plan but it forms only a part of it. Thus, in a way, this plan marks the first step taken towards disaster risk management of critical infrastructures in India; a step towards the management of risks of technological disasters due to natural hazards.

Applying Transfer Learning to Improve Machine Learning Impact Model at Extremes

*Peter Lawrence Watson[1], Manos Anagnostou[1], David Wanik[1]

1. University of Connecticut

Machine learning can be useful for modeling the impacts of natural hazards on infrastructural systems. By relying on empirical observations, these methods lack the prohibitive complexity of large-scale physical models, but can also operate in high-dimensional spaces: where a large number factors contribute to the observed damages to the system. However, modeling extreme events can be challenging with machine learning. Unlike parametric models, the dynamic range of these models is constrained to the training data, and the training data from extreme events is as rare as the events themselves. However, transfer learning, where a model trained on data from one system is retrained for another system, may enable the use of additional training data to improve the prediction of extreme events. This would allow for more examples of extreme events from more places to be included in the training data, and should improve the performance of machine learning based impact models at the extremes. In this study, we apply transfer learning methods to the University of Connecticut's Outage Prediction Model (OPM), a machine-learning based electrical power outage model. The OPM has a large domain that spans three states in the US: Connecticut, Massachusetts, and New Hampshire, and there is much more training data available for Connecticut than the other states. We investigate the effects of applying this additional data on the accuracy and dynamic range of models for the other states using transfer learning methods, in an effort to better predict the impacts of the most extreme weather events.

rescEU, the European Union Civil Protection System UCPM and the future role of Geosciences in natural disaster reduction

*Andreas Nikolaus Kueppers[1]

1. GFZ - Deutsches Geoforschungszentrum - Helmholtz Zentrum Potsdam

On February 12, 2019, the European Parliament in Strassbourg adopted the decision* for a substantial enhancement of the Union Civil Protection Mechanism which includes the 28 EU Member States plus a major number of affiliated nations. The actual legislational move had been directly instigated by the very serious impact of large wildfires in Europe with many fatalities in Portugal, Greece, Spain, Sweden, among others. It became clear in a dramatic way that sufficient technical resources for fire fighting, in particular aircraft, were neither available on a national nor an international base. The new and financially strengthened Mechanism embraces a large number of disaster types where geology based disasters like earthquakes, tsunami, volcanic eruptions including volcanic ash clouds and gravitational movements are among the most prominent. Expressis verbis, the decision calls for substantial foresight for the early discovery of future disasters which even may be not known to us today. While this without doubt means a great chance for broad geosciences to actively contribute from the start, the integration of more nations into the system and a possible globalisation constitute next stage challenges.

*Official text is expected to be published by the European Commission in due time.

The Probability of Satellite Anomalies by a Disastrous Solar Flare

*Daikichi SEKI[1,2,3]

1. Graduate School of Advanced Integrated Studies in Human Survivability, Kyoto University, 2. Centre for the Study of Existential Risk, University of Cambridge, 3. Astronomical Observatory, Kyoto University

The Sun has a potential risk of various socioeconomic impacts on our human society. It often produces various eruptive phenomena such as a solar flare and a coronal mass ejection, which sometimes bring adverse effect to us like satellite anomalies, radiation exposure, and huge blackouts. For example, in 2003 October 28, X17-class flares (roughly once-in-10-year level severity) occurred and more than 60 % of NASA scientific satellites were affected.

Similar to other terrestrial disasters like an earthquake, the solar eruptive phenomena also follow the power-law distribution between frequency and severity, and low-frequency-high-impact solar disaster could also happen. Recently, it was revealed that a “super-flare”, a flare whose energy is 100 times larger than X10-class flare, can occur once in 1000 years from statistical and theoretical points of view [Maehara et al. 2012, Shibayama et al. 2013, Shibata et al. 2013].

However, though there are many assessment studies of “moderate” solar eruptive phenomena, the assessment of “disastrous” solar eruptive phenomena like a super-flare has been little conducted. For this reason, this research aims to evaluate the frequency (or probability) and the possible socioeconomic damage of a super-flare, especially focusing on satellite anomalies.

Using various data sets about satellites, their anomalies, flares, and plasma environment around the Earth*, 154 X-class flare events with 9 relating parameters (peak flux of X-ray (0.1–0.8 nm), integral fluxes of electron (> 2 MeV) and of proton (> 1, 5, 10, 30, 50, 60, 100 MeV)) were selected. To avoid multi-collinearity, Ridge regression model was used to compute the regression to the satellite anomaly rate (1/satellite/event). Also 10-fold cross validation was performed. After obtaining the model, the possible plasma parameters in case of X1000-class flare assumed by Takahashi et al. 2016 were input into the model.

As a result, we obtained the model with its coefficient of determination of 0.607 and its Pearson correlation coefficients of 0.691±0.212 (for 100 times randomly chosen dataset). Assuming that electron and proton follow the same scaling law, with applying scaling law by Takahashi et al. 2016, 0.573 satellite anomaly rate (57.3% per satellite per event) was obtained. It should be noted that the scaling law provided by Takahashi et al. 2016 is upper limit, so in the actual case, rate should be lower. The validity of assumption, the comparison between this research and others (Pilipenko et al. 2006; Iucci et al. 2005; Odenwald et al, 2006, 2007), and the possible socioeconomic loss will be also discussed.

Discussion

Management and Maintenance for Disaster prevention park in Tokyo Metropolitan Government

*Masayshi Kikuchi[1]

1. Tokyo Metropolitan Park Association

Tokyo has experienced great damage by many earthquakes since ancient times, has a history that has repeatedly been destroyed and reconstructed. Every time Tokyo suffered an earthquake disaster, the park has been required to have new functions. Every time Tokyo suffered an earthquake disaster, the park has been required to have new functions. The first is a role as evacuation site and the second is a role as Base for Large-scald and Life-saving Operations. Currently, there are 82 parks in metropolitan parks, but the 21 major parks are not only functions as evacuation places but also Base for Large-scald and Life-saving Operations when disasters such as large earthquakes occur in the capital Tokyo Function. We name them as disaster prevention parks and manage them. First, the function as an evacuation site is a function that all parks have and is to secure places where many citizens can escape as safe places in the event of a disaster. To that end, there are three distinctive park facilities. One is a "solar-type park light" so that you can check the location from anywhere even at the time of a power outage. The second type is "manhole type disaster prevention toilet" directly connected to the drain pipe so that many evacuees can use it even if they temporarily stay in the park. The third one is a normal bench in peacetime, but in the event of a disaster it is a "kamado bench" that can be used as a "kettle" that can be boiled. Next, the function as Base for Large-scald and Life-saving Operations is a function that serves as a helicopter departure station or a large emergency vehicle collecting base as an activity base of relief units, medical troops, etc. in the afflicted area. Therefore, although a park having a large-scale square is designated as a large-scale rescue and relief activity base, the characteristic maintenance is to expand and strengthen the school path so that large vehicles can pass, securing helicopter take-off and landing spots, etc. is there. What you need to fully demonstrate these functions is day-to-day disaster prevention drills. In the park, including citizens, police, fire fighting companies, companies, etc., training is conducted several times a year "Manhole type disaster prevention toilet" and "Kamado bench", and helicopter takeoff and landing training etc. are also carried out.

Rebuilding Tourism after the Great East Japan Earthquake and Examining Post-Disaster Tourism in Kamaishi City

*Satoshi Sasaki[1], Kiyotatsu Yamamoto[2], Kaoruko Sasaki[3]

1. Iwate University, 2. The University of Tokyo, 3. Hokkaido University

1. Introduction

Natural hazards can have a devastating effect on tourism. In the case of the Great East Japan Earthquake (GEJE) of 2011, the tsunami caused damage to not only human lives but also to critical infrastructures in coastal areas in the Tohoku region. Tourist attractions and facilities were also damaged by the tsunami, and people who lived in the metropolitan and Kinki regions understood that they should avoid traveling to the Tohoku region (Yamamoto, 2013). Thus, a decrease in the number of visitors to the tsunami-hit area was reported in the Tohoku region immediately following the disaster (Igarashi et al., 2017). Fortunately, after suffering a drop in the number of tourists, the disaster area is experiencing a trend in recovery these days. “Disaster tourism”—defined as the practice of visiting natural or man-made environmental disaster sites (Amujo et al., 2012)—has succeeded in bringing visitors to the disaster area. However, eight years have already passed since the disaster, and the time lapse should be taken into account for promoting post-disaster tourism (Sasaki et al., 2018). From this viewpoint, the purposes of this study were established as follows: 1) to clarify the current situation of tourism after the GEJE of 2011 and 2) to examine post-disaster tourism in the Tohoku region.

2. Methods

The case study area for this study was Kamaishi City, which is located in Iwate Prefecture in northeast Japan; it was hit by the tsunami in 2011 and more than 1,000 lives were lost to the disaster. Thanks to disaster prevention efforts, however, almost all of the nearly 3,000 elementary and junior high school students miraculously survived (i.e., the “Miracle of Kamaishi”). Accordingly, many people have been infused with hope. To grasp the awareness and behaviors of visitors to the city, two post-recall questionnaires were distributed to Japanese people over age 17 from July to September in 2018. One was disseminated to visitors who participated in the guided tours conducted by storytellers with the Kamaishi Volunteer Guide Association. The other was given to tourists at the JR Kamaishi Station, Kamaishi Sennin-toge roadside rest area, and Hashino Iron Mining and Smelting Site (listed as a UNESCO World Heritage Site). The survey focused on the following aspects: (1) visitor attributes (e.g., age, gender), (2) characteristics of visits (e.g., number of visits, group size, objectives of trips, places visited), (3) familiarity with guided tours (e.g., expectations, sources of information), (4) changes in awareness after a visit, (5) appreciation for disaster lore, and (6) the satisfaction and intention to revisit.

3. Results and Conclusion

In total, 478 people (guided: N = 155, non-guided: N = 323) participated in the survey, representing a response rate of 22%. As a result, the largest proportion of respondents included people over age 59 (47%); further, the total number was almost equally divided between the two genders (male: 51%, female: 47%). The most frequent group size of visitors was two or three people (43%); moreover, approximately 50% of visitors used private cars. The most common trip type was the day trip (46%), and the majority of visitors were not there for the first time (32%). The most commonly mentioned trip objectives were engaging in tourism (46%), visiting the disaster area (29%), and eating delicious food (25%). Additionally, the degree to which visitors intended to join a tour guided by a storyteller was high (77%), with the most common contents of interest being stories recounted from the time of the disaster (77%) and lessons from

©2019. Japan Geoscience Union. All Right Reserved.

the disaster (68%). A few people acknowledged enjoying the storytelling tour locally (12%) and on the Web (6%). On the whole, the GEJE experience was regarded as worth handing down to future generations and sharing with the world (very valuable: 82%, somewhat valuable: 11%). Compared to non-guided visitors, guided visitors had a greater sense of being present during the disaster ($P < .01$, T-test) and were encouraged to change their attitudes toward disasters ($P < .01$, based on a single regression analysis). In conclusion, Kamaishi City still functions as a disaster tourism site but it is thought that efforts to increase the city’ s appeal in the future are necessary.

Population Change in Ishinomaki City, Miyagi Prefecture, with a Focus on the Area around the Earthquake Ruins

*Ryo Nishisaka[1], Katsunori Furuya[1]

1. Chiba University

1. Introduction

Eight years have passed since the Great East Japan Earthquake of 2011. There is a movement to preserve buildings and structures affected by the earthquake and resulting tsunami as earthquake ruins and to utilize them for storytelling and disaster prevention. In the Tohoku region, where the birthrate is declining and the population is aging, sustainable management of the earthquake ruins will be an issue.

So far, the bereaved families and storytellers (called the kataribe) who live around the earthquake ruins of Ishinomaki are known to have been working on the management of flowers from visitors, cleaning up the earthquake ruins, and improving the flowerbeds. At the same time, residents around the earthquake ruins might be affected by the increase in the number of visitors when the earthquake ruins are opened to the public, so consideration of them is necessary. Therefore, this paper aims to clarify the population change around the former Kadonowaki Elementary School and the former Okawa Elementary School, which are the two earthquake ruins in Ishinomaki.

2. Methods

We investigated mesh population data of 500-meter mesh areas from “Population Census,” published by the Statistics Bureau, Ministry of Internal Affairs and Communications, Japan, and analyzed the population change of Ishinomaki between 2010, before the earthquake, and 2015, after the earthquake, using Geographic Information Systems (GIS). We extracted the two earthquake ruins and created buffers of 2,000 meters. We considered the population change within 2,000 meters of the two earthquake ruins as well as the situation regarding Ishinomaki’s recovery.

3. Results

As a general overview of the population change in the whole city of Ishinomaki, we can confirm a large population decline in coastal areas that were reached by the tsunami, such as Kadonowaki-*cho*. In addition, large-scale temporary housing was constructed and a population migration to the inland area was confirmed.

Although the overall population decline was significant within 2,000 meters of the former Kadonowaki Elementary School, a population increase was confirmed in a small area near the temporary housing in Hiyorigaoka.

Even within 2,000 meters of the former Okawa Elementary School, the population was decreasing as a

©2019. Japan Geoscience Union. All Right Reserved.

whole, but we could confirm an area where the population increased slightly. There were no large temporary housing structures around the former Okawa Elementary School, and the population did not accumulate.

4. Discussion

In Ishinomaki, after the Great East Japan Earthquake, the population of the coastal area drastically decreased, and population increase in the inland area was confirmed. Both the former Kadonowaki Elementary School and the former Okawa Elementary School had a drastic decrease in population within 2,000 meters. However, the existence of areas where the population was increasing even within 2,000 meters was confirmed. It seems that the presence of temporary housing greatly influenced the change in population.

The population changes around both earthquake ruins were large, so it is thought that there were many cases in which bereaved families and residents involved in the elementary schools had relocated. Particularly concerning the former Okawa Elementary School, there is a possibility that there was a large-scale relocation to the southwestern part of the city, where population increase advanced. In Ishinomaki, the situation with tenancy in temporary housing continues to change even after 2015, and now temporary housing is being demolished and residents are moving into public housing. In the future, it is necessary to track the population changes and consider how to support the activities in the earthquake ruins by residents who cannot easily get there.

The Way of Seeing the Atomic Bomb Dome and the Relationship with Viewers' Attributes

*yasuhara arisa[1], Kiyotatsu Yamamoto[1], Akio Shimomura[1]

1. Graduate School of Agricultural and Life Sciences, The University of Tokyo

1. Introduction

The Atomic Bomb Dome (ABD) is one of the major atomic bombing sites in Hiroshima. In 1996, it was registered as an UNESCO World Heritage Site under the name "Hiroshima Peace Memorial," and its lasting preservation was secured. However, like other world heritage sites, its maintenance and management were not easy. Hiroshima City, taking charge of the management, established "Preservation and maintenance policies of peace memorial museums (2006)," in which the role of the ABD was specified as "The witness of history who suffered heavy damage by an atomic bomb" and "The symbol of hope for nuclear weapon extinction and lasting peace." This policy considered the mindset of the people who wished for peace, tried to preserve the history, and achieve World heritage-registration. This description meant regarding the ABD as the memory of Hiroshima. In other words, it was aimed to include not only the Dome's visual image (the visual aspect) but also the history of Hiroshima and people who had an emotional connection with the town (the semantic aspect), and to preserve both. To embody the idea in a preservation plan, it is necessary to clarify the history of Hiroshima as the background of the ABD and the mindset of people. This study analyzes the "way of seeing" to reveal "how" and "by whom" the ABD has been seen until today, and to understand the memory of Hiroshima.
In light of the above issues and viewpoints, the objectives of this study are 1) to classify the way of seeing the dome and 2) to address the meaning of the relationship between the landscape types and viewers' attributes.

2. Methods

Photographs were collected to understand how ABD is seen by a variety of viewers. Approximately 561 photographs in which the ABD appeared were found in 52 books at the Hiroshima City Central Library. These were selected as materials for analysis, excluding those wherein who took the photograph and when it was taken could not be identified. Time, locations, and photographers were identified, and the constituent elements of each scene were counted to understand the characteristics of the photographs. The attributes of photographing through identification are as follows: (1) time: year of photographing; (2) locations: 6 areas of photographing; and (3) photographers: 4 categories extracted by combining "people who visited Hiroshima," "people who were born or lived in Hiroshima," "photographers," and "amateur photographers." After this process, the sceneries were divided into typical patterns by using quantification method of the third type and cluster analysis. Finally, the relationship between the landscape types and the photographers' attributes was analyzed.

3. Results and Conclusion

The ways of seeing were classified into 6 types, which were related to photographers' attributes. These were: I) landscape hit by atomic bomb, II) landscape with low buildings, III) landscape viewed through the Hiroshima Peace Memorial Monument, IV) landscape of the ABD, V) landscape with plants, and VI) landscape with high buildings. Moreover, it was revealed that landscape I) was photographed more by "people who visited Hiroshima." Likewise, II), III), and IV) were related to "photographers who were born or lived in Hiroshima," "people who were born or lived in Hiroshima," and "photographers who visited Hiroshima," respectively. Additionally, the elements included in the photographs, the main period

©2019. Japan Geoscience Union. All Right Reserved.

of photographing, and the viewpoint of photographing differ according to the landscape types. In conclusion, it was suggested that the meaning of Hiroshima’ s memory as understood by the photographers was diverse and it was necessary to provide the visitors to ABD with various landscape experiences related to the ways of seeing the ABD.

Flood Disaster Risk Analysis at Ratnapura in Sri Lanka

*Tsuchida Ryo[1], Kaoru Takara[1]

1. Graduate School of Advanced Integrated Studies in Human Survivability, Kyoto University

This paper describes disaster risk at a flood-prone area in southwest Sri Lanka where a severe flood disaster took place in May 2017. First, the author conducted frequency analysis at Ratunapura by using a 125-year annual maximum rainfall series to evaluate the probability of the 2017 event. Second, land use change was also detected by Landsat-8 images before and after the flood. Visiting Ratunapura a couple of times, the author interviewed people and the local government to understand the situation of the flood disaster and how they coped with the flood by utilizing a framework based on disaster ethnography. Results obtained from the interview survey showed that the residents, who acted on their own experience and knowledge, could not respond to disasters when enormous floods occurred, and the flood disaster brought them bad influences in many ways. In addition, external organizations including governments, UN agencies and Non Profits Organizations for disaster relief could not provide adequate supports to reflect the needs of residents worth covering vulnerabilities. Moreover, this survey found that the government’s assessment of the house and livelihood damage was delayed. Also, distribution of allowance and supplementary from the government was delayed. The research results in this paper would be useful for flood disaster risk reduction and for understanding recovery proesses in Sri Lanka.

Functions of Real-time Tsunami Inundation Forecast System Using S-net Pressure Data

*Wataru Suzuki[1], Naotaka YAMAMOTO CHIKASADA[1], Takayuki Miyoshi[1], Shin Aoi[1]

1. National Research Institute for Earth Science and Disaster Resilience

We have developed real-time tsunami inundation forecast system using S-net ocean bottom pressure data (Aoi et al., 2019, JDR). The forecast methodology of the system is mainly based on the multi-index method (Yamamoto et al., 2016, EPS) coupled with tsunami scenario bank (Chikasada et al., 2019, Technical Note NIED). In addition, the system has many functions to perform appropriate forecast considering a nature of the observed S-net pressure data, additional seismological data, regression targeted for specific region and alerting for tsunami without search for tsunami scenario bank. In this presentation, we introduce the developed forecast system focusing on these various functions.

The system has a redundancy and robustness in processing the observed S-net data by receiving the data from dual receiver with quality check. The pressure data are corrected for offset, band-pass filtered to extract the tsunami components. It was found that high waves due to typhoon or storm cause noises even in the ocean bottom pressure data and scenarios are selected by multi-index method. Therefore, the system does not make forecast information if no stations have larger amplitude than criterion value.

Forecast information, i.e., coastal tsunami heights and inundation depth distribution, is produced from the selected scenarios from the multi-index method by taking the maximum and average value of the selected scenarios. The scenario with the largest variance reduction between the observed and scenario data can be forecast information too. Standard deviation can be used to present the scattering of the forecast. As additional information, the system imposes the consistency with the hypocenter information on the selected scenarios by the multi-index method. This works well for the tsunamis generated at the edge or outside of S-net region. Moreover, most possible tsunami scenario for specific region can be derived from the selected scenarios in comparison with the forecast tsunami inundation depth at representative points based on neural network regression. The system also has functions to alert the tsunami by detecting the large pressure changes as well as using the tsunami warnings issued by the Japan Meteorological Agency. Detailed information based on the tsunami simulation based on 10-m mesh topography model is output for Kujukuri-Sotobo region of Chiba prefecture and rough and limited information is output from Ibaraki prefecture to Pacific coast of Hokkaido.

Improvement of Real-time Tsunami Forecast System for Outer-rise Earthquake

*Naotaka YAMAMOTO CHIKASADA[1], Toshitaka Baba[2]

1. NIED, 2. Tokushima University

The outer-rise earthquakes often induce the behavior of the unusual tsunamis. For example, it induces an abnormally larger tsunami than expected from its seismic ground motion, called tsunami earthquake and/or contains short wavelength components produced by sea floor displacements caused by shallow depth fault slip. Additionally, the depressed wave usually arrives preceding the first elevated wave for the normal fault earthquake tsunamis. National Research Institute for Earth Science and Disaster Resilience (NIED) has developed real-time tsunami inundation forecasting method using real-time ocean bottom pressure data taken by the dense offshore observation network such as the Seafloor observation network for earthquakes and tsunamis (S-net) that has been constructed along the Japan Trench (Chikasada et al., 2019, Technical Report of NIED; Yamamoto et al., 2016, EPS). They calculated synthetic tsunami waveforms at the observation locations by solving nonlinear long-wave equations using a staggered leapfrog finite-difference scheme. A run-up boundary condition was applied to the coastal regions and an open boundary condition was applied to the rims of calculation region. But they did not consider about dispersive wave (Baba et al., 2017, Ocean Modeling) neither the attenuation effect of ocean bottom pressure changes (Chikasada et al., 2018, AGU).
Therefore, we reconsidered the effects of the dispersion term and the attenuation for a few thousands tsunami scenarios stored in the Tsunami Scenario Bank (TSB). As a result, we confirmed that these two effects possibly cause underestimation in real-time tsunami forecast. Therefore, we need to update waveforms calculated and registered for outer-rise earthquake into the TSB with a dispersion term. However, it is quite time-consuming task to solve non-linear long-wave equations with Boussinesq terms. In order to reduce calculation time, the linear long-wave equations with Boussinesq terms could be used to generate offshore synthetic waveforms. We considered the attenuation effect as well.
This work was partially supported by JSPS KAKENHI Grant Number JP15H05718 and JP18K04674.

Maximum tsunami height prediction using Ocean-Bottom Pressure Values based on Gaussian Process Regression

*Kotaro Takahashi[1], Kenjiro Kashiwabara[1], Yasuhiko Igarashi[1,2], Toshitaka Baba[3], Takane Hori[4], Masato Okada[1]

1. Graduate School of Frontier Sciences, The University of Tokyo, 2. Japan Science and Technology Agency PRESTO, 3. Institute of Technology and Science, The University of Tokushima, 4. Research and Development Center for Earthquake and Tsunami, Japan Agency for Marine-Earth Science and Technology

Tsunami early warning systems using water pressure gauges operate around the world to cope with human damage caused by tsunami waves. The systems use a correlation between observed pressure gauges value around coast and tsunami height at prediction points near shore, based on prior insights such that tsunami height highly depends on the topography (bathymetry) during its propagation.

In predicting the tsunami height, it is important both to avoid underestimation for minimizing the damage and to increase accuracy for minimizing the evacuation cost. Takahashi et al. [2018] proposed a method making use of a database of the tsunami height and the observed pressure-gauge-values. While it is good at avoiding underestimation, it puts the prediction accuracy second; its prediction is likely to be highly overestimated. To improve the accuracy, Igarashi et al. [2016] proposed a method based on Gaussian Process regression, but it does not avoid underestimation. In this work, we extend the method by Igarashi et al. [2016], and proposed a prediction method with less underestimation and higher accuracy. We used pressure gauges data from the Dense Ocean-floor Network System for Earthquakes and Tsunamis (DONET) in the Nankai trough to investigate the prediction accuracy and the possibility of underestimation by our proposed method. Compared to the method by Takahashi et al. [2018], our method dropped the average prediction error from 4.44m to 1.61m, at the cost of an increase in the average underestimation rate of only 3.5%. Likewise, compared to the method by Igarashi et al. [2016],

our method dropped the average underestimation rate from 43.2% to 4.38%, at the cost of an increase in the average prediction error of only 0.84m. These facts prove the effectiveness of our method, which is good at making predictions with both little underestimation and high accuracy.

Improvement for Finite-Difference Formula of Non-Linear Longwave Equations to Express Tsunami Decay

*Masaaki MINAMI[1]

1. Meteorological Research Institute

In the current, we can not correctly express the decay process of the tsunami by numerical calculation. In the meantime, social demands for accurately expressing the tsunami decay are strengthening, for judging the timing of cancellation of the tsunami warning and information on the outlook of the tsunami. Therefore, at the Meteorological Research Institute, we are conducting research to improve the accuracy of the subsequent wave and decay process of the far-field tsunami and modeling of the decay process using observation waveforms (Hayashi et al., 2010, JSCE papers B2 (coastal engineering) etc.). We are conducting large-scale and highly accurate tsunami calculations using supercomputer using nonlinear longwave equations, which is a conventional tsunami numerical calculation method. (Minami et al., 2018, Japan Seismological Society Autumn Meeting etc.) Nevertheless, the decay process of the tsunami was not correctly expressed like the results of various calculations so far.

In this paper, we focused on bottom friction of tsunamis, which is an important factor in decay, and improved the differential formula of nonlinear longwave equations. First, in the friction term in the equation, the position difference of the total water depth (D) for calculating the friction term has been calculated as the arithmetic mean of the two adjacent meshes (central difference). If you use arithmetic averaging, there is a possibility that non-negligible errors may occur compared to when solving continuously. This is because D changes in the friction term on the order of -1/3. Therefore, the positional difference was improved to the one using the average value theorem (fig1). Furthermore, with regard to the time difference, assuming that dt is dt/n within one calculation step dt seconds and assuming that the calculation is repeated n times, it is possible to take the limit at $n \rightarrow \infty$, and the difference expression can be transformed as shown in fig 2.

Using these improved difference formula and appropriate coefficients, we calculated in the case of the 2010 Chile earthquake tsunami (Mw 8.8), and as a result its deay is larger than the conventional formula. In the example of fig3, the total energy amount of the later part, which became larger than the observation amount, decreased by about 4% and approached the observation amount. As a calculation condition of the tsunami, all areas including the entire Pacific Ocean (E100° to W90°) are assumed to be 30 seconds mesh (GEBCO 30 sec-grid), and in the area surrounding Hokkaido, Honshu, Shikoku and Kyushu, nesting is performed with a 10 second mesh, and we calculated for a long time (72 hours) in order to see the decay process. For the calculation we use JAGURS (Baba et al., 2015) , considering the elastic loading of the crust and the density effect of seawater, and using the result of the fault parameter (Fujii & Satake, 2013).

By using this formula, the decay of the tsunami becomes larger than the conventional formula by about 5%, and it is 10% or more in large case when the total depth D is small (generally less than 1 m) such as run-up and exposure. Also, by improving the time difference, it is possible to take longer time steps and it is possible to shorten the calculation time.

Although the decay process of the tsunami was not correctly expressed by the previous numerical calculation, it became possible to express the decay process more correctly by this method. In the future,

©2019. Japan Geoscience Union. All Right Reserved.

we will continue to study this method and apply this method to various cases to improve the accuracy of the tsunami decay process.

Real time tsunami inundation forecast method developed for Central America Region

*Yuichiro Tanioka[1], Ulbert Gleb Grillo[2], Greyving Jose Argrello[2], Amilcar Cabrera[2]

1. Hokkaido University, Institute of Seismology and Volcanology, 2. Nicaraguan Institute of Territorial Studies, Nicaragua

In 1992, the Nicaragua tsunami earthquake generated a large tsunami which caused a significant disaster along the coast. In Central America, it has been an issue to develop a tsunami warning system which can manage a tsunami earthquake such as the 1992 Nicaragua earthquake. Recently, the Intergovernmental Oceanographic Commission of UNESCO (IOC/USESCO) decided to make the Central America Tsunami Advisory Center (CATAC) in Nicaragua. Therefore, Japan International Cooperation Agency (JICA) with Japan Meteorological Agency (JMA) run a technical program to support the establishment of CATAC. In this paper, we develop a tsunami inundation forecast method for CATAC which can manage a tsunami earthquake.

First, we previously developed the method to appropriately estimate the source model (Tanioka et al., 2017). The technique was tested for four large earthquakes, the 1992 Nicaragua tsunami earthquake (Mw7.7), the 2001 El Salvador earthquake (Mw7.7), the 2004 El Astillero earthquake (Mw7.0), and the 2012 El Salvador-Nicaragua earthquake (Mw7.3), which occurred off Central America. At first, fault parameters were estimated from the W-phase inversion. Then the fault length and width were determined from scaling relationships. To estimate a slip amount, we constructed a depth dependent rigidity curve, similar to that suggested by Bilek and Lay (1999). The curve with a central depth estimated by the W-phase inversion was used to calculate the slip amount of the fault model. Using that slip amount, the tsunami numerical simulation with inundations was carried out. The result indicated that the observed tsunami heights, run-up heights, and inundation areas for the 1992 Nicaragua tsunami earthquake were well explained by the computed one. The other tsunamis from the other large earthquakes were also reasonably well explained by the computed ones.

In this paper, we applied the near-field tsunami forecast method (NearTIF) using a data base (Gusman et al., 2014) by computing a tsunami from the appropriate fault model which estimated in the above. First, we built a data-base which contained tsunami waveforms at several reference points for each region and inundation results at 6 regions, Gulf of Fonseca, Corinto, Puerto Sandino, El Transito, Masachapa,El Astillero, along the Pacific coast of the Central America. We put source models of Mw7.0, 7.2, 7.4, 7.6, 7.8, 8.0, 8.2 along the subduction interface. Totally, 135 source models are in the data base. The best tsunami inundation distribution for the forecast will be chosen by comparing the tsunami waveforms at the reference points computed in a real time with the tsunami waveforms at those points in the data base. Nest, the method is applied for the 1992 Nicaragua tsunami earthquake case. The source model for the 1992 Nicaragua earthquake was previously estimated from the W-phase inversion with the scaling relationship. The slip amount is estimated using the depth dependent rigidity curve. The tsunami forecast result shows that the observed tsunami heights, run-up heights, and inundation areas are reasonably well explained by the tsunami forecasted inundation map. The method developed in this paper should be useful for the tsunami early warning system at CATAC.

Near-fault observations of an offshore earthquake by DONET: Comparison of ocean bottom pressure gauges and strong-motion accelerometers

*Ayumu Mizutani[1], Kiyoshi Yomogida[1]

1. Natural History Science, Graduate School of Science, Hokkaido University, Earth and Planetary Dynamics

New ocean-bottom networks for earthquakes and tsunami such as S-net and DONET have been recently deployed in the offshore Japan. One important feature of these networks is that seismometers and ocean bottom pressure (OBP) gauges are installed at the same sites. Tsunamis are designed to be recorded in terms of water pressure changes. During an earthquake, the water pressure near its fault area changes not only by tsunamis (i.e., sea surface heights) but also by water depth change of instruments themselves, vertical accelerations of a seafloor itself (i.e., reaction force from water column), and the seismic waves radiated (including ocean acoustic waves) (e.g. Saito and Tsushima, 2016).

In this study, we analyzed the OBP and strong-motion accelerogram records provided by DONET1 that associated with the 2016 Off-Mie earthquake (Mw 6). First, we compared the pressure records in the forms of acceleration, velocity and displacement recorded in strong-motion accelerograms. Velocity and displacement records were calculated by integrations of accelerometer seismograms. Because a simple integration leads to unreasonable results, we conducted the baseline correction by the method based on Iwan et al. (1985). Second, we estimated tsunami heights at stations near the fault in near real-time basis, using the records of OBPs and accelerograms combined.

We obtained the following results by these comparisons: (1) the pressure change proportional to ocean-bottom velocity especially for each first motion, (2) in contrast, at around 0.1Hz, the pressure proportional to ocean-bottom acceleration at some stations, and (3) during the coseismic period, the effect of displacement not contributing to the pressure change at the same site. (1) and (2) are consistent with the numerical simulations by Saito (2017).

Next, we removed the effect of accelerations using 0.05-0.1Hz band-pass filter from the OBP records that were processed by 0.1Hz low-pass filtering, enabling us to extract tsunami and displacement signals at 10s intervals. The resulted waveforms are matched well with 0.01Hz low-pass filtered OBP records, suggesting that this method would be useful for tsunami early warning with near-fault combined records of OBP and accelerograms.

Many researchers have developed numerical models based on the nonlinear shallow water equations to estimate the propagation and inundation of tsunamis. Several models have been distributed as the software packages including source code, thus tsunami inundation simulation can be performed easily with bathymetric and topographic data available free. However, the tsunami modelling researchers also empirically understand that no tsunami simulation results agree perfectly with that of other research institutes even if the same numerical model is used. The maximum inundation depth, flow velocity and inundated area are different to a certain extent. To clarify the variation in tsunami simulation is very important to establish the standard method that confirm the reliability of tsunami inundation models and it will be useful for the tsunami countermeasure/mitigation planning.

The present study aims to evaluate magnitude of the variation in tsunami inundation simulation quantitatively. We conducted tsunami simulations under the same input data: the initial source model of tsunami, bathymetry, topography and land-use model provided by Cabinet Office, Government of Japan are adopted. A total of eight research institutes participated this project using four kinds of numerical models that are widely employed for the tsunami hazard/risk assessment. Comparison of the time history of water surface elevation and flow velocity at the specific points indicated that a significant difference was confirmed among the model results to the maximum value of physical quantities. The spatial distribution maps of the maximum inundation depth also showed that large variation occurs around the front of tsunami run-up. In order to explain the variation in tsunami inundation model quantitatively, the total flooded volume and the total momentum flux were newly defined. By statistical procedures using these variables, we were able to show the mean value, confidence interval and coefficient of variation of the tsunami inundation models.

Numerical Modeling of Tsunami Inundation in Urban Area using Sub-Grid Scale Drag Force Model

*Nobuki Fukui[1], Nobuhito Mori[2]

1. Graduate School of Engineering, Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University

Numerical simulation of tsunami inundation using high-resolution topography (resolution is less than 1m) needs to consider the effect of structures on wave run-up. However, numerical simulation with medium resolution (resolution over 50m to 100m) is still important for practical use due to computational cost. This study developed Drag Force Model (DFM) and individual Drag Force Model (iDFM) as an urban roughness parameterization to obtain acceptable accuracy in medium resolution tsunami inundation model based on physical modeling. The model treats the effect of structures as grid-averaged drag force and projected area in x and y-direction in Cartesian coordinate and characteristic structure height are used as parameters representing the sub-grid scale structure. Furthermore, iDFM considers the number of structures and structure height in the area of interests individually. The edge detection technology for image processing tool is used to count the number of structures. Moreover, various mesh size 10cm to 40cm (25m to 100m in real scale) are used to check mesh size dependency. The validation DFM and iDFM is conducted using numerical simulation and physical modeling of tsunami inundation targeting available tsunami inundation experiments.

Numerical experiment of tsunami deposits related to fault parameters by sediment transport model

*Ako YAMAMOTO[1], Tomoyuki Takahashi[2], Kenji Harada[3]

Large tsunamis cause extensive damage to coastal areas. Underestimation of the tsunami risk can increase the extent of damage and delay reconstruction. To improve tsunami estimation requires review of many records of tsunami cycles and sources (i.e., geologic faults). Sand deposits from tsunamis provide many paleo tsunami records; however, the relationship between tsunami sand deposits and the magnitude of tsunamis is not understood. Takahashi et al. (1999) proposed a sediment transport model for tsunamis. This model was adapted using data from the 1960 Chilean tsunami in Kesennuma Bay, although the amount of sand transportation was underestimated due to the local topography. Takahashi et al. (2011) improved the model based on a hydraulic experiment using three types of sand grains, although verification using other grain sizes and mixed sand compositions has not been conducted. Furthermore, numerical analysis focusing on tsunami sand deposits in inundation areas has fewer verification examples. Yamamoto et al. (2017, 2018) carried out a hydraulic experiment to validate the sediment transport model. This experiment used three types of sand grains, which had sizes different from those used by Takahashi et al. (2011). The model of Takahashi et al. (2011) was confirmed to be very accurate for medium sand. However, the relationship between the tsunami sand deposits and fault parameters has not been verified.

To clarify the relation between tsunami sand deposits and fault parameters, we carried out numerical experiments of sediment transport in a simple topography. The numerical experiments consisted of two steps. The first step investigated the influence of fault conditions on the tsunami waveform. The fault condition was changed according to fault width, length, slip, and position. The waveform observed in this experiment was used as the boundary condition for the second step of the experiment. The second step investigated the effect of the tsunami waveform on the sand deposits in the land area. The topography conditions were changed by changing the slope of the sea area and land area. Furthermore, we investigated the effect of setting a structure in the land area on the sand deposits. Numerical experiments confirmed the points at which the nature of sediment deposits changes according to fault and topography conditions.

Evaluation of potential impact of tsunami-induced sediment transport in Kochi Prefecture during the Nankai Trough megathrust earthquake and tsunami

*Kei Yamashita[1], Daisuke Sugawara[2], Shuji Seto[1], Taro Arikawa[3], Tomoyuki Takahashi[4], Fumihiko Imamura[1]

1. International Research Institute of Disaster Science, Tohoku University, 2. Museum of Natural and Environmental History, Shizuoka, 3. Faculty of Science and Engineering , Chuo University, 4. Faculty of Societal Safety Sciences, Kansai University

Introduction

Strong flows due to giant tsunamis may cause large-scale sediment erosion, deposition and resulting morphological changes in coastal areas, in which sometimes alter the nature and size of tsunami hazards (e.g., Sugawara, 2017). The tsunamis flow loaded with a large amount of sediments possesses an increased hydrodynamic force, which causes not only loss of lives and properties but also incidental injuries to human healths, such as “Tsunami lung”. Flush-out of coastal sediments into deeper sea often cause irreversible changes in sandy beaches, on which post-tsunami natural coastal processes may form an altered beach morphology. Sediment deposition on lands and shallow waters hampers not only emergent rescue and support, but also post-disaster recovery and reconstruction. Environmental pollutions due to chemical elements in sludge deposits are additional consequences of the tsunami-induced sediment transport.

In 2012, the Cabinet Office of Japan updated the tsunami risk assessment of the Nankai Trough earthquake and tsunami. However, influences of the sediment transport have not been included quantitatively in the tsunami scenarios. In this study, numerical simulations of tsunami sediment transport caused by the Nankai Trough earthquake have been performed to investigate the potential impacts of sediment erosion, deposition and morphological change in Tosa Bay, Kochi Prefecture, where severest damages are presumed by the Case 4 of the assessment of the Nankai Trough earthquake.

Numerical Calculation Methods

The tsunami sediment transport model (STM) proposed by Takahashi et al. (1999) was used. The STM takes into account exchange of bed- and suspended loads, in which parameters of the transport formula depend on the grain size of the sediment. Computational region covers a wide area of Tosa Bay including Kure Bay in Takaoka-gun to Hane Cape in Muroto City. To assess the uncertainties due to the grain size, three types of median size d_{50} were assumed, i.e., d_{50} = 0.127, 0.267 and 0.394 mm.

Results and Discussion

The numerical simulations demonstrated that in the mouths of class A (Niyodo and Mononobe) and B

©2019. Japan Geoscience Union. All Right Reserved.

(Shinjo, Aki, Ioki and Nahari) rivers, strong flows caused severe erosion greater than 10 m in depth, regardless of the choice of the grain size. A large amount of the sediments were flushed out to the offshore zone deeper than the wave base. In addition, extensive sediment deposition occurred on the lands neighborhood of the class A rivers. For example, deposit thickness near Niyodo River was as large as 1 m. Note that thickness of known paleotsunami deposits in this area is much smaller than the simulations. Further comparison of the field data and modeling results is needed to examine the assumptions of the size of the Nankai Trough earthquake. Based on the findings from the 2011 Tohoku tsunami, averaged deposit thickness is estimated at 4-5 cm. Choice of the grain size caused variations of the averaged deposit thickness ranging from 4.2 to 11.3 cm.

Sediment erosion and deposition were significant around harbors and bays along the coast. Bottom sediments of the mouth and inner part of Susaki Bay were eroded and that the sediments were deposited over a wide area of Susaki City. However, the simulated thickness of the deposit on Ikenouchi area including Tadasu-ike was quite thin compared to the paleotsunami deposits (Okamura and Matsuoka, 2012). Coastal defenses and changes in the land use might have affected to the difference between the deposits. In the mouth of Usa and Urado Bays, the simulations showed that part of the sediments were transported to the land near the source meanwhile most sediments were deposited on the seaward the bay mouth and the head of the bay.

The simulated morphological changes became larger with decreasing grain size. Increase in the maximum inundation heights was 2 and 1 m for d_{50} = 0.127 and 0.394 mm, respectively. In some of the investigated areas (i.e., Geisei-mura), effect of the morphological change to the inundation height was totally different. These results imply importance of sediment transport modeling for regional tsunami hazard assessments.

Conclusions

In Kochi Prefecture, tsunami-induced sediment transport may cause not only large-scale morphological changes of the coasts but also increase in tsunami hazards. Note that the influences of the sediment transport depend significantly on uncertainties in bed materials. Acquisition of detailed sedimentary data will benefit improved assessment of impacts from tsunamis. Further discussions are needed regarding countermeasures to tsunami hazards considering the regional characteristics of tsunami-induced sediment transport.

We conducted field survey of the tsunami damaged coast of the Keicho 9 earthquake of February 3rd, 1605 on the coasts of Tokai, Shikoku And Kyushu and tsunami inundation or run-up heights were measured newly at 17 points by using GPS. Tsunami height distribution along Boso Peninsula had been clarified by Tsuji et al(2018). At Nishina, Nishiizu Town, Shizuoka prefecture, sea water went upstream along Nishina River about 1.4 km from the river mouth and run up height was estimated at 8.9 meters above mean sea level. At Hashimoto in Arai Town, Kosai City, Shizuoka prefecture, 80 houses out of 100 houses were swept away, and tsunami height was 8.2 meters. At Shirasuka, a post town of Tokaido houses were swept away and severel people, horses, and cows were killed, and tsunami height was 9.4 meters. At Horikiri village, Tahara city, near the to of Atsumi Peninsula, Aichi preffecture, all fishing ships were wrecked but no house and human damage took place, and height was estimeted at 3 meters. At Sakihama, Muroto city, Kochi prefecture, sea water rose up to the entrance step stone of the main building of Dainichiji temple, and tsunami height was 14.4 meters. Coastal villages near cape Muroto, about 400 people were killed due to the tsunami. At Saga, Kuroshio Town, documents given by Lord Motochika Chosokabe was lost in Sakamoto's house, where tsunami height was estimated at 6.2 meters. At Misaki, in Tosashimizu city, 153 peoples were killed due to the tsunami, and tsunami height was estimated at 8.1 meters. Tsunami height distribution is illustrated in the figure.
This research was supported by MEXT (“Research project for compound disaster mitigation on the great earthquakes and tsunamis around the Nankai Trough region”).

Re-examination of tsunami heights distribution during the 1854 Ansei Tokai Earthquake

*Kentaro Imai[1], ebina yuichi[2], Yoshinobu Tsuji[3], Hiroyuki Iwase[4], Takane Hori[1], Narumi Takahashi[1,5], Takashi Furumura[6]

1. Japan Agency for Marine-Earth Science and Technology, 2. International Research Institute of Disaster Science, 3. Shimanto City, 4. ECOH CORPORATION, 5. National Research Institute for Earth Science and Disaster Resilience, 6. Earthquake Research Institute The University of Tokyo

The great Nankai Trough earthquake has been accepted for the recurrence on the characteristic earthquake based on the plate tectonic interpretation. On the other hand, Seno (2012) pointed out the possibility that overlapping regions are few and complementary in the seismic zone of the Ansei Tokai Earthquake and the Showa Tonankai Earthquake. It is necessary to similar reinterpretation of the tsunami source. In this research, we reexamined the historical documents related to the Ansei Tokai earthquake Tsunami, along the coast of the Izu Peninsula from the coast of the Kii Peninsula, close to the source area of the Ansei Tokai earthquake. Furthermore, field survey for tsunami trace height based on historical documents conducted to clarify the characteristics of the tsunami height distributions.

We extracted historical materials on the 1854 Ansei Tokai Earthquake published in the Japan Earthquake reference material as “Zotei Dai Nippon Jishin shiryo”, “Shinshu Nihon Jishin Shiryo” and so on. 801 documents stored in these collections were selected and checked for newly found documents that have not been used in previous research. We conducted a field survey on tsunami trace height information obtained through historical document. We reviewed carefully these selected historical documents, and evaluation for tsunami trace height on the field was carried out by GNSS and laser range finder measurement. For the comprehensive tsunami trace height distribution, the data evaluated by previous research [Hatori (1977); Tsuji et al. (1991); Namegaya & Tsuji (2005); Tsuji et al. (2013); Tsuji & Saito (2014); Imai et al. (2017)] were partially used.
There are two peaks of the tsunami height during the tsunami trace height distributions on the Ansei Tokai earthquake tsunami, the one as the tsunami trace height was reached 22 m at Kuzaki the east of the Shima Peninsula. the other one as the tsunami trace height was exceeding 15 m at Iruma the south east of Izu Peninsula. This information are extremely important clues to re-examine for the tsunami source of the Ansei Tokai earthquake. We examine the tsunami source that explains such tsunami trace height distribution in this presentation.

Acknowledgments: This research was supported by MEXT (“Research project for compound disaster mitigation on the great earthquakes and tsunamis around the Nankai Trough region”).

Ore deposits containing valuable elements and minerals at high concentrations in supracrustal rocks are formed by the Earth's dynamics including magmatism, hydrothermal activity, metamorphism, and weathering. The formation of ore deposits is also closely associated with global environmental changes and biological evolution in the Earth's history. Involvement of difference academic fields in earth sciences including geology, petrology, geochemistry, mineralogy, and microbiology is required to understand the genesis of ore deposits. The field of resource geology is essential not only for efficient exploration and development of ore deposits but also for better understanding and assessment of hazardous elements that may be caused by the resource development. This session widely covers various topics of field investigation and observation, laboratory experiments, theoretical calculation, development of analytical methods and others related to the supracrustal migration and concentration of elements.

The role of water in the concentration of Cr

*Shoji Arai[1]

1. Department of Earth Sciences, Faculty of Science, Kanazawa University

The role of water in the formation of chromitites, which have been designated as a typical orthomagmatic ores, has been long controversial. Johan et al. (1983, 2017), for example, concluded that chromites are precipitated from water-rich fluids at relatively low temperatures (< 1000 ºC) to form podiform chromitites in the mantle. Those arguments are mainly based on two observations; (1) podiform chromitites and surrounding peridotites have been preferentially hydrated, which may mean the initial water enrichment, and (2) chromite grains contain fluid and hydrous mineral inclusions of apparently primary origin. I criticize the related interpretations based on those observations. The selective hydration in and around chromitite pods is due to the Mg-rich character of olivines, which has been obtained during a subsolidus cooling stage (Arai, 1978), and does not definitely show the involvement of water-rich fluid in chromitite formation. The origin of the chromite-hosted hydrous mineral inclusions has not been left unclear. Many authors a priori interpreted the inclusions as being representative of the trapped melts or fluids that precipitated the host chromites. This is, however, highly questionable. The inclusions are most probably formed during a stage of peridotite-melt reaction within a complicated igneous stage of podiform chromitite generation in the mantle. Hydrothermal fluids can transport Cr and precipitate chromite, but may not form most of the podifrom chromitites.

Mineralogical Features of Silver-Bearing Minerals in Chimney Ore from Myojinsho Caldera, Myojin Knoll and Bayonnaise Knoll Seafloor Hydrothermal Area, Izu-Bonin Arc

Shinji Kawaguchi[1], *Kotaro Yonezu[1], Thomas Tindell[1], Jun-ichiro Ishibashi[2], Tatsuo Nozaki[3], Yoko Ohtomo[4], Koichiro Watanabe[1]

1. Deaprtment of Earth Resources Engineering, Faculty of Engineering, Kyushu University, 2. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, 3. Research and Development Center for Submarine Resources, Japan Agency for Marine-Earth Science and Technology, 4. Faculty of Engineering, Hokkaido University

Submarine hydrothermal deposits in western Pacific is characterized as volcanic massive sulfide deposits mainly consisting of Cu-Pb-Zn (± Au ±Ag). Recent explorations have resulted in discoveries of submarine mineral resources in the exclusive economic zones around Japan. The previous study reported chimney ores collected from Izu-Bonin arc are of high grade (Au; 24.1 ppm, Ag; 1275 ppm, Cu: 1.14%, Pb: 5.57%, Zn: 35.03%), (Tanahashi et al, 2004). According to this study, chimney ores were characterized by porous constituents and concentric ring structures, white colored barite layer and sulfide mineral layer mainly composed of sphalerite and galena are recognized from the outer surface to the center part. This concentric ring structures may be attributed to order of precipitations during formation of the chimney ores, however only few studies have discussed mineralization of the chimney along the growth axis (e.g., Watanabe & Hayashi, 2014). Purpose of our research is to clarify mineralogical features of silver minerals in chimney ore by identifying the precipitation conditions of hydrothermal fluids in the Izu-Bonin arc. We studied chimney ores collected during the NT13-09 scientific cruise and NT14-06 scientific cruise.The chimney ores collected from Izu-Bonin arc have quite similar mineralogical features. They have a tubular structure and can be divided into three groups along growth axis from outside to inside of chimney; G1: composed of barite; G2: mainly composed of barite and the principal sulfide minerals of submarine hydrothermal ore deposit (sphalerite, pyrite, chalcopyrite and galena); and G3: composed of main sulfides. According to EPMA analysis, barite is observed in G1 and G2 in addition to pore filling barite in G3. These barite formations are considered to mixing of the hydrothermal fluid with ambient seawater and formation temperature estimated for the initial barite mineralization recognized in G1 and G2 as 190-215℃, and for the second barite mineralization in G3 is as 150-195℃, suggesting temperature decrease of the hydrothermal fluid during the formation of chimney ores (Iizasa, et al. 1997). Based on these results, we propose following formation stages. First, G1 are formed by mixing of the hydrothermal fluid with seawater. Subsequently, porous G2 is formed by a change in the mixing ratio of seawater and hydrothermal fluid. Finally, the hydrothermal contribution becomes greater, so that exclusively sulfide mineral can be precipitated in G3. In addition, as shown in barite observed in G3, after the hydrothermal activity stopped, the second barite is precipitated in the void of the porous chimney ore by mixing ambient seawater and hydrothermal fluid. We noticed that the silver-bearing minerals can be observed in G2 and G3 as tetrahedrite-tennantite series minerals (Ave (wt.%): Ag; 2.9, Cu: 11.1, Zn: 7.0, Pb: 46.6, Sb: 4.0, As: 3.0 and S: 10.9) of 1-20 μm. Silver bearing minerals are associated with sphalerite and galena. According to Ag vs. Sb/(Sb+As) diagram, relatively silver-rich hydrothermal fluids contributed to form the chimney ore in Izu-Bonin arc as compared to that of typical with Kuroko type deposits. Especially from the chimney ore of the Bayonaissea knoll, 1-10 μm of tetrahedrite-tennantite series containing a high content of silver (Ave (wt.%): Ag: 52.9, Cu: 9.6, Zn: 1.6, Pb: 37.5 and S: 13.8) are observed at the rims of galena in the boundary between G1 and G2. Silver mineralization may be explained as follows. Firstly, silver present in galena formed during the principal sulfide mineralization moves by equilibrium equation,

©2019. Japan Geoscience Union. All Right Reserved.

$2Pb^{2+} = Ag^{+} + Sb^{3+}$ (Karup-Moller, 1971 and Foord, 1989) towards the right side by decreasing in temperature. As a result, tetrahedrite-tennantite series minerals are precipitated at G2 and G3. After hydrothermal active vent stopped, further temperature drop was introduced and furutobeite is formed from tetrahedrite-tennantite series minerals.

Organic matters and acid-sulfate alteration in Itomuka Mine, Hokkaido, Japan: implications for the transportation and deposition mechanisms of mercury

*Takuya Echigo[1], Mitsuyoshi Kimata[2], Masahiro Shimizu[2]

1. Graduate School of International Resource Sciences, Akita University, 2. Graduate School of Life and Environmental Sciences, University of Tsukuba

We investigated the ore and hydrothermal alteration minerals and solid organic matters from Itomuka mercury mine which is located in the eastern part of central Hokkaido to examine the transportation and deposition mechanisms of mercury. In addition to the ore minerals, native mercury and cinnabar, powder X-ray diffraction (XRD) analysis showed that the mercury ore consist of quartz, marcasite, alunite, kaolinite and minor amounts of pyrite and smectite. This mineral assemblage suggests that mercury deposition occurred with the advanced argillic alteration under low temperature and low pH condition. Two types of solid organic matter were recognized in quartz vein by yellow-green fluorescence under the ultraviolet radiation: (1) film-shaped organic matter occurring on the surface of quartz vein and (2) globule-shaped organic matter filling pores of quartz vein. Both of these organic matters occur with mercury minerals, cinnabar, native mercury and calomel (Hg_2Cl_2). These organic matters were analyzed with SEM-EDS, micro-X-ray diffraction and micro-FTIR. SEM-EDS analysis showed that film-shaped organic matter is closely associated with mercury and silica minerals though globule-shaped organic matter is not associated with such minerals. Micro-FTIR spectra of both organic matters are similar and suggested that these contain aromatic rings, carboxyl group (-COOH) and adamantine ($C_{16}H_{10}$). Micro-XRD showed that film-shaped organic matter consists quartz, opal- and adamantine crystals and globule-shaped organic matter consists of quartz and amorphous organic matter, respectively. The occurrence of these organic matters suggests that hydrothermal fluid which transported mercury was highly reduced. Because the solubility of Hg in acidic fluid is low, neutral to alkaline fluid seems to have leached mercury from the basement sedimentary rocks of Hidaka formation. The mercury-bearing fluid ascended along the faults in Itomuka formation and oxidized at near the surface. Reduced sulfur (HS^-) in the fluid oxidized into sulfate (SO_4^{2-}) and reduced pH, which resulted in mercury deposition and advanced argillic alteration. Probably, rapid oxidation of ore-forming fluid promoted the precipitation of marcasite, a metastable phase of iron sulfide. The dominance of native mercury over cinnabar indicates that mercury was transported by biphase (liquid+vapor) hydrothermal fluid.

Significances of 12 Ma manganese ores in the Hokuroku district, Akita: unique Mn accumulation and interaction with organic matter during submarine hydrothermal activities

*Yuya Tsukamoto[1], Takeshi Kakegawa[1]

1. Tohoku Univ.

Various Mn ores are found in the Hokuroku district in Akita through the course of the present study. Stratified and veined Mn ores, which lengths are up to 10 cm, are formed during volcanic recession periods (less than 1 Ma) with associated with carbonaceous sediments and local hydrothermal systems. Such short-term precipitation of “pure” Mn ores is unusual, compared to normal Fe-Mn nodules or crusts. In order to understand detailed mechanisms, in particular, role of organic matter, of Mn ore formations, we performed standard mineralogical characterization, magnetic field analyses and oxygen isotope analyses on Mn ores. The first type of Mn ores appear on mudstone and veins in hydrothermally altered hyaloclastite of rhyolite lavas. Detailed geological and geochemical studies revealed that local submarine hydrothermal processes mobilized Mn and Fe in host rocks, Fe-oxides were precipitated first and then discharged Mn were precipitated as oxides (rhodonite and todorokite) on mudstone. $\delta^{18}O_{SMOW}$ value of Mn oxide is + 7.7‰ showing the precipitation temperature less than 112 C. Mn carbonate (rhodochlosite and kutnohorite) also appears in the same region. $\delta^{13}C_{PDB}$values of Mn carbonate were -21‰ (PDB), suggesting interaction with organic matters during intrusive activities of later rhyolite. The second type of Mn ores appear as veins in rhyolitic tuff or stratified lenticular forms with mud/tuffs. Ca. 30 μm colloform structures consisted of organic matter and Mn oxides can be observed. Major Mn mineral in these second type is todorokite. $\delta^{18}O_{SMOW}$value of second types of Mn ores is + 8.5‰ indicating low temperature precipitation of Mn oxides less than 101 C. Magnetic field was detected on Mn oxides in colloform structure by magnetic field microscopy (MFM). Such magnetic fields indicate high cation vacancies and abundance of Mn^{4+}, which are common in biogenic Mn oxides. Formational processes of both Mn ores provide new insight of the unique formational process of Mn ores, especially geological separation from $Fe^{2+}$and interaction with organic matter, in hydrothermal systems at the subseafloor on felsic volcanic setting. Further, this study indicates that low temperature (<100 C) hydrothermal activities can form the Mn ores with high precipitation rates.

Microbial communities around ca. 2.7 Ga submarine hydrothermal fields at the Potterdoal deposit in Abitibi Greenstone Belt, Canada

*Takeru Osato[1], Akizumi Ishida[1], Takeshi Kakegawa[1]

1. Tohoku University

The Archean submarine hydrothermal environment is often considered as a cradle of early life. Large uncertainties still exist as to which microorganisms were active around Archean submarine hydrothermal systems and if hydrothermal communities could be the primary producers for the global biosphere. To approach this problem, we studied ca. 2.7 Ga volcanogenic massive sulfides (VMSs) and associated sedimentary rocks at the Potterdoal deposit in Abitibi Greenstone Belt, Canada. Purposes of the present study are (1) to evaluate which type of microorganisms were active in 2.7 Ga submarine hydrothermal environments, and (2) to find new biosignature in nanoscale analysis of organic matter (OM).
VMS ores were mainly composed of chalcopyrite, sphalerite, pyrrhotite and pyrite, mostly showing layered and sorting textures. They often contained brecciated shale or actinolite or chlorite. Chert and sandstone appeared in the distal area from the VMSs. Most examined VMSs did not have OM, but some samples had up to 0.5 wt.% of carbon concentration. Those OM were found together with actinolite or chlorite or shale fragments trapped in VMSs. Carbon concentration in sedimentary rocks were moderate in general, ranging from 0.0 to 0.9 wt.%C. The thermal alteration temperature was estimated as below 300 ˚C based on the full widths of half maximum of the D1 band in the Raman spectra of kerogen, indicating that less altered features. Overall carbon isotope compositions of kerogen were ranging from -44.6 to -23.6 ‰ (PDB). These values suggest that the presence of contrast microbial ecosystems at this region, utilizing either hydrothermal CH_4 or atmospheric CO_2. Transmitted electron microscope analysis revealed that examined kerogen were mainly composed of immature OM with minor graphene layers. Novel nanostructures of Mo-sulfides stacked with graphene or Fe-sulfides were newly found in immature kerogen structures.These nano-sulfides associated with kerogen may suggest incorporation of biological sulfides in OM during the early diagenesis, possibly giving new evidence of sulfur metabolisms for the early life.

In order to explore accessible and profitable natural resources, scientific elucidation of their origin and evolution are an essential issue. The natural resources often have fine-grained textures and minute mineral/fluid inclusions in the host minerals. Therefore, microanalysis is required to clarify their mineralogical and geochemical characteristics in detail. Focused-ion beam (FIB) microfabrication and transmission electron microscopy (TEM) are potentially effective techniques for this purpose. FIB allows to precisely extract portions of interest in sub-micron scale from various types of samples. Using TEM, microtextural, chemical, and crystallographic information can be obtained in nano-scale spatial resolution from ultrathin-film (100–200 nm) samples. With taking these technical advantages, state-of-the-art FIB and TEM at JAMSTEC KOCHI have been applied to a variety of geosciences including clay mineralogy [1], biomineralization [2], mantle rheology [3], and meteoritics [4].

One of uniqueness of the FIB/TEM laboratory at KOCHI is a combined FIB-FESEM instrument equipped with an energy dispersive spectrometer (EDS) and a cryo-holder system [5]. We are currently developing a FIB-fabrication scheme of fluid inclusions in minerals such as olivine and halite, so that those fluids are exposed in frozen state for their in-situ chemical analysis including X-ray elemental mapping using EDS [6]. 3D tomography by micro X-ray CT is effective to visualize distribution of fluid inclusions especially in nontransparent minerals prior to nanofabrication and analysis by the FIB-FESEM system.

The nanoscale occurrence of fluid (as voids) and mineral inclusions can be further characterized by high-resolution TEM. This technique would be useful for mineralogical analysis of fine-grained resource materials such as deep-sea mud containing abundant rare-earth elements [7] and manganese deposits. As a typical example, we have mineralogically characterized several-micron-sized Mn-rich microparticles recently discovered in seafloor sediments, and found vernadite-like mineral therein based on their electron diffraction patterns and elemental mappings [8]. We are further developing the linkage fabrication/analysis scheme to extend toward more comprehensive sample analysis including trace elemental and isotopic analyses using NanoSIMS [9]. These microanalysis techniques would play a key role for our better understanding of environments for the formation of resource materials.

Microscopic study on rare earth elements in ion-adsorption type ore of China

*Hiroki Mukai[1], Yoshiaki Kon[1], Kenzo Sanematsu[1], Yoshio Takahashi[2], Motoo Ito[3]

1. National Institute of Advanced Industrial Science and Technology, 2. Graduate School of Science, the University of Tokyo, 3. Kochi Institute for Core Sample Research JAMSTEC

At present, China constitutes more than 80 % of the rare earth elements (REE) production in the world. Among REE ores, ion-adsorption type ones existing mainly in southern China are a major supply source of heavy REE (HREE) which are especially valuable. The ion-adsorption type ore is formed under weathering of the underlying parent granite rocks. This ore typically contains more than 50 % of ion-exchangeable REE that can be extractable with electrolyte solution such as ammonium sulfate $(NH_4)_2SO_4$ solution. It has been estimated that permanent negative charge on clay minerals, such as kaolinite, leads to surface adsorption of REE in the ore. However, the direct observations or analyses for the individual minerals have been rarely conducted due to the relatively low concentrations of REE (<2000 ppm). In the present study, we analyzed weathered granite collected from an ion-adsorption ore in Dingnan County, Jiangxi Province, China on a submicroscopic scale by using various experimental apparatuses.
XRD measurements indicated that the weathered granite is mainly composed of quartz, K-feldspar and kaolinite. The results of SEM-EDS and LA-ICP-MS measurements showed that “kaolinitic particle” is abundant with REE compared to the other minerals. These results suggest that the kaolinitic particles are major reservoir of REE in the ore. The elemental mapping for a kaolinitic particle by LA-ICP-MS showed that each element is distributed heterogeneously in the particle. The SEM-EDS analyses also suggested that the kaolinitic particle is composed of several minerals. For further micro-analyses, cross sections were processed from the kaolinitic particles by FIB. XAFS study on the cross sections suggested that REE are basically hydrated in the particle. STEM-EDS analyses revealed that the kaolinitic particle contains illite and hematite in addition to kaolinite. Considering general weathering process, it can be assumed that K-feldspar was altered into illite and further into kaolinite during chemical weathering. Elemental mapping with high spatial resolution by NanoSIMS clarified that REE are distributed in kaolinite and illite.

The occurrence of gold in ore is one of the most important information in gold deposit research. This information allows us to optimize beneficiation and smelting processes, as well as providing valuable insights into the mineralization mechanism, which can improve exploration strategies (e.g., [1]).

In hydrothermal gold deposits, gold is not always visible as native gold, electrum, caraverite (AuTe2) or other gold minerals. In many cases, it also exists as submicrometer-size inclusions and solid solution in other minerals, which is so-called “*invisible gold*” [2]. Pyrite is the most ubiquitous and well-known host mineral for this invisible gold, and its trace element geochemistry has been increasingly recognized as a useful tool to understand the mineralization processes (e.g., [3]).

In this study, we report the geochemical features of invisible gold in pyrites collected from the Akeshi and Kasuga deposits. These deposits, located in the southern part of the Kagoshima Prefecture, Japan, are currently under operation, and are classified as high-sulfidation gold deposits. In both Akeshi and Kasuga, gold minerals are only reported from high-grade ores, and other hosts of gold in lower-grade ores remain still uncertain [4]. Pyrite is the most common sulfide mineral in these deposits. Here, we report the results of EPMA (Electron Probe Micro Analyzer) and LA-ICP-MS (Laser Ablation Inductively Coupled Plasma Mass Spectrometry) trace element analyses of pyrite, in order to determine their mineralization processes.

Hydrothermal Mineral Assemblage of the Southwest Prospect, in the Vicinity Sto. Tomas II (Philex) Porphyry Cu-Au Deposit, Baguio District, Philippines

*Avriel Venis Literal Cirineo[1], Akira Imai[2], Ryohei Takahashi[1], Noel C. Oliveros[3], Redempta P. Baluda[3], Victor B. Maglambayan[3], Roy Ronald C. Luis[3], Maria Lourdes M. Faustino[3]

1. Graduate School of International Resource Sciences, Akita University, 2. Faculty of Engineering, Kyushu University, 3. Philex Mining Corporation

Overprinting relationship between intrusive rocks, diatreme-breccias and mineralized porphyry-type veinlets are documented in the Southwest prospect was recently discovered along the contact of the basement Pugo metavolcanics and conglomerates of the Zigzag formation, overlain by dacitic tuff termed as the Keratophyre (KTP). The prospect is located at the southwestern periphery of the Sto. Tomas II orebody, a 60-year old porphyry Cu-Au mine being operated by Philex Mining Corporation (PMC).
At least four intrusive rocks were recognized. In chronological order, they are the: (1) coarse-grained biotite quartz diorite (ODP –Old Diorite Porphyry), (2) fine-grained quartz diorite porphyry (EMD -Early Mineralization Diorite), (3) medium-grained porphyritic hornblende quartz diorite (LD –Late Diorite) and (4) hornblende andesite porphyry (DP –Diorite Porphyry). Meanwhile, at least five breccia facies were identified: (1) Phreatomagmatic Breccia facies 1 or PMBx1, (2) Phreatomagmatic facies 2a or PMBx2a, (3) Phreatomagmatic Breccia facies 2b or PMBx2b, (4) Early Mineralization Diorite Breccia or EMDBx and (5) Diorite Porphyry Breccia or DPBx. The PMBx facies are polymictic breccias with chaotic mixture of clasts set in a matrix composed of rock flour of earlier formed rocks and juvenile tuffaceous matrix. They are sub-vertical pipes that flare upwards and may represent diatreme breccias (Sillitoe, 1985, Baker et al., 1986, Lawless and White, 1990). On the other hand, EMDBx and DPBx are intrusion breccias that were formed during the emplacement of their intrusive equivalents (Sillitoe, 1985). Porphyry-type veinlets are observed overprinting ODP, EMD and PMBx1, while at the same time, quartz vein fragments are included in the latter. These veinlets are also commonly found along the contacts between LD and the PMBx1. PMBx2a and PMBx2b crosscut all the earlier intrusions and breccias. Spatial and temporal associations suggest syn-mineralization timing of the EMD, PMBx1 during porphyry-type quartz veining, while LD and some of the porphyry-type veinlets associated with the LD suggest a late-mineralization timing.
Intense potassic alteration is characterized by secondary biotite-quartz-magnetite-anhydrite-chalcopyrite-bornite. It is exhibited by EMD and andesitic clasts of Pugo Metavolcanics occurring as clasts in the diatreme breccias. It is also well-developed in the EMD at the deeper central portion of the prospect, in the matrix of the adjacent EMDBx and PMBx1. Secondary biotite is present as fine disseminations in the groundmass and as polygrain aggregates completely altering former ferromagnesian minerals, such as hornblende. It is often accompanied with quartz, anhydrite, magnetite and copper iron sulfides. Occasional K-feldspar, chlorite, illite and epidote are present in the assemblage. Associated sheeted quartz and granular quartz veinlets indicated a wide range of liquid-vapor homogenization temperature (T_h(L-V)) from 436˚C to 578˚C and 461˚C to >720˚C, respectively, and salinities from 41 to 43 wt% $NaCl_{equivalent}$ and 37 to 43 wt% $NaCl_{equiv.}$ This alteration is overprinted by illite-chlorite-carbonate-magnetite±K-feldspar alteration with abundant chalcopyrite and bornite. It pervasively overprinted the quartz stockwork zone hosted in the PMBx1 adjacent to the EMD at the central deeper portion of the prospect. Associated banded quartz veinlets indicated Th(L-V) >720˚C and salinities ranging from 55 to 70 wt% $NaCl_{equiv.}$ The shallower portions dominated by the later breccias were altered by chlorite-illite-pyrite±chalcopryite with associated quartz-gypsum cement. Lastly, propylitic

©2019. Japan Geoscience Union. All Right Reserved.

alteration is exhibited by LD. It is characterized by chlorite-epidote-calcite±illite. Associated crystalline quartz-chlorite veinlets indicated lower Th(L-V) 246˚C and lower salinity of 40 wt% $NaCl_{equivalent.}$
K-Ar ages determined on the secondary biotite of the EMD sample that exhibited intense hydrothermal biotitization typical at the potassic core in Southwest and on the hornblende grains of LD that showed no hydrothermal alteration are both 3.5Ma. This indicates that the hydrothermal biotitization prevalent in the potassic alteration in EMD and the emplacement of the LD could have happened in a single magmatic-hydrothermal event. This may also indicate that the timing between the potassic alteration and intrusion are close in Southwest, and also constrained an older age than the mineralization at the Sto. Tomas II orebody (Imai, 2001, Waters et al., 2011).

Characteristics and genesis of weathering REE deposits

*Kenzo Sanematsu[1]

1. Mineral Resource Research Group, Institute for Geo-Resources and Environment, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

The world rare earth deposits can be classified into carbonatite, alkaline-rocks related, placer and ion-adsorption types. Rare earth elements (REE) which are present as trace elements in the mantle and crusts can be geologically condensed by either or both of the formation of alkaline magma and weathering. This talk reviews on the characteristics and genesis of weathering REE deposits consisting of weathered carbonatites, placer and ion-adsorption type deposits.

Weathered carbonatite deposits are characterized by high REE grades. Carbonatites are high in REE (>1%, approximately) and these elements are condensed by dissolution of carbonate minerals during chemical weathering. The dominant REE minerals are primary and secondary phosphate minerals including monazite. The ores are rich in LREE (light REE) and Th and poor in HREE (heavy REE), reflecting compositions of the unweathered carbonatites. REE minerals are generally fine-grained compared to unweathered carbonatites and this may influence the recovery of REE during mineral processing.

Placer deposits are formed by weathering and erosion of igneous and metamorphic rocks and deposition of heavy minerals in alluvium and beach sands. Placer ore minerals are mainly Ti minerals (ilmenite and rutile), zircon and cassiterite. REE-bearing placer deposits contain monazite and lesser amount of xenotime. Although the bulk REE grade is low, the ore consisting of sand and gravels can be mined and heavy minerals are processed easily. This deposit type was the leading world REE producer in the world until 1965. Since monazite is the dominant REE mineral, placer deposits are rich in LREE and Th and poor in HREE. Zircon is the common HREE-bearing mineral in placer deposits, however they are not economically extractable.

Contrasting to the two types of residual deposits mentioned above, ion-adsorption type deposits are characterized by REE adsorbed electrostatically on the surface of clays (not in the crystal structure of minerals) and they are extractable by ion exchange from the REE ores. The ores, called ion-adsorption ores, are formed mainly from granite by chemical weathering. Although these deposits are generally low in REE, they can be rich HREE. Parent granites contain weatherable REE bearing minerals such as fluorocarbonates (e.g., bastnaesite, synchysite) and REE-bearing silicates (e.g., allanite, titanite) and LREE/HREE ratios of these minerals constrain those of ion-adsorption ores. In contrast, parent granite rich in phosphate minerals (e.g., monazite and apatite) tends to form weathered granites with low ion-exchangeable REE because most REE are incorporated in phosphate minerals which resistant to chemical weathering. Kaolinite, halloysite, illite and vermiculite appear to have ion-exchangeable REE. Since the ores and extracted solutions are generally low in Th, ion-adsorption type deposits are poor in Th compared with the other REE deposits.

Mineral Chemistry and Petrogenesis of the Mazua Ultramafic Massif, Northern Mozambique: Constraints on the Associated Fe-Ti Oxides Deposit

*David Augusto Bene Unganai[1], Akira Imai[2], Ryohei Takahashi[1], Daud Liace Jamal[3], Takashi Hoshide[1]

Economic magmatic Fe-Ti-V deposits are commonly hosted by mafic-ultramafic intrusions and massif-type anorthosites. The Mazua Ultramafic Massif (MUM), located in northeast Mozambique, is one of the most promising intrusions that host Fe-Ti oxides ore deposit in the country. The orebody is a 10-km long ilmenite-rich hornblende pyroxenite, which is in sharp contact with a banded biotite gneiss. The ore commonly occurs as layers/lenses, massive and dissemination in host rocks. The average grade of the ore is 27 wt.% TiO_2, 35 wt.% Fe_2O_{3tot} and ~2 ppm V (Norconsult Consortium, 2007). However, detailed studies regarding the petrogenesis of the intrusion and its related Fe-Ti oxides ores are still scarce. Thus, we carried out microprobe and petrographic analyses to elucidate these issues.

The hornblende pyroxenite consists of ilmenite, diopside, and magnesiohornblende as main phases. Petrography reveals that the Fe-Ti oxides and pyroxenes are syngenetic. The composition of diopside ($Wo_{43.5–48.5}En_{36.0–41.4}Fs_{11.1–20.5}$) and occurrence of magnesiohornblende suggest tholeiitic, non-alkaline and hydrous (>3.0 wt.% H_2O) parental ultrabasic melt. In addition, the absence of olivine and orthopyroxene supported by wide range of #Mg in diopside (63.8–78.7) and magnesiohornblende (68.9–85.4) confirms the idea that the magma which formed MUM was differentiated.

Texture and variable mineral composition suggest that Fe-Ti oxides underwent extensive subsolidus re-equilibration during cooling, supported by the following evidences: (1) The Fe-Ti oxides show different types of micro-intergrowths such as (a) lamellae of ilmenite with clothing textures hosted in magnetite, (b) fine pattern exsolution lamellae (trellis) and blebs of aluminous spinel in magnetite, (c) reaction rims of aluminous spinel distributed along the boundary between magnetite and ilmenite and (d) re-equilibration textures involving Fe-Ti oxides and silicate phases. (2) The very low MgO content of primary ilmenite (<2 wt.%) is interpreted as a result of postcumulus oxide-silicate re-equilibration involving clinopyroxene and amphibole. (3) Determination of equilibrium conditions using geothermobarometer by Spencer & Lindsley (1981) indicates that Mazua Fe-Ti oxides last equilibrated at subsolidus temperatures (<600 ˚C) and high oxygen fugacity ($\log fO_2 > -20.0$ bars). The reconstruction of the primary composition of Fe-Ti oxides, by reintegration of exsolved with the host phases, leads to primary titanomagnetite with an ulvospinel component of ~20 mol%.

Ni-Cu-PGM Mineralisation in the Bastard Reef and Merensky Reef of the Flatreef section, Turfspruit Farm, Northern Limb, Bushveld Igneous Complex, South Africa.

*MOKHIRI MALESELA MAKHAFOLA[1], Tsubasa Otake[1], Tsutomu Sato[1], Danie Grobler[2]

1. Hokkaido University, 2. Ivanplats Pty. Ltd

The Bushveld Igneous Complex of South Africa is the largest layered igneous complex in the world and it is the current leading producer of platinum group metals globally. The Northern Limb is the northern extension of the complex currently mined (open pit) for a Ni-Cu-PGM rich deposit hosted in a lithologically variable igneous sequence dipping at about 45 degrees and has been intensively affected by contamination and alteration termed the Platreef (Kinnaird et al, 2005). Westwards of the Platreef lies the Flatreef section, which is a recently discovered sub-horizontal down-dip extension of the Platreef. It hosts the Ni-Cu-PGM rich deposit in two successive high-grade reefs termed the Bastard Reef and the Merensky Reef that are amenable for underground mining methods (Grobler et al, 2018). The Flatreef has not been studied in detail and this study reports on the petrographical and semi-quantitative investigations done on the mineralized reefs.
Logging and petrographical investigations revealed the Bastard Reef to comprise a fine to medium-grained equigranular feldspathic orthopyroxenite. Several metres below the Bastard Reef lies the Merensky Reef, which has been subdivided into 3 different units (M2, M1U and M1L) mainly based on mineralogical and textural variations. The M2 is the uppermost layer comprising medium to coarse-grained equigranular orthopyroxenite, denoted by cumulus orthopyroxene and is bound irregularly by a chromite seam at its top contact. The M2 orthopyroxenite is underlain by the M1U denoted by a cumulate textured pegmatoidal orthopyroxenite and is commonly bound by a chromite stringer at its top contact and a less consistent one at its base. The M1L, which is laterally less continuous, comprises a poikilitic textured harzburgite and/or varied-textured olivine-bearing orthopyroxenite. SEM analysis revealed sulphide mineral assemblages in the reefs usually comprising pyrrhotite, pentlandite and chalcopyrite as fine to medium-grained disseminations, blebs and net-textured sulphides. PGM mineralisation comprise a wide range of PGMs, mostly Platinum and Palladium dominated, grouped into bismithotellurides (-Bi-Te), antimonides, arsenides, Fe and Sn alloys, sulphides, as well as laurite (RuS_2) and Ir-Ru-Rh-Pt-Pd sulfoarsenides alongside chromite seams. Semi-quantitative analysis illustrates the Flatreef section to be an undisturbed magmatic sequence that is much less affected by assimilation and contamination. It retains much of its magmatic characteristics and provides a great opportunity to furthermore study magmatic processes that resulted in the formation of such an enigmatic deposit.

Characteristics of Porphyry Copper-Gold Mineralization in the Grasberg Mine, Papua, Indonesia

*Kanehiko Kawasaki[1], Kotaro Yonezu[2], Reza Al Furqan[3], Benny Bensaman[4], Mega Fatimah Rosana[4]

1. Kyushu University Facurity of Engineering, 2. Deaprtment of Earth Resources Engineering, Faculty of Engineering, Kyushu University, 3. PT Freeport Indonesia, 4. Department of Geology, Padjadjaran University

The Grasberg-Ertsberg district is located in the west of the remote highlands of the Sudirman Mountain in the province of Papua, Indonesia. The district is well-known copper-gold mine area as “Grasberg mine” in the world. In this district, Pliocene intrusive rocks host copper and gold mineralization. These intrusive rocks are named “Grasberg Igneous Complex” (GIC), which is composed of Kali Intrusion (KI), Main Grasberg Intrusion (MGI) and Dalam Intrusion (DI). The purpose of this study is to clarify characteristics of ore forming fluid and copper-gold mineralization, especially in the western part of MGI hosted porphyry mineralization in the Grasberg district.
In this study, all samples used is collected from a drill core, AM-30-08H-05. It penetrates KI and DI through MGI. Petrography revealed that Cu bearing mineralization style can be divided into three types: Cu(-Fe) sulfides vein type in quartz vein, Cu(-Fe) sulfides veinlet type and disseminated Cu(-Fe) sulfides type. Chalcopyrite is major ore mineral in vein type and veinlet type. In these types, bornite is often distributed in or by the chalcopyrite, therefore it could be explained by exsolution from intermediate solid solution and bornite solid solution. In disseminated Cu(-Fe) sulfides, chalcopyrite and bornite is major and primary Cu bearing minerals. They are often co-existing, therefore they also seemed to be exsoluted from intermediate solid solution and bornite solution. However, the other Cu bearing minerals (chalcocite, covellite, digenite) sometimes form foliated texture with chalcopyrite and bornite, clearly indicating that those Cu bearing minerals are formed by replacement from bornite. In addition, rim of bornite is sometimes replaced by chalcocite, covellite and digenite, suggesting interaction with ground water after primary mineralization. Native gold is precipitated in chalcopyrite vein in quartz vein and in disseminated chalcopyrite. In chalcopyrite vein, native gold is precipitated with bornite and merenskyite, which is determined by SEM-EDX as $Pd_{1.0}Te_{2.0}$. Merenskyite is newly identified in the western part of GIC, while it has already reported in northern and southern part of GIC. Merenskyite is a common in ultramafic rocks related to PGE mineralization (e.g., merensky reef in Bushveld Igneous Complex). Precipitation of merenskyite in this area suggests the presence and contribution of primitive mafic magma. The fact merenskyite can be observed widely in MGI, the contribution may cover the whole MGI.
Since clear cross-cutting relationship among quartz veins is not observed in this research, SEM-Cathodoluminescence observation is conducted for identifying quartz crystal growth pattern in quartz vein, hosting chalcopyrite vein. Luminescence contrast anomaly can be recognized in quartz vein, suggesting that there are two different occurrence of quartz veins which are early quartz vein and later quartz vein. Only late quartz vein is associated with chalcopyrite vein. Fluid inclusion microthermometry in early quartz vein was conducted. Homogenization temperature of fluid inclusion in early quartz is over 600 degree Celsius with high salinity (61.32 wt%). These results are harmonious with previous research, suggesting weak or none of Cu and Au mineralization is associated with early quartz vein, however late quartz vein introduced intensive copper-gold mineralization.

Formation of Ni-bearing minerals during chemical weathering of ultramafic rocks in Myanmar

*Ayaka Murofushi[1], Akane Ito[1], Tsubasa Otake[2], Kenzo Sanematsu[3], Kyaw Zay Ya[1,4], Tsutomu Sato[2]

1. Graduate school of Engineering, Hokkaido University, 2. Facility of Engineering, Hokkaido University, 3. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, 4. Department of Geological Survey and Mineral Exploration

Ni laterite deposit, an important resource for Ni, is formed by chemical weathering of ultramafic rocks under tropical climate conditions. Whereas many studies have aimed to understand the formation processes of Ni laterites in Indonesia and Philippines, few studies have investigated those in Myanmar, which also has a high potential of Ni laterite resources. The highest grade of Ni in a weathering profile is usually found in a saprolite zone, a weakly weathered section underlain by intensively-weathered laterite zone. Mobilization of Ni from the bedrock as well as laterite zone together with Fe has been proposed to be an important process for Ni enrichment in saprolite zone (e.g., Golightly, 2010). However, formation of various Ni-bearing minerals in saprolite zone (Tauler et al., 2017) may also govern the Ni enrichment though the common Ni-bearing mineral in saprolite zone is secondary-formed serpentine (Ser-II). It is important to understand the formation processes of Ni laterite deposits for efficient exploration and mine development. Therefore, in this study, we are focused on the formation of secondary minerals at different weathering degrees and its relationship to Ni enrichment during chemical weathering of ultramafic rocks in Myanmar by investigating 6 different weathering profiles in the Western and Central Ophiolite Belts.

The results of the bulk chemical analysis by XRF show that Ni is concentrated in saprolite zones up to 1.6 wt% as chemical weathering progresses as indicated by thickness of profiles and depletion of major elements (e.g., Mg). Ni is associated more closely with 0.2-2 μm fraction (e.g., clay minerals) of the samples as Ni concentration in this fraction was determined by acid digestion and ICP-AES. The results of mineralogical analysis by XRD and petrographic microscope show that minerals formed in saprolite zones varies depending on the degree of weathering regardless that all the bedrocks are serpentinite. Whereas smectite dominates in the saprolite zone of the least weathered profile, both smectite and Ser-II were present in the saprolite zone of the most weathered profile. This suggests that smectite is formed at the initial stage of chemical weathering of the ultramafic rocks in Myanmar. However, the results of SEM-EDS analysis show that Mn-oxide (e.g., asbolane) is the main mineral concentrating Ni in the least weathered profile whereas secondary silicate minerals (e.g., Ser-II, smectite, unidentified Fe-Ni silicates) are the main minerals in the most weathered profile. Therefore, Ni is preferentially associated with Mn-oxide possibly because of a strong electrostatic interaction. However, as weathering progresses and Mn-oxide dissolved away, Ni is enriched into secondary silicate minerals (e.g., Ser-II, smectite). No preferential incorporation of Ni was observed between Ser-II and smectite. Further progress in chemical weathering may result in the transformation of other silicate minerals into Ser-II, which would be then the main Ni-bearing mineral in Ni laterite deposit in Myanmar.

Geological Characteristics and Mineralogy of the Makorungo and Nalia Gold Prospects, Northeastern Mozambique

*Manuel Augusto Manuel Nopeia[1], Ryohei Takahashi[1], Akira Imai[2], Daud Liace Jamal[3]

1. Akita University, 2. Kyushu University, 3. Eduardo Mondlane University

The northeastern Mozambique is composed of medium-high grade metamorphic complexes of the Mozambique Belt, intruded by Neoproterozoic-Paleozoic granitoids (Norconsult, 2007). Mozambique Belt (MB) is a part of the East African Orogeny and has been associated with a large variety of mineralization, including base metals, gemstones, and gold (Lächelt, 2004). The lack of studies on gold deposits associated with metamorphic terrains in Mozambique weakens the discovery and further exploration of gold. This study focuses on the Makorungo and Nalia gold prospects, northeastern Mozambique, where artisanal and small-scale mining of placer and primary gold is conducted mainly by local people. These prospects belong to Xixano complex, interpreted as a Pan-African nappe, which is composed of supercrustal rocks, enveloping mafic and ganulitic rocks (Viola et al, 2008). This study aims to reveal the geological and mineralogical characteristics of the gold prospects to better understand the ore-forming process. Field observation and laboratory analysis, including petrography of host rocks and ores, and whole-rock and ore chemistry were applied. Quartz veins parallel and at low angle to amphibolite foliation host the gold mineralization in the Nalia and Makorungo prospects. The amphibolites in the Nalia prospect are strongly foliated and composed mainly of hornblende, plagioclase, quartz and clinopyroxene with minor titanite. Secondary minerals include hornblende replacing clinopyroxenes, and biotite replacing hornblende. Whole-rock geochemistry of the amphibolites indicates high silica and total alkali ($K_2O + Na_2O$) contents, 50 to 64 wt. % and 3.3 to 5.2 wt. %, respectively. On the other hand, the amphibolite rocks in the Makorungo prospect are less foliated and mainly comprises amphiboles, plagioclase, and biotite, with minor quartz. Secondary biotite replaces amphiboles. Based on the extinction angles, the plagioclase in the Makorungo prospect is more Na-rich, while the plagioclase from the Nalia prospect is more Ca-rich. The TiO_2 vs. MnO diagram shows that the amphibolites in both prospects are ortho-amphibolites. Total alkali and silica diagram (TAS diagram) indicates protolith of basaltic composition. The mineralized veins in the Nalia prospect show deformation textures including triple-point texture, undulose extinction and variability in cathodoluminescence brightness within individual quartz grain. Evidence of post-deformation is less common in the Makorungo prospect. The ore mineralogy in the Nalia and Makorungo prospects is very similar, despite the absence of sphalerite in the former. Pyrite, pyrrhotite, galena, magnetite and chalcopyrite commonly occur with minor tellurides and electrum (the Makorungo prospect) or native gold (the Nalia prospect). Bismuth, Te, Pb, and W bearing minerals commonly occur as sulfides and tellurides in both prospects. Sphalerite in the Makorungo prospect is characterized by high Fe and Cd contents, ranging 9.2-11.8 wt. %, and 2.9-3.4 wt. %, respectively. Pressure formation estimated from FeS contents in sphalerite coexisting with pyrite and pyrrhotite (sphalerite geobarometry) is within 1.6 and 2.1 Kb, which corresponds to a depth from 5.9 to7.4 Km. The coeval existence of pyrrhotite and sphalerite in the Makorungo prospect suggests a low sulfidation state, along the pyrite-pyrrhotite equilibrium.

Geochemical features of the Hishikari epithermal gold deposit based on simultaneous multi-element analysis

*Sota Nishida[1], Mizuki Ishida[1], Kazutaka Yasukawa[1,2], Kentaro Nakamura[1], Koichiro Fujinaga[2,1], Yasuhiro Kato[3,1,2]

1. Department of Systems Innovation, School of Engineering, The University of Tokyo, 2. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology, 3. Frontier Research Center for Energy and Resources, School of Engineering, The University of Tokyo

The Hishikari gold deposit, located in the northern part of Kagoshima prefecture, Japan, is known as one of the highest-grade gold deposits in the world. The origin of this low-sulfidation vein-type deposit has been extensively investigated since its discovery in the early 1980s. For example, Ishihara et al. (1986) suggested a magmatic source for gold (Au) and sulfur (S) based on sulfur isotope compositions of pyrites [1]. More recently, Morishita et al. (2018) demonstrated a positive correlation between Au and arsenic (As) in pyrites of the Hishikari veins and discussed their genetic relationship [2].

Understanding the mineralization process of the Hishikari deposit can provide key insights into an exploration strategy for new and high-grade gold deposits. To this end, identifying elements that show behaviors closely associated with Au can be one of the effective approaches. In this study, therefore, major and trace element geochemistry of the Hishikari ore samples have been investigated in order to obtain a new constraint on the Au mineralization processes. We determined multi-elemental composition (including Au) of the host rocks and vein samples by inductively coupled plasma mass spectrometry (ICP-MS).

Previous studies suggested that adularia content is closely related to the Au content of the ore [3]. In the present study, however, we found no correlation between Au and adularia contents in the vein samples. The results of X-ray diffraction (XRD) analysis indicated that the samples with high Au mostly consist of quartz. The Au mineralization thus seems to have occurred concurrently with the quartz mineralization that followed the adularia mineralization.

Among the 49 elements measured in this study, silver (Ag) content was positively correlated with Au content, which is consistent with the fact that electrum is the main host of Au in the Hishikari deposit. Arsenic (As) content had no correlation with Au, although it is well known for a coupling behavior with Au. Most notably, bismuth (Bi) content had clear correlation with Ag ($r = 0.88$) and Au ($r = 0.91$) contents, whereas it had no clear correlation with cobalt (Co), copper (Cu), iron (Fe), zinc (Zn), lead (Pb), or As contents. Bi is known to be enriched in high-sulfidation gold deposits where the common host of Bi is sulfide minerals (e.g. [4]), and closely associated with Au in these deposits. However, elemental behavior of Bi in low-sulfidation gold deposits has so far been poorly understood. Our results imply that Bi in the Hishikari deposit is likely to be involved not in sulfide but in electrum. This in turn suggests that Bi could be an important tracer for Au mineralization in low-sulfidation deposits such as the Hishikari deposit.

Transformation of ore minerals and their geochemical signatures in submarine hydrothermal ore deposits in Izena Hole, Okinawa Trough

*IKESHIMA TAKURO[1], Tsubasa Otake[1], Tsutomu Sato[1], Akane Ito[1], Shuji Ono[1], Jun-ichiro Ishibashi[2], Tatsuo Nozaki[3], Hidenori Kumagai[3], Lena Maeda[3]

1. Hokkaido University, 2. Kyushu University, 3. Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

It is important for exploration and development of submarine hydrothermal ore deposits to understand zoning of ore bodies and their mineral assemblages, particularly with depth from the seafloor. Transformation of ore minerals via dissolution and re-precipitation may cause such a zoning corresponding to the evolution of a hydrothermal system because geochemical conditions may then vary with the depth from the seafloor. In this study, we aimed (1) to clarify the mineral assemblage changes with increasing depth of a mound sulfide deposit by microscopic observations and SEM-EDS analyses, (2) to understand geochemical evolution of hydrothermal fluids based on Fe contents in sphalerite determined by EPMA, and (3) to understand the formation processes of Fe sulfides by analyzing Fe isotopic composition of the bulk samples with MC-ICP-MS. The samples used for the analyses were obtained from Site C9027, which drilled up to 72.5 meter below seafloor (mbsf) through a mound sulfide deposit in Hakurei site, Izena Hole, middle Okinawa Trough during the CK16-05 cruise operated from November to December, 2016 under the SIP program.
Results of microscopic observations show that sphalerite and galena are comparatively dominant with minor occurrence of pyrrhotite and anglesite in the samples at shallow depths. In contrast, samples from middle and deep depths are more abundant on pyrite and chalcopyrite, and pyrite, respectively. The texture that pyrrhotite was dissolved and replaced by pyrite or marcasite was observed in the samples in the depth of 0.05 –44.0 mbsf. The Fe content in sphalerite tends to decrease with increasing depth, and also change within single sphalerite grain. These results suggest that hydrothermal fluid geochemistry such as fugacity of S_2 and O_2, and temperature changes for the depth and time. The δ^{56}Fe values (δ^{56}Fe (‰) = 1000 * [(^{56}Fe/^{54}Fe) sample / (^{56}Fe/^{54}Fe)$_{IRMM-014}$ -1]) of the bulk samples range from -0.62 to +0.11‰, which tends to increase toward the deeper part. This indicates that Fe sulfides at shallow depths was formed by non-equilibrium precipitation with a rapid cooling, which caused a kinetic isotope effect. In contrast, those at deeper depths were likely formed near the equilibrium conditions.

Geochemical behavior of heavy metals during wastewater treatment in Chingola Stream of the Zambia Copperbelt

*Cryton Phiri[1], Daiki Shimazui[2], Tsutomu Sato[2], Tsubasa Otake[2]

1. University of Zambia, 2. Hokkaido University

The study focuses on an area at a copper mine in Chingola town of the Zambian Copperbelt where wastewater containing heavy metals (Cu-Co-Mn) at variable pH (3.5-6.5) mixes with a nearby municipal wastewater in Chingola Stream. The metal concentration of discharge is below the regulation limit because lime treatment has been conducted in the stream. However, remaining volume of ponds for sludge produced by lime treatment was limited. The objective of the study was therefore to understand the geochemical behavior of the metals for the optimization of wastewater treatment. Representative water and soil samples were obtained along the affected stream and analyzed for their target heavy metal content and geochemical distribution using ICP-AES/MS and sequential extraction (SQE) methods. Analyses of sediment mineralogy were made by XRD, optical microscopy, FE-SEM/EDS and TEM/EDS. Water chemistry results revealed relatively low metal concentrations of Cu-Co-Mn ranging from below detection limit (bdl) to 60mg/l. SQE analyses show high total target metal concentrations ranging from (1-12000mg/kg) in sediments, which obviously supports the possible adsorption and precipitation processes to be taking place. Low concentrations are as a result of the increasing pH and possible metal adsorption and precipitation on sediment. The target metal contents were highest in exchangeable fraction Cu (100-2500mg/kg), Co (1-50mg/kg), Mn (bdl-2g/kg), and in carbonate fraction Cu (2-500mg/kg), Co (0.5-20mg/kg), Mn (bdl-1.2g/kg) and in amorphous Fe mineral fraction Cu (2-1000mg/kg), Co (1-100mg/kg) and Mn (0.5-2.5g/kg) respectively. The other remaining fractions had very low metal concentrations. FE-SEM/EDS and TEM/EDS techniques showed some metal adsorption phases on biotite and kaolinite confirming the earlier results of SQE. The amorphous Fe mineral determined using SQE reveal an average of between 3.5-12 g/kg. From the surface complexation modeling between amorphous Fe mineral and the metals shows that the range of pH condition, 6.5-7.5 is strongly recommended for better sorbed fraction of Cu-Co-Mn on amorphous Fe mineral. From the above results, it was found that the geochemical partitioning of metals to the most labile exchangeable fraction which easily releases metals to the environment depending on the prevailing conditions (i.e pH) can as well be treated by ion exchange, surface complexation by amorphous Fe mineral and carbonation. The advantages of this treatment method is that heavy metal can easily be recovered from sludge through the application of relatively weak acid and at the same time reducing the sludge volumes through utilization of the sediments as sand for engineering purposes.

Wed. May 29, 2019 5:15 PM - 6:30 PM JST | Wed. May 29, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_22

[H-RE16] Resource Geology

convener:Tsubasa Otake(Division of Sustainable Resources Engineering, Faculty of Engineering, Hokkaido University), Daisuke Araoka(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology), Ryohei Takahashi(Graduate School of International Resource Sciences, Akita University), Tatsuo Nozaki(Research and Development Center for Submarine Resources, Japan Agency for Marine-Earth Science and Technology)

Ore deposits containing valuable elements and minerals at high concentrations in supracrustal rocks are formed by the Earth's dynamics including magmatism, hydrothermal activity, metamorphism, and weathering. The formation of ore deposits is also closely associated with global environmental changes and biological evolution in the Earth's history. Involvement of difference academic fields in earth sciences including geology, petrology, geochemistry, mineralogy, and microbiology is required to understand the genesis of ore deposits. The field of resource geology is essential not only for efficient exploration and development of ore deposits but also for better understanding and assessment of hazardous elements that may be caused by the resource development. This session widely covers various topics of field investigation and observation, laboratory experiments, theoretical calculation, development of analytical methods and others related to the supracrustal migration and concentration of elements.

Mineral Chemistry and Petrogenesis of the Mazua Ultramafic Massif, Northern Mozambique: Constraints on the Associated Fe-Ti Oxides Deposit

*David Augusto Bene Unganai[1], Akira Imai[2], Ryohei Takahashi[1], Daud Liace Jamal[3], Takashi Hoshide[1]

1. Akita University, 2. Kyushu University, 3. Eduardo Mondlane University

Economic magmatic Fe-Ti-V deposits are commonly hosted by mafic-ultramafic intrusions and massif-type anorthosites. The Mazua Ultramafic Massif (MUM), located in northeast Mozambique, is one of the most promising intrusions that host Fe-Ti oxides ore deposit in the country. The orebody is a 10-km long ilmenite-rich hornblende pyroxenite, which is in sharp contact with a banded biotite gneiss. The ore commonly occurs as layers/lenses, massive and dissemination in host rocks. The average grade of the ore is 27 wt.% TiO_2, 35 wt.% Fe_2O_{3tot} and ~2 ppm V (Norconsult Consortium, 2007). However, detailed studies regarding the petrogenesis of the intrusion and its related Fe-Ti oxides ores are still scarce. Thus, we carried out microprobe and petrographic analyses to elucidate these issues.

The hornblende pyroxenite consists of ilmenite, diopside, and magnesiohornblende as main phases. Petrography reveals that the Fe-Ti oxides and pyroxenes are syngenetic. The composition of diopside ($Wo_{43.5–48.5}En_{36.0–41.4}Fs_{11.1–20.5}$) and occurrence of magnesiohornblende suggest tholeiitic, non-alkaline and hydrous (>3.0 wt.% H_2O) parental ultrabasic melt. In addition, the absence of olivine and orthopyroxene supported by wide range of #Mg in diopside (63.8–78.7) and magnesiohornblende (68.9–85.4) confirms the idea that the magma which formed MUM was differentiated.

Texture and variable mineral composition suggest that Fe-Ti oxides underwent extensive subsolidus re-equilibration during cooling, supported by the following evidences: (1) The Fe-Ti oxides show different types of micro-intergrowths such as (a) lamellae of ilmenite with clothing textures hosted in magnetite, (b) fine pattern exsolution lamellae (trellis) and blebs of aluminous spinel in magnetite, (c) reaction rims of aluminous spinel distributed along the boundary between magnetite and ilmenite and (d) re-equilibration textures involving Fe-Ti oxides and silicate phases. (2) The very low MgO content of primary ilmenite (<2 wt.%) is interpreted as a result of postcumulus oxide-silicate re-equilibration involving clinopyroxene and amphibole. (3) Determination of equilibrium conditions using geothermobarometer by Spencer & Lindsley (1981) indicates that Mazua Fe-Ti oxides last equilibrated at subsolidus temperatures (<600 ˚C) and high oxygen fugacity ($\log fO_2 > -20.0$ bars). The reconstruction of the primary composition of Fe-Ti oxides, by reintegration of exsolved with the host phases, leads to primary titanomagnetite with an ulvospinel component of ~20 mol%.

Ni-Cu-PGM Mineralisation in the Bastard Reef and Merensky Reef of the Flatreef section, Turfspruit Farm, Northern Limb, Bushveld Igneous Complex, South Africa.

*MOKHIRI MALESELA MAKHAFOLA[1], Tsubasa Otake[1], Tsutomu Sato[1], Danie Grobler[2]

1. Hokkaido University, 2. Ivanplats Pty. Ltd

The Bushveld Igneous Complex of South Africa is the largest layered igneous complex in the world and it is the current leading producer of platinum group metals globally. The Northern Limb is the northern extension of the complex currently mined (open pit) for a Ni-Cu-PGM rich deposit hosted in a lithologically variable igneous sequence dipping at about 45 degrees and has been intensively affected by contamination and alteration termed the Platreef (Kinnaird et al, 2005). Westwards of the Platreef lies the Flatreef section, which is a recently discovered sub-horizontal down-dip extension of the Platreef. It hosts the Ni-Cu-PGM rich deposit in two successive high-grade reefs termed the Bastard Reef and the Merensky Reef that are amenable for underground mining methods (Grobler et al, 2018). The Flatreef has not been studied in detail and this study reports on the petrographical and semi-quantitative investigations done on the mineralized reefs.
Logging and petrographical investigations revealed the Bastard Reef to comprise a fine to medium-grained equigranular feldspathic orthopyroxenite. Several metres below the Bastard Reef lies the Merensky Reef, which has been subdivided into 3 different units (M2, M1U and M1L) mainly based on mineralogical and textural variations. The M2 is the uppermost layer comprising medium to coarse-grained equigranular orthopyroxenite, denoted by cumulus orthopyroxene and is bound irregularly by a chromite seam at its top contact. The M2 orthopyroxenite is underlain by the M1U denoted by a cumulate textured pegmatoidal orthopyroxenite and is commonly bound by a chromite stringer at its top contact and a less consistent one at its base. The M1L, which is laterally less continuous, comprises a poikilitic textured harzburgite and/or varied-textured olivine-bearing orthopyroxenite. SEM analysis revealed sulphide mineral assemblages in the reefs usually comprising pyrrhotite, pentlandite and chalcopyrite as fine to medium-grained disseminations, blebs and net-textured sulphides. PGM mineralisation comprise a wide range of PGMs, mostly Platinum and Palladium dominated, grouped into bismithotellurides (-Bi-Te), antimonides, arsenides, Fe and Sn alloys, sulphides, as well as laurite (RuS_2) and Ir-Ru-Rh-Pt-Pd sulfoarsenides alongside chromite seams. Semi-quantitative analysis illustrates the Flatreef section to be an undisturbed magmatic sequence that is much less affected by assimilation and contamination. It retains much of its magmatic characteristics and provides a great opportunity to furthermore study magmatic processes that resulted in the formation of such an enigmatic deposit.

Characteristics of Porphyry Copper-Gold Mineralization in the Grasberg Mine, Papua, Indonesia

*Kanehiko Kawasaki[1], Kotaro Yonezu[2], Reza Al Furqan[3], Benny Bensaman[4], Mega Fatimah Rosana[4]

1. Kyushu University Facurity of Engineering, 2. Deaprtment of Earth Resources Engineering, Faculty of Engineering, Kyushu University, 3. PT Freeport Indonesia, 4. Department of Geology, Padjadjaran University

The Grasberg-Ertsberg district is located in the west of the remote highlands of the Sudirman Mountain in the province of Papua, Indonesia. The district is well-known copper-gold mine area as “Grasberg mine” in the world. In this district, Pliocene intrusive rocks host copper and gold mineralization. These intrusive rocks are named “Grasberg Igneous Complex” (GIC), which is composed of Kali Intrusion (KI), Main Grasberg Intrusion (MGI) and Dalam Intrusion (DI). The purpose of this study is to clarify characteristics of ore forming fluid and copper-gold mineralization, especially in the western part of MGI hosted porphyry mineralization in the Grasberg district.
In this study, all samples used is collected from a drill core, AM-30-08H-05. It penetrates KI and DI through MGI. Petrography revealed that Cu bearing mineralization style can be divided into three types: Cu(-Fe) sulfides vein type in quartz vein, Cu(-Fe) sulfides veinlet type and disseminated Cu(-Fe) sulfides type. Chalcopyrite is major ore mineral in vein type and veinlet type. In these types, bornite is often distributed in or by the chalcopyrite, therefore it could be explained by exsolution from intermediate solid solution and bornite solid solution. In disseminated Cu(-Fe) sulfides, chalcopyrite and bornite is major and primary Cu bearing minerals. They are often co-existing, therefore they also seemed to be exsoluted from intermediate solid solution and bornite solution. However, the other Cu bearing minerals (chalcocite, covellite, digenite) sometimes form foliated texture with chalcopyrite and bornite, clearly indicating that those Cu bearing minerals are formed by replacement from bornite. In addition, rim of bornite is sometimes replaced by chalcocite, covellite and digenite, suggesting interaction with ground water after primary mineralization. Native gold is precipitated in chalcopyrite vein in quartz vein and in disseminated chalcopyrite. In chalcopyrite vein, native gold is precipitated with bornite and merenskyite, which is determined by SEM-EDX as $Pd_{1.0}Te_{2.0}$. Merenskyite is newly identified in the western part of GIC, while it has already reported in northern and southern part of GIC. Merenskyite is a common in ultramafic rocks related to PGE mineralization (e.g., merensky reef in Bushveld Igneous Complex). Precipitation of merenskyite in this area suggests the presence and contribution of primitive mafic magma. The fact merenskyite can be observed widely in MGI, the contribution may cover the whole MGI.
Since clear cross-cutting relationship among quartz veins is not observed in this research, SEM-Cathodoluminescence observation is conducted for identifying quartz crystal growth pattern in quartz vein, hosting chalcopyrite vein. Luminescence contrast anomaly can be recognized in quartz vein, suggesting that there are two different occurrence of quartz veins which are early quartz vein and later quartz vein. Only late quartz vein is associated with chalcopyrite vein. Fluid inclusion microthermometry in early quartz vein was conducted. Homogenization temperature of fluid inclusion in early quartz is over 600 degree Celsius with high salinity (61.32 wt%). These results are harmonious with previous research, suggesting weak or none of Cu and Au mineralization is associated with early quartz vein, however late quartz vein introduced intensive copper-gold mineralization.

Formation of Ni-bearing minerals during chemical weathering of ultramafic rocks in Myanmar

*Ayaka Murofushi[1], Akane Ito[1], Tsubasa Otake[2], Kenzo Sanematsu[3], Kyaw Zay Ya[1,4], Tsutomu Sato[2]

1. Graduate school of Engineering, Hokkaido University, 2. Facility of Engineering, Hokkaido University, 3. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, 4. Department of Geological Survey and Mineral Exploration

Ni laterite deposit, an important resource for Ni, is formed by chemical weathering of ultramafic rocks under tropical climate conditions. Whereas many studies have aimed to understand the formation processes of Ni laterites in Indonesia and Philippines, few studies have investigated those in Myanmar, which also has a high potential of Ni laterite resources. The highest grade of Ni in a weathering profile is usually found in a saprolite zone, a weakly weathered section underlain by intensively-weathered laterite zone. Mobilization of Ni from the bedrock as well as laterite zone together with Fe has been proposed to be an important process for Ni enrichment in saprolite zone (e.g., Golightly, 2010). However, formation of various Ni-bearing minerals in saprolite zone (Tauler et al., 2017) may also govern the Ni enrichment though the common Ni-bearing mineral in saprolite zone is secondary-formed serpentine (Ser-II). It is important to understand the formation processes of Ni laterite deposits for efficient exploration and mine development. Therefore, in this study, we are focused on the formation of secondary minerals at different weathering degrees and its relationship to Ni enrichment during chemical weathering of ultramafic rocks in Myanmar by investigating 6 different weathering profiles in the Western and Central Ophiolite Belts.

The results of the bulk chemical analysis by XRF show that Ni is concentrated in saprolite zones up to 1.6 wt% as chemical weathering progresses as indicated by thickness of profiles and depletion of major elements (e.g., Mg). Ni is associated more closely with 0.2-2 μm fraction (e.g., clay minerals) of the samples as Ni concentration in this fraction was determined by acid digestion and ICP-AES. The results of mineralogical analysis by XRD and petrographic microscope show that minerals formed in saprolite zones varies depending on the degree of weathering regardless that all the bedrocks are serpentinite. Whereas smectite dominates in the saprolite zone of the least weathered profile, both smectite and Ser-II were present in the saprolite zone of the most weathered profile. This suggests that smectite is formed at the initial stage of chemical weathering of the ultramafic rocks in Myanmar. However, the results of SEM-EDS analysis show that Mn-oxide (e.g., asbolane) is the main mineral concentrating Ni in the least weathered profile whereas secondary silicate minerals (e.g., Ser-II, smectite, unidentified Fe-Ni silicates) are the main minerals in the most weathered profile. Therefore, Ni is preferentially associated with Mn-oxide possibly because of a strong electrostatic interaction. However, as weathering progresses and Mn-oxide dissolved away, Ni is enriched into secondary silicate minerals (e.g., Ser-II, smectite). No preferential incorporation of Ni was observed between Ser-II and smectite. Further progress in chemical weathering may result in the transformation of other silicate minerals into Ser-II, which would be then the main Ni-bearing mineral in Ni laterite deposit in Myanmar.

Geological Characteristics and Mineralogy of the Makorungo and Nalia Gold Prospects, Northeastern Mozambique

*Manuel Augusto Manuel Nopeia[1], Ryohei Takahashi[1], Akira Imai[2], Daud Liace Jamal[3]

1. Akita University, 2. Kyushu University, 3. Eduardo Mondlane University

The northeastern Mozambique is composed of medium-high grade metamorphic complexes of the Mozambique Belt, intruded by Neoproterozoic-Paleozoic granitoids (Norconsult, 2007). Mozambique Belt (MB) is a part of the East African Orogeny and has been associated with a large variety of mineralization, including base metals, gemstones, and gold (Lächelt, 2004). The lack of studies on gold deposits associated with metamorphic terrains in Mozambique weakens the discovery and further exploration of gold. This study focuses on the Makorungo and Nalia gold prospects, northeastern Mozambique, where artisanal and small-scale mining of placer and primary gold is conducted mainly by local people. These prospects belong to Xixano complex, interpreted as a Pan-African nappe, which is composed of supercrustal rocks, enveloping mafic and ganulitic rocks (Viola et al, 2008). This study aims to reveal the geological and mineralogical characteristics of the gold prospects to better understand the ore-forming process. Field observation and laboratory analysis, including petrography of host rocks and ores, and whole-rock and ore chemistry were applied. Quartz veins parallel and at low angle to amphibolite foliation host the gold mineralization in the Nalia and Makorungo prospects. The amphibolites in the Nalia prospect are strongly foliated and composed mainly of hornblende, plagioclase, quartz and clinopyroxene with minor titanite. Secondary minerals include hornblende replacing clinopyroxenes, and biotite replacing hornblende. Whole-rock geochemistry of the amphibolites indicates high silica and total alkali ($K_2O + Na_2O$) contents, 50 to 64 wt. % and 3.3 to 5.2 wt. %, respectively. On the other hand, the amphibolite rocks in the Makorungo prospect are less foliated and mainly comprises amphiboles, plagioclase, and biotite, with minor quartz. Secondary biotite replaces amphiboles. Based on the extinction angles, the plagioclase in the Makorungo prospect is more Na-rich, while the plagioclase from the Nalia prospect is more Ca-rich. The TiO_2 vs. MnO diagram shows that the amphibolites in both prospects are ortho-amphibolites. Total alkali and silica diagram (TAS diagram) indicates protolith of basaltic composition. The mineralized veins in the Nalia prospect show deformation textures including triple-point texture, undulose extinction and variability in cathodoluminescence brightness within individual quartz grain. Evidence of post-deformation is less common in the Makorungo prospect. The ore mineralogy in the Nalia and Makorungo prospects is very similar, despite the absence of sphalerite in the former. Pyrite, pyrrhotite, galena, magnetite and chalcopyrite commonly occur with minor tellurides and electrum (the Makorungo prospect) or native gold (the Nalia prospect). Bismuth, Te, Pb, and W bearing minerals commonly occur as sulfides and tellurides in both prospects. Sphalerite in the Makorungo prospect is characterized by high Fe and Cd contents, ranging 9.2-11.8 wt. %, and 2.9-3.4 wt. %, respectively. Pressure formation estimated from FeS contents in sphalerite coexisting with pyrite and pyrrhotite (sphalerite geobarometry) is within 1.6 and 2.1 Kb, which corresponds to a depth from 5.9 to7.4 Km. The coeval existence of pyrrhotite and sphalerite in the Makorungo prospect suggests a low sulfidation state, along the pyrite-pyrrhotite equilibrium.

Geochemical features of the Hishikari epithermal gold deposit based on simultaneous multi-element analysis

*Sota Nishida[1], Mizuki Ishida[1], Kazutaka Yasukawa[1,2], Kentaro Nakamura[1], Koichiro Fujinaga[2,1], Yasuhiro Kato[3,1,2]

1. Department of Systems Innovation, School of Engineering, The University of Tokyo, 2. Ocean Resources Research Center for Next Generation, Chiba Institute of Technology, 3. Frontier Research Center for Energy and Resources, School of Engineering, The University of Tokyo

The Hishikari gold deposit, located in the northern part of Kagoshima prefecture, Japan, is known as one of the highest-grade gold deposits in the world. The origin of this low-sulfidation vein-type deposit has been extensively investigated since its discovery in the early 1980s. For example, Ishihara et al. (1986) suggested a magmatic source for gold (Au) and sulfur (S) based on sulfur isotope compositions of pyrites [1]. More recently, Morishita et al. (2018) demonstrated a positive correlation between Au and arsenic (As) in pyrites of the Hishikari veins and discussed their genetic relationship [2].

Understanding the mineralization process of the Hishikari deposit can provide key insights into an exploration strategy for new and high-grade gold deposits. To this end, identifying elements that show behaviors closely associated with Au can be one of the effective approaches. In this study, therefore, major and trace element geochemistry of the Hishikari ore samples have been investigated in order to obtain a new constraint on the Au mineralization processes. We determined multi-elemental composition (including Au) of the host rocks and vein samples by inductively coupled plasma mass spectrometry (ICP-MS).

Previous studies suggested that adularia content is closely related to the Au content of the ore [3]. In the present study, however, we found no correlation between Au and adularia contents in the vein samples. The results of X-ray diffraction (XRD) analysis indicated that the samples with high Au mostly consist of quartz. The Au mineralization thus seems to have occurred concurrently with the quartz mineralization that followed the adularia mineralization.

Among the 49 elements measured in this study, silver (Ag) content was positively correlated with Au content, which is consistent with the fact that electrum is the main host of Au in the Hishikari deposit. Arsenic (As) content had no correlation with Au, although it is well known for a coupling behavior with Au. Most notably, bismuth (Bi) content had clear correlation with Ag ($r = 0.88$) and Au ($r = 0.91$) contents, whereas it had no clear correlation with cobalt (Co), copper (Cu), iron (Fe), zinc (Zn), lead (Pb), or As contents. Bi is known to be enriched in high-sulfidation gold deposits where the common host of Bi is sulfide minerals (e.g. [4]), and closely associated with Au in these deposits. However, elemental behavior of Bi in low-sulfidation gold deposits has so far been poorly understood. Our results imply that Bi in the Hishikari deposit is likely to be involved not in sulfide but in electrum. This in turn suggests that Bi could be an important tracer for Au mineralization in low-sulfidation deposits such as the Hishikari deposit.

Transformation of ore minerals and their geochemical signatures in submarine hydrothermal ore deposits in Izena Hole, Okinawa Trough

*IKESHIMA TAKURO[1], Tsubasa Otake[1], Tsutomu Sato[1], Akane Ito[1], Shuji Ono[1], Jun-ichiro Ishibashi[2], Tatsuo Nozaki[3], Hidenori Kumagai[3], Lena Maeda[3]

1. Hokkaido University, 2. Kyushu University, 3. Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

It is important for exploration and development of submarine hydrothermal ore deposits to understand zoning of ore bodies and their mineral assemblages, particularly with depth from the seafloor. Transformation of ore minerals via dissolution and re-precipitation may cause such a zoning corresponding to the evolution of a hydrothermal system because geochemical conditions may then vary with the depth from the seafloor. In this study, we aimed (1) to clarify the mineral assemblage changes with increasing depth of a mound sulfide deposit by microscopic observations and SEM-EDS analyses, (2) to understand geochemical evolution of hydrothermal fluids based on Fe contents in sphalerite determined by EPMA, and (3) to understand the formation processes of Fe sulfides by analyzing Fe isotopic composition of the bulk samples with MC-ICP-MS. The samples used for the analyses were obtained from Site C9027, which drilled up to 72.5 meter below seafloor (mbsf) through a mound sulfide deposit in Hakurei site, Izena Hole, middle Okinawa Trough during the CK16-05 cruise operated from November to December, 2016 under the SIP program.
Results of microscopic observations show that sphalerite and galena are comparatively dominant with minor occurrence of pyrrhotite and anglesite in the samples at shallow depths. In contrast, samples from middle and deep depths are more abundant on pyrite and chalcopyrite, and pyrite, respectively. The texture that pyrrhotite was dissolved and replaced by pyrite or marcasite was observed in the samples in the depth of 0.05 –44.0 mbsf. The Fe content in sphalerite tends to decrease with increasing depth, and also change within single sphalerite grain. These results suggest that hydrothermal fluid geochemistry such as fugacity of S_2 and O_2, and temperature changes for the depth and time. The δ^{56}Fe values (δ^{56}Fe (‰) = 1000 * [(^{56}Fe/^{54}Fe) sample / (^{56}Fe/^{54}Fe)$_{IRMM-014}$ -1]) of the bulk samples range from -0.62 to +0.11‰, which tends to increase toward the deeper part. This indicates that Fe sulfides at shallow depths was formed by non-equilibrium precipitation with a rapid cooling, which caused a kinetic isotope effect. In contrast, those at deeper depths were likely formed near the equilibrium conditions.

Geochemical behavior of heavy metals during wastewater treatment in Chingola Stream of the Zambia Copperbelt

*Cryton Phiri[1], Daiki Shimazui[2], Tsutomu Sato[2], Tsubasa Otake[2]

1. University of Zambia, 2. Hokkaido University

The study focuses on an area at a copper mine in Chingola town of the Zambian Copperbelt where wastewater containing heavy metals (Cu-Co-Mn) at variable pH (3.5-6.5) mixes with a nearby municipal wastewater in Chingola Stream. The metal concentration of discharge is below the regulation limit because lime treatment has been conducted in the stream. However, remaining volume of ponds for sludge produced by lime treatment was limited. The objective of the study was therefore to understand the geochemical behavior of the metals for the optimization of wastewater treatment. Representative water and soil samples were obtained along the affected stream and analyzed for their target heavy metal content and geochemical distribution using ICP-AES/MS and sequential extraction (SQE) methods. Analyses of sediment mineralogy were made by XRD, optical microscopy, FE-SEM/EDS and TEM/EDS. Water chemistry results revealed relatively low metal concentrations of Cu-Co-Mn ranging from below detection limit (bdl) to 60mg/l. SQE analyses show high total target metal concentrations ranging from (1-12000mg/kg) in sediments, which obviously supports the possible adsorption and precipitation processes to be taking place. Low concentrations are as a result of the increasing pH and possible metal adsorption and precipitation on sediment. The target metal contents were highest in exchangeable fraction Cu (100-2500mg/kg), Co (1-50mg/kg), Mn (bdl-2g/kg), and in carbonate fraction Cu (2-500mg/kg), Co (0.5-20mg/kg), Mn (bdl-1.2g/kg) and in amorphous Fe mineral fraction Cu (2-1000mg/kg), Co (1-100mg/kg) and Mn (0.5-2.5g/kg) respectively. The other remaining fractions had very low metal concentrations. FE-SEM/EDS and TEM/EDS techniques showed some metal adsorption phases on biotite and kaolinite confirming the earlier results of SQE. The amorphous Fe mineral determined using SQE reveal an average of between 3.5-12 g/kg. From the surface complexation modeling between amorphous Fe mineral and the metals shows that the range of pH condition, 6.5-7.5 is strongly recommended for better sorbed fraction of Cu-Co-Mn on amorphous Fe mineral. From the above results, it was found that the geochemical partitioning of metals to the most labile exchangeable fraction which easily releases metals to the environment depending on the prevailing conditions (i.e pH) can as well be treated by ion exchange, surface complexation by amorphous Fe mineral and carbonation. The advantages of this treatment method is that heavy metal can easily be recovered from sludge through the application of relatively weak acid and at the same time reducing the sludge volumes through utilization of the sediments as sand for engineering purposes.

[E] Poster | H (Human Geosciences)：H-TT Technology & Techniques

Wed. May 29, 2019 1:45 PM - 3:15 PM JST | Wed. May 29, 2019 4:45 AM - 6:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_2

[H-TT21] Non-destructive techniques applied to stone cultural heritage

convener:Chiaki T. Oguchi(Institute for Environmental Science and Technology, Graduate School of Science and Engineering, Saitama University), Celine Elise Thomachot-Schneider(Groupe d'etude des environnements naturels, anthropiques et archeologiques - Universite de Reims-Champagne-Ardenne (France)), Wonsuh Song(Waseda University), Miguel Gomez-Heras(Universidad Autonoma de Madrid)

Non-destructive and non-invasive techniques applying to cultural heritage made of stones, soils and earthen materials have been significantly developed over past years, and thus, the interest in such techniques has greatly increased. Here, we focus the session on new devices, new protocols and new data treatments that allow better understanding of weathering mechanisms, decay states and response to treatments.
A few topics would be listed as follows: 1) The development of new techniques and devices in cultural heritage and new protocols using non-destructive techniques; 2) The application of these techniques and protocols on indoor and outdoor case studies and laboratory studies; 3) The assessment of weathering mechanisms, weathering kinetics, decay state, and response to treatments; and 4) The modeling and simulation of decay processes.

Comparison and Analysis of GNSS-RTK Combined with 3D LiDAR Technology on Monument Maintenance Project

*Lih-Shinn Hwang[1], Chien-Hua Chiu[1], Chien-Wen Wang[1], Hsiao-Hung Chen[1]

1. National Defense Univ.

The Precision is the first face problem in the restoration and preservation of Monument Maintenance Project. It may be that the initial coordinates of the position cannot be effectively determined by each object of historical antiquities or buildings, which seriously affects the proportional position when the combination is later reconstructed; or because the relative relationship with the natural environment is neglected, the restoration project is time consuming and even there may be errors that cannot be recovered.
Therefore, external reference control points play an important role in the 3D laser scanning operation of historical antiquities or buildings. Especially for long-term monitoring, it almost determines the accuracy of the following article scanning.
However, due to the unexpected situation on the spot, there are often control points lost, and there is a need for a rebuild-point project, which affects the 3D scanning operation of the later cultural relics. Rebuild-point project requires not only consistent precision, but also convenience and speed. This team takes the ancient house of Li-Tengfang, a national monument, as an example. When this term is studying on the restoration and preservation of Monument Maintenance Project, it is, and proposes newly method of rebuild-point project by comparison. A new method based on the viewpoint of engineering measurement is proposed to improve the lack of traditional operations.
The experimental results show that the GNSS-RTK rapidly-precise-positioning technology can replace the traditional static-measurement to practice rebuild-point project, and the 3D LiDAR ground control measurement which accuracy is enough can also be used as a reference for the other control points. Under the premise of high efficiency and constant accuracy, our team not only successfully introduced the concept of engineering measurement into the restoration and preservation of Monument Maintenance Project, but also completed the all 3D laser scanning operation on Li-Tengfang ancient house. All research processes can be provided to relevant units for reference.

Non-destructive field measurement for investigation of deteriorated parts of an artificial cave

Kaisei Sakane[1], *Chiaki T. Oguchi[1], Yasuhiko TAMURA[2]

1. Institute for Environmental Science and Technology, Graduate School of Science and Engineering, Saitama University, 2. The Exective Committee for the Preservation of Taya Cavern

Non-destructive measurements are useful methods for evaluating weathering degree without any damage on geoarchaeological sites. The present study aims to extract the deteriorated parts by using Silver Schmidt hammer and ultrasonic measurement on the Taya cave in Yokohama city. It is a manmade cave excavated from Kamakura to late Edo periods. Many sculptures and reliefs were carved on the surface of the cave wall made of soft rock. The cave has a complex three-layer structure with a total length of 570 m. Firstly, distribution maps showing cracks and exfoliation parts were created. Then, the points showing low rebound values and slow ultrasonic rates were plotted on the same map. After these on-site measurements, many dangerous parts were turned out within the worship route.

Ultra-portable thermal cameras for moisture detection

*Miguel Gomez-Heras[1], Laura Lopez-Gonzalez[2], Maria Teresa Gil-Muñoz[3]

1. Universidad Autonoma de Madrid, 2. Artfabrik, 3. Universidad Complutense de Madrid

Thermal imaging technology has grown and costs have decreased exponentially from 1987, when the first portable commercially available radiometric system appeared. Several firms produce nowadays ultra-portable thermal cameras that can be fitted in smartphones and tablets, giving resolutions of thermal images up to 320x240 p at a low cost. This facilitates the use of this tool for practitioners as a part of assessment of the state of conservation of heritage buildings and control and monitoring of conservation measurements. Moisture detection is a particular case in which thermal imaging is useful. This communication presents a case study of ultra-portable thermal camera usage for moisture detection and monitoring in two north-facing chapels in the ambulatory of the 14th to 16th Century Cathedral of Palencia (Spain). [Supported by Top Heritage (P2018/NMT-4372) programe from the Regional Government of Madrid (Spain)]

A laboratory experiment on stone decay by combination of salt and ice crystallization

*Masato Sato[1], Tsuyoshi Hattanji[2]

1. Graduate School of Life and environmental Sciences, 2. Faculty of Life and EnvironmentalSciences, University of Tsukuba

A laboratory weathering experiment simulating combination of salt and ice crystallization was carried out using four types of rocks (porous tuff, dense tuff, dense sandstone, and porous andesite) with three types of salts (sodium chloride, sodium sulfate, or magnesium sulfate). The rock specimens were subjected to freeze-thaw cycles in a climatic cabinet where air temperature ranged from -30℃ to 10℃ within 24 hours. Prior to the freeze-thaw experiment, the specimens were immersed in saturated salt solutions at 10˚C or distilled water for 72 hours, and covered with foil for preventing the specimens from drying.
The specimens immersed in saturated salt solutions showed greater weight losses, reductions in Equotip rebound value and longitudinal wave velocity and surface expansion than those immersed in distilled water. Saturated solution of magnesium sulfate induced the greatest damage on rock specimens, although magnesium sulfate has been regarded as an inactive salt in the previous freeze-thaw experiments in which rock specimen were partly immersed in salt solution with dilute or mild concentration. Sodium sulfate induced rock damages comparable with sodium chloride. Sodium and magnesium sulfate crystallized from saturated solution and induced rock expansion prior to freezing. These salt crystals may fill micro-pores in rock and facilitates rock expansion and breakdown due to freezing.

Study of the micro-climatic monitoring on the Saint-Remi Basilica (Rheims, France)

*Emilie Huby[1], Celine Elise Thomachot-Schneider[1], Patricia Vazquez[1], Gilles Fronteau[1]

1. Universite de Reims-Champagne-Ardenne

Historical buildings are subjected to weathering through different factors such as temperature and humidity variations, that have a direct influence on different weathering processes. Insolation produces thermal expansion differences within the stone creating stresses at grain boundaries that can lead to disaggregation. If water is involved, a low temperature can cause the freezing of water inducing ice expansion and cryosuction. These repetitive stresses can damage the stone through fatigue failure. The measurement of environmental parameters on site is essential in order to study the weathering of the stone in its particular environment and anticipate risk areas.
To identify the micro-climatic conditions on a monument, an in situ monitoring was achieved on the Saint-Remi Basilica of Rheims, listed as a UNESCO World Heritage site. A sensor network was set up on the two towers of the monument in December 2017: fourteen temperature-humidity i-Buttons facing different directions, at different heights and recording with a time step of 1 hour, or a time step of 2 minutes for short measurement campaigns.
The data obtained by the sensor network highlighted the microclimates on the building. The height of the measured points had no significant impact on the results, whereas the orientation of the façade had an influence on the surface temperature. This was directly related to the longer solar exposure of the stone throughout the day and allowed to identify micro-climates. The façades exposed to the sun (South, East in the morning, West in the afternoon) present higher temperatures and lower relative humidity compared to the shadowed areas (North, East in the afternoon, West in the morning, other shadowed zones). The relative humidity measured was linked to the temperature: a temperature increase induces a humidity decrease. A mean difference of temperature between South and North of 2,7˚C with a maximum of 18˚C and a mean difference of relative humidity of 4,3% with a maximum of 48% were observed.
Climatic cycles on different time ranges were identified: an annual cycle alternating between winter and summer, a daily cycle due to sun exposure and short cycles identified during short term monitoring. These short abrupt variations of temperature (1-2˚C) on façades lasted between 5 and 40 minutes and were due to cloud cover and/or wind-speed. Four typical days inducing strains were identified: sunny days with a temperature increase superior to 10˚C, rainy days inducing wet/dry cycles, frost days presenting frost/thaw cycles and stormy days where a sudden rain on heated stones caused abrupt temperature and humidity variations. A year can thus be fragmented in those 4 categorized days. This repartition of typical days over a year depended on the micro-climatic variations previously identified: the shadowed zones experienced less sunny days and more rainy days.
This study of climatic monitoring will help anticipate the stone weathering on the Saint-Remi Basilica. The monitoring will continue for the next two years in order to obtain reproducible data and will be coupled with an infrared thermography monitoring. The strains corresponding to the four identified types of day are reproduced through accelerated ageing experiments using the parameters recorded on site. From the repartition of these typical days in one year, this will allow to estimate the behavior of a stone during a year on a sun-exposed façade and on a shadowed zone of the Basilica. The final goal is to be able to anticipate the stone weathering on the monument and identify risk areas.

[H-TT21] Non-destructive techniques applied to stone cultural heritage

convener:Chiaki T. Oguchi(Institute for Environmental Science and Technology, Graduate School of Science and Engineering, Saitama University), Celine Elise Thomachot-Schneider(Groupe d'etude des environnements naturels, anthropiques et archeologiques - Universite de Reims-Champagne-Ardenne (France)), Wonsuh Song(Waseda University), Miguel Gomez-Heras(Universidad Autonoma de Madrid)

Non-destructive and non-invasive techniques applying to cultural heritage made of stones, soils and earthen materials have been significantly developed over past years, and thus, the interest in such techniques has greatly increased. Here, we focus the session on new devices, new protocols and new data treatments that allow better understanding of weathering mechanisms, decay states and response to treatments.
A few topics would be listed as follows: 1) The development of new techniques and devices in cultural heritage and new protocols using non-destructive techniques; 2) The application of these techniques and protocols on indoor and outdoor case studies and laboratory studies; 3) The assessment of weathering mechanisms, weathering kinetics, decay state, and response to treatments; and 4) The modeling and simulation of decay processes.

SfM (Structure-from-Motion) photogrammetry is one of the methods for creating 3D models of objects by extracting feature points in the images. Taya Cave, the investigation site of the present study, is a historical site of Yokohama City. It has about 200 base-reliefs on the surface of the cave tunnel walls, however, they are suffering from weathering and difficult to preserve from it in the future. The cave was excavated in Kamakura Era originally, and has a total length of 570 m with a three-layer structure. The present study tried to make a 3D model of this complicated, dark and narrow cave by SfM photogrammetry. The accuracy of the created 3D model were evaluated by comparing the values of distances between from the 3D model and from 2016 actual survey data.

Conservation of an underground cultural heritage is often a controversial issue due partly to its invisibility and insufficient awareness in the local society. Also, the safety assessment is necessary to promote sustainable protection of an underground cultural heritage. The developments in high-definition topographic measurements enable to acquire detailed three-dimensional morphological data of a cave, which can be further utilized for the visualization and structural analyses. Regarding the measurements and visualization, we present a case study at the Taya Cave, a registered cultural heritage in Yokohama City, Kanagawa Prefecture in central Japan. The terrestrial laser scanning was performed from multiple scan positions throughout the cave, and the point clouds were registered using the feature-based iterated closest point algorithm. The registered point clouds were then converted into a mesh model, to which face error corrections and a solid filling were applied. After these processes, the mesh model can be printed out in three dimensions. The 3D print model of the cave is used for the class teaching in an elementary school in the local area, and such the visualization of the cave successfully enhanced the recognition by students regarding the underground cultural heritage. The 3D data can also be utilized for the structural assessment of the cave. Effective and sustainable protection of the cave will further be possible by integrating such geotechnical assessments and outreach activities in the local society.

Conservation restoration of the world heritage of Okinawa Prefecture, Sonohyan-utaki Ishimon - Situation after 30 years since filling with mortar and applying silicone resin.

*Wonsuh Song[1], Tadateru Nishiura[2], Chiaki T. Oguchi[3]

1. Waseda University, 2. Kokushika Univeristy, 3. Saitama University

Sonohyan-utaki Ishimon in the Shuri Castle Park has been registered as a World Heritage Site in 2000 as a place of "Gusuku and related heritage group of the Ryukyu Kingdom". The stone gate (Ishimon) and the forest behind it are called Sonohyan-utaki and used as a place of worship for praying for safety when the King of the Ryukyu Kingdom goes out. It was built with Ryukyu Limestone in 1519, was designated as the old national treasure in 1933 but was destroyed in the battle against Okinawa, was restored in 1957, and repaired in 1986. It became the national designated building in 1972. At the time of demolition repair, an old roof stone was used, but cleaning and water repellent silicone resin impregnation and surface filling were done at this time. Currently, as can be seen in Figure 1, the color of the entire stone gate becomes darker, the difference in color between the filling part of the roof and the original stone is becoming noticeable. The purpose of this study is to be used for the repair treatment in the future.
In order to understand the color of the surface of the repaired roof and the overall color of the stone gate, quantitative measurements were made using a spectroscopic colorimeter (Konica Minolta, CM-700d) at 51 locations on the surface of the stone gate. The proportion of blackened parts was determined from the front of the stone gate using Photoshop. To measure the surface temperature of the stone gate, we grasped the temperature distribution of the surface using the FLIR thermal camera.
We installed a button type temperature and humidity measuring instrument in the upper left side of the stone gate with the permission of Naha City to grasp the change of temperature and humidity in the year-round. As a result of the measurement by the spectrophotometer, the color of limestone was bright, and it was almost the same color as the repair material in the roof part. However, the discoloration rate and the situation were different after 30 years. The repair material was gray, and it was found that the original stone was darker. The average annual temperature observed under the roof of the stone gate was 24 ˚c, and the average humidity was 81.5%, and the characteristics of the hot and humid subtropical climate were observed. The average temperature in winter was 22.1 ˚c, and the humidity was 80% and the lowest temperature was 8.5 ˚c. Therefore, it seems that the growth of vegetation is very fast and it may affect the color of rock surface.

Application of portable XRF analysis for provenance of seabed worked stone in coastal are of Kochi Prefecture

*Wataru Tanikawa[1], Go-Ichiro Uramoto[2], Masafumi MURAYAMA[2], Yohei Hamada[1], Yuhji Yamamoto[2], Osamu Tadai[3]

1. Japan Agency for Marine-Earth Science and Technology, Kochi Instutute for Core Sample Research, 2. Kochi University, Center for Advanced Marine Core Research, 3. Marine Works Japan LTD.

Many stone pillars around 1m long, which look like artifacts, lie on the seafloor in off Tsumajiro, Kochi Prefecture, Japan. Tsumajiro area has been repeatedly damaged by tsunami from Nankai earthquakes, and extreme rainfalls by typhoon events. Therefore, we suggest that a tsunami or river floods might have transported the pillars offshore, or coseismic land subsidence might have caused them to become submerged. To assess the origin of the submerged stone pillars in the Tsumajiro area (Tsumajiro pillars), we analyzed mineralogy, geochemistry and physical property of Tsumajiro pillars, of rocks from natural expores and quarries in Tsumajiro and neighboring areas, and of building stones in use in the Tsumajiro area. We analyzed concentrations of major and trace elements in samples using a portable X-ray fluorescence (pXRF) spectrometer, and estimated mineral composition of samples using powdered XRD analysis. Porosity and grain density were also measured on all samples.

In the XRF spectral data, we clearly recognized peaks for 12 elements (Mg, Si, S, K, Ca, Ti, Mn, Fe, Rb, Sr, Zr, and Pd) in all samples. Therefore, we selected these 12 elements for PCA. In the PCA results for all samples, we could clearly divide those into sandstone group and shale group from the first principle component, where components of Mg, Fe, and Ti strongly influenced. In PCA results for sandstone only, we could see the characteristics of each samples much more clearly. Submerged pillars showed similar characteristics, where a component of Zr was strongly contributed, with Tatsukushi formation in Misaki group (natural exposures and quarries) and foundation stones for main building at Tsumajiro area. Porosity, grain density, and mineral composition were also similar between Tsumajiro pillars, Tatsukushi formation, and a foundation stone.
Our results suggest that the submerged stone pillars were made from Tatsukushi sandstone and had been utilized as building stones for structures such as steps and foundations in Tsumajiro village.

pXRF analyses on Assyrain sculptures

*Ryo Anma[1], Ki-Cheol Shin[2], Chikako Watanabe[3], Akihiro Tuji[4]

1. Graduate School of Technology, Industrial and Social Sciences, Tokushima University, 2. Research Institute for Humanity and Nature, 3. Faculty of International Studies, Osaka Gakuin University, 4. National Museum of Nature and Science

To evaluate a possibility of reconstruction and understanding the provenance of stone materials used in the ancient cities of Western Asia, some of which have been destroyed and/or dismantled, and are moved to different places of the world, we characterized the bulk geochemical composition of gypsum-carbonate rocks, on which the Assyrians carved sculptures to decollate their palaces, using an Olympus VANTA portable X-ray fluorescence spectroscopy (pXRF). To establish the methodology, we started with the Assyrian sculptures with known provenance: i.e. the collections of the British Museum, the Ashmolean Museum, Magdalen College (Oxford), the Okayama Orient Museum and the MIHO museum.
The pXRF analysis was performed using a Rh target at 40 kV and 100 μA. Beam time was 20 seconds for Beam 1 and 15 and 30 seconds, in later sessions, for Beam 2. The accuracy and precision of the analyses were assessed by analyzing several powdered reference samples of igneous rocks (JB-2 basalt, JA-1, JA-2 andesites, JR-2 rhyolite JG1, JG2 granites and JGb-1 gabbro) and sedimentary rocks (JLk-1 lake sediment, JSd-1 and JSd-2 river sediments, JLs-1 limestone and JDo-1 dolomite) distributed by the Geological Survey of Japan, and gypsum samples (alabaster, selenite and satin spar) distributed by Nichika Inc. We performed the measurement three-times for each spot to assess repeatability of the measurement and/or inhomogeneity of the samples.
Our results showed that ~ 99% of the measured Assyrian sculptures were made of gypsum-anhydrate rocks. Although their distribution fields largely overlap, the gypsum sculptures from Nineveh tend to have more impurities when compared with those from Nimrud and Khorsabad. Visually, the stone materials used in the sculptures in Nimrud often have homogeneously distributed large gypsum crystals, whereas those from Nineveh are rather inhomogeneous and finer in grain size, and often exhibit developed bedding planes. Together with the textural changes, we provisionally conclude that degraded stone materials became used over time.
The Til-Tuba sculpture from Room 33 of the Southwest Palace of Nineveh has higher Ca and lower S contents compared with others. Visually, it contains numerous foraminifera shells of *Alveolinidae Sp*. The different chemical composition could be attributed to the amount of the included foraminifera shells. Stones from Room 36 of Nineveh Southwest Palace have slightly higher Al and Fe contents than others. Although, few such examples have somewhat different compositions, the exact provenance would not be able to identify from a single chemical data. More information obtained through destructive analyses would be necessary for the reconstruction and understanding the provenance of stone materials, such as textural and mineralogical information through thin-section observation, crystallographic information through XRD analysis and analyses of micro-fossils.
Nevertheless, our observation from a material science point of view can provide evidence to what Sennacherib (705-681 BCE) described in his text. The king states that he used “Na_4.^{d}Še.tir” stone from Nipur (Judi Dagh in SE Turkey) that looks like cucumber seeds to construct the statues of Aladlammû and *Apsātu*. Based on this, Mitchel and Middleton (2002) speculated that this same stone was used for the reliefs in Room 33 of the Southwest Palace, Nineveh. If their speculation is correct, evaporites of the middle to late Miocene Fars formation should have comprised the quarry.

[E] Poster | H (Human Geosciences)：H-CG Complex & General

Wed. May 29, 2019 3:30 PM - 5:00 PM JST | Wed. May 29, 2019 6:30 AM - 8:00 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_15

[H-CG25] International Comparison of Landscape Appreciation

convener:Anastasia Petrova(Institute of Oriental Studies of the Russian Academy of Sciences), yoji aoki(Open University of Japan)

Evaluation of landscape has been developed in a variety of fields, such as geography, landscape architecture, nature protection, and some others. Landscape appreciation is a complex and sophisticated psychological phenomenon. There is no consensus among researchers on what the phenomenon of "landscape" truly is, how people physiologically and mentally experience it, which human attributes affect the perception of it, and why it is apprehended the way it is. The concept of landscape appreciation has yet to be clearly defined and there is a lack of agreement on evaluation methods, the factors that determine landscape preferences, the steps in appreciation, and so forth. This session aims to discuss the research findings of landscape evaluation in various fields, including geography, geomorphology, landscape planning, architecture, engineering, social sciences, environmental psychology, meteorology, phenology, and so on.

The Globally Important Agricultural Heritage of Aso from the perspective of landscape and its supporting systems

*REIKO MACHIDA[1]

1. TOKYO UNIVERSITY OF AGRICULTURE

Globally Important Agricultural Heritage Systems (GIAHS) is a partnership initiative of the Food and Agriculture Organization of the United Nations which began in 2002 with the aim to identify, support and safeguard remarkable land use systems and landscapes that are rich in globally significant biological diversity evolving from the co-adaptation of a community with its environment and its needs and aspirations for sustainable development. There are 19 countries and 45 areas around the world, and among them 9 areas in Japan that are listed as GIAHS at present.The Aso area located in Northern Kyusyu features the world's largest caldera, which is 25 km wide from north to south and 18 km from east to west and grassland landscapes. The vast grasslands of the Aso area have been managed throughout history by local agricultural activities such as controlled burning, mowing and pasturage since the Heian period. The historical land use in Aso has been a balanced combination of rice fields at the caldera floor, forestry and fungiculture at the foot of the caldera, and grazing pasture at the top of caldera, which is carried out in harmony with the environment. The management of the Aso grasslands for sustainable agriculture have been recognized and certified as Globally Important Agricultural Heritage Systems (GIAHS) in 2013.In terms of landscape, the values of Aso as Globally Important Agricultural Heritage System are the dynamic grassland landscapes of the large caldera, the historical paddies and rice terraces, which vary in size from small to large as a result of the local human activities. There are beautiful rural landscapes on various scales.However, the productivity oriented rural development and the division of land has been having a negative impact on the landscape value of the GIAHS. There are cases of rice paddies and buildings that contribute to the landscape value being lost. From such cases, it is evident that the landscape structures that should be protected since they are GIHS are not recognized widely enough.This study investigated the landscape value and landscape structure as GIAHS and its value supports landscape policy. As a result, it became clear that the landscape structure of Minamiaso village consist of the traditional combination of grasslands and paddy fields retains significant wildlife habitat and picturesque agricultural landscapes. It has become clear that development activities do not influence to landscape in large-scale, however development activities as land readjustment project influenced to landscape in small and medium-scale. "Landscape planning" "Landscape agricultural development plan" can support the landscape structure in small and medium -scale. It is important to plan the land use for the landscape value of GIAHS.

Hazardous natural phenomena and weather conditions appreciation in Russian landscape painting

*ELENA PETROVA[1]

1. Lomonosov Moscow State University, Faculty of Geography

The fixation of various natural phenomena by landscape artists of different historical periods in different regions and countries has not only purely aesthetic interest, but also particular interest to science. During the period of Romanticism that has spread in the European and Russian art in the 19th century, Russian art turned to real living nature. Landscapes of the native country began to play a dominant role in the formation of landscape image. Romanticism aroused interest not only in the picturesque and exotic landscapes, but also in the majestic forces of nature. Volcanic eruptions, earthquakes, storms, thunderstorms, floods, and other natural hazards were new motifs for artists of that time. Romantic artists were inclined to exaggerate the power and destructive forces of natural phenomena they portrayed, elevating any event of this kind to the rank of a natural disaster. Often, they portrayed the rather ordinary storm, thunderstorm, flood as a universal natural catastrophe, comparable, perhaps, only to the biblical flood. What to say about really extraordinary events. Most vividly, the theme of the turbulent, dramatic landscape was developed in the works by Aivazovsky who quite realistically showed the sea element in various stages of its manifestation - from complete calm to the strongest storm. Being in Italy, Russian artists could not disregard such an extraordinary event as the violent eruption of the volcano Vesuvius, which occurred in 1822; many have captured it in their landscape images.

Thanks to the rapid development of scientific knowledge and discoveries in the field of geosciences, including meteorology, artists were encouraged to observe various atmospheric phenomena and weather conditions. Gradually, the sky ceased to be depicted simply as a smooth blue background, as was customary in the tradition of classicism; carefully traced clouds of various types, shapes and shades began to appear in pictures. In addition, various evaporations, fogs, haze, etc. became objects of the landscape image. Romantic artists were little interested in depicting winter and snow, despite the fact that the cold season with a steady snow cover continues in Russia for almost half a year from November to early April. The painting “Russian Winter” (1827) by Nikifore Krylov became perhaps the first winter landscape image in Russian painting. Krylov depicted a somewhat naive, but quite real, winter landscape on the bank of the Tosna River in the vicinity of St. Petersburg, which he painted from life. He was able to reliably convey the atmosphere of the Russian winter: a valley covered with snow, a frozen river, a dark strip of forest in the distance and the peasants with their daily affairs on the road down to the river in the foreground. The first bright and joyful snow-covered landscape image was created, apparently, by Alexey Savrasov in his famous painting “The Rooks Have Come Back” (1871). The spring snow melting and sparkling in the sun became later the favorite motif of the Russian painting. Comparative analysis of landscape pictures can be an important tool, in addition to scientific methods, in studying the nature and dynamics of various hazardous natural processes and phenomena, including hydrological and meteorological ones in conditions of changing climate.

Trends of evaluation items to landscape appreciation until 2017 in the English journals

*yoji aoki[1], keisuke mukagai[2], Anastasia Petrova[3]

1. Open University of Japan, 2. Nagano University, 3. Institute of Oriental Studies, Russian Academy of Sciences

Introduction
We have considered trends of landscape appreciation since JpGU2013-2018. According to the definition of landscape phenomena proposed by Prof. O. Shinohara (Fig. 1), we reported the trends of studies in each part of the phenomena.

Aoki, Y. (1999) described the first landscape evaluation using psychometrical methods to be pioneered by Peterson, G.L. (1967). Before this development, they tried to find the landscape appreciation using various descriptors. They were mostly belonging to the literature or the paintings. As for the literature, the first description of mountain was found in Francesco Petrarca in 1336 of France (Kondo, T. 2002). But his description has no reliable evidence to ensure the landscape. In the field of art, Albrecht Altdorfer drew the first natural landscape in the beginning of 15th century of Germany (Cavaliere, B. 1989). But we could not measure the physical data from his picture. The literature and the art found the beauty of natural landscape by these examples. They recorded the aesthetic beauty in landscape (Thiel, P. 1968).

Jay Appleton (1980) explained the scientific reason of the landscape phenomena with physical data, e.g. geomorphysical data and meteorological data. He explained the landscape phenomena of two pictures, Constable's Weymouth Bay and Constable's sunset study of Hampstead Heath. His approach must be the scientific based explanation to find psychological phenomena of landscape using the geology and meteorology. But the psychological phenomena could deviate by the person observed and the results must be happened statistically. So the process of the landscape phenomena should be explained by stochastic process of psychology. Then scientists developed psychological approach to it.

Here, we summarize the appreciation item (the third component of the landscape phenomena).

1. The developments to establish the psychological scale of appraisal

In the trial of psychometrical method, Ekman & Kuennapas (1962) tested the difference of Nominal scale and Interval scale, and the development of SD method promoted to use many adjectives in the visual complexities (Berlyne & Peckham 1966). Hart & Graham (1967) considered “How to rate & rank landscape”.

In the development of the psychological scale, Heise (1969) tested the scale -3 to 3, and Zube, Anderson & Pitt (1973) used the numerical scale 3 to 14.

2. The psychological evaluation item of preference

Kaplan, Kaplan, & Wendt (1972) proposed to use preference for the landscape appreciation. Compared to the results obtained by SD method, “preference” is easy to understand among different cultural back ground and was popularized in many countries.

©2019. Japan Geoscience Union. All Right Reserved.

3. The developments and the use of SD method

As for the SD method proposed by Osgood & Suci (1955), it employed many pairs of adjectives to evaluate landscape and provided detailed impressions of landscape. The largest number of 240 adjectives was tested by Craik (1975). The results were too complicated and scientists would like to summarize the results. SBE (Terry & Boster 1976), AVQ (Arriaza etc. 2004) and others were statistical aggregation examples of this trial and the example of meaningful aggregation was “Coherence, Complexity, Legibility and Mystery” proposed by Kaplan (1987). These indicators were tested with the relation to the preference and other appreciations by many scientists (Stamps III 2004, and so on.).

4. Method of monetary term evaluation

Monetary term is another evaluation of landscapes and sometimes used in the physical planning (Fukahori & Kubota 2003).

5. Items based on the human behavior of landscape evaluation

The origin of the landscape appreciation was explained from the animal behavior of predation (Appleton 1975). This theory had discussed for a long time. And this behavior might propose a base appreciation of landscape (Aoki & Kitamura 2001). Consideration on the human activities, the reason of visit (Andereck et al. 1989) and the visitability (Abdulkarim & Nasar 2014) were examined and the photographing (Oku & Fukamachi 2006, Sugimoto 2013) were reported.

6. Other appraisals

There are many appreciation descriptors and even now the scientists are finding new descriptors (Collier & Scott 2008). Until now, we could find examples of this trial in absorption (Berlyne 1958), quietness (Womble & Studebaker 1981), beauty (Hull IV, Buhyoff & Daniel 1984), size (Coeterier 1994), fear and stress (Nasar & Jones 1997), positive and negative (Ryan 1998), aggression and violence (Kuo 2001), satisfaction (Kaplan & Austin 2004), overcrowding (Manning & Freimund 2004), openness (Dramstad et al. 2006), ugly (Ruell, Halleux & Teller 2013), and other descriptions.

Table Historical review of landscape appreciation items

Interesting subject	Name of authors	Year
Development of the SD method	Osgood, C.E. and Suci, G.J.	1955
absorption	Berlyne, D.E.,	1958
descriptive appreciation as aesthetic beauty	Thiel, P.,	1961
difference of Nominal scale and Interval scale	Ekman, G. and Kuennapas, T.	1962
SD method	Wright, B. and Rainwater, L.	1962
description	Halprin, L.,	1965
absorption	Berlyne, D.E. and Peckham, S.	1966
description	Noe, S. and Abernathy, B.L.	1966
landscape type	Hart W. J. and William W. Graham,	1967
absorption	Wohlwill, J.F.	1968
numerical scale from -3 to +3	Heise, D.R.,	1969
aesthetic and emotional	Shafer, E.L. and Mietz, J.	1969
objectivity	Craik, K.H.	1972
preference	Kaplan, S., Kaplan, R. and Wendt, J.S.	1972
scaling	Acking, C.A and Sorte, G.J.	1973
numerical scale from 3 to 14	Zube, E.H., Anderson, T. and Pitt, D.	1973
prospect-refuge theory	Appleton, J.	1975
SD method with 240 pairs of adjectives	Craik, K.H.	1975
SBE method; normalization of the results	Daniel, T.C. and Boster, R.S.	1976
monetary	McConnell, K.E.,	1977
SD method	Pedersen, D.M.	1978
SD method	Shuttleworth, S.	1980
preference	Nasar, J.L.,	1981
meaning	Russell, J.A. and Ward, L.M.	1981
quiet	Womble, P. and Studebaker, S.	1981
quiet	Hammitt, W.E.,	1982
preference	Mudrak, L.Y.,	1983
preference	Nasar, J.L.,	1983
SD method	Ruiz, J.P. and Gonzalez-Bernaldez, F.	1983
scenic beauty	Hull IV, R.B., Buhyoff, G.J. and Daniel, T.C.	1984
needs and fears	Talbot, J.F. and Kaplan, R.	1984
preference	Herzog, T.R.	1985
SD method	Abello, R.P., Bernaldez, F.G. and Galiano, E.F.	1986
preference	Talbot, J.F. and Kaplan, R.	1986
survey paper: Coherence, Complexity, Legibility, Mystery	Kaplan, S.	1987
SD method	Kobayashi, M., Higashiyama, J. and Kawasaki, K.	1987
preference	Talbot, J.F., Bardwell, L.V. and Kaplan, R.	1987
monetary	Anderson, L.M. and Cordell, H.K.	1988
preference	Herzog, T. and Smith, G.A.	1988
motivation to visit	Andereck, K. et al.	1989
evaluation by monetary term	Daniel, T.C., et al.	1989
SD method	Kaplan, R., Kaplan, S. and Brown, T.	1989
SD method	Ruiz, M. and Ruiz, J.P.	1989
preference	Gimblett, H.R.	1990
monetary	Green, C.H., et al.	1990
motivation to visit	Uysal, M., McDonald, C.D. and Reid, L.J.	1990
quiet	Ulrich, R.S. et al.	1991
preference	Chokor, B.A	1992
preference	Herzog, T.	1992
refuge provides shelter	Hudson, B.J.	1992
effect to land price	Orland, B., Vinning, J. and Ebreo, A.	1992
familiarity	Purcell, A.T.	1992
description: literature works	Ikeda, T. and Konno, A.	1993
size of space	Coeterier, J.F.,	1994
identity	Hull IV, R.B., Lam, M. and Vigo, G.	1994
preference	Stamps III, A.E.	1994
preference	Strumse, E.	1994
preference	Sullivan III, W.C.,	1994
prospect-refuge theory reviewed	Appleton, J.,	1995
motivation to visit	Cha, S., McCleary, K.W. and Uysal, M.	1995
preference	Mealey, L.	1995
preference on tree form	Sommer, R. and Summit, J.	1995
preference	Herzog, T.R. and Gale, T.A.	1996
scenic preference in Finland	Karjalainen, E.	1996
scaling	Tahvanainen, L., Tyrvainen, L. and Nousiainen, I.	1996
Notation for a Participatory Envirotecture	Thiel, P.,	1996
fear and stress	Nasar, J.L. and Jones, K.M.	1997
landscape preferences of USA, Ireland, Senegal	Newell, P.B.	1997
quiet	Caffyn, A. and Prosser, B.	1998
preference	Herzog, T.R.,	1998
consistency of evaluation by rank order and graphical scale	Karjalainen, E. and Komulainen, M.	1998
preference	Kuo, F.E., Bacaicoa, M. and Sullivan, W.C.	1998
preference and naturalness using Scrub-forest, wide-close view, nature-altered	Purcell, A.T. and Lamb, R.J.	1998
positive and negative scenery of river frontland	Ryan, R.L.	1998
monetary	Tyrvainen, L. and Vaananen, H.	1998
preference	Brown, T.J., Kaplan R. and Quaderer, G.	1999
tranquility and preference	Herzog, T.R. and Barnes, G.J.	1999
preference	Summit, J. and Sommer, R.	1999
landscape preference in Australia	Herzog, T.R. et al	2000
landscape preference in Israel	Misgav, A.	2000
Phylogenic and Ontogenic evolution of landscape appreciation	Aoki, Y. and Kitamura, S.	2001
correlation between preference and likeliness	Hagerhall, C.M.	2001
motivation of ecological behavior	Hartig, T.	2001
aggression and violence	Kuo, F.E.,	2001
preference and danger	Herzog, T.R. and Kutzli, G.E.	2002
landscape preference in Norway	Kaltenborn, B.P. and Bjerke, T.	2002
positive and negative scenery of rural living	Ryan, R.L.,	2002
comparison of VOC and SBE	Franco, D. et al.	2003
cost and amenity level of road scenery	Fukahori, K. and Kubota, Y.	2003
preference	Herzog, T.R. and Leverich, O.L.	2003
AVQ index for visual quality	Arriaza, M. et al.	2004
preference	Herzog, T.R. and Kropscott, L.S.	2004
satisfaction of nature	Kaplan, R. and Austin, M.E.	2004
over crowding by photo montage method	Manning, R.E. and Freimund, W.A	2004
SBE difference 1976-1996	Palmer, J.F.	2004
preference did not correlate to mystery, complexity, legibility, coherence	Stamps, III, A.E.	2004
preference and danger by visibility	Herzog, T.R., & Kirk, K.M.	2005
preference by pair comparison	Rodiek, S.D. and Fried, J.T.	2005
proper openness, student and locals	Dramstad, W.E., et al.	2006
essential features for scenic beauty	Ergin, A., Williams, A.T. and Micallef, A.	2006
landscape preferred in Turkey	Kaplan, A., Taskin, T. and Onenc, A.,	2006
photographing by activity	Oku, H., & Fukamachi, K.	2006
disturbance, naturalness, visual scale, place identity in the photographs	Tveit, M., Ode, A. and Fry, G.	2006
mystery did not affect preference	Herzog, T.R. and Bryce, A.G.,	2007
words interested in the interview	Collier, M.J. and Scott, M.J.	2008
preference of transportation system; vegetation, distance, side fascia affected	Bernasconi, C. et al.	2009
beautiful high mountain, Sherpa appreciate flora, ugly garbage site no vegetation at Everest	Beza, B.B.	2010
species-rich of middle ground affect like of alpine landscape	Lindemann-Matthies, P. et al.	2010
naturalness, unity affect preference of Spruce forest landscape in Turkey	Eroglu, E. and Acar, C.	2011
surprise and Mystery affect preference, Turkey find Mystery at curved street	Nasar, J.L. and Cubukcu, E.	2011
ugly impression of brown fields and montage support improvement in Belgium	Ruelle, C., Halleux, J.-M. & Teller, J.	2013
Visitability	Abdulkarim, D. and Nasar, J. L.	2014
oppressiveness	Asgarzadeh, M. et al.	2014
threat	Chiang, Y-C., Nasal, J. and Ko, C-C.	2014
variance affected by evaluation value	Kalivoda, O. et al.	2014
forest and park affected stress relief	Tyrvainen, L., Ojala, A., Korpela, K. Lanki, T., Tsunetsugu, Y., Kagawa, T.	2014
proper understorey affect preference	van der Wal, R., Miller, D., Irvine, J., Fiorini, S., Amar, A., Yearley, S. Gill, R. & Dandy, N.	2014
openness	Weitkamp, G., Lammeren, R. and Bregt, A.	2014
risk of bushfire	Gill, N. et al.	2015
water use affect landscaping preference	Hayden, L., et al	2015
panorama tree cover density affect to preference	Jiang, B., et al.	2015
green roof affect restorativeness	Lee, K.E., Williams,K.J.H., Sargent, L.D., Williams, N.S.G., Johnson, K.A	2015
aesthetic, morphological condition and ecological integrity	McCormick, A, Fisher, K. and Brierley, G.	2015
water, reed, litter, dead wood affected preference	Eder, R., & Arnberger, A.	2016
tree coverage affect stress recovery	Jiang, B., Li, D., Larsen, L. & Sullivan, W.C.	2016
visual realism and sound affect preference	Lindquist, M., Lange, E. & Kang J.	2016
change of motivation	Shalev, I.	2016
cultural values in visual object	Sowinska-Swierkosz, B.N., Chmielewski, T.J.	2016
visual green reduces noise annoyance	Van Renterghem, T. & Botteldooren, D.	2016
public litter and fishing litter affect preference	Wyles, K.J., Pahl, S. Thomas, K. & Thompson, R.	2016
disorder affect fear of crime	Biasi, Alaina De	2017
nature contact reduce depression, anxiety, stress in outside experience	Brooks, A.M. et al.	2017

[E] Poster | H (Human Geosciences)：H-CG Complex & General

Wed. May 29, 2019 5:15 PM - 6:30 PM JST | Wed. May 29, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_24

[H-CG25] International Comparison of Landscape Appreciation

convener:Anastasia Petrova(Institute of Oriental Studies of the Russian Academy of Sciences), yoji aoki(Open University of Japan)

Evaluation of landscape has been developed in a variety of fields, such as geography, landscape architecture, nature protection, and some others. Landscape appreciation is a complex and sophisticated psychological phenomenon. There is no consensus among researchers on what the phenomenon of "landscape" truly is, how people physiologically and mentally experience it, which human attributes affect the perception of it, and why it is apprehended the way it is. The concept of landscape appreciation has yet to be clearly defined and there is a lack of agreement on evaluation methods, the factors that determine landscape preferences, the steps in appreciation, and so forth. This session aims to discuss the research findings of landscape evaluation in various fields, including geography, geomorphology, landscape planning, architecture, engineering, social sciences, environmental psychology, meteorology, phenology, and so on.

The Globally Important Agricultural Heritage of Aso from the perspective of landscape and its supporting systems

*REIKO MACHIDA[1]

1. TOKYO UNIVERSITY OF AGRICULTURE

Globally Important Agricultural Heritage Systems (GIAHS) is a partnership initiative of the Food and Agriculture Organization of the United Nations which began in 2002 with the aim to identify, support and safeguard remarkable land use systems and landscapes that are rich in globally significant biological diversity evolving from the co-adaptation of a community with its environment and its needs and aspirations for sustainable development. There are 19 countries and 45 areas around the world, and among them 9 areas in Japan that are listed as GIAHS at present.The Aso area located in Northern Kyusyu features the world's largest caldera, which is 25 km wide from north to south and 18 km from east to west and grassland landscapes. The vast grasslands of the Aso area have been managed throughout history by local agricultural activities such as controlled burning, mowing and pasturage since the Heian period. The historical land use in Aso has been a balanced combination of rice fields at the caldera floor, forestry and fungiculture at the foot of the caldera, and grazing pasture at the top of caldera, which is carried out in harmony with the environment. The management of the Aso grasslands for sustainable agriculture have been recognized and certified as Globally Important Agricultural Heritage Systems (GIAHS) in 2013.In terms of landscape, the values of Aso as Globally Important Agricultural Heritage System are the dynamic grassland landscapes of the large caldera, the historical paddies and rice terraces, which vary in size from small to large as a result of the local human activities. There are beautiful rural landscapes on various scales.However, the productivity oriented rural development and the division of land has been having a negative impact on the landscape value of the GIAHS. There are cases of rice paddies and buildings that contribute to the landscape value being lost. From such cases, it is evident that the landscape structures that should be protected since they are GIHS are not recognized widely enough.This study investigated the landscape value and landscape structure as GIAHS and its value supports landscape policy. As a result, it became clear that the landscape structure of Minamiaso village consist of the traditional combination of grasslands and paddy fields retains significant wildlife habitat and picturesque agricultural landscapes. It has become clear that development activities do not influence to landscape in large-scale, however development activities as land readjustment project influenced to landscape in small and medium-scale. "Landscape planning" "Landscape agricultural development plan" can support the landscape structure in small and medium -scale. It is important to plan the land use for the landscape value of GIAHS.

Hazardous natural phenomena and weather conditions appreciation in Russian landscape painting

*ELENA PETROVA[1]

1. Lomonosov Moscow State University, Faculty of Geography

The fixation of various natural phenomena by landscape artists of different historical periods in different regions and countries has not only purely aesthetic interest, but also particular interest to science. During the period of Romanticism that has spread in the European and Russian art in the 19th century, Russian art turned to real living nature. Landscapes of the native country began to play a dominant role in the formation of landscape image. Romanticism aroused interest not only in the picturesque and exotic landscapes, but also in the majestic forces of nature. Volcanic eruptions, earthquakes, storms, thunderstorms, floods, and other natural hazards were new motifs for artists of that time. Romantic artists were inclined to exaggerate the power and destructive forces of natural phenomena they portrayed, elevating any event of this kind to the rank of a natural disaster. Often, they portrayed the rather ordinary storm, thunderstorm, flood as a universal natural catastrophe, comparable, perhaps, only to the biblical flood. What to say about really extraordinary events. Most vividly, the theme of the turbulent, dramatic landscape was developed in the works by Aivazovsky who quite realistically showed the sea element in various stages of its manifestation - from complete calm to the strongest storm. Being in Italy, Russian artists could not disregard such an extraordinary event as the violent eruption of the volcano Vesuvius, which occurred in 1822; many have captured it in their landscape images.

Thanks to the rapid development of scientific knowledge and discoveries in the field of geosciences, including meteorology, artists were encouraged to observe various atmospheric phenomena and weather conditions. Gradually, the sky ceased to be depicted simply as a smooth blue background, as was customary in the tradition of classicism; carefully traced clouds of various types, shapes and shades began to appear in pictures. In addition, various evaporations, fogs, haze, etc. became objects of the landscape image. Romantic artists were little interested in depicting winter and snow, despite the fact that the cold season with a steady snow cover continues in Russia for almost half a year from November to early April. The painting “Russian Winter” (1827) by Nikifore Krylov became perhaps the first winter landscape image in Russian painting. Krylov depicted a somewhat naive, but quite real, winter landscape on the bank of the Tosna River in the vicinity of St. Petersburg, which he painted from life. He was able to reliably convey the atmosphere of the Russian winter: a valley covered with snow, a frozen river, a dark strip of forest in the distance and the peasants with their daily affairs on the road down to the river in the foreground. The first bright and joyful snow-covered landscape image was created, apparently, by Alexey Savrasov in his famous painting “The Rooks Have Come Back” (1871). The spring snow melting and sparkling in the sun became later the favorite motif of the Russian painting. Comparative analysis of landscape pictures can be an important tool, in addition to scientific methods, in studying the nature and dynamics of various hazardous natural processes and phenomena, including hydrological and meteorological ones in conditions of changing climate.

Trends of evaluation items to landscape appreciation until 2017 in the English journals

*yoji aoki[1], keisuke mukagai[2], Anastasia Petrova[3]

1. Open University of Japan, 2. Nagano University, 3. Institute of Oriental Studies, Russian Academy of Sciences

Introduction
We have considered trends of landscape appreciation since JpGU2013-2018. According to the definition of landscape phenomena proposed by Prof. O. Shinohara (Fig. 1), we reported the trends of studies in each part of the phenomena.

Aoki, Y. (1999) described the first landscape evaluation using psychometrical methods to be pioneered by Peterson, G.L. (1967). Before this development, they tried to find the landscape appreciation using various descriptors. They were mostly belonging to the literature or the paintings. As for the literature, the first description of mountain was found in Francesco Petrarca in 1336 of France (Kondo, T. 2002). But his description has no reliable evidence to ensure the landscape. In the field of art, Albrecht Altdorfer drew the first natural landscape in the beginning of 15th century of Germany (Cavaliere, B. 1989). But we could not measure the physical data from his picture. The literature and the art found the beauty of natural landscape by these examples. They recorded the aesthetic beauty in landscape (Thiel, P. 1968).

Jay Appleton (1980) explained the scientific reason of the landscape phenomena with physical data, e.g. geomorphysical data and meteorological data. He explained the landscape phenomena of two pictures, Constable's Weymouth Bay and Constable's sunset study of Hampstead Heath. His approach must be the scientific based explanation to find psychological phenomena of landscape using the geology and meteorology. But the psychological phenomena could deviate by the person observed and the results must be happened statistically. So the process of the landscape phenomena should be explained by stochastic process of psychology. Then scientists developed psychological approach to it.

Here, we summarize the appreciation item (the third component of the landscape phenomena).

1. The developments to establish the psychological scale of appraisal

In the trial of psychometrical method, Ekman & Kuennapas (1962) tested the difference of Nominal scale and Interval scale, and the development of SD method promoted to use many adjectives in the visual complexities (Berlyne & Peckham 1966). Hart & Graham (1967) considered “How to rate & rank landscape”.

In the development of the psychological scale, Heise (1969) tested the scale -3 to 3, and Zube, Anderson & Pitt (1973) used the numerical scale 3 to 14.

2. The psychological evaluation item of preference

Kaplan, Kaplan, & Wendt (1972) proposed to use preference for the landscape appreciation. Compared to the results obtained by SD method, “preference” is easy to understand among different cultural back ground and was popularized in many countries.

©2019. Japan Geoscience Union. All Right Reserved.

3. The developments and the use of SD method

As for the SD method proposed by Osgood & Suci (1955), it employed many pairs of adjectives to evaluate landscape and provided detailed impressions of landscape. The largest number of 240 adjectives was tested by Craik (1975). The results were too complicated and scientists would like to summarize the results. SBE (Terry & Boster 1976), AVQ (Arriaza etc. 2004) and others were statistical aggregation examples of this trial and the example of meaningful aggregation was “Coherence, Complexity, Legibility and Mystery” proposed by Kaplan (1987). These indicators were tested with the relation to the preference and other appreciations by many scientists (Stamps III 2004, and so on.).

4. Method of monetary term evaluation

Monetary term is another evaluation of landscapes and sometimes used in the physical planning (Fukahori & Kubota 2003).

5. Items based on the human behavior of landscape evaluation

The origin of the landscape appreciation was explained from the animal behavior of predation (Appleton 1975). This theory had discussed for a long time. And this behavior might propose a base appreciation of landscape (Aoki & Kitamura 2001). Consideration on the human activities, the reason of visit (Andereck et al. 1989) and the visitability (Abdulkarim & Nasar 2014) were examined and the photographing (Oku & Fukamachi 2006, Sugimoto 2013) were reported.

6. Other appraisals

There are many appreciation descriptors and even now the scientists are finding new descriptors (Collier & Scott 2008). Until now, we could find examples of this trial in absorption (Berlyne 1958), quietness (Womble & Studebaker 1981), beauty (Hull IV, Buhyoff & Daniel 1984), size (Coeterier 1994), fear and stress (Nasar & Jones 1997), positive and negative (Ryan 1998), aggression and violence (Kuo 2001), satisfaction (Kaplan & Austin 2004), overcrowding (Manning & Freimund 2004), openness (Dramstad et al. 2006), ugly (Ruell, Halleux & Teller 2013), and other descriptions.

Table Historical review of landscape appreciation items

Interesting subject	Name of authors	Year
Development of the SD method	Osgood, C.E. and Suci, G.J.	1955
absorption	Berlyne, D.E.,	1958
descriptive appreciation as aesthetic beauty	Thiel, P.,	1961
difference of Nominal scale and Interval scale	Ekman, G. and Kuennapas, T.	1962
SD method	Wright, B. and Rainwater, L.	1962
description	Halprin, L.,	1965
absorption	Berlyne, D.E. and Peckham, S.	1966
description	Noe, S. and Abernathy, B.L.	1966
landscape type	Hart W. J. and William W. Graham,	1967
absorption	Wohlwill, J.F.	1968
numerical scale from -3 to +3	Heise, D.R.,	1969
aesthetic and emotional	Shafer, E.L. and Mietz, J.	1969
objectivity	Craik, K.H.	1972
preference	Kaplan, S., Kaplan, R. and Wendt, J.S.	1972
scaling	Acking, C.A and Sorte, G.J.	1973
numerical scale from 3 to 14	Zube, E.H., Anderson, T. and Pitt, D.	1973
prospect-refuge theory	Appleton, J.	1975
SD method with 240 pairs of adjectives	Craik, K.H.	1975
SBE method; normalization of the results	Daniel, T.C. and Boster, R.S.	1976
monetary	McConnell, K.E.,	1977
SD method	Pedersen, D.M.	1978
SD method	Shuttleworth, S.	1980
preference	Nasar, J.L.,	1981
meaning	Russell, J.A. and Ward, L.M.	1981
quiet	Womble, P. and Studebaker, S.	1981
quiet	Hammitt, W.E.,	1982
preference	Mudrak, L.Y.,	1983
preference	Nasar, J.L.,	1983
SD method	Ruiz, J.P. and Gonzalez-Bernaldez, F.	1983
scenic beauty	Hull IV, R.B., Buhyoff, G.J. and Daniel, T.C.	1984
needs and fears	Talbot, J.F. and Kaplan, R.	1984
preference	Herzog, T.R.	1985
SD method	Abello, R.P., Bernaldez, F.G. and Galiano, E.F.	1986
preference	Talbot, J.F. and Kaplan, R.	1986
survey paper: Coherence, Complexity, Legibility, Mystery	Kaplan, S.	1987
SD method	Kobayashi, M., Higashiyama, J. and Kawasaki, K.	1987
preference	Talbot, J.F., Bardwell, L.V. and Kaplan, R.	1987
monetary	Anderson, L.M. and Cordell, H.K.	1988
preference	Herzog, T. and Smith, G.A.	1988
motivation to visit	Andereck, K. et al.	1989
evaluation by monetary term	Daniel, T.C., et al.	1989
SD method	Kaplan, R., Kaplan, S. and Brown, T.	1989
SD method	Ruiz, M. and Ruiz, J.P.	1989
preference	Gimblett, H.R.	1990
monetary	Green, C.H., et al.	1990
motivation to visit	Uysal, M., McDonald, C.D. and Reid, L.J.	1990
quiet	Ulrich, R.S. et al.	1991
preference	Chokor, B.A	1992
preference	Herzog, T.	1992
refuge provides shelter	Hudson, B.J.	1992
effect to land price	Orland, B., Vinning, J. and Ebreo, A.	1992
familiarity	Purcell, A.T.	1992
description: literature works	Ikeda, T. and Konno, A.	1993
size of space	Coeterier, J.F.,	1994
identity	Hull IV, R.B., Lam, M. and Vigo, G.	1994
preference	Stamps III, A.E.	1994
preference	Strumse, E.	1994
preference	Sullivan III, W.C.,	1994
prospect-refuge theory reviewed	Appleton, J.,	1995
motivation to visit	Cha, S., McCleary, K.W. and Uysal, M.	1995
preference	Mealey, L.	1995
preference on tree form	Sommer, R. and Summit, J.	1995
preference	Herzog, T.R. and Gale, T.A.	1996
scenic preference in Finland	Karjalainen, E.	1996
scaling	Tahvanainen, L., Tyrvainen, L. and Nousiainen, I.	1996
Notation for a Participatory Envirotecture	Thiel, P.,	1996
fear and stress	Nasar, J.L. and Jones, K.M.	1997
landscape preferences of USA, Ireland, Senegal	Newell, P.B.	1997
quiet	Caffyn, A. and Prosser, B.	1998
preference	Herzog, T.R.,	1998
consistency of evaluation by rank order and graphical scale	Karjalainen, E. and Komulainen, M.	1998
preference	Kuo, F.E., Bacaicoa, M. and Sullivan, W.C.	1998
preference and naturalness using Scrub-forest, wide-close view, nature-altered	Purcell, A.T. and Lamb, R.J.	1998
positive and negative scenery of river frontland	Ryan, R.L.	1998
monetary	Tyrvainen, L. and Vaananen, H.	1998
preference	Brown, T.J., Kaplan R. and Quaderer, G.	1999
tranquility and preference	Herzog, T.R. and Barnes, G.J.	1999
preference	Summit, J. and Sommer, R.	1999
landscape preference in Australia	Herzog, T.R. et al	2000
landscape preference in Israel	Misgav, A.	2000
Phylogenic and Ontogenic evolution of landscape appreciation	Aoki, Y. and Kitamura, S.	2001
correlation between preference and likeliness	Hagerhall, C.M.	2001
motivation of ecological behavior	Hartig, T.	2001
aggression and violence	Kuo, F.E.,	2001
preference and danger	Herzog, T.R. and Kutzli, G.E.	2002
landscape preference in Norway	Kaltenborn, B.P. and Bjerke, T.	2002
positive and negative scenery of rural living	Ryan, R.L.,	2002
comparison of VOC and SBE	Franco, D. et al.	2003
cost and amenity level of road scenery	Fukahori, K. and Kubota, Y.	2003
preference	Herzog, T.R. and Leverich, O.L.	2003
AVQ index for visual quality	Arriaza, M. et al.	2004
preference	Herzog, T.R. and Kropscott, L.S.	2004
satisfaction of nature	Kaplan, R. and Austin, M.E.	2004
over crowding by photo montage method	Manning, R.E. and Freimund, W.A	2004
SBE difference 1976-1996	Palmer, J.F.	2004
preference did not correlate to mystery, complexity, legibility, coherence	Stamps, III, A.E.	2004
preference and danger by visibility	Herzog, T.R., & Kirk, K.M.	2005
preference by pair comparison	Rodiek, S.D. and Fried, J.T.	2005
proper openness, student and locals	Dramstad, W.E., et al.	2006
essential features for scenic beauty	Ergin, A., Williams, A.T. and Micallef, A.	2006
landscape preferred in Turkey	Kaplan, A., Taskin, T. and Onenc, A.,	2006
photographing by activity	Oku, H., & Fukamachi, K.	2006
disturbance, naturalness, visual scale, place identity in the photographs	Tveit, M., Ode, A. and Fry, G.	2006
mystery did not affect preference	Herzog, T.R. and Bryce, A.G.,	2007
words interested in the interview	Collier, M.J. and Scott, M.J.	2008
preference of transportation system; vegetation, distance, side fascia affected	Bernasconi, C. et al.	2009
beautiful high mountain, Sherpa appreciate flora, ugly garbage site no vegetation at Everest	Beza, B.B.	2010
species-rich of middle ground affect like of alpine landscape	Lindemann-Matthies, P. et al.	2010
naturalness, unity affect preference of Spruce forest landscape in Turkey	Eroglu, E. and Acar, C.	2011
surprise and Mystery affect preference, Turkey find Mystery at curved street	Nasar, J.L. and Cubukcu, E.	2011
ugly impression of brown fields and montage support improvement in Belgium	Ruelle, C., Halleux, J.-M. & Teller, J.	2013
Visitability	Abdulkarim, D. and Nasar, J. L.	2014
oppressiveness	Asgarzadeh, M. et al.	2014
threat	Chiang, Y-C., Nasal, J. and Ko, C-C.	2014
variance affected by evaluation value	Kalivoda, O. et al.	2014
forest and park affected stress relief	Tyrvainen, L., Ojala, A., Korpela, K. Lanki, T., Tsunetsugu, Y., Kagawa, T.	2014
proper understorey affect preference	van der Wal, R., Miller, D., Irvine, J., Fiorini, S., Amar, A., Yearley, S. Gill, R. & Dandy, N.	2014
openness	Weitkamp, G., Lammeren, R. and Bregt, A.	2014
risk of bushfire	Gill, N. et al.	2015
water use affect landscaping preference	Hayden, L., et al	2015
panorama tree cover density affect to preference	Jiang, B., et al.	2015
green roof affect restorativeness	Lee, K.E., Williams,K.J.H., Sargent, L.D., Williams, N.S.G., Johnson, K.A	2015
aesthetic, morphological condition and ecological integrity	McCormick, A, Fisher, K. and Brierley, G.	2015
water, reed, litter, dead wood affected preference	Eder, R., & Arnberger, A.	2016
tree coverage affect stress recovery	Jiang, B., Li, D., Larsen, L. & Sullivan, W.C.	2016
visual realism and sound affect preference	Lindquist, M., Lange, E. & Kang J.	2016
change of motivation	Shalev, I.	2016
cultural values in visual object	Sowinska-Swierkosz, B.N., Chmielewski, T.J.	2016
visual green reduces noise annoyance	Van Renterghem, T. & Botteldooren, D.	2016
public litter and fishing litter affect preference	Wyles, K.J., Pahl, S. Thomas, K. & Thompson, R.	2016
disorder affect fear of crime	Biasi, Alaina De	2017

Wed. May 29, 2019 1:45 PM - 3:15 PM JST | Wed. May 29, 2019 4:45 AM - 6:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_3

[S-SS09] Earthquake prediction and forecast

convener:Masayuki Obayashi(Japan Agency for Marine-Earth Science and Technology), Toshitaka Baba(Graduate School of Science and Technology, Tokushima University)

This session provides the opportunity for contributions that fall within the scientific spectrum of earthquake prediction and forecasting. We welcome theoretical, observational or numerical papers that are either on long- or short-term predictions, and either based on deterministic or probabilistic approaches.

[SSS09-P01] A method to ditect seismic precursors

A method to ditect seismic precursors

*Kozo Takahashi

A method to detect seismic precursors precursory seismic electric fields
earthquake prediction Introduction
Many precursors have been observed before a big earthquake. Most of them are regarded as the result of microcracks in the source region. Therefore, if we can detect the microcracks, it will become possible to predict directly or indirectly the earthquakes. Detection of microcracks
By arranging four electrodes around the earthquake region, we measure the electric potential and resistance (though this method is difficult at seabed), then we can detect the microcrack. But this method is nearly impossible, as we can't know the precise location of the earthquake region.
If Gravitational Waves (GWs)are
emitting from the source region, it becomes possible to detect the region and to predict the earthquakes. But the following shows this is perfectly impossible.
Receiving GW
First the intensity of GW is shown which was detected.
The intensity of GW150914, which emitted when the two Black Holes (BHs) combined, is calculated as follows:
Symbols and approximate values of constants are as follows:
???Fraise to the power ˜
Light velocity:????3?˜(10??5) km/sec
One light-year??9.46?˜(10??12) km
Solar Mass:?Q?˜(10??30) kg
The values of GW150914 when it combined: The distance to the BHs:
??=13 hundred million light-years
The mass of the smaller BH:
M=29 Solar mass
The collision between BHs means that the each BH enters partner's Event Horizon. So the collision means the combine. Then the kinetic energy turns into wave energy of GW.
The relative speed between BHs can't be beyond the light speed, so the speed of each BH is less than about c/2.
The GW is generated by the rapid change of the gravitational field, so the wave is also generated by the change of the momentum. As the GW is a kind of wave, so GW is inversely proportional to the square of the distance r to the observing point. Therefore the GW150914 observed on the earth is proportional to the value expressed by the following formula:
GWbh?? 29 ?˜2?˜(10??30)?˜1.5?˜(10??5)??{(13?˜9.46?˜(10??12)?p??2
?@?? 5.75 ?˜10??8) (kg?^sec?Ekm)
The GW which might be generated accompanied by a earthquake is calculated as follows:
The energy E of a earthquake, magnitude M is expressed as follows:
?@?@log E??4.8 + 1.5 M When M=7,
log E ?? 4.8 + 10.5 ?? 15.3
E ?? 10??15.3 J??2?˜10??15 J
??2?˜10??9 kg (km?^sec)??2
The mass which moves by the earthquake is calculated from
?@ E??0.5?˜m ?˜v??2

©2019. Japan Geoscience Union. All Right Reserved.

When the speed of the earthquake wave on the surface v=5.45 km/sec is substituted, the momentum is
??v ??2 E?^??
?? 4?˜10??9?^5.45 kg?E?q?^sec
??0.734?˜10??9 kg?E?q?^sec
In the case of GW150914, only the speed of more than about c/2 contributed to generate the GW, so it is thought that only when the speed is more than about c/2, the GW is generated.
In general, the speed is distributed as normal distribution. The part of the earthquake wave speed more than c/2 becomes neglectfully small, when it is calculated from the mean value and standard deviation of earthquake wave speed. So, it will be concluded that any earthquake never generates GW.
Now let try in any case we can observe the GW
Let calculate GW when a meteorite falls on the earth with the speed of c/2. By the way, the moon never falls on the earth, because the tidal force breaks the moon into pieces, and the falling pieces burn out in the atmosphere. And the radar can't detect the object which approach with the speed of more than c/2, because the object with the speed more than c/2 arrives before it is detected.
The observed GW, when the Meteorite of the mass of the moon falls at the distance of r, is proportional to
GWme??m v?^????2 ?@kg?^km?Esec
where
mass of the moon: m??7.343?˜10??22?s
r??10000 km
GWme??1.10 ?˜10??21?@ kg?^?q?Esec
Now,
GWme?^GWbh??1.10?˜10??21?^5.75?˜10??8
??1.91?˜10??11
This value means that the meteor of the mass of 1?^1.91?˜10??11 of the moon causes the GW.
The maximum Meteor we know is about ten thousand tons, so if more than one hundred thousand tons meteor falls on the earth, all the life on the earth disappears. Ending Remark
It will be clear that predicting all earthquakes is impossible because even the precursors are difficult to predict. Even the locating the place of the microcrack, which is origin of precursors, is nearly impossible.

Difference of foreshock characteristics between real data and synthetic ETAS catalogs: through the application of an empirical earthquake forecast model based on foreshocks

*Fuyuki Hirose[1], Koji Tamaribuchi[1], Kenji Maeda[2]

1. Seismology and Tsunami Research Department, Meteorological Research Institute, 2. Seismology and Volcanology Department, Japan Meteorological Agency

It is pointed out that there is no effective earthquake forecast model than ETAS model [Ogata, 1988, JASA] because earthquakes are probabilistic phenomena driven by seismically cascading process represented by a superposition of background activity and epidemic-type aftershock sequence [e.g., Felzer et al., 2004, BSSA; 2015, NatureGeo]. On the other hand, it is also pointed out that the information of foreshock characteristics could be an effective clue of earthquake forecast because foreshocks are a part of the nucleation process, including precursory slips, which ETAS model cannot represent [e.g., Lippiello et al., 2012, SciRep; Bouchon et al., 2013, NatureGeo].
To investigate reproducibility of real data by ETAS model, we made synthetic earthquake catalogs (hereafter ETAS catalogs) based on ETAS parameters obtained from real data, and then we applied the earthquake forecast model that was formulated using real foreshock data [e.g., Maeda & Hirose, 2017, Yochiren98] to ETAS catalogs, and investigated the efficiency of the forecast. The forecast model optimized for Izu Islands is as follows: when 3 events (foreshocks) of M >= 3.0 occur in area of latitude 0.2˚ ×longitude 0.2˚ during 3 days, a mainshock of M >= 5.0 will occur within 5 days just after the event. This model with specific parameters is the most efficient one among those with other parameters by the measurement of likelihood.
Our investigation resulted in that real data yielded higher scores than ETAS catalogs. In other words, it is hard for ETAS model to reproduce foreshock characteristics, which might be related to precursory slips, well, indicating the earthquake forecast model based on foreshock characteristics is more efficient rather than ETAS model. However, our investigation might be biased because our forecast model based on foreshocks was optimized for real data. To perform reliable testing, it may also be necessary to investigate using our forecast model parameters optimized for ETAS catalogs.

The increase in missing waveform images of the F-net broadband seismograph network preceding the 2011 Tohoku earthquake (2)

*Yoshiki SUE[1]

1. none

1. Introduction
For the themed earthquake, it is reported that number of the stations with missing waveform images (i.e. data) in the broadband seismic network F-net increased over several months before and after the main shock.
There was the first increase from December 22, 2010 to January 18, 2011, and reached the number of 4. Then there was the 2nd increase from February 16, 2011 to March 2, 2011. Especially from February 19 to March 2, it again became 4 stations (Sapporo (Code: HSS), Yamagata (IYG, Iwate pref.), Kesennuma (KSN) and Shiramine (SRN)). ... The period of 2nd increase overlapped seismically active period of February 13 to March 2 when M5 earthquakes occurred continuously in the epicentral region. (Sue, 2013)

2. Further investigations
We conducted further investigations for the period from the middle of February 2011 to the beginning of March 2011 and obtained the following results.
<Slow slip>
·Slow slip occurred near the epicenter before occurrence of the main shock. Slow slip began on January 29, 2011, expanded the active area around February 19, existed till the time just before occurrence of the Off Sanriku earthquake M7.3 on March 9. The slow slip induced the earthquake, which is thought the foreshock. (Uchida, Kato, Ito, Ota, 2014)
<Missing data of F-net>
·The second deterioration started from February 16, 2011, and from February 19 to March 2, it became the worst condition with 4 data-missing stations (Sapporo (HSS), Iwate Yamagata (IYG), Kesennuma (KSN), and Shiramine (SRN)).
·Sapporo (HSS) and Iwate Yamagata (IYG) were the stations with missing data before starting of deterioration.
·Kesennuma station (KSN) joined this group from February 16 to March 2.
·Shiramine station (SRN) joined this group from February 19 to April 25. Shiramine station is located in Hakusan city, Ishikawa prefecture where is far from off-Sanriku area, but on February 27, there was an earthquake swarm including a M5.5 Earthquake in Hida area near the station.
·The increase of data-missing stations ended on March 2, then number decreased. On March 8, the day before occurrence of the foreshock with a magnitude of 7.3, two stations; Iwate Yamagata (IYG) and Shiramine (SRN) remained.

3. Summary
Increase of missing data for the F-net stations from mid February to early March coincides the slow slip which occurred from January 29 through March 9 as well as the earthquake activities in off-Sanriku region from mid-February to late February in terms of time and location. On February 19, slow slip expanded the area, and on the same day, it reached the largest number of missing stations of F-net. It is thought that F-net responded to some kind of vibration generated near the future epicentral region.

On the *b*-value of the OBS seismic observation around the Suruga Bay Senoumi

*Taiyo Sotani[1], Hisatoshi Baba[4], Takahito Nishimiya[2], Nakao Nagisa[1], Toshiyasu Nagao[3]

1. Toukai Univrsity, 2. Meteorological Research Institute, Japan Meteorological Agency, 3. Institute of Oceanic Research and development, Tokai University, 4. Department of Marine and Earth Science, Tokai University

Suruga Bay is a steep bay with Suruga trough and is presumed to be the focal region of the Tokai earthquake. At the plate boundary from the Suruga Through to the Nankai Trough, massive earthquakes of M 8.0 classes have repeatedly occurred in the past. In Suruga Bay, in August 2009, "Shizuoka Offshore Earthquake (M6.5)" and August 2011 "Suruga Bay Earthquake (M6.2)" as an opportunity, from November 2011, we set up the pup-up ocean bottom seismograph (OBS) at the sea area around Senoumi in central Suruga Bay and started seismic observation.

We will make the presentation about the following.
The *b*-value every 3 months using the hypocenters located by OBS observation from October 2012 to August 2018 The comparison of the *b*-value calculated every 3 months and the data of Japan Meteorological Agency (JMA) from October 2012 to August 2018. The *b*-values in the vicinity of the Senoumi located a lot of hypocenters.

Trial Result of Long-term Occurrence Probabilities with The Moderate Repeating Earthquakes Using The Lognormal Distribution Model with Bayesian Approach

*Masayuki Tanaka[1]

1. Meteorological Research Institute

We are investigating the moderate repeating earthquakes. And we are verifying the long-term probability forecast using the log-normal distribution model with Bayesian approach (LN-Bayes) by Okada et al. (2007). This model is that probability distribution of recurrence interval is given in the inverse gamma prior distribution. The parameters of inverse gamma use shape, ϕ=2.5 and scale, ζ=0.23. This model can be calculated from one sample. We calculated the probability of occurrence during one year from February 2016 (2016.2). Then in February 2017 (2017.2) and February 2018 (2018.2) we did the same calculation. We confirm the outcome of the forecast using evaluation index. Then compares with the result of another model.
We use three models for comparison.
(1) LN-SST: Lognormal distribution model base on the small sample theory.
(2) BPT: BPT distribution model. The coefficient of variation α use 0.24. This value is based on the Headquarters for Earthquake Research Promotion (2010).
(3) Exp: Exponential distribution model. The parameter plugged is the sample mean.

The "Mean log-likelihood (*MLL*)" and "Brier Score (*BS*)" mentioned below are used to score the forecast results.
MLL: Average of $Ev \log_e (P) + (1-Ev) \log_e (1-P)$
BS: Average of $(P - Ev)^2$
Here *P* means forecast probability for event and *Ev* means presence (*Ev*=1) or absence (*Ev*=0) of the event. The *MLL* has a negative value. The closer to 0, the better. The *MLL* is -0.693 when the probability is 0.5, and it is very bad if the value is smaller than that. The *BS* has a positive value. The closer to 0, the better. The *BS* is 0.25 when the probability is 0.5, and it is very bad if the value is larger than that.

In Figure 1 shows the forecast results of the MLL for the four models. With the 2016.2 trial, The LN-SST model is better than other models. With the 2017.2 and 2018.2 trials, result of the LN-Bayes model is better than the other models one. Three predictions are independent, and combining of results for three times, the result of the LN-Bayes model is superior to the other models. But results of the LN-Bayes, the LN-SST and the Exp models are gradually getting worse. The results of the LN-SST model change more than the other two models. In February 2018 results, result of the LN-SST model is inferior to result of the Exp model. The cause is unknown. The BPT model is a very bad results in all three times.

Structural heterogeneity under the 2018 Mw6.6 Eastern Iburi earthquake in Hokkaido, Japan and its implications for rupture initiations

*ZHI WANG[1]

1. Key Laboratory of Marginal Sea Geology at South China Sea Institute of Oceanology of CAS of China

On September 6, 2018, an Mw6.6 (moment magnitude) crustal earthquake occurred at Eastern Iburi on the island of Hokkaido, Japan (hereafter referred to as the Iburi Earthquake), where the northeastern Japan arc obliquely collides with the Kuril arc. It is the first time an earthquake has ever reached a maximum intensity of 7 (on scale of JMA: Japan Meteorological Agency) in Hokkaido. The 2018 Iburi earthquake caused serious damage across Hokkaido Prefecture and adjacent regions, including the death of 44 people, as many as 680 injuries, and a large number of landslides around the town of Atsuma. The focal mechanism solution of the earthquake showed that initiation occurred on either a moderately dipping reverse fault striking northwest (NW), or on a shallow-to-moderately dipping fault striking southeast (SE).

The hypocenter area is characterized by the mutual interactions of three plates: the Pacific plate, the North American (Okhotsk) plate, and the Eurasian plate. This reverse-faulting earthquake occurred close to the Hidaka main thrust belt, whose tectonics are driven by the convergence of the above three plates. The plate boundary between the Eurasian and Okhotsk plates is located near the eastern coastline of the Japan Sea. Under the Iburi earthquake, the Pacific slab is subducting towards the west (W) -NW beneath the Eurasian and North American plates from the northeastern (NE) Japan and Kuril Trenches. In the Hokkaido subduction zone, there have been 18 earthquakes (M_J > 6.5: JMA magnitude) recorded since 1926; however, the majority are interplate thrust earthquakes associated with the Pacific slab subduction, and only five of these occurred at shallow depths under Hokkaido according to JMA focal depths.
The hypocenter determined by JMA indicated a focal depth of ~37 km. Given the focal mechanism solutions and depth, the main-shock was likely an intraplate event within the North American (upper) plate (or Okhotsk microplate), rather than on the interface between the subducting Pacific and North America plates. This was because the iso-depth of the upper boundary for the Pacific slab was about ~100 km beneath the epicenter. Although numerous seismic tomographic studies in the crust and uppermost mantle have been conducted in Hokkaido, the structure in the 2018 Iburi source area remains poorly resolved. It is worth noting that the seismic velocity and Poisson ratio images, together with geology and geothermal data, in the source area could provide some important information for a better understanding of earthquake generation. To investigate the rupture initiation of the earthquake, we conduct a high resolution seismic tomography study to determine the seismic velocity and Poisson ratio structures under the entire Hokkaido arc. Our results indicated that the main-shock was likely located at a blind-thrust fault close to the boundary between the negative and positive seismic anomalies. A strong low velocity and high Poisson ratio body that extended to a depth of ~120 km was clearly imaged northwest of the hypocenter under the back-arc side of the mantle wedge, indicating fluids were released from the subducting Pacific slab dehydration. Fluids released from the great depth of the back-arc mantle wedge would intrude into the positive anomaly from the more saturated negative side in the lower crust, leading to high pore-fluid pressure accumulation in that region. The descending brittle crustal material sandwiched by two negative zones in the hypocenter was sufficiently large, resulting in strain concentration, decrease of rock effective stress in the hypocenter, and contributing to brittle deformation.

A method to ditect seismic precursors

*Kozo Takahashi

A method to detect seismic precursors precursory seismic electric fields
earthquake prediction Introduction
Many precursors have been observed before a big earthquake. Most of them are regarded as the result of microcracks in the source region. Therefore, if we can detect the microcracks, it will become possible to predict directly or indirectly the earthquakes. Detection of microcracks
By arranging four electrodes around the earthquake region, we measure the electric potential and resistance (though this method is difficult at seabed), then we can detect the microcrack. But this method is nearly impossible, as we can't know the precise location of the earthquake region.
If Gravitational Waves (GWs)are
emitting from the source region, it becomes possible to detect the region and to predict the earthquakes. But the following shows this is perfectly impossible.
Receiving GW
First the intensity of GW is shown which was detected.
The intensity of GW150914, which emitted when the two Black Holes (BHs) combined, is calculated as follows:
Symbols and approximate values of constants are as follows:
???Fraise to the power ˜
Light velocity:????3?˜(10??5) km/sec
One light-year??9.46?˜(10??12) km
Solar Mass:?Q?˜(10??30) kg
The values of GW150914 when it combined: The distance to the BHs:
??=13 hundred million light-years
The mass of the smaller BH:
M=29 Solar mass
The collision between BHs means that the each BH enters partner's Event Horizon. So the collision means the combine. Then the kinetic energy turns into wave energy of GW.
The relative speed between BHs can't be beyond the light speed, so the speed of each BH is less than about c/2.
The GW is generated by the rapid change of the gravitational field, so the wave is also generated by the change of the momentum. As the GW is a kind of wave, so GW is inversely proportional to the square of the distance r to the observing point. Therefore the GW150914 observed on the earth is proportional to the value expressed by the following formula:
GWbh?? 29 ?˜2?˜(10??30)?˜1.5?˜(10??5)??{(13?˜9.46?˜(10??12)?p??2
?@?? 5.75 ?˜10??8) (kg?^sec?Ekm)
The GW which might be generated accompanied by a earthquake is calculated as follows:
The energy E of a earthquake, magnitude M is expressed as follows:
?@?@log E??4.8 + 1.5 M When M=7,
log E ?? 4.8 + 10.5 ?? 15.3
E ?? 10??15.3 J??2?˜10??15 J
??2?˜10??9 kg (km?^sec)??2
The mass which moves by the earthquake is calculated from
?@ E??0.5?˜m ?˜v??2

©2019. Japan Geoscience Union. All Right Reserved.

When the speed of the earthquake wave on the surface v=5.45 km/sec is substituted, the momentum is
??v ??2 E?^??
?? 4?˜10??9?^5.45 kg?E?q?^sec
??0.734?˜10??9 kg?E?q?^sec
In the case of GW150914, only the speed of more than about c/2 contributed to generate the GW, so it is thought that only when the speed is more than about c/2, the GW is generated.
In general, the speed is distributed as normal distribution. The part of the earthquake wave speed more than c/2 becomes neglectfully small, when it is calculated from the mean value and standard deviation of earthquake wave speed. So, it will be concluded that any earthquake never generates GW.
Now let try in any case we can observe the GW
Let calculate GW when a meteorite falls on the earth with the speed of c/2. By the way, the moon never falls on the earth, because the tidal force breaks the moon into pieces, and the falling pieces burn out in the atmosphere. And the radar can't detect the object which approach with the speed of more than c/2, because the object with the speed more than c/2 arrives before it is detected.
The observed GW, when the Meteorite of the mass of the moon falls at the distance of r, is proportional to
GWme??m v?^????2 ?@kg?^km?Esec
where
mass of the moon: m??7.343?˜10??22?s
r??10000 km
GWme??1.10 ?˜10??21?@ kg?^?q?Esec
Now,
GWme?^GWbh??1.10?˜10??21?^5.75?˜10??8
??1.91?˜10??11
This value means that the meteor of the mass of 1?^1.91?˜10??11 of the moon causes the GW.
The maximum Meteor we know is about ten thousand tons, so if more than one hundred thousand tons meteor falls on the earth, all the life on the earth disappears. Ending Remark
It will be clear that predicting all earthquakes is impossible because even the precursors are difficult to predict. Even the locating the place of the microcrack, which is origin of precursors, is nearly impossible.

Difference of foreshock characteristics between real data and synthetic ETAS catalogs: through the application of an empirical earthquake forecast model based on foreshocks

*Fuyuki Hirose[1], Koji Tamaribuchi[1], Kenji Maeda[2]

1. Seismology and Tsunami Research Department, Meteorological Research Institute, 2. Seismology and Volcanology Department, Japan Meteorological Agency

It is pointed out that there is no effective earthquake forecast model than ETAS model [Ogata, 1988, JASA] because earthquakes are probabilistic phenomena driven by seismically cascading process represented by a superposition of background activity and epidemic-type aftershock sequence [e.g., Felzer et al., 2004, BSSA; 2015, NatureGeo]. On the other hand, it is also pointed out that the information of foreshock characteristics could be an effective clue of earthquake forecast because foreshocks are a part of the nucleation process, including precursory slips, which ETAS model cannot represent [e.g., Lippiello et al., 2012, SciRep; Bouchon et al., 2013, NatureGeo].
To investigate reproducibility of real data by ETAS model, we made synthetic earthquake catalogs (hereafter ETAS catalogs) based on ETAS parameters obtained from real data, and then we applied the earthquake forecast model that was formulated using real foreshock data [e.g., Maeda & Hirose, 2017, Yochiren98] to ETAS catalogs, and investigated the efficiency of the forecast. The forecast model optimized for Izu Islands is as follows: when 3 events (foreshocks) of M >= 3.0 occur in area of latitude 0.2˚ ×longitude 0.2˚ during 3 days, a mainshock of M >= 5.0 will occur within 5 days just after the event. This model with specific parameters is the most efficient one among those with other parameters by the measurement of likelihood.
Our investigation resulted in that real data yielded higher scores than ETAS catalogs. In other words, it is hard for ETAS model to reproduce foreshock characteristics, which might be related to precursory slips, well, indicating the earthquake forecast model based on foreshock characteristics is more efficient rather than ETAS model. However, our investigation might be biased because our forecast model based on foreshocks was optimized for real data. To perform reliable testing, it may also be necessary to investigate using our forecast model parameters optimized for ETAS catalogs.

The increase in missing waveform images of the F-net broadband seismograph network preceding the 2011 Tohoku earthquake (2)

*Yoshiki SUE[1]

1. none

1. Introduction
For the themed earthquake, it is reported that number of the stations with missing waveform images (i.e. data) in the broadband seismic network F-net increased over several months before and after the main shock.
There was the first increase from December 22, 2010 to January 18, 2011, and reached the number of 4. Then there was the 2nd increase from February 16, 2011 to March 2, 2011. Especially from February 19 to March 2, it again became 4 stations (Sapporo (Code: HSS), Yamagata (IYG, Iwate pref.), Kesennuma (KSN) and Shiramine (SRN)). ... The period of 2nd increase overlapped seismically active period of February 13 to March 2 when M5 earthquakes occurred continuously in the epicentral region. (Sue, 2013)

2. Further investigations
We conducted further investigations for the period from the middle of February 2011 to the beginning of March 2011 and obtained the following results.
<Slow slip>
·Slow slip occurred near the epicenter before occurrence of the main shock. Slow slip began on January 29, 2011, expanded the active area around February 19, existed till the time just before occurrence of the Off Sanriku earthquake M7.3 on March 9. The slow slip induced the earthquake, which is thought the foreshock. (Uchida, Kato, Ito, Ota, 2014)
<Missing data of F-net>
·The second deterioration started from February 16, 2011, and from February 19 to March 2, it became the worst condition with 4 data-missing stations (Sapporo (HSS), Iwate Yamagata (IYG), Kesennuma (KSN), and Shiramine (SRN)).
·Sapporo (HSS) and Iwate Yamagata (IYG) were the stations with missing data before starting of deterioration.
·Kesennuma station (KSN) joined this group from February 16 to March 2.
·Shiramine station (SRN) joined this group from February 19 to April 25. Shiramine station is located in Hakusan city, Ishikawa prefecture where is far from off-Sanriku area, but on February 27, there was an earthquake swarm including a M5.5 Earthquake in Hida area near the station.
·The increase of data-missing stations ended on March 2, then number decreased. On March 8, the day before occurrence of the foreshock with a magnitude of 7.3, two stations; Iwate Yamagata (IYG) and Shiramine (SRN) remained.

3. Summary
Increase of missing data for the F-net stations from mid February to early March coincides the slow slip which occurred from January 29 through March 9 as well as the earthquake activities in off-Sanriku region from mid-February to late February in terms of time and location. On February 19, slow slip expanded the area, and on the same day, it reached the largest number of missing stations of F-net. It is thought that F-net responded to some kind of vibration generated near the future epicentral region.

On the *b*-value of the OBS seismic observation around the Suruga Bay Senoumi

*Taiyo Sotani[1], Hisatoshi Baba[4], Takahito Nishimiya[2], Nakao Nagisa[1], Toshiyasu Nagao[3]

1. Toukai Univrsity, 2. Meteorological Research Institute, Japan Meteorological Agency, 3. Institute of Oceanic Research and development, Tokai University, 4. Department of Marine and Earth Science, Tokai University

Suruga Bay is a steep bay with Suruga trough and is presumed to be the focal region of the Tokai earthquake. At the plate boundary from the Suruga Through to the Nankai Trough, massive earthquakes of M 8.0 classes have repeatedly occurred in the past. In Suruga Bay, in August 2009, "Shizuoka Offshore Earthquake (M6.5)" and August 2011 "Suruga Bay Earthquake (M6.2)" as an opportunity, from November 2011, we set up the pup-up ocean bottom seismograph (OBS) at the sea area around Senoumi in central Suruga Bay and started seismic observation.

We will make the presentation about the following.
The *b*-value every 3 months using the hypocenters located by OBS observation from October 2012 to August 2018 The comparison of the *b*-value calculated every 3 months and the data of Japan Meteorological Agency (JMA) from October 2012 to August 2018. The *b*-values in the vicinity of the Senoumi located a lot of hypocenters.

Trial Result of Long-term Occurrence Probabilities with The Moderate Repeating Earthquakes Using The Lognormal Distribution Model with Bayesian Approach

*Masayuki Tanaka[1]

1. Meteorological Research Institute

We are investigating the moderate repeating earthquakes. And we are verifying the long-term probability forecast using the log-normal distribution model with Bayesian approach (LN-Bayes) by Okada et al. (2007). This model is that probability distribution of recurrence interval is given in the inverse gamma prior distribution. The parameters of inverse gamma use shape, ϕ=2.5 and scale, ζ=0.23. This model can be calculated from one sample. We calculated the probability of occurrence during one year from February 2016 (2016.2). Then in February 2017 (2017.2) and February 2018 (2018.2) we did the same calculation. We confirm the outcome of the forecast using evaluation index. Then compares with the result of another model.
We use three models for comparison.
(1) LN-SST: Lognormal distribution model base on the small sample theory.
(2) BPT: BPT distribution model. The coefficient of variation α use 0.24. This value is based on the Headquarters for Earthquake Research Promotion (2010).
(3) Exp: Exponential distribution model. The parameter plugged is the sample mean.

The "Mean log-likelihood (*MLL*)" and "Brier Score (*BS*)" mentioned below are used to score the forecast results.
MLL: Average of $Ev \log_e (P) + (1-Ev) \log_e (1-P)$
BS: Average of $(P - Ev)^2$
Here *P* means forecast probability for event and *Ev* means presence (*Ev*=1) or absence (*Ev*=0) of the event. The *MLL* has a negative value. The closer to 0, the better. The *MLL* is -0.693 when the probability is 0.5, and it is very bad if the value is smaller than that. The *BS* has a positive value. The closer to 0, the better. The *BS* is 0.25 when the probability is 0.5, and it is very bad if the value is larger than that.

In Figure 1 shows the forecast results of the MLL for the four models. With the 2016.2 trial, The LN-SST model is better than other models. With the 2017.2 and 2018.2 trials, result of the LN-Bayes model is better than the other models one. Three predictions are independent, and combining of results for three times, the result of the LN-Bayes model is superior to the other models. But results of the LN-Bayes, the LN-SST and the Exp models are gradually getting worse. The results of the LN-SST model change more than the other two models. In February 2018 results, result of the LN-SST model is inferior to result of the Exp model. The cause is unknown. The BPT model is a very bad results in all three times.

Structural heterogeneity under the 2018 Mw6.6 Eastern Iburi earthquake in Hokkaido, Japan and its implications for rupture initiations

*ZHI WANG[1]

1. Key Laboratory of Marginal Sea Geology at South China Sea Institute of Oceanology of CAS of China

On September 6, 2018, an Mw6.6 (moment magnitude) crustal earthquake occurred at Eastern Iburi on the island of Hokkaido, Japan (hereafter referred to as the Iburi Earthquake), where the northeastern Japan arc obliquely collides with the Kuril arc. It is the first time an earthquake has ever reached a maximum intensity of 7 (on scale of JMA: Japan Meteorological Agency) in Hokkaido. The 2018 Iburi earthquake caused serious damage across Hokkaido Prefecture and adjacent regions, including the death of 44 people, as many as 680 injuries, and a large number of landslides around the town of Atsuma. The focal mechanism solution of the earthquake showed that initiation occurred on either a moderately dipping reverse fault striking northwest (NW), or on a shallow-to-moderately dipping fault striking southeast (SE).

The hypocenter area is characterized by the mutual interactions of three plates: the Pacific plate, the North American (Okhotsk) plate, and the Eurasian plate. This reverse-faulting earthquake occurred close to the Hidaka main thrust belt, whose tectonics are driven by the convergence of the above three plates. The plate boundary between the Eurasian and Okhotsk plates is located near the eastern coastline of the Japan Sea. Under the Iburi earthquake, the Pacific slab is subducting towards the west (W) -NW beneath the Eurasian and North American plates from the northeastern (NE) Japan and Kuril Trenches. In the Hokkaido subduction zone, there have been 18 earthquakes (M_J > 6.5: JMA magnitude) recorded since 1926; however, the majority are interplate thrust earthquakes associated with the Pacific slab subduction, and only five of these occurred at shallow depths under Hokkaido according to JMA focal depths.
The hypocenter determined by JMA indicated a focal depth of ~37 km. Given the focal mechanism solutions and depth, the main-shock was likely an intraplate event within the North American (upper) plate (or Okhotsk microplate), rather than on the interface between the subducting Pacific and North America plates. This was because the iso-depth of the upper boundary for the Pacific slab was about ~100 km beneath the epicenter. Although numerous seismic tomographic studies in the crust and uppermost mantle have been conducted in Hokkaido, the structure in the 2018 Iburi source area remains poorly resolved. It is worth noting that the seismic velocity and Poisson ratio images, together with geology and geothermal data, in the source area could provide some important information for a better understanding of earthquake generation. To investigate the rupture initiation of the earthquake, we conduct a high resolution seismic tomography study to determine the seismic velocity and Poisson ratio structures under the entire Hokkaido arc. Our results indicated that the main-shock was likely located at a blind-thrust fault close to the boundary between the negative and positive seismic anomalies. A strong low velocity and high Poisson ratio body that extended to a depth of ~120 km was clearly imaged northwest of the hypocenter under the back-arc side of the mantle wedge, indicating fluids were released from the subducting Pacific slab dehydration. Fluids released from the great depth of the back-arc mantle wedge would intrude into the positive anomaly from the more saturated negative side in the lower crust, leading to high pore-fluid pressure accumulation in that region. The descending brittle crustal material sandwiched by two negative zones in the hypocenter was sufficiently large, resulting in strain concentration, decrease of rock effective stress in the hypocenter, and contributing to brittle deformation.

Objective evaluationof precursory seismic quiescence and activation phenomenon in wide area

*Sumio Yoshikawa[1]

1. Meteorological Research Institute

The 1995 Kobe earthquake of M7.3 is an earthquake known to have observed abnormal changes in seismic activity accompanied by various changes such as crustal deformation, groundwater and electromagnetism before the main shock. Especially Mogi (1995) pointed out the seismicity gap and the quiescent phenomenon of the seismic activity with a long-term and wide-area perspective. Yoshida (1995) pointed out the wide range of the preceding phenomena of seismic activity and showed that the area wider than the epicenter area is involved in the earthquake occurrence process. Therefore, if any prediction method is supposed, it is a problem how much accuracy it is possible to know based on such a preceding phenomenon in wide area.

eMAP is a tool to evaluate the appearance probability of seismic activity by Poisson's probability (Yoshikawa et al., 2017). In this method a region is set for each individual epicenter and the degree of abnormality is displayed in all regions. In order to consider the above problem, we examined the possibility of diagnosis of wide area seismic activity by this method.

By analysis of the quiescence and activation phenomenon in wide area during the Kobe earthquake, mainly in the Kinki, Chugoku and Shikoku districts, the following features were found. At that time, in the JMA seismic catalog before the unification, the magnitude threshold is considered to be around M 2.0 since 1988. The spatial distribution of the seismic activity has changed in a relatively short time scale and a stable pattern is not seen until 5 to 6 years before the main shock, but about 2 years before, a quiet phenomenon is confirmed in the area with the range of 50 km in the eastern part of Hyogo Prefecture. About a year before to the main shock, we can see activation in the epicenter area and a wide area surrounding it. This seems to be due to the small foreshock activity occurred along various active faults and geological lineaments. Based on this seismic sequence, it is possible to suppose a forecasting tactics as follows. First of all, by grasping the location and extent of the quiescence phenomenon, we assume the location and the scale of the main shock (Yoshikawa, 2015), and then estimate the urgency of earthquake occurrence by detecting the simultaneity of temporal changes.

Long-term Probability of a Great Earthquake along the Kurile Trench, Hokkaido Japan (2)

*Masajiro Imoto[1], Morilkawa Nobuyuki[1], Fujiwara Hiroyuki[1]

1. National Research Institute for Earth Science and Disaster Resilience

Great earthquakes (M8 and larger) repeatedly occur along the Kurile Trench off Hokkaido. A much larger one in the 17-th century (17-th type earthquake) is indicated by studies of tsunami deposits, which is considered as representing the simultaneous of Tokachi-oki and Nemuro-oki earthquakes. The Earthquake Research Committee, the Government of Japan has reported the long-term probability of the 17-th type earthquake. We discuss the uncertainty of the long-term probability of the 17-th type earthquake, applying the method by Parsons (2008) to compare the likelihood of both the Brownian Passage Time distribution and the Poisson distribution for recurrent earthquakes. We adopted the seven probable ranges of origin times observed at Mochirippu-toh, and the five ranges at Kiritappu Marsh (Table 7 in the ERC report). Considering two probable ranges of 68% and 95% listed, two different functions of a origin time are adopted as weights; a modified Gaussian function and a step-function. The latter function is fixed so as to reserve the 68% and 95% probabilities in their ranges.
The likelihood ratios of the BPT model to the Poisson one are 0.70-0.79 for the Mochirippu-toh and 1.9-2.0 for the Kiritappu Marsh. The mean of the 17-th type earthquake probability in the next 30 years over the model parameters is about 11% for the Mochirippu-toh and around 21% for the Kiritappu Marsh. Only slight differences of both likelihood ratios and the thirty year probabilities among the three weight functions are observed.

Parallel and Focused Increase Trends in Time Series (M-T Diagram) of Earthquake Occurrences

*Satoshi Hashimoto[1]

1. none

Usually time sequence of earthquakes is not used as continuous variations because of special property of its occurrences. A few cases such as aftershocks and repeated earthquakes are attributed to continuous series. However, in a time series downloaded from HP of earthquake catalog continuous increase variations are seen clearly in almost all M-T diagrams, here M and T mean magnitude and occurrence time of earthquakes, respectively.

For example, since 2000 a time series of earthquake is shown under the conditions that M > 5.5, D (depth) < 50km, and main 4 islands of Japan with sea areas. In this series clear increase trend consisted from 13 earthquakes (M > 6) can be recognized on a time period from 2002 to 2005. Note that 3 points deviated largely from the straight line are excluded. Surprisingly the straight line connects roughly to the M9 of 2011/3/11 Tohoku-oki Earthquake. If we focus our attention to the increase trend, several lines with similar slope can be seen in other time durations since 2000. These lines are parallel with each other and interrupted at some value of M.

One more important character is seen in the M-T diagram since 2000. Before 2011/3/11 extrapolated more lines gather to the value M9 of Tohoku-oki Earthquake in detailed observations. These are called focused lines. Focused lines are coexisted with the parallel series. Both series are exhibited in whole time span of about 100 years of the catalog. The excluded points described above are probably included by other parallel or focused lines. In short, almost all earthquakes are included in many increase trends of earthquake time sequences.

Little work has be done to the regularity shown above. If several focused time series are found for a few and several years at present, extrapolation of the series will cross in near future. Just the crossing point is the predicted point.

In order to obtain further information about two kinds of the time series, several blocks of Japanese islands are analyzed together with sea areas. From the results two kinds of the time series can be seen in the all blocks. In a small region, increase trend of M~7 does not appear, but in a case of M~6, focused trends are also seen. This fact means that possibility of the prediction is successfully performed to M~6.

Appearance of two kinds of time series is not understood at present. Statistical rule of earthquake occurrences called G-R (Gutenberg-Richter) law is well known. This is one of the power laws, in which number of very large earthquakes are very small, and number of small earthquakes are order of magnitude greater than that of large earthquakes. Comparison of this law with the present results can give us important suggestion. This law does not include the factor of time. Present results shows linear increase trends are very simple but real time series are very complex. Time plays main role in the time series. G-R law is obtained from just after many earthquake occurrences. Present results do not show the individual earthquakes, but show continuous processes in earthquake preparation time span.

At the first stage of this study, present trends are presumably attributed to the constant rate of strain

©2019. Japan Geoscience Union. All Right Reserved.

energy accumulation. However, this idea does not interpret the both parallel and focused trend in the time series. Namely mechanism that long time of several years are spent for accumulating the energy is not adequate in the present results. Perhaps critical state of the crust on the earth did exist hundreds of millions of years ago. At present the state can occur the earthquake both at all time and all places, crust give rise to the earthquake occurrences depending on the time durations. Trial of the prediction is now under planning, but origin of the mechanism is an important problem to be solved.

Revisiting a simple method for short-term earthquake probabilities derived from past Seismicity

*Mamoru Kato[1]

1. Graduate School of Human and Environmental Studies Kyoto University

We revisit the method of Kato (2016, doi:10.4294/zisin.68.163) to estimate the probability that random earthquake predictions would hit using the seismicity data after 2011. When the seismicity rate is high, a random earthquake prediction without scientific evidence often becomes successful. Accidental, occasional hits will not guarantee that such methods of earthquake prediction are worthy of trust, and we should have a measure to judge whether the method is reliable. Kato (2016) proposed a method to roughly compute the probability that a random earthquake prediction accidentally hits. In this method, assuming that the rate of background seismicity is nearly constant in any period. This presentation is a follow-up to this study, and we reevaluate the method of Kato using the other seismicity data in Japan. We also revisit two probabilities of Utsu (1977) and argue how to make apparently successful earthquake predictions

Recent anomalous groundwater temperature and water level changes at the frontier land zone of Nanki region for impending great earthquakes at the Nankai trough

*Tameshige Tsukuda[1]

1. none

Earthquakes are generated by the anisotropic principal stress regime in the rock medium. In the preparing process of a large earthquake, the medium would be deformed generating regions of contraction and dilatation around the nucleus of the shearing stresses. According to a hydraulic model, pore fluid flow is driven upward to the ground surface through crack systems serving as flowing pipes by high pressure pumps at a deep spot. The change in the quantity of the upwelling hot water from deep underground causes a change of groundwater temperature(Tsukuda et al., 2005).
We have 16 groundwater observation stations for temperature, and 3 stations for water level in the Tokai and Nanki regions, central and southwest Japan, respectively, where are close to the source regions of the great Nakai-trough earthquakes. This paper reports the seismological meaning of the data from Nanki region.
At stations HA and WA in Shionomisaki, Nanki region, Wakayama Prefecture, the long-term trend of the water level is rising, corresponding to the ground subsidence found by levelling and GNSS data (Kobayashi, 2013). The trend of temperature is similarly rising, suggesting contraction of the rock medium under Shionomisaki, the southernmost end of Honshu. At KZ(Kozagawa)about 15km northeast of HA or WA in the Nanki region, the temperature is monotonously falling since the observation started in 2002. However, the decreasing temperature changed to severely increase in the middle of 2015, and changed to decrease again in 2017.
As mentioned above, the deformations of the rock medium are accelerated under the regions close to the source regions of the great erthquakes at the Nankai trough. For prediction studies for the impending great erthquakes, we should start to conduct detailed and multidisciplinary observations.

Keywords: dilatation, contraction , groundwater temperature, water level, precursor, earthquake prediction

What happen on the East Japan Megaquake; answer to sufferers

*Nobuaki Niitsuma[1]

1. Institute of Geosciences,Shizuoka University

Significant change on stress field was appeared on Northeast Japan. The difference on stress field can be identified by Euler rotation of principal stress axes (Niitsuma, JpGU2015, s-ss27), and the stress fields rotated toward trench side in southeastern part of Northeast Japan but not in northwestern, comparing to stress field of Megaquake. The foci of Megaquake was located on the boundary of the rotation, which indicate the rotation was caused by Megaquake.

Hida area in the central Japan sits on the southwest extinction of the rotation boundary. Hida area had earthquakes from 6 February 2011, 10 days before foreshocks of Megaquake. The activity was complementary with the foreshocks, and the polarities of the stress field (Niitsuma, JpGU2017, sss05-P01) were normal, except the last of 6th March with reversed polarity, comparing with stress field of Megaquake. The maximum foreshock happened 3 days and mainshock of Megaquake 4 days later the polarity reversal, which means Hida area was a part of the constitution to block subduction of Pacific Plate along Japan Trench. The southwestern extinction of Hida area consistent of continental crust, connecting to Korean Peninsula, and the strain for Megaquake had been accumulated in the longest continental crust in Japan and Pacific Plate.

The activity of earthquakes can be converted to Plate relative motion, using area of earthquake fault S from the magnitude M based on log S =1.2M −9.9 (Matsuda,1975). The total area of earthquake faults in North East Japan from 1923/9/2 (just after Kanto Earthquake) to 2011/3/10 (just before East Japan Megaquake) is stepwise increasing on Benioff Chart and reaches to area of M9.0 as same for East Japan Megaquake. The area of relative Plate motion along the Japan Trench for the time interval is 9% less than the earthquake faults, which means the strain for East Japan Megaquake could not be accumulated after Kanto Earthquake, but before.

The area of earthquake faults in North East Japan reached to area for M9.0 before Kanto Earthquake 1923 from 1793, for which area of relative Plate motion was 1.34 of M9.0 and could accumulate strain of 0.34 for M9.0. The Plate motion is not enough for the strain of M9.0 which should be accumulated before 1793.

Because records on historical earthquakes in Northeast Japan are poor comparing with Southwest Japan, the ratio 1.65 on areas of historical earthquake faults in Northeast to Southwest Japan from 1793 to 1923 for calculation on corrected area of earthquake faults in Northeast Japan before 1793.

The corrected area of earthquake faults in Northeast Japan is 0.73 of M9.0 from 1611 to 1793, whose area of Plate motion is 2.06 in which 1.33 could be accumulated enough for the Megaquake. The history of strain accumulation indicates that the Megaquake strain could be kept after filled up with spending for usual earthquake.

Before Megaquake, the focal distribution around non seismic Megaquake foci indicates that rupture was reaching to Megaquake foci. The difference in magnitude of CMT to initial moment in CMT solutions for Hida-side were small than 0.4, which means the main moments were smaller than one forth of estimated

©2019. Japan Geoscience Union. All Right Reserved.

moment from initial moment. Such magnitude differences were identified on the foreshock of Kumamoto Earthquake in April 2016.

[S-SS14] Fault Rheology and Earthquake Physics

convener:Keishi Okazaki(Japan Agency for Marine-Earth Science and Technology), Hideki Mukoyoshi(Department of Geoscience Interdisciplinary Graduate School of Science and Engineering, Shimane University), Hiroyuki Noda(Kyoto University, Disaster Prevention Research Institute), Keisuke Yoshida(Tohoku University), Chairperson:Hideki Mukoyoshi, Shunya Kaneki(Osaka University)

The goal of this session is to integrate theoretical, experimental, observational, and numerical perspectives from various fields such as seismology, geodesy, geology, mineralogy, and so on, to define what is known about earthquake source processes and the physical and chemical elementary processes of faulting. This session welcomes studies that address such issues as pre-, co-, and post-seismic processes, the rheology of seismogenic faults and fault rocks, laboratory experiments on elementary processes, numerical models based on frictional laws, and estimates of the stress field in the seismogenic zones. We also welcome studies on fault-zone drilling projects and in situ stress measurements.

Slickenside is a glossy and smoothly surface developed on the fault slip plane. Although the slickenside is a common and well-known microstructure, its microstructural characterization and effect on the fault behaviour have not fully studied so far. To understand these points, we characterized the microstructures of natural samples and conducted the frictional experiments. The recovery samples from the experiments were also characterized.

Samples and experiment: The natural samples we characterized were slickensides found on the following rocks collected from several localities. 4-Cherts, 3-Limestones, 1-Amphibolite, 1-Serpentinite, 1-Chromitite, 1-Sandstone, 2-Mudstones, 1-Coaly mudstone and 1-Tuff breccia. The frictional experiments were conducted using limestone and gabbro blocks, and calcite powder with 45 to 75 μm in grain size, with a biaxial friction apparatus. The experimental conditions were 3 - 80 MPa of normal stress, 0.1 m/s and 30 μm/s of slip velocity. The characterization methods of samples were optical microscopy, SEM, TEM, AFM and XANES measurements.
Results and conclusion: The present characterization of natural samples demonstrates that the slickenside is composed of nano-size grains, whose aspect ratio (h/d) of height (h) and diameter (d) is constant at about 0.02 –0.05 for each sample. These nano-size grains can be identified as same minerals, not amorphous, composed of the parent rocks with some minor exceptions. This fact indicates that the nano-size grains were created during fault slip only by grinding of parent rocks without any reaction including the heating-induced reaction. Therefore, our first conclusion is that the slickenside is a product of aseismic faulting. The slickensides were created by all frictional experiments. The characteristics of these slickensides are same as those of natural samples described above. The interesting results are that the aspect ratio (h/d) of nano-size grains is constant for each experiment and tends to decrease with increasing normal stress from ca. 0.23 to ca. 0.07. The h/d values of nano-size grains composed of natural samples are much smaller than those of the recovered samples, which suggests that the studied natural slickensides were created by faulting at the higher normal stress conditions than at least 80 MPa, and preserved during exhumation from original depth to earth’ s surface. This consideration indicates that the fault having slickenside exists at depth corresponding to at least 80 MPa normal stress, ca. 3 km and more. The experimental results using limestone block having pre-existing mirror polished slip plane show that the static and dynamic friction coefficients are very low, ca. 0.3 and 0.2, respectively. In general, it is believed that the frictional sliding on pre-existing fault governs the crustal strength. Therefore, our second conclusion is that the slip behaviour of fault having slickenside might governs the crustal strength. However, the experiments using gabbro block did not show the low static and dynamic friction coefficients. Hence the further detail experiments using simulated slickenside are needed to understand the crustal strength.

Dehydroxylation kinetics of clay minerals and its application to friction heating along an imbricate thrust in an accretionary prism

*Hirokazu Masumoto[1], Jun Kameda[1]

1. Faculty of Science, Hokkaido University

Dehydroxylation of clay minerals within fault gouges is significant for assessing transient thermogenesis due to high-velocity, frictional slip along fault zones. The clay minerals kaolinite and chlorite are common in fault zones hosted in sedimentary rocks at subduction margins. To better understand the dehydroxylation processes of these clay minerals, high-temperature X-ray diffraction (XRD) analyses were carried out by using a 1:1 mixture of kaolinite and chlorite standard samples. We evaluated the kinetic parameters of each dehydroxylation reaction by thermogravimetric analysis Thermal models of frictional heating employing this calibration show that the frictional heating can explain the reported clay mineralogy in a fossil imbricate thrust from a shallow part in an ancient accretionary prism (Shirako Fault, Japan). This result supports the previous assertion, and the observed temperature anomaly appears to demonstrate the frictional heating caused by coseismic slip on this fault.

Origin of frictional melt in the Jurassic accretionary complex of the Mino Belt on the basis of trace element and isotope analysis

*Chizuru Ozawa[1], Tsuyoshi Ishikawa[2], Kohtaro Ujiie[1]

1. University of Tsukuba, 2. JAMSTEC

Pseudotachylytes (solidified frictional melts) in exhumed accretionary complexes have great significance for understanding the dynamics of earthquake faulting in subduction zones. However, they are rarely preserved in a recognizable form mainly due to subsequent hydrothermal alteration. Recently, a pseudotachylyte was found in the Jurassic accretionary complex of the Mino Belt, central Japan. The pseudotachylyte is ~2 mm-thick and separates gray chert above from cataclasite below. Although the pseudotachylyte has been hydrothermally altered, its microstructures are characterized by presence of fault and injection veins, intensely cracked gray chert fragments incorporated from wall rocks, and locally embayed and rounded wall rocks, suggesting thermal cracking and thermal erosion associated with increased heating. Here, we analyzed major and trace elements and Sr and Pb isotopes of the milligram-level samples taken by micro-milling technique along the structures of the pseudotachylyte, cataclasite and gray chert, as well as the black chert and black carbonaceous mudstone near the pseudotachylyte. The pseudochylyte exhibits remarkably high trace element concentrations compared to those of gray chert. The trace element composition of the pseudotachylyte requires the involvement of black carbonaceous mudstone as well as gray chert, suggesting that the frictional melt originated from the mixture of gray chert and black carbonaceous mudstone. Based on major and trace element chemistry, the mixing ratio is estimated to be ~50–60% of gray chert and ~40–50% of black carbonaceous mudstone, and the ratio is consistent with the Sr and Pb isotope compositions. Despite the hydrothermally alteration, the chemistry of the pseudotachylyte well preserves melt-derived characteristics, thus provides useful information for understanding the frictional melting on faults and its source materials.

Geochemical constraint on the origin of albite-bearing black fault rocks in the Kodiak accretionary complex

*Tsuyoshi Ishikawa[1], Asuka Yamaguchi[2]

1. Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology, 2. AORI, The University of Tokyo

The Pasagshak Point thrust in the Kodiak accretionary complex is considered to represent the paleo-plate-boundary décollement at seismogenic depths. The fault rocks in this thrust consist of cataclasites and ultrafine-grained black fault rocks (BFRs), and the latter makes up the principal shear zones (Rowe et al., 2005; Meneghini et al., 2010). The BFRs contain crystalline microlayers characterized by the presence of fine-grained albitic plagioclase (Meneghini et al., 2010). Previously Yamaguchi et al. (2014) showed that the trace element characteristics of BFRs are consistent with the occurrence of fluid-rock interactions at >350 deg. C. Here we present further trace element and isotope analyses on the same samples, and re-examine the data in detail. Plagioclase abundances (albite + anorthite) calculated from major element compositions are distinctly higher in BFRs than in host rocks and cataclasites. Distinctly high Sr concentrations and low 87Sr/86Sr ratios observed in BFRs are well correlated with the plagioclase abundances. This indicates that the petrogenesis of BFRs requires additions of Na and Sr derived from external sources, possibly migrating saline fluids. The 87Sr/86Sr ratio estimated for end-component fluid is as low as 0.705, strongly suggesting the involvement of fluids from basaltic source. Li isotope ratios of BFRs are also consistent with equilibration with basalt-derived fluids. Thus, it is likely that saline fluids largely derived from basaltic oceanic crust of the lower plate migrated through the plate boundary décollement, and frictional heating combined with comminution induced high-temperature fluid-rock interactions at >350 deg. C to produce the unique geochemical characteristics observed for BFRs.

Importance of initial maturity and reaction kinetics on maturation of carbonaceous material and its implications for thermal maturity as a proxy for temperature in estimation of coseismic slip parameters

*Shunya Kaneki[1], Ichiba Tatsuya[1], Shuhei Yamashita[1], Tetsuro Hirono[1]

1. Graduate School of Science, Osaka University

Most of total seismic energy during earthquake slip is considered to convert into frictional heat, which activates many physicochemical reactions in faults. Various thermal indicators for detecting frictional heat recorded in fault rocks have been suggested, such as formation of pseudotachylyte and thermal transformation of fault-forming minerals. Among these reactions, thermal maturation of carbonaceous materials (CM) has been received a considerable attention, because CM changes its maturity in response to ambient temperature even with short-term heating duration.

On the basis of these backgrounds, CM maturity has been applied to estimate maximum temperature and coseismic slip parameters experienced by various faults during earthquakes (e.g., Hirono et al., 2015; Kaneki et a., 2016). These studies, however, may contain several concerns when evaluating amount of frictional heat from CM maturity: (1) mechanochemical effect, (2) kinetic effect of heating rate, (3) effect of initial maturity, and (4) cumulative effect of repeated earthquakes. Recently, Kaneki et al. (2018) and Kaneki and Hirono (2018) experimentally investigated the impacts of (1) and (2), and suggested that kinetic effects of both shear-induced mechanochemistry and heating rate can strongly dominate maturation process of CM, indicating that such kinetic effects should be considered to establish CM as a more rigorous fault geo-thermometer. However, the impacts of (3) and (4) on CM maturation process still remain unknown, leading to uncertainties in estimation of maximum temperatures from CM maturity.

In this study, we aim to understand the impact of (3) on CM maturation process and its implication for CM-based fault geo-thermometer. We adopted four grades of CM for our starting materials (lignite, bituminous coal, anthracite, and graphite), and performed low-velocity friction experiments with slip rate of 1 mm $s^{-1}$and normal stresses of 1 and 3 MPa under dry condition, to reproduce coseismic shear damage on CM samples without frictional heating. We then conducted heating experiments on both intact and sheared CM samples with targeted temperatures of 100, 200, 300, ..., 1300 ˚C (100 ˚C interval) and heating rates of approximately 1 and several hundreds of ˚C s^{-1}. We finally carried out infrared and Raman spectroscopies to evaluate maturity of both intact CM samples and products after friction and heating experiments. The results show that mechanochemical effect can enhance maturation process of lignite by ~100 ˚C whereas no significant difference between maturities of intact and sheared CM samples are present in bituminous coal, anthracite, and graphite. All CM samples, except for graphite that showed no significant change in maturity with heating, show higher reaction temperature by ~500 ˚C in heating experiments with higher heating rate. These results indicate that kinetic effects of both mechanochemistry and heating rate affect CM maturation process and the effects depends on initial maturity of CM. Thus, by taking consideration into initial maturity and kinetic effects, thermal maturation of CM could be an universal proxy for temperature in estimation of coseismic slip parameters.

Experimental investigation of cumulative effect on thermal maturation of carbonaceous material as a proxy for earthquake slip

*Tetsuro Hirono[1], Yuhtaro Shimamura[1], Shunya Kaneki[2]

1. Department of Earth and Space Science, Graduate School of Science, Osaka University, 2. Disaster Prevention Research Institute, Kyoto University

Estimation of the maximum temperature recorded in fault rocks gives us important information about earthquake enegetics and fault slip behavior, because the frictional heat is directly related to dynamic parameters and to fault-weakening mechanisms. The thermal maturity of carbonaceous material (CM) has received considerable attention as a new temperature proxy because the organochemical characteristics of CM change irreversibly with increasing temperature. Various approaches by using infrared and Raman spectroscopies, elemental composition analyzer, biomarker method, and vitrinite reflectance measurement have been performed. However, for more accurate estimation of frictional heat, not only shear-enhanced mechanochemical effects but also chemical kinetics should be considered. In particular, cumulative effect by repeated earthquake events, related to the kinetics of the maturation, has not well understood. Here we demonstrated repeated heating events on bituminous coal and anthracite by using a tube furnace. We heated the samples 1, 10, and 100 times under conditions of 100, 300, 500, 700, 900, 1100, and 1300 degree C and 40-s heating duration, and conducted infrared and Raman spectroscopic analyses on the samples after heating. The disappearance of aliphatic C-H at 500 degree C were observed on all samples, and the intensity ratio of D and G bands on the Raman spectra of all samples increased beyond 700 degree C. Thus, we could conclude no significant cumulative effect on the thermal maturation of CM under rapid heating, indicating that the detected temperature on a fault corresponds to the largest earthquake slip event.

Fault rheology at the depth limits of the seismogenic zone

*Berend Antonie Verberne[1]

1. Geological Survey of Japan, National Institute of Industrial Science and Technology

The limits of the seismogenic zone demarcate changes in fault behaviour with increasing depth in Earth's crust, from aseismic, velocity (*v*-)strengthening to seismogenic, *v*-weakening, and vice versa. Significantly, the *v*-dependence of fault strength is a material property of the sliding medium present in the core of fault, or the fault gouge. I conducted shear tests using simulated fault gouge composed of calcite ($CaCO_3$) at an effective normal stress of 50 MPa, at temperatures of 20 to 600ºC, employing sliding velocities (*v*) of 0.03 to 300 μm/s –sufficient to span the brittle-plastic transition in this material. Mechanical results showed (unstable) *v*-weakening behaviour from ~80-100ºC to ~550ºC, but stable *v*-strengthening for <80-100ºC and >550ºC. All gouges sheared at temperatures <=550˚C showed localization into nanocrystalline principal slip zones, while samples sheared at >550˚C were characterized by distributed deformation. Using the post-test micro- and nanostructures observed in calcite gouge as a basis, plus a previously established microphysical model, I argue that transitions in fault stability are caused by changes in the (nano)granular flow processes accommodating shear. Specifically, the rate of intergranular compaction by Arrhenius-type processes such as diffusion or crystal plasticity, is key to thermally-activated transitions in the velocity dependence of gouge-filled faults. At the low-temperature transition from *v*-strengthening to *v*-weakening, at shallow crustal levels representing the upper-limit of the seismogenic zone, diffusion creep (e.g. pressure solution) may be dramatically accelerated due to the nanogranular nature of the fault rock that forms. At higher temperatures, towards the base of the seismogenic zone, a transition occurs from nanogranular flow in localized faults to distributed, fully creep-controlled flow in ductile shear zones.

Fault models revisited based on friction to flow law

*Toshihiko Shimamoto[1]

1. State Key Laboratory of Earthquake Dynamics, Institute of Geology, China Earthquake Administration

Friction to flow law (Shimamoto and Noda, 2014, JGR) can describe a transition from friction to flow using only friction and flow parameters, and shear zone width *w*. Friction and flow laws are described in terms of velocity and displacement, and shear strain rate and shear strain, respectively, and *w* is needed to relate velocity and shear strain rate to merge the two laws. The friction to flow law is a mixing law connecting friction and flow laws smoothly, and no other parameters are required probably because no new deformation mechanisms operate in the intermediate regime. In JpGU last year, Shimamoto and Noda argued (i) that the velocity dependency of shear resistance is by far the most heterogeneous in the intermediate regime between friction and flow, and (ii) that frictional patches can be surrounded by viscous matrix in the middle part of lithosphere because temperature for the onset of flow depends on rock types. This presentation will discuss (1) how fault models change in view of the friction to flow law, (2) how to construct realistic mechanical models of faults and plate boundaries that are usable in modelling earthquake generation, and (3) how to reproduce friction to flow transition for important rocks in laboratory.

Shimamoto and Noda (cited above) already discussed a revised fault model using results from earthquake modelling based on friction to flow law. A new problem addressed here is a question which of power law (dislocation creep) and grain-size sensitive flow law (diffusion creep or superplasticity) should be used as a flow law to describe fault properties. The latter law has often be favoured because the cores of deep shear zones are often composed of very fine-grained ultramylonites, grain size being on the order of microns or even smaller. Both flow laws are determined for calcite and plagioclase (Heard and Raleigh, 1972, GSA Bull.; Schmit et al., 1977, Tectonophysics; Rybacki and Dresen, 2000, JGR). Thus, strength profiles were constructed with the friction to flow law, assuming $w = 0.1 \sim 10$ m and velocity = 10 mm/yr. Results clearly show that diffusion creep occurs at lower stresses for both minerals (although this is not the case in laboratory experiments). Power-law creep is expected in the middle and lower parts of lithospheres, whereas diffusion creep is expected to be dominant in fault and plate-boundary zones. Thus, frictional patches can be surrounded by linear or nearly linear viscous flow matrix at some depths, and this can be quite important in analysing low-frequency earthquakes and slow slips.

Traditional fault models, started from Sibson (1977, J. Geol. Soc. London), have proposed how materials controlling friction and flow properties, types of fault rocks reflecting deformation mechanisms, and fault geometry such as fault and shear zone widths changes with increasing depth. Such models are bases for constructing realistic mechanical models for faults and plate boundaries. However, the models alone are not usable in modelling earthquakes and plate-boundary behaviours. Friction to flow law captures essential changes in fault properties with depth in a very simplified manner. Both transient and steady-state properties are included and the law can be used in earthquake modelling. However, the law for single material can never describe complex and variable properties of faults and plate boundaries. I want to discuss what has to be done to connect fault and earthquake studies, as much as possible in my presentation. Here I point out the importance of three problems; (I) to check if the friction to flow laws holds for important rocks or not in laboratory experiments, (II) to determine flow laws for important rocks constituting fault and plate-boundary zones, and (III) to determine transient flow properties in flow laws (see Noda and Shimamoto, 2010, GRL). I will give apparatus capabilities required for (I). Unfortunately,

Timing of Earthquakes on Intraplate Active Faults Subjected to Stress Perturbation by Megathrust Earthquakes: Insights from Earthquake Sequence Simulation

*Hiroyuki Noda[1]

1. Kyoto University, Disaster Prevention Research Institute

Estimation of likelyhood of occurrence of intraplate large earthquakes is crutially important because of expected large amplitude of ground motion in nearby cities and short distance between source and human society which makes earthquake early warning difficult. Currently issued National Seismic Hazard Maps for Japan [2018, the Headquarter for Earthquake Research Promotion] adopts assumptions of Poisson process or Brownian passage time distribution depending on available information for each active fault. They yield rather wide distribution of temporal probability density for a timescale of the reccurence interval or the estimation error of history of events. The timelscale is typicaly much longer than recurrence intervals of megathrust earthquakes T_{cyc} which causes semi-periodic stress perturbation to intraplate faults. In the present study, effects of the semi-periodic stress perturbation to an intraplate active fault having a ductile shear zone beneath the seismogenic part [e.g., Shimamoto and Noda, 2014] are investigated by means of dynamic earthquake sequence simulation using a spectral boundary integral method [e.g., Lapusta et al., 2000].

Utsu [1974] pointed out that historical earthquakes in Southwest Japan are concentrated in -50 and +10 years from Nankai trough megathrust earthquakes. Such active periods of intraplate earthquakes may be due to semi-periodic stress perturbation by the megathrust earthquakes [e.g., Hori and Oike, 1996; Shikakura et al., 2014]. An important question is how its duration is scaled for different tectonic settings. T_{cyc} of megathrust earthquakes in Japan trench subduction zone is 500-800 years [e.g., Sawai et al., 2015] and much longer than in Nanka trough. Parameter studies on T_{cyc} and amplitude of the stress perturbation have been conducted to elucidate what controls the timing of intraplate earthquakes.

A 2D numerical simulation of a strike-slip fault [e.g., Lapusta et al., 2000] with ductile shear zone was considered as a model for an intraplate fault, accounting for a friction-to-flow fault constitutive law [Shimamoto and Noda, 2014] composed of the aging law and a quartzite flow law [Hirth et al., 2001], and effective normal stress distribution with maximum value of 50 MPa. The model was drived by far-field shear stress which was perturbed as a sawtooth wave function of variable amplitude about 1 MPa and T_{cyc} from 100 to 1000 years. If the perturbation was perfectly periodic, the system synchronized with the perturbation and the intraplate earthquakes ocurr at a specific phase in the cycle of megathrust earthquakes. If the interval was randomized by Gaussian distribution of 10% standard deviation, then the timing of the intraplate earthquakes distributed more widely, and concentrate in the latter half of the cycle, consistently with the notion of the active period. The shape of the distribution can be explained by a seismicity model based on ΔCFF [e.g., Shikakura et al., 2014], not by a rate-and-state spring-slider model [Dieterich, 1994; Ader et al., 2014]. The result of the parameter study suggests that not only the history of the activity of the fault, but also stress change on it due to recurring megathrust earthquakes or other events may be useful in constrainig the likelihood of intraplate earthquakes.

Physics of earthquake triggering: effect of stress perturbation to slip acceleration

*Takahiro Hatano[1]

1. Earthquake Research Institute, University of Tokyo

Recent observation studies have revealed that the occurrence of tremors is sensitive to faint stress changes such as ocean tides. This might not be surprising in light of the low stress drop caused by tremors. Interestingly, however, ordinary earthquakes too may be sensitive to weak stress perturbations, although it is not so common as for tremors. Dynamic triggering should be the most prominent illustration of such sensitivity, but the occurrence of ordinary earthquakes could be also correlated to ocean tides, snowfalls, and rainfalls.

To understand such sensitivities to stress perturbation in a unified point of view, here we analyze the rupture nucleation process on a fault subject to weak periodic stress modulation. Assuming the rate- and state-dependent friction law with one state variable, we calculate the threshold amplitude above which the rupture initiation exhibits correlation with the perturbation phase. It is found that the crack-like nucleation is more sensitive to the perturbations than the patch-like nucleation. The estimated threshold amplitude for the crack-like nucleation is significantly lower than the tidal stress change. Time-to-failure for the both nucleation types in the presence of perturbation is estimated, and it is not significantly affected by the stress perturbation. We also discuss the optimum frequency at which the correlation is enhanced.

Foreshock activities controlled by slip rate on a 4-meter-long laboratory fault

*Futoshi Yamashita[1], Eiichi Fukuyama[1], Shiqing Xu[1]

1. National Research Institute for Earth Science and Disaster Resilience

We report foreshock activities associated with evolving local slow slip events preceding the main rupture on a laboratory fault. To investigate the preparation process of laboratory earthquake with enough spatial resolution, we used a large-scale friction apparatus newly developed and installed at National Research Institute for Earth Science and Disaster Resilience (NIED) as shown in Figure 1. We used two rectangular metagabbro blocks as experimental specimens, whose nominal contacting area was 4.0 m long and 0.1 m wide. Height of each specimen was 0.2 m. Normal load was applied by eight flat jacks on the top surface of the upper specimen, and the associated pressures were kept at around 6 MPa during the experiments. After applying normal load, we applied shear load to the side surface of the lower specimen by manually pumping up a hydraulic jack, which was fixed at the western end of the apparatus. To monitor local phenomena on the fault, we installed 16 AE sensors, 40 triaxial rosette strain gauges, and 10 eddy current displacement sensors along the fault. We conducted experiments with relatively high shear loading rate (67-185 kPa/s) and low shear loading rate (2-7 kPa/s). In each experiment, displacement data showed that both the eastern and western edges of the fault kept slipping during the shear loading, though the slip rate was very low (< ~20 μm/s). It is consistent with FEM calculation that fault should start to slip at both edges in this configuration. This steady slip was significant during the experiments with low loading rate, in both quantity and area. However, such steady slip did not immediately trigger seismic events. Most of seismic events occurred just before the main rupture, and therefore should better be termed foreshocks. To understand what controls the occurrence of foreshocks, we first investigated the amount of stable slow slip accumulated after the previous main rupture. We found that foreshocks were not activated at around both fault edges even after the accumulated slip attained around 10 μm there (Figure 2a). On the other hand, foreshocks occurred around the central locked area with only a small amount of slip. We next compared the spatiotemporal distribution of foreshocks with that of slip rate. Displacement and strain data indicated that precursory slow slip began at the central locked area and then propagated outward over the fault area preceding the main rupture. We found that this slow slip had caused high slip rate (several hundreds of μm/s), which coincided with the occurrence of foreshocks (Figure 2b). These observations suggest that the key factor controlling the occurrence of foreshocks in this experiment is not the amount of accumulated slip but that of slip rate. The mechanism may be associated with the unstable fault slip triggered by fast loading in the laboratory (McLaskey and Yamashita, 2017, JGR; Xu et al., 2018, Tectonophysics), and the seismicity episodically activated in nature such as emergence of repeating earthquakes due to increased loading rate by afterslip of the 2011 *M*9.0 Tohoku-oki earthquake (Hatakeyama et al., 2017, JGR).

Supersonic propagation of slow slip rupture during rock friction experiments

*Eiichi Fukuyama[1], Futoshi Yamashita[1], Shiqing Xu[1]

1. National Research Institute for Earth Science and Disaster Resilience

Rupture propagation speed on the fault has been considered to be slower than elastic wave velocities of the material. Exceptions were when extremely high energy is imposed, much higher than the fracture energy needed for the rupture to advance. The rupture propagating faster than the elastic velocities is called supersonic rupture. We observed such supersonic rupture propagation of slow slip events during large scale rock on rock friction experiments on a 1.5×0.1 m^2 fault using Indian metagabbro rock specimens. Such slow slip events were accompanied by low frequency vibrations whose onsets were synchronized with those of slow slip events; they also propagated faster than the elastic wave velocities of the rock. Since typical precursory slow slip and coseismic slip events have been observed on the same fault in a sequence of the friction experiment, the slow slip events with supersonic rupture might share the same friction environment as that for the typical preslip-mainshock type events. We interpret this phenomenon as an occurrence of non-linear deformation of a very thin layer on the fault surface. For linear deformation case, the limitation of propagation velocity comes from the elastic property of rock specimens, but non-linear deformation can propagate independently of the material elastic constants but the propagation velocity tend to be proportional to the strain rate. In addition, because there are several similarities between the present observation and the slow slip events observed in the subduction zone worldwide, it may provide a clue to understand these phenomena.

The powerful M 7.2 earthquake that shock the Sulawesi island of Indonesia on September 28, 2018, was a seismic standout for many reasons, not the least of which is that it triggers tsunami and landslides and causes major life and economic loss in the city of Palu. In this study, integrated geophysical observations of the 2018 Mw 7.5 Palu, Indonesia earthquake, provide robust evidence of an early and persistent supershear rupture speed. Slowness-enhanced back-projection (SEBP) of teleseismic data provides a sharp image of the rupture process, consistently across multiple arrays. The inferred rupture path agrees with the surface rupture trace inferred from the net surface displacement field derived by sub-pixel InSAR image correlation. The SEBP results indicate a sustained rupture velocity of 4.1 km/s from the rupture initiation to the end, despite large fault bends. The persistent supershear speed is further validated by evidence of far-field Rayleigh Mach waves in regional seismograms. Supershear earthquakes with rupture velocity exceeding shear-wave speeds, previously observed in laboratory experiments and large strike-slip events, often have an initial sub-shear stage before they transition to supershear. The rupture speed of the 2018 Palu earthquake is supershear from very early on. The short or absent supershear transition distance can be caused by high initial shear stress or short critical slip-weakening distance, and promoted by fault roughness near the hypocenter. Steady rupture propagation at a supershear speed considered to be unstable, lower than the Eshelby speed, could result from the presence of a damaged fault zone.

The role of curvature in earthquake mechanics

*Pierre Romanet[1], Daisuke Sato[2], Ryosuke Ando[1]

In recent years, many studies have tried to catch the influence of geometry in earthquake mechanics. In this paper, we suggest a new interpretation of the effect of geometry on the stress on a fault, as a direct effect of local curvature and torsion of line field of slip along the surface of the fault. Within this framework, it is possible to unify the understanding of bends, kinks and roughness, as an effect of local parameters along the fault. Starting from the representation theorem, that links the displacement in a medium to the slip distribution on his boundary, and assuming homogeneous infinite medium, we first derive a new regularized boundary element method. Using this equation, we were able to separate the influence of geometry, express by curvature and torsion of the fault surface geometry and the slip direction, from the effect of the gradient of slip. This allows us to shed a new light on the mechanical effects of geometrical complexities on fault surface. We used that new discovery to solve a paradox between smooth and abrupt kink [Tada and Fukuyama 1996] as well as re-interpret the effect of roughness on the fault: It can be shown that the effect of drag stress [Fang and Dunham 2013] along the fault it actually exactly equal to the effect of curvature along the fault.

Numerical modeling is a necessary tool for the assessment of variability strong ground motions in potential devastating large earthquakes. In a simulation-based seismic hazard analysis, it is critical to be able to generate a large number of physically self-consistent source models whose rupture process captures the main physics of earthquake rupture and is consistent with the spatio-temporal heterogeneity of past earthquakes. An inherent difficulty in such efforts is that, from a mechanical point of view, stress and strength heterogeneities cannot be prescribed arbitrarily as was done in earlier work. Their interdependence must be consistent with a mechanical model of deformation and stress evolution over the longer time scale of the earthquake cycle.

In this work, a set of spontaneous source models have been generated in a wide magnitude range (*Mw* 5.5-7.5) by using multicycle simulations under the rate-and-state friction law with the goal of studying the characteristics of source scaling relations and strong ground motions. To get realistic irregular seismic sequence, several realizations of 2D correlated heterogeneous random distributions of characteristic weakening distance "*Dc*" in rate and state friction are tested. A mesh grid size of 125 meters has been used to resolve properly the nucleation and cohesive zone of the seismic events. The fault is 128 km in length and 30km in width, the seismogenic width is 18km. The quasi-dynamic solver QDYN (Luo, et al., 2017) has been used to nucleate the seismic events and SPECFEM3D (Galvez et al, 2014; 2016) to resolve the rupture process. Other important parameters are the normal stress, which controls the stress drop and rupture velocity during an earthquake, and the maximum value of *Dc* distribution, that controls rupture velocity but not stress drop. Following these ideas, we perform dynamic rupture modeling to take into account the free surface effects and perform a parametrization study; parameters of our final friction model are shown in Fig.1.

In order to validate source models we compare the source scaling relations vs. seismic moment *Mo* for the modeled rupture area *S*(*Mo*), average slip of the ruptures *Dave*(*Mo*) and the slip asperity area *Sa*(*Mo*), with similar scaling relations from the source inversions. Fig. 2 shows result for *S*(*Mo*). The seismogenic zone width plays a fundamental role in the *S* vs *Mo* scaling. In fact, Luo et al. (2017) reported that events which break the whole seismogenic width and reach the free surface are exposed to an attraction effect from the free surface. This attraction effect may explain the transition regime from Stage 1 (self-similar rupture, $Mw < 6.5$) to Stage 2 ($6.5 < Mw < 7.4$). Ground motions have been also computed from our models. Their peak ground velocities (*PGV*) agree well with the GMPE values.

Strain energy released by an earthquake: Contributions of random slip fluctuations

*Tatsuhiko Saito[1], Akemi Noda[1]

1. National Research Institute for Earth Science and Disaster Resilience

Strain energy in the lithosphere is the source of earthquake generation. For example, the shear strain energy change caused by the interplate coupling along the Nankai Trough, Japan affects the seismicity in the inland area (Saito et al. 2018 JGR). The aftershocks of the 2016 Kumamoto earthquakes were activated by the shear strain energy brought by the mainshocks (Noda et al. 2018 ACES; Tanaka et al. 2018 JpGU). The strain energy change caused by an earthquake is one of the most fundamental quantity for earthquake mechanics. When the stress change occurs uniformly on the earthquake fault (constant stress drop), a simple theoretical equation gives the relation between the seismic moment, initial stress, stress drop, and the strain energy liberated by the earthquake (e.g., Aki and Richards 2002). This relation leads that the strain energy released by an earthquake is proportional to the seismic moment. However, for actual earthquakes, the stress change on the fault is considerably heterogeneous.

The present study theoretically investigates the relation between the strain energy released by an earthquake and the seismic moment when the stress change is not uniform on the fault plane due to heterogeneous slip distribution. We assume that the initial stress is homogeneous in space and suppose that the heterogeneous slip distribution is given by the sum of the reference slip distribution causing the constant stress drop and the randomly fluctuating slip distribution. We adopt a stochastic approach using an ensemble of the slip fluctuations characterized by the power spectral density functions such as Gaussian and von Karman type function. The derived theoretical relation gives a scaling law of the strain energy with the power spectral density function of the slip fluctuation. This deduces the following results. (1) When an earthquake contains randomly fluctuating slip distribution, the liberated strain energy is smaller than that of the constant stress-drop earthquake. (2) This indicates that a representative value of stress drop becomes large due to the randomly fluctuating slip distribution in the view point of the energy partition. This study refers to this stress drop as effective stress drop. This was also reported by some studies such as Noda et al (2003 GJI) and Hirano and Yagi (2017 GJI). This study derived a theoretical equation of the effective stress drop with the power spectral density function of the random slip fluctuation. (3) When the stress change is not constant on the fault, the strain energy is not proportional to the seismic moment unless the correlation distance of the slip fluctuation is proportional to cube root of the seismic moment. (4) The energy balance gives a value of the initial stress that is required for the earthquake generation. In order to generate an earthquake, the initial stress needs to be larger than the sum of the half of the effective stress drop and the apparent stress (the apparent stress is given by rigidity, radiation energy, and seismic moment (Wyss and Brune 1968,1971)).

The change in the elastic strain energy due to the 1992 Landers earthquake and triggering mechanisms of aftershock activity

*Toshiko Terakawa[1], Mitsuhiro Matsu'ura[2], Akemi Noda[3]

1. Graduate School of Environmental Studies, Nagoya University, 2. Institute of Statistical Mathematics, 3. National Research Institute for Earth Science and Disaster Resilience

Earthquakes are physical processes to release elastic strain energy stored in the Earth’s crust by shear faulting. This quantity is essentially important for understanding earthquake generation. However, we have little knowledge on the quantity, because it is difficult to measure stress in-situ. Recently, Terakawa and Hauksson (2018) developed a method to model and estimate the 3-D absolute stress field from earthquake focal mechanism data, using the reference pore pressure as a single parameter (the reference pore pressure). In this study, we directly investigated changes in elastic strain energy, based on 3-D abosolute stress fields modeled by Terakawa and Hauksson (2018). Then, we tried to propose a new criterion to understand aftershock activity following large earthquakes instead of the change in Coulomb Failure Function (CFF), based on elastic strain energy.

First, we investigated partitioning of changes in shear and volumetric strain energies due to the 1992 Landers earthquake (M_W 7.3). Changes in volumetric strain energy did not depend on the reference pore pressure, or the level of deviatoric stress field. On the other hand, those in shear strain energy was closely related to the parameter. More shear strain energy were released when the background deviatoric stress magnitudes were higher. The elastic strain energy released by the mainshock is consumed as radiated, fracture and thermal energies. The amount of change (decrease) in the elastic stain energy must be at leaset larger than radiatied energy, which can be estimated (e.g., Kostrov, 1974; Ide, 2002). Therefore, the change in shear strain energy plays a crucial role to constrain the the most plausible reference pore pressure and eventually the level of the (absolute) deviatoric stress field.

When a stress field is compressed due to the mainshock, frictional strength as well as volumetric strain energy in the region will increase after the mainshock. This means that an increase in elastic strain energy do not necessarily mean activation of seismicity. The shear and volumetric strain energy are closely related to the average shear and normal stresses acting on faults randomly and isotropically distributed in the crust (e.g., Saito et al., 2018; Matsu’ura et al., under review). Increases in shear and volumetric strain energies have positive and negative effects on triggering aftershocks following the mainshock. In order to understand aftershock activity, we need to correctly consider both effects of the two kinds of strain energies into account. As the elastic strain energy is scalar quantity, we do not have to set any receiver faults, unlike using the change in CFF. In the source region of the Big Bear earthquake (M_W 6.5), which is the largest aftershock following the Landers mainshock, the shear strain energy increased, but the volumetric strain energy decreased. Both changes would have promoted this event. In the region just south of the hypocenter of the mainshock, the total effect from the two kinds of strain energies suggest that seismicity would have become inactive, contrary to the actual activation. Focal mechanism solutions of some of these events were normal faulting with NW-SE tension. We can understand that these events would have reactivated by decrease in fault strength under the stress field characterized by strike-slip faulting with NE-SW compression and NW-SE tension. This suggest that many aftershocks in the region may have been triggered by overpressurized fluids.

Toward understanding generation mechanism of crustal earthquakes based on accumulation/release of elastic strain energy

*Akemi Noda[1]

1. National Research Institute for Earth Science and Disaster Resilience

Although the physical process of interplate earthquakes has been modeled from the viewpoint of accumulation and release of shear stress on plate boundaries, it is difficult to apply the framework directly to cycles of crustal (inland) earthquakes. It is necessary to assume a fault plane to obtain shear stress in a stress field, but the faults in the crust are not a continuous and unique plane of weakness like plate boundaries. Furthermore, there are many unknown faults covered by sedimentary layers.

The shear strain energy is a scalar quantity appropriate for evaluating the potential of earthquake occurrence in the case that the fault plane cannot be specified. The scalar quantity corresponds to the average value of the shear stress acting on randomly distributed cracks in the crust (Saito et al., 2018). In other words, an increase and decrease in the shear strain energy correspond to the accumulation and release of crustal stress, respectively. In addition, since the work done for shear faulting is related to the release of elastic strain energy in the surrounding region (Aki & Richards, 1980; Matsu'ura et al., 2019), the strain energy can be thought of as an essential physical quantity for earthquake generation. Evaluating the accumulate and release of the shear strain energy in the crust, therefore, would help to understand the generation mechanism of crustal earthquakes.

To evaluate the shear strain energy changes, we must have not only stress changes but also background stress fields. However, it is difficult to know the absolute value of the background stress. Under the assumption that the absolute level of the background stress is much greater than the stress changes, Saito et al. (2018) derived an expression of shear strain energy changes normalized by the differential stress of the background stress using the spatial pattern of background stress orientation and the stress changes. Then, they calculated the normalized shear strain energy changes in the inland seismogenic layer caused by interplate coupling along the Nankai Trough, and found the correlation between the shear strain energy changes and seismicity in the southwestern Japan.

In order to apply this framework to tectonic zones in the crust, Noda et al. (2018 AGU) developed a method to evaluate the shear strain energy changes using elastic/inelastic strain analysis method (Noda & Matsu'ura, 2010). Firstly, we inverted the 3-D moment tensor density distribution in the crust as the source of crustal deformation from GNSS displacement data. The 3-D elastic/inelastic strain distribution in the crust was obtained from the estimated moment tensor density distribution. The stress changes were calculated by multiplying the elastic strain distribution by assumed elastic constants. Secondly, given a background stress field, the 3-D shear strain energy changes in the crust was evaluated from the calculated stress changes.
This method was applied to coseismic and preseismic GNSS data associated with the 2016 Kumamoto earthquake. For the background stress, we used the 3-D tectonic stress field estimated by CMT data inversion (Terakawa & Matsu'ura, 2010). The coseismic shear strain energy changes were estimated from the coseismic GNSS displacement data and showed its correlation with the spatial pattern of aftershock activity. Next, we evaluated preseismic changes in shear strain energy from GNSS displacement rate data (2005~2011), and found an increase (accumulation) in a part of the Futagawa fault, which is one of the main faults coseismically slipped during the earthquake, and a large decrease (release) in the

©2019. Japan Geoscience Union. All Right Reserved.

northeastern end of the fault, where the coseismic slip terminated. The shear strain energy change was caused by a large inelastic deformation (brittle fracture/plastic deformation) in the shallow crust along the Aso-Kuju volcanoes.

Wed. May 29, 2019 3:30 PM - 5:00 PM JST | Wed. May 29, 2019 6:30 AM - 8:00 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_16

[S-SS14] Fault Rheology and Earthquake Physics

convener:Keishi Okazaki(Japan Agency for Marine-Earth Science and Technology), Hideki Mukoyoshi(Department of Geoscience Interdisciplinary Graduate School of Science and Engineering, Shimane University), Hiroyuki Noda(Kyoto University, Disaster Prevention Research Institute), Keisuke Yoshida(Tohoku University)

The goal of this session is to integrate theoretical, experimental, observational, and numerical perspectives from various fields such as seismology, geodesy, geology, mineralogy, and so on, to define what is known about earthquake source processes and the physical and chemical elementary processes of faulting. This session welcomes studies that address such issues as pre-, co-, and post-seismic processes, the rheology of seismogenic faults and fault rocks, laboratory experiments on elementary processes, numerical models based on frictional laws, and estimates of the stress field in the seismogenic zones. We also welcome studies on fault-zone drilling projects and in situ stress measurements.

Measurement of shear-wave polarization anisotropy in crack-bearing Aji granite during shear experiment

*Jinki Tanaka[1], Ikuo Katayama[1]

1. Hiroshima University

The stress drop at the time of the earthquake not only releases the stress applied to the fault plane but also causes the rotation of the principal stress axis applied to the fault plane. In fact, the change in the direction of the principal stress axis after the earthquake is reported by the mechanism solution of aftershocks and the seismic wave anisotropy(e.g. Tadokoro and Ando 2002; Boness and Zoback 2006). It is thought that this is because the closing (opening) direction of the cracks around the fault plane correspond to the stress axis. Therefore, in this study, the elastic wave velocity was monitored during the shear experiment of the rock and the relation between the shear stress and the principal stress axis and elastic wave velocity was measured in the laboratory. Since the shear-wave polarization anisotropy has a characteristic which is sensitive to the direction of the crack, measurement of different vibration components of S wave is performed in addition to measurement of P wave velocity.

For the experiment, we investigated the change in elastic wave velocity according to shear deformation using a High-T biaxial frictional testing machine in Hiroshima University. For the experimental samples, Aji granite which generated thermal cracks inside by heating to 600 degrees Celsius was used. In the shear experiment, it was carried out by loading the central rock block at a constant speed while keeping the vertical stress constant. The shear sliding velocity was about 0.9 μm/s and the normal stress was 5 MPa. For measurement of elastic waves, probes with a resonance frequency of 1 MHz (manufactured by Olympus Corporation) were used, and S wave and P wave were measured by pulse transmission method. The propagation direction of elastic wave is parallel to the shear plane and perpendicular to the shear sliding direction, and for the S wave, we measured two components, wave (SH) oscillating in the plane orthogonal to the shear plane and wave (SV) oscillating parallel to the shear plane.

From the experimental results, with the increase of the shear stress, it was found that the velocity of SH wave rises earlier and the SV wave rises late. In addition, there was a phenomenon in which the initial motion of the SV wave jumped suddenly as the shear stress increased. This means that when the shear stress is low and the maximum principal stress axis in the sample is close to the direction of the normal stress, the shear direction cracks are frequently closed and the SH wave velocity increases, and the shear stress increases, when the inclination of the maximum principal stress axis becomes steeper with respect to the normal stress, it is considered that the direction of the crack which closes is correspondingly inclined. In this way, since the SH wave and SV wave behave differently due to the increase of the shear stress and the corresponding change of the principal stress axis angle, by utilizing this property, a good index for monitoring the stress state around the fault.

Effects of talc content on frictional properties of quartz gouge

Risako Shirahige[1], Inori Tatara[1], *Ken-ichi Hirauchi[1], Takato Takemura[2]

1. Department of Geosciences, Faculty of Science, Shizuoka University, 2. Department of Earth and Environmental Sciences, College of Humanities and Sciences, Nihon University

Phyllosilicates have low coefficients of friction and an effect of weakening fault strength. To understand effects of talc content on frictional strength and sliding stability, we conducted frictional sliding experiments on dry gouge mixtures of quartz and talc at room humidity, room temperature, a normal stress of 10 MPa and sliding velocities of 0.66–2 μm/s, using a single direct-shear apparatus. The coefficient of friction for the mixture ranged from 0.18 to 0.69 and fell between pure quartz and talc values. The overall trend was a decrease in the coefficient of friction with increasing talc content. The velocity dependence of friction, ($a-b$), ranged from −0.0018 to 0.0039 and increased with increasing talc content. The ($a-b$) values are highest in the mixture with a talc content of 80 wt.%. For the mixture with talc contents below 10 wt.%, the ($a-b$) values become negative, with the occurrence of slow to fast stick-slip behavior.

Mechanism controlling the frictional strength of quartz rocks at intermediate slip rates

*Kyuichi Kanagawa[1], Asuka Sugita[2], Miki Takahashi[3], Michiyo Sawai[1]

1. School of Science, Chiba University, 2. Faculty of Science, Chiba University, 3. Research Institute of Earthquake and Volcano Geology, Geological Survey of Japan

Frictional strength of quartz rocks is known to be extraordinary low at subseismic slip rates ranging from 1 mm/s to 10 cm/s, which has been ascribed to the hydration of comminuted amorphous silica, i.e., silica gel. In order to testify this hypothesis, we conducted rotary-shear friction experiments on intact agate or silica gel gouge at a normal stress of 1.5 MPa and slip rates (V) ranging from 1 mm/s to 10 cm/s. We also measured temperature (T) adjacent to the slip surface or the gouge layer during the experiments.

Steady-state friction coefficient of agate μ_{ss} was ≈0.6 at V = 1 mm/s, ≈0.5 at V = 7 mm/s, and ≦0.1 at V = 10 cm/s. T was ≈25˚C at V = 1 mm/s, ≈30˚C at V = 7 mm/s, and up to 85˚C at V = 10 cm/s, but the actual temperature along the slip surface must have been much higher. μ_{ss} of silica gel gouge was ≈0.7 at V = 1 mm/s, 0.4–0.5 at V = 7 mm/s, and ≦0.2 at V = 10 cm/s. T was 25–28˚C at V = 1 mm/s, 30–37˚C at V = 7 mm/s, and 80–100˚C at V = 10 cm/s, but again, the actual temperature in the gouge layer must have been much higher.

Thus our results show that agate or silica gel exhibits weakening with increasing T, and that the presence of silica gel does not reduce the frictional strength when T is not high enough. Shear strength of quartz rocks is high so that significant amount of frictional heat would be produced at asperity contacts even at V ≈1 cm/s, which must be responsible for weakening of quartz rocks at intermediate slip rates.

Evolution of hydraulic and frictional properties of incoming hemipelagic sediments during diagenetic reactions

*Keishi Okazaki[1], Ikuo Katayama[2], Asuka Yamaguchi[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. Dept. of Earth & Planetary Systems Science, Hiroshima University, 3. AORI, the University of Tokyo

Deployments of seismic and geodetic observation networks had revealed the activity of slow earthquakes along the subduction plate boundaries, which are characterized as intermediate fault slip rate between earthquake (~1m/s) and stable sliding along the plate boundary (~1 nm/s). Diagenesis of subducting sediments has stimulated interest in their relationship to regular and slow seismicity in the subduction zone. We report experimental results on the effect of diagenetic reactions to hydraulic and frictional properties of incoming hemipelagic sediments. Hemipelagic sediments taken from KS-15-3 Shinseimaru cruise are used as the starting sample. Friction experiments and permeability measurements were carried out with a confining pressure of 150 MPa and a pore pressure of 58 MPa and temperatures ranging RT–230 degC. When the sample is sheared immediately after reaching the experimental condition, all experimental data at the temperature below 150 degC showed a velocity-strengthening behavior. On the other hand, at the temperature of 230 degC, the frictional behavior is no longer stable, but stick-slip behavior was observed during the experiments. We also measured a time-dependent permeability evolution of hemipelagic sediments to assess how diagenetic reactions consolidate the sediments. Permeability decreased about an order magnitude due to the mechanical compaction from the effective pressure of 3 MPa to 92 MPa, and decrease additional an order magnitude of permeability is observed during the hot-pressing of the sample at the pressure and the temperature of 92 MPa and 100 degC, respectively. Those experimental observations suggest that thermally activated compactions, possibly pressure solution creep, could contribute key role for understanding the physical property of subducting sediments.

Contrasting silica precipitation via flash vaporization and fluid flow and possible effects on fault properties

*Takamasa Niibe[1], Atsushi Okamoto[1], Takashi Amagai[2], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies, Tohoku University, 2. Japan Oil, Gas and Metals National Corporation

It is thought that precipitation of silica plays crucial roles on mechanical and hydrological properties of faults. The solubility of silica minerals varies significantly depending on temperature and water density (e.g., Manning, 1994). Okamoto *et al.* (2010) conducted the hydrothermal flow-through experiments at vapor-like supercritical condition (430 ℃, 31 MPa) and showed that silica precipitation predominantly occurred via quartz overgrowth and quartz nucleation (Okamoto *et al.*, 2010). In contrast, precipitation of silica is thought to be induced by decompression of fluids. Weatherley and Henley (2013) suggested that silica particles precipitate by flash vaporization at fault jog; however, the process of silica precipitation under such extreme condition has not been verified experimentally. The purpose of this study is to understand the mechanism of silica precipitation by hydrothermal experiments. In particular we focus on the difference in the mode of occurrences of silica precipitates between flashing and fluid flow system.
We conducted two types of experiments: (1) flash + batch experiments, and (2) flow-through experiments. Both experiments were carried out with using high-silica solutions (Si = 250-300 mg/kgH_2O, Na, Al, K = 4-6 mg/kgH_2O), that was prepared by dissolution of granite sand at 370 ℃ and 40 MPa. In the flashing experiments, after the input solution was enclosed into the autoclaves, elevated pressure and temperature, and flashed by opening the valve. Alumina filter (average pore size of 60 μm) was placed on the flow pathway to catch the silica particles. The flash P-T conditions were 261 ℃, 353 ℃, 400 ℃, and 450 ℃ at pressure of 35-38 MPa. In all conditions, silica precipitates did not include quartz, but spherical particles of amorphous silica with size of 0.1-10 μm were produced. Such amorphous silica was probably formed by nucleation and aggregation during the evaporation of water droplet. Then, we investigated the transformation of the flashing products (removed from the alumina filter and enclosed in Au tube) by the batch experiments at 261 ℃ and 351 ℃ at vapor saturated pressure, and at 400 ℃ and 450 ℃ under supercritical conditions. There was no change of silica after the batch experiments at 261℃ and 351℃ conditions within 5 days. In contrast, small quartz crystals (size of less than 10 μm) were produced in 5 days at 400 ℃ and in 3 days at 450 ℃. Albite was partly produced as the results of interaction with alumina-filter.
The silica precipitation was also investigated by the flow-through experiments at 390-430 ℃ and 25 MPa (supercritical condition) with constant flow-rate of 0.5 or 1 mL/min by using the granite-dissolved solution similar to the flash experiments. The silica was precipitated in alumina tube filled with alumina ball (diameter with 1 and 2mm). We found the silica precipitates clogged the pores within few days. Based on the XRD and SEM observation, the products of the flow-through experiments were mixture of amorphous silica and quartz. Some quartz crystals grew up to 100 micrometers and amorphous silica were precipitated on the alumina balls and the alumina pipe.
In both cases, amorphous silica was easily produced in response to the drop of water density at high temperatures. Such amorphous silica can move and clog effectively the pores. Also, our experiments revealed that such amorphous silica was changed to quartz, which depends on the temperature and fluid states (flow or batch). Such variation of silica by precipitation and transformation potentially would provide a significant influence on the fault strength.

Temporal variations of reflected and transmitted wave during a slide-hold-slide experiment on a biaxial friction testing machine

*Miyuu Uemura[1], Yoshihiro Ito[2], Ikuo Katayama[3]

1. Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University, 3. Department of Earth and Planetary Systems Science, Hiroshima University

Slow slip events (SSEs), which is one of the slow earthquakes differing from regular earthquakes, have been detected at both shallower and deeper portions of the seismogenic zones, such as Japan and New Zealand. We carried slide-hold-slide experiments with gouge layer under a slip velocity of an SSE using a biaxial friction testing machine under the condition with the temperature and the humidity of room. We measured temporal changes of acoustic impedance in the gouge layer with reflected and transmitted wave during slides and holds. As a result, we detected variations in travel time, amplitude, and cross-correlation coefficient on first arrival of reflected and transmitted wave.

The features of observed waveforms were classified clearly by a slide-hold-slide conditions into two categories: sliding and holing. We chose two materials as gouge powder, which were clay mineral (Ca-montmorillonite) and quartz. Regardless of the kinds of the gouge powder, the amplitude both of reflected and transmitted waves showed opposite temporal variation during the slide-hold-slide sequences; the amplitude of transmitted wave decreased during slides and increased during holds, respectively. This suggests that the amplitudes of reflected and transmitted waves indicate a change of an elastic-wave speed in the gouge layer.

The travel times of transmitted waves increased during slides and decrease during holds. According to Birch (1961), a propagation speed of elastic waves normally decreases as the density of media decreases, or as the porosity increases. Increasing travel times of transmitted waves in our experiments may indicate the change of the density, or porosity in the gouge layer. Although the travel times of reflected waves decreased during slides and increased during holds in the case of clay mineral, the travel time on quartz powder did not change through our experiment.

The temporal change on correlation of observed transmitted wave also shows significant changes from a slide to a hold. The change of travel time, the amplitude, and the cross-correlation coefficient of transmitted waves were more sensitive to a slide-hold-slide condition, such as slip rate on the gouge later than those of reflected wave. Those result suggests that a transmitted wave is more suitable for monitoring SSE although a reflected wave is also useful for monitoring, and that a beginning and an end of an SSE can be detected by reflected and transmitted waves.

Monitoring stress-induced changes of laboratory fault by ultrasonic coda wavesMonitoring stress-induced changes of laboratory fault by ultrasonic coda waves

*Fan XIE[1], Yaqiong REN[1]

1. Institute of Geophysics, China Earthquake Administration

It is increasing important to understand evolution in fault zone and find clear precursors to the earthquake. Nevertheless, the evolving behavior of crustal faults remains changeling due to its inaccessible and weakness.

Duo to their highly sensitivity, the seismic coda waves have been long used at kilometer scale to investigate stress changes by tracking seismic relative velocity changes during earthquake. However, detecting such changes and imaging their spatial distribution with satisfied resolution are still an ongoing project, for which laboratory developments may be useful.

This work aims to explore the applicability of coda waves to monitor spatiotemporal changes of laboratory fault.

Laboratory-scale experiments are performed by meter-scale biaxial loading apparatus in which coda waves at ultrasonic frequencies (100 kHz to 400 kHz) are transmitted and received by 16 broadband piezoelectric transducers using the state-of-the-art ultrasound research platform (Verasonics Vantage 64 Low Frequency Edition) across a 1.5-meter long granite simulated fault.

Before stick-slip events occurred by increasing shear stress at loading rate of 1 um/s , the normal stress was kept 500KPa constant for 60 minutes. The ultrasonic coda waves were recorded throughout the entire process of stress accumulation along the fault.

Coda wave interferometry (CWI) and Coda wave decorrelation (CWD) are performed to detect relative velocity changes and microstructural changes along the fault by measuring phase shifts and loss of coherence of received coda waves respectively.

We observe a ~0.4e-3 velocity increase and ~0.5% coherence loss within logarithm of stationary contact time during 1-hour normal stress holding time. A significant 1.4e-3 increase in relative velocity changes and 8% coherence loss during shear stress increasing test followed by 0.5e4 decease in relative velocity changes and 2% decrease in coherence loss respectively caused by ~200kPa stress drop of the emerging stick-slip event. We also observe that the such changes are localized at upper center of the fault by comparing the changes extracted at different transducers along the fault.

The results suggest that ultrasonic coda waves are a promising means to monitor weak but localized stress-induced changes of laboratory fault by detecting and characterization velocity and micro-structural changes. Considering such advantages, further works to temporal critical observations, such as nucleation process of laboratory earthquake, are conceivable from a practical and instrumental point of view.

Longer duration of meta-instability stage of laboratory earthquakes on a 1.5m granite fault

*yaqiong Ren[1]

1. Institute of Geophysics, China Earthquake Administration

Laboratory earthquakes are a series of stick slip events occurred on an old or newly formed fracture in laboratory. It is widely used to study the properties and mechanisms of earthquake nucleation, dynamic rupture and post-seismic process since its similarities with nature earthquakes. Meta-instability stage is the later stage of the nucleation process. It holds that when the stress release accelerates and synergizes, the deformation enters an irreversible stage to instability. Thus studying its evolutionary characteristics is more conducive to identifying the arrival of earthquakes in advance.

We perform a series stick slip experiments on a 1.5m granite fault. Using a meter-scale rock as experimental sample can indirectly improve the spatial resolution of observation. More importantly, the scale effect of earthquake preparation process can be studied by comparing the results of centimeter-scale and meter-scale samples, which is helpful to the field application of experimental results.

The experiment was carried out on a large horizontal two-direction servo-control press at the Institute of Geophysics, China Earthquake Administration. The maximum loading capacity of the press in two directions is 100 tons and 200 tons respectively. The local variations of stress and displacement along the fault as well as the variation of the whole sample were recorded during the experiment. The stiffness of the meter-scale sample and press system is 0.003 MPa/um, which is one order of magnitude smaller than that of the centimeter-scale sample and press system in the Institute of Geology, China Earthquake Administration. This enables us to obtain stick-slip events with small stress drop, large displacement and audible energy release at lower confining pressure.

For a single stick-slip event, the beginning of meta-instability stage and quasi-dynamic stage (the later stage of meta-instability stage) can be identified based on the relative displacement and strain observations along the fault. The meta-instability begins in the middle of the fault and extends toward both ends as the instability approaches. During the meta-instability stage, the variation rate of different parts of the fault varies greatly, and tends to synergize with the approach of instability.

The duration of meta-instability is longer under lower loading rate, and the change of normal stress has little effect on the duration of meta-instability under lower normal stress. The duration of meta-instability increases with the increase of fault scale, showing obvious scale effect. The results suggest that meta-instability on natural faults in the field may last for several years, and could be monitored. The non-uniformity of faults with the increase of fault scale may be an important mechanism for the scale effect of the duration of meta-instability.

Estimation of the frictional heat and the amount of wall rock incorporation by thermal fracturing during an earthquake: An example from the pseudotachylyte in Jurassic accretionary complex

*Ayaka Nagate[1], Kohtaro Ujiie[1]

1. University of Tsukuba

Estimation of frictional heat is crucial to evaluate dynamic shear strength and fault behavior during an earthquake. Pseudotachylyte produced by solidification of frictional melt is an unequivocal geological evidence of seismic slip on faults. Here, we estimated frictional heat and amount of wall rock incorporation into coseismic slipping zone during an earthquake, based on microstructural observation and numerical analysis of the pseudotachylyte in the Jurassic accretionary complex. The pseudotachylyte-bearing thrust develops as an out-of-sequence thrust in the coherent chert-clastic sequence, which bounds middle Triassic chert above from early Jurassic siliceous mudstone below. The pseudotachylyte is ~2 mm-thick and sharply separates fractured grey chert above from cataclasite below. The pelagic black carbonaceous mudstone layer is distributed at the stratigraphic equivalent interval of the pseudotachylyte.

The microstructures of the pseudotachylyte are characterized by fault and injection veins, fragments of grey chert and quartz in the dark matrix of illite composition, and irregularly and embayed pseudotachylyte boundaries. The gray chert adjacent to the pseudotachylyte and fragments in the pseudotachylyte consisted of grey chert are intensely cracked, showing jigsaw puzzle-like structure. These microstructural features suggest that thermal erosion, thermal fracturing, and preferential melting of illite occurred during earthquake faulting. Frictional heat, which was estimated from temperature rise, volume fraction of fragments, and pseudotachylyte thickness, is ~7.1 MJ m^{-2}.

The comparison of volume fraction of fragments in the matrix between the pseudotachylyte and the black carbonaceous mudstone layer suggests that half amount of fragments in the pseudotachylyte were derived from wall rocks. The numerical modeling considering temperature rise, heating duration, and thermal properties of gray chert indicates that the temperatures of wall rocks a few millimeters away from the pseudotachylyte boundaries exceed the temperature of a-b transition in quartz (~573 ˚C) during earthquake faulting. This distance is consistent with spatial distribution of crack density, which shows exponentially decrease away from the pseudotachylyte boundaries. Thus, intensely cracked wall rocks are considered to represent thermal expansion of quartz grains in gray chert, which could contribute to unstable fault slip associated with decrease in stiffness of surrounding rocks.

Porosity variation of fault rocks accompanied the Median Tectonic Line in Shikoku, southwestern Japan

*Michiharu Ikeda[1], Takeshi Tsuji[2], Tomohiro Tsuji[1], Kozo Onishi[3], Naoki Nishizaka[3]

1. Shikoku Research Institute Incorporated, 2. Kyushu University, 3. Shikoku Electric Power Company, Incorporated

Petrophysical properties of fault rocks are important information to understand evolution processes of fault rocks. Among their properties, hydraulic properties of fault rocks are closely related to fault dynamics and potential of reservoirs of fluid or gas. In this research, we focused on distribution of porosities through fault rocks of the Median Tectonic Line in Shikoku.

The Median Tecotnic Line (MTL) is the longest geological terrane boundary fault. The northern and southern parts from the MTL are Ryoke Belt composed of low P/T metamorphic rocks, granitic rocks and sedimentary rocks and Sanbagawa metamorphic rocks consisted of high P/T metamorphic rocks, respectively. We drilled a bore hole to obtain a geological core sample penetrating the MTL. The total core length is 250 m-long. The fault plane of the MTL is within 37.45 m-depth. The hanging wall and foot wall zones are Izumi Group in Ryoke Belt and Sanbagawa metamorphic rocks, respectively.

The fault rocks in Izumi Group are composed of three zones, fault breccia zone (ca.4– ca.12.5 m-depth), transition zone (ca.12.5–ca.31.6 m-depth) and fault gouge zone (ca.31.6–ca.37.2 m-depth), based on geological observation. On the other hand, the fault rocks of the Sanbagawa metamorphic rocks are cataclasite just below the MTL fault plane (37.45–ca.47 m-depth) and intact rocks in the deeper parts of the core (ca.47–250.0 m-depth).

We measured 49 samples (24 samples in Izumi Group and 20 samples in Sanbagawa metramorphic rocks) from the core. In addition to them, 5 samples from outcrops of Izumi Group were measured to get porosities of intact rocks of Izumi Group, because all parts of Izumi Group in the core are damaged.

The porosities of the hanging wall (Izumi Group) range between 4.54% and 20.35%, whereas those of the foot wall (Sanbagawa metamorphic rocks) are lower (2.06%–11.4%) than those of the hanging wall. Additionally, the porosities of the outcrop samples of Izumi Group show quite low (0.97%–1.75%), corresponding to those of intact rocks of Izumi Group, whereas those of the intact rocks of Sanbagwa metamorphic rocks are estimated to be ca.2%–ca.3%. These porosities are measured for samples in the deep zone (ca.75–ca.200 m-depth) of the core, which are quite far from the fault plane. The porosities of the three zones of fault rocks in the hanging wall are 5.19%–15.27% for the fault breccia zone, 4.54–15.30% for the transition zone and 11.02–20.35% for the gouge zone. It should be noted that the porosities are corrected on the basis of CT values. As the fault rocks of Izumi Group are composed of matrix and clasts, we measured the porosities of both matrix and clasts (or blocks) for each sample. Then, we calculated the correction porosities based on the ratio of matrix and clasts of CT values.
The porosities in the hanging wall (Izumi Group) widely vary depending on characteristics of fault damage, however those gradually increase toward the fault plane. In addition, the porosities are quite higher than those of intact rocks. On the other hand, the high porosity zone in the foot wall (Sanbagawa metamorphic rocks) is limited in a narrow zone (37.45–ca.50 m-depth). These facts suggest that the hanging wall (Izumi Group) are strongly damaged compared to the foot wall (Sanbagawa metamorphic rocks). This is an intriguing characteristics for understanding petrophysical properties of fault rocks.

Characteristics of inactive section of the Median Tectonic Line from drillcore samples in Shikoku, southwestern Japan

*Hideto Uchida[1], Michiharu Ikeda[1], Takeshi Tsuji[2], Kozo Onishi[3], Naoki Nishizaka[3]

1. Department of Civil Engineering, Shikoku Research Institute incorporated, 2. Department of Earth Resources Engineering, Kyusyu University, 3. Shikoku Electronic Power

The Median Tectonic Line (MTL) is a geological boundary fault that divides southwestern Japan into Inner and Outer zones. The MTL is generally considered to be a long-lived fault system from the middle Cretaceous, although the details of the movement history are complex. On the other hand, it has been revealed from geomorphological and paleo-seismological surveys that the MTL from Shikoku to western Kii Peninsula has caused right-lateral slip during Quaternary. Therefore, the part of the MTL is active, and called as the Median Tectonic Line active fault system (MTLAFS) (e.g., Ikeda et al.,2017). To estimate present seismic condition (or environment) of the MTLAFS, we should understand details of its paleo-activities. However, outcrops widely exposed for geological survey about paleo-activities inactive MTL are limited. In this study, we obtained a geological core sample (125 m-long) penetrating the MTL and conducted downhole logging in Saijyo city, Ehime prefecture.
We focused on three points as follows. Firstly, we observed and described the core samples in detail. Secondly, we obtained structural data from the geological core and a borehole image data in order to predict paleo-stress conditions. Finally, we estimated physical properties around a fracture zone of the MTL based on the geological and geophysical data.

[Description of fault rocks]
The fault plane of the MTL is at about 109.45 m-depth in the borehole. The hanging wall and footwall of the fault system are Izumi Group (mainly alternating beds of mud and sand) and Sanbagawa metamorphic rocks (mainly pelitic schist), respectively. Orientation of the fault plane of the MTL is NE-SW strike with moderate-angle northwest dipping in our study area, and its fault zone is approximately 4m-width. The fault zone is composed of fault gouge, fault breccia and cataclasite. The altered dikes that is Ishizuchi volcanic rocks erupted in c.a. 15 Ma distribute in the fault zone. The MTL in this region reactivated after 15 Ma, because the altered dikes are fragmentated in the fault zone.

[Structural analysis]
Orientations of bedding planes of Izumi Group and schistosity planes of Sanbagawa metamorphic rocks are generally N–S strike with low-angle east dipping and ENE–WSW strike with low-angle north dipping. The dikes intrude into the fault zone in orientation of NE–SW strike with moderate-angle northwest dipping. Orientations of fractures concentrate in N–S strike with east dipping and E–W strike with north dipping based on the borehole camera data.
Moreover, we conducted paleo-stress analysis based on fault orientations and slickenlines and slickensteps on the fault surfaces. We adopted Hough transform inverse method (Sato, 2006) to estimate paleo-stress conditions of the MTL. As the result, a stress condition around the MTL is dominantly normal-faulting stress-regime, however strike-slip and reverse-faulting stress-regimes are also recognized.

[Physical properties]
There is a remarkable trend of the elastic wave velocity data around the fracture zone. P-wave velocity *Vp* in fracture zone (95–109.5 m-depth) drastically decreases as compared with host rock in the upper zone due to intensive crack and lower elastic moduli. On the other hand, S-wave velocity *Vs* does not change in

©2019. Japan Geoscience Union. All Right Reserved.

the fracture zone such as the trend of *Vp*.

The paleo-stress condition data are useful information for inactiveness of the MTL. And the physical properties are also crucial to understand the physical conditions what the MTL in this region have experienced. Therefore, the information derived in this study could contribute to understand fault evolution processes and activities of the MTL.

Surface and internal textures of clasts in incohesive fault rocks and their significance

*Tetsuhiro Togo[1], Toshihiko Shimamoto[2], Michiyo Sawai[3]

1. THE EARTH, 2. Institute of Geology, China Earthquake Administration, 3. Chiba Univ.

Fault rocks are classified based on the fraction of clasts (visible under naked eyes) and fine-grained matrix (e.g., Sibson, J. Geol. Soc. London). Studies on clasts are important at least for the following three purposes. First, clasts must have formed by fracturing of host rocks and/or old cohesive fault rocks during their formation and past movements, and hence clasts may provide us with old fault rocks and may yield information on deeper parts of fault zones. Second, clasts must have undergone series of physical and chemical intrafault processes and might give clues to recover some of those processes. Third, comparison of surface and internal textures of clasts with those of borehole cuttings may lead to identifying fault zones from the cuttings. Recovering all cores in drilling is very costly and the textural studies on fault-zone clasts may have many practical applications.

Kanaori and his coworkers conducted very detailed SEM (scanning electron microscope) observations on quartz or quartz-rich clasts in fault gouge, collected from more than ten mostly-active faults (e.g., Kanaori et al., 1980, Eng. Geol.). They demonstrated that characteristic surface textures, completely different from those of fresh fracture surfaces, developed on clasts primarily due to dissolution of surface materials. They pointed out that those textures were similar to the surface textures of quartz grains in sediments that had been reported in many publications (note that fault-zone clasts and clastic sediments were exposed to underground water in geological time scale). They classified the surface textures of quartz clasts into 8 types and 4 groups, and proposed a sequence of changes in surface textures with time. The primary target of the work by Kanaori and others was to make rough estimate of timing of fault motion from the surface textures. However, this was not easy and their pioneering work did not progress further.

Present work was motivated from the third purpose listed above. We have not followed the classifications of Kanaori et al, but rather we have intended to study surface and cross-sectional textures of clasts, using all clasts from all parts of fault zones, with broad perspectives. We have studied so far Nojima fault and Arima-Takatsuki Tectonic Line in Japan, and Yangsan fault and Yeongdeok fault in southeast Korea (all granitic fault zones). We have recognized surface textures similar to the orange peel-like and fish scale-like textures of Kanaori and others, but we have not yet confirmed all textures that they have classified. A broken clast from clayey fault gouge in Yeongdeok fault zone exhibits quite interesting internal texture with a broken mineral (probably feldspar) in the center, mantled by thick fine-grained and still-porous fault rock that is rich in phyllosilicates. The texture clearly demonstrates that the surface textures of this clast did not form simply by dissolution of surface material, and there is a possibility that reactions between the clast and matrix formed the fault rock surrounding the clast. If this is the case, such textures may record some physical and chemical processes in fault zones (useful for the second purpose listed above), and we plan to do more detailed work on such textures. Pulverized rock is reported in a wide granitic fault zone along the Arima-Takatsuki Tectonic Line (Mitchell et al., 2011, EPSL). Distinction between clasts and matrix is not always clear in this fault rock and we could observe many fractures in minerals under a SEM. Interestingly, many of those fractures exhibit dissolution textures similar to those of fault-zone clasts and clastic sediments, and old existing fractures in rocks can be distinguished from fresh new fractures from surface textures. All of those textures will be useful in identifying faults from borehole cuttings.

Fault Displacement Assessment of Surface-rupturing Earthquakes for Nuclear Installations and the use of Physics-based Rupture Models

*Luis Angel Dalguer[1], Yoshimitsu Fukushima[2]

1. 3Q-Lab GmbH, 2. International Atomic Energy Agency

Surface-rupturing faulting is usually expected from large earthquakes, but this phenomenon has been also observed sometimes in moderate earthquakes. The coseismic fault displacement (defined as the surface rupture offset or slip on the free-surface) associated to earthquakes can seriously compromise the safety of critical infra-structures located near faults, such as bridges, dams, railroads, pipelines, nuclear installations (NI) and nuclear waste repositories. The draft IAEA specific safety requirements (Site Evaluation for Nuclear Installations No.SSR-1, DS484) requires that the capability for surface faulting shall be assessed for the site of a NI. But current practices of fault displacement hazard assessments (FDHA) are in general very challenging and quite limited because recorded fault displacement data to develop empirical models are very sparse, as such, at present very few empirical models with large uncertainty are available for this purpose. IAEA has already recognised this issue and currently is making the effort to implement the physics-based rupture modelling in practice for FDHA. In general for seismic hazard assessments (SHA), the empirical and physics-based rupture models complement each other and all available efforts are encouraged for the nuclear safety. These efforts have been discussed through different international working group activities, being the most outstanding two international workshops on **Best** Practices in **P**hysics-based Fault Rupture Models for **S**eismic **H**azard **A**ssessment of **N**uclear **I**nstallations (BestPSHANI) in 2015 and 2018. Here we discuss the feasibility of the use of Physics-based rupture models for FDHA and presenting couple of examples of fault displacement prediction of past earthquakes.

Dynamic rupture simulation for seismic hazard assessment: Application to the Futagawa and Hinagu fault zones (Part 2)

*Yuko Kase[1]

1. Geological Survey of Japan, AIST

For probabilistic seismic hazard assessment, evaluations of rupture area to estimate a magnitude for a scenario earthquake and frequency are needed. We propose to provide the basic information for the evaluations using dynamic rupture simulations. Kase et al. (2017) applied the dynamic rupture model for seismic hazard assessment to the Futagawa and Hinagu fault zones. They simulated dynamic rupture models based on information observed before the 2016 Kumamoto earthquake, and showed that the rupture processes initiated at the northeastern end of the Takano-Shirahata segment were consistent with the rupture process of the 2016 Kumamoto earthquake. In this study, we investigate the effect of variations in initial crack locations and the other source parameters on simulation results.
A fault geometry and tectonic stress fields are assumed in the same way as Kase et al. (2017). The Futagawa segment of the Futagawa fault zone and the Takano-Shirahata and Hinagu segments of the Hinagu fault zone are modeled as a continuous vertical right-lateral strike-slip fault plane about 75 km long with surface rupture, based on HERP (2013). Azimuths of the minimum principal stress and stress ratios are assumed, considering the stress inversion result of Matsumoto et al. (2015). We also assume that the principal stresses are proportional to depth, and that the intermediate principal stress is vertical and overburden load.
Two initial crack locations, the southwestern ends of the Futagawa and Takano-Shirahata segment, are assumed. We calculate dynamic rupture processes, using a finite-difference method (Kase and Day, 2006), to search the azimuth of the minimum principal stress and depth coefficient of stress drop consistent with observed right-lateral dislocation on each segment.
Among ruptures initiating at the southwestern end of the Futagawa segment, the ruptures propagating only on the Futagawa segment have right-lateral slips consistent with the observation. Among ruptures initiating at the southwestern end of the Takano-Shirahata segment, on the other hand, the ruptures propagating on the Takano-Shirahata and Futagawa segments have right-lateral slips consistent with the observation. These results agree with the cases initiating at the northeastern ends of both segments (Kase et al., 2017). Thus, the initial crack location does not affect the rupture propagation to the adjacent segments in the ruptures initiating on the Futagawa and Takano-Shirahata segments. In the ruptures initiating on the Hinagu segment, a rupture initiating at the southwestern end is easier to propagate to the Takano-Shirahata segment than that initiating at the northeastern end (AIST, 2018). The difference is caused by rupture directivity. The lengths of the Futagawa and Takano-Shirahata segments are less than 20 km, while the Hinagu segment is 40 km long. Thus, the difference of rupture propagation between the initial crack locations clearly appears in the Hinagu segment.
We also investigate the effect of variations in a critical displacement and a ratio of strength excess and stress drop on simulation results.

Acknowledgment: This research was funded by the project commissioning disaster prevention for nuclear facilities (consideration of uncertainty factors in probabilistic seismic hazard analysis) in FY2018 by Regulatory Standard and Research Department, Secretariat of Nuclear Regulation Authority.

Quantification of gaps between slip-length scaling law of earthquakes and stick-slip experiments.

*Shinichi Oba[1], Yuta Mitsui[2]

1. Graduate School of Science and Tecnology, Shizuoka University, 2. Faculty of Science, Shizuoka University

Scaling relations of natural earthquake (over km scales) have been well studied, but their extension to smaller scales is difficult because of limited observation resolution. This study focuses on experimental stick-slip data and compares them with a slip-length scaling law of natural earthquakes. There seem gaps between the extension of the earthquake scaling and the stick-slip experiments. Here we perform correlation and multivariate analyses to investigate effects of apparatus type, mass and stiffness on the gaps. We find that a characteristic time composed of the mass and the stiffness shows a strong correlation with the gaps against the natural scaling in case of direct shear apparatus.

Effect of Wear Process on Earthquake Recurrence

*Jeen-Hwa Wang[1]

1. Academia Sinica

Earthquake recurrence is studied from the temporal variation in slip through numerical simulations based on the normalized form of equation of motion of a one-body spring-slider model with thermal-pressurized slip-weakening friction and viscosity. The wear process, whose effect is included in the friction law, is also taken into account in this study. The main parameters are the normalized characteristic displacement, U_c, of the friction law and the normalized damping coefficient (to represent viscosity), η. Define T_R, D, and t_D to be the recurrence time of events, the final slip of an event, and the duration time of an event, respectively. Simulation results show that T_R increases when U_c decreases or η increases; D and t_D decrease with increasing η; and t_D increases with U_c. The time- and slip-predictable model can describe the temporal variation in cumulative slip. When the wear process is considered, the thickness of slip zone, h which depends on the cumulated slip, $S(t)=\Sigma D(t)$, i.e., $h(t)=CS(t)$ (C=a dimensionless increasing rate of h with S) is an important parameter influencing T_R and D. U_c is a function of h and thus depends on cumulated slip, ΣU, with an increasing rate of C. In the computational time period, the wear process influences the recurrence of events and such an effect increases with C when C>0.0001. When viscosity is present, the effect due to wear process becomes stronger. Both T_R and D decrease when the fault becomes more mature, thus suggesting that it is more difficult to produce large earthquakes along a fault when it becomes more mature. Neither the time-predictable model nor the slip-predictable one can describe the temporal variation in cumulative slip of earthquakes under the wear process with large C.

On the Mechanical Relation between Individual Interaction and Collective Behavior of Multiple Fault Sets Subjected to Quasi-Static Loading

*Koji Uenishi[1,2], Yuki Fukuda[2], Nobuki Kame[3]

1. Department of Advanced Energy, The University of Tokyo, 2. Department of Aeronautics and Astronautics, The University of Tokyo, 3. Earthquake Research Institute, The University of Tokyo

In order to deepen our essential understanding of the connection between the local and the global or collective mechanical behavior of sets of geological faults in the solid earth, we have been performing laboratory rupture experiments using two-dimensional rectangular, linear elastic solid specimens with preset parallel cracks that model multiple fault planes under quasi-static tensile (mode-I) or tensile with in-plane shearing (mixed mode) loading conditions (Uenishi et al., SSJ Fall Meeting, 2017, 2018). Our special attention has been paid to the identification of when and how ruptures develop on each individual fault plane and interact with one another, and how the interaction influences the global nature of the solid. For that purpose, we have observed the local evolution of the isochromatic fringe patterns, i.e. the contours of the maximum in-plane shear stress, around the modeled fault planes in the photoelastic polycarbonate specimens with a high-speed digital video camera. At the same time, we have measured the global stress-strain relation utilizing a tensile testing machine that externally exerts a prescribed constant displacement rate to the specimen, and have compared its time history with the local observations of the isochromatic fringe patterns. Although the externally applied displacement or strain rate has been still in a relatively low, quasi-static range, the comparison may imply the effect of the local rupture development on the global properties of the solid specimen, and we have found that local rupture may not always propagate unidirectionally in the prepared specimens and ruptures may run into each other even on a single fault plane under very simple external loading conditions. We are now trying to investigate the mechanical characteristics of multiple fault sets that are subjected to more dynamic, impact loads and identify difference in the local-global relation, if any, between the dynamically-controlled and quasi-statically governed ruptures.

Inelastic deformation in a region of the transient and forced extensional horizontal crustal strain

*Takao Eguchi, Yasuyuki Iwase[1]

1. National Defense Academy, Japan

Just after the focal rebound displacement by the 2011 Off-Tohoku Earthquake *(M~9)*, forced horizontal extension was confirmed in the Japanese archipelago. For example, from Miyagi to Yamagata prefectures on the overriding lithosphere, it was approximately stretching in the E-W direction.
We here investigate the "*transient inelastic deformation process*" in the adjacent island-arc environment immediately after such horizontally forced arc-extension.
For simplicity, let us assume that the main origin of inelastic island-arc deformation is not due to biaxial extension but due to transient elongation in a specific direction.
Since the island-arc is not necessarily an isotropic homogeneous elastic body, the mode of inelastic deformation depends on geometrical characteristics such as zonal contrast in elastic constants at pre-existing material block boundaries and/or at active faults within the island-arc.
We discuss the stress-strain relationship in the island-arc as an inelastic deformable body in the environment after the above-mentioned unidirectional elongation.
The response to the stress change in the subsequent environment becomes a nonlinear phenomenon that is transiently time-space dependent at least, and it will be different from the case of the linear elastic body.
In particular, even a small subsequent stress change will result in greater strain than in the case of linear elastics.
In this study, incorporating rheology such as thixotropy, we present some hypothetic models on the inelastic deformation of the island-arc system with the geometric distributed blocks, etc.

Representation Theorem and Green's Function (3) -- Strain, Stress, and Density Perturbation Fields due to a Point Source Using 2nd Derivative of Green's Function in an Unbounded Homogeneous Isotropic Elastic Medium --

*Masaya Kimura[1], Nobuki Kame[1]

1. Earthquake Research Institute,The University of Tokyo

Here we derive the second spatial derivative of Green's fuction in an unbounded homogeneous isotropic elastic medium. Following this formula, we obtain the expressions for strain, stress, and density perturbation fields due to a point source described by a moment tensor or a single force. These fomulae are useful for theoretical modeling of the prompt detection of earthquake occurrences by means of piezoelectricity, piezomagneticity, and transient gravity perturbations. We propose two applications of the formulae: (1) volumetric moment tensor mass redistribution and (2) dynamically induced quadratic earthquake mass redistribution. Regarding the latter application, we show the relationship between the moment magnitude M_w of an earthquake and dynamically induced quadratic earthquake mass redistribution (Table 1).

Table 1. The relationship between M_w of an earthquake and dynamically induced quadratic earthquake mass redistribution.

Development of a method of visualization of abrupt changes in slip-rate and rupture velocity toward better understanding of high-frequency radiation on a fault.

*Takahiro ayukai[1], Yuji Yagi[2], Ryo Okuwaki[3], Keita Kayano[3], Kousuke Shimizu[3]

1. School of Life and Environmental Sciences, University of Tsukuba, 2. Graduate School of Life and Environmental Sciences, University of Tsukuba, Tsukuba, 3. Graduate School of Life and Environmental Sciences, University of Tsukuba

High-frequency waves are thought to be generated by abrupt changes of slip-rate or rupture velocity on a fault during an earthquake rupture based on theoretical studies (e.g. Spudich and Frazer, 1984, BSSA). Finite-fault inversion of seismic waveforms is a tool to estimate spatiotemporal distribution of slip-rate function. Slip-rate function is composed of some basis functions at each subfault which an assumed fault is divided into in a reticular pattern. Back Projection (BP) (Ishii et al., 2005, Nature) and Hybrid BP (HBP) (Yagi et al., 2012, EPSL) methods are techniques for tracking high-frequency radiation sources and have been used to discuss the detailed source process by comparison with slip distribution resolved by waveform inversion. However, the physical meaning of the BP/HBP images is ambiguous, and the quantitative evaluation of the high-frequency radiation has been difficult solely by the BP/HBP methods. In order to reveal what rupture behavior generates high-frequency radiation, we proposed a method to image acceleration and deceleration of slip and rupture from spatiotemporal distribution of slip-rate function resolved by waveform inversion. We derived a representative slip-rate as a maximum value of slip-rate function and a representative rupture time at each sub-fault, and then calculated spatial gradients of the slip-rates and the rupture time to derive acceleration and deceleration of slip and rupture front, respectively. We used the slip-rate function which was obtained by the waveform inversion introducing uncertainty of Green’ s function (Yagi and Fukahata, 2011, GJI), where the high-frequency components of observed waveform were well reproduced compared to the conventional scheme because the waveform inversion can get a slip-rate functions which have a number of basis functions. We applied the developed method to the slip-rate functions of the M_W 7.9 2015 Gorkha, Nepal and the M_W 8.8 2010 Maule, Chile, earthquakes, which were presented in Yagi & Okuwaki (2015, GRL) and Pulido et al. (2011, EPS), respectively. For both the two earthquakes, the results showed that the rapid acceleration of slip was found at the edge of the large slip area facing to the hypocenter, while rapid deceleration of slip was found at the edge across the large slip area. The results also showed that the rapid deceleration of rupture was observed just before the rupture front penetrates into and escaped out of the large slip area. The estimated areas of rapid acceleration and deceleration are consistent with the spatial distribution of intense high-frequency radiation sources tracked by HBP methods (Yagi & Okuwaki, 2015, GRL; Okuwaki et al., 2014, Sci. Rep.). Our developed method well distinguished the behavior of slip evolution related to the generation of high-frequency waves, that is, spatiotemplrally separated slip and rupture front acceleration/deceleration, which has not been evaluated by the BP/HBP methods alone.

Issues in earthquake-source-inversion analysis, evaluated through singular value decomposition

*Keita Kayano[1], Yuji Yagi[1], Ryo Okuwaki[1], Kousuke Shimizu[1]

1. Tsukuba University

Toward solving an inverse problem in Geophysics (e.g., earthquake-source inversion), prior information is used for stabilizing the solution, and an optimal weight between the observed data and prior information is objectively determined by minimizing Akaike's Bayesian Information Criterion (ABIC; Akaike, 1980). However, individual role of observed data and prior information on the resultant solution has not been evaluated in ABIC-based inversion, which makes it difficult to evaluate how much the prior information and its strength are valid in the solution, even though its weight is determined statistically by minimizing ABIC.

Here we resolved each characteristic of the observed data and the prior information that constrains the resultant image by applying singular value decomposition to a kernel of an inverted-source model of the Mw 7.0, 2016 Kumamoto, Japan, earthquake. The source model is represented as five-basis moment tensors (Kikuchi & Kanamori, 1991) distributed at 0.3-sec time and 2-km space intervals in the model space, which can simultaneously model slip evolution and fault geometry (Shimizu et al., 2019, under review). We used models with different weight: one with the weight minimizing ABIC, and the others with the weight artificially weakened and strengthened compared to the ABIC minimum. As prior information, we tested two types of condition: smoothing and L2-norm minimization.

Under the condition of smoothing, the model showed north side uplifting and reverse faulting at the weight stronger and weaker than the one minimizing ABIC, respectively, which is not consistent with the aftershock distribution and field observations (e.g., Yoshida et al., 2016; Shirahama et al., 2016). We found that the specific moment-tensor components, where the amplitudes of Green's function are larger, determining the characteristic of the singular vectors. It is suggested that if the weight of the prior information is stronger and weaker than the one minimizing ABIC, observed-data kernel (corresponding to Green's function) and smoothing-information kernel heavily controls the model characteristics, respectively. Under the condition of the L2 norm, the model showed north side uplifting, which is not evidenced by the aftershock distribution and the field surveys, even though we used ABIC for determining the "optimal" weight of the prior information. We found that the specific moment-tensor components, where the amplitudes of Green's function are larger, determining the characteristic of the singular vectors as is the case under the condition of smoothing. However, regardless of the weight of prior information, Green's function heavily controls the model characteristics.

Our study highlights that, under the condition of smoothing, the ABIC-based inversion works successfully for suppressing bias that violates the final solution generated by kernels of observed data and prior information. We also clarify that the L2-norm-minimization condition does not work properly for constraining source process of the 2016 Kumamoto earthquake.

Source process of recent M6-class inland earthquakes in Japan

*Ritsuya Shibata[1], Naofumi Aso[1], Junichi Nakajima[1], Satoshi Ide[2]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. Department of Earth and Planetary Science, University of Tokyo

In recent years, inland earthquakes frequently occur in Japan including the 2016 Kumamoto earthquake (Mw7.0). Among them, M6-class events are the best targets to study the mechanics of two-dimensional rupture propagation, since smaller events are more difficult to study finite slip distribution while rupture area of larger events tend to be restricted in depth. For this purpose, we investigate the source process of the 2016 Central Tottori earthquake (Mw6.2) and the 2018 Hokkaido Eastern Iburi earthquake (Mw6.6), which are characterized by strike-slip and reverse-fault types, respectively, by applying slip inversion to strong-motion seismograms.

We use KiK-net stations deployed and maintained by NIED (National Research Institute for Earth Science and Disaster Resilience) within 50 km from the epicenter for both earthquakes. Fault geometry is assumed to be same as Kubo et al. (2017) for the 2016 Central Tottori earthquake, while we assume the fault geometry of the 2018 Hokkaido Eastern Iburi earthquake from the aftershock distribution. Fault discretization, source duration, source time discretization, and band-pass filters are optimized manually for each event.

Regarding 2016 Central Tottori earthquake, there has been discrepancies between previous studies. While Kubo et al. (2017) reported the slip of 0.3–0.6 m widely distributed over 5×8 km^2, Ross et al. (2018) estimated concentrated slip of >4 m in 3×3 km^2. Recently, Meneses-Gutierrez et al. (2019) obtained the slip of 1–2 m over 5×5 km^2 by analyzing GNSS (Global Navigation Satellite System) data. Our results mainly agree with Kubo et al. (2017), but larger slip is distributed more heterogeneously in our model because we do not apply smoothing. The concentration of slip near the hypocenter as reported by Ross et al. (2018) is also confirmed especially when we use finer model resolution. Therefore, the discrepancy reported in the previous studies may be due to the resolvability of slip with strong directivity in ordinary finite fault inversion, which usually requires sparse discretization and/or a smoothing constraint.

As a result of slip distribution of the 2018 Hokkaido Eastern Iburi earthquake, we obtained the slip in between right-lateral strike-slip type and reverse-fault types at the beginning, which is consistent with the mechanism determined by JMA (Japan Meteorological Agency) using first-motion polarities, while total slip is predominated by the reverse-fault component, which is consistent with the CMT (centroid moment tensor) solution determined by NIED using surface wave amplitudes. The final slip is separated in the shallow part and the deep part, similar to the distribution of aftershocks.

In both earthquakes, the rupture tends to expand in the direction parallel to the slip regardless of the rake direction. The prevailing mode II rupture over mode III rupture is consistent with the expectation from rupture mechanics (e.g., Day, 1982; Madariaga et al., 1998).

Expected slip direction on assumed fault planes of large earthquakes inferred from stress field after the 2016 Kumamoto earthquake sequence, in central Kyushu, Japan

*Ayaho Mitsuoka[1], Satoshi Matsumoto[2], Azusa Shito[2], Hiroshi Shimizu[2], Group for urgent joint seismic observation of the 2016 Kumamoto earthquake

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University, 2. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University

In order to understand generation of earthquake, knowing the force acting on a fault plane is the great interest problem for us. We should find with which direction and magnitude a fault plane slips. Shear and normal stresses on a fault plane can be estimated from the stress field around a fault. Maximum shear stress direction on a fault plane constrains the slip direction of an earthquake on the fault based on Wallace-Bott hypothesis. In this study, we estimated the maximum shear stress directions on some fault planes from the stress field at hypocentral area of the 2016 Kumamoto earthquake sequence.
The 2016 Kumamoto earthquake sequence occurred at Hinagu and Futagawa fault zones in Kumamoto prefecture, central Kyushu Island, Japan. The area was high seismicity area before the sequence. The largest foreshock with Mj 6.5 (Mj: magnitude by Japan Metrological Agency) on April 14, 2016 was located in Hingau fault zone. The mainshock (Mj 7.3) occurred on April 16, 2016. Many earthquakes occurred around these faults after the mainshock and continue until now. Some fault planes are determined from the aftershock hypocenter distribution.
Maximum shear stress direction on a fault is a projection of a traction vector that is calculated from the fault geometry and the stress field. In other word, we can consider slip direction on a fault from stress tensor and fault geometry. In the hypocentral area of the 2016 Kumamoto Earthquake sequence, evaluation of strong ground motion is important to mitigate damage of further coming earthquake. Slip direction is one of the key for the evaluation. Here, we showed expected slip direction on fault plane proposed by Iwata et al. [2019] from their geometry and the stress field estimated by Mitsuoka et al. [2019] using the seismic moment tensors.Most of the expected slip direction on the assumed faults reveal either simple strike slip or normal fault types. However the maximum shear stress directions on some faults change to have large upward component at shallow depth. The result suggests complicated slip could occur on the candidate faults in a case of large earthquake faulting.

Keywords: stress field, shear stress, 2016 Kumamoto earthquake

Spaciotemporal change of source parameters of repeaters due to the 2011 Tohoku-Oki earthquake

*Kazuya Tateiwa[1], Tomomi Okada[1], Toshio Kono[1], Naoki Uchida[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

A number of small to moderate repeating earthquakes occur at the upper boundary of subducting Pacific plate in NE Japan. Understanding the source characteristics of repeating earthquakes and their spaciotemporal changes give us insight about the loading rate and its variation due to the plate motion and physical mechanisms of earthquakes, which can be common with major earthquakes because they would have the same occurrence structure as the small repeaters. In this study, we investigated the spatiotemporal change of source parameters of repeating earthquakes occurred on the Pacific interplate before and after the 2011 Tohoku-Oki earthquake. We analyzed seismic waveforms from about 3,000 repeating earthquake groups and about 7,000 repeating earthquakes in total. In this study, we show the results obtained by analysis of repeaters located off-Kamaishi and near Iwaizumi, Iwate, NE Japan.
In off-Kamaishi, repeaters are observed in a very constant recurrence cycle (~5.5 yr) and magnitude (~4.9) before the Tohoku-Oki earthquake, however, the recurrence interval was extremely shortened and the size of the earthquake was substantially enlarged immediately after the Tohoku-Oki earthquake. The recurrence interval and magnitude are becoming close to those of before the Tohoku-Oki earthquake with time. Although stress drop calculated with spectral ratio method is about 14 MPa before the Tohoku-Oki earthquake, it is estimated that stress drop after the Tohoku-Oki earthquake became smaller than before to have roughly a constant value (~2 MPa). The radius of ruptured fault estimated from corner frequency become about 5 times larger just after the Tohoku-Oki earthquake and later it became about 1 km. The radius of rupture fault of post-Tohoku events is becoming close to that of pre-Tohoku event with time. These results agree with Uchida et al. (2015) that estimated the rupture area of off-Kamaishi sequence by slip inversion. We consider that these changes of source parameters before and after the Tohoku-Oki earthquake are caused by its afterslip.
On the other hand, the repeating earthquake sequences in Iwaizumi does not have obvious changes in magnitude and stress drop before and after the Tohoku-Oki earthquake. If this region was less affected by afterslip than off-Kamaishi, small aftership might make the difference from the results of off-Kamaishi. We found the directivity estimated from corner frequency is observed only for repeaters of M<4, which indicates these small repeating earthquakes are composed of complex rupture. As it was suggested that repeaters of Iwaizumi sometimes rupture multiple patches in previous study (Arao et al., 2007), such complexities in rupture and the interaction between small ruptures would affect the recurrence of repeaters.

Slip distributions and relation of slip-rate and shear stress for the Boso slow slip events

*Takuma Kobayashi[1], Toshinori Sato[2]

1. Graduate School of Science and Engineering, Chiba University, 2. Graduate School of Science, Chiba University

Slow slip events (SSEs), which radiate no seismic waves, were detected 6 times off the Boso Peninsula since the GNSS observation in Japan started in 1996. This presentation shows slip distributions and stress changes of 6 SSEs, and discusses frictional properties on the plate boundary where the SSEs occur.

We used the daily F3 coordinate values of GNSS stations from the Geospatial Information Authority of Japan. The GNSS data were fitted with a time series model that takes account of the linear trend and seasonal variations in the data, and then the fitted data were smoothed. We made every 3 days transient movements from the smoothed data. From the 3 days data, we estimated slip distributions using ABIC inversion method. We calculated stress changes from the slip distributions using Coulomb 3.3.

The results show that the amount and location of the slip distributions differ each events. Maximum amount of slips is about 7 cm for 1996 and 2014 events, and 14-20 cm for the other events (2002, 2007, 2011, 2018). 1996 and 2014 events slipped at a location during the event. The other events, on the other hand, moved southward during the event. Shear stress changes were about 0.1-0.3 MPa at main slip areas. From graphs of logarithm of slip rate and the stress change, we can see starting phase, stable phase, and stopping phase for the SSEs. Slopes of the stable phase increase with depth.

The slopes of the stable phase represent (a-b)* σn, where σn is normal stress, from an equation of steady state friction for rate and state dependent friction low. Since the SSEs are quasi stable slip, the shear stress changes estimated from slip distributions may equal to frictional stress changes. Using also results of quasi stable slip simulation, we can estimate (a-b) and effective normal stresses from the slope of the stable phase for the SSEs. Assuming (a-b)=-0.003, the effective normal stresses are estimated about 2-20 MPa. These values are much smaller than lithostatic stresses at the depth. This indicates a possibility of very high pore pressure on the plate boundary.

Acknowledgements: We used the daily F3 coordinate values by GSI, and Coulomb 3.3 program by USGS.

Keywords: slow slip, slip rate, stress change, effective normal stress, rate and state dependent friction low

Repeating inland earthquakes in northern Ibaraki Prefecture activated after the 2011 Tohoku-Oki earthquake

Ryo Takahashi[1], *Keisuke Yoshida[1], Akira Hasegawa[1], Toru Matsuzawa[1]

1. Tohoku University

The 2016 M6.3 earthquake in northern Ibaraki Prefecture is estimated to have reruptured the same portion of the fault already ruptured in 2011 by an M6.1 earthquake (Fukushima et al., 2018) in 2011. Since repeated slips with such a short interval are rare in inland area far from the plate boundary, it provides a unique opportunity to investigate the earthquake cycle. In this presentation, we introduce our ongoing study about the generation processes of the 2011 and 2016 M6 earthquakes in northern Ibaraki Prefecture.

We start by relocating hypocenters using precise differential arrival time obtained by the waveform cross-correlation. The target is 13,410 earthquakes with M>2 listed in the JMA unified catalog for the period from Apr. 2003 to Oct. 31, 2018 in the M6.3 and M6.1 earthquake sequences near the Ibaraki-Fukushima border. We applied the double-difference hypocenter relocation method (Waldhauser & Ellsworth, 2002) to the differential arrival times of P- and S-wave based on a similar procedure to that by Yoshida & Hasegawa (2018).

Although the distribution of relocated hypocenters shows some complicated features, there is one dominant planar structure with west-dipping in northern Ibaraki prefecture. Comparison with the focal mechanisms supports that this planar structure corresponds to the fault plane of the 2011 and the 2016 M6 earthquakes. A planar structure of hypocenter did not newly appear after the 2016 earthquake; their aftershocks are concentrated on the existing planar structure. This supports that the 2011 and 2016 M6 earthquakes ruptured the same fault as pointed out by Fukushima et al. (2018).

The existence of repeating M6 earthquakes suggests that there are other smaller-magnitude repeating earthquake sequences along the plane. Based on the precise hypocenter locations and the waveform similarity, we detected many small repeating earthquakes (M>2) along the plane, which surround the large coseismic slip area of the M6 earthquakes. These small repeating earthquakes are estimated to be caused by the afterslip of the 2011 and 2016 M6 earthquakes. According to the empirical relationship between seismic moment and slip amount (Nadeau & Johnson, 1998), the slip amount is roughly estimated to be a few tens centimeter, which is comparable to the slip amounts of the two mainshocks. Moreover, the slip amount after the 2011 earthquake is larger than that after the 2016 earthquake, which is consistent with Fukushima et al. (2018). These suggest the importance of the effects of afterslip for the aftershock occurrence and the earthquake cycle.

Keywords: repeating earthquake, afterslip, the 2011 Tohoku-Oki earthquake

[J] Poster | S (Solid Earth Sciences)：S-SS Seismology

Wed. May 29, 2019 5:15 PM - 6:30 PM JST | Wed. May 29, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_26

[S-SS14] Fault Rheology and Earthquake Physics

convener:Keishi Okazaki(Japan Agency for Marine-Earth Science and Technology), Hideki Mukoyoshi(Department of Geoscience Interdisciplinary Graduate School of Science and Engineering, Shimane University), Hiroyuki Noda(Kyoto University, Disaster Prevention Research Institute), Keisuke Yoshida(Tohoku University)

The goal of this session is to integrate theoretical, experimental, observational, and numerical perspectives from various fields such as seismology, geodesy, geology, mineralogy, and so on, to define what is known about earthquake source processes and the physical and chemical elementary processes of faulting. This session welcomes studies that address such issues as pre-, co-, and post-seismic processes, the rheology of seismogenic faults and fault rocks, laboratory experiments on elementary processes, numerical models based on frictional laws, and estimates of the stress field in the seismogenic zones. We also welcome studies on fault-zone drilling projects and in situ stress measurements.

Measurement of shear-wave polarization anisotropy in crack-bearing Aji granite during shear experiment

*Jinki Tanaka[1], Ikuo Katayama[1]

1. Hiroshima University

The stress drop at the time of the earthquake not only releases the stress applied to the fault plane but also causes the rotation of the principal stress axis applied to the fault plane. In fact, the change in the direction of the principal stress axis after the earthquake is reported by the mechanism solution of aftershocks and the seismic wave anisotropy(e.g. Tadokoro and Ando 2002; Boness and Zoback 2006). It is thought that this is because the closing (opening) direction of the cracks around the fault plane correspond to the stress axis. Therefore, in this study, the elastic wave velocity was monitored during the shear experiment of the rock and the relation between the shear stress and the principal stress axis and elastic wave velocity was measured in the laboratory. Since the shear-wave polarization anisotropy has a characteristic which is sensitive to the direction of the crack, measurement of different vibration components of S wave is performed in addition to measurement of P wave velocity.

For the experiment, we investigated the change in elastic wave velocity according to shear deformation using a High-T biaxial frictional testing machine in Hiroshima University. For the experimental samples, Aji granite which generated thermal cracks inside by heating to 600 degrees Celsius was used. In the shear experiment, it was carried out by loading the central rock block at a constant speed while keeping the vertical stress constant. The shear sliding velocity was about 0.9 μm/s and the normal stress was 5 MPa. For measurement of elastic waves, probes with a resonance frequency of 1 MHz (manufactured by Olympus Corporation) were used, and S wave and P wave were measured by pulse transmission method. The propagation direction of elastic wave is parallel to the shear plane and perpendicular to the shear sliding direction, and for the S wave, we measured two components, wave (SH) oscillating in the plane orthogonal to the shear plane and wave (SV) oscillating parallel to the shear plane.

From the experimental results, with the increase of the shear stress, it was found that the velocity of SH wave rises earlier and the SV wave rises late. In addition, there was a phenomenon in which the initial motion of the SV wave jumped suddenly as the shear stress increased. This means that when the shear stress is low and the maximum principal stress axis in the sample is close to the direction of the normal stress, the shear direction cracks are frequently closed and the SH wave velocity increases, and the shear stress increases, when the inclination of the maximum principal stress axis becomes steeper with respect to the normal stress, it is considered that the direction of the crack which closes is correspondingly inclined. In this way, since the SH wave and SV wave behave differently due to the increase of the shear stress and the corresponding change of the principal stress axis angle, by utilizing this property, a good index for monitoring the stress state around the fault.

Effects of talc content on frictional properties of quartz gouge

Risako Shirahige[1], Inori Tatara[1], *Ken-ichi Hirauchi[1], Takato Takemura[2]

1. Department of Geosciences, Faculty of Science, Shizuoka University, 2. Department of Earth and Environmental Sciences, College of Humanities and Sciences, Nihon University

Phyllosilicates have low coefficients of friction and an effect of weakening fault strength. To understand effects of talc content on frictional strength and sliding stability, we conducted frictional sliding experiments on dry gouge mixtures of quartz and talc at room humidity, room temperature, a normal stress of 10 MPa and sliding velocities of 0.66–2 μm/s, using a single direct-shear apparatus. The coefficient of friction for the mixture ranged from 0.18 to 0.69 and fell between pure quartz and talc values. The overall trend was a decrease in the coefficient of friction with increasing talc content. The velocity dependence of friction, ($a-b$), ranged from −0.0018 to 0.0039 and increased with increasing talc content. The ($a-b$) values are highest in the mixture with a talc content of 80 wt.%. For the mixture with talc contents below 10 wt.%, the ($a-b$) values become negative, with the occurrence of slow to fast stick-slip behavior.

Mechanism controlling the frictional strength of quartz rocks at intermediate slip rates

*Kyuichi Kanagawa[1], Asuka Sugita[2], Miki Takahashi[3], Michiyo Sawai[1]

1. School of Science, Chiba University, 2. Faculty of Science, Chiba University, 3. Research Institute of Earthquake and Volcano Geology, Geological Survey of Japan

Frictional strength of quartz rocks is known to be extraordinary low at subseismic slip rates ranging from 1 mm/s to 10 cm/s, which has been ascribed to the hydration of comminuted amorphous silica, i.e., silica gel. In order to testify this hypothesis, we conducted rotary-shear friction experiments on intact agate or silica gel gouge at a normal stress of 1.5 MPa and slip rates (V) ranging from 1 mm/s to 10 cm/s. We also measured temperature (T) adjacent to the slip surface or the gouge layer during the experiments.

Steady-state friction coefficient of agate μ_{ss} was ≈0.6 at V = 1 mm/s, ≈0.5 at V = 7 mm/s, and ≦0.1 at V = 10 cm/s. T was ≈25˚C at V = 1 mm/s, ≈30˚C at V = 7 mm/s, and up to 85˚C at V = 10 cm/s, but the actual temperature along the slip surface must have been much higher. μ_{ss} of silica gel gouge was ≈0.7 at V = 1 mm/s, 0.4–0.5 at V = 7 mm/s, and ≦0.2 at V = 10 cm/s. T was 25–28˚C at V = 1 mm/s, 30–37˚C at V = 7 mm/s, and 80–100˚C at V = 10 cm/s, but again, the actual temperature in the gouge layer must have been much higher.

Thus our results show that agate or silica gel exhibits weakening with increasing T, and that the presence of silica gel does not reduce the frictional strength when T is not high enough. Shear strength of quartz rocks is high so that significant amount of frictional heat would be produced at asperity contacts even at V ≈1 cm/s, which must be responsible for weakening of quartz rocks at intermediate slip rates.

Evolution of hydraulic and frictional properties of incoming hemipelagic sediments during diagenetic reactions

*Keishi Okazaki[1], Ikuo Katayama[2], Asuka Yamaguchi[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. Dept. of Earth & Planetary Systems Science, Hiroshima University, 3. AORI, the University of Tokyo

Deployments of seismic and geodetic observation networks had revealed the activity of slow earthquakes along the subduction plate boundaries, which are characterized as intermediate fault slip rate between earthquake (~1m/s) and stable sliding along the plate boundary (~1 nm/s). Diagenesis of subducting sediments has stimulated interest in their relationship to regular and slow seismicity in the subduction zone. We report experimental results on the effect of diagenetic reactions to hydraulic and frictional properties of incoming hemipelagic sediments. Hemipelagic sediments taken from KS-15-3 Shinseimaru cruise are used as the starting sample. Friction experiments and permeability measurements were carried out with a confining pressure of 150 MPa and a pore pressure of 58 MPa and temperatures ranging RT–230 degC. When the sample is sheared immediately after reaching the experimental condition, all experimental data at the temperature below 150 degC showed a velocity-strengthening behavior. On the other hand, at the temperature of 230 degC, the frictional behavior is no longer stable, but stick-slip behavior was observed during the experiments. We also measured a time-dependent permeability evolution of hemipelagic sediments to assess how diagenetic reactions consolidate the sediments. Permeability decreased about an order magnitude due to the mechanical compaction from the effective pressure of 3 MPa to 92 MPa, and decrease additional an order magnitude of permeability is observed during the hot-pressing of the sample at the pressure and the temperature of 92 MPa and 100 degC, respectively. Those experimental observations suggest that thermally activated compactions, possibly pressure solution creep, could contribute key role for understanding the physical property of subducting sediments.

Contrasting silica precipitation via flash vaporization and fluid flow and possible effects on fault properties

*Takamasa Niibe[1], Atsushi Okamoto[1], Takashi Amagai[2], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies, Tohoku University, 2. Japan Oil, Gas and Metals National Corporation

It is thought that precipitation of silica plays crucial roles on mechanical and hydrological properties of faults. The solubility of silica minerals varies significantly depending on temperature and water density (e.g., Manning, 1994). Okamoto *et al.* (2010) conducted the hydrothermal flow-through experiments at vapor-like supercritical condition (430 ℃, 31 MPa) and showed that silica precipitation predominantly occurred via quartz overgrowth and quartz nucleation (Okamoto *et al.*, 2010). In contrast, precipitation of silica is thought to be induced by decompression of fluids. Weatherley and Henley (2013) suggested that silica particles precipitate by flash vaporization at fault jog; however, the process of silica precipitation under such extreme condition has not been verified experimentally. The purpose of this study is to understand the mechanism of silica precipitation by hydrothermal experiments. In particular we focus on the difference in the mode of occurrences of silica precipitates between flashing and fluid flow system.
We conducted two types of experiments: (1) flash + batch experiments, and (2) flow-through experiments. Both experiments were carried out with using high-silica solutions (Si = 250-300 mg/kgH_2O, Na, Al, K = 4-6 mg/kgH_2O), that was prepared by dissolution of granite sand at 370 ℃ and 40 MPa. In the flashing experiments, after the input solution was enclosed into the autoclaves, elevated pressure and temperature, and flashed by opening the valve. Alumina filter (average pore size of 60 μm) was placed on the flow pathway to catch the silica particles. The flash P-T conditions were 261 ℃, 353 ℃, 400 ℃, and 450 ℃ at pressure of 35-38 MPa. In all conditions, silica precipitates did not include quartz, but spherical particles of amorphous silica with size of 0.1-10 μm were produced. Such amorphous silica was probably formed by nucleation and aggregation during the evaporation of water droplet. Then, we investigated the transformation of the flashing products (removed from the alumina filter and enclosed in Au tube) by the batch experiments at 261 ℃ and 351 ℃ at vapor saturated pressure, and at 400 ℃ and 450 ℃ under supercritical conditions. There was no change of silica after the batch experiments at 261℃ and 351℃ conditions within 5 days. In contrast, small quartz crystals (size of less than 10 μm) were produced in 5 days at 400 ℃ and in 3 days at 450 ℃. Albite was partly produced as the results of interaction with alumina-filter.
The silica precipitation was also investigated by the flow-through experiments at 390-430 ℃ and 25 MPa (supercritical condition) with constant flow-rate of 0.5 or 1 mL/min by using the granite-dissolved solution similar to the flash experiments. The silica was precipitated in alumina tube filled with alumina ball (diameter with 1 and 2mm). We found the silica precipitates clogged the pores within few days. Based on the XRD and SEM observation, the products of the flow-through experiments were mixture of amorphous silica and quartz. Some quartz crystals grew up to 100 micrometers and amorphous silica were precipitated on the alumina balls and the alumina pipe.
In both cases, amorphous silica was easily produced in response to the drop of water density at high temperatures. Such amorphous silica can move and clog effectively the pores. Also, our experiments revealed that such amorphous silica was changed to quartz, which depends on the temperature and fluid states (flow or batch). Such variation of silica by precipitation and transformation potentially would provide a significant influence on the fault strength.

Temporal variations of reflected and transmitted wave during a slide-hold-slide experiment on a biaxial friction testing machine

*Miyuu Uemura[1], Yoshihiro Ito[2], Ikuo Katayama[3]

1. Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University, 3. Department of Earth and Planetary Systems Science, Hiroshima University

Slow slip events (SSEs), which is one of the slow earthquakes differing from regular earthquakes, have been detected at both shallower and deeper portions of the seismogenic zones, such as Japan and New Zealand. We carried slide-hold-slide experiments with gouge layer under a slip velocity of an SSE using a biaxial friction testing machine under the condition with the temperature and the humidity of room. We measured temporal changes of acoustic impedance in the gouge layer with reflected and transmitted wave during slides and holds. As a result, we detected variations in travel time, amplitude, and cross-correlation coefficient on first arrival of reflected and transmitted wave.

The features of observed waveforms were classified clearly by a slide-hold-slide conditions into two categories: sliding and holing. We chose two materials as gouge powder, which were clay mineral (Ca-montmorillonite) and quartz. Regardless of the kinds of the gouge powder, the amplitude both of reflected and transmitted waves showed opposite temporal variation during the slide-hold-slide sequences; the amplitude of transmitted wave decreased during slides and increased during holds, respectively. This suggests that the amplitudes of reflected and transmitted waves indicate a change of an elastic-wave speed in the gouge layer.

The travel times of transmitted waves increased during slides and decrease during holds. According to Birch (1961), a propagation speed of elastic waves normally decreases as the density of media decreases, or as the porosity increases. Increasing travel times of transmitted waves in our experiments may indicate the change of the density, or porosity in the gouge layer. Although the travel times of reflected waves decreased during slides and increased during holds in the case of clay mineral, the travel time on quartz powder did not change through our experiment.

The temporal change on correlation of observed transmitted wave also shows significant changes from a slide to a hold. The change of travel time, the amplitude, and the cross-correlation coefficient of transmitted waves were more sensitive to a slide-hold-slide condition, such as slip rate on the gouge later than those of reflected wave. Those result suggests that a transmitted wave is more suitable for monitoring SSE although a reflected wave is also useful for monitoring, and that a beginning and an end of an SSE can be detected by reflected and transmitted waves.

Monitoring stress-induced changes of laboratory fault by ultrasonic coda wavesMonitoring stress-induced changes of laboratory fault by ultrasonic coda waves

*Fan XIE[1], Yaqiong REN[1]

1. Institute of Geophysics, China Earthquake Administration

It is increasing important to understand evolution in fault zone and find clear precursors to the earthquake. Nevertheless, the evolving behavior of crustal faults remains changeling due to its inaccessible and weakness.

Duo to their highly sensitivity, the seismic coda waves have been long used at kilometer scale to investigate stress changes by tracking seismic relative velocity changes during earthquake. However, detecting such changes and imaging their spatial distribution with satisfied resolution are still an ongoing project, for which laboratory developments may be useful.

This work aims to explore the applicability of coda waves to monitor spatiotemporal changes of laboratory fault.

Laboratory-scale experiments are performed by meter-scale biaxial loading apparatus in which coda waves at ultrasonic frequencies (100 kHz to 400 kHz) are transmitted and received by 16 broadband piezoelectric transducers using the state-of-the-art ultrasound research platform (Verasonics Vantage 64 Low Frequency Edition) across a 1.5-meter long granite simulated fault.

Before stick-slip events occurred by increasing shear stress at loading rate of 1 um/s , the normal stress was kept 500KPa constant for 60 minutes. The ultrasonic coda waves were recorded throughout the entire process of stress accumulation along the fault.

Coda wave interferometry (CWI) and Coda wave decorrelation (CWD) are performed to detect relative velocity changes and microstructural changes along the fault by measuring phase shifts and loss of coherence of received coda waves respectively.

We observe a ~0.4e-3 velocity increase and ~0.5% coherence loss within logarithm of stationary contact time during 1-hour normal stress holding time. A significant 1.4e-3 increase in relative velocity changes and 8% coherence loss during shear stress increasing test followed by 0.5e4 decease in relative velocity changes and 2% decrease in coherence loss respectively caused by ~200kPa stress drop of the emerging stick-slip event. We also observe that the such changes are localized at upper center of the fault by comparing the changes extracted at different transducers along the fault.

The results suggest that ultrasonic coda waves are a promising means to monitor weak but localized stress-induced changes of laboratory fault by detecting and characterization velocity and micro-structural changes. Considering such advantages, further works to temporal critical observations, such as nucleation process of laboratory earthquake, are conceivable from a practical and instrumental point of view.

Longer duration of meta-instability stage of laboratory earthquakes on a 1.5m granite fault

*yaqiong Ren[1]

1. Institute of Geophysics, China Earthquake Administration

Laboratory earthquakes are a series of stick slip events occurred on an old or newly formed fracture in laboratory. It is widely used to study the properties and mechanisms of earthquake nucleation, dynamic rupture and post-seismic process since its similarities with nature earthquakes. Meta-instability stage is the later stage of the nucleation process. It holds that when the stress release accelerates and synergizes, the deformation enters an irreversible stage to instability. Thus studying its evolutionary characteristics is more conducive to identifying the arrival of earthquakes in advance.

We perform a series stick slip experiments on a 1.5m granite fault. Using a meter-scale rock as experimental sample can indirectly improve the spatial resolution of observation. More importantly, the scale effect of earthquake preparation process can be studied by comparing the results of centimeter-scale and meter-scale samples, which is helpful to the field application of experimental results.

The experiment was carried out on a large horizontal two-direction servo-control press at the Institute of Geophysics, China Earthquake Administration. The maximum loading capacity of the press in two directions is 100 tons and 200 tons respectively. The local variations of stress and displacement along the fault as well as the variation of the whole sample were recorded during the experiment. The stiffness of the meter-scale sample and press system is 0.003 MPa/um, which is one order of magnitude smaller than that of the centimeter-scale sample and press system in the Institute of Geology, China Earthquake Administration. This enables us to obtain stick-slip events with small stress drop, large displacement and audible energy release at lower confining pressure.

For a single stick-slip event, the beginning of meta-instability stage and quasi-dynamic stage (the later stage of meta-instability stage) can be identified based on the relative displacement and strain observations along the fault. The meta-instability begins in the middle of the fault and extends toward both ends as the instability approaches. During the meta-instability stage, the variation rate of different parts of the fault varies greatly, and tends to synergize with the approach of instability.

The duration of meta-instability is longer under lower loading rate, and the change of normal stress has little effect on the duration of meta-instability under lower normal stress. The duration of meta-instability increases with the increase of fault scale, showing obvious scale effect. The results suggest that meta-instability on natural faults in the field may last for several years, and could be monitored. The non-uniformity of faults with the increase of fault scale may be an important mechanism for the scale effect of the duration of meta-instability.

Estimation of the frictional heat and the amount of wall rock incorporation by thermal fracturing during an earthquake: An example from the pseudotachylyte in Jurassic accretionary complex

*Ayaka Nagate[1], Kohtaro Ujiie[1]

1. University of Tsukuba

Estimation of frictional heat is crucial to evaluate dynamic shear strength and fault behavior during an earthquake. Pseudotachylyte produced by solidification of frictional melt is an unequivocal geological evidence of seismic slip on faults. Here, we estimated frictional heat and amount of wall rock incorporation into coseismic slipping zone during an earthquake, based on microstructural observation and numerical analysis of the pseudotachylyte in the Jurassic accretionary complex. The pseudotachylyte-bearing thrust develops as an out-of-sequence thrust in the coherent chert-clastic sequence, which bounds middle Triassic chert above from early Jurassic siliceous mudstone below. The pseudotachylyte is ~2 mm-thick and sharply separates fractured grey chert above from cataclasite below. The pelagic black carbonaceous mudstone layer is distributed at the stratigraphic equivalent interval of the pseudotachylyte.

The microstructures of the pseudotachylyte are characterized by fault and injection veins, fragments of grey chert and quartz in the dark matrix of illite composition, and irregularly and embayed pseudotachylyte boundaries. The gray chert adjacent to the pseudotachylyte and fragments in the pseudotachylyte consisted of grey chert are intensely cracked, showing jigsaw puzzle-like structure. These microstructural features suggest that thermal erosion, thermal fracturing, and preferential melting of illite occurred during earthquake faulting. Frictional heat, which was estimated from temperature rise, volume fraction of fragments, and pseudotachylyte thickness, is ~7.1 MJ m^{-2}.

The comparison of volume fraction of fragments in the matrix between the pseudotachylyte and the black carbonaceous mudstone layer suggests that half amount of fragments in the pseudotachylyte were derived from wall rocks. The numerical modeling considering temperature rise, heating duration, and thermal properties of gray chert indicates that the temperatures of wall rocks a few millimeters away from the pseudotachylyte boundaries exceed the temperature of a-b transition in quartz (~573 ˚C) during earthquake faulting. This distance is consistent with spatial distribution of crack density, which shows exponentially decrease away from the pseudotachylyte boundaries. Thus, intensely cracked wall rocks are considered to represent thermal expansion of quartz grains in gray chert, which could contribute to unstable fault slip associated with decrease in stiffness of surrounding rocks.

Porosity variation of fault rocks accompanied the Median Tectonic Line in Shikoku, southwestern Japan

*Michiharu Ikeda[1], Takeshi Tsuji[2], Tomohiro Tsuji[1], Kozo Onishi[3], Naoki Nishizaka[3]

1. Shikoku Research Institute Incorporated, 2. Kyushu University, 3. Shikoku Electric Power Company, Incorporated

Petrophysical properties of fault rocks are important information to understand evolution processes of fault rocks. Among their properties, hydraulic properties of fault rocks are closely related to fault dynamics and potential of reservoirs of fluid or gas. In this research, we focused on distribution of porosities through fault rocks of the Median Tectonic Line in Shikoku.

The Median Tecotnic Line (MTL) is the longest geological terrane boundary fault. The northern and southern parts from the MTL are Ryoke Belt composed of low P/T metamorphic rocks, granitic rocks and sedimentary rocks and Sanbagawa metamorphic rocks consisted of high P/T metamorphic rocks, respectively. We drilled a bore hole to obtain a geological core sample penetrating the MTL. The total core length is 250 m-long. The fault plane of the MTL is within 37.45 m-depth. The hanging wall and foot wall zones are Izumi Group in Ryoke Belt and Sanbagawa metamorphic rocks, respectively.

The fault rocks in Izumi Group are composed of three zones, fault breccia zone (ca.4– ca.12.5 m-depth), transition zone (ca.12.5–ca.31.6 m-depth) and fault gouge zone (ca.31.6–ca.37.2 m-depth), based on geological observation. On the other hand, the fault rocks of the Sanbagawa metamorphic rocks are cataclasite just below the MTL fault plane (37.45–ca.47 m-depth) and intact rocks in the deeper parts of the core (ca.47–250.0 m-depth).

We measured 49 samples (24 samples in Izumi Group and 20 samples in Sanbagawa metramorphic rocks) from the core. In addition to them, 5 samples from outcrops of Izumi Group were measured to get porosities of intact rocks of Izumi Group, because all parts of Izumi Group in the core are damaged.

The porosities of the hanging wall (Izumi Group) range between 4.54% and 20.35%, whereas those of the foot wall (Sanbagawa metamorphic rocks) are lower (2.06%–11.4%) than those of the hanging wall. Additionally, the porosities of the outcrop samples of Izumi Group show quite low (0.97%–1.75%), corresponding to those of intact rocks of Izumi Group, whereas those of the intact rocks of Sanbagwa metamorphic rocks are estimated to be ca.2%–ca.3%. These porosities are measured for samples in the deep zone (ca.75–ca.200 m-depth) of the core, which are quite far from the fault plane. The porosities of the three zones of fault rocks in the hanging wall are 5.19%–15.27% for the fault breccia zone, 4.54–15.30% for the transition zone and 11.02–20.35% for the gouge zone. It should be noted that the porosities are corrected on the basis of CT values. As the fault rocks of Izumi Group are composed of matrix and clasts, we measured the porosities of both matrix and clasts (or blocks) for each sample. Then, we calculated the correction porosities based on the ratio of matrix and clasts of CT values.
The porosities in the hanging wall (Izumi Group) widely vary depending on characteristics of fault damage, however those gradually increase toward the fault plane. In addition, the porosities are quite higher than those of intact rocks. On the other hand, the high porosity zone in the foot wall (Sanbagawa metamorphic rocks) is limited in a narrow zone (37.45–ca.50 m-depth). These facts suggest that the hanging wall (Izumi Group) are strongly damaged compared to the foot wall (Sanbagawa metamorphic rocks). This is an intriguing characteristics for understanding petrophysical properties of fault rocks.

Characteristics of inactive section of the Median Tectonic Line from drillcore samples in Shikoku, southwestern Japan

*Hideto Uchida[1], Michiharu Ikeda[1], Takeshi Tsuji[2], Kozo Onishi[3], Naoki Nishizaka[3]

1. Department of Civil Engineering, Shikoku Research Institute incorporated, 2. Department of Earth Resources Engineering, Kyusyu University, 3. Shikoku Electronic Power

The Median Tectonic Line (MTL) is a geological boundary fault that divides southwestern Japan into Inner and Outer zones. The MTL is generally considered to be a long-lived fault system from the middle Cretaceous, although the details of the movement history are complex. On the other hand, it has been revealed from geomorphological and paleo-seismological surveys that the MTL from Shikoku to western Kii Peninsula has caused right-lateral slip during Quaternary. Therefore, the part of the MTL is active, and called as the Median Tectonic Line active fault system (MTLAFS) (e.g., Ikeda et al.,2017). To estimate present seismic condition (or environment) of the MTLAFS, we should understand details of its paleo-activities. However, outcrops widely exposed for geological survey about paleo-activities inactive MTL are limited. In this study, we obtained a geological core sample (125 m-long) penetrating the MTL and conducted downhole logging in Saijyo city, Ehime prefecture.
We focused on three points as follows. Firstly, we observed and described the core samples in detail. Secondly, we obtained structural data from the geological core and a borehole image data in order to predict paleo-stress conditions. Finally, we estimated physical properties around a fracture zone of the MTL based on the geological and geophysical data.

[Description of fault rocks]
The fault plane of the MTL is at about 109.45 m-depth in the borehole. The hanging wall and footwall of the fault system are Izumi Group (mainly alternating beds of mud and sand) and Sanbagawa metamorphic rocks (mainly pelitic schist), respectively. Orientation of the fault plane of the MTL is NE-SW strike with moderate-angle northwest dipping in our study area, and its fault zone is approximately 4m-width. The fault zone is composed of fault gouge, fault breccia and cataclasite. The altered dikes that is Ishizuchi volcanic rocks erupted in c.a. 15 Ma distribute in the fault zone. The MTL in this region reactivated after 15 Ma, because the altered dikes are fragmentated in the fault zone.

[Structural analysis]
Orientations of bedding planes of Izumi Group and schistosity planes of Sanbagawa metamorphic rocks are generally N–S strike with low-angle east dipping and ENE–WSW strike with low-angle north dipping. The dikes intrude into the fault zone in orientation of NE–SW strike with moderate-angle northwest dipping. Orientations of fractures concentrate in N–S strike with east dipping and E–W strike with north dipping based on the borehole camera data.
Moreover, we conducted paleo-stress analysis based on fault orientations and slickenlines and slickensteps on the fault surfaces. We adopted Hough transform inverse method (Sato, 2006) to estimate paleo-stress conditions of the MTL. As the result, a stress condition around the MTL is dominantly normal-faulting stress-regime, however strike-slip and reverse-faulting stress-regimes are also recognized.

[Physical properties]
There is a remarkable trend of the elastic wave velocity data around the fracture zone. P-wave velocity *Vp* in fracture zone (95–109.5 m-depth) drastically decreases as compared with host rock in the upper zone due to intensive crack and lower elastic moduli. On the other hand, S-wave velocity *Vs* does not change in

©2019. Japan Geoscience Union. All Right Reserved.

the fracture zone such as the trend of *Vp*.

The paleo-stress condition data are useful information for inactiveness of the MTL. And the physical properties are also crucial to understand the physical conditions what the MTL in this region have experienced. Therefore, the information derived in this study could contribute to understand fault evolution processes and activities of the MTL.

Surface and internal textures of clasts in incohesive fault rocks and their significance

*Tetsuhiro Togo[1], Toshihiko Shimamoto[2], Michiyo Sawai[3]

1. THE EARTH, 2. Institute of Geology, China Earthquake Administration, 3. Chiba Univ.

Fault rocks are classified based on the fraction of clasts (visible under naked eyes) and fine-grained matrix (e.g., Sibson, J. Geol. Soc. London). Studies on clasts are important at least for the following three purposes. First, clasts must have formed by fracturing of host rocks and/or old cohesive fault rocks during their formation and past movements, and hence clasts may provide us with old fault rocks and may yield information on deeper parts of fault zones. Second, clasts must have undergone series of physical and chemical intrafault processes and might give clues to recover some of those processes. Third, comparison of surface and internal textures of clasts with those of borehole cuttings may lead to identifying fault zones from the cuttings. Recovering all cores in drilling is very costly and the textural studies on fault-zone clasts may have many practical applications.

Kanaori and his coworkers conducted very detailed SEM (scanning electron microscope) observations on quartz or quartz-rich clasts in fault gouge, collected from more than ten mostly-active faults (e.g., Kanaori et al., 1980, Eng. Geol.). They demonstrated that characteristic surface textures, completely different from those of fresh fracture surfaces, developed on clasts primarily due to dissolution of surface materials. They pointed out that those textures were similar to the surface textures of quartz grains in sediments that had been reported in many publications (note that fault-zone clasts and clastic sediments were exposed to underground water in geological time scale). They classified the surface textures of quartz clasts into 8 types and 4 groups, and proposed a sequence of changes in surface textures with time. The primary target of the work by Kanaori and others was to make rough estimate of timing of fault motion from the surface textures. However, this was not easy and their pioneering work did not progress further.

Present work was motivated from the third purpose listed above. We have not followed the classifications of Kanaori et al, but rather we have intended to study surface and cross-sectional textures of clasts, using all clasts from all parts of fault zones, with broad perspectives. We have studied so far Nojima fault and Arima-Takatsuki Tectonic Line in Japan, and Yangsan fault and Yeongdeok fault in southeast Korea (all granitic fault zones). We have recognized surface textures similar to the orange peel-like and fish scale-like textures of Kanaori and others, but we have not yet confirmed all textures that they have classified. A broken clast from clayey fault gouge in Yeongdeok fault zone exhibits quite interesting internal texture with a broken mineral (probably feldspar) in the center, mantled by thick fine-grained and still-porous fault rock that is rich in phyllosilicates. The texture clearly demonstrates that the surface textures of this clast did not form simply by dissolution of surface material, and there is a possibility that reactions between the clast and matrix formed the fault rock surrounding the clast. If this is the case, such textures may record some physical and chemical processes in fault zones (useful for the second purpose listed above), and we plan to do more detailed work on such textures. Pulverized rock is reported in a wide granitic fault zone along the Arima-Takatsuki Tectonic Line (Mitchell et al., 2011, EPSL). Distinction between clasts and matrix is not always clear in this fault rock and we could observe many fractures in minerals under a SEM. Interestingly, many of those fractures exhibit dissolution textures similar to those of fault-zone clasts and clastic sediments, and old existing fractures in rocks can be distinguished from fresh new fractures from surface textures. All of those textures will be useful in identifying faults from borehole cuttings.

Fault Displacement Assessment of Surface-rupturing Earthquakes for Nuclear Installations and the use of Physics-based Rupture Models

*Luis Angel Dalguer[1], Yoshimitsu Fukushima[2]

1. 3Q-Lab GmbH, 2. International Atomic Energy Agency

Surface-rupturing faulting is usually expected from large earthquakes, but this phenomenon has been also observed sometimes in moderate earthquakes. The coseismic fault displacement (defined as the surface rupture offset or slip on the free-surface) associated to earthquakes can seriously compromise the safety of critical infra-structures located near faults, such as bridges, dams, railroads, pipelines, nuclear installations (NI) and nuclear waste repositories. The draft IAEA specific safety requirements (Site Evaluation for Nuclear Installations No.SSR-1, DS484) requires that the capability for surface faulting shall be assessed for the site of a NI. But current practices of fault displacement hazard assessments (FDHA) are in general very challenging and quite limited because recorded fault displacement data to develop empirical models are very sparse, as such, at present very few empirical models with large uncertainty are available for this purpose. IAEA has already recognised this issue and currently is making the effort to implement the physics-based rupture modelling in practice for FDHA. In general for seismic hazard assessments (SHA), the empirical and physics-based rupture models complement each other and all available efforts are encouraged for the nuclear safety. These efforts have been discussed through different international working group activities, being the most outstanding two international workshops on **Best** Practices in **P**hysics-based Fault Rupture Models for **S**eismic **H**azard **A**ssessment of **N**uclear **I**nstallations (BestPSHANI) in 2015 and 2018. Here we discuss the feasibility of the use of Physics-based rupture models for FDHA and presenting couple of examples of fault displacement prediction of past earthquakes.

Dynamic rupture simulation for seismic hazard assessment: Application to the Futagawa and Hinagu fault zones (Part 2)

*Yuko Kase[1]

1. Geological Survey of Japan, AIST

For probabilistic seismic hazard assessment, evaluations of rupture area to estimate a magnitude for a scenario earthquake and frequency are needed. We propose to provide the basic information for the evaluations using dynamic rupture simulations. Kase et al. (2017) applied the dynamic rupture model for seismic hazard assessment to the Futagawa and Hinagu fault zones. They simulated dynamic rupture models based on information observed before the 2016 Kumamoto earthquake, and showed that the rupture processes initiated at the northeastern end of the Takano-Shirahata segment were consistent with the rupture process of the 2016 Kumamoto earthquake. In this study, we investigate the effect of variations in initial crack locations and the other source parameters on simulation results.
A fault geometry and tectonic stress fields are assumed in the same way as Kase et al. (2017). The Futagawa segment of the Futagawa fault zone and the Takano-Shirahata and Hinagu segments of the Hinagu fault zone are modeled as a continuous vertical right-lateral strike-slip fault plane about 75 km long with surface rupture, based on HERP (2013). Azimuths of the minimum principal stress and stress ratios are assumed, considering the stress inversion result of Matsumoto et al. (2015). We also assume that the principal stresses are proportional to depth, and that the intermediate principal stress is vertical and overburden load.
Two initial crack locations, the southwestern ends of the Futagawa and Takano-Shirahata segment, are assumed. We calculate dynamic rupture processes, using a finite-difference method (Kase and Day, 2006), to search the azimuth of the minimum principal stress and depth coefficient of stress drop consistent with observed right-lateral dislocation on each segment.
Among ruptures initiating at the southwestern end of the Futagawa segment, the ruptures propagating only on the Futagawa segment have right-lateral slips consistent with the observation. Among ruptures initiating at the southwestern end of the Takano-Shirahata segment, on the other hand, the ruptures propagating on the Takano-Shirahata and Futagawa segments have right-lateral slips consistent with the observation. These results agree with the cases initiating at the northeastern ends of both segments (Kase et al., 2017). Thus, the initial crack location does not affect the rupture propagation to the adjacent segments in the ruptures initiating on the Futagawa and Takano-Shirahata segments. In the ruptures initiating on the Hinagu segment, a rupture initiating at the southwestern end is easier to propagate to the Takano-Shirahata segment than that initiating at the northeastern end (AIST, 2018). The difference is caused by rupture directivity. The lengths of the Futagawa and Takano-Shirahata segments are less than 20 km, while the Hinagu segment is 40 km long. Thus, the difference of rupture propagation between the initial crack locations clearly appears in the Hinagu segment.
We also investigate the effect of variations in a critical displacement and a ratio of strength excess and stress drop on simulation results.

Acknowledgment: This research was funded by the project commissioning disaster prevention for nuclear facilities (consideration of uncertainty factors in probabilistic seismic hazard analysis) in FY2018 by Regulatory Standard and Research Department, Secretariat of Nuclear Regulation Authority.

Quantification of gaps between slip-length scaling law of earthquakes and stick-slip experiments.

*Shinichi Oba[1], Yuta Mitsui[2]

1. Graduate School of Science and Tecnology, Shizuoka University, 2. Faculty of Science, Shizuoka University

Scaling relations of natural earthquake (over km scales) have been well studied, but their extension to smaller scales is difficult because of limited observation resolution. This study focuses on experimental stick-slip data and compares them with a slip-length scaling law of natural earthquakes. There seem gaps between the extension of the earthquake scaling and the stick-slip experiments. Here we perform correlation and multivariate analyses to investigate effects of apparatus type, mass and stiffness on the gaps. We find that a characteristic time composed of the mass and the stiffness shows a strong correlation with the gaps against the natural scaling in case of direct shear apparatus.

Effect of Wear Process on Earthquake Recurrence

*Jeen-Hwa Wang[1]

1. Academia Sinica

Earthquake recurrence is studied from the temporal variation in slip through numerical simulations based on the normalized form of equation of motion of a one-body spring-slider model with thermal-pressurized slip-weakening friction and viscosity. The wear process, whose effect is included in the friction law, is also taken into account in this study. The main parameters are the normalized characteristic displacement, U_c, of the friction law and the normalized damping coefficient (to represent viscosity), η. Define T_R, D, and t_D to be the recurrence time of events, the final slip of an event, and the duration time of an event, respectively. Simulation results show that T_R increases when U_c decreases or η increases; D and t_D decrease with increasing η; and t_D increases with U_c. The time- and slip-predictable model can describe the temporal variation in cumulative slip. When the wear process is considered, the thickness of slip zone, h which depends on the cumulated slip, $S(t)=\Sigma D(t)$, i.e., $h(t)=CS(t)$ (C=a dimensionless increasing rate of h with S) is an important parameter influencing T_R and D. U_c is a function of h and thus depends on cumulated slip, ΣU, with an increasing rate of C. In the computational time period, the wear process influences the recurrence of events and such an effect increases with C when C>0.0001. When viscosity is present, the effect due to wear process becomes stronger. Both T_R and D decrease when the fault becomes more mature, thus suggesting that it is more difficult to produce large earthquakes along a fault when it becomes more mature. Neither the time-predictable model nor the slip-predictable one can describe the temporal variation in cumulative slip of earthquakes under the wear process with large C.

On the Mechanical Relation between Individual Interaction and Collective Behavior of Multiple Fault Sets Subjected to Quasi-Static Loading

*Koji Uenishi[1,2], Yuki Fukuda[2], Nobuki Kame[3]

1. Department of Advanced Energy, The University of Tokyo, 2. Department of Aeronautics and Astronautics, The University of Tokyo, 3. Earthquake Research Institute, The University of Tokyo

In order to deepen our essential understanding of the connection between the local and the global or collective mechanical behavior of sets of geological faults in the solid earth, we have been performing laboratory rupture experiments using two-dimensional rectangular, linear elastic solid specimens with preset parallel cracks that model multiple fault planes under quasi-static tensile (mode-I) or tensile with in-plane shearing (mixed mode) loading conditions (Uenishi et al., SSJ Fall Meeting, 2017, 2018). Our special attention has been paid to the identification of when and how ruptures develop on each individual fault plane and interact with one another, and how the interaction influences the global nature of the solid. For that purpose, we have observed the local evolution of the isochromatic fringe patterns, i.e. the contours of the maximum in-plane shear stress, around the modeled fault planes in the photoelastic polycarbonate specimens with a high-speed digital video camera. At the same time, we have measured the global stress-strain relation utilizing a tensile testing machine that externally exerts a prescribed constant displacement rate to the specimen, and have compared its time history with the local observations of the isochromatic fringe patterns. Although the externally applied displacement or strain rate has been still in a relatively low, quasi-static range, the comparison may imply the effect of the local rupture development on the global properties of the solid specimen, and we have found that local rupture may not always propagate unidirectionally in the prepared specimens and ruptures may run into each other even on a single fault plane under very simple external loading conditions. We are now trying to investigate the mechanical characteristics of multiple fault sets that are subjected to more dynamic, impact loads and identify difference in the local-global relation, if any, between the dynamically-controlled and quasi-statically governed ruptures.

Inelastic deformation in a region of the transient and forced extensional horizontal crustal strain

*Takao Eguchi, Yasuyuki Iwase[1]

1. National Defense Academy, Japan

Just after the focal rebound displacement by the 2011 Off-Tohoku Earthquake *(M~9)*, forced horizontal extension was confirmed in the Japanese archipelago. For example, from Miyagi to Yamagata prefectures on the overriding lithosphere, it was approximately stretching in the E-W direction.
We here investigate the "*transient inelastic deformation process*" in the adjacent island-arc environment immediately after such horizontally forced arc-extension.
For simplicity, let us assume that the main origin of inelastic island-arc deformation is not due to biaxial extension but due to transient elongation in a specific direction.
Since the island-arc is not necessarily an isotropic homogeneous elastic body, the mode of inelastic deformation depends on geometrical characteristics such as zonal contrast in elastic constants at pre-existing material block boundaries and/or at active faults within the island-arc.
We discuss the stress-strain relationship in the island-arc as an inelastic deformable body in the environment after the above-mentioned unidirectional elongation.
The response to the stress change in the subsequent environment becomes a nonlinear phenomenon that is transiently time-space dependent at least, and it will be different from the case of the linear elastic body.
In particular, even a small subsequent stress change will result in greater strain than in the case of linear elastics.
In this study, incorporating rheology such as thixotropy, we present some hypothetic models on the inelastic deformation of the island-arc system with the geometric distributed blocks, etc.

Representation Theorem and Green's Function (3) -- Strain, Stress, and Density Perturbation Fields due to a Point Source Using 2nd Derivative of Green's Function in an Unbounded Homogeneous Isotropic Elastic Medium --

*Masaya Kimura[1], Nobuki Kame[1]

1. Earthquake Research Institute,The University of Tokyo

Here we derive the second spatial derivative of Green's fuction in an unbounded homogeneous isotropic elastic medium. Following this formula, we obtain the expressions for strain, stress, and density perturbation fields due to a point source described by a moment tensor or a single force. These fomulae are useful for theoretical modeling of the prompt detection of earthquake occurrences by means of piezoelectricity, piezomagneticity, and transient gravity perturbations. We propose two applications of the formulae: (1) volumetric moment tensor mass redistribution and (2) dynamically induced quadratic earthquake mass redistribution. Regarding the latter application, we show the relationship between the moment magnitude M_w of an earthquake and dynamically induced quadratic earthquake mass redistribution (Table 1).

Table 1. The relationship between M_w of an earthquake and dynamically induced quadratic earthquake mass redistribution.

Development of a method of visualization of abrupt changes in slip-rate and rupture velocity toward better understanding of high-frequency radiation on a fault.

*Takahiro ayukai[1], Yuji Yagi[2], Ryo Okuwaki[3], Keita Kayano[3], Kousuke Shimizu[3]

1. School of Life and Environmental Sciences, University of Tsukuba, 2. Graduate School of Life and Environmental Sciences, University of Tsukuba, Tsukuba, 3. Graduate School of Life and Environmental Sciences, University of Tsukuba

High-frequency waves are thought to be generated by abrupt changes of slip-rate or rupture velocity on a fault during an earthquake rupture based on theoretical studies (e.g. Spudich and Frazer, 1984, BSSA). Finite-fault inversion of seismic waveforms is a tool to estimate spatiotemporal distribution of slip-rate function. Slip-rate function is composed of some basis functions at each subfault which an assumed fault is divided into in a reticular pattern. Back Projection (BP) (Ishii et al., 2005, Nature) and Hybrid BP (HBP) (Yagi et al., 2012, EPSL) methods are techniques for tracking high-frequency radiation sources and have been used to discuss the detailed source process by comparison with slip distribution resolved by waveform inversion. However, the physical meaning of the BP/HBP images is ambiguous, and the quantitative evaluation of the high-frequency radiation has been difficult solely by the BP/HBP methods. In order to reveal what rupture behavior generates high-frequency radiation, we proposed a method to image acceleration and deceleration of slip and rupture from spatiotemporal distribution of slip-rate function resolved by waveform inversion. We derived a representative slip-rate as a maximum value of slip-rate function and a representative rupture time at each sub-fault, and then calculated spatial gradients of the slip-rates and the rupture time to derive acceleration and deceleration of slip and rupture front, respectively. We used the slip-rate function which was obtained by the waveform inversion introducing uncertainty of Green’ s function (Yagi and Fukahata, 2011, GJI), where the high-frequency components of observed waveform were well reproduced compared to the conventional scheme because the waveform inversion can get a slip-rate functions which have a number of basis functions. We applied the developed method to the slip-rate functions of the M_W 7.9 2015 Gorkha, Nepal and the M_W 8.8 2010 Maule, Chile, earthquakes, which were presented in Yagi & Okuwaki (2015, GRL) and Pulido et al. (2011, EPS), respectively. For both the two earthquakes, the results showed that the rapid acceleration of slip was found at the edge of the large slip area facing to the hypocenter, while rapid deceleration of slip was found at the edge across the large slip area. The results also showed that the rapid deceleration of rupture was observed just before the rupture front penetrates into and escaped out of the large slip area. The estimated areas of rapid acceleration and deceleration are consistent with the spatial distribution of intense high-frequency radiation sources tracked by HBP methods (Yagi & Okuwaki, 2015, GRL; Okuwaki et al., 2014, Sci. Rep.). Our developed method well distinguished the behavior of slip evolution related to the generation of high-frequency waves, that is, spatiotemplrally separated slip and rupture front acceleration/deceleration, which has not been evaluated by the BP/HBP methods alone.

Issues in earthquake-source-inversion analysis, evaluated through singular value decomposition

*Keita Kayano[1], Yuji Yagi[1], Ryo Okuwaki[1], Kousuke Shimizu[1]

1. Tsukuba University

Toward solving an inverse problem in Geophysics (e.g., earthquake-source inversion), prior information is used for stabilizing the solution, and an optimal weight between the observed data and prior information is objectively determined by minimizing Akaike's Bayesian Information Criterion (ABIC; Akaike, 1980). However, individual role of observed data and prior information on the resultant solution has not been evaluated in ABIC-based inversion, which makes it difficult to evaluate how much the prior information and its strength are valid in the solution, even though its weight is determined statistically by minimizing ABIC.

Here we resolved each characteristic of the observed data and the prior information that constrains the resultant image by applying singular value decomposition to a kernel of an inverted-source model of the Mw 7.0, 2016 Kumamoto, Japan, earthquake. The source model is represented as five-basis moment tensors (Kikuchi & Kanamori, 1991) distributed at 0.3-sec time and 2-km space intervals in the model space, which can simultaneously model slip evolution and fault geometry (Shimizu et al., 2019, under review). We used models with different weight: one with the weight minimizing ABIC, and the others with the weight artificially weakened and strengthened compared to the ABIC minimum. As prior information, we tested two types of condition: smoothing and L2-norm minimization.

Under the condition of smoothing, the model showed north side uplifting and reverse faulting at the weight stronger and weaker than the one minimizing ABIC, respectively, which is not consistent with the aftershock distribution and field observations (e.g., Yoshida et al., 2016; Shirahama et al., 2016). We found that the specific moment-tensor components, where the amplitudes of Green's function are larger, determining the characteristic of the singular vectors. It is suggested that if the weight of the prior information is stronger and weaker than the one minimizing ABIC, observed-data kernel (corresponding to Green's function) and smoothing-information kernel heavily controls the model characteristics, respectively. Under the condition of the L2 norm, the model showed north side uplifting, which is not evidenced by the aftershock distribution and the field surveys, even though we used ABIC for determining the "optimal" weight of the prior information. We found that the specific moment-tensor components, where the amplitudes of Green's function are larger, determining the characteristic of the singular vectors as is the case under the condition of smoothing. However, regardless of the weight of prior information, Green's function heavily controls the model characteristics.

Our study highlights that, under the condition of smoothing, the ABIC-based inversion works successfully for suppressing bias that violates the final solution generated by kernels of observed data and prior information. We also clarify that the L2-norm-minimization condition does not work properly for constraining source process of the 2016 Kumamoto earthquake.

Source process of recent M6-class inland earthquakes in Japan

*Ritsuya Shibata[1], Naofumi Aso[1], Junichi Nakajima[1], Satoshi Ide[2]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. Department of Earth and Planetary Science, University of Tokyo

In recent years, inland earthquakes frequently occur in Japan including the 2016 Kumamoto earthquake (Mw7.0). Among them, M6-class events are the best targets to study the mechanics of two-dimensional rupture propagation, since smaller events are more difficult to study finite slip distribution while rupture area of larger events tend to be restricted in depth. For this purpose, we investigate the source process of the 2016 Central Tottori earthquake (Mw6.2) and the 2018 Hokkaido Eastern Iburi earthquake (Mw6.6), which are characterized by strike-slip and reverse-fault types, respectively, by applying slip inversion to strong-motion seismograms.

We use KiK-net stations deployed and maintained by NIED (National Research Institute for Earth Science and Disaster Resilience) within 50 km from the epicenter for both earthquakes. Fault geometry is assumed to be same as Kubo et al. (2017) for the 2016 Central Tottori earthquake, while we assume the fault geometry of the 2018 Hokkaido Eastern Iburi earthquake from the aftershock distribution. Fault discretization, source duration, source time discretization, and band-pass filters are optimized manually for each event.

Regarding 2016 Central Tottori earthquake, there has been discrepancies between previous studies. While Kubo et al. (2017) reported the slip of 0.3–0.6 m widely distributed over 5×8 km^2, Ross et al. (2018) estimated concentrated slip of >4 m in 3×3 km^2. Recently, Meneses-Gutierrez et al. (2019) obtained the slip of 1–2 m over 5×5 km^2 by analyzing GNSS (Global Navigation Satellite System) data. Our results mainly agree with Kubo et al. (2017), but larger slip is distributed more heterogeneously in our model because we do not apply smoothing. The concentration of slip near the hypocenter as reported by Ross et al. (2018) is also confirmed especially when we use finer model resolution. Therefore, the discrepancy reported in the previous studies may be due to the resolvability of slip with strong directivity in ordinary finite fault inversion, which usually requires sparse discretization and/or a smoothing constraint.

As a result of slip distribution of the 2018 Hokkaido Eastern Iburi earthquake, we obtained the slip in between right-lateral strike-slip type and reverse-fault types at the beginning, which is consistent with the mechanism determined by JMA (Japan Meteorological Agency) using first-motion polarities, while total slip is predominated by the reverse-fault component, which is consistent with the CMT (centroid moment tensor) solution determined by NIED using surface wave amplitudes. The final slip is separated in the shallow part and the deep part, similar to the distribution of aftershocks.

In both earthquakes, the rupture tends to expand in the direction parallel to the slip regardless of the rake direction. The prevailing mode II rupture over mode III rupture is consistent with the expectation from rupture mechanics (e.g., Day, 1982; Madariaga et al., 1998).

Expected slip direction on assumed fault planes of large earthquakes inferred from stress field after the 2016 Kumamoto earthquake sequence, in central Kyushu, Japan

*Ayaho Mitsuoka[1], Satoshi Matsumoto[2], Azusa Shito[2], Hiroshi Shimizu[2], Group for urgent joint seismic observation of the 2016 Kumamoto earthquake

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University, 2. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University

In order to understand generation of earthquake, knowing the force acting on a fault plane is the great interest problem for us. We should find with which direction and magnitude a fault plane slips. Shear and normal stresses on a fault plane can be estimated from the stress field around a fault. Maximum shear stress direction on a fault plane constrains the slip direction of an earthquake on the fault based on Wallace-Bott hypothesis. In this study, we estimated the maximum shear stress directions on some fault planes from the stress field at hypocentral area of the 2016 Kumamoto earthquake sequence.
The 2016 Kumamoto earthquake sequence occurred at Hinagu and Futagawa fault zones in Kumamoto prefecture, central Kyushu Island, Japan. The area was high seismicity area before the sequence. The largest foreshock with Mj 6.5 (Mj: magnitude by Japan Metrological Agency) on April 14, 2016 was located in Hingau fault zone. The mainshock (Mj 7.3) occurred on April 16, 2016. Many earthquakes occurred around these faults after the mainshock and continue until now. Some fault planes are determined from the aftershock hypocenter distribution.
Maximum shear stress direction on a fault is a projection of a traction vector that is calculated from the fault geometry and the stress field. In other word, we can consider slip direction on a fault from stress tensor and fault geometry. In the hypocentral area of the 2016 Kumamoto Earthquake sequence, evaluation of strong ground motion is important to mitigate damage of further coming earthquake. Slip direction is one of the key for the evaluation. Here, we showed expected slip direction on fault plane proposed by Iwata et al. [2019] from their geometry and the stress field estimated by Mitsuoka et al. [2019] using the seismic moment tensors.Most of the expected slip direction on the assumed faults reveal either simple strike slip or normal fault types. However the maximum shear stress directions on some faults change to have large upward component at shallow depth. The result suggests complicated slip could occur on the candidate faults in a case of large earthquake faulting.

Spaciotemporal change of source parameters of repeaters due to the 2011 Tohoku-Oki earthquake

*Kazuya Tateiwa[1], Tomomi Okada[1], Toshio Kono[1], Naoki Uchida[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

A number of small to moderate repeating earthquakes occur at the upper boundary of subducting Pacific plate in NE Japan. Understanding the source characteristics of repeating earthquakes and their spaciotemporal changes give us insight about the loading rate and its variation due to the plate motion and physical mechanisms of earthquakes, which can be common with major earthquakes because they would have the same occurrence structure as the small repeaters. In this study, we investigated the spatiotemporal change of source parameters of repeating earthquakes occurred on the Pacific interplate before and after the 2011 Tohoku-Oki earthquake. We analyzed seismic waveforms from about 3,000 repeating earthquake groups and about 7,000 repeating earthquakes in total. In this study, we show the results obtained by analysis of repeaters located off-Kamaishi and near Iwaizumi, Iwate, NE Japan.
In off-Kamaishi, repeaters are observed in a very constant recurrence cycle (~5.5 yr) and magnitude (~4.9) before the Tohoku-Oki earthquake, however, the recurrence interval was extremely shortened and the size of the earthquake was substantially enlarged immediately after the Tohoku-Oki earthquake. The recurrence interval and magnitude are becoming close to those of before the Tohoku-Oki earthquake with time. Although stress drop calculated with spectral ratio method is about 14 MPa before the Tohoku-Oki earthquake, it is estimated that stress drop after the Tohoku-Oki earthquake became smaller than before to have roughly a constant value (~2 MPa). The radius of ruptured fault estimated from corner frequency become about 5 times larger just after the Tohoku-Oki earthquake and later it became about 1 km. The radius of rupture fault of post-Tohoku events is becoming close to that of pre-Tohoku event with time. These results agree with Uchida et al. (2015) that estimated the rupture area of off-Kamaishi sequence by slip inversion. We consider that these changes of source parameters before and after the Tohoku-Oki earthquake are caused by its afterslip.
On the other hand, the repeating earthquake sequences in Iwaizumi does not have obvious changes in magnitude and stress drop before and after the Tohoku-Oki earthquake. If this region was less affected by afterslip than off-Kamaishi, small aftership might make the difference from the results of off-Kamaishi. We found the directivity estimated from corner frequency is observed only for repeaters of M<4, which indicates these small repeating earthquakes are composed of complex rupture. As it was suggested that repeaters of Iwaizumi sometimes rupture multiple patches in previous study (Arao et al., 2007), such complexities in rupture and the interaction between small ruptures would affect the recurrence of repeaters.

Slip distributions and relation of slip-rate and shear stress for the Boso slow slip events

*Takuma Kobayashi[1], Toshinori Sato[2]

1. Graduate School of Science and Engineering, Chiba University, 2. Graduate School of Science, Chiba University

Slow slip events (SSEs), which radiate no seismic waves, were detected 6 times off the Boso Peninsula since the GNSS observation in Japan started in 1996. This presentation shows slip distributions and stress changes of 6 SSEs, and discusses frictional properties on the plate boundary where the SSEs occur.

We used the daily F3 coordinate values of GNSS stations from the Geospatial Information Authority of Japan. The GNSS data were fitted with a time series model that takes account of the linear trend and seasonal variations in the data, and then the fitted data were smoothed. We made every 3 days transient movements from the smoothed data. From the 3 days data, we estimated slip distributions using ABIC inversion method. We calculated stress changes from the slip distributions using Coulomb 3.3.

The results show that the amount and location of the slip distributions differ each events. Maximum amount of slips is about 7 cm for 1996 and 2014 events, and 14-20 cm for the other events (2002, 2007, 2011, 2018). 1996 and 2014 events slipped at a location during the event. The other events, on the other hand, moved southward during the event. Shear stress changes were about 0.1-0.3 MPa at main slip areas. From graphs of logarithm of slip rate and the stress change, we can see starting phase, stable phase, and stopping phase for the SSEs. Slopes of the stable phase increase with depth.

The slopes of the stable phase represent (a-b)* σn, where σn is normal stress, from an equation of steady state friction for rate and state dependent friction low. Since the SSEs are quasi stable slip, the shear stress changes estimated from slip distributions may equal to frictional stress changes. Using also results of quasi stable slip simulation, we can estimate (a-b) and effective normal stresses from the slope of the stable phase for the SSEs. Assuming (a-b)=-0.003, the effective normal stresses are estimated about 2-20 MPa. These values are much smaller than lithostatic stresses at the depth. This indicates a possibility of very high pore pressure on the plate boundary.

Acknowledgements: We used the daily F3 coordinate values by GSI, and Coulomb 3.3 program by USGS.

Repeating inland earthquakes in northern Ibaraki Prefecture activated after the 2011 Tohoku-Oki earthquake

Ryo Takahashi[1], *Keisuke Yoshida[1], Akira Hasegawa[1], Toru Matsuzawa[1]

1. Tohoku University

The 2016 M6.3 earthquake in northern Ibaraki Prefecture is estimated to have reruptured the same portion of the fault already ruptured in 2011 by an M6.1 earthquake (Fukushima et al., 2018) in 2011. Since repeated slips with such a short interval are rare in inland area far from the plate boundary, it provides a unique opportunity to investigate the earthquake cycle. In this presentation, we introduce our ongoing study about the generation processes of the 2011 and 2016 M6 earthquakes in northern Ibaraki Prefecture.

We start by relocating hypocenters using precise differential arrival time obtained by the waveform cross-correlation. The target is 13,410 earthquakes with M>2 listed in the JMA unified catalog for the period from Apr. 2003 to Oct. 31, 2018 in the M6.3 and M6.1 earthquake sequences near the Ibaraki-Fukushima border. We applied the double-difference hypocenter relocation method (Waldhauser & Ellsworth, 2002) to the differential arrival times of P- and S-wave based on a similar procedure to that by Yoshida & Hasegawa (2018).

Although the distribution of relocated hypocenters shows some complicated features, there is one dominant planar structure with west-dipping in northern Ibaraki prefecture. Comparison with the focal mechanisms supports that this planar structure corresponds to the fault plane of the 2011 and the 2016 M6 earthquakes. A planar structure of hypocenter did not newly appear after the 2016 earthquake; their aftershocks are concentrated on the existing planar structure. This supports that the 2011 and 2016 M6 earthquakes ruptured the same fault as pointed out by Fukushima et al. (2018).

The existence of repeating M6 earthquakes suggests that there are other smaller-magnitude repeating earthquake sequences along the plane. Based on the precise hypocenter locations and the waveform similarity, we detected many small repeating earthquakes (M>2) along the plane, which surround the large coseismic slip area of the M6 earthquakes. These small repeating earthquakes are estimated to be caused by the afterslip of the 2011 and 2016 M6 earthquakes. According to the empirical relationship between seismic moment and slip amount (Nadeau & Johnson, 1998), the slip amount is roughly estimated to be a few tens centimeter, which is comparable to the slip amounts of the two mainshocks. Moreover, the slip amount after the 2011 earthquake is larger than that after the 2016 earthquake, which is consistent with Fukushima et al. (2018). These suggest the importance of the effects of afterslip for the aftershock occurrence and the earthquake cycle.

We conducted a paleoseimological survey on the Shibetsu fault zone in the eastern part of Hokkaido in 2018.
This fault zone has a length more than 52 km but no data was obtained about slip-rate and history of fault activeity in previous study (Hokkaido, 2004 and 2005). On a detailed topographic map with an air-borne LiDAR data, we found a new fault scarp with height of 2-5 m on fan produced the lastglacial age at Kotanuka site, and excurvated a trench (25 m in length, 8 m in width, 4 m in depth) and 4 drilling surveys (5 m in depth). We observed a high-angle fault cutting a tephra layer (Ma-l: ca.12,000 yrBP) and black soil with 40 cm on the trench wall. Based on drilling survey, the fan gravel layers, which covered with sandy sediment containing humic silt with 14C ages of 22,140-21,690 cal.BC and 20,587-20,343 cal.BC, is offset ca.3 m in vertical. We discuss the fault event and slip-rate of this fault with careful, because there are deformation of strata not only faulting but also periglacial process in the trench walls.

Deformation of marine terrace surfaces associated with active Rokkasho fault in southern Shimokita peninsula, northern Japan

*Mitsuhisa Watanabe[1]

1. Faculty of Sociology, Toyo University

The marine terrace surfaces formed in MIS 5e and MIS 5c have successively deformed, resulting in a 1 km wide flexural scarp tilting to the east. These surfaces dipping to the same direction converged upon in the scarp. The flexure is consistent with the prevailing Neogene structure. Some bedding reverse faults are observed, which indicates that the structure is an active one. The marine terrace surfaces and the Tertiary system have been folded convincingly owing to the activity of west-dipping blind active thrust (the active Rokkasho fault), merging into the extensive submarine fault along shelf edge in the north.

Keywords: marine terrace, flexural scarp, bedding reverse fault, active fault

Vertical crustal movement during the past 600 years in the Kikai Island, deduced from the height distribution and ages of coral microatolls

*Masanobu Shishikura[1], Hideaki Maemoku[2], Tomoo Echigo[3], Yuichi Namegaya[1], Tatsuya Ishiyama[4], Ryo Kinjo[2], Naoto Inoue[3]

1. Institute of Earthquake and Volcano Geology, National Institute of Advanced Industrial Science and Technology, 2. Hosei University, 3. Geo-Reserch Institute, 4. Earthquake Research Institute, University of Tokyo

The Kikai Island is known as a tectonically active region due to the MIS 5e coral terrace reaching over 200 m in altitude. Holocene marine terraces divided into four levels suggest that 1-2 m of uplift has intermittently occurred every 1500-2000 years (Sugihara et al., 2003). However, recently simulation results propose that the main factor of terrace formation is a combination of steady uplift and erosive action triggered by relatively small coseismic uplift (Shikakura, 2014). According to the geodetic observation, GNSS data shows uplifting at about 2 mm/year, but it is contradictory that the leveling survey results (comparison between Sep. 1997 and Apr. 2014) indicate subsiding at approximately 1 mm/year (Ito et al., 2015).

As described above, there are various views and observation results on the crustal vertical movement pattern of the Kikai Island. Therefore, we focused on coral microatoll which is a natural tide gauge and reconstructed the long-term crustal vertical deformation based on its distribution and age.

Since the microatoll formed by *Polites sp.*, grows on the basis of the low tide level, and records sea level change annually, it is good paleoshoreline indicator to reconstruct past crustal vertical deformation. We found a total of 25 living microatolls at three areas in the northern part, eastern part and southern part of the Kikai Island and one emerged microatoll. We obtained detailed cross-sections of five living micro-atolls and sliced samples of emerged microatoll to take a CT-scan image, and also obtained some samples for 14C age which were calibrated of marine reservoir effect based on data of Hirabayashi et al. (2017).

In the northern area (Onozu), the height of the top surface of all living microatolls was almost flat at -1.01 - 1.07 m (TP), and the maximum was 78.8 cm in radius. Emerged microatoll found in this area is 270 cm in radius. Its shape of the top surface is almost flat but the altitude is decreasing gently from the center (-0.80 m TP) to the edge (-0.87 m TP) and is 20 cm higher than the living microatolls. From the CT scan image, 237 lines of annual band can be counted in the range of 260 cm showing clearly growing in the horizontal direction. Therefore, the mean horizontal growth rate is estimated to 1.1 cm/year. It is consistent with 14C age data which shows AD 1305-1425 in the center and AD 1489-1650 in the margin. Based on the growth rate obtained from analysis of emerged microatoll, the age of growth of the living microatoll in this region can be estimated to about 72 years ago.

The largest one of the living microatolls confirmed in the eastern area (Kadon) has a radius of 145.6 cm and can be estimated to about 132 years ago, which is no contradiction to the 14C age of the center (AD 1680-1880). The shape of the top surface is roughly horizontal throughout the growth period, but the altitude is slightly uneven between -1.06 m (TP) and -1.20 m (TP).

©2019. Japan Geoscience Union. All Right Reserved.

Based on the above results, the relative sea level change of the Kikai Island slowly decreased by 7 + α cm within 300 years from the 14th to the 17th century, and rapidly fall by 20 - α cm at the 17th century or in the period until the 19th century. Also, since at least 137 years ago, the sea level is almost stable while fluctuating about 10 cm at the maximum. Although it is difficult to distinguish the crustal deformation and the eustatic sea level change, if it is regarded that all of the change was the tectonic influence, it can be denied the steady uplift at a constant rate for the past 600 years. The rapid sea level fall during the 17th century or until the 19th century may have been an intermittent coseismic uplift.

Variation of coseismic fault displacements on multiple seismic cycles at a site: An example from the Kamishiro fault, Itoigawa-Shizuoka Tectonic Line active fault system, central Japan

*Naoya Takahashi[1], Shinji Toda[2]

1. Graduate school of Science, Department of Earth Science, Tohoku University, 2. International Research Institute of Disaster Science, Tohoku University

Predicting coseismic fault slip at a site on an active fault is crucial from the view point of fault displacement hazard assessment. The characteristic earthquake model, where an amount of coseismic slip at a point on a fault is roughly consistent through seismic cycles (Schwartz & Coppersmith, 1984), has been widely accepted and applied for hazard assessment. However, recent paleoseismic studies, high-resolution topographic data and quantitative more precise dating techniques have revealed that many faults do not repeat persistently their characteristic displacements (e.g., Zielke, 2018).To further discuss this issue, however, more case studies in particular on a dip-slip fault are required.
We estimated co-seismic slips of paleo-earthquakes at Oide site (36.7˚N, 137.87˚E) on the Kamishiro fault and evaluated variability in co-seismic slips through seismic cycles. The Kamishiro fault is a reverse fault which is located at the northernmost part of the Itoigawa-Shizuoka Tectonic Line active fault system in Japan. Advantages of this fault are that the co-seismic slip distribution of the most recent event, the 2014 Nagano-ken-hokubu earthquake (Mw 6.2), is precisely measured by field observation and differential LiDAR analysis, and that there is a flight of displaced terraces that record slips of recent earthquakes. Several paleoseismic studies share the evidence for the penultimate and the antepenultimate events that occurred in AD 1714 and ~1.2 ka (AD 841 or AD 762) respectively, whereas the event ages older than 1.2 ka are not well constrained. Here we mapped five displaced terraces (T1-T5, from the older) at Oide using aerial photographs taken by the US Armed Forces in the 1940s. Then, we estimated cumulative net slip of T1, T2 and T5 terraces using a tool developed by Wolfe et al. (2018) which incorporates topographic and fault properties with uncertainties and enables us to objectively estimate a plausible cumulative net slip. We made 30 topographic profiles for each terrace, and sought the mean and standard deviation of the cumulative net slip. We also constrained terrace ages based on radio carbon dating. As a result, we estimated coseismic slips of the penultimate and the antepenultimate events, 1.5±0.2 m and 2.7±0.4 m, respectively. Next, we performed a Monte Carlo simulation to estimate slips of events before the antepenultimate earthquake and then explore a possible range of CV (Coefficient of Variation) for co-seismic slips. CV is a ratio of a data set’ s standard deviation to mean and used to assess variability. Low CV indicates co-seismic slips are nearly the among seismic cycles, and high CV (close to 1) means slips are variable. Because previous paleoseismic studies found one to three earthquakes occurred between T1 formation (5-2.7 ka) and 1.2 ka, we iteratively computed one to three co-seismic slips before 1.2 ka so that the simulated slip sequences can reproduce the cumulative terrace offsets. This approach enabled us to calculate CV that ranged from 0.3 to 0.5 (1 σ), which indicates that a recent sequence of co-seismic slips at Oide does not follow the characteristic earthquake model but varies in a narrow range.

Coseismic net fault slip based on very shallow fault trajectories offers insights to understand properties of source faults for assessing seismic risk from crustal earthquakes in the overriding plate. To illuminate very shallow fault geometries, we carried out new shear-wave very shallow seismic reflection profiling across coseismic surface ruptures emerged along the Kamishiro fault, a northernmost segment of the Itoigawa-Shizuoka tectonic line (ISTL) active fault system, during the 2014 Nagano-ken-hokubu earthquake (Mw = 6.2) (c.f., Hirouchi et al., 2015; Ishimura et al., 2015; Katsube et al., 2017; Okada et al., 2015).

We collected seismic data along six seismic lines (Shiojima, North-Oide, South-Oide, Wing-21, Iimori, Horinouchi, respectively) in 2017 and 2018 by using Electrodynamic Vibrator System (ELVIS; GEOSYM) as an SH seismic source, a land streamer composed of 96 channels, and recording system GEODE (GeoMetrics). Acquisition parameters are: sweep length, 10 sec: sweep frequency, 20-120 Hz: source intervals, 1 m (2 m only in the Wing 21 seismic line); receiver intervals: 0.5 m; sampling rate: 1 msec.

By correlation of processed depth sections based on standard CMP stacking with surface geology and drill-hole data, the seismic sections up to a depth of approximately 100 m resolve thrust geometries extending from the 2014 coseismic surface ruptures that are mostly consistent with previous results in field mapping (e.g., Togo and Hasegawa, 2015; Lin et al., 2015; Okada et al., 2015), ground-penetrating radar (Kimura and Taniguchi, 2015; Nakano and Une, 2015). Our new seismic sections also successfully illuminate previously unrecognized blind thrust faults deforming Quaternary sediments which were not activated during the 2015 event. Our results show that shear-wave seismic reflection surveys using Electrodynamic Vibrator System and a land streamer are very effective to obtain detailed subsurface images of not only active faults but also unrecognized blind thrust structures.

Discussion

Paleoseismic investigations on the un-ruptured section during the 2014 earthquake along the Kamishiro fault, ISTL active fault zone, Central Japan

*Hisao Kondo[1], Hideki Kurosawa[2], Yoko Hirakura[2], Keita Takada[3], Kohei Abe[2], Miwako Ito[2], Atsuo Igarashi[3], Tetsuya Ikeda[3], Atsushi Miwa[2]

We perfomed paleoseismological invetigations on the un-ruptured fault section along the Kamishiro fault, ISTL active fault zone, central Japan. The un-ruptured section extends for about 15 km, consisting of the southernmost section of the Kamishiro fault. The northern most section have activated during the 2014 Nagano-ken Hokubu earthquake, Mj 6.7. Near Lake Nakatsuna, the Kamishiro fault forms tentonic geomorphic features such as fault scarp on the lucustrin terrace and fluvial terrace, monoclinal scarp on the lowland. Beside the eastern side of Lake Nakatsuna, we obtained two bore holes in order to estimate vertical slip rate based on lucustrin terrace deposite at hanging-wall side and fine sediments at foot-wall side. We estimated about 1.0 mm/yr of vertical slip rate as the minimum value. The fault exposure at the depth of -29 m in the borehole core at the foot-wall side implies that thrust front is located at the west of the borehole site. It indicates that the slip rate at present is the minimum estimatation. 350 meter south of this site, we obtained several Geoslicer across the fault scarp. The scarp hight is about 2 m. Based on geomorphic and geologica section, we identified two paleoseismic events after the depositon of alluvial fun deposite. At this moment, we estimated that the most recent event occurred after 664 A.D. More carbon dating samples will allow us to constrain teh timing of paleoseismic events. Near the sourthern most termination of the Kamishiro fault, south of Lake Kizaki, we re-investigated timing and slip per event during 5-6 paleoseismic events. Here, 2-3 events has been identified based on the shallow geologic section up to 6 m deep revealed by Geoslicer technique. We added four borehole cores to identify thrust structures and older events. At present, fine sediments and carbon dating results yeild 1.0 mm/yr of vertical slip rate after 1.2 ka. More dating results will provide high-resolution chronology of past events and slip per events, that will help us to discuss the occurrence of past multi-segment earthquakes.

History of interplate earthquakes along the Sagami Trough from uplifted coasts in the Boso Peninsula

*Junki Komori[1], Masanobu Shishikura[2], Ryosuke Ando[1]

1. The University of Tokyo, 2. The National Institute of Advanced Industrial Science and Technology

We surveyed tectonically uplifted coast, Heisa-ura, in the southernmost part of the Boso Peninsula, central Japan, for the estimation of the recurrence history of subduction earthquakes. The megathrust earthquakes along the Sagami Trough, located to the south of Tokyo, are known to repeatedly occur as represented by the 1703 M8.2 Genroku Kanto Earthquake. The interval time of these earthquakes is previously believed to be longer than 2,000 years from the investigations of the marine terraces in the Boso Peninsula (e.g. Nakata+, 1980). However, the recent dating survey indicated that their interval time might be 500–800 years at the shortest (Komori+, 2017) and required more detailed investigation. The Heisa-ura coast, we surveyed in this study, has not been investigated well before because no significant landform such as marine terraces are developed there. This region is, however, considered to suffer the fastest averaged uplift rate in the surrounding area from the recent study of the marine terrace distribution. Thus the buried sedimentary structure in Heisa-ura possibly records the emergence history of this coast. Here we show the result of the detailed geological survey using Geoslicer done in Heisa-ura for the first time. We obtained 8 sedimentary structure ~2 m deep along a survey line perpendicular to the coast. This investigation revealed that shoreface deposit contains shell fragments is placed deeper than 0.5–1.0 m beneath the surface. Additionally, the sedimentary structure is different between the survey points above and below the estimated elevation of the paleo-shoreline angle. These results indicate that the sedimentary structure beneath the Heisa-ura coast might records the chronicle of crustal deformations which has not been explored. This survey would give us several important factors for the discussion of the mechanisms of the subduction earthquakes along the Sagami Trough and the future hazard assessment of them.

Inferring location and activity of the Iriyamase fault, the Fujikawa-kako fault zone, based on boring core sample analyses and physical fault model

*Namiki Ryo[1], Ryosuke Ando[1], Masanobu Shishikura[2]

1. The University of Toyko, 2. National Institute of Advanced Industrial Science and Technology

The Fujikawa-kako (estuary) fault zone, located in the northern end of the Suruga-Nankai-trough, is claimed to be possible to be activated with the Nankai megathrust earthquakes, resulting in fatal damage in this region. However, it is difficult to accurately estimate the activity of the Iriyamase fault, which is considered as one of the most active faults in this fault zone, because no clear tectonic landform is found on the alluvial fan developed in the Fujikawa estuary area. Recently, three boring cores drilled in the Fujikawa estuary area are preliminarily analyzed by Shisikura et al. (2018). The KNB core is taken at the west side of the Fuji river as well as the hanging wall side of the Iriyamase fault, whose location is estimated by AIST (2016); The SKB core is at the west side of the Fuji river and the footwall side; the FGB core is at the east side of the river and the footwall side.

Based on the result of these analyses, it is estimated that the average displacement rate of Iriyamase fault is about 1~3 m / ky, which is smaller than the previous estimates (Yamazaki, 1992). Moreover, it is also pointed out that the both hanging wall and footwall sides of Iriyamase fault has been subsiding in the long term because Late Holocene terrestrial sediments are buried at the depth beneath the present sea level even in the KNB core located at the hanging side. According to the depth of layers deposited in the peak of the postglacial transgression, this subsiding rate is estimated to be at the 3m/ky.

In this presentation, we show the result of radiocarbon dating and a diatom analysis in these three cores based on more detail analyses of the core samples. Furthermore, we construct physical models based on these results to consider the underlying tectonic conditions.

The diatom analysis of the SKB core shows that diatoms are rarely found at depths shallower than 56 m, and the shallower strata are found to be terrestrial sediments. This result agrees with the long-term subsidence suggested by Shisikura et al. (2018). Moreover, the average displacement rate of Iriyamase fault is estimated about 2 m / ky by comparing the results of the diatom analyses of two cores (KNB and SKB). In order to understand the tectonic origin of the long-term subsidence in the Fujikawa estuary area, we construct the two physics-based models, called the Fuji volcano model and the fault model. In the Fuji volcano model, we calculated the amount of the subsidence caused by the isostasy effects due to the development of the Fuji volcano; the amount of subsidence is calculated to be about 0.7m by the volume increase of Fuji volcano in the past 17 thousand years, 41.37 km^3 (Miyazi, 2007). Thus, this result is far smaller than the amount of the long-term subsidence based on the boring core analysis. In the fault model, we calculate the average displacement rate of the Iriyamase fault, assuming faults as the finite rectangles in the semi-infinite elastic medium based on Okada (1992). We assume two faults to explain both the subsidence at the KNB core and the vertical offset between KNB and SKB; fault A is located between KNB and SKB and Fault B is located in the western side of KNB. The result shows that the average displacement rate of fault B is required to be much larger than that of fault A, because subsidence due to fault B in its footwall side must overcome the uplift due to fault A in the hanging side of fault A.

Coastal submergence events identified by fossil diatoms and plant macrofossils at Ukishima-ga-hara adjacent to the Suruga Trough (eastern Nankai Trough), central Japan

*Yuki Sawai[1], Arata Momohara[2], DAN MATSUMOTO[1], Yumi Shimada[1,3]

1. Geological Survey of Japan, AIST, 2. Chiba University, 3. University of Tsukuba

We identified eight episodic submergence events based on paleontological analyses on peaty sediment samples at Ukishima-ga-hara lowland in Shizuoka Prefecture, central Japan. Lithostratigraphy of sediment samples from Ukushima-ga-hara has no clear changes in facies, but changes in compositions of diatom assemblages and plant macrofossils suggest episodic submergence events. For example, at about 2.3 m and 3.1 m below the ground surface, while aerophilic diatoms (such as *Diadesmis contenta*) dominate underlying peaty layer, freshwater and brackish planktonic taxa (*Aulacoseira* and *Thalassiosira*) abound in overlying layer. Radiocarbon ages of plant macrofossils taken from samples just above and below the event horizons were used to constrain event ages. As the results of applying Bayesian estimation, the youngest one may be correlated with either 1707 or 1498 earthquake. The second one was with either 1361 or 1498 earthquake. The third one covers ages of 1096 and 887 earthquakes. These submergence events may be generated with coastal deformation associated with subduction zone earthquake along Suruga Trough and/or active fault earthquake at Fujikawa-kako-fault zone.

Shallow structures and tectonic geomorphology of active blind thrusts imaged by new hi-resolution seismic reflection profiling, Hokkaido, Northern Japan

*Tatsuya Ishiyama[1], Naoko Kato[1], Hiroshi Sato[1], Taro Koike[2], Katsuya Noda[2]

1. Earthquake Research Institute, University of Tokyo, 2. Geosys, Inc.

Active structures of central Hokkaido are characterized by north-striking active thrusts along the western flanks of the Hidaka Mountains and eastern flanks of the Kabato Mountains. Whereas structural styles and positions of active thrusts along the Umaoi and Kurisawa Hills are clearly related to frontal Hidaka fold-and-thrust belt, structural relations between east-facing folded fluvial terraces along the eastern flanks of the Kabato Mountains and pre-Neogene basement-cored folds remain poorly understood. In addition, geomorphic expression of active faults/folds along the northern Yubari Mountains is quite insufficiently recognized in contrast to both their northern southern extension. To define these unsolved questions, we collected new seismic reflection data from the eastern flank of the Kabato Mountains, through alluvial plain of the Ishikari River to the western flank of the northern Yubari Mountains, by use of both ca. 14.5 km long array of seismic recorders at 20 m intervals and a vibroseis truck as seismic sources at 10 m intervals. Our processed seismic profile based on standard CMP stacking and its preliminary interpretation suggest the eastern flank of the Kabato Mountains is underlain by a tight, east-vergent, asymmetric anticline that deforms Paleogene to Pliocene sediments. Synclinal and anticlinal axial surfaces newly identified on folded, middle to late Pleistocene fluvial terraces on the eastern flank of the Kabato Mountains are apparently consistent with those recognized in the seismic section. This may suggest recent growth of the fault-related anticline and activities of underling west-dipping blind thrusts imaged in this experiment. In contrast to the east-vergent asymmetric anticline beneath the eastern flank of the Kabato Mountains, structural styles beneath the western flank of the northern Yubari Mountains in the eastern half of the section include more gentle westerly dipping Pliocene-Pleistocene (?) sedimentary units with steeper dip panels, possibly suggesting an east-dipping blind thrust fault. Previously unrecognized, very subtle, west facing scarps on alluvial plain and late Pleistocene fluvial terraces are consistent with these underlying thrusts and may indicate their recent fault activities.

Research Center for Volcanic Hazards and Their Mitigation, Tokyo Metropolitan University, 7. Sedimentary Environments Research

In the 2016 Kumamoto earthquake, surface ruptures appeared not only on the Futagawa fault, source fault of this event but also on the other active faults. Especially, on the Idenokuchi fault located about 2 km south of and subparallel to the Futagawa fault, normal fault scarps (10 km length and Max. 2 m vertical offset) appeared (Toda et al., 2016). Toda et al. (2016) presented that the slip-partition occurred using the Futagawa (strike-slip fault) and Idenokuchi (normal fault) faults, indicating the structural relationship between both faults. Additionally, in considering the 2016 event, there is one question whether the activity of Idenokuchi fault coincides that of the Futagawa fault or not. Recent paleoseismological survey (Kumahara et al., 2017; Iwasa et al., 2018; Shirahama et al., 2018; Toda et al., 2018; Tsutsumi et al., 2018; Ueta et al., 2018) revealed that 3 or 4 events including the 2016 event were estimated since Kikai-Akahoya (K-Ah) tephra (7.3 ka; Machida and Arai, 2003) fall. Thus, if the Idenokuchi fault ruptures together with the Futagawa fault, we would find multi-events on the Idenokuchi fault during the last seven thousand years.

We excavated a 14-m-long, 6-m-wide, 3-m-deep trench on the antithetic fault of the Idenokuchi fault, where we found 30-60 cm vertical offset associated with the 2016 event. In the laboratory, we conducted tephra analysis and radiocarbon dating. Now, we are measuring radiocarbon dates, and thus will estimate depositional and event ages in our presentation.

On the trench walls, we recognized clear, but complex normal and reverse faults. A main normal fault with a high dip angle bounded basement rocks and soil just below the 2016 surface rupture. On the hanging wall side, we found many antithetic normal faults and reverse faults. In the soil sediments, we identified K-Ah tephra (thickness of 40 cm) based on volcanic glass morphology and refractive index. Soil sequence on the hanging wall side is shown from the surface: surface soil, brown soil, black soil (paleosol1), brown soil, K-Ah, black soil (paleosol2) and yellowish soil.
At present, we identified at least four events including the 2016 event since paleosol2. Especially, after K-Ah deposition, we confidently three events including the 2016 event, corresponding with the frequency of the Futagawa fault activity (Kumahara et al., 2017; Toda et al., 2018; Tsutsumi et al., 2018; Ueta et al., 2018). This preliminary result suggests that the Idenokuchi fault ruptured with the Futagawa fault. Additionally, we also identified a few probable events and will discuss this with radiocarbon dates in the presentation.

We conducted paleoseismic investigations such as drilling and trenching surveys across the Hinagu segment of the Hinagu fault zone, Kumamoto, Japan. The result based on the careful trench wall observation and preliminary radiocarbon dating of sediments show that paleoearthquake cycle of the Hinagu segment is shorter than previous evaluation of the fault.

Seismic trenching on offshore part of the Hinagu Fault Zone, Kyushu, Japan −3D structure and paleo-seismicity of offshore dextral strike-slip fault

*Takashi OGAMI[1], Shintaro Abe[2], Kenjiro Mukaiyama[3], Shigeyuki Suda[4]

1. Geological Survey of Japan, AIST, 2. ADEP, 3. Kawasaki Geological Engineering Co. Ltd., 4. JGI Inc.

As a part of "Comprehensive research project for the major active faults related to the 2016 Kumamoto earthquake" of MEXT, we conducted offshore-fault surveys at the offshore part of the Hinagu-Fault-Zone, Kyushu, Japan. We have obtained ultra-high-resolution 3D-seismic data and two offshore drilling cores, and integrated them to clarify detailed geological structure and paleo-seismicity of the fault zone since the Last glacial maximum (LGM).

We chose coastal area of the Yatsushiro Sea, off the Tsunagi town, Kumamoto Prefecture, as study area. The sedimentary body of the postglacial period is formed thicker than 10 m at the area. Inside a rectangle area of 1 km by 2 km, we obtained ultra-high-resolution 3D-seismic data using the boomer source. Two drilling cores are obtained at both sides of the target fault.

3D geological structure and shape of the fault are figured out based on the 3D-seismic data. We distinguished extensional duplex structure at right-stepover section along the fault, which strongly suggest dextral strike-slip faulting. The structural depression associated with the extensional duplex would emphasize vertical faulting, which would provide clues to clarify the paleo-seismic events based on sedimentary analysis.

Two drilling cores penetrates the sedimentary body of the postglacial period, and are classified into Facies B, A4, A3, A2 and A1, in ascending order. Our interpretion of them are followings. Facies B: Sediment before LGM. Facies A4: Terrestrial sediment after LGM. Facies A3: Muddy bay sediment of transgressive stage. Facies A2: Sandy sediment overlapping ravinement surface. Facies A1: Sandy and muddy bay sediment of highstand. Based on 3D-seismic data, we classified strata of facies A4, A3, A2 and A1 into 7 seismic units (U7-U1, in ascending order) . The seismic units of U7-U3 are composed of facies A4 and A3. The seismic unit of U2 and U1 correspond with facies A2 and A1, respectively. The basement of seismic unit of U7 corresponds to the boundary of facies B/A4, and is interpreted as an erosional surface during lowstand of LGM around 18 ka.
Thickness of the seismic unit of U7, U5, U3, U2 and U1 changes abruptly at the fault, which should have result of 5 faulting events of E5-E1, in ascending order. Based on age-depth curve at drilling site on the downthrown side of the fault, faulting events of E5-E3 could be estimated as followings. E5: 18 ka-12.01 cal kBP, E4: 9.96-9.50 cal kBP, E3: 8.86-8.62 cal kBP. E2 should occurred during formation of seismic unit U2, which corresponds to the sediment of facies A2 (8.31-1.65 cal kBP). E1 displaces top of seismic unit U2, and we don’ t recognize displacement inside U1 and sea floor. Therefore, E1 should have occurred just before U1 deposition. Facies A1 corresponds to U1 and its deposition started after 1.59 cal kBP. Therefore, E1 should have occurred just before 1.59 cal kBP.
This study successfully demonstrated "3D-seismic trenching", which comprises ultra-high-resolution 3D seismic survey and offshore drilling surveys, can figure out detailed geological structure and paleo-seismicity of strike-slip fault.

Conductivity Structure models of large and small slip regions at the 2016 Kumamoto earthquake sequence

*Satoru Yamaguchi[1], Yuto Yamanaka[2], Akira Mimura[1], Kazuki Fkue[1], Daigo Furukawa[1], Tada-nori Goto[3], Hisatoshi Koji[3], Sota Kawaguchi[3], Koki Aizawa[4], Shinichi Takakura[5]

1. Department of Geosciences, Graduate School of Science, Osaka City University, 2. Faculty of Science, Osaka City University, 3. Department of Urban Management, Graduate School of Engineering, Kyoto University, 4. Institute of Seismology and Volcanology, Kyushu University, 5. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

The 2016 Kumamoto earthquake sequence in Japan started with M_{JMA} 6.5 foreshock and the M_{JMA} 7.3 mainshock occurred 28 hours after the foreshock. The events occurred mainly within the Hinagu and Futagawa fault zone, which are known to be active faults.
Asano and Iwata (2016), Kubo *et al.* (2016), and Kobayashi *et al.* (2017) analyzed the detailed source rupture process of the foreshock, mainshock, and another notable event and proposed the source rupture models. It is important and interesting to reveal conductivity structure of the fault and compare it the source rupture models above mentioned because resistivity structure is one of the crucial elements to reveal subsurface structure of the fault.
We made magnetotelluric (MT) surveys using an audio- frequency MT (AMT) method, which is suitable for revealing shallow part (0 -2 km in depth) with high spatial resolution, along two lines (MSK and NSH lines) of ~2 km across the Futagawa Fault. The MKS line crosses the large slipped region and along the line, we made measurements at 11 stations. The NSH line crosses the small slipped region and along the line, we made measurements at 14 stations. We obtained two-dimensional resistivity models between depths 0 - ~1.0 km along the two lines, we call them MSK model and NSH model, respectively.
We recognize two common conducive regions in both models. One is highly and near vertical conductor below the surface fault traces of the Futagawa Fault. The conductor is located just beneath the surface fault trace in the MSK model and is shifted south in the NSH model. Another is deep and wider conductor which includes deep part of the conductor mentioned above. This conductor of the MSK model is wider and shallower than that of the NSH model. These features are consistent with that of source rupture models, further we can say that our conductivity models figured out more detailed subsurface structure of the Futagawa Fault.

The Timing and Extent of the Last Surface Rupture Event on the Himalayan Frontal Thrust in Central Nepal around Butwal

*Koji Okumura[1], Soma Nath Sapkota[2], Prakash Pokhrel[2], Hisao Kondo[4], Takuya Furuhashi[3]

1. Graduate School of Letters, Hiroshima University, 2. Department of Mines and Geology, 3. Taiheiyo Cement Corporation, 4. Geological Survey of Japan, AIST

The 2015 Gorkha earthquake ruptured only the deeper northern part of the thrust during the Mw 7.8 earthquake, but did not rupture the surface and shallow portion of the Himalayan Frontal Thrust (HFT) in south. Since then, the evaluation of the potential of the future surface rupture event on the HFT in central Nepal in south of 2015 rupture became an important task for paleoseismology. Mishra et al. (2016), Bollinger et al. (2016), and Wesnousky et al. (2017) proposed respective 1100 CE, 1344 CE and/or 1408 CE, and 1221 CE to 1262 CE (possibly 1255 CE) for the timing of the last surface-rupture event. Each report eliminates the timing of earthquake proposed by the other authors. Therefore, it is necessary to think over the possibility of multiple events in short (less than 100 km) segments or of misleading radiocarbon dates. Also, the existence and the east termination of 1505 CE Indian central seismic gap event (Malik et al., 2017) are not certain yet. In order to solve the rupture history and rupture extents in central and western Nepal, we excavated two trenches across the HFT around the city of Butwal. One is at 12 km west of Butwal at Sorauli (27.70˚N 83.36˚E) and another is at 60 km ESE of Butwal at Susto (27.48˚ N 83.86˚E). Around the Sorauli trench site there is no clear continuous scarp along the Siwalik hill front, but ~100 m wide zone of alluvial surface adjacent to the foot of the hills tilt toward south and juxtaposed to flat alluvial surface. The boundary between the tilted surface and the flat plain is continuous and looks like the active front of a flexure scarp. The trench across a small scarp on the tilted surface did not expose any fault, but a fine sand layer was tilted towards the boundary. An Baesian model of radiocarbon dates indicates the timing of tilting is between 1328 CE and 1435 CE. This period coincides with the 1344 CE earthquake (Bollinger et al., 2016). The Susto trench in the east of Butwal was dug into the foot of ~20 m high fault/flexure scarp below an uplifted terrace surface. In this trench also, 13˚ south-dipping fine sand layers appeared but the fault was below the water table and not exposed. The timing of the tilt in Susuto trench as well as results from investigation in further west in the boundary area between 1344 CE and 1505 CE event will be reported.

Discussion

Linear surface ruptures detected by SAR -- *the Kumamoto earthquake, the Northern Osaka earthquake and the Hokkaido Eastern Iburi earthquake*

*Satoshi Fujiwara[1], Hiroshi Une[1], Takayuki Nakano[1], Hiroshi Yarai[1], Tomokazu Kobayashi[1], Yu Morishita[1]

1. GSI of Japan

1. Introduction

The radar interferogram of ALOS-2 for the 2016 Kumamoto earthquake (M7.3) generally shows elastic deformation caused by the main earthquakes but many other linear discontinuities showing displacement are also found (Fujiwara et al., 2016).

We also found similar linear surface ruptures of the Northern Osaka earthquake on June 18, 2018 (M6.1) and the 2018 Hokkaido Eastern Iburi earthquake (M6.7).

In this presentation, we will show the characteristics of these linear surface ruptures.

2.General characteristics of the linear surface ruptures

The linear surface ruptures are those that Sangawa *et al.* (1985) presented about active faults in the southern part of Suruga Bay West Coast, and did not cause a large earthquake independently and the faults moved as a result of other large earthquakes.

The followings are the common features of the linear surface ruptures:

(1) The standard length of them is several kilometers, with linear or gentle curvilinear shape. The displacement is on the order of a few centimeters to several tens of centimeters.
(2) They are far from the seismogenic fault, and it is unlikely that they are the main seismic fault itself or the branch faults.
(3) There is no evidence that they generated large earthquake ground motions at the time of the main earthquake.
(4) They were likely moved passively, and it is considered to be the resultant faults, not the cause of the main big earthquake.
(5) Since there is a correlation between the topography and the displacement, some of them are recognized as "active faults" from their topographical features. Therefore, there is a possibility that similar fault movements have been accumulating from the past.
(6) The direction of strike and the displacement pattern of them are consistent with the surrounding stress field.

3. Characteristics for each earthquake

3-1) 2016 Kumamoto Earthquake
(1) About 230 linear surface ruptures have been confirmed.

©2019. Japan Geoscience Union. All Right Reserved.

(2) The form of displacement accounts for most of the normal fault.
(3) The interval, depth and displacement of them are almost constant and uniform for each area, and they form several groups of the linear surface faults.
(4) There are fault groups of similar shape from Beppu Bay to Unzen in the central part of Kyushu, Japan. This implies a possibility that there is a common form of them in central Kyushu.
(5) ΔCFF based on the fault model of the Futagawa fault zone and the Hinagu fault zone for the Kumamoto earthquake can not explain the cause of the displacement of them.

3-2) Northern Osaka earthquake on June 18, 2018
(1) The linear surface rupture was recognized at a place coincident with one of the faults of the Arima–Takatsuki fault zone (Makami fault). Makami fault has been confirmed that it moved at the time of the 1596 Keicho–Fushimi earthquake (M 7.5).
(2) Although the right–lateral fault component is dominant, the rupture does not reach the surface of the ground, but the displacement of the deviation component spreads by a width of about several hundred meters.
(3) On the linear surface rupture, vertical displacement of the south side down is found.
(4) According to the long-term observation before the earthquake, a wide belt around the linear surface rupture has continuously sunk.
(5) The general crustal deformation due to the main shock is small, and it is about several cm at the maximum.

3-3) 2018 Hokkaido Eastern Iburi earthquake
(1) The displacement shows east–west shortening, and there are almost no vertical components. Then, they can be described as reverse fault motion with very low dip angle.
(2) The trace on the ground surface is not a straight line but a somewhat complicated curve that follows the terrain.
(3) The traces of them have not been recognized as active faults.
(4) In the seismic exploration (Yokokura et al., 2014), deviations in the basement are recognized just under them and they may be a hidden fault.

Acquisition of micro-landforms in the forest using small UAV-LiDAR: An example from surface rupture of the 2008 Iwate-Miyagi Nairiku, Japan, earthquake

*Asaka Konno[1], Taro Suzuki[2], Shinji Toda[1]

1. International Research Institute of Disaster Science, Tohoku University, 2. Waseda University

For active fault research, photogrammetry (e.g., Photoscan) with UAV (Unmanned Aerial Vehicle) has been introduced to map surface ruptures for the recent earthquakes. However, this method has mainly two drawbacks: it is necessary to set reference points (GCP: Ground Control Point), and it cannot be applied to ground in the dense forest. A small LiDAR equipment attached to the UAV laser is expected to overcome these issues. Although this approach is considered to be effective for detailed mapping of earthquake surface ruptures, none of the papers has been published such an application in the forest. Here we investigate the effectiveness of UAV laser surveying under the forest comparing to the topographical data acquired by terrestrial laser survey (Maruyama et al., 2008; Yoshimi et al., 2010) for the surface rupture that appeared at the 2008 Iwate Miyagi Nairiku earthquake.

Our study field is along the ~0.7-km-long surface rupture located in the north-east of the Aratozawa Dam. The heights of the free faces was several tens of cm to 2 m. We conducted the UAV flights at an altitude of 50-70 m on November 15, 2018. The area is densely covered with cedar plantations and broad-leaved trees, and thus surface rupture is almost invisible from aerial photographs. For the UAV aviation laser surveying, DJI Matrice 600 Pro owned by Waseda University was used. Six GNSS receivers mounted on the UAV allows us to precisely calculate the UAV location only with the errors of the attitude (0.1 °) and the position (1 cm). Based on the precise position information of the UAV, we attached the LiDAR equipment Velodyne's VLP-32C to the UAV to acquire detailed topographical data in the forest. We filtered the point cloud data using Landforms of ISP's software, and then extracted only the ground surface removing the points reflected from vegetation. The swath of ~0.16 km^2 along the surface rupture, measured in about 15 minutes of flight, enable us to provide about 69-million-point cloud data. Among them, the ground point data of ~200,000 points were only screened (~0.3%). Even though it is much fewer than the 8 million points obtained by terrestrial laser surveying of Mariuyama et al. (2008), the points are more homogeneously distributed and data loss is small. Since the terrestrial laser irradiates the beam to the horizontal direction from the installed machine, the data could not be acquired from a blind spot behind trees. In terms of data precision, we confirmed the DEM model from UAV LiDAR is comparable with the terrestrial LiDAR DEM with centimeter-order accuracy. An absolute advantage of the UAV LiDAR is overwhelmingly short operation that allows us to perform not only urgent post-earthquake survey but also repeating measurements to follow degradation process of fault scarps.

Bayesian Inference and Forecast on Renewal Processes for Recurrent Earthquakes with Uncertain Occurrence Times

*Shunichi Nomura[1], Yosihiko Ogata[1]

1. The Institute of Statistical Mathematics

We discuss parameter inference and forecast in renewal processes for recurrent earthquakes suffering from uncertainties in their occurrence times. Exact likelihood and hazard evaluation in point process theory involves multiple integral with respect to uncertain occurrence dates and are often difficult to calculate even numerically. Alternatively, Monte Carlo simulation of the uncertain occurrence histories can be used for the evaluation by calculating the integrated functions for respective simulated histories and simply averaging them. We apply a renewal model with the Brownian Passage Time (BPT) distribution to Japanese paleoseismic catalog in which at least 2 latest events are specified for each fault segment. It is shown that the Monte Carlo method yields almost the same results as numerical integration. In parameter inference, we assume a common coefficient of variation (COV) parameter for recurrence intervals of Japanese paleoearthquakes due to scarcity of their histories. From datasets in 73 inland paleoseismic sites in Japan, we obtain a Bayes estimate of the common COV at 0.50, which is significantly larger than the COV estimate at 0.24 currently applied in the long-term forecast held by the Headquarters for Earthquake Research Promotion (HERP) of Japan. The difference in COV’ s estimates makes critical influences on long-term probability forecast in several fault segments. We also show numeric experiments of parameter inference and forecast for virtual active fault and compare Bayesian inference and forecast to plug-in methods with maximum likelihood estimates.

Slip rate of the Chaman fault: estimates based on ^{10}Be exposure dating for offset geomorphic surfaces in Afghanistan

*Zakeria Shnizai[1], Yuki Matsushi[2], Hiroyuki Tsutsumi[1]

1. Doshisha University, 2. Kyoto University

Afghanistan is located in a tectonically active part of the world near the collision boundary between the Eurasian and Indian plates. The Chaman fault traverses the eastern part of the country and is a major left-lateral strike-slip fault that accommodates much of the differential movement between the Indian and Eurasian plates. The fault starts from Makaran coast and extends to northeast through the Chaman City, Pakistan. Then it extends to north-northeast into Afghanistan and runs in west of Kabul and finally merges with the Pamir faults system. It is ~1000 km long and strikes from N10˚E to N35˚E. High slip-rates of the fault are known by previous works in the Pakistan side. In Afghanistan no research has been done, therefore we prepared a detailed fault map based on visual images interpretation and previous literatures. The fault offset older and younger alluvial fans and stream deposits of late Pleistocene and Holocene age. Along the fault, relative ages of geomorphic surfaces are known but their absolute ages are unknown. In the absence of absolute ages for faulted deposits, it is not possible to determine the fault slip-rate. Therefore we have conducted cosmogenic dating as was done in Pakistan side to provide age controls for fluvial deposits in the study area. Terrestrial Cosmogenic Nuclide (TCN) uses the interactions between cosmic rays and nuclides in transported boulders, and therefore is an excellent method to directly date alluvial deposits. TCN is particularly useful in Afghanistan due to lack of terrestrial organic materials for radiocarbon dating. Our study focuses on three different areas located at Wardak Province. One of the sites is Ghat Bandakul south of Kabul where the distal part of alluvial fan deposited at the mouth of a stream channel is offset left-laterally. The fan slopes 3-5˚ westward for ~1 km from the foot of the Syah-Tapa Mountain. The deposits are composed of clay, sandstone and granitic clasts originating from bedrocks. Analysis of ALOS images and field work indicate that younger and older terrace risers are displaced left-laterally along the fault for 165 m and 235 m respectively. We collected 6 samples from the top 1-3 cm of each desired sandstone boulders that were >1m in diameter and well-embedded in surface to ensure their long-term stability. The sandstone has large amounts of quartz mineral, which yields ^{10}Be TCN nuclide ideal for dating deposits over Quaternary timescale. Samples were processed at the laboratories of DPRI, Kyoto University and MALT, University of Tokyo.
Based on ~165 m displaced alluvial fan with a ^{10}Be exposure age of ~46 kyr, we obtained the first geomorphologically determined slip-rate of 3.5 mm/yr along the Chaman fault. This slip-rate is considerably smaller than the geologically and geomorphologically defined slip-rates of 19–24 mm/yr and 33 mm/yr along the fault in the border region of Afghanistan and Pakistan. Along the southern section at Ghazni and Zabul Provinces, we mapped east-dipping thrust faults as well as the multiple fault splays indicating a complex interplay between left-lateral faulting and northwest compression, which may cause slower slip-rate at the northern end of the fault. We plan to date two other alluvial surfaces in the southern part of the study area to determine exact slip-rate of the fault in Afghanistan.

[S-SS17] Seismic evidence of volcanic roots

convener:Naofumi Aso(Tokyo Institute of Technology), Yohei Yukutake(Hot Springs Research Institute of Kanagawa Prefecture), Chairperson:Naofumi Aso, Yohei Yukutake

Magma transport system beneath volcanoes is a key to understand long-term geodynamics and the evolution of the Earth. Especially, deep long-period earthquakes around the Moho beneath active volcanoes are supposed to relate to the magma transport system, although their activities and mechanisms are not understood well. Revealing the role of deep long-period earthquakes in the magma transport system is a key to understand deep volcanic roots around the lower crust, including deep magma chambers. It is therefore essential to estimate complete seismicity with a high-resolution hypocenter distribution and focal mechanisms of deep long-period earthquakes, based on innovative techniques including template matching, relocation methods using waveform cross-correlations, and waveform inversions. Also, high-resolution seismic imaging using advanced tomography techniques, including tomography using ambient noise interferometry, with a dense seismic network is essential to visualize the magma transport system. We welcome studies to understand volcanic roots from a variety of seismological approaches including but not limited to the methods mentioned above.

Spectral characteristics of deep low frequency earthquakes at Mount Fuji

*Motoo Ukawa[1]

1. Nihon University

Source processes of deep low frequency (DLF) earthquakes beneath volcanoes have poorly understood, mainly because of the small magnitudes of the earthquakes. In this study, we investigate spectral characteristics of the DLF earthquakes beneath Mount Fuji, focusing 11 events with long durations of 5 to 20 minutes including relatively large maximum earthquakes of M0.9 to M1.8. Spectral characteristics of earthquakes, as well as the amplitudes of seismic waves, provide us constraints for their source models. In the present spectral analysis, wavelet analysis with Morlet analyzing wavelet is applied to the DLF events. The results show following characteristics of the DLF earthquakes. The predominant frequencies of the 11 events range relatively narrow frequency band of 1 to 2 Hz. High frequency components of mainly 5-10 Hz are superposed onto the main low frequency waves in the events with large amplitudes. One event shows gradual change of the predominant frequency from 1.5 Hz to 1.0 Hz during 5 minutes. Source models of DLF earthquakes should explain the above spectral characteristics.

Deep low-frequency earthquakes corresponding to the 2011 and 2018 eruptions in Kirishima volcano

*Ryo Kurihara[1], Kazushige Obara[1], Akiko Takeo[1], Yusaku Tanaka[1]

1. Earthquake Research Institute, The University of Tokyo

Deep low-frequency earthquakes (LFEs), or sometimes called as deep long-period earthquakes (DLPs), are earthquakes whose dominant frequencies are lower than those of regular earthquakes of the same magnitudes. Deep LFEs occur beneath Kirishima volcano in southwest Japan at the depths of about 10-15 km and 20-25 km according to the catalog of Japan meteorology agency (JMA), while deep LFEs at most volcanoes in Japan occur at the depth of about 30 km.The LFEs near volcanoes can be a key to reveal physical processes of volcanic activities including eruptions because deep LFE activities are supposed to correlate with eruptions. For example, White (1996) showed that the deep long-period earthquakes (DLPs), so-called LFEs, occurred before the 1991 eruption of Pinatubo volcano, Philippine. Shapiro et al. (2017) showed the relationship between DLPs and long period earthquake near the surface beneath the Klyuchevskoy volcano group at Kamchatka, Russia. However, the relationships are still unknown in many volcanoes in Japan. Takahashi and Miyamura (2009) analyzed deep LFEs all over Japan using the catalog of JMA and concluded that they could not find deep LFEs corresponding with the surface volcanic activity such as eruptions. In fact, LFEs were constantly observed in Kirishima volcano in the JMA catalog. In this study, in order to reveal the relationships between activities of volcano such as eruptions and activities of deep LFEs, we first investigated spatial distribution of LFEs by relocation of the hypocenters of LFEs occurred from April 2004 to December 2015 in the JMA catalog using Network correlation coefficient method (Ohta and Ide, 2011). We then obtained time-series change of LFEs by comprehensive detection of deep LFEs based on matched filter technique (Gibbons and Ringdal, 2006; Shelly et al., 2007) from April 2004 to March 2018.

In results of relocation, hypocenters of the deep LFEs are concentrated in small clusters at the depth of 13 km and 22 km, especially many LFEs are located at the depth of about 22 km. On the other hand, result of the matched filter technique shows that deep LFEs at the depth of 23-25 km are activated for about two years including 2011 subplinian eruptions of Shinmoe-dake in Kirishima volcano group. The period of activation corresponds to the period of crustal deformation due to the volume change of the magma reservoir located beneath Ebino plateau at the depth of about 8 km (Nakao et al., 2013). From both results, we find that deep LFEs activated in the two years are located at the depth of 23-25 km, deeper than the locations of deep LFEs which constantly occurred from 2004 to 2018. Waveforms of deep LFEs activated around the 2011 eruptions have different characteristics such as lower frequencies and weak P wave onsets. The locations of activated deep LFEs migrated from shallow part to deep part of the small cluster at the depth of about 23-25 km during the two years of activation. In addition, there are some characteristic deep LFEs which were intensively observed in the periods of phreatic eruptions from March 2010 to July 2010 and phreatomagmatic eruptions from June 2011 to September 2011.Activation of deep LFEs was also observed in the period of eruptions in 2018, however, the depth and waveforms of the deep LFEs are same as those of deep LFEs which constantly occur at the depth of 20-23 km.
These results suggest that the deep LFEs occurring at the depths of 20-25 km are triggered by fluid flow. The difference of deep LFEs in 2011 and 2018 suggest that the fluid paths of the 2011 eruptions and 2018 eruptions are different. Activation of deep LFEs was not observed at the depth of 13 km in the periods of both eruptions, therefore, this deep LFEs may correspond to Ohachi volcano which did not erupt in the periods.

Origin of long-duration of deep low-frequency earthquakes and activity of shallow low-frequency earthquakes beneath northeastern Japan

*Masahiro Kosuga[1], Taichi Haruyama[1], Yuki Matsuno[2], Iori Narita[2], Takuto Maeda[1]

1. Graduate School of Science and Technology, Hirosaki University, 2. Faculty of Science and Technology, Hirosaki University

We investigated the origin of long duration of deep low-frequency (DLF) earthquakes and the activity of shallow low-frequency (SLF) earthquakes beneath northeastern Japan. Source mechanism of DLF events has attracted attention because the events are anomalous with very low predominant frequencies and with a very deep hypocentral location, suggesting a possible link to a magma transport system. Previous studies have shown that the source mechanisms are variable, double couple, CLVD, and single force, among the events. However, the other aspect of the characteristics of DLF events, long duration of the seismic signal, has not been well studied. We firstly searched for typical DLF events with low frequency and long duration. ThenWe we evaluatedthe frequency content by employing frequency index (FI) defined by the logarithm of the amplitude ratio of spectra between high- low-frequency ranges. We specify specified the range as 2–4 Hz and 10–20 Hz for low- and high-frequency ranges, respectively. These ranges correspond to the predominant frequencies of DLF and shallow ordinary earthquakes. We specified determined the location of typical DLF eventsbased on the FI and durationmeasurements. For the case of Hijiori in Yamagata prefecture, long-lasting (> 10 s) monochromatic vibration is was in phase among the stations, which suggests that the source effect is the origin of extended coda is a source origin rather than some path effects. Spectrogram of this event shows no hint of overtones expected from a resonance mechanism. We next numericallysimulated seismograms from several source models by the OpenSWPC code for seismic wave propagation in 2D/3D media. Simulation indicates that the resonance of seismic waves in a low-velocity body could produce monochromatic vibration, but under an exceptional condition of the size and physical properties of the resonant body, and restricted location of the initial source that trigger the resonance. We are conducting the following simulation for a moving source through multiple channels of the fluid transport system.

Event detection using FI is effective for SLF earthquakes that have no low-frequency flag in the JMA earthquake catalog. We searched for the SLF events in the Hakkoda area in Aomori prefecture and the Hakodate area in southern Hokkaido. SLF events in Hakkoda exhibit a cylindrical distribution beneath the Odake volcano in a depth range from the surface to about 5 km, clearly separated from the distribution of VT earthquakes around the volcano. Since the activity of SLF events are restricted in time when the expansion of volcanic body was suggested by GNSS observation, the SLF activity probably related to a magmatic activity of the volcano. In Hakodate area, the SLF earthquakes are located apart from the active volcano, Esan, and with focal depths shallower than 10 km. We confirmed the depth of several SLF earthquakes by adding travel time data from our two temporary seismic stations just above the SLF sources. Thus, the SLF events in this area are collocated with ordinary high-frequency events. Investigation of the generation mechanism of SLF earthquakes in the brittle regime is also important to comparably understand the mechanism of DLF earthquakes in the ductile regime.

Deep low-frequency earthquakes, tomography and magmatic system beneath active volcanoes

*Dapeng Zhao[1]

1. Department of Geophysics, Tohoku University

We made a systematic study of deep low-frequency earthquakes, high-resolution tomography and magmatic system beneath active volcanoes on the Japan Islands. Low-frequency earthquakes (LFEs) in the lower crust and uppermost mantle are widely observed, and they occur not only along the subducting Philippine Sea (PHS) slab interface but also beneath active arc volcanoes. The volcanic LFEs are still not well understood because of their limited quantities and less reliable hypocenter locations. We used seismic tomography to determine detailed three-dimensional (3-D) P and S-wave velocity (Vp and Vs) models of the crust and upper mantle beneath the Japan Islands, and used the obtained 3-D Vp and Vs models to relocate the volcanic LFEs precisely (Niu et al., 2008; Yu et al., 2018). Our results show that the volcanic LFEs can be classified into two types: pipe-like and swarm-like LFEs, and both of them are located in or around zones of low-velocity (low-V) and high-Poisson's ratio (high-σ) in the crust and uppermost mantle beneath the active volcanoes. The pipe-like LFEs may be related to fluid migration from the lower crust or the uppermost mantle, whereas the swarm-like LFEs may be related to local magmatic activities or small magma chambers. The number of LFEs sometimes increases sharply before or after a nearby large crustal earthquake that may cause cracks and fluid migration. The spatiotemporal distribution of the LFEs may indicate the track of migrating fluids. As compared with the tectonic LFEs along the PHS slab interface, the volcanic LFEs are more sensitive to fluid migration and local magmatic activities. High pore pressures play an important role in triggering both types of LFEs.

We also investigated the 3-D seismic structure of source areas of the 6 October 2000 Western Tottori earthquake (M 7.3) and the 21 October 2016 Central Tottori earthquake (M 6.6) that occurred near the Daisen volcano in SW Japan (Zhao et al., 2018a). The two large events took place in a high-velocity (high-V) zone in the upper crust, whereas low-V and high-σ anomalies are revealed in the lower crust and upper mantle. LFEs (M 0.0–2.1) occurred in or around the low-V and high-σ zones, which reflect upward migration of magmatic fluids from the upper mantle to the crust under the Daisen volcano. The nucleation of the Tottori earthquakes may be affected by the ascending fluids. The flat subducting PHS slab has a younger lithosphere age and so a higher temperature beneath the Daisen and Tottori area, facilitating the PHS slab melting. It is also possible that a PHS slab window has formed along the extinct Shikoku Basin spreading ridge beneath SW Japan, and mantle materials below the PHS slab may ascend to the shallow area through the slab window. These results suggest that the Daisen adakite magma was affected by the PHS slab melting and upwelling flow in the upper mantle above the subducting Pacific slab.

Detailed 3-D Vp, Vs and σ images of the crust and upper mantle beneath Kyushu are determined, with a focus on the source area of the 2016 Kumamoto earthquake (M 7.3) that occurred in the Beppu-Shimabara graben (BSG) where four active volcanoes and many active faults exist (Zhao et al., 2018b). The 2016 Kumamoto earthquake took place in a high-V and low-σ zone in the upper crust, which is surrounded and underlain by low-V and high-σ anomalies in the upper mantle. This result suggests that, in and around the source zone of the 2016 Kumamoto earthquake, strong structural heterogeneities relating to active volcanoes and magmatic fluids exist, which may affect the seismogenesis. Along the BSG, low-V and high-σ anomalies do not exist everywhere in the upper mantle but mainly beneath the active volcanoes, suggesting that hot mantle upwelling is not the only cause of the

©2019. Japan Geoscience Union. All Right Reserved.

graben. The BSG was most likely formed by joint effects of northward extension of the Okinawa Trough, westward extension of the Median Tectonic Line, and hot upwelling flow in the mantle wedge beneath the active volcanoes.

Seismic imaging of deep structure beneath active volcanoes

*Junichi Nakajima[1]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology

Seismological observations clearly show that flux melting in the mantle wedge is a deep source of magmatism in subduction zones and generated melts are transported to the continental crust through a mantle upwelling flow. However, physical processes of magmatism beneath deep crust are poorly understood. Here I review seismological structures (seismic velocity and attenuation, S-wave reflectors, and low-frequency earthquakes) beneath active volcanoes in Japan, focusing on deep magma chambers and possible pathways of magmatic fluids to the upper crustal levels.

Deep low-frequency volcanic earthquakes and their implication for deep crustal processes in the magmatic arc

*Haruhisa Nakamichi[1]

1. Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University

Under temperatures and pressures of the lower crust and the upper mantle, rocks typically deform in a ductile manner, and it is unlikely that a sufficient deviatoric stress accumulates to generate brittle failure. However, earthquakes do occur in the upper mantle and in the lower crust beneath active volcanoes, and they are known as volcanic deep low-frequency earthquakes (VDLFs). They release energy mostly in the low-frequency range (<5 Hz), and are characterized by emergent arrivals and long-duration codas. VDLF activity observed at depths of 10-50 km in Japan, the Philippines, Alaska, and the Western US (Power et al., 2004; Ukawa, 2005; Nichols et al. 20011) has generally been attributed to magma transport in the mid-to-lower crustal and uppermost mantle regions. However, because VDLF seismicity is infrequent, with relatively weak and emergent signals, the relationship between deep magma transport and seismic radiation remains poorly understood. Dense seismic observation systems in boreholes, such as the high-sensitivity seismograph network “Hi-net” in Japan (Obara et al. 2005), are effective at detecting not only non-VDLFs (Obara, 2002) but also VDLFs. Since 1997, the Japan Meteorological Agency has routinely detected and located DLFs using the Hi-net dataset, and have identified DLFs in and around most quaternary volcanoes in Japan (Takahashi and Miyamura, 2009). Several studies have attempted to estimate source mechanisms of VDLFs in Japan. The first attempt, carried out by Ukawa and Ohtake (1987), provided a single force as the source mechanism of a VDLF beneath Izu-Ohshima by using the particle motion directions of *S*-waves. More recently, strike-slip type and non-double-couple source mechanisms were obtained using waveform inversions for VDLFs in Northeast Japan (Nishidomi and Takeo 1996; Okada and Hasegawa, 2000). Nakamichi et al. (2003; 2004) estimated the source mechanisms of Mts. Iwate and Fuji through the moment tensor inversion of spectral ratios of body waves, using data from a dense seismic network. The authors explained the source mechanisms as the motion of a tensile crack coupled either with a shear crack or with a chamber. No significant common features have been found in these estimated source mechanisms of VDLFs in Japan. The depths of VDLFs correspond to the depth interval where CO_2-rich fluids are expected to be liberated from ascending basaltic magmas, suggesting that such fluids play an important role in facilitating earthquake instabilities in the presence of tectonic stresses. The striking temporal correlation between VDLF activity and CO_2 gas emissions has been pointed out by Mammoth Mountain (Hill, 1996) and Izu-Ohshima (Watanabe, 2013). However, a temporal correlation between the VDLF activity and surficial geological and shallow geophysical activity is currently debated. The intrusion of basaltic magma before the eruption of Mt. Pinatubo in 1991 was correlated with VDLFs (White, 1996), and temporal correlations are clear for the 1998-1999 unrest of Mt. Iwate, where VDLF seismicity started 5 days before the initiation of the volcano tectonic (VT) seismicity (Nakamichi et al., 2003). We are currently investigating this correlation for the volcanic activity of Sakurajima, which is located in the southern part of the Aira caldera. There is a correlation between VT and VDLF seismicity in the Aira caldera since 2000. For example, both VT and VDLF increased in number between 2017 and 2018. On the other hand, no clear correlation between the VDLF seismicity and the eruption activity of Sakurajima volcano has been identified thus far.

[S-SS17] Seismic evidence of volcanic roots

convener:Naofumi Aso(Tokyo Institute of Technology), Yohei Yukutake(Hot Springs Research Institute of Kanagawa Prefecture)

Magma transport system beneath volcanoes is a key to understand long-term geodynamics and the evolution of the Earth. Especially, deep long-period earthquakes around the Moho beneath active volcanoes are supposed to relate to the magma transport system, although their activities and mechanisms are not understood well. Revealing the role of deep long-period earthquakes in the magma transport system is a key to understand deep volcanic roots around the lower crust, including deep magma chambers. It is therefore essential to estimate complete seismicity with a high-resolution hypocenter distribution and focal mechanisms of deep long-period earthquakes, based on innovative techniques including template matching, relocation methods using waveform cross-correlations, and waveform inversions. Also, high-resolution seismic imaging using advanced tomography techniques, including tomography using ambient noise interferometry, with a dense seismic network is essential to visualize the magma transport system. We welcome studies to understand volcanic roots from a variety of seismological approaches including but not limited to the methods mentioned above.

Research on reflected S wave around volcanic regions and inland earthquake faults has been conducted throughout Japan. Mizoue et al. (1982) showed the spatial distribution of S wave reflection points in Nikko-Ashio area, and the amplitude ratio of SxP wave and SxS wave was explained by layered partially melt. In the Tohoku region, reflected S wave is from reflector contains fluid which was released during the cooling process of the melt suggested by Umino et al. (2002) and Hori et al. (2004). It is pointed out that the dehydrated fluid is involved in the mechanism of the occurrence of an inland earthquake [e.g., Hasegawa et al., 2005], and it is important to understand the behavior of the fluid in the crust in the Tohoku region in more details.

In the Yonezawa - Kitakata area, NE Japan, which is the target area of this research, it is thought that a swarm earthquake occurred 7 days after the 2011 Tohoku Region Pacific Offshore Earthquake, and the cause is the decrease in strength due to increase in fluid pressure [eg, Okada et al., 2015]. The focal region is located in and around the Otoge caldera [Yamamoto et al., 1994] which formed in the Miocene, and the possibility of existence of the fluid dehydrated from the melt as described above is sufficient. Since S wave reflected waves in Yonezawa - Kitakata area have already been discovered by Hasemi et al. (2016), this study aims to obtain the spatial distribution of the S wave reflector. In this area, temporary stations are deployed densely by Group of the aftershock observations of 2011 off the Pacific coast of Tohoku Earthquake. In this research, seismic waveform data at these temporal stations and the permanent stations by Hi-net is used. In order to accurately obtain the spatial distribution of the S wave reflector, we use the hypocenters determined by the Double Difference method using the temporary observation data.

First of all, I carefully read the travel time of the S wave reflected wave visually. For ten observation stations/clusters pairs which were able to confirm the S wave reflected wave remarkably, the travel time of the seismic waveform was converted to the depth as in Inamori et al. (1992). As a result, 16 reflectors in the northeast clusters, 14 in the center, and 3 in the southwest were read.

Next, using the read travel time, the mirror observation stations were calculated by grid search [e.g., Horiuchi et al., 1988]. We assume that the reflector is a single plane, and the wave ray path is a straight line with a uniform velocity structure of 3.4 km/s. We will find the reflector with minimum of the least squared square root between observed and calculated traveling times. From the equation of the reflector obtained by the above process, the strike/dip and the position of the reflection point with respect to each epicenter were obtained.

As a result, the reflectors are located from the lower part of the source region to the depth of 10 - 20 km below it. The strike seems to be drawing a circle or an arc, and the dips are smaller beneath the source region. Comparing this reflector distribution with the seamless geological map [AIST], for the reflectors just beneath the Otoge caldera their strikes seems to be along the edge of the caldera, and for the

©2019. Japan Geoscience Union. All Right Reserved.

reflector in the western part, their strikes follows the western marginal fault zone of Aizu Basin and the boundaries of geological structure. Comparing this with the seismic velocity structure, the reflectors are located at the periphery of the low velocity zone, being consistent with the results obtained by Umino et al. (2002) and Hori et al. (2004). By this reason, fluids promoting swarm earthquakes in the Yonezawa - Kitakata area may be migrated from the melt below the epicenter area and may have passed boundary of the existing geological structure.

Imaging of the magma pathway beneath Kirishima volcanoes by seismic interferometry

*Yutaka Nagaoka[1], Kiwamu Nishida[2], Yosuke Aoki[2], Minoru Takeo[2], Takahiro Ohkura[3], Shin Yoshikawa[3]

1. Volcanology Research Department, Meteorological Research Institute, 2. Earthquake Research Institute, The University of Tokyo, 3. Aso Volcanological Laboratory, Institute for Geothermal Sciences, Graduate School of Science, Kyoto University

Shinmoe-dake, one of Kirishima volcanoes, experienced magmatic eruptions in 2011. The analysis of ground deformation shows that the pressure source locates 5 km to the northwest of the Shinmoe-dake summit at a depth of 8 km, which implies the existence of a magma reservoir. We are trying to resolve a better image by a seismological technique toward ensuring its existence and deriving precise crustal structure and reveal a magma pathway.

The technique we employed is seismic wave interferometry, which extracts the seismic wave propagation between two seismic stations by taking cross correlations of random wavefields, such as the ambient seismic noise or the seismic coda wave. The cross correlations of random wavefields recorded at two stations can be represented as if the source is at one station and the recorder is at the other. This technique is suitable for exploring local structure since the extracted wave is sensitive to the internal structure between the two stations.

We inferred the crustal phase velocity anomaly using three-component records of the ambient seismic noise recorded by a seismic array between April 2011 and December 2013. Rayleigh and Love waves are extracted by taking cross correlations (Rayleigh waves from cross correlation functions of pairs of vertical components, and Love waves from transverse components). We derived reference dispersion curves of Rayleigh and Love waves, respectively, using all possible pairs of stations, then measured phase velocity anomalies of all possible pairs with respect to the reference in multiple frequency bands (0.1-0.2 Hz, 0.2-0.4 Hz, 0.3-0.6 Hz, and 0.4-0.8 Hz). Finally, three-dimensional V_{SV} and V_{SH} structures were obtained from a collection of local one-dimensional velocity profiles derived by inverting phase velocities of Rayleigh and Love waves, respectively, at each grid point.

Kirishima volcanoes exhibit a low V_{SV} body that is embedded beneath the deformation source and extends horizontally by about 15 km at around 10 km below sea level beneath the volcanoes. We interpret it as a crustal magma reservoir. V_{SH} did not detect low velocity bodies, implying the radial anisotropy generated by a sill complex in the magma reservoir. The ground deformation source of the eruptions in 2011 locates at uppermost and northwesternmost of the low velocity body, indicating that the low velocity body is a magma reservoir of the volcanoes. Moreover, low frequency earthquakes occur beneath the southeasternmost of the low velocity body. We can, therefore, present a model of a magma pathway that magma rising up from the deeper region right beneath the volcanoes is once stored at a magma reservoir and further ascend toward the surface from the uppermost and northwesternmost of the magma reservoir.

Our study presents the effectiveness of the estimation of S wave velocity structure using phase velocities of Rayleigh and Love waves in deciphering the magma pathway beneath the active volcanoes and the importance of further investigation of magma plumbing systems beneath various types of volcanoes.

Finite element three-dimensional seismic waveform calculations of volcanic deep low frequency earthquake including true topographic effects of Hakone volcano

*Lina Yamaya[1], Kimihiro Mochizuki[1], Tsuyoshi Ichimura[1], Kohei Fujita[1], Takeshi Akuhara[1], Takane Hori[2], Ryou Honda[3], Yohei Yukutake[3]

1. Earthquake Research Institute, Univ. of Tokyo, 2. JAMSTEC, 3. Hot Springs Research Institute of Kanagawa

Volcanic deep low frequency (DLF) earthquakes play an important role on revealing magma volcanic system because they are thought to reflect movements of volcanic fluid. Nakamichi et al. (2003) showed that the DLF earthquakes occurring beneath Iwate volcano have compensated linear vector dipole components, which suggests the relation with volcanic fluid.

Hakone volcano also has DLF earthquakes whose depths are from 10 to 30 km. Yukutake et al. (2018) showed that the number of DLF earthquakes increased just before crustal movement or increase of volcanic tremors in 2006, 2013, 2015, but mechanisms of the DLF earthquakes are still unrevealed. JMA reported that DLF earthquakes occur not just beneath Owakudani (the main crater of Hakone volcano) but around 10 km north from Owakudani, which is needed to be studied in detail. One of the difficulties to infer the source mechanisms and centroids is that the volcanic structure is complex not only due to its velocity structure but also due to its geometry. Calculation of three-dimensional seismic wave propagation are still challenging due to its computational cost, but it has become less difficult due to the recent development of efficient calculation techniques of computational science.

In this study, we used a technique of finite element three-dimensional waveform computation (Ichimura et al., 2017) to calculate the synthetic waveforms of the DLF earthquakes in Hakone volcano with respect to two different structure representations; direct inclusion of topography and flat surface with squashed topography in to the subsurface (Aagaard et al. 2008), and compared the resulted synthetic waveforms. We assumed the modified seismic velocity model reported in Yukutake et al. (2014). We used K computer and calculated the synthetics up to 1.5 Hz. As a result, although the arrival times of direct waves are similar, shapes of subsequent arrival phases are different. The amplitudes of subsequent arrival waves calculated including the true topography are larger than those calculated for the flat surface model with squashed topography. Observed data have such large amplitudes in subsequent arrival phases. Therefore, it is needed to calculate the synthetics including true topography for comparisons between data and synthetics. We further investigate generation mechanisms of such DLF earthquakes by synthetic modeling of the observed waveforms.

Magma transport system beneath Hakone volcano inferred from deep low frequency earthquakes

*Yohei Yukutake[1], Yuki Abe[1]

1. Hot Springs Research Institute of Kanagawa Prefecture

It has been recognized that the occurrence of deep low-frequency earthquakes (DLFEs) beneath a volcano is related to a behavior of magmatic fluid (e.g. Nakamichi et al., 2003). On the other hand, the linkage between the DLFE and shallow volcanic activities such as a swarm activity and crustal deformation has not been well understood. In the present study, we compared the temporal sequence of the DLFEs occurred around the depth of 25 km beneath Hakone volcano, central Japan, with the swarm activity and the inflation of pressure source occurred in the area shallower than the depth of 10 km.

During recent two decades, we observed the remarkable swarm activities at Hakone volcano in 2001, 2006, 2009, 2013 and 2015. In each swarm activity, crustal deformation associated with an inflation of pressure source was estimated at the depth of 7km beneath the central cone of caldera, by using the GNSS data (Harada et al., 2018). Tthe tomography analysis (Yukutake et al., 2015; Yukutake et al., 2018) reveals that the crystalizing magma body locates around the depth of 10km and the hydrothermal fluid dehydrated from the magma exists above it.

The DLFEs were detected by using the Matched Filter method. We used continuous seismic waveforms at 12 permanent stations around Hakone volcano in the period from January, 2000 to January, 2017. The template waveforms of 94 DLFs were prepared on the basis of the JMA catalog. We also estimated the temporal sequence of b-value by using the DLFE catalog. The temporal change was calculated by using the method in Wiemer and Wyss (2000), using the moving time-windows containing a constant event number of 300 events.

As a result, we could detect the numerous DLFEs corresponding to 46 times in comparison with the number detected by JMA. It is clearly evident that the DLFEs activated prior the swarm activity in 2006, 2009, 2013 and 2015, and synchronized with the onset time of crustal expansion caused by the inflation of pressure source. We estimated the increment of b-values by accompanied with the activation of DLFEs. An increase of b-values during the swarm activity in several volcanic regions can be explained by assuming the increment of pore pressure or the change of thermal gradient associated with the intrusion of magma/hydrothermal fluid (Jacobs and McNutt, 2010; Nanjo et al., 2018). It is likely that the activation of DLFEs accompanied by the increase of b-values reflects the inclusion of magma at the depth. The inflation of pressure source at the depth of 7 km may suggest the increase of a volatile component at the shallow magma/hydrothermal fluid from the deep intruded magma at the source region of DLFEs or the increment of temperature due to the migration of hot material. The increase of strain rate due to the inflation can promote the migration of highly pressurized to the shallow brittle zone (Fournier, 1999), triggering the earthquake swarms. On the other hand, the remarkable activation of DLFE was observed in the later stage of swarm activity in 2001, rather than precursory activity for the earthquake swarms. This result may imply that the activation of volcanic phenomena such as the shallow swarm activity and crustal deformation is not necessary initiated by the deep magma intrusion.

Hypocenter and waveform characteristics of deep low-frequency earthquakes beneath Zao volcano

*Takuma Ikegaya[1], Mare Yamamoto[1]

1. Graduate School of Science, Tohoku University

The 2011 Tohoku Earthquake (Mw 9.0) caused large crustal deformation in and around the Tohoku region, and strongly affected volcanic fluids in the crust. As an example suggesting such influence, the change in activities of deep low-frequency earthquakes (DLFs) occurring in the lower crust. The analysis of DLFs is thus considered to be one of the important keys to infer the activity of deep magma and to assess the potential risks of mid- to long-term volcanic activity after a huge earthquake. In this presentation, we report the results of our analysis of the DLFs beneath Zao volcano where activation of volcanic activities has been observed after the 2011 Tohoku Earthquake.

Zao volcano is located on the border between Yamagata and Miyagi prefectures. After the 2011 Tohoku Earthquake, the number of DLFs beneath Zao volcano started increasing, and increase in shallow seismicity have been observed since 2013. To investigate such seismic activities, the JMA unified hypocenter catalog (JMA catalog) is often used. However, the completeness of the catalog is not guaranteed in small DLFs. To improve the completeness of event detection, Ikegaya and Yamamoto (2018, JpGU) applied Matched Filter method (MF method) to the continuous waveform data recorded in 2015 and detected DLFs having high correlation to the template DLFs listed in JMA catalog. They successfully increased the number of small DLFs and revealed the spatial distribution of hypocenters showing two clusters above and below 28 km. However, due to the assumption that the hypocenters of the detected events are the same as those of the templates yielding maximum correlation value, it is difficult to discuss the details of the hypocenter clustering. In this study, aiming to understand the detailed spatio-temporal characteristics of DLF activity, we apply MF method to the waveform data for the last seven years, and determine relative hypocenters of the detected events.

In the analysis, we used the continuous three-components waveform data recorded at four permanent stations operated by Tohoku Univ., NIED, and JMA. 146 DLFs listed in JMA catalog between Jan. 2012 and Sept. 2016 were selected as templates for the MF analysis. We used a frequency band of 1-8 Hz and set the detection threshold to 0.2. The time windows exceeding the threshold were visually checked to eliminate false detections. For each detected DLFs, using cross spectrum and correlation functions, we estimated the differential travel times between the detected DLF and the template having maximum correlation, and determined the relative hypocenter using the master event method.

As a result, we detected 1361 DLFs between Jan. 2012 to May 2018, which is about 10 times the number of templates, and determined 1357 hypocenters which spread over wider depth range compared to those estimated with the assumption that the hypocenters of the detected events are the same as those of the templates having maximum correlation. We also checked the individual waveforms of the detected DLFs to understand the spatial clustering of DLFs, and revealed that DLFs can be classified into the following two types in a large sense: the first type (354 events) shows high-frequency (3-4 Hz) component in the initial part (1-2 s) of the waveform, and low-frequency (1-2 Hz) component in the remaining part of the waveform; the second type (1007 events) shows low-frequency (1-2 Hz) component over the entire waveform. The depth distribution of the former type has a peak around 33 km and widely spreads (20-38 km) whereas that of the latter type is confined within a narrow range (20-26 km). These results suggest

©2019. Japan Geoscience Union. All Right Reserved.

that source processes of DLFs differ between two types. On the other hand, there is no clear difference in the Gutenberg-Richter law *b* values of both types.

Our further analysis including estimation of the source mechanisms of the detected DLFs may contribute to the understanding of the distribution and activities of deep volcanic fluid.

Mechanisms transition of LFEs beneath Zao volcano due to the stress change induced by the 2011 Tohoku earthquake

*Genki Oikawa[1], Naofumi Aso[1], Junichi Nakajima[1], Toru Matsuzawa[2]

1. Tokyo Institute of Technology, 2. Tohoku University

Deep low-frequency earthquakes (LFEs) with dominant frequencies of 2–8 Hz occur at depths of 20–40 km, which is deeper than the depth of regular crustal earthquakes. Many previous studies indicated that focal mechanisms of LFEs have non-double-couple components such as CLVD (compensated linear vector dipole) and volumetric deformation. Therefore, LFEs are thought to be related to the magma or crustal fluid, but their physical mechanisms are still unknown. The focal mechanisms of LFEs are key information for understanding the physics underlying LFEs. Seismicity of LFEs in Zao has increased about two years after the Tohoku earthquake, so we are also interested in the potential variations of focal mechanisms in association with the seismicity change.
We analyze the mechanisms of 48 LFEs beneath Zao volcano by using the amplitude ratios of S-wave to P-wave.The site effect at each station is corrected using the radiation from regular earthquakes with known mechanisms. We assume four focal models (double-couple, CLVD, tensile-crack, and single-force) and determine an optimal model based on AIC (Akaike information criteria), to minimize the residuals between observed and theoretical S/P ratios with a penalty for the number of parameters.
We successfully determined focal mechanisms of 29 events. While the majorities are double couples (18 events; 62%), there are notable numbers of non-double-couple LFEs. The obtained mechanisms are classified into five groups, three types of double-couple (DC-A, DC-B, DC-C), a CLVD type (CLVD-D) and a single-force type (SF-E). Whereas the DC-A LFEs are observed only before the increase of LFE seismicity, most of the other types are generated after the increase of seismicity. The DC-A is consistent with the local stress field, and the symmetry axis of CLVD-D is sub-parallel to the P-axis of DC-A, so the CLVD-D is interpreted to be a shear-tensile-crack under the similar stress field. Considering that the transition of focal mechanisms was two years later than the Tohoku earthquake, we suggest that the lateral compressional stress field became less dominant near the source of LFEs two years after the Tohoku Earthquake, probably associated with afterslip and viscoelastic relaxation, and the change in local stress field altered the occurrence of LFEs.

Magma/gas intrusion process of Shinmoedake Eruption in 2017 suggested by volcanic tremors location with ASL method

Shoya Imamura[1], *Makoto OKUBO[2]

1. Faculty of Science, Kochi University, 2. Natural Science Cluster, Kochi University

Kirishima volcanoes, which located on border Miyazaki and Kagoshima prefecture in Kyushu, is still active after the large scale eruption in 2011. In this study, by using volcanic tremor/events distribution, we would like to discuss magma/gas intrusion process around magma chamber.

Recentlly, source location of volcanic tremors is usually determined by ASL (Amplitude Source Location) method (*c.f.* Nakamichi *et.al.*, 2017). ASL method is based on the idea that seismic (S) waves at higher frequency range (> 5 Hz) will propagate isotropically, an its amplitude will be simply attenuate with distance. If we can use dense seismic observation records around volcano, we can calculate the volcanic tremor location in automatically every time window. Thus, using with ASL we can easily discuss volcanic tremor/events distribution and its time variation.

According to Kirishima volcanoes activities reported by JMA (Oct, 2017), numbers of volcanic earthquakes/tremors located at southwestward of the Shinmoedake have been rapidly increased from Oct. 2017, and erupsed on 11th until 16th. Therefore, In this study we analyzed three stages, **(1)** stable condition on 9th, **(2)** earthquake/tremor activation on 10th, and **(3)** continuous eruption on 16th.

In this study, we choiced and used 10 stations, which were operated by JMA, NIED and ERI, established around Shinmoedake. For analysis, we assumed V_S = 2.2 km/s, Q_f = 175 @10Hz for volcanic events, and Q_f = 300 for volcanic tremors beneath Shinmoedake and used 5 - 10 Hz band-passed envelope amplitude for ASL. Thus, we obtained three stages time-spatial volcanic tremor/events distribution.

According to Volcanic tremor/events distribution, these were located at southward of magma source at ~ 4 km depth estimated with GPS observations (Nakao et al., 2013); stage (1). After 18 o'clock, volcanic tremor/events were activated with numbers and magnitudes around magma source, and these location were move to shallower until -1 km; stage (2). Small magnitude and shallower tremors occurred continuously at Oct. 10th.
On 16th, tremor activity became in quiet, and just only located around southward of magma source; stage (3).

These results imply that magma/gas intrusion was occurred at stage (2), might have been occurred after magma vaporization in chamber. And we can considered that at stage(2), magma vent was already constructed, magma/gas was continuously supplyed from chamber at stage (3).

Acknowledgments:
In this study, we used seismic observation records obtained by JMA, NIED, ERI(University of Tokyo). A tool of ASL method was provided by Dr. Nakamichi, Kyoto university. We are very thanks to these cooperation.

Source depth estimation of a magmatic inflation in 2008-2010 at Mt. Fuji, Japan, based on sparsity-promoting L1 inversion of GNSS data

*Yuta Mitsui[1], Takahiro Kato[2]

1. Department of Geosciences, Shizuoka University, 2. formerly at Department of Geosciences, Shizuoka University

Mt. Fuji has not erupted since the Plinian eruption in 1707, but its volcanic activity such as low-frequency earthquakes has not finished. Here, using GNSS (Global Navigation Satellite System) time-series data, we investigate an inflation event of Mt. Fuji in 2008-2010. Referring to recent studies of igneous processes, we focus on “vertically-extensive” magma systems and estimate depth distribution of geodetic inflation sources. A sparsity-promoting L1 regularization algorithm for inversion analysis allows us to estimate concentrated distribution of the sources with sufficient performance of data fitting. Our result shows that the inflation sources were mainly distributed in a depth range from 20 km to 15 km, and the total volume change was on the order of 0.01 cubic kilometers. The magma clot might move upward, and not move back downward as far as we observed. Our sparsity-promoting method is useful to constrain magma movement from limited observation data.

[S-SS17] Seismic evidence of volcanic roots

convener:Naofumi Aso(Tokyo Institute of Technology), Yohei Yukutake(Hot Springs Research Institute of Kanagawa Prefecture)

Magma transport system beneath volcanoes is a key to understand long-term geodynamics and the evolution of the Earth. Especially, deep long-period earthquakes around the Moho beneath active volcanoes are supposed to relate to the magma transport system, although their activities and mechanisms are not understood well. Revealing the role of deep long-period earthquakes in the magma transport system is a key to understand deep volcanic roots around the lower crust, including deep magma chambers. It is therefore essential to estimate complete seismicity with a high-resolution hypocenter distribution and focal mechanisms of deep long-period earthquakes, based on innovative techniques including template matching, relocation methods using waveform cross-correlations, and waveform inversions. Also, high-resolution seismic imaging using advanced tomography techniques, including tomography using ambient noise interferometry, with a dense seismic network is essential to visualize the magma transport system. We welcome studies to understand volcanic roots from a variety of seismological approaches including but not limited to the methods mentioned above.

Research on reflected S wave around volcanic regions and inland earthquake faults has been conducted throughout Japan. Mizoue et al. (1982) showed the spatial distribution of S wave reflection points in Nikko-Ashio area, and the amplitude ratio of SxP wave and SxS wave was explained by layered partially melt. In the Tohoku region, reflected S wave is from reflector contains fluid which was released during the cooling process of the melt suggested by Umino et al. (2002) and Hori et al. (2004). It is pointed out that the dehydrated fluid is involved in the mechanism of the occurrence of an inland earthquake [e.g., Hasegawa et al., 2005], and it is important to understand the behavior of the fluid in the crust in the Tohoku region in more details.

In the Yonezawa - Kitakata area, NE Japan, which is the target area of this research, it is thought that a swarm earthquake occurred 7 days after the 2011 Tohoku Region Pacific Offshore Earthquake, and the cause is the decrease in strength due to increase in fluid pressure [eg, Okada et al., 2015]. The focal region is located in and around the Otoge caldera [Yamamoto et al., 1994] which formed in the Miocene, and the possibility of existence of the fluid dehydrated from the melt as described above is sufficient. Since S wave reflected waves in Yonezawa - Kitakata area have already been discovered by Hasemi et al. (2016), this study aims to obtain the spatial distribution of the S wave reflector. In this area, temporary stations are deployed densely by Group of the aftershock observations of 2011 off the Pacific coast of Tohoku Earthquake. In this research, seismic waveform data at these temporal stations and the permanent stations by Hi-net is used. In order to accurately obtain the spatial distribution of the S wave reflector, we use the hypocenters determined by the Double Difference method using the temporary observation data.

First of all, I carefully read the travel time of the S wave reflected wave visually. For ten observation stations/clusters pairs which were able to confirm the S wave reflected wave remarkably, the travel time of the seismic waveform was converted to the depth as in Inamori et al. (1992). As a result, 16 reflectors in the northeast clusters, 14 in the center, and 3 in the southwest were read.

Next, using the read travel time, the mirror observation stations were calculated by grid search [e.g., Horiuchi et al., 1988]. We assume that the reflector is a single plane, and the wave ray path is a straight line with a uniform velocity structure of 3.4 km/s. We will find the reflector with minimum of the least squared square root between observed and calculated traveling times. From the equation of the reflector obtained by the above process, the strike/dip and the position of the reflection point with respect to each epicenter were obtained.

As a result, the reflectors are located from the lower part of the source region to the depth of 10 - 20 km below it. The strike seems to be drawing a circle or an arc, and the dips are smaller beneath the source region. Comparing this reflector distribution with the seamless geological map [AIST], for the reflectors just beneath the Otoge caldera their strikes seems to be along the edge of the caldera, and for the

©2019. Japan Geoscience Union. All Right Reserved.

reflector in the western part, their strikes follows the western marginal fault zone of Aizu Basin and the boundaries of geological structure. Comparing this with the seismic velocity structure, the reflectors are located at the periphery of the low velocity zone, being consistent with the results obtained by Umino et al. (2002) and Hori et al. (2004). By this reason, fluids promoting swarm earthquakes in the Yonezawa - Kitakata area may be migrated from the melt below the epicenter area and may have passed boundary of the existing geological structure.

Imaging of the magma pathway beneath Kirishima volcanoes by seismic interferometry

*Yutaka Nagaoka[1], Kiwamu Nishida[2], Yosuke Aoki[2], Minoru Takeo[2], Takahiro Ohkura[3], Shin Yoshikawa[3]

1. Volcanology Research Department, Meteorological Research Institute, 2. Earthquake Research Institute, The University of Tokyo, 3. Aso Volcanological Laboratory, Institute for Geothermal Sciences, Graduate School of Science, Kyoto University

Shinmoe-dake, one of Kirishima volcanoes, experienced magmatic eruptions in 2011. The analysis of ground deformation shows that the pressure source locates 5 km to the northwest of the Shinmoe-dake summit at a depth of 8 km, which implies the existence of a magma reservoir. We are trying to resolve a better image by a seismological technique toward ensuring its existence and deriving precise crustal structure and reveal a magma pathway.

The technique we employed is seismic wave interferometry, which extracts the seismic wave propagation between two seismic stations by taking cross correlations of random wavefields, such as the ambient seismic noise or the seismic coda wave. The cross correlations of random wavefields recorded at two stations can be represented as if the source is at one station and the recorder is at the other. This technique is suitable for exploring local structure since the extracted wave is sensitive to the internal structure between the two stations.

We inferred the crustal phase velocity anomaly using three-component records of the ambient seismic noise recorded by a seismic array between April 2011 and December 2013. Rayleigh and Love waves are extracted by taking cross correlations (Rayleigh waves from cross correlation functions of pairs of vertical components, and Love waves from transverse components). We derived reference dispersion curves of Rayleigh and Love waves, respectively, using all possible pairs of stations, then measured phase velocity anomalies of all possible pairs with respect to the reference in multiple frequency bands (0.1-0.2 Hz, 0.2-0.4 Hz, 0.3-0.6 Hz, and 0.4-0.8 Hz). Finally, three-dimensional V_{SV} and V_{SH} structures were obtained from a collection of local one-dimensional velocity profiles derived by inverting phase velocities of Rayleigh and Love waves, respectively, at each grid point.

Kirishima volcanoes exhibit a low V_{SV} body that is embedded beneath the deformation source and extends horizontally by about 15 km at around 10 km below sea level beneath the volcanoes. We interpret it as a crustal magma reservoir. V_{SH} did not detect low velocity bodies, implying the radial anisotropy generated by a sill complex in the magma reservoir. The ground deformation source of the eruptions in 2011 locates at uppermost and northwesternmost of the low velocity body, indicating that the low velocity body is a magma reservoir of the volcanoes. Moreover, low frequency earthquakes occur beneath the southeasternmost of the low velocity body. We can, therefore, present a model of a magma pathway that magma rising up from the deeper region right beneath the volcanoes is once stored at a magma reservoir and further ascend toward the surface from the uppermost and northwesternmost of the magma reservoir.

Our study presents the effectiveness of the estimation of S wave velocity structure using phase velocities of Rayleigh and Love waves in deciphering the magma pathway beneath the active volcanoes and the importance of further investigation of magma plumbing systems beneath various types of volcanoes.

Finite element three-dimensional seismic waveform calculations of volcanic deep low frequency earthquake including true topographic effects of Hakone volcano

*Lina Yamaya[1], Kimihiro Mochizuki[1], Tsuyoshi Ichimura[1], Kohei Fujita[1], Takeshi Akuhara[1], Takane Hori[2], Ryou Honda[3], Yohei Yukutake[3]

1. Earthquake Research Institute, Univ. of Tokyo, 2. JAMSTEC, 3. Hot Springs Research Institute of Kanagawa

Volcanic deep low frequency (DLF) earthquakes play an important role on revealing magma volcanic system because they are thought to reflect movements of volcanic fluid. Nakamichi et al. (2003) showed that the DLF earthquakes occurring beneath Iwate volcano have compensated linear vector dipole components, which suggests the relation with volcanic fluid.

Hakone volcano also has DLF earthquakes whose depths are from 10 to 30 km. Yukutake et al. (2018) showed that the number of DLF earthquakes increased just before crustal movement or increase of volcanic tremors in 2006, 2013, 2015, but mechanisms of the DLF earthquakes are still unrevealed. JMA reported that DLF earthquakes occur not just beneath Owakudani (the main crater of Hakone volcano) but around 10 km north from Owakudani, which is needed to be studied in detail. One of the difficulties to infer the source mechanisms and centroids is that the volcanic structure is complex not only due to its velocity structure but also due to its geometry. Calculation of three-dimensional seismic wave propagation are still challenging due to its computational cost, but it has become less difficult due to the recent development of efficient calculation techniques of computational science.

In this study, we used a technique of finite element three-dimensional waveform computation (Ichimura et al., 2017) to calculate the synthetic waveforms of the DLF earthquakes in Hakone volcano with respect to two different structure representations; direct inclusion of topography and flat surface with squashed topography in to the subsurface (Aagaard et al. 2008), and compared the resulted synthetic waveforms. We assumed the modified seismic velocity model reported in Yukutake et al. (2014). We used K computer and calculated the synthetics up to 1.5 Hz. As a result, although the arrival times of direct waves are similar, shapes of subsequent arrival phases are different. The amplitudes of subsequent arrival waves calculated including the true topography are larger than those calculated for the flat surface model with squashed topography. Observed data have such large amplitudes in subsequent arrival phases. Therefore, it is needed to calculate the synthetics including true topography for comparisons between data and synthetics. We further investigate generation mechanisms of such DLF earthquakes by synthetic modeling of the observed waveforms.

Magma transport system beneath Hakone volcano inferred from deep low frequency earthquakes

*Yohei Yukutake[1], Yuki Abe[1]

1. Hot Springs Research Institute of Kanagawa Prefecture

It has been recognized that the occurrence of deep low-frequency earthquakes (DLFEs) beneath a volcano is related to a behavior of magmatic fluid (e.g. Nakamichi et al., 2003). On the other hand, the linkage between the DLFE and shallow volcanic activities such as a swarm activity and crustal deformation has not been well understood. In the present study, we compared the temporal sequence of the DLFEs occurred around the depth of 25 km beneath Hakone volcano, central Japan, with the swarm activity and the inflation of pressure source occurred in the area shallower than the depth of 10 km.

During recent two decades, we observed the remarkable swarm activities at Hakone volcano in 2001, 2006, 2009, 2013 and 2015. In each swarm activity, crustal deformation associated with an inflation of pressure source was estimated at the depth of 7km beneath the central cone of caldera, by using the GNSS data (Harada et al., 2018). Tthe tomography analysis (Yukutake et al., 2015; Yukutake et al., 2018) reveals that the crystalizing magma body locates around the depth of 10km and the hydrothermal fluid dehydrated from the magma exists above it.

The DLFEs were detected by using the Matched Filter method. We used continuous seismic waveforms at 12 permanent stations around Hakone volcano in the period from January, 2000 to January, 2017. The template waveforms of 94 DLFs were prepared on the basis of the JMA catalog. We also estimated the temporal sequence of b-value by using the DLFE catalog. The temporal change was calculated by using the method in Wiemer and Wyss (2000), using the moving time-windows containing a constant event number of 300 events.

As a result, we could detect the numerous DLFEs corresponding to 46 times in comparison with the number detected by JMA. It is clearly evident that the DLFEs activated prior the swarm activity in 2006, 2009, 2013 and 2015, and synchronized with the onset time of crustal expansion caused by the inflation of pressure source. We estimated the increment of b-values by accompanied with the activation of DLFEs. An increase of b-values during the swarm activity in several volcanic regions can be explained by assuming the increment of pore pressure or the change of thermal gradient associated with the intrusion of magma/hydrothermal fluid (Jacobs and McNutt, 2010; Nanjo et al., 2018). It is likely that the activation of DLFEs accompanied by the increase of b-values reflects the inclusion of magma at the depth. The inflation of pressure source at the depth of 7 km may suggest the increase of a volatile component at the shallow magma/hydrothermal fluid from the deep intruded magma at the source region of DLFEs or the increment of temperature due to the migration of hot material. The increase of strain rate due to the inflation can promote the migration of highly pressurized to the shallow brittle zone (Fournier, 1999), triggering the earthquake swarms. On the other hand, the remarkable activation of DLFE was observed in the later stage of swarm activity in 2001, rather than precursory activity for the earthquake swarms. This result may imply that the activation of volcanic phenomena such as the shallow swarm activity and crustal deformation is not necessary initiated by the deep magma intrusion.

Hypocenter and waveform characteristics of deep low-frequency earthquakes beneath Zao volcano

*Takuma Ikegaya[1], Mare Yamamoto[1]

1. Graduate School of Science, Tohoku University

The 2011 Tohoku Earthquake (Mw 9.0) caused large crustal deformation in and around the Tohoku region, and strongly affected volcanic fluids in the crust. As an example suggesting such influence, the change in activities of deep low-frequency earthquakes (DLFs) occurring in the lower crust. The analysis of DLFs is thus considered to be one of the important keys to infer the activity of deep magma and to assess the potential risks of mid- to long-term volcanic activity after a huge earthquake. In this presentation, we report the results of our analysis of the DLFs beneath Zao volcano where activation of volcanic activities has been observed after the 2011 Tohoku Earthquake.

Zao volcano is located on the border between Yamagata and Miyagi prefectures. After the 2011 Tohoku Earthquake, the number of DLFs beneath Zao volcano started increasing, and increase in shallow seismicity have been observed since 2013. To investigate such seismic activities, the JMA unified hypocenter catalog (JMA catalog) is often used. However, the completeness of the catalog is not guaranteed in small DLFs. To improve the completeness of event detection, Ikegaya and Yamamoto (2018, JpGU) applied Matched Filter method (MF method) to the continuous waveform data recorded in 2015 and detected DLFs having high correlation to the template DLFs listed in JMA catalog. They successfully increased the number of small DLFs and revealed the spatial distribution of hypocenters showing two clusters above and below 28 km. However, due to the assumption that the hypocenters of the detected events are the same as those of the templates yielding maximum correlation value, it is difficult to discuss the details of the hypocenter clustering. In this study, aiming to understand the detailed spatio-temporal characteristics of DLF activity, we apply MF method to the waveform data for the last seven years, and determine relative hypocenters of the detected events.

In the analysis, we used the continuous three-components waveform data recorded at four permanent stations operated by Tohoku Univ., NIED, and JMA. 146 DLFs listed in JMA catalog between Jan. 2012 and Sept. 2016 were selected as templates for the MF analysis. We used a frequency band of 1-8 Hz and set the detection threshold to 0.2. The time windows exceeding the threshold were visually checked to eliminate false detections. For each detected DLFs, using cross spectrum and correlation functions, we estimated the differential travel times between the detected DLF and the template having maximum correlation, and determined the relative hypocenter using the master event method.

As a result, we detected 1361 DLFs between Jan. 2012 to May 2018, which is about 10 times the number of templates, and determined 1357 hypocenters which spread over wider depth range compared to those estimated with the assumption that the hypocenters of the detected events are the same as those of the templates having maximum correlation. We also checked the individual waveforms of the detected DLFs to understand the spatial clustering of DLFs, and revealed that DLFs can be classified into the following two types in a large sense: the first type (354 events) shows high-frequency (3-4 Hz) component in the initial part (1-2 s) of the waveform, and low-frequency (1-2 Hz) component in the remaining part of the waveform; the second type (1007 events) shows low-frequency (1-2 Hz) component over the entire waveform. The depth distribution of the former type has a peak around 33 km and widely spreads (20-38 km) whereas that of the latter type is confined within a narrow range (20-26 km). These results suggest

©2019. Japan Geoscience Union. All Right Reserved.

that source processes of DLFs differ between two types. On the other hand, there is no clear difference in the Gutenberg-Richter law *b* values of both types.

Our further analysis including estimation of the source mechanisms of the detected DLFs may contribute to the understanding of the distribution and activities of deep volcanic fluid.

Mechanisms transition of LFEs beneath Zao volcano due to the stress change induced by the 2011 Tohoku earthquake

*Genki Oikawa[1], Naofumi Aso[1], Junichi Nakajima[1], Toru Matsuzawa[2]

1. Tokyo Institute of Technology, 2. Tohoku University

Deep low-frequency earthquakes (LFEs) with dominant frequencies of 2–8 Hz occur at depths of 20–40 km, which is deeper than the depth of regular crustal earthquakes. Many previous studies indicated that focal mechanisms of LFEs have non-double-couple components such as CLVD (compensated linear vector dipole) and volumetric deformation. Therefore, LFEs are thought to be related to the magma or crustal fluid, but their physical mechanisms are still unknown. The focal mechanisms of LFEs are key information for understanding the physics underlying LFEs. Seismicity of LFEs in Zao has increased about two years after the Tohoku earthquake, so we are also interested in the potential variations of focal mechanisms in association with the seismicity change.
We analyze the mechanisms of 48 LFEs beneath Zao volcano by using the amplitude ratios of S-wave to P-wave.The site effect at each station is corrected using the radiation from regular earthquakes with known mechanisms. We assume four focal models (double-couple, CLVD, tensile-crack, and single-force) and determine an optimal model based on AIC (Akaike information criteria), to minimize the residuals between observed and theoretical S/P ratios with a penalty for the number of parameters.
We successfully determined focal mechanisms of 29 events. While the majorities are double couples (18 events; 62%), there are notable numbers of non-double-couple LFEs. The obtained mechanisms are classified into five groups, three types of double-couple (DC-A, DC-B, DC-C), a CLVD type (CLVD-D) and a single-force type (SF-E). Whereas the DC-A LFEs are observed only before the increase of LFE seismicity, most of the other types are generated after the increase of seismicity. The DC-A is consistent with the local stress field, and the symmetry axis of CLVD-D is sub-parallel to the P-axis of DC-A, so the CLVD-D is interpreted to be a shear-tensile-crack under the similar stress field. Considering that the transition of focal mechanisms was two years later than the Tohoku earthquake, we suggest that the lateral compressional stress field became less dominant near the source of LFEs two years after the Tohoku Earthquake, probably associated with afterslip and viscoelastic relaxation, and the change in local stress field altered the occurrence of LFEs.

Magma/gas intrusion process of Shinmoedake Eruption in 2017 suggested by volcanic tremors location with ASL method

Shoya Imamura[1], *Makoto OKUBO[2]

1. Faculty of Science, Kochi University, 2. Natural Science Cluster, Kochi University

Kirishima volcanoes, which located on border Miyazaki and Kagoshima prefecture in Kyushu, is still active after the large scale eruption in 2011. In this study, by using volcanic tremor/events distribution, we would like to discuss magma/gas intrusion process around magma chamber.

Recentlly, source location of volcanic tremors is usually determined by ASL (Amplitude Source Location) method (*c.f.* Nakamichi *et.al.*, 2017). ASL method is based on the idea that seismic (S) waves at higher frequency range (> 5 Hz) will propagate isotropically, an its amplitude will be simply attenuate with distance. If we can use dense seismic observation records around volcano, we can calculate the volcanic tremor location in automatically every time window. Thus, using with ASL we can easily discuss volcanic tremor/events distribution and its time variation.

According to Kirishima volcanoes activities reported by JMA (Oct, 2017), numbers of volcanic earthquakes/tremors located at southwestward of the Shinmoedake have been rapidly increased from Oct. 2017, and erupsed on 11th until 16th. Therefore, In this study we analyzed three stages, **(1)** stable condition on 9th, **(2)** earthquake/tremor activation on 10th, and **(3)** continuous eruption on 16th.

In this study, we choiced and used 10 stations, which were operated by JMA, NIED and ERI, established around Shinmoedake. For analysis, we assumed V_S = 2.2 km/s, Q_f = 175 @10Hz for volcanic events, and Q_f = 300 for volcanic tremors beneath Shinmoedake and used 5 - 10 Hz band-passed envelope amplitude for ASL. Thus, we obtained three stages time-spatial volcanic tremor/events distribution.

According to Volcanic tremor/events distribution, these were located at southward of magma source at ~ 4 km depth estimated with GPS observations (Nakao et al., 2013); stage (1). After 18 o'clock, volcanic tremor/events were activated with numbers and magnitudes around magma source, and these location were move to shallower until -1 km; stage (2). Small magnitude and shallower tremors occurred continuously at Oct. 10th.
On 16th, tremor activity became in quiet, and just only located around southward of magma source; stage (3).

These results imply that magma/gas intrusion was occurred at stage (2), might have been occurred after magma vaporization in chamber. And we can considered that at stage(2), magma vent was already constructed, magma/gas was continuously supplyed from chamber at stage (3).

Acknowledgments:
In this study, we used seismic observation records obtained by JMA, NIED, ERI(University of Tokyo). A tool of ASL method was provided by Dr. Nakamichi, Kyoto university. We are very thanks to these cooperation.

Source depth estimation of a magmatic inflation in 2008-2010 at Mt. Fuji, Japan, based on sparsity-promoting L1 inversion of GNSS data

*Yuta Mitsui[1], Takahiro Kato[2]

1. Department of Geosciences, Shizuoka University, 2. formerly at Department of Geosciences, Shizuoka University

Mt. Fuji has not erupted since the Plinian eruption in 1707, but its volcanic activity such as low-frequency earthquakes has not finished. Here, using GNSS (Global Navigation Satellite System) time-series data, we investigate an inflation event of Mt. Fuji in 2008-2010. Referring to recent studies of igneous processes, we focus on “vertically-extensive” magma systems and estimate depth distribution of geodetic inflation sources. A sparsity-promoting L1 regularization algorithm for inversion analysis allows us to estimate concentrated distribution of the sources with sufficient performance of data fitting. Our result shows that the inflation sources were mainly distributed in a depth range from 20 km to 15 km, and the total volume change was on the order of 0.01 cubic kilometers. The magma clot might move upward, and not move back downward as far as we observed. Our sparsity-promoting method is useful to constrain magma movement from limited observation data.

[S-IT26] New perspectives on the geodynamics of East Asia

convener:Timothy B Byrne(University of Connecticut), Asuka Yamaguchi(Atomosphere and Ocean Research Institute, The University of Tokyo), Jonny Wu(University of Houston), Kyoko Okino(Atmosphere and Ocean Research Institute, The University of Tokyo)

The Pacific, Indo-Australia and Eurasian plates converge around the Philippine Sea plates in south and East Asia, resulting in one of the most tectonically active regions on earth. The area is also geologically and tectonically complex with numerous active tectonic environments, ranging from subduction to collision, and a long history of plate boundary interactions. The last decade has yielded a wide range of new observations, including detailed geologic data and high resolution crustal to mantle imaging. Here we seek oral and poster presentations that bear on the geologic history and geophysical character of modern and ancient plates in East Asia and their interactions since the Mesozoic. We also invite geodynamic models that integrate these diverse datasets into a more holistic view of this dynamic environment.

Geochemical characteristics of effusive rocks (greenstones) in the Hidaka Belt, Hokkaido, Japan

*Toru Yamasaki[1], Futoshi Nanayama[1]

1. Geol. Survey of Japan (AIST)

Igneous rocks in a subduction complex typically occur as greenstones, and petrological and geochemical investigations of such greenstones can provide important insights into the oceanic magmatism, origin of the accretionary complex, and growth of the continental margin. The Hidaka Belt in Central Hokkaido, Japan consists of an early Paleogene subduction complex, referred to as the Hidaka Supergroup (HSG), dominated by clastic rocks. Locally, the terrigenous sediments of the HSG were intruded by the contemporary, normal-type mid-ocean ridge basalts (“*in situ*N-MORBs”) that were formed at an oceanic ridge near the Eurasian continent (Miyashita and Katsushima, 1986: GSJ). The southern area of the HSG has been referred to as the Nakanogawa Group (NKG), which gradually leads to the high-temperature Hidaka metamorphic belt (HMB) in the western part. The lower sequence of the HMB consists mainly of high-grade metabasites, which are assumed to be equivalent to the N-MORBs in the HSG, based on their geochemical features. Recently, Yamasaki and Nanayama (2018a: Lithos) reported about the unique Daimaruyama greenstones from the NKG, formed by an immature intra-oceanic arc-type volcanism. In addition, highly-alkaline basalts, presumably formed at the seamount, exist as exotic blocks in the NKG and are named as Tachiiwa blocks (Owada et al., 1992: JMPEG). In fact, the N-MORBs in the HSG and the Tachiiwa alkaline rocks are characterized by the whole-rock major and minor element geochemistry, but the trace element geochemistry, including the rare earth elements (REEs), has not been reported yet for these rocks. Therefore, we collected 18 samples of greenstones from the entire Hidaka Belt and examined their whole-rock major and trace element geochemistry.

Including those in our previous reports (Yamasaki and Nanayama, 2018a, b: JpGU Abs.), there are three distinct types of greenstones in the Hidaka Belt. The first type are the MORB-type greenstones which show relatively flat chondrite-normalized (CN) REE patterns and N-MORB-normalized (NMN) multi-element patterns with Ti/V = 26–53 and Zr/Nb = 21–117. Although Miyashita and Kiminami (1999: MemGSJ) showed the flat NMN minor element (Nb, P, Zr, Ti, and Y) patterns of basalts from the northern HSG, trace element patterns of the MORB-type rocks in this study show rather light REE (LREE)-rich NMN multi-element patterns. The second type are the ocean island basalt (OIB)-type greenstones. The NMN multi-element and CN REE patterns for this type of greenstones show a gentle slope up to the left, with Ti/V>62 and Zr/Nb<15. The third type are the Daimaruyama greenstones. This type of greenstones show similar NMN multi-element patterns and CN REE patterns to those in the OIB-type, but with a clear relative depletion of Nb, Ta, and Ti. In addition, their Ti-V relations are similar to those in the MORB-type greenstones.

MORB-type greenstones are distributed from the northernmost part of the HSG to the southern Rakko River area in the NKG. OIB-type greenstones occur in the Tachiiwa block and the Rakko River area. Daimaruyama greenstones occur only in the Daimaruyama megablock in the NKG. Since the Tachiiwa and Daimaruyama blocks are presumably derived from the neighboring Tokoro Belt, the absence of the OIB-type and Daimaruyama greenstones in the northern HSG implies a difference in provenance between the HSG and NKG. The MORB-type greenstones do not show the typical N-MORB-type (LREE-depleted) trace element patterns, whereas the metabasite in the HMB shows the typical N-MORB-type geochemical features. In addition, the distribution of the MORB-type greenstones is separated from the metabasites of

©2019. Japan Geoscience Union. All Right Reserved.

the HMB in the southern Hidaka Belt. These lines of evidence suggest that the protolith of the HMB is not an equivalent of the “*in-situ*MORB” in the HSG, and is probably an accreted fragment of the older oceanic plate.

Large gas reservoir in continental back-arc basin, revealed by automatic seismic velocity analysis in the Okinawa Trough

*Kota Mukumoto[1], Takeshi Tsuji[1], Andri Hendriyana[1]

1. Kyushu University

P-wave velocity acquired from seismic reflection data allows us to quantify submarine geological structures. In the Iheya North Knoll of the Okinawa Trough, intense hydrothermal activity occurs due to continental rifting. The hydrothermal system in the Iheya North Knoll has been explored by geophysical surveys, geochemical measurements and drilling campaign. Based on these surveys, gas reservoir could be considered to exist around the Iheya North Knoll. However, gas reservoir around the Iheya North Knoll has not been identified in previous studies. Here we show P-wave velocity structure derived from automatic velocity analysis of multi-channel seismic reflection data. P-wave velocity is sensitive to free gas in sediments. Therefore, P-wave velocity is key information to quantify gas distribution in sediments. Automatic velocity analysis estimated P-wave velocity structure with remarkable high spatial and temporal resolution. The P-wave velocity structure revealed gas reservoirs around the Iheya North Knoll. Although many gas components can be generated by magmatic activity, hydrothermal alteration of organic-rich sediments and biogenic processes, CH_4 and CO_2 could be major gas components which is derived by hydrothermal system in marine sediment. Therefore, main gas components could be CH_4 or CO_2. The strong amplitude reflector above the gas reservoir could be the interface between CH_4 hydrate and gas, because the depth of strong amplitude reflector is well consistent with pressure-temperature conditions of the phase transition. If the main gas component is CH_4, the gas reservoir could be important as resource. Whereas, if the gas reservoir includes CO_2, the gas distribution could be important to consider carbon flux between earth and ocean. Furthermore, widely distributed gas reservoir may influence on the chemical components of hydrothermal fluids in the Iheya North Knoll.

Characterize coseismic deformation of Mw 7.5 Palu earthquake in a triple junction in Sulawesi, Indonesia

*MIN-CHIEN TSAI[1], Ying-Hui Yang[2], Chun-Ying Chiu[3], Jyr-Ching Hu[3]

1. Seismological center, Central Weather Bureau, Taipei, Taiwan, R.O.C., 2. School of Civil Engineering and Architecture, Southwest Petroleum University, Chengdu, China, 3. Department of Geosciences, National Taiwan University, Taipei, Taiwan, R.O.C.

We first use SAR satellite data to map the coseismic deformation for the 2018 Mw=7.5 strike-slip earthquake of 28 September 2018 in Palu, Sulawesi, Indonesia. The seismogenic fault is a left-lateral a strike-slip event along the Palu-Koro fault at shallow depth that occurred within the interior of the Molucca Sea microplate, which is part of the Sunda plate. We use D-InSAR technique with ALOS-2 descending orbit radar images to characterize coseismic and deformation pattern induced by Palu earthquake.We also plan to use with sub-pixel correlation form Sentinel-2 and Planet imagery to map the surface rupture area and the coseismic offsets in order to provide the near-field deformation data located in decorrelation zone from the D-InSAR result. Thus we can inverse the distribution of slip on the fault patches. In addition, we also calculate the Coulomb stress transfer for assessing the stress increasing and shadow on the major fault systems, such as the active Poso Fault Zone and Mamuju –Lariang Active Fault Zone. In particular, we will assess the seismic potential by Coulomb stress transfer in Minahasa Active Subduction Zone together with two events with Mw 7.9 and Mw 7.0 happened on 1996/01/01 and 1996/07/22. We try to assess the seismogenic potential in terms of interseismic slip rate, slip rate deficit and coupling ratio for the Palu-Koro fault system in a triple junction of the Sulawesi island.

How to solve controversies in Cenozoic tectonics in western Pacific margin

*Gaku Kimura[1]

1. Tokyo University of Marine Science and Technology

Tectonics and their geodynamic backgrounds are difficult theme and keep controversial. Cenozoic tectonics in the western Pacific margin are of them. 1) Oceanic ridge subduction, 2) Back-arc spreading, 3) interaction between the Philippine Sea Plate and SW Japan, 4) collision and bending of the Japanese islands, 5) onset of present tectonic and dynamic frameworks, and 6) dynamic background of the earthquakes and volcanic eruption are key events but controversial.

To solve these controversies, a classic geological philosophy of “uniformitarianism” is significant. It means “the present is the key to the past”.

1. To solve the controversy of the Izanagi-Pacific Ridge subduction in early Cenozoic, a comparative study with modern examples of the ridge subduction at the Chile triple junction, Woodlrack Basin and Middle America trench with a new data set and simlation is a key.
2. To solve the back arc spreading controversy of Kuril and Japan Basins and Okinawa Trough, the promotion of International collaboration to acquire a new data set is necessary together with a comparative study among the modern backarc spreading. A classic controversy of double door opening vs pull-apart spreading will be progressed by comparison with progressed modern examples. A large scale perspective beyond the back-arc basins themselves is also necessary for geodynamic solution for the back-arc spreading.
3. To solve the controversy of the interaction between the Philippine Sea Plate and SW Japan; switch from the Pacific plate to Philippine Sea Plate at ~15Ma vs ~12Ma- 6Ma, detailed tomographic study with new perspectives and data sets from on-and geology and geophysics is necessary with simulation.
4. To solve the controversy of the collision and bending of the Japanese islands, not only the geological data set but more comprehensive data set of geophysics and geochemistry with simulation are necessary. Differentiation between the hypothesis and fact promotes a constructive controversy. In geology, data reliability and re-productablity is the most significance part of science.
5. To solve the controversy of onset of present tectonic and dynamic frameworks is the most essential part of “uniformitarianism”. The definition of “present” depends on the scientific field even in geoscience, Seismological “present” is a moment to minutes, days and month scale, That of geodesy is ~10s to 100 years. Geomorphology combined with geology is 100s to 10^4 scale. That of most geology is beyond 10^4 scale. Establishment of seamless “uniformitarianism” with seamless space perspective is a key to understand this controversy.
6. To solve dynamic background of the earthquakes and volcanic eruption, I like to emphasize the viewpoint of evolving effect of hysteresis. A final trigger of earthquakes and volcanic eruption is no doubt of physical consequence resulted from long and short term hysteresis.

Plio-Pleistocene plate interactions associated the Philippine Sea Plate

*Timothy B Byrne[1], Gaku Kimura[3], Jonny Wu[2]

1. University of Connecticut, 2. University of Houston, 3. Tokyo University of Science and Technology

Geologists have long recognized the possible significance of a change in motion of the Philippine Sea Plate (PSP) in the middle to late Cenozoic (Huchon, 1983; Seno and Maruyama, 1984), although the detailed timing and kinematics have remained elusive. The most recent reconstructions suggest a ~50° counterclockwise rotation of the plate motion vector relative to Eurasia possibly as recently as 2 Ma (Wu et al., 2015), which would have significant implications for the tectonics of east-central Asia. In southern Japan, for example, CCW rotation of the plate motion vector predicts a change from generally orthogonal plate convergence to the present NW-directed and oblique motion. In Taiwan, in contrast, plate convergence obliquity would decrease significantly. To better understand and possibly better constrain the geometry, kinematics and timing of this change in motion, we review the geologic histories of different geologic units and terranes along the boundary of the PSP, including: the Okinawa Trough, Kyushu and Shikoku Islands, Kumano Basin, Boso and Miura Peninsulas, the southern Marianas, the Philippines and Taiwan. Several areas in southern Japan also appear to provide critical constraints on the kinematics and timing of a possible change in motion. For example, geological and geophysical studies of the accretionary prism in SW Japan show a transition from shortening perpendicular to the plate boundary to extension perpendicular to the boundary <1.0 Ma (Gulick et al., 2010, and Sacks et al., 2013). Although these authors suggest that this change reflects changes in subduction zone dynamics, we propose that the change to extension relates to the decrease in the rate of convergence across the prism as the plate motion changed from nearly orthogonal to more oblique at ~1.0 Ma. Hayman et al. (2012) also documented a CCW rotation in the shortening direction deep in the Nankai accretionary prism just south of Shikoku Island, although the timing of this rotation was only constrained to be younger than ~5 Ma (the age of the youngest deformed sediments). In the eastern Nankai, Yamaji et al. (2003) interpreted a similar suite of faults to be related to a similar change in plate motion at ~1 Ma. Further landward, studies of the Median Tectonic Line on Shikoku Island document a change from thrusting to right-lateral strike-slip faulting at about ~0.8 Ma (Mizuno, 1999; Sato et al., 2015). This change in kinematics and timing is consistent with previous ideas on the age of formation of the Nankai forearc sliver (~0.8 Ma) based primarily on geologic and geomorphic data from Shikoku Island (Ohmori, 1978; Saito, 1999; Okamura, 1990). Finally, in Taiwan, Hsu et al. (2016) have proposed an acceleration in rock uplift at ~0.8 Ma based on low-temperature thermochronology data that may reflect an acceleration in plate convergence related to changing plate motions. Taken together, these observations suggest that a significant change in the plate motion vector (i.e., CCW rotation) occurred relatively recently and probably < 1 Ma.

A regional mylonite zone between the Mesozoic metamorphic basement and the subducted Miocene covered schists in eastern Range of Taiwan: A possible Plio-Pleistocene transform fault between Eurasia and the Philippine Sea plate

*Gong-Ruei Ho[1], Jian-Cheng Lee[1], Timothy B Byrne[2], En-Chao Yeh[3]

1. Institute of Earth Sciences, Academia Sinica, 2. Department of Geography, University of Connecticut, 3. Department of Earth Sciences, National Taiwan Normal University

As one of the youngest orogenic belts, Taiwan offers insights into mountain building processes operating from the Earth’ s surface. In the eastern Central Range of the Taiwan mountain belt, the Tananao metamorphic belt, comprising the Tailuko Belt, high temperature/low pressure Mesozoic basement, was attached by the Yuli belt, a Miocene pelitic quartz-mica schist with high-pressure exotic mafic to ultra-mafic blocks (Yen, 1960; Tsai et al., 2013). Observations of meso- and microscopic structures show predominant asymmetric folds with top-to-east S2/S3 on the eastern Yuli belt and isoclinal folds with west dipping S2 on the western Tailuko belt. In the boundary between these two geological rock units, we observed a mylonite zone distributed about 2 kilometers wide, which has been called the Shoufeng Fault, which indicated sinistral sense of shear and shallow stretching lineation within the mylonite zone. The structural style of other area is relatively irregular and disordered (Stanley et al., 1981; Lu and Wang Lee, 1986; Pulver et al., 2002; Ho, 2007; Liao, 2011; Ji, 2011). This pattern was found from north to south in a distance of 100 km along the Yuli belt along the Mugua, Shoufeng, Wanliqiao, and Chinshui Rivers to the Southern Cross island highway and the Dawushan map (Usami, 1940). The above observations pointed out an apparently down-dip folding coupled with a dominant orogen-parallel lineation pattern around the Shoufeng mylonite zone between the Miocene Yuli belt and the Mesozoic Tananao complex. It provides structural constraints on the deformation associated with ductile metamorphism of the high-pressure Yuli belt terrane while attached against the much older continental crust of the Tananao complex as well as during the subsequent rapid exhumation processes.

Coeval exhumation or subduction channel extrusion of the high pressure Yuli belt? Insights from the Shoufeng fault in eastern Taiwan

*Jian-Cheng Lee[1,5], Gong-Ruei Ho[1,5], Timothy B Byrne[2], Yuan Hsi Lee[3,5], En-Chao Yeh[4,5]

1. Academia Sinica, 2. Univerity of Connecticut, 3. National Chung Cheng University, 4. National Taiwan Normal University, 5. The Yuli Exhumation Study team (YES Team)

Based on field investigations, microscopic observations, and available geophysical, geochemical and geochronological data, this study intends to better understand the structural characteristics of the Eurasian continental margin (e.g., the eastern Central Range in Taiwan) during subduction and exhumation while the Philippine Sea plate has been approaching in the vicinity of Taiwan since the Miocene time. The eastern Central Range is composed of two major geological units: 1) the Tailuko belt, the Mesozoic metamorphic subduction complex, retro-metamorphosed in green schist facies and exhumed since late Miocene, and 2) the Yuli belt, continental margin rocks that contain high-pressure minerals (omphacite, glaucophane, garnet) with Miocene-Pliocene ages suggesting rapid exhumation from mantle depths of 40-50 km.

We conducted detailed field surveys around the Shoufeng fault which represents the boundary between the Tailuko belt and the Yuli belt. We found a mylonite zone of several kilometers wide in the boundary of these two belts. Based on the meso- and microscopic scale observations we define the boundary as ultra-mylonite, mylonite, and proto-mylonite zones. Within the ultra-mylonite and mylonite zones, rocks from two belts are intercalated each other in varied widths. The main dominant schistosity/cleavage in the mylonite zones (Sm/S3) remains the same orientation of striking in NE/NNE and dipping to the west. Also, the main composition layers, which we tentatively called S2 for the sake of field investigations, were more intensively deformed (i.e., crenulated, folded, etc.) from outside toward the core of the mylonite zones. As a result, the Sm/S3 becomes less persistent outside of the mylonite zones in the Yuli belt.
The mylonite zones exhibit left-lateral Sm/S3-related shearing without significant down-dip component. We also observed a general S2/S3-related top-to-west sense of shear across the two belts. As a consequence, we tend to interpret that the Yuli belt and the Tailuko belt have been mylonitically sheared (Sm/S3) in a left-lateral movement at the depth and that they exhumed coevally up to the surface level. The schistosity of the main composition layers S2 probably occurred before the mylonization during the transition from subduction to exhumation. The shallow dipping and less dominant S3 outside the mylonite zone might imply a upward and unroofing process during the rapid exhumation of the eastern Central Range of Taiwan.

Metamorphic temperature variation across the Yuli belt: a clue about exhumation of high-pressure rocks?

*Chin-Ho Tsai[1], Chih-Ying Yeh[1], Yui Kouketsu[2], Masaki Enami[3]

1. Department of Natural Resources & Environmental Studies, National Dong Hwa Univ., 2. Department of Earth & Planetary Sciences, Nagoya Univ., 3. Institute for Space-Earth Environmental Research, Nagoya Univ.

We applied Raman spectra of carbonaceous material (RSCM) geothermometer to estimate peak metamorphic temperatures of pelitic and psammitic schists across the Yuli belt, eastern Taiwan. The analyzed samples mainly consist of phengitic mica, quartz, chlorite, and albite, with accessory graphitic carbonaceous material, titanite, zircon, and tourmaline. In samples from the Juisui Schist and Chinshuichi Plantation units (both containing high-pressure allochthonous blocks), garnet, ilmenite, and paragonite may occur and albite tends to be porphyroblastic. Serpentinite and metabasite pods occur in these units, whereas the neighboring metasedimentary units lack such rocks and porphyroblastic phases. The yielded metamorphic temperatures reveal a systematic variation in spatial distribution across the Yuli belt. In the Wanjung and Juisui areas, peak temperatures of the four schist units are in the range of 430-510˚C, 410-470˚C, 560-620˚C and 420-450˚C, from west (structurally upper) to east (lower), respectively. In the Chinshuichi area, temperatures of the two units are in the range of 540-560˚C (structurally lower) and 400-450˚C (higher), whereas the temperatures of the low-grade Slate unit (Chulai Formation) bordering the Yuli belt in the east are 330-340˚C. The high-pressure Juisui Schist and Chinshuichi Plantation are apparently warmer than their neighboring units in each area, although boundaries of the units are poorly exposed or characterized. The spatial distribution of metamorphic temperatures requires a structural explanation. Possible interpretations include doming, extension, or extrusion, and the inferred structures and processes may shed new lights on the exhumation of high-pressure metamorphic rocks in the Yuli belt.

Thermal state, slab metamorphism and interface seismicity in Mariana based on 3-D modeling

*Yingfeng Ji[1,2,3], Shoichi Yoshioka[3,4]

1. Center of Excellence in Tibetan Plateau Earth Science, Chinese Academy of Sciences, 2. Key laboratory of continental collision and plateau uplift, Institute of Tibetan Plateau, Chinese Academy of Sciences, 3. Research Center for Urban Safety and Security, Kobe University, 4. Graduate School of Science, Kobe University

The Marina arc system represents a typical mode of intra-oceanic convergent boundary characterizing circum-Pacific subduction zones, together with the Izu-Bonin, Kuril and Tonga-Kermadec margins well known for the tectonically formed deep trenches. Active back-arc extension driven by hydrothermal mantle upwell comprises one of the significant features of Mariana caused by steep subduction. Previous studies document that the narrow subduction constrains the seismicity in Mariana to be less than M7. However, the subduction thermal regime remains still unclear in detail. Based on the 3-D thermal model constructed for Mariana, we found that the highly curved Mariana arc presenting such a particular tectonic setting caused by trench retreat produces a cold thermal structure beneath the central and northern Mariana influenced by an oblique subduction. The deep earthquakes (>100 km) are therefore frequently detected compared with the southern Mariana. The subducted Pacific plate entraining the oceanic crust components is calculated to obtain their pressure-temperature conditions for different petrological faces undergoing multiple phase transition including the paths from amphibolite to eclogite or harzburgite at a high temperature of >500 degrees in Celsius which is conjectured to facilitate the deep earthquakes at Mariana. The dewatered oceanic plate is expected to releases ample fluids for the backarc volcanism and hydrous circulation at Mariana mantle wedge. The 3-D temperature structure of Mariana obtained in this study sheds lights on regional earthquake genesis and slab metamorphism in such an intro-oceanic subduction system featured by deep events.

[S-IT26] New perspectives on the geodynamics of East Asia

convener:Timothy B Byrne(University of Connecticut), Asuka Yamaguchi(Atomosphere and Ocean Research Institute, The University of Tokyo), Jonny Wu(University of Houston), Kyoko Okino(Atmosphere and Ocean Research Institute, The University of Tokyo), Chairperson:Asuka Yamaguchi(Atomosphere and Ocean Research Institute, The University of Tokyo), Tim Byrne

The Pacific, Indo-Australia and Eurasian plates converge around the Philippine Sea plates in south and East Asia, resulting in one of the most tectonically active regions on earth. The area is also geologically and tectonically complex with numerous active tectonic environments, ranging from subduction to collision, and a long history of plate boundary interactions. The last decade has yielded a wide range of new observations, including detailed geologic data and high resolution crustal to mantle imaging. Here we seek oral and poster presentations that bear on the geologic history and geophysical character of modern and ancient plates in East Asia and their interactions since the Mesozoic. We also invite geodynamic models that integrate these diverse datasets into a more holistic view of this dynamic environment.

Contrasted plate tectonic reconstructions have been proposed for the northeast Asian margin during the late Cretaceous, including: an Andean-type subduction margin, the existence of marginal seas, the subduction of a spreading ridge, the subduction of remnant arcs, or continental block collision and continental subduction. Here we investigate which scenarios are consistent with tomography models by mapping and unsubducting the vanished western Pacific slabs along the Kurile-Kamchatka, Japan, and Izu-Bonin-Marianas trenches from global tomography models. We show that a mapped 4,000 km-long slab gap within the East Asian lower mantle is the tomographic signature of the subducted Izanagi-Pacific spreading ridge based on a comparison to global mantle flow models. We reconstruct the size of the lost Izanagi conjugate from the geometry of the unsubducted western Pacific slabs, the age of Pacific oceanic crust, and published synthetic seafloor isochrons.

Our tomography-based plate reconstruction implies that: (1) the Izanagi ocean basin crust (i.e. formed by Pacific MORB) first reached and subducted along Sikhote-Alin and northern Japan around ~100 Ma; (2) subduction of the Izanagi plate along northeast Asia during the late Cretaceous ~75 Ma was limited to north of southernmost Korea and Bohai Bay, China, and west of westernmost Alaska; and, (3) the Izanagi-Pacific ridge intersected with the northeast Asian margin at a low angle in the early Cenozoic. We discuss our plate model against proposed northeast Asian margin plate tectonics during the Cretaceous.

Geodynamic models of late Mesozoic intraoceanic subduction offshore NE Asia caused by growing Izanagi plate

*Lorenzo Colli[1], Jonny Wu[1], Yi-An Lin[1]

1. University of Houston

The existence of the Izanagi plate is well established both from magnetic lineations and fracture zones in the western Pacific and from tomographic imaging of the deep mantle underneath East Asia. But its spatial extent, position and motion through time remain poorly known.

A common scenario envisages the Izanagi as a large and long-lived plate extending from central Panthalassa to the eastern margin of Eurasia. In this scenario the Izanagi plate is conjugate to the Farallon and Phoenix plates before the inception of the Pacific plate and it subducts continuously beneath East Asia during the Mesozoic (e.g. Müller et al., 2016).

A conservative choice for the spatial and temporal extent of the Izanagi plate, limiting it to what can be extrapolated using the conjugate Pacific plate, leads to a very different scenario: in this case the Izanagi plate is born together with the Pacific plate around 190 Ma and grows triangular in shape. It overrides preexisting oceanic lithosphere causing extended intraoceanic subduction in western Panthalassa characterized by fast trench retreat towards the Eurasian margin. The tip of the Izanagi plate reaches the Eurasian continental margin near Japan and Sikhote-Alin around 100 Ma.

Here we assimilate these two scenarios in geodynamic models of global mantle convection in the form of time-dependent velocity boundary condition at the Earth’ s surface. Their implications for the evolution of mantle structure in East Asia during Mesozoic time up to present-day are presented and discussed.

Early Cretaceous to Paleocene magmatism in the Sikhote-Alin area and their implications for Paleo-Pacific plate subduction and continental evolution

*Tsung-Jui Wu[1], Jonny Wu[1], Igor Alexandrov[2], Thomas Lapen[1]

1. Department of Earth and Atmospheric sciences, University of Houston, Houston, U.S., 2. Far East Geological Institute, Russian Academy of Sciences, Vladivostok, Russia

The Sikhote-Alin area in southern Russian Far East is one of the few places in the East Asian margin that has extensively exposed Mesozoic geological units. In particular, Cretaceous to Cenozoic igneous rocks are abundant and formed in response to periodic subduction of Paleo-Pacific plates. Previous geochemical studies of igneous rocks, mainly from southern Sikhote-Alin, resulted in significant insights into the continental evolution of East Aisan margin and subduction history of Paleo-Pacific plates (Kruk et al., 2014; Jahn et al., 2015; Grebennikov et al., 2016). In this study, we present new zircon U-Pb chronology and geochemical data from ~50 samples in across the entire Sikhote-Alin area. We combine our new results with published data to discuss the history of arc magmatic evolution in the region.

In general, the data show a cycle of arc magmatism that started from the early Cretaceous to Paleocene in Sikhote-Alin. Zircon U-Pb geochronology of igneous rocks indicate a major population of granitoids that had ages of 135-57 Ma; a small population of volcaniclastic rocks were dated at 55-53 Ma. Three magmatic episodes with distinct geochemical characteristics were recognized: 135-120 Ma, 110-100 Ma and 100-57 Ma. The 135-120 Ma granitoids are dominated by S-type granites; zircons with inherited cores were frequently observed in this episode. The 110-100 Ma episode has mostly I-type granites, whereas the 100-57 Ma magmatism had I-type granites that show greater degrees at fractional crystallization than the other groups. Some magmatic rocks with 67-57 Ma and ~100 Ma were A2 type granites, suggesting that two periods of intraplate magmatism could had occurred within this subduction setting. The La/Yb ratio and Nd isotopic ratios of the granitoids remained relatively similar during the Cretaceous and even showed a La/Yb ratio decrease in the late Cretaceous, implying that the Andean subduction margin crustal thickening model (Haschke et al., 2002) may not applicable to the Sikhote-Alin area.

Processes of subduction initiation revealed by P-T paths of amphibolite and blueschist tectonic blocks in serpentinite mélange: An example from the Kamuikotan high-P/T metamorphic rocks in Hokkaido, northern Japan

*Toru Takeshita[1], Ayumi S. Okamoto, Wonji Shin[1], Mizuho Ando[1]

1. Department of Natural History Sciences, Graduate School of Science, Hokkaido University

It has been recently noted that serpentinite mélange which contains tectonic blocks of high-*P/T* type metamorphic rocks such as blueschist and eclogite and their counterclockwise P-T paths could indicate the subduction initiation (e.g. Willner et al., 2004; Escuder-Viruete et al., 2011; Agard et al., 2016; Bhowmik and Ao, 2016; Hunziker et al., 2017). We investigated tectonics in amphibolite and blueschist tectonic blocks in mélange, which are distributed at the highest structural level of the high-*P/T* type Kamuikotan metamorphic rocks in Hokkaido, northern Japan. We reconstructed their individual pressure-temperature (*P-T*) paths based on petrography, mineral chemistry and phase equilibria modeling. As a result, tectonic blocks in this study area are divided into six rock types: garnet-epidote amphibolite, epidote amphibolite, amphibolite, plagioclase-poor amphibolite, blueschist and quartz-rich blueschist. From the reconstruction of *P-T* paths, it is found that most of the tectonic blocks experienced blueschist facies metamorphism probably at the maximum depth, while the initial paths vary from a counterclockwise *P-T* path shown by different kinds of amphibolite to a prograde *P-T* path shown by blueschist and quartz-rich blueschist. We have concluded that these *P-T* paths, on the whole, could have reflected the cooling history of subduction channel from the beginning to steady state of subduction. The geothermal gradient could have been changed from ~25 ˚C/km to ~10 ˚C/km within *c.* 25 myr estimated by previously reported radiometric ages. These tectonic blocks could have started to subduct at a different timing to show the different *P-T* paths, and juxtaposed against each other at a certain depth in the subduction channel. Since these tectonic blocks show little deformation structures formed during exhumation stage, they might have behaved as a rigid body in serpentinite (i.e. mélange matrix) after they were incorporated in it during subduction stage.

Metamorphism in the Sanbagawa belt of SW Japan as a record of subduction processes

*Simon Richard Wallis[1]

1. University of Tokyo

The Sanbagawa belt of SW Japan records Cretaceous suduction processes off the eastern Asian margin. The Sanbagawa belt can be traced for around 800 km throughout SW Japan, but the main exposure is found in Shikoku. The main constituent rock types are pelitic, quartz and mafic schists which were derived from the subducted oceanic slab. These are associated with widespread blocks and lenses of serpentinite and related rocks types derived from the mantle wedge.

A long running dispute about the age of peak metamorphism has recently been resolved. Evidence for an early stage of subduction associated at around 115 Ma is locally preserved with anticlockwise P-T paths. This is followed at around 90 Ma by the main been long disputed with estimates of the peak

Subduction and exhumation of the high pressure metamorphic rocks: What we know and what we need to know.

*Timothy B Byrne[1]

1. University of Connecticut

Although great strides have been made in understanding the subduction and, to a lesser extent the exhumation, of high pressure rocks, the links between these two processes is much less clear. As a result, many of the regional-scale models of these processes are poorly constrained and weakly supported by data. In this discussion session, we would like to better understand the data and observations that provide evidence for exhumation of high pressure rocks and, in areas were data gaps remain, what data are necessary to advance our understanding.

Argon release mechanism of deformed phengite

*Tetsumaru Itaya[1]

1. Engineering Geology Center, Hiruzen Institute for Geology and Chronology

The author has proposed the argon release from phengites in HP-UHP metamorphic rocks by their ductile deformation in the exhumation and cooling of the metamorphic sequences to explain the relationships between K-Ar phengite ages and the metamorphic grade since Itaya and Takasugi (1988). This argon release hypothesis has not been accepted for 20 years until Nuong et al. (2008) described the age (K-Ar phengite)-temperature-structure relations in the Ishigaki high-pressure schist belt, southern Ryukyu Arc, Japan. Its main reason would be that the argon release mechanism is vague. Recently, the author made its mechanism clear in the literature that is in submission to journal. This paper will focus on the argon release mechanism of deformed phengites.

Cosca et al. (2011) described the effect of deformation on radiogenic argon retentivity from high pressure experiments (10kb and 600 ˚C over a period of 29 hours, giving ca. 10% shortening) performed on rock samples of peraluminous granite containing euhedral muscovite and biotite. Intragrain in-situ $^{40}Ar/^{39}Ar$ analyses for deformed muscovite provided 309 to 264 Ma, consistent with 0-16 % argon loss relative to the undeformed muscovite (311 Ma). They interpreted that the reduction in the effective diffusion length scale in naturally deformed rocks occurs most probably through productions of mesoscopic and submicroscopic defects such as stacking faults. The extreme size reduction of phengite observed at domains close to the rigid garnet in pelitic schists of the Sanbagawa belt are identical to the reduction in the effective diffusion length scale described by Cosca et al. (2011), likely enhancing the argon release. The Sanbagawa pelitic schists suffered extremely long deformation (longer than 31 million years) during the exhumation and had the extremely slow exhumation rate (slower than 0.7 mm/y). In this case, the phengite could grow up with “Ostwald ripening phenomenon” consuming the extremely fine-grained phengite close to the rigid garnet. The size reduction and “Ostwald ripening” growth would continue to become final stage of static phengite crystal size (0.02-0.06 mm in width and 0.4-1.0 mm in length) observed in matrix. During these processes phengite could experience chemical change depending on local bulk chemistry under the P/T conditions changing from moment to moment during the exhumation, making heterogeneous chemistry. On the other hand, Lago di Cignana UHP unit in western Alps suffered relatively quick deformation (shorter than 5 million years) during the exhumation and had the extremely fast exhumation rate (15 - 26 mm/y). In this case, the phengite crystals could record heterogeneously deformed domains in a crystal as well as among the grains, resulting in heterogeneous argon release. In fact, the laser step heating $^{40}Ar/^{39}Ar$ analyses of single phengite crystal in the UHP schists of Lago di Cignana provided significantly irregular age spectrum in comparison with the phengite from the Sanbagawa schists of which the age spectra show the perfect plateau for both the phengite separates and a phengite crystal.

A muscovite in metagranitoid from Grand Paradiso Massif in western Alps yielded heterogeneous age values, giving 54 to 218 Ma (Beltrando et al., 2013). The dated points by the crystal edge are significantly younger than the ages in the part far from the edge. These features suggest that the submicrosopic defects occurring preferentially near the crystal edges are affected by the rubbing with other phases, enhancing preferentially the argon release.

Detrital zircons from a traverse along the Asemi River (Sanbagawa Metamorphic Belt, Shikoku, Japan): U-Pb geochronology and Hf isotopic composition

*Ulrich Knittel[1], Shigeyuki Suzuki[2], Monika Walia[3], Juan-Hsi Lee[4], Hao-Yang Lee[5]

1. RWTH Aachen University, 2. Okayama University, 3. Nat. Taiwan University , 4. Chung Cheng University, 5. Academia Sinica

Sanbagawa Belt is a classic high-P/low-T metamorphic belt that is exposed over a distance of about 1000 km on Kyushu, Shikoku and Honshu Islands in Japan. The age of this belt has been the focus of many studies in recent years since the discovery of young detrital zircon grains (80 - 95 Ma), younger than the presumed age of peak metamorphism.

Samples for this study come from a traverse along the Asemi River in central Shikoku. Dating of single zircon grains using the LA–ICP–MS U–Pb dating method shows that zircons from all sites investigated are younger than 90 Ma and thus the protoliths are younger than the previously accepted age of metamorphism for this part of the Sanbagawa Belt at ca. 116 Ma. Our sampling sites include the site sampled by Minamishin et al. (1979) which is the reference for metamorphism at ca. 116 Ma in this part of the belt. We therefore conclude that the linear arrays found by Minamishin et al. are mixing lines rather than isochrones. Another sample was taken within the area recently delineated as having experienced eclogite facies metamorphism prior to overprinting in the epidote-amphibolite facies(Taguchi et al., 2018). This implies that the eclogite facies metamorphim took place after 90 Ma, the maximum deposition age of the protolith.

Within the detrital zircon populations contained in the Sanbagawa meta-sediments several age groups are recognized that are also known from SE China. However, compared to those from mainland China, zircons from the Sanbagawa meta-sediments are usually characterized by higher eHf(T) values suggesting higher input of material derived from the depleted mantle. For example, eHf(T) values of zircons of the age group 82-116 Ma range from -2.4 to +9.6 and those of the 127–146 Ma group have altogether positive eHf(T) values of +11.5 to +19.0 indicating depleted mantle sources. We envisage these zircons to have been derived from the ocean side of a magmatic arc. All grains in the range 215-250 Ma are characterized by negative eHf(T) ranging from -2.3 to -15.2, suggesting re-melting of already existing crust.

Tectonic process of the Sanbagawa eclogite: zircon U–Pb and REE composition analyses

*Shogo Aoki[1], Kazumasa Aoki[2], Tatsuki Tsujimori[3], Yuta Tsuchiya[1], Daichi Kato[2]

1. Department of Biosphere-Geosphere Science, Okayama University of Science, 2. Department of Applied Science, Okayama University of Science, 3. Center for Northeast Asian Studies, Tohoku University

High-pressure and low-temperature (HP) metamorphic rocks in the Pacific-type orogeny are relicts of deeply-subducted accretionary prisms along the past subduction zones. The geochronological data of the HP rocks provide us with the time-scale information involved in material cycle from surface to deep mantle.
The Sanbagawa metamorphic belt in SW Japan is one of well-studied HP metamorphic belts in the world. However, the timing of the prograde metamorphism, especially of the eclogite-facies metamorphism has been controversial (e.g. Okamoto et al., 2004; Wallis et al., 2009).In order to solve this issue, we applied in-situ zircon U–Pb age and rare earth element (REE) composition analyses to the Sanbagawa eclogite in central Shikoku.
Igneous core and metamorphic rim domains of the separated zircons can be recognized, based on their cathodoluminescence images and Th/U ratios. The U–Pb datings of those domains clearly show existence of two different metamorphic units in the Sanbagawa metamorphic belt; i.e., one is ca. 120-100 Ma older metamorphic unit and the other is ca. 90 Ma younger one. Chondrite-normalized REE patterns obtained from the metamorphic rims in both units show no Eu anomaly and HREE depletion. These characteristics suggest that each unit suffered the eclogite-facies metamorphism at ca. 120-100 Ma and ca. 90 Ma, respectively.
Our new data combined with the mode of occurrence of the Sanbagawa eclogite in Shikoku are suggestive of the following tectonic scenario:
1. The highest-grade part of the older unit was subducted to the depth over 15 kbar at ca. 120 Ma, and stagnated there until ca. 90Ma.
2. The highest-grade part of the younger unit underwent the eclogite-facies metamorphism at ca. 90 Ma, and was juxtaposed with the eclogite of the older unit at the depth.
3. Both units were exhumed at the same time after the juxtaposition.

Petrological implications of a new occurrence of retrogressed eclogite from the Sanbagawa belt of southwest Japan

*Tomoki Taguchi[1], Shunsuke Endo[2], Yohei Igami[1,3], Akira Miyake[1]

1. Graduate School of Science, Kyoto University, 2. Interdisciplinary Faculty of Science and Engineering, Shimane University, 3. Institute of Materials and Systems for Sustainability, Nagoya University

The Sanbagawa belt is one of the most famous subduction-related high-pressure (HP) metamorphic belts in the world, and the metamorphic facies series of the belt reaches the eclogite facies. Sanbagawa eclogites are found within coarse-grained mafic-ultramafic masses (Iratsu type) and their surrounding fine-grained mafic, pelitic, and siliceous schists (Seba type) in central and eastern Shikoku, southwest, Japan (Aoya & Endo, 2017 JGSJ). However, the regional extent of the eclogite facies region (eclogite unit) has not yet been established because most were overprinted by lower-pressure assemblages during the exhumation stage. In order to document the eclogite facies metamorphic features of the belt, we recently conducted comprehensive petrological studies of the pelitic schists in the Asemi-gawa region of central Shikoku (Taguchi & Enami, 2014a, 2014b JMPS; Taguchi et al., 2019 JMG). Our previous studies have revealed that a new eclogite unit exists in a limited high-grade area of this region and is composed primarily of pelitic schists. A number of petrological studies have been conducted on the mafic lithology of this region (e.g. Otsuki & Banno, 1990 JMG; Aoki et al. 2009 Lithos; Uno et al., 2015 CMP). However, none of these works recognize the presence of a definitive eclogitic indicator (omphacite, jadeite) within the mafic lithologies, which contrasts with the other eclogite units of Shikoku. This hinders the reliable reconstruction of the extent of the eclogite facies metamorphism in the Sanbagawa belt. Based on an integrated petrological and mineralogical approach, this study reports that mafic schist with garnet + omphacite + quartz paragenesis was first discovered in the Asemi-gawa region. The mafic schist occurs as thin layers within pelitic schist of the albite–biotite zone. This rock includes abundant garnet porphyroblasts up to 5 mm in diameter and shows prograde-type compositional zoning with no textural or compositional break. Omphacite in the mafic schist only occurs as inclusions in garnet, and albite is the major Na phase in the matrix, suggesting that the mafic schist represents highly retrogressed eclogite. The omphacite in the sample displays a strong Raman peak at 678 cm^{-1}, and concomitant Raman peaks are all consistent with those of the reference omphacite Raman spectrum. Transmission electron microscopy (TEM) observations showed that the selected area electron diffraction pattern of the omphacite is compatible with the common $P2/n$ omphacite structure. The combination of Raman geothermobarometries and conventional thermodynamic calculations gives peak (pressure–temperature) P–T conditions of 1.7–2.0 GPa and 440–540 ˚C for the mafic schist. The peak P–T values are comparable to those of the schistose eclogitic rocks (Seba type) in other Sanbagawa eclogite units of Shikoku. These findings suggest that most of the schistose eclogites and associated metasedimentary rocks along the Sanbagawa subduction zone probably share similar simple P–T histories.

P-T estimations of Kashio mylonite in Oshika, Nagano, Japan: Constraints on the amalgamation of Ryoke and Sambagawa belts

*Yoshihiro Nakamura[1], Yutaka Takahasi[1], Tohru Danhara[2], Hideki Iwano[2], Takehumi Hirata[3]

Sambagawa (*LTHP*-type) and Ryoke (*HTLP*-type) metamorphic belts are classically termed as a “paired metamorphic belt” and closely related to the island arc magmatism and regional metamorphism in subduction zone (e.g., Brown, 2010). Although almost all Ryoke metamorphic belt in SW Japan are not directly in contact with Sambagawa metamorphic belt, Oshika area in Nagano prefecture, Japan, is one of the few examples of the geological field where can be directly observed the amalgamation of Ryoke and Sambagawa belts along the Median Tectonic Line (MTL). Hence, it is the best place for discussing the relationship between metamorphism and deformation related to the tectonic evolution of MTL. Our detailed investigations of both metamorphic rocks lead to be constraints on the exhumation tectonics of *HPLT*-type metamorphic rocks and tectonic evolution from ductile to brittle deformations in subduction zone.

In this area, it is well known that the medium-*T* mylonite (so called “Kashio mylonite”) is widely exposed along the MTL (Takagi, 1986). We newly found that the low-*T* mylonites, as indicated by the Z-maximum *c*-axis lattice preferred orientations (LPOs) of recrystallized quartz, were also distributed. Both Ryoke and Sambagawa metamorphic rocks were deformed by low-*T* mylonitization within ~500m of the MTL. The mineral stretching with a gentle plunge to the NNE or SSW, suggesting the sinistral shearing, are well developed on the mylonite foliation. In the low-*T* mylonite zone, garnet porphyroclasts showed a significant chemical zoning of the grossular (X_{Grs}) from core to rim. The mylonite foliation was composed of white mica (Si in apfu = 3.38-3.49) and chlorite (X_{Mg} = 0.39-0.41). Based on the chemical analyses of recrystallized minerals, we attempted to apply the geothermometry and barometry. The *P-T* conditions of the low-*T* mylonites were estimated at 420~450 ˚C /0.5-0.6 GPa. A part of the Ryoke pelitic gneiss origin mylonites was estimated at ~540 ˚C /0.9 GPa. These *P-T* conditions of the mylonites are consistent of peak *P-T* conditions during Sambagawa metamorphism (e.g., Enami et al., 1994), suggesting the amalgamation of Ryoke and Sambagawa metamorphic belt during mylonitization.

In addition, U-Pb ages of zircons in the Kashio mylonite of Ryoke metamorphic belt were analysed by LA-ICPMS. The prominent age spectra of the mylonite showed 69.0 +/- 0.6 Ma (*n*=10), suggesting the solidification age of host Ryoke granite. Our data on protolith demonstrate a younger age than previously reported ages during mylonitization (>83 Ma, Kubota and Takeshita, 2008; or 95~85 Ma, Takagi, 1997). This suggests that the host Ryoke granite and Sambagawa metamorphic rocks were deformed by low-*T* mylonitization during 58-69 Ma. After the mylonitization and amalgamation of both metamorphic rocks, the exhumation of Ryoke and Sambagawa belts might be occurred owing to the change in plate motion at around 55 Ma (Seton et al. 2015).

Static phenomena retained by garnet during exhumation of metamorphic rocks

*Masaki Enami[1], Yui Kouketsu[2]

1. Institute for Space–Earth Environmental Research, Nagoya University, 2. Nagoya University

Electron back scatter diffraction (EBSD) method was employed for the analysis of crystallographic orientations of garnet grains to discuss tectonic behavior of various types of metamorphic rocks during exhumation. Selected metamorphic rocks were coesite-eclogite from the Sulu belt, China, granulite in the Mogok belt, Myanmar, and epidote-amphibolite and quartz schist of eclogite and non-eclogite units, respectively, in the Sanbagawa belt, Japan. The garnet grains are grouped into segmentation and honeycomb types. The segments forming an aggregate, which formed by hydration reaction during the exhumation stage, share similar crystallographic orientations, with misorientations of less than 3—4°. This suggests that the segmentation textures were not formed by deformational crush and the grains recorded a static environment during exhumation. The Sulu and Mogok garnet grains segmented under granulite-upper amphibolite facies conditions have been continually exhumed to the earth's surface without incurring specific deformation and/or rotation. The garnet grains in the epidote-amphibolite from the Sanbagawa eclogite unit were once fragmented by hydration reactions during exhumation and have subsequently become unified by hydration reactions during prograde epidote-amphibolite facies metamorphism. This fact indicates that the Sanbagawa garnet grains in the eclogite unit have recorded static conditions during the hydration and dehydration stages. Honeycomb garnet in a quartz schist from the Sanbagawa non-eclogite unit, which formed during prograde stage under the lower epidote-amphibolite facies, also shows no evidence suggesting deformation processes. This sample might not have undergone significant deformation during exhumation from depths of 25—30 km (0.8—0.9 GPa) to the earth's surface. Such undeformed phenomena recorded in these metamorphic garnet grains during exhumation might have been promoted by episodic exhumation, buoyancy-driven and static exhumation of the metamorphic belt, or local concentration of tectonic stress and heterogeneities of deformation impacts caused by the contrast of lithologic competency and tectonic discontinuity development.

Garnet zoning suggesting the correlation between the Higo and Abukuma metamorphic rocks

*Tadao Nishiyama[1], Yuto Wakida[1]

1. Department of Earth and Environmental Sciences, School of Science, Graduate School of Science and Technology, Kumamoto University

The Higo and Abukuma metamorphic rocks are both Cretaceous low P/T metamorphic rocks, located in central Kyushu (the former) and in northeast Japan (the latter), respectively. The correlation between the two metamorphic rocks has been discussed in terms of SHRIMP U-Pb ages of plutonism, metamorphism and sedimentation (Sakashima et al., 2003), although they are separated by more than 1,000 km. This paper presents new evidence for this hypothesis by reporting garnet zoning in the Higo metamorphic rock (HMR) which is very similar to that in the Abukuma metamorphic rock (AMR).

Pelitic and psammitic gneisses in the garnet-cordierite zone in the HMR contains commonly garnet crystals, which are subhedral to euhedral grains of several millimeters in size. We examined chemical zoning of these garnets from 41 samples of pelitic gneiss in the Kousadake area, Kousa and Tomochi Towns, Kumamoto Prefecture. Typical mineral assemblage of the pelitic gneiss is garnet + biotite + K-spar + plagioclase + quartz ± cordierite ± sillimanite. Ilmenite, titanite, and rutile (less common) occur as inclusions in garnet. Garnet zoning can be classified into three types: flat, simple and complex types. The flat type shows no concentration gradient of any component from the core to the rim. The composition ranges from Prp9Alm68Sps3Grs20 to Prp20Alm73Sps3Grs4, depending on the bulk composition of the sample. The simple type shows a gradual change in composition from the core richer in Sps and Grs components (Prp15Alm51Sps26Grs8) to the rim richer in Alm component (Prp15Alm61Sps19Grs3). The complex type has several variations in the zoning, however, all the variations show discontinuous or rapid changes in composition. The complex A type consists of the plateau-like core richer in Sps and Grs components (Prp2Alm36Sps33Grs29) and the rim richer in Alm and Prp components (Prp23Alm67Sps7Grs3). The complex B type shows a core-mantle-rim structure. The core is nearly constant composition with Prp6Alm61Sps14Grs19, followed by a rapid increment of Grs component up to 28 mol % associated with counterpart decrement of Alm and Sps components in the mantle (Prp6Alm58Sps8Grs28). In the rim, Grs and Sps components gradually decrease with counterpart increment of Prp and Alm components to Prp12Alm73Sps5Grs10. The Grs contents in the core of the complex A type and also in the mantle of the complex B type are much higher than those of the simple and flat types, indicating higher pressure condition for the formation. Garnets with these three types of zoning occur randomly in the garnet-cordierite zone of the studied area, suggesting the different nucleation timing of these garnets rather than diffusive homogenization of zoning in higher grade rocks (Yoshimura,1995).

The complex A and B types of zoning are quite similar to those of sector-zoned garnets from the AMR reported by Hiroi et al. (1998), who suggested the followings. These zonings may indicate three stages of garnet growth at different pressures: the earliest stage characterized by relatively low T (~650 C) and medium P (~0.6 GPa), the second stage with much higher pressure up to 1.2 GPa, and the third stage with higher T (~800 C) and lower P (~0.5 GPa). Thus, the HMR may have experienced the P-T path similar to that of the AMR. This similarity of the P-T path together with the consistency of the age of plutonism, metamorphism and sedimentation (Sakashima et a., 2003) strongly suggests that the HMR and AMR may have formed the same geological terrane. The tectonics leading to the large-sale displacement between

©2019. Japan Geoscience Union. All Right Reserved.

the HMR and AMR can be either a nappe tectonics or strike-slip tectonics, although this study cannot provide any information on the tectonics.

$FeAlO_3$ phase at ultrahigh-temperature metamorphic conditions: Evidences from the sillimanite—Fe_2O_3 and sillimanite—Fe_3O_4 systems at 9 kbar and 1050 ℃

*Toshisuke Kawasaki[1], Tatsuro Adachi[2], Hiroaki Ohfuji[1], Yasuhito Osanai[2]

1. Ehime University, 2. Kyushu University

Two high pressure experiments at 9 kbar and 1050 ℃ under moisture condition reveal $FeAlO_3$ phase is stable under ultrahigh-temperature metamorphic conditions. $FeAlO_3$ and corundum newly crystallised accompanying SiO_2-rich melt and vapour among sillimanite crystals from the mixture of Rundvågshetta sillimanite and reagent-grade Fe_2O_3 (weight ratio of 95:5) within Pt capsule. We found no hematite in the charge. In contrast, we found $FeAlO_3$ phase, SiO_2-rich melt and vapour among sillimanite from the mixture of Rundvågshetta sillimanite and reagent-grade Fe_3O_4 at (weight ratio of 86:14) within AuPd capsule. We found a domain composed by $FeAlO_3$, corundum, magnetite—hercynite spinel and ulvöspinel at the bottom part of the charge. The domain was contact with melt among sillimanite. The present results suggest the possibility that $FeAlO_3$ phase would be an index mineral of ultrahigh-temperature metamorphism for the partially melted Fe—Al-rich granulites under hydrous and oxidised environments.

Keywords: FeAlO3 phase, sillimanite, corundum, spinel, ultrahigh-temperature granulies

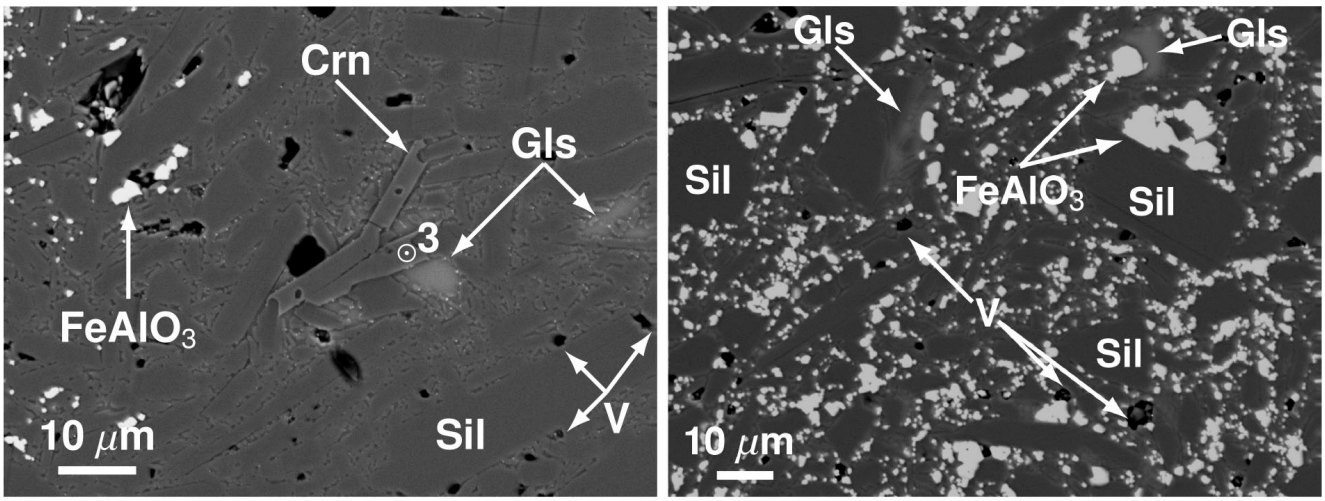

Fig. 1. Backscattered electron image (BSEI) of run products recrystallised from the mixture of Rundvågshetta sillimanite and Fe_2O_3 in the Pt capsule (left: run no. 171018A) and the mixture of Rundvågshetta sillimanite and Fe_3O_4 in the AuPd capsule (right: run no. 171018D) at 9 kbar 1050 ℃ under moisture condition. Left: euhedral corundum with fine vapour hole, $FeAlO_3$ phase, glass and vapour (dark holes) fill among sillimanite crystals. Number 3 is the analysed point by Raman spectroscopy. Right: euhedral 5–10 μm size $FeAlO_3$ phase and fine (<1 μm) $FeAlO_3$ phase are scattered among sillimanite crystals accompanying melt and vapour (dark hole). Crn, corundum. $FeAlO_3$, $FeAlO_3$ phase. Gls, glass. Sil, sillimanite. V, vapour.

Halogens in nanogranitoids entrapped during granulite facies to ultrahigh-temperature metamorphism in the lower crust

*Fumiko Higashino[1], Tetsuo Kawakami[2]

1. Graduate School of Environmental Studies, Tohoku University, 2. Graduate School of Science, Kyoto University

Granulite facies to ultrahigh-temperature (UHT) metamorphic terranes in the deep crust are considered as a potential source region of granitoid melts that eventually form plutons (e.g., Sawyer et al., 2011; Brown et al., 2011). Melt inclusions such as “nanogranitoids” and “felsite inclusions” recently found from such granulite facies and UHT metamorphic terranes are the explicit evidence of partial melting (Cesare et al., 2009; 2015; Hiroi et al., 2014). Such inclusions enable us to estimate the melt composition formed by partial melting (Cesare et al., 2015) and to estimate the timing of partial melting when combined with pressure-temperature-time (*P-T-t*) paths (Kawakami et al., 2013; 2016).
In determining the melt compositions using nanogranitoids, re-melting and re-homogenization of nanogranitoid inclusions using piston cylinder is often performed, and nanogranitoids with decrepitation texture are avoided from such experiments (Cesare et al., 2015). However, nanogranitoids that has decrepitation texture are common in high-*T* pelitic gneisses (e.g., Hiroi et al., 2014; Cesare et al., 2015; Kawakami et al., 2016) and if development of such texture is related to the *P-T* path of the host rock as in the case of fluid inclusions (Vityk and Bodnar, 1995), neglecting the decrepitated nanogranitoids might mean neglecting of specific metamorphic history. Therefore, efforts in determining chemical compositions of melt inclusions of decrepitated nanogranitoid inclusions is also valuable. Among various chemical aspects, information on major halogens (F and Cl) in lower crustal nanogranitoids is extremely poor (e.g., Cesare et al., 2015; Acosta-Vigil et al., 2016; Ferrero et al., 2018). This study aims to provide some new data on the halogen contents in nanogranitoids to better understand the partial melting in the granulite facies active lower crust using fully crystallized nanogranitoids.
Nanogranitoid inclusions are found as inclusions in garnet from granulite facies mafic and pelitic gneisses from Balchenfjella (Sør Rondane Mountains, East Antarctica). Mineral assemblages of the large-sized (>100 μm) nanogranitoid inclusions are Bt + Pl + Qtz in mafic gneiss, and Bt + Pl + Qtz + And + Sil in pelitic gneiss. Mesoperthite in the nanogranitoid inclusion and in the matrix of the pelitic gneiss gave temperature of >900 ºC based on ternary feldspar thermometry. These observation evidences that Balchenfjella experienced UHT metamorphism and the nanogranitoid inclusions represent the UHT melt. The re-integrated composition of nanogranitoids range from granodioritic in the mafic gneiss to granitic in the pelitic gneiss, and mostly peraluminous. The peraluminous melt compositions might be a result of post-entrapment interaction between the melt and host garnet. F/Cl ratio of biotite in the nanogranitoids can be an indicator of F/Cl of the nanogranitoid melts, and low F/Cl ratio observed in this study contrasts with high values observed in peraluminous silicic melts from intrusive and extrusive igneous rocks. This suggests that F/Cl ratio in shallower level silicic igneous rocks is mainly controlled by the magmatic processes in the shallow crust, and chemical characteristics of source rocks or F/Cl ratio of the original melts in the source region is of secondary importance.

Significance of high-Ti biotite and anatectic conditions of paragneiss in the Oki-Dogo Island, Japan

Hiroshi Yoshida[1], *Shunsuke Endo[1], Mai Fujiwara[1], Atsushi Kamei[1]

1. Department of Earth Science, Interdisciplinary Faculty of Science and Engineering, Shimane University

The Oki Gneiss exposed on the eastern side of the Oki-Dogo Island in SW Japan consists mainly of paragneiss and subordinate orthogneiss. These lithologies were originated from Paleoproterozoic (~1800 Ma) clastic rocks and granitoids, and subjected to low-P/T type metamorphism associated with anatexis at around 240 Ma (Tsutsumi et al., 2006; Cho et al., 2012). The Oki Gneiss must be a key to understand the correlation with Precambrian basements in the Korean Peninsula and Permo-Triassic tectonic framework of East Asia. In the present study, we conducted field survey in the entire areas of the Oki Gneiss and examined the spatial extent and P–T conditions of high-grade metamorphism and anatexis. Although structures of the Oki Gneiss were affected by intensive Cenozoic volcanic activities, the main foliation (gneissosity) largely strikes E–W and dips to the south or north. Migmatitic gneiss shows complex ptigmatic folding, but outcrops showing polyphase deformation are uncommon and the main foliation probably represents a single deformation phase. Migmatitic pelitic gneiss consists of biotite- and sillimanite-rich melanosome and plagioclase- and quartz-rich leucosome parallel to the main foliation, and is commonly cut by discordant leucogranite dikes. The peak mineral assemblage of aluminous pelitic gneiss is garnet + biotite + sillimanite + cordierite + plagioclase + quartz + spinel (hercynite-gahnite) + ilmenite + rutile + graphite or its partial assemblages. Spinel only occurs in southern areas. Occasionally, euhedral andalusite enclosing sillimanite occurs in the leucosome, and they might be cotectic minerals crystallized during cooling. Garnet grains are chemically homogeneous except for the reverse-zoned (i.e., increase in Mn and decrease in Mg) grain margins. However, some garnet in northern localities faintly preserves growth zoning characterized by high Mn, Ca and Y contents at the core of garnet grains. To estimate peak-T conditions, we used Ti-in-biotite and Zr-in-rutile geothermometers for biotite and rutile in equilibrium with quartz and zircon. High-Ti biotite (up to 5.9 wt% TiO_2) is found as inclusions in garnet and tiny rounded grains completely enclosed within single crystals of matrix quartz or plagioclase. These high-Ti biotite grains imply high-T metamorphism (up to 760˚C), but high-Ti biotite in garnet shows significantly higher Mg#, suggesting Fe-Mg exchange with the host garnet during cooling. Coarse-grained platy biotite aligned in the gneissosity shows low Ti and is associated with low-Zr rutile and sillimanite, suggesting re-equilibration (~550–650˚C) and pervasive ductile deformation during an early retrograde stage. High-Zr rutile (1200–1700 ppm Zr) only occurs as inclusions in garnet with no any associated cracks, and implies high-T conditions of ~750–780˚C. Presuming high-Ti biotite in quartz/plagioclase and homogenous core of garnet are in equilibrium at the thermal peak, combination of conventional geothermobarometers gives peak P–T conditions of ~0.42–0.60 GPa and 760–780˚C for samples from widely-spaced localities. Samples from southern localities tend to show lower P conditions. Calculated phase equilibria verify the coexistence of cordierite, garnet and spinel during anatexis at the estimated peak conditions for the southern samples. The ubiquitous occurrence of high-Ti biotite implies the Oki Gneiss entirely underwent high-grade metamorphism (transitional upper amphibolite to granulite facies). Taken together, the Oki Gneiss represents a Paleoproterozoic basement that was overprinted by a 240 Ma thermal event associated with ductile flow, low-P/T metamorphism and anatexis at mid-crustal levels (~15–20 km).

Eclogite-to-granulite transition in the Ufipa Complex (Tanzania): the time-lag between collision and the granulitization

*Morita Isamu[1], Tatsuki Tsujimori[1], Nelson Boniface[2], Shogo Aoki[3], Kazumasa Aoki[3]

1. Tohoku University, 2. University of Dar es Salaam, 3. Okayama University of Science

Eclogite-to-granulite transition found in the collisional tectonic regime can provide not only regional tectonic history but also basic principles underlying crustal thickening attributed to the continent-continent collision at convergent plate boundary. In order to understand the dynamics and timescale of collision-induced crustal thickening, we conducted petrological and geochronological research for partially granulitized eclogite and associated metamorphic rocks of the Ufipa Complex (Tanzania).

The Ufipa Complex is a newly confirmed Neoproterozoic metamorphic complex that is equivalent to the Mozambique Belt formed during 'Pan-African orogeny'. Granulitized eclogite is a coarse-grained kyanite-bearing retrograde eclogite with the major mineral assemblage of garnet + omphacite + kyanite + rutile; kyanite contains both omphacite and clinozoisite. Kyanite-free eclogite is medium-grained less-retrograded, bimineralic eclogite. Garnet–omphacite–kyanite–quartz geothermobarometry yielded a P = ~1.9–2.1 GPa and T = ~920–960°C for eclogite stage and P = ~1.3–1.6 GPa and T = ~900–940℃ for high-pressure granulite stage.

LA-ICPQMS zircon U–Pb geochronology for the eclogites revealed that time-lag Δt between collision at ~588 Ma and granulite-facies recrystallization at ~559 Ma was ~30 m.y. Zircon growth during eclogite-facies was confirmed by both mineral inclusions and trace-element abundances. In-situ zircon dating using petrographic thin-sections also confirmed the timing of granulitization. The inferred Δt of ~30 m.y. is consistent with other continental collision zones even in Cenozoic orogens in the literatures.

Keywords: Eclogite, Granulitization, Zircon U-Pb age, In-situ dating, Neoproterozoic, East Africa

Switching of metamorphic growth kinetics due to volume fraction of metamorphic fluid

*Kazuhiro Miyazaki[1]

1. Orogenic Processes Research Group, Institute of Geology and Geoinformation, Geological Survey of Japan/National Institute of Advanced Industrial Science and Technology

In general, it is predicted that the growth kinetics should switch from interface-controlled to diffusion-controlled kinetics with increasing grain size. Rate constant and diffusion coefficient are required for estimate the critical grain size for the switching. It is assumed that the effective diffusivity is a product among diffusivity of solute in water, volume fraction of metamorphic fluid and tortuosity. Using rate constant of silicate in aqueous fluid and diffusion coefficient of solutes in aqueous fluids, the switching will occur around 1 mm in diameter at 500 degree C and 1 G Pa with 0.02 volume % of metamorphic fluid. The switching will occur around 1 cm with 0.2 volume % of metamorphic fluid, and will occur around 10 cm with 2 % volume of metamorphic fluid, respectively. Accompanying the switching with diffusional instability, growth kinetics can be predicted by degree of supersaturation. Recently, degree of supersaturation or reaction affinity, which is a function of degree of supersaturation, were reported from different metamorphic belts (e.g. Miyazaki, 2015; Spear and Pattison, 2017). Typical value for reaction affinity of the nucleation of a porphyroblast, such as garnet, is 300 J/mol oxygen (Spear and Pattison, 2017). Using this value, diffusional instability will occur above 1 μm. Therefore, garnet should grow unstable and result in highly irregular morphology after the switching. However, such garnet is rare in general regional metamorphic belt. In other word, existence of euhedral to subhedral garnet larger than cm-scale implies interface-controlled growth under sufficient metamorphic fluid condition at deep crustal depths. Unlike in the case of garnet porphyroblast, matrix mineral, such as phengite, probably grew by interface-controlled dissolution-precipitation with non-hydrostatic condition, because supersaturation of the dissolution-precipitation is perhaps much lower than that of net-transfer reaction and size of phengite is usually less than 1 mm.

[J] Poster | S (Solid Earth Sciences)：S-MP Mineralogy & Petrology

Wed. May 29, 2019 1:45 PM - 3:15 PM JST | Wed. May 29, 2019 4:45 AM - 6:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_4

[S-MP32] Deformed rocks, Metamorphic rocks and Tectonics

convener:Yumiko Harigane(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST)), Yoshihiro Nakamura(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology)

We invite all researchers who aim to understand the dynamics of the earth's crust and mantle at the plate boundaries, to discuss the latest results from various viewpoints. The scope will include contributions through petrology and structural geology as well as various techniques including rheology and transformation of heat and mass.

Pressure-temperature estimates of the Lützow-Holm Complex utilizing distributions of trace elements and inclusions in garnet porphyroblasts in pelitic gneisses

*Kota Suzuki[1], Tetsuo Kawakami[1], Yohei Igami[2]

1. Department of Geology and Mineralogy, Graduate School of Science, Kyoto University, 2. Institute of Materials and Systems for Sustainability, Nagoya University

The Lützow-Holm Complex (LHC) in East Antarctica is a late Neoproterozoic to early Cambrian orogenic belt, formed during the amalgamation of Gondwana and composed of various bulk compositions of high-grade metamorphic rocks. Based on matrix mineral assemblages of mafic to intermediate mafic rocks, the LHC has been divided into three metamorphic facies zones; upper-amphibolite facies zone, transitional zone and granulite facies zone [1]. Because of the continuous distribution of upper-amphibolite facies to granulite facies metamorphic rocks, the LHC has been considered as a good exposure of the cross section of lower crust during continental collision events.
However, recent studies have found that high-*T* conditions above 850 °C are common even in the transitional zone and such temperatures are attained under kyanite stability field [3, 6, 7]. The aim of this study is to re-examine the peak metamorphic *P-T* conditions and *P-T* paths of selected regions in the LHC (Rundvågshetta, Skallen, Skarvsnes and Akarui Point) utilizing distributions of trace elements and inclusions such as Al_2SiO_5 minerals and rutile in garnet porphyroblasts in high-grade pelitic gneisses.
The Zr content of rutile coexisting with zircon+quartz strongly depends on the temperature condition and has been calibrated as Zr-in-rutile geothermometers that is more robust than the traditional Fe-Mg exchange type geothermometers during high-*T* metamorphism. In this study, experimentally calibrated Zr-in-rutile geothermometer [8] was applied to rutile grains in garnet and matrix.
The polymorphs of Al_2SiO_5 minerals are known as valuable indicators of the *P-T* conditions. In the course of this study, sillimanite with a characteristic Raman peak around 420 cm^{-1} which is not listed as a sillimanite peak in the Lyon database (http://www.geologie-lyon.fr/Raman/) were found as inclusion minerals in garnet and as matrix minerals from all of the four studied regions. In order to examine whether such a peak is related to the phase transition from kyanite or mullite to sillimanite, we observed them in detail by TEM. However, no evidence for such transition was found. Therefore, sillimanite with 420 cm^{-1} peak is dealt as normal sillimanite in this study.
Chemical zoning of garnet in high-*T* metamorphic rocks in terms of major elements (Fe, Mg, Ca and Mn) are commonly obscured by the diffusion under high-*T* conditions. On the other hand, chemical zoning of garnet in terms of trace elements, especially P, is less affected by the later diffusion, and commonly preserves sharp growth zoning [e.g., 2, 4]. Utilizing the sharp P zoning as a contemporaneous surface during garnet growth to define core and rim of garnet, and utilizing relic inclusions in garnet such as Al_2SiO_5 minerals and rutile to constrain the *P-T* conditions of each metamorphic stage [e.g., 5], we estimated metamorphic *P-T* conditions recorded in pelitic gneisses from the four regions in the LHC. Although Akarui Point is located in the “transitional zone” and three other regions are in the “granulite facies zone”, all of the inferred *P-T* paths of high-grade pelitic gneisses from Skallen, Skarvsnes and Akarui Point indicate nearly isothermal decompression starting from kyanite stability field at temperature around 850 °C. From Rundvågshetta, although pressure condition could not be well constrained, extremely high peak metamorphic temperature (> 900 °C) was inferred.
Since the peak metamorphic grades inferred from inclusion minerals in garnet porphyroblasts from Skallen, Skarvsnes and Akarui Point are almost the same, the traditional metamorphic zone mapping

based on matrix mineral assemblages does not represent the highest metamorphic conditions attained, and needs re-evaluation utilizing petrochronological approach.

Microstructures and pressure-temperature condition in pelitic gneisses from the Lützow-Holm Complex at Akarui Point, East Antarctica

*Hayato Yodoya[1], Takeshi Ikeda[2]

1. Department of Earth and Planetary Sciences, Graduate School of Scinece, Kyushu University, 2. Department of Earth and Planetary Sciences, Faculty of School of Scinece, Kyushu University

Metamorphic rocks have been considered to preserve the mineral assemblage and composition at the peak condition in each pressure (*P*) –temperature (*T*) path. If this assumption is valid, the metamorphic rocks in the same outcrop are expected to show the same *P-T* condition. However, different *P-T* conditions have been estimated based on different geothermobarometers for rocks even from the same outcrop. Systematic difference among the methods could be responsible for these differences. However, this study revealed that use of the same pair of geothermobarometers provides significantly different P-T conditions for two pelitic gneisses from the same outcrop of the Lützow-Holm Complex, at Akarui Point, East Antarctica. An alternative interpretation is proposed to account for this difference.

The mineral assemblages of the studied gneisses are garnet, biotite, plagioclase, K-feldspar, quartz with and without sillimanite. Garnet grains in the Sil-bg. sample show round shape and contain large amount of fine quartz inclusions, whereas those in the Sil-free sample represent irregular shape and sporadically include coarse-grained plagioclase.

Garnet in both samples have chemically heterogeneity such that X_{Ca} (=Ca/Fe+Mg+Ca+Mn) and Mg/Fe decrease from the core to the rim. Furthermore, garnet in contact with biotite represents lower Mg/Fe than that in contact with other minerals. Garnet in the Sil-bg. sample is low in X_{Ca} and Mg/Fe as compared with garnet in the Sil-free sample. Phosphorus in garnet of the Sil-bg. sample represents euhedral shape of chemical contour in contrast to the garnet in the Sil-free sample where phosphorus shows no zoning. Biotite in the Sil-bg. sample shows Al-rich and low Mg/Fe as compared with that in the Sil-free sample. No systematic difference in Ti content in biotite is recognized. The Sil-free sample contains plagioclase with higher anorthite content than the Sil-bg. sample.

In the AFM approximation, garnet and biotite coexisting with sillimanite are expected to show higher Mg/Fe than those free from sillimanite. However, the present observations disagree with the prediction. Garnet contains significant amount of Ca, requiring addition of CaO to the chemical system. A calculated garnet composition diagram with respect to Ca-Mg-Fe shows that garnet coexisting with sillimanite represents a univariant line lower Ca and Mg/Fe than that free from sillimanite, and the present data are consistent with it. This suggests that two samples were not necessarily equilibrated at different *P-T* condition.

Geothermobarometry, in contrast, indicates significant difference in *P-T* condition. That is, garnet-biotite geothermometer (Ferry and Spear., 1978) and garnet-biotite-plagioclase-quartz geobarometer (Hoisch., 1990) show 685-718 ℃ at 6.4-6.6 kbar for the Sil-free sample and 828-855 ℃ at 7.2-7.8 kbar for the Sil-bg. sample.

It is puzzling feature that different samples from the same outcrop provide different *P-T* estimations using

©2019. Japan Geoscience Union. All Right Reserved.

the same geothermobarometers. The Sil-bg. sample records higher temperature than the Sil-free sample, as described before. Preservation of euhedral chemical contour of phosphorus in the Sil-bg. sample would indicate that the garnet grew maintaining surface equilibrium, at high temperatures. In contrast, absence of such euhedral contour and highly-rough surface of garnet in the Sil-free sample suggest relatively high growth rate, at low temperatures.

The *P-T* path of Akarui Point contains pressure decrease during temperature decrease (Iwamura et al., 2013). Considering this *P-T* path, it is expected that the garnet of Sil-free sample didn't exist at high temperatures and formed at low pressures and temperatures. The difference in estimated *P-T* conditions in the same outcrop can be attributed to not only the difference in the method but also the difference in the timing of the formation of minerals.

The Southern Granulite Terrane in India is composed of various Archean to Neoproterozoic continental blocks, magmatic arcs, and supracrustal units amalgamated through complex subduction-accretion-collision event and high-grade metamorphism during the Latest Neoproterozoic to Cambrian Gondwana amalgamation. The Trivandrum Block corresponds to a unit in the southern part of the terrane with abundant metasediments and orthogneisses. The pressure-temperature (*P-T*) evolution of the high-grade metamorphism and its time scale are important for unraveling metamorphic processes during the collisional event. The *P-T* evolution recorded in various lithologies in the Trivandrum Block has been argued in numerous previous studies, and it is a subject of ongoing debate. The peak metamorphic ages reported in previous studies from the Trivandrum Block also show a wide range of ca. 600-510 Ma. It is therefore still not known whether the Trivandrum Block underwent single metamorphism with *P-T* variations within the block, or it experienced two discrete metamorphic events at 800-900 ˚C and >950 ˚C. In this study, we present new petrological, geothermobarometric, and geochronological data from khondalites, charnockites, bleached charnockites in the western part of the Trivandrum Block and discuss pressure-temperature-time (*P–T–t*) evolution of the block for unraveling the duration and heat source of high-grade metamorphism.

Phase equilibria modeling of the khondalite from Elavinmoodu quarry located in the western part of the Trivandrum Block indicates peak *P-T* condition of 920-1030 ˚C and 6.0-7.6 kbar, suggesting UHT metamorphism. Prograde and retrograde *P-T* conditions of ~750 ˚C/~7 kbar and ~750 ˚C/~4 kbar, respectively, were also obtained, based on which a clockwise *P-T* path with geotherm-parallel slow cooling is inferred. Consistent *P-T* conditions are obtained from khondalite exposed at Kakkod quarry where incipient charnockite patches within khondalite and foliation-parallel bleached layers within massive charnockite are preserved. Phase equilibria modeling of the incipient charnockite and the bleached rock indicate metamorphic *P-T* conditions of 820-950 ˚C/ 5-10 kbar and 800-1000 ˚C/~6 kbar, respectively. These data suggest that the bleaching of charnockite occurred during high-grade (or UHT) metamorphism, possibly because of fluid flow around the peak metamorphism.

Zircon and monazite U-Pb geochronology for a khondalite sample from Elavinmoodu quarry suggests that prograde, peak, and retrograde metamorphisms took place at around 582±17 Ma, 555.1±8.1 Ma, and 527.3±8.0 to 501.9±8.5 Ma, respectively. Later infiltration of hydrous fluid and hydration of garnet to form biotite occurred at around 489±12 Ma. Our results suggest that high-grade metamorphism continued at least 90 Myr, from 582 Ma to 489 Ma, suggesting a long-lived thermal event possibly related to the input of radiogenic heat from the crust and/or magmatic heat from syn- to post-tectonic intrusions.

The results of this study suggest single metamorphic event along a clockwise *P-T* path. The duration of

©2019. Japan Geoscience Union. All Right Reserved.

high-grade metamorphism (>90 Myr) is nearly consistent with that of metasediments from the Wanni Complex (>50 Myr; Hirayama et al., 2018), but it is shorter than that of long-lived high-grade metamorphism of the Highland Complex (~180 Myr; He et al., 2018). Although previous studies suggested that the supracrustal units of the Trivandrum Block could be a continuation of the Highland Complex (e.g., Dharmapriya et al., 2016; Takamura et al., 2018), the high-grade metamorphism of the Highland Complex might have started earlier than that of the Trivandrum Block possibly due to complex and multi-stage collisional processes related to the amalgamation of Gondwana Supercontinent.

Dislocation microstructures in garnet: Thermal effect during deeper crustal seismic slip in orogen-boundary shear zone

*Kaushik Das[1], Naotaka Tomioka[2], Proloy Ganguly[3], Jun-ichi Ando[1], Gautam Ghosh[3], Sankar Bose[3]

1. Hiroshima University, 2. Kochi Institute for Core Sample Research, JAMSTEC, 3. Presidency University, India

A considerable amount of information regarding the growth and evolution of old continents are preserved at the boundaries between the orogenic belts and pre-existing cratonic blocks. These are the areas of intense and repeated deformation, metamorphism and activities of crustal fluids. Apart from the precise estimation of the pressure-temperature-fluid evolution through time, one of the major existing challenges is to understand the deformation mechanisms operated in the deep to shallow crustal depths for such geologically complex areas. The Phulbani domain in the north-western part of the Eastern Ghats Granulite Belt, India (EGB) provides a good opportunity as it is juxtaposed in its north and west by the Archean Singbhum Craton and Bastar Craton, respectively. Recent petrological and geochronological works of our group on the metapelitic granulite-charnockite-granitic gneiss of this domain reveal the pressure-temperature-fluid evolution with time. Though this domain is differentiated from the Visakhapatnam domain situated further south-southwest, the overall evolutionary history is observed to be very similar in style and time of occurrence. The Si-poor aluminous granulites preserve exotic reaction textures implying prograde heating-dominated path culminating at UHT condition (~1000 ˚C at 8 Kbar) followed by a retrograde cooling-decompression path, both in presence of CO_2-rich fluids. The age of metamorphism and associated magmatism ranges between ca. 1000 Ma and 900 Ma, similar to that of the Visakhapatnam domain.
The Phulbani domain, however, is bound on its north by a pronounced east-west shear zone, known as the Ranipathar shear zone. This deep crustal shearing affected the pelitic granulite and granitic gneiss. The mylonitic garnet-bearing granite gneiss preserves east-west foliation-parallel ultramylonite layers. Moreover, broadly east-west and north-south oriented black veins occur in these rocks. Thick (cm-scale) to thin (mm-scale) veins have mesoscopic characters of a pseudotachylite, e.g. injection veins. The microscopic observations on the foliation-parallel veins reveal that the vesicular groundmass of the veins is composed of micron-scale quartz-feldspar-biotite with clasts of garnet, at places. These veins, in certain cases, contain mm-scale clasts of the host granite mylonite gneiss.

U-Pb zircon ages of migmatitic rocks from the Ryoke belt in the Mikawa and eastern Sanuki areas

*Keiichi Kazuratachi[1], Tetsuo Kawakami[1], Etienne Skrzypek[1], Shuhei Sakata[2], Takafumi Hirata[3]

1. Kyoto University, 2. Gakushuin University, 3. The University of Tokyo

Petrochronological studies of the migmatitic part of the high-temperature, low-pressure type Ryoke metamorphic belt enables us to understand the duration of partial melting of the mid-crustal depths during the Cretaceous ignimbrite flare-up event (Takatsuka et al., 2018a). In order to link multiple metamorphic zircon growths in migmatitic rocks with metamorphic stages of the Ryoke metamorphism, we performed LA-ICP-MS U-Pb zircon dating for samples from the Mikawa and eastern Sanuki areas (Ryoke belt, SW Japan).

In the Mikawa area, U-Pb ages of zircon from ~20 cm thick leucosome subparallel to the migmatitic banding of the psammitic metatexite has been already reported (Takatsuka et al., 2018a). The U-Pb dates of metamorphic rims in this part continuously spread on concordia from ~103 Ma to ~83 Ma. These metamorphic rims were separated into two stages of rim growth by discontinuous zoning in CL images, supported by their chronological and chemical difference: Inner rims were interpreted as the zircon growth during prograde metamorphism (97.0±4.4 Ma) and outer rim as the zircon crystallization from the partial melt during early retrograde metamorphism (88.5±2.5 Ma) (Takatsuka et al., 2018a). However, since the sample used in Takatsuka et al. (2018a) was a notably thick leucosome sample different from the surrounding metatexite leucosomes, whether zircon in the typical metatexite migmatites from the same area give the similar characteristics or not has been not clear.

In this study, we performed LA-ICP-MS U-Pb zircon dating for 4 migmatitic rock samples from the high-grade part of the Mikawa area. Migmatite samples mainly consist of Qtz+Pl+Kfs+Bt±Crd+Sil±Grt. Zircon grains commonly have metamorphic rims in which sillimanite and muscovite inclusions are found. We obtained continuous spread of U-Pb dates on concordia from ~98 Ma to ~81 Ma. Based on presence/absence of sillimanite inclusions, Th/U ratio, and U concentration of zircon rims in addition to the U-Pb dates, three metamorphic stages were recognized; (1) 91.4±0.8 Ma (weighted average age, MSWD=1.4, Th/U<0.08, n=29) possibly representing the zircon rim growth in the presence of partial melts during regional metamorphism, (2) 87.1±1.7 Ma (weighted average age, MSWD=2.1, Th/U=~0.002-0.01, n=3) representing the formation of U-rich zircon through fluid-rock interaction at early retrograde metamorphism, (3) ~81 Ma (80.9±2.9 Ma and 81.5±7.3 Ma; Th/U<0.03) overgrowth on metamorphic rim (1). The zircon rim (3) might represent the growth or recrystallization during contact metamorphism caused by the intrusion of 81-75 Ma granitoids (Takatsuka et al., 2018b), as sampling point of the migmatite was 1.7 km distant from the 81-75 Ma granitoids and the obtained U-Pb zircon dates are close to the granitoids.

We also determined U-Pb ages of metamorphic zircon in 2 samples from the eastern Sanuki area (Kutsukake et al., 1979) where ages of metamorphic zircon have not been reported so far. One sample is a pelitic gneiss from a metamorphic rock body of about 800 m in size surrounded by granitoids, and mainly consists of Qtz+Pl+Kfs+Bt+Grt. Zircon grains in this sample have metamorphic rims (Th/U=~0.02-0.18). The weighted average U-Pb age of the metamorphic zircon rims is 93.4±0.7 Ma (MSWD=0.85, n=27). Another sample is a pelitic gneiss from a metamorphic rock body of 4 km wide, surrounded by gneissose granitoids. The gneissose structure of pelitic gneiss is concordant with surrounding granitoids. This sample mainly consists of Qtz+Pl+Kfs+Bt+Sil. Metamorphic rims (Th/U=~0.05-0.08) of zircon include sillimanite, and the weighted average U-Pb age is 95.4±2.4 Ma (MSWD=0.47, n=6). As these ages are consistent with U-Pb zircon ages of surrounding ~93 Ma gneissose granitoids (Iida et al., 2015), it is likely

©2019. Japan Geoscience Union. All Right Reserved.

that the rims grew during contact metamorphism by the granitoids under sillimanite-stable condition.

Structural geology of Hidaka metamorphic belt in the Mt.Nozuka area, Hokkaido, Japan -Growth and formation process of the Cenozoic continental crust by island arc/arc join and its mechanism-

*Moeko Kanno[1], Tsuyoshi Toyoshima[2]

1. Graduate school of Science and Technology, Niigata University , 2. Department of Geology,Faculty of Science,Niigata University

The Hidaka Metamorphic Belt (HMB) in Hokkaido, northern Japan, consists of metamorphic and plutonic rocks, and is regarded as a crustal section of Tertiary immature parts of the Kurile island arc exposed along with collision to the NE Japan arc in the Miocene (Komatsu et al., 1982 etc.) . Metamorphic grade increases from very low-grade sediments in the east to granulite facies in the west. It was considered to be a single and coherent crustal section, however, Shimura et al. (2015) proposed that HMB is a composite of two crusts of 19 Ma and 37 Ma. This hypothesis should be tested by detailed filed relationships of rocks of different ages. This paper presents deformation phase of metamorphic rock and plutonic rock and zircon U-Pb ages along the Niobetsu River route of the Nozuka dake area, southern HMB, and discusses on the mode of crustal evolution there.

In the study area, HMB consists mainly of S-Type tonalite (Grt Tonalite, Grt-Bt Tonalite), I-Type tonalite (Hbl-Bt tonalite), Diorite, Amphibolite, Gneiss.
Most of the rocks aligned with NW—SE trends except for a diorite intrusion with N—S margins. The diorite is accompanied with migmatite along its margins. Blocks of metamorphic rocks are included in I-Type tonalite and Diorite. Imbricated hornblende crystals in marginal parts of the diorite imply a normal fault-sense magmatic flow. Heterogeneous amphibolite on the southern margin of the diorite are severely folded and deformed with S-C fabric suggesting partial melting.
Mylonitization is observed in S-type tonalite near the Hidaka Main Thrust (HMT), the western margin of HMB. The mylonites show right lateral shear structures with or without normal-slip component. The mylonitization can be classified into 3 stages: 1st Mylonitization by shear deformation of nomal dip-slip, 2nd Mylonitization by shear deformation of normal dip-slip ~ dextral shear, 3rd Mylonitization by shear deformation of dextral shear ~ reverse dip-slip.

We obtained zircon U-Pb ages from S-type tonalites, I-type tonalite, and Diorite.
S-type: about 45Ma, I-type: About 33Ma, Diorite: about 19Ma.

Heterogeneous amphibolite is considered as the boundary deformation zone between 19 Ma plutonic and metamorphic rocks and the older plutonic and metamorphic rocks, because Heterogeneous amphibolite is severely folded and deformed with partial melting. Diorite is penetration in a tensile field is expected. Because the asymmetric flow structure inside the diorite shows normal fault sense.

Zircon U - Pb ages suggest three magmatic stages (about 33 Ma, about 19 Ma and older then 33Ma) in HMB of this area. Igneous rocks include migmatite and metamorphic rocks . So, it is suggested that the magmatism activities of 3 stages are accompanied by metamorphism. Therefore, it is considered that the Hidaka metamorphic belt was formed by three stage metamorphisms.

THE PRESSURE-TEMPERATURE PATH AND MINERAL ASSEMBLAGE OF THE KHONICHIIN OVOO AREA, SOUTHEASTERN MONGOLIA.

*Undarmaa Batsaikhan[1], Noriyoshi Tsuchiya[1], Masaoki Uno[1], Yukio Isozaki[2], Uyanga Bold[2], OTGONBAYAR DANDAR[1], Hikaru Sawada[2]

1. Graduate School of Environmental Studies, Tohoku University, 2. Graduate School of Arts and Sciences the University of Tokyo

The Khonichiin ovoo area is located in the southeastern part of Mongolia of the Central Asian Orogenic belt, which is largest amalgamation history of during Phanerozoic time. The Khonichiin ovoo area mainly consists of the Khutaguul, the Norovzeeg metamorphic complexes that underwent high grade facies metamorphism, with rare igneous rocks. The Khutaguul metamorphic complex is composed of garnet-biotite, amphibolite-biotite, two mica gneiss, amphibolite schist, quartzite, marble, granite-gneiss, granulite and migmatites. The Norovzeeg metamorphic complex is composed of metasedimentary and metavolcanic rocks. P-T condition and mineral assemblage data/information for these metamorphic complexes are extremely limited. This is because international and local researchers had focused on investigations on Paleozoic igneous, volcanic and sedimentary rocks, which are somehow related to the porphyry copper deposits (Tsagaan suvarga Cu-Mo, Kharmagtai Cu-Au) in the south of Mongolia in the last two-decade years.
We will show new age dating and P-T conditions of the Khutaguul and the Norovzeeg metamorphic rocks.

Pressure-temperature conditions of contact metamorphism in Nokita area, Itoshima Peninsula, northwest Kyushu

*Takeshi Ikeda[1], Kento Ota[2]

1. Department of Earth and Planetary Sciences,Faculty of Scinece, Kyushu University, 2. Department of Earth and Planetary Sciences,Graduate School of Scinece, Kyushu University

Gneissose granitic rocks are common in high-grade areas of high-temperature low-pressure metamorphic complex. Similarity in age and concordant relation to the surrounding rocks imply that they supplied heat to cause the high-temperature low-pressure metamorphism. Parallelism of internal structures of granitic and metamorphic rocks also suggests that both rocks underwent simultaneous deformation during and after the intrusion of the granitic rocks. The post-metamorphic deformation would rearrange the thermal structure formed at the heat supply.

The Renge metamorphic complex in the Nokita area of Itoshima Peninsula, northwest Kyushu, was intruded by the Kitazaki and Itoshima granodiorites on the north and south at Cretaceous, respectively. The complex was recrystallized by thses intrusions and underwent significant deformation that belongs to flattening after the peak of contact metamorphism (Yamasaki & Ikeda, 2018). This study estimates the pressure-temperature condition preserved in pelitic rocks to evaluate the post-metamorphic deformation.

The pelitic schists in the study area are composed of leucocratic and melanocratic layers depending on the modal amount of biotite. The common constituent minerals are quartz, plagioclase, biotite. Garnet, muscovite, and K-feldspar locally occur. In addition, chlorite is present as veins and schistosity-forming mineral, which is interpreted as retrograde products.

Four pelitic schists were employed to estimate the metamorphic conditions. Garnet shows euhedral shape and so-called normal zoning where Mg increases and Fe and Mn decreases towards the rim. The composition of rim ranges such that Xalm=0.72-0.80, Xprp=0.09-0.12, Xsps=0.06-0.16, and Xgrs=0.04-0.06. On the other hand, that of core varies Xalm=0.50-0.66, Xprp=0.03-0.05, Xsps=0.24-0.40, and Xgrs=0.04-0.10. The Mg/Fe of rim and core ranges 0.13-0.15 and 0.06-0.08, respectively. Biotite also shows significant variation in composition, i.e., Ti of 0.15 - 0.46 based on 22 oxygen, and Mg/Fe of 0.44 - 0.76. The Ti content of biotite near chlorite is low as compared with that far from chlorite. Plagioclase is chemically homogeneous in one sample. The anorthite content shows southward increase from 0.23 to 0.42.

We chose the composition equilibrated at peak of the metamorphism such as the highest Mg/Fe in the rim of garnet, highest Ti in biotite and highest anorthite content in plagioclase. Geothermobarometry using garnet-biotite geothermometer (Ferry & Spear 1978) and a garnet-biotite-plagioclase-quartz geobarometer (Hoisch 1990) provide the metamorphic conditions of 590 °C, 1.4 kbar, 650 °C, 3.5 kbar, 770 °C, 4.2 kbar, and 650 °C, 2.8 kbar from south to north ,which corresponds to 5.3-16 km depth. The pressure and temperature vary by 2.8 kbar and 180 °C, respectively, within ca. 300 m distance. The lithostatic pressure relevant to 300 m thickness cannot explain the pressure difference of 2.8 kbar. The present result also supports the significant thinning deformation after the contact metamorphism.

Evidence of Partial Melting of Migmatitic Felsic Gneiss from Nagasaki Metamorphic Complex in Amakusa-Shimoshima, western Kyushu, Japan

*Yuki Mori[1], Takeshi Ikeda[2], Kazuhiro Miyazaki[3]

1. Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, 2. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, 3. Research Institute of Geology and Geoinformation, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

The Nagasaki Metamorphic Complex in Amakusa-Shimoshima is divided into the lower and upper units. The former and the latter are composed mainly of pelitic schists and gneisses with mafic and felsic composition, respectively. The upper unit is considered to have located at lower crust that was shortened due to ductile flow toward trench side (Miyazaki et al., 2013). The unit belongs to the high-pressure granulite facies and represents migmatitic mode of occurrence, which implies potential presence of melt that enhanced the ductile deformation. This study reports microstructural features indicative of partial melting in a felsic migmatitic gneiss.

The migmatitic felsic gneiss dealt with this study represents U-Pb zircon age of 125.8±1.8 Ma (Mori et al., 2018 JpGU). It is composed mainly of garnet, quartz, muscovite, zoisite and aggregate of fine-grained zoisite + albite + muscovite that is former plagioclase. Minor amounts of graphite, zircon, apatite, rutile, chlorite, and iron sulfide also occur. Tiny grains of hornblende are included in the rim of garnet. The matrix zoisite commonly includes epidote in the core. The epidote contains significant amounts of rare earth elements (REE) and is composed of Y-poor core and Y-rich rim. The garnet grains are roughly divided into two types of coarse- and fine-grained. The X_{Mg} [=Mg/(Mg+Fe)] of the coarse-grained garnet increases from the core to the rim and decreases at the extreme periphery, while that of the fine-grained garnet monotonically decreases from the core to the rim. The coarse-grained garnet represents Y-rich and P-poor core and Y-poor and P-rich rim whereas Y-poor and P-rich domain is dominant in the fine-grained garnet. A polyphase inclusion composed of chlorite + muscovite + quartz + $CaCO_3$ is found from the rim of coarse-grained garnet. The inclusion shows polygonal shape and has cuspate offshoots filled with chlorite or muscovite. Apatite is included in the core of the coarse-grained garnet but is not found from the rim. The fine-grained garnet and the rim of the coarse-grained garnet include Y-rich REE-epidote.

We applied Zr-in-rutile geothermometer (Ferry & Watson, 2007), garnet-hornblende geothermometers (Graham & Powell, 1984; Powell, 1985; Ravna, 2000), and hornblende-plagioclase geothermometer (Holland & Blundy, 1994). These results are consistent among them within their errors and represent 720 −770 ˚C as the peak condition. The pressure at the peak condition was estimated utilizing garnet-hornblende-plagioclase-quartz geobarometer of Kohn & Spear (1990), and we obtained the pressure of 9.1 −10.2 kbar.

The estimated condition lies above the melting reaction of zoisite + muscovite + quartz + water = kyanite + melt (cf. Schliestedt & Johannes, 1984). The polygonal shape of the polyphase inclusion in the rim of coarse-grained garnet could represent negative crystal of garnet. Combining the constituent minerals of the inclusion, it is likely that the polyphase inclusion was originally melt inclusion.

The concentration of yttrium and phosphorus in the rim of coarse-grained garnet is similar to that in fine-grained garnet. Based on the presence of melt inclusion in the rim of coarse-grained garnet, we

©2019. Japan Geoscience Union. All Right Reserved.

consider that fine-grained garnet nucleated during the partial melting with the formation of the rim of coarse-grained garnet. The Y-rich REE-epidote is in the matrix and included in the fine-grained garnet and the rim of the coarse-grained garnet, so we consider that Y-poor garnet and Y-rich REE-epidote coexisted with the melt. The lack of apatite inclusion in P-rich domain of both garnets may indicate that the phosphorus in P-rich domain in garnet was supplied by breakdown of apatite during the melting.

Keywords: partial melting, melt inclusion, garnet, REE-epidote, apatite

Microstructural Analysis of Quartz grains in Monomineralic and Polyphase domains: A case study from Main Central Thrust (MCT) Zone Mylonites, western Himalaya, India

*Shivaji Saha[1], Toru Takeshita[1], Subhajit Ghosh[2], Hari Bahadur Srivastava[3]

1. Department of Natural History Sciences, Hokkaido University, 2. Earthquake Research Institute, The University of Tokyo, 3. Department of Geology, Banaras Hindu University

Ongoing collision in the Himalayan orogeny causes crustal deformation owing to the thrust activity. Hence, the movement along the Main Central Thrust (MCT) enhances ductile deformation of the crust widely distributed across the orogenic belt. Therefore, detailed microstructural analysis is necessary to define the shear zone by the degree of strain intensification across the MCT. A study area along Madhmaheswar Ganga valley, Rudraprayag district, Uttarakhand, India, has been chosen. Purpose of this study is to perceive the heterogeneity of the deformational behavior of quartz grains in terms of thickness of quartz layers and other associated phases along with the understanding of fabric development with respect to the MCT. In this research, the lower Greater Himalayan Sequence (L-GHS) of *c.* 1.5 km thickness on the hangingwall side and upper Lesser Himalayan Sequence (U-LHS or Munsiari formation) of *c.* 4 km thickness on the footwall side of the MCT, has been studied.

Microstructural observations are essentially focused on the quartzo-feldspathic gneiss of the Munsiari formation and L-GHS. At lower Munsiari formation, Quartz microstructures are characterized by subgrain rotation recrystallization (SGR). Polygonal quartz grains with triple point junction indicate SGR followed by static grain growth. At upper Munsiari formation, lobate boundaries of quartz grains with sweeping extinction and deformation lamellae indicate high temperature grain boundary migration (GBM) overprinted by late stage low temperature deformation. Quartz grains in the lower GHS rocks are coarser than that of the Munsiari rocks and highly amoeboid in shape. High temperature deformation is evidenced by the presence of elongated sub-grains within these irregular grains.

To carry out further microstructural studies, 14 samples were selected for EBSD analysis. Quartz *c*-axis fabric from ~500-829 μm thick quartz-rich monomineralic layer shows a series of type-*II* crossed girdle fabrics with *Y*-maximum. Here, the quartz *c*-axes are aligned parallel to intermediate finite strain axis *Y*, revealing the intracrystalline deformation by active prism {10 -10} *a* slip system. In contrast, c-axis orientations obtained from thin monomineralic quartz layers (thickness ~72-163 μm) records girdles ranging from small circle girdles to type-*I* crossed girdle fabric with r-maxima. In this case, the rhombohedral plane of quartz is aligned parallel to the foliation plane (*XY*), which indicate basal (0001) *a* slip and rhomb {10 -11} *a* slip system activity. Thus, there is an effect of thickness of monophase layers on fabric development and, perhaps the role of other phases has a strong impact on the fabric development for thin monomineralic layers.

On the other hand, polyphase domains are characterized by the quartz grains totally surrounded by other phases. The size of recrystallized quartz grains within polyphase domain increases from ~64.4 μm in Munsiari to ~109 μm in L-GHS. C-axes orientations are random for the Munsiari samples. Whereas, C-axis fabric with point maxima is observed for the L-GHS samples. However, those fabric patterns are strengthened with increasing modal abundance of quartz.

©2019. Japan Geoscience Union. All Right Reserved.

The strength of the quartz *c*-axis fabric is quantified as a function of eigenvectors (λ_1 = maximum; λ_2 = intermediate; λ_3 = minimum) from *c*-axes orientation distribution. Following, Vollmer (1990), three end member fabric types are determined from these eigenvectors; those are point (*P*), girdle (*G*) and random (*R*). Then, by introducing cylindricity index (*B*) of Vollmer (1990), the variation in fabric strength of quartz LPO is shown as a function of strain localization throughout the Munsiari formation. Progressive increase in fabric intensity for both thin and thick monomineralic quartz layers indicate an increase in strain towards the MCT.

Tectono-thermal evolution of the Main Central Thrust (MCT) zone rocks of the Himalayan Crystalline Complex (*HCC*), Darjeeling-Sikkim Himalaya

*Subhajit Ghosh[1,2], Santanu Bose[2,3], Nibir Mandal[4], Arijit Laik[2]

1. Earthquake Research Institute, The University of Tokyo, 1-1-1 Yayoi, Bunkyo-Ku, Tokyo 113-0032, 2. Department of Geology, University of Calcutta, 35, Ballygunge Circular Road, Kolkata 700019, India, 3. Department of Geology, Presidency University, 86/1 College Street, Kolkata 700073, India, 4. Department of Geological Sciences, Jadavpur University, Kolkata 700032, India

The rheology of the Himalayan Crystalline Complex (*HCC*) laying above the Main Central Thrust (MCT), is the key boundary condition for all the tectonic models that deals with extrusion of lower crustal material. Therefore, it is important to understand the intricate relationship between the processes of crustal thickening, Barrovian metamorphism and strain localization in the high-grade rocks of the *HCC* that controls the rheology of a deforming wedge. Initially deformation was distributed and a series of repeated folding leads to crustal thickening and pro-grade metamorphism. The similarity between the peak metamorphic and peak deformation temperature, as documented by frozen high-temperature microstructures is indicative of this phase. The '*locked in*' deformation microstructures and syn-kinematic growth of metamorphic index minerals reveal that the MCT related shearing begins at or near the peak metamorphic condition (16-12 Ma), where grain size reduction by dislocation-controlled creep was the most effective mechanism for strain localization. The observed deformation microstructures and the available P-T data shows that the peak deformation and metamorphic condition progressively increases (~500 to >700˚C) towards the mountain interior. It is further evident that the now-exposed *HCC* begun to extrude under dominantly ductile mid-crustal condition at a temperature >700˚C, where the hotter mid-crustal rocks can flow in a viscous manner by melt enhanced depth-dependent ductile flow. Hence, initially the MCT represents a rheological and metamorphic boundary that separates material which can or cannot flow. Then with subsequent exhumation, cooling and strengthening of the *HCC* produced diffuse ductile shear zones along the same rheological boundary, where deformation was distributed for 4-6 km width (~ MCT zone). The base of the high strain zone is marked by base of the compressed reverse paleo-isograds that coincides with the SGR-GMB transition for quartz, leading to steep P-T gradient locally constrained within the MCT zone before it flattened in the migmatite gneisses. At further lowering of temperature (shallower depth), the MCT localized into narrow shear zone under dominantly brittle condition, transporting the entire *HCC* thrust sheets to the foreland.

Thermal structure and deformation history of the low-grade Sanbagawa belt in the central of Kii Peninsula and tectonic implications

*Ken Yamaoka[1,2], Simon Wallis[1], Hiroshi Mori[2]

1. University of Tokyo, 2. Shinshu University

The Sanbagawa belt in SW Japan is one of the best-documented regions of relatively warm subduction-type metamorphism and information from such regions are important to clarify our understanding of convergent plate margins. Much of the present knowledge is based on petrological studies in the higher grade parts of this belt. However, most of the Sanbagawa belt belongs to the lowest grade domain, the chlorite zone. The lack of reliable methods to determine the thermal structure in this low-grade zone has meant that information from the majority of the belt has been underrepresented. Development of the Raman carbonaceous material thermometer (RCMT) has opened up possibilities of determining the temperature structure of low-grade metamorphic domains such as the chlorite zone of the Sanbagawa metamorphism. Application of RCMT to pelitic rocks of the central Kii peninsula shows a progressive decrease in T from ~390 ˚C close to the northern boundary marked by the Median Tectonic Line (MTL) to ~270 ˚C ~7 km to the south and roughly constant thereafter. The thermal structure is not significantly affected by fault boundaries between different geological units. Meso and microstructural observations combined with strain analysis based on deformed shapes of detrital grains in metamudstone indicate a similar deformation history throughout the area and no correlation between strain and temperature gradients. These features can be used to asses possible models for the observed temperature rise. On this basis, we suggest the rise in T was not due to return flow of high T material in a subduction channel. We also conclude that the rise in T takes place over too narrow a distance to be explained as part of the expected thermal warping in a warm subduction zone. We find no evidence for heating related to the rise of magma or hot fluids. Shear heating along the MTL does provide a plausible explanation for the observed thermal structure compatible with all observations. One-dimensional thermal modeling shows that to account for the observed thermal structure requires slip rates of several mm/yr and relatively high coefficients of friction (μ=??). A similar result was reported from an area to the east but with a much more limited domain of elevated temperatures, probably due to late-stage thinning related to normal faulting. Our results imply that long-lived major crustal faults such as the MTL are at least locally associated with high stresses and are relatively strong. Evidence for the faults being weak at shallow depth implies there is a rapid decrease in strength over the upper few km of the MTL fault zone.

Antigorite Raman spectrum: a case study in Shiraga region of the central Shikoku, Sanbagawa metamorphic belt, SW Japan

*Kota Ando[1], Yui Kouketsu[1], Katsuyoshi Michibayashi[1]

1. Nagoya University

Serpentinites are important rocks and are associtated with water circulating in the earth's interior. However, it is difficult to estimate their metamorphic conditions because serpentine minerals are stable at wide P-T condition. In this study, we compared Raman spectrum of antigorite in different metamorphic grade samples and determined whether Raman spectrum could constrain metamorphic conditions of serpentinites. Serpentinites in this study have been sampled from Shiraga region of the central Shikoku, the Sanbagawa metamorphic belt, SW Japan. All samples experienced the metamorphic conditions in which olivine were formed by the dehydration reaction of antigorite with brucite. Some samples show retrograde antigorite formed during exhumation. Raman spectrum were measured from various sizes and textures of antigorite grains. Comparing full width at half maximum (FWHM) of Raman spectrum, we found that the prograde-antigorite had different features from retrograde-antigorite. As a consequence, FWHM of Antigorite Raman spectrum could be used to constrain the timing of antigorite formation.

A fluid inclusion study from the late Paleozoic retrograde eclogite from the Yunotani Valley of the Omi area, Hida-Gaien Belt, Japan

*Yuzuki Shinji[1], Tatsuki Tsujimori[1], Tatsuhiko Kawamoto[2]

1. Tohoku University, 2. Shizuoka University

Primary fluid inclusions trapped in subduction metamorphic rocks can provide direct information concerning composition and origin of slab-derived fluids. In order to investigate fluid signatures at the mantle wedge beneath forearc regions, we conducted microthermometry for primary fluid inclusions in both prograde eclogite-stage omphacite and retrograde blueschist-stage quartz, in the late Paleozoic retrograde eclogite from the Yunotani Valley of the Omi area, Hida-Gaien Belt, Japan. Note that the investigated blueschist-stage quartz forms a microvein along cracks of omphacite. The investigated eclogite occurs as mafic layers or lenses which are intercalated in metasedimentary rocks with the mineral assemblage paragonite + phengite + garnet ±glaucophane + quartz + rutile. Recent study confirmed that the retrograde blueschist-stage reached the pumpellyite stability field of P = ~0.62–0.70 GPa and T = ~280–320°C (Shinji and Tsujimori 2019 doi:10.2465/jmps.180716).

The primary fluid-inclusions in both omphacite and quartz are aqueous two-phase inclusions of liquid and vapor. Their molecular species in a liquid and gas phase were identified using micro-Raman spectroscopy. The fluid inclusions of the eclogite-stage omphacite are characterized by relatively high salinity of ~8.0–8.2 wt% NaCl equivalent and the brine freezing temperatures at ~-70°C suggests presence of divalent ions such as Ca^{2+} and/or Mg^{2+}. In contrast, fluid inclusion in blueschist-stage quartz shows relatively low value of ~2.4 wt% NaCl equivalent. The liquid phase of the fluid inclusion transforms completely into solid phases at ~-38°C, suggesting existence of the limited monovalent ions such as Na^{+} or/and K^{+} in the fluids.

Our preliminary data demonstrates that the pervasive fluids entrapped at prograde eclogite-stage and retrograde blueschist-stage had different chemical compositions. This suggests different fluid sources at eclogite and blueschist depth. Our observation is consistent with the different fluid compositions recorded in zoned lawsonite in Guatemalan eclogite (Hara et al. 2018 doi: 10.1016/j.lithos.2018.09.001). In our study, the existence of higher salinity fluids in the eclogite-facies conditions can suggest more effective transportation of the lithophile elements into the mantle wedge at deeper forearc regions.

Development of reaction-induced stress and permeability in MgO-H_2O system

*Hisamu Kasahara[1], Masaoki Uno[1], Atsushi Okamoto[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies, Tohoku University

Fractures are dominant flow path of fluid transport in the crust, and fluid flow through the fractures is important for the progress of fluid-rock interaction and material transport in the crust. The fractures enhance permeability in rocks, which has significant effects on the efficiency oil mining, geothermal development and Carbon dioxide Capture and Storage (CCS). Thus, the research on the fracture formations and associated permeability developments are increasingly important for geoscience and engineering.

Especially during fluid-rock interactions in the crust, hydration reactions increase solid-volume and generate stress. Recently such reaction-induced stress has been investigated as a new fracture generation process. For example, the fractures associated with reaction-induced stress are observed in serpentinized olivine (Jamtveit and Austrheim, 2010). In addition, the stress exceeding rock strength is reported from thermodynamic prediction (Kelemen and Hirth, 2012) and experimental measurements (e.g., Lambart et al., 2018). However, the existence of non-fractured rocks despite the volumetric expansion reaction (Centerrea et al., 2015) and the discrepancies between the experimental and theoretical values of reaction-induced stress have not yet been clarified. To understand the causes of these phenomena, it is important to constrain the controlling factors and the generation processes of reaction-induced stress. Therefore, we conducted direct measurements of reaction-induced stress and permeability development during hydration reactions, to clarify the relation between the reaction, stress generation, fracturing and permeability developments.

In our previous study, we measured the reaction-induced stress in MgO–H_2O system, and observed stress generation of approximately 40 MPa, exceeding common tensile strength of rocks. It is indicated that temperature dependence exists in stress generation behavior: the higher the temperature, the higher stress are generated and the stronger stress relaxation are observed after a peak stress. We also showed that this behavior can be explained by competition between reaction and deformation strain rate. This result was consistent to a certain extent with the result of $CaSO_4 \cdot 1/2H_2O$–H_2O system reported by Skarbek et al. (2018).

In this report, we aimed to clarify the influence of reaction and deformation rate on stress generation and the permeability development during volumetric expansion reaction. We conducted two experiments, the stress measurement experiments and the permeability experiments. In the former, experiments were conducted using pellets (ϕ=45–55%) of MgO powder as a starting material under conditions of approximately 80 to 120 ˚C and fluid pressure of approximately 0.100 MPa. The developments of reaction-induced stress were measured as a function of temperature. In the same experimental systems, the reaction and deformation rate were determined by measuring the strain and the reaction rate. In the latter, the experiment was conducted using the sintered MgO as a starting material under the conditions of approximately 100 to 300 ˚C, a fluid pressure of 0 to 10 MPa, and a confining pressure of 0 to 50 MPa. The permeability developments were measured under conditions of various temperatures, confining pressures and fluid pressures. From the results, we consider the relation between stress, fracturing and permeability and discuss the modes of rock fracturing and fluid transfer enhancement during hydration

Crystal orientation analysis of olivine in ultra-mylonite using TKD method: progress in spatial resolution from EBSD

*Yohei Igami[1], Katsuyoshi Michibayashi[2], Kakihata Yuki[2], Yui Kouketsu[2]

1. Institute of Materials and Systems for Sustainability, Nagoya University, 2. Graduate School of Environmental Studies, Nagoya University

Mantle, which is the dominant component consisting of the earth making up 80 %, is the key to understanding material cycle and/or formation history of the earth. The uppermost part of the mantle is composed of peridotite which is aggregate mostly of olivine [$(Mg,Fe)_2SiO_4$] grains. Olivine has orthorhombic crystal system and its mechanical property is anisotropic. Thus the olivine polycrystalline in peridotite shows various crystal-preferred orientation (CPO) patterns formed by share deformation processes (Karato et al., 2008). Therefore, the CPO pattern can be an indicator of deformation environment and is also used as a key parameter to estimate seismic anisotropy. Thus, the CPO is very important for tectonic geology.

To evaluate CPO of olivine, Scanning Electron Microscope equipped with Electron BackScatter Diffraction detector (SEM-EBSD) is widely used. The SEM-EBSD is a method to analyze crystal orientation using the Kikuchi diffraction pattern formed by the interaction between scattered electrons and lattice planes of sample surface. Recently, improvements of high-speed detectors and userfriendly computer programs have enabled automatic, rapid and easy EBSD mapping. Using the method, olivine CPO patterns in peridotite of various localities have been studied. However, effect of fine grains (<1 μm in diameter) might have been overlooked in such studies, because it is difficult to obtain clear EBSD pattern from sub-micrometric mineral grains.

On the other hand, it was reported that the Kikuchi pattern can be obtained also by transmitted electrons through thin film (~100 nm) using SEM (Keller and Geiss, 2011). This method, which is called transmission EBSD (t-EBSD) or transmission Kikuchi diffraction (TKD), can restrict area in which electrons are scattered and improve spatial resolution even by the conventional SEM-EBSD system. In this study, therefore, we tried CPO analysis for ultra-mylonite using the TKD, to investigate usefulness of this method for tectonic geology.

The analyzed sample is an ultra-mylonite from Marion Transform fault by PROTEA5 cruise. The sample contains amphibole and olivine as porphyroclasts and fine-grained matrix, with a small amount of orthopyroxene and spinel (Kakihata et al., 2018, AGU). We obtained EBSD map from petrographic-thin section of this sample, and then an ultra-thin section for TKD was made using a focused ion beam apparatus(FIB, HITACHI FB2100). Finally, TKD map of the ultra-thin section was obtained. For both of the EBSD and TKD analyses, the same SEM-EBSD system (HITACH, S-3400N + OXFORD Instruments, NordlysNano) was used.

As the result, we successfully obtained TKD map dataset, in which patterns are indexed even at the region over boundaries between sub-micrometric olivine grains. This TKD map which was obtained by W-filament gun SEM is clearer than the FESEM-EBSD map we obtained from the same sample. The TKD map dataset was able to be processed by the same software with EBSD (following configuration parameters suggested by Miyake et al., 2016, JAMS). The processed TKD map of olivine displays CPO of *b* -axis perpendicular to shear plane. In addition, spatial distribution of sub-grain boundaries and irregular shaped grains is well displayed. TKD requires much less time and labor than TEM analyses in such orientation analysis throughout the ultra-thin section, although TEM is of course much better in spatial resolution or detailed crystallographic/chemical analyses. The TKD should be useful as a pre-analysis before the detailed TEM analyses for polycristalline samples such as ultra-mylonite. Application of the

TKD method may reveal various effects of fine grains in tectonic geology.

Keywords: EBSD, TKD, crystal preferred orientation, ultra-mylonite, peridotite

Elucidation of effective diffusion coefficient along grain boundaries by hydrothermal experiment using low porosity rocks

*Naoki Sugisawa[1], Masaoki Uno[1], Noriyoshi Tsuchiya[1]

1. Graduate school of environmental studies Tohoku university

Elucidation of the time scale of the fluid activity recorded in the rock is important for understanding the actual condition of fluid activity in the crust. In recent years, it has become possible to estimate time-scale of fluid activity in the crust from isotopes and element concentration profile of natural metamorphic rocks. (e.g.John et al.,2012) To estimate the time-scale, the effective diffusion coefficient (Deff) is important as an indicator of diffusion via grain boundary fluid. It is known that the effective diffusion coefficient depends on the porosity (Φ) of rock and time due to grain boundary diffusion. (e.g.Boving and Grathwohl, 2001) The effective diffusion coefficient is conventionally substituted by the product of self-diffusion coefficient (D_{self}) and porosity ($D_{self}\Phi^{x}$). However, the effective diffusion coefficient varies depending on the power factor (x) of the porosity, and the estimated timescales depend significantly on the power factor (x). Therefore, we clarified the relationship between porosity vs effective diffusion coefficient and confining pressure vs effective diffusion coefficient using hydrothermal experiment under crustal condition with various low porosity granite. In this paper, we mention the following two experiments as the first step : (1) Fluorapatite (F-Ap) substitution reaction (2) Determination of effective diffusion coefficient using low porosity hydroxyapatite sintered body (OH-Ap).

In this study, natural F-Ap from Mexico and OH-Ap (Wako Pure Chemical corporation) were used as starting materials. In experiment (1), first, natural F-Ap was cut in the c-axis direction. And it was put in the gold tube with 0.0006-6 M HCl or 0.01-1 M NaOH two types solution. After that gold tube was putted in the batch type hydrothermal equipment and conducted hydrothermal experiment under 400 ℃, 50 MPa for168 hour. In experiment (2), OH-Ap powder was pressed under 200 MPa for 30 minutes and then the porosity was varied by sintering at deference temperature from 1500 ℃ to 1200 ℃. After cooling, the porosity was measured by the wet method. NaF solution saturated at room temperature and OH-Ap sintered body was added to the same apparatus as above and a hydrothermal experiment was conducted at 300 ℃ and 20 MPa for 168 hours. After the experiment (1) and (2), the samples were evaluated by quantitative analysis and mapping analysis with EPMA in both cases. Before the experiment, phase diagram of apatite under experimental temperature and pressure was prepared using SUPCRT92, GEMS to expect these reactions.

As a result of the hydrothermal experiment, in the experiment (1), it is suggested that the OH in F-Ap is substituted with Cl under HCl solution and the NaOH substitutes OH for F. In experiment (2), F diffusion zoning was generated along the clacks in the sintered OH-Ap, and an effective diffusion coefficient was calculated using diffusion equation. There was no apparent porosity dependency of the effective diffusion coefficient at porosities 1.68-5.83%. The effective diffusion coefficient obtained in this experiment was equivalent to the self-diffusion coefficient of fluorine multiplied by the porosity 2.26 power. ($D_{eff} = D_{self}\Phi^{x}$) (e.g. Oelkers and Helgeson, 1988) However, the porosity measured by the wet method needs to be investigated because it contains the cracks generated in making the sintered body. (e.g. mercury porosimeter)

Based on the above experimental results, it is discussed that the influence of temperature, pressure, solution condition, on substitution of monovalent halogen and hydroxyl group between apatite and fluid and relationship between porosity and effective diffusion coefficients.

Seismic slipping events recorded in a fault gouge zone: evidence from the Nojima Fault drill holes, SW Japan

*Aiming Lin[1], Takafumi Nishiwaki[1]

1. Department of Geophysics, Graduate School of Science, Kyoto University

It is well known that large intra-continental earthquakes occur repeatedly along mature active faults and that the seismic slip may be recorded by cataclastic rocks, including fault gouge zones, that form at shallow depths in the upper crust (e.g., Lin, 2008). A fault gouge zone, bounded by a principal fault plane, is considered to represent the seismic slip zone that accommodates most of the accumulated fault displacement in the seismogenic regime. Therefore, studies of fault gouge zones along mature active faults would provide important information for reconstructing the long-term seismic faulting behavior of such faults, as well as providing new insights into the individual seismic slipping processes of active faults and their paleoseismic histories.

In the present study, we focused on the structural features of the fault gouge zone observed in drill cores acquired from nine holes that were drilled through the Nojima Fault (NF) at different depths from ~260 to 900 m at the Ogura site (Lin and Nishiwaki, 2019). Drilling investigations and structural analyses of drill cores reveal that a ~60 m wide fault damage zone containing a 10–30 cm thick fault gouge zone developed along the Nojima Fault (NF), on which the 1995 M_w 6.9 Kobe (Japan) earthquake occurred. The fault gouge zone was observed at depths of ~260 to 900 m in nine drill holes that intersected the NF. Our findings show that i) the fault gouge zone observed at different depths in the nine drill cores is the principal fault slip zone of the NF, ii) the fault gouge zone can be divided into 11–20 thin layers of different color, and iii) the individually colored layers contain different color breccias of fault gouge that are offset and/or cut by cracks and crack-filled calcite and quartz veinlets. Our results reveal that the fault gouge zone probably records more than 11–20 paleoseismic faulting events along the NF during the late Pleistocene-Holocene.

Evolution of fluid chemistry during basalt-water and basalt-seawater interactions revealed by hydrothermal flow-through experiments

*Yusuke Netsu[1], Atsushi Okamoto[1], Nobuo Hirano[1], Masaoki Uno[1], Noriyoshi Tsuchiya[1]

1. Tohoku University, Graduate School of Environment Studies

Recently, several deep drilling projects for exploiting the supercritical geothermal reservoirs in the world. For example, in 2017, the Island Deep Drilling Project (IDDP-2) reached 427 ˚C and 34 MPa, which exceeds the critical point of seawater. The drillcores revealed that the intense water-rock interaction under greenschist to amphibolite facies metamorphism. Although such deep drilling provides us direct information of active metamorphic processes. however, it is still unclear whether conventional petrological analyses could apply to reaction processes in open systems at high temperature hydrothermal alteration at seafloor. There have been few experiment studies on the water-rock interaction under supercritical conditions with some exceptions (Yardley et al. 2014).

In this study, we conducted hydrothermal flow-through experiments on the basalt-H_2O, basalt-NaCl.aq, basalt-seawater systems under the sub or supercritical conditions. The temperature and pressure were set to be 400 ˚C and 37 - 39 MPa, and the input solutions was flowed at constant flow rate (0.1 ml/min) for 1 –6 days. We placed a powder of MORB (Island, 250-500 μm), which is composed of plagioclase (Pl), olivine (Ol) phenocrysts and clinopyroxnene (Cpx), Pl groundmass, with lessor amount of volcanic glass, in a Ti inner tube (L=275 mm, I.D.= 4.35 mm). During the run, the solution was continuously pumped into the reaction vessel, and the output solution was collected every few hours. The concentration of Si, Al, Ti, Fe, Mg, Ca, Na, and K in the output solution was analyzed by ICP-AES.

In the basalt-H_2O experiment, the products varied with distance from the inlet. At the inlet and middle of tube, Ca-rich Pl (An# 0.98) formed around primary Pl grain with producing abundant pores, whereas chlorite was dominantly formed around Ol and Pl at the middle to outlet of inner tube. The solution chemistry evolves with time: Si concentration was initially high and then decreases toward the steady state. pH, Na and Al increases with decreasing Si, whereas the Ca, Mg and Fe concentrations were low. These features indicate the dissolution of volcanic glass at the initial stage, and then the solution chemistry was controlled by preferential leaching of albite component of plagioclase.

In the basalt-saline water (2.5 wt% of NaCl) experiment, we observed pH rises accompanying the decrease Si concentration, indicating the leaching of Si and dissolution of Pl similar to the basalt- H_2O experiment. One of the large differences between the two experiments was the extremely high Na concentration of saline water, resulting in the leaching of Ca (Ca concentration of the output solution was 40 to 80 times that of H_2O experiment), or breakdown of Ca-bearing minerals. In the basalt reaction with artificial seawater, which contains a lot of Mg^{2+}, SO_4^{2-}, CO_3^{2-} ions, revealed that the significant amount of precipitation of sulfate minerals occurred in the pre-heating parts of the vessel (before pass through the fluid reached the basalt sand), and that chlorite was formed throughout the reaction tube, which clogged the reaction vessel in a day. In contrast to the H_2O and saline water experiments, pH decreased to 3. In spite that we conducted the experiments with the same rock sample (basalt sand) and the same P-T conditions, the products and solubitions after the water-rock interaction were quite different in response to the input solutions, probably because the open system, in which new fluids are continuously supplied, is never rock-buffered. We will analyse the complicated reaction systems which control te evolution of solutions and minerals, based on the analyses of speciation of aqueous species, saturation of minerals

©2019. Japan Geoscience Union. All Right Reserved.

and variation of replacement textures of minerals.

3D microstructural analyses of fault rocks using CT and μCT scanning techniques

*Bingcheng Liu[1], Aiming Lin[1], Takafumi Nishiwaki[1]

1. Kyoto University

Meso- and microstructures of fault rocks including fault gouge developed in the active fault shear zone can reflect the deformation processes of fault motion and faulting mechanisms (Lin, 2008). Therefore, the study on structural features of fault rocks may provide new insights for understanding the nature of active faults. However, it is difficult to understand the spatial variation of microstructures of fault core zone based on traditional methods using two dimensional images under naked-eye and microscopic observations. Accordingly, it is necessary to develop an analytical method for three dimension (3D) analysis for understanding the spatial variation and internal structures of fault core zone. Computed tomography (CT) apparatus with micro-CT (μCT) accessories is a powerful tool which allows non-destructive 3D X-ray imaging and analyzing the spatial and internal structures within non-transparent objects, mainly determined by variations in density, chemical composition (effective atomic number) as well as thickness (Cnudde, 2005).

In this study, the CT and μCT imaging techniques are exploited to observe the 3D internal structures of a series of representative fault rocks: 1) pseudotachylytes of different origins (melting and crushing), and 2) cataclasitic rocks including fault gouge, fault breccia and cataclasite, by utilizing two types of scanning apparatuses (Bruker microCT, 2014): 1) μCT flat panel (FP), and 2) μCT charge coupled device (CCD). The samples of pseudotachylyte are from Fuyun, NW China (Lin, 1994), Ohsumi, Japan (Fabbri et al., 2000), and Musgrave Mt, Australia (Lin et al., 2005), respectively. The samples of fault gouge were acquired from two typical active fault zones in Japan: The Nojima Fault and Arima-Takatsuki Tectonic Line, SW Japan (Lin and Nishiwaki, 2019). The FP analysis shows that 1) the flow structures within the melting-origin pseudotachylytes are denoted by parallel colored glassy matrix layers with numerous rounded quartz clasts and quartz-filled amygdules which are oriented along the flow layers, and 2) chilled margins are characterized by fine-grained microlites orientated parallel to the margins. The 3D scanning images show that the layering structures developed within the fault gouge and fault breccia zones which are marked by sharp colored boundaries, oriented clasts and fine-grained matrixes. Our results demonstrate that 1) the CCD imaging makes it possible to observe sub-micron and even nano-scale 3D microsturctures fault rocks without destruction, and 2) μCT imaging can be further combined with traditional methods (such as optical microscope and SEM observation) to determine the spatial variations for both the meso- and microstructures and chemical compositions of fault rocks.

Dissolution kinetics of forsterite olivine at >200 ˚C: implication for the kinetics of serpentinization.

*Ryosuke Oyanagi[1], Tatsu Kuwatani[1], Katsuhiko Suzuki[1]

1. Japan Agency for Marine-Earth Science and Technology

Serpentinization (hydration of mantle peridotite) gives significant changes to both chemical and physical properties of the oceanic lithosphere. Several studies suggested that the rate of serpentinization is maximized at 250-300˚C, and the rate-limiting process of serpentinization is the dissolution of primary mineral (e.g., Malvoisin et al., 2012). Therefore, the dissolution rate of olivine at 250-300˚C is consequently a critical parameter to understand the progress of serpentinization in the oceanic lithosphere. However, the olivine dissolution rates at > 150˚C have never been measured (Rimstidt et al. 2012), and the olivine dissolution rate extrapolatory calculated at 300˚C was inconsistent with the olivine serpentinization kinetics (Malvoisin et al., 2012). Towards the improved understanding of serpentinization kinetics, measuring dissolution rates of olivine as a function of solution composition and the temperature is required.

In this study, the dissolution rate of natural olivine ($(Mg_{0.91}, Fe_{0.09})_2SiO_4$) was measured at 200-400 ˚C and 50 MPa using a flow-through reactor (Suzuki et al., 2015). A 0.5 mol/kg NaCl solution was introduced at a constant rate of 2.0 mL/min during experiments. A preliminary experiment revealed that steady-state dissolution rate of olivine at 200 ˚C and far-from-equilibrium conditions was ca. -4.8 [mol/m^2/s] in log units. The obtained dissolution rate was consistent with the extrapolated dissolution rate (log_{10}(Rate) = ca. -4.72 [mol/m^2/s]), which was extrapolated from their pH-temperature dependence at 25-150 ˚C (Rimstidt et al., 2012). Based on dependences of temperature, salinity, and ΔG on dissolution rate, the timescales on hydrothermal alteration of peridotite will be discussed.

[J] Poster | S (Solid Earth Sciences)：S-MP Mineralogy & Petrology

Wed. May 29, 2019 5:15 PM - 6:30 PM JST | Wed. May 29, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_29

[S-MP32] Deformed rocks, Metamorphic rocks and Tectonics

convener:Yumiko Harigane(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST)), Yoshihiro Nakamura(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology)

We invite all researchers who aim to understand the dynamics of the earth's crust and mantle at the plate boundaries, to discuss the latest results from various viewpoints. The scope will include contributions through petrology and structural geology as well as various techniques including rheology and transformation of heat and mass.

Pressure-temperature estimates of the Lützow-Holm Complex utilizing distributions of trace elements and inclusions in garnet porphyroblasts in pelitic gneisses

*Kota Suzuki[1], Tetsuo Kawakami[1], Yohei Igami[2]

1. Department of Geology and Mineralogy, Graduate School of Science, Kyoto University, 2. Institute of Materials and Systems for Sustainability, Nagoya University

The Lützow-Holm Complex (LHC) in East Antarctica is a late Neoproterozoic to early Cambrian orogenic belt, formed during the amalgamation of Gondwana and composed of various bulk compositions of high-grade metamorphic rocks. Based on matrix mineral assemblages of mafic to intermediate mafic rocks, the LHC has been divided into three metamorphic facies zones; upper-amphibolite facies zone, transitional zone and granulite facies zone [1]. Because of the continuous distribution of upper-amphibolite facies to granulite facies metamorphic rocks, the LHC has been considered as a good exposure of the cross section of lower crust during continental collision events.
However, recent studies have found that high-*T* conditions above 850 °C are common even in the transitional zone and such temperatures are attained under kyanite stability field [3, 6, 7]. The aim of this study is to re-examine the peak metamorphic *P-T* conditions and *P-T* paths of selected regions in the LHC (Rundvågshetta, Skallen, Skarvsnes and Akarui Point) utilizing distributions of trace elements and inclusions such as Al_2SiO_5 minerals and rutile in garnet porphyroblasts in high-grade pelitic gneisses.
The Zr content of rutile coexisting with zircon+quartz strongly depends on the temperature condition and has been calibrated as Zr-in-rutile geothermometers that is more robust than the traditional Fe-Mg exchange type geothermometers during high-*T* metamorphism. In this study, experimentally calibrated Zr-in-rutile geothermometer [8] was applied to rutile grains in garnet and matrix.
The polymorphs of Al_2SiO_5 minerals are known as valuable indicators of the *P-T* conditions. In the course of this study, sillimanite with a characteristic Raman peak around 420 cm^{-1} which is not listed as a sillimanite peak in the Lyon database (http://www.geologie-lyon.fr/Raman/) were found as inclusion minerals in garnet and as matrix minerals from all of the four studied regions. In order to examine whether such a peak is related to the phase transition from kyanite or mullite to sillimanite, we observed them in detail by TEM. However, no evidence for such transition was found. Therefore, sillimanite with 420 cm^{-1} peak is dealt as normal sillimanite in this study.
Chemical zoning of garnet in high-*T* metamorphic rocks in terms of major elements (Fe, Mg, Ca and Mn) are commonly obscured by the diffusion under high-*T* conditions. On the other hand, chemical zoning of garnet in terms of trace elements, especially P, is less affected by the later diffusion, and commonly preserves sharp growth zoning [e.g., 2, 4]. Utilizing the sharp P zoning as a contemporaneous surface during garnet growth to define core and rim of garnet, and utilizing relic inclusions in garnet such as Al_2SiO_5 minerals and rutile to constrain the *P-T* conditions of each metamorphic stage [e.g., 5], we estimated metamorphic *P-T* conditions recorded in pelitic gneisses from the four regions in the LHC. Although Akarui Point is located in the “transitional zone” and three other regions are in the “granulite facies zone”, all of the inferred *P-T* paths of high-grade pelitic gneisses from Skallen, Skarvsnes and Akarui Point indicate nearly isothermal decompression starting from kyanite stability field at temperature around 850 °C. From Rundvågshetta, although pressure condition could not be well constrained, extremely high peak metamorphic temperature (> 900 °C) was inferred.
Since the peak metamorphic grades inferred from inclusion minerals in garnet porphyroblasts from Skallen, Skarvsnes and Akarui Point are almost the same, the traditional metamorphic zone mapping

based on matrix mineral assemblages does not represent the highest metamorphic conditions attained, and needs re-evaluation utilizing petrochronological approach.

Microstructures and pressure-temperature condition in pelitic gneisses from the Lützow-Holm Complex at Akarui Point, East Antarctica

*Hayato Yodoya[1], Takeshi Ikeda[2]

1. Department of Earth and Planetary Sciences, Graduate School of Scinece, Kyushu University, 2. Department of Earth and Planetary Sciences, Faculty of School of Scinece, Kyushu University

Metamorphic rocks have been considered to preserve the mineral assemblage and composition at the peak condition in each pressure (*P*) –temperature (*T*) path. If this assumption is valid, the metamorphic rocks in the same outcrop are expected to show the same *P-T* condition. However, different *P-T* conditions have been estimated based on different geothermobarometers for rocks even from the same outcrop. Systematic difference among the methods could be responsible for these differences. However, this study revealed that use of the same pair of geothermobarometers provides significantly different P-T conditions for two pelitic gneisses from the same outcrop of the Lützow-Holm Complex, at Akarui Point, East Antarctica. An alternative interpretation is proposed to account for this difference.

The mineral assemblages of the studied gneisses are garnet, biotite, plagioclase, K-feldspar, quartz with and without sillimanite. Garnet grains in the Sil-bg. sample show round shape and contain large amount of fine quartz inclusions, whereas those in the Sil-free sample represent irregular shape and sporadically include coarse-grained plagioclase.

Garnet in both samples have chemically heterogeneity such that X_{Ca} (=Ca/Fe+Mg+Ca+Mn) and Mg/Fe decrease from the core to the rim. Furthermore, garnet in contact with biotite represents lower Mg/Fe than that in contact with other minerals. Garnet in the Sil-bg. sample is low in X_{Ca} and Mg/Fe as compared with garnet in the Sil-free sample. Phosphorus in garnet of the Sil-bg. sample represents euhedral shape of chemical contour in contrast to the garnet in the Sil-free sample where phosphorus shows no zoning. Biotite in the Sil-bg. sample shows Al-rich and low Mg/Fe as compared with that in the Sil-free sample. No systematic difference in Ti content in biotite is recognized. The Sil-free sample contains plagioclase with higher anorthite content than the Sil-bg. sample.

In the AFM approximation, garnet and biotite coexisting with sillimanite are expected to show higher Mg/Fe than those free from sillimanite. However, the present observations disagree with the prediction. Garnet contains significant amount of Ca, requiring addition of CaO to the chemical system. A calculated garnet composition diagram with respect to Ca-Mg-Fe shows that garnet coexisting with sillimanite represents a univariant line lower Ca and Mg/Fe than that free from sillimanite, and the present data are consistent with it. This suggests that two samples were not necessarily equilibrated at different *P-T* condition.

Geothermobarometry, in contrast, indicates significant difference in *P-T* condition. That is, garnet-biotite geothermometer (Ferry and Spear., 1978) and garnet-biotite-plagioclase-quartz geobarometer (Hoisch., 1990) show 685-718 ℃ at 6.4-6.6 kbar for the Sil-free sample and 828-855 ℃ at 7.2-7.8 kbar for the Sil-bg. sample.

It is puzzling feature that different samples from the same outcrop provide different *P-T* estimations using

©2019. Japan Geoscience Union. All Right Reserved.

the same geothermobarometers. The Sil-bg. sample records higher temperature than the Sil-free sample, as described before. Preservation of euhedral chemical contour of phosphorus in the Sil-bg. sample would indicate that the garnet grew maintaining surface equilibrium, at high temperatures. In contrast, absence of such euhedral contour and highly-rough surface of garnet in the Sil-free sample suggest relatively high growth rate, at low temperatures.

The *P-T* path of Akarui Point contains pressure decrease during temperature decrease (Iwamura et al., 2013). Considering this *P-T* path, it is expected that the garnet of Sil-free sample didn't exist at high temperatures and formed at low pressures and temperatures. The difference in estimated *P-T* conditions in the same outcrop can be attributed to not only the difference in the method but also the difference in the timing of the formation of minerals.

Long-lived (>90 Myr) granulite-facies metamorphism in the Trivandrum Block, southern India.

*Hikaru Kadowaki[1], Toshiaki Tsunogae[2], Santosh M.[3], Shaji E.[4], Yusuke Takamura[5], Yukiyasu Tsutsumi[6]

1. College of Geoscience, Graduate School of Life and Environmental Sciences, University of Tsukuba, 2. Faculty of Life and Environmental Sciences, University of Tsukuba, 3. Doctoral Program in Earth Evolution Sciences, Graduate School of Life and Environmental Sciences, University of Tsukuba, 6. Department of Geology and Paleontology, National Museum of Nature and Science

The Southern Granulite Terrane in India is composed of various Archean to Neoproterozoic continental blocks, magmatic arcs, and supracrustal units amalgamated through complex subduction-accretion-collision event and high-grade metamorphism during the Latest Neoproterozoic to Cambrian Gondwana amalgamation. The Trivandrum Block corresponds to a unit in the southern part of the terrane with abundant metasediments and orthogneisses. The pressure-temperature (*P-T*) evolution of the high-grade metamorphism and its time scale are important for unraveling metamorphic processes during the collisional event. The *P-T* evolution recorded in various lithologies in the Trivandrum Block has been argued in numerous previous studies, and it is a subject of ongoing debate. The peak metamorphic ages reported in previous studies from the Trivandrum Block also show a wide range of ca. 600-510 Ma. It is therefore still not known whether the Trivandrum Block underwent single metamorphism with *P-T* variations within the block, or it experienced two discrete metamorphic events at 800-900 ˚C and >950 ˚C. In this study, we present new petrological, geothermobarometric, and geochronological data from khondalites, charnockites, bleached charnockites in the western part of the Trivandrum Block and discuss pressure-temperature-time (*P–T–t*) evolution of the block for unraveling the duration and heat source of high-grade metamorphism.

Phase equilibria modeling of the khondalite from Elavinmoodu quarry located in the western part of the Trivandrum Block indicates peak *P-T* condition of 920-1030 ˚C and 6.0-7.6 kbar, suggesting UHT metamorphism. Prograde and retrograde *P-T* conditions of ~750 ˚C/~7 kbar and ~750 ˚C/~4 kbar, respectively, were also obtained, based on which a clockwise *P-T* path with geotherm-parallel slow cooling is inferred. Consistent *P-T* conditions are obtained from khondalite exposed at Kakkod quarry where incipient charnockite patches within khondalite and foliation-parallel bleached layers within massive charnockite are preserved. Phase equilibria modeling of the incipient charnockite and the bleached rock indicate metamorphic *P-T* conditions of 820-950 ˚C/ 5-10 kbar and 800-1000 ˚C/~6 kbar, respectively. These data suggest that the bleaching of charnockite occurred during high-grade (or UHT) metamorphism, possibly because of fluid flow around the peak metamorphism.

Zircon and monazite U-Pb geochronology for a khondalite sample from Elavinmoodu quarry suggests that prograde, peak, and retrograde metamorphisms took place at around 582±17 Ma, 555.1±8.1 Ma, and 527.3±8.0 to 501.9±8.5 Ma, respectively. Later infiltration of hydrous fluid and hydration of garnet to form biotite occurred at around 489±12 Ma. Our results suggest that high-grade metamorphism continued at least 90 Myr, from 582 Ma to 489 Ma, suggesting a long-lived thermal event possibly related to the input of radiogenic heat from the crust and/or magmatic heat from syn- to post-tectonic intrusions.

The results of this study suggest single metamorphic event along a clockwise *P-T* path. The duration of

©2019. Japan Geoscience Union. All Right Reserved.

high-grade metamorphism (>90 Myr) is nearly consistent with that of metasediments from the Wanni Complex (>50 Myr; Hirayama et al., 2018), but it is shorter than that of long-lived high-grade metamorphism of the Highland Complex (~180 Myr; He et al., 2018). Although previous studies suggested that the supracrustal units of the Trivandrum Block could be a continuation of the Highland Complex (e.g., Dharmapriya et al., 2016; Takamura et al., 2018), the high-grade metamorphism of the Highland Complex might have started earlier than that of the Trivandrum Block possibly due to complex and multi-stage collisional processes related to the amalgamation of Gondwana Supercontinent.

Dislocation microstructures in garnet: Thermal effect during deeper crustal seismic slip in orogen-boundary shear zone

*Kaushik Das[1], Naotaka Tomioka[2], Proloy Ganguly[3], Jun-ichi Ando[1], Gautam Ghosh[3], Sankar Bose[3]

1. Hiroshima University, 2. Kochi Institute for Core Sample Research, JAMSTEC, 3. Presidency University, India

A considerable amount of information regarding the growth and evolution of old continents are preserved at the boundaries between the orogenic belts and pre-existing cratonic blocks. These are the areas of intense and repeated deformation, metamorphism and activities of crustal fluids. Apart from the precise estimation of the pressure-temperature-fluid evolution through time, one of the major existing challenges is to understand the deformation mechanisms operated in the deep to shallow crustal depths for such geologically complex areas. The Phulbani domain in the north-western part of the Eastern Ghats Granulite Belt, India (EGB) provides a good opportunity as it is juxtaposed in its north and west by the Archean Singbhum Craton and Bastar Craton, respectively. Recent petrological and geochronological works of our group on the metapelitic granulite-charnockite-granitic gneiss of this domain reveal the pressure-temperature-fluid evolution with time. Though this domain is differentiated from the Visakhapatnam domain situated further south-southwest, the overall evolutionary history is observed to be very similar in style and time of occurrence. The Si-poor aluminous granulites preserve exotic reaction textures implying prograde heating-dominated path culminating at UHT condition (~1000 ˚C at 8 Kbar) followed by a retrograde cooling-decompression path, both in presence of CO_2-rich fluids. The age of metamorphism and associated magmatism ranges between ca. 1000 Ma and 900 Ma, similar to that of the Visakhapatnam domain.
The Phulbani domain, however, is bound on its north by a pronounced east-west shear zone, known as the Ranipathar shear zone. This deep crustal shearing affected the pelitic granulite and granitic gneiss. The mylonitic garnet-bearing granite gneiss preserves east-west foliation-parallel ultramylonite layers. Moreover, broadly east-west and north-south oriented black veins occur in these rocks. Thick (cm-scale) to thin (mm-scale) veins have mesoscopic characters of a pseudotachylite, e.g. injection veins. The microscopic observations on the foliation-parallel veins reveal that the vesicular groundmass of the veins is composed of micron-scale quartz-feldspar-biotite with clasts of garnet, at places. These veins, in certain cases, contain mm-scale clasts of the host granite mylonite gneiss.

U-Pb zircon ages of migmatitic rocks from the Ryoke belt in the Mikawa and eastern Sanuki areas

*Keiichi Kazuratachi[1], Tetsuo Kawakami[1], Etienne Skrzypek[1], Shuhei Sakata[2], Takafumi Hirata[3]

1. Kyoto University, 2. Gakushuin University, 3. The University of Tokyo

Petrochronological studies of the migmatitic part of the high-temperature, low-pressure type Ryoke metamorphic belt enables us to understand the duration of partial melting of the mid-crustal depths during the Cretaceous ignimbrite flare-up event (Takatsuka et al., 2018a). In order to link multiple metamorphic zircon growths in migmatitic rocks with metamorphic stages of the Ryoke metamorphism, we performed LA-ICP-MS U-Pb zircon dating for samples from the Mikawa and eastern Sanuki areas (Ryoke belt, SW Japan).

In the Mikawa area, U-Pb ages of zircon from ~20 cm thick leucosome subparallel to the migmatitic banding of the psammitic metatexite has been already reported (Takatsuka et al., 2018a). The U-Pb dates of metamorphic rims in this part continuously spread on concordia from ~103 Ma to ~83 Ma. These metamorphic rims were separated into two stages of rim growth by discontinuous zoning in CL images, supported by their chronological and chemical difference: Inner rims were interpreted as the zircon growth during prograde metamorphism (97.0±4.4 Ma) and outer rim as the zircon crystallization from the partial melt during early retrograde metamorphism (88.5±2.5 Ma) (Takatsuka et al., 2018a). However, since the sample used in Takatsuka et al. (2018a) was a notably thick leucosome sample different from the surrounding metatexite leucosomes, whether zircon in the typical metatexite migmatites from the same area give the similar characteristics or not has been not clear.

In this study, we performed LA-ICP-MS U-Pb zircon dating for 4 migmatitic rock samples from the high-grade part of the Mikawa area. Migmatite samples mainly consist of Qtz+Pl+Kfs+Bt±Crd+Sil±Grt. Zircon grains commonly have metamorphic rims in which sillimanite and muscovite inclusions are found. We obtained continuous spread of U-Pb dates on concordia from ~98 Ma to ~81 Ma. Based on presence/absence of sillimanite inclusions, Th/U ratio, and U concentration of zircon rims in addition to the U-Pb dates, three metamorphic stages were recognized; (1) 91.4±0.8 Ma (weighted average age, MSWD=1.4, Th/U<0.08, n=29) possibly representing the zircon rim growth in the presence of partial melts during regional metamorphism, (2) 87.1±1.7 Ma (weighted average age, MSWD=2.1, Th/U=~0.002-0.01, n=3) representing the formation of U-rich zircon through fluid-rock interaction at early retrograde metamorphism, (3) ~81 Ma (80.9±2.9 Ma and 81.5±7.3 Ma; Th/U<0.03) overgrowth on metamorphic rim (1). The zircon rim (3) might represent the growth or recrystallization during contact metamorphism caused by the intrusion of 81-75 Ma granitoids (Takatsuka et al., 2018b), as sampling point of the migmatite was 1.7 km distant from the 81-75 Ma granitoids and the obtained U-Pb zircon dates are close to the granitoids.

We also determined U-Pb ages of metamorphic zircon in 2 samples from the eastern Sanuki area (Kutsukake et al., 1979) where ages of metamorphic zircon have not been reported so far. One sample is a pelitic gneiss from a metamorphic rock body of about 800 m in size surrounded by granitoids, and mainly consists of Qtz+Pl+Kfs+Bt+Grt. Zircon grains in this sample have metamorphic rims (Th/U=~0.02-0.18). The weighted average U-Pb age of the metamorphic zircon rims is 93.4±0.7 Ma (MSWD=0.85, n=27). Another sample is a pelitic gneiss from a metamorphic rock body of 4 km wide, surrounded by gneissose granitoids. The gneissose structure of pelitic gneiss is concordant with surrounding granitoids. This sample mainly consists of Qtz+Pl+Kfs+Bt+Sil. Metamorphic rims (Th/U=~0.05-0.08) of zircon include sillimanite, and the weighted average U-Pb age is 95.4±2.4 Ma (MSWD=0.47, n=6). As these ages are consistent with U-Pb zircon ages of surrounding ~93 Ma gneissose granitoids (Iida et al., 2015), it is likely

©2019. Japan Geoscience Union. All Right Reserved.

that the rims grew during contact metamorphism by the granitoids under sillimanite-stable condition.

Structural geology of Hidaka metamorphic belt in the Mt.Nozuka area, Hokkaido, Japan -Growth and formation process of the Cenozoic continental crust by island arc/arc join and its mechanism-

*Moeko Kanno[1], Tsuyoshi Toyoshima[2]

1. Graduate school of Science and Technology, Niigata University , 2. Department of Geology,Faculty of Science,Niigata University

The Hidaka Metamorphic Belt (HMB) in Hokkaido, northern Japan, consists of metamorphic and plutonic rocks, and is regarded as a crustal section of Tertiary immature parts of the Kurile island arc exposed along with collision to the NE Japan arc in the Miocene (Komatsu et al., 1982 etc.) . Metamorphic grade increases from very low-grade sediments in the east to granulite facies in the west. It was considered to be a single and coherent crustal section, however, Shimura et al. (2015) proposed that HMB is a composite of two crusts of 19 Ma and 37 Ma. This hypothesis should be tested by detailed filed relationships of rocks of different ages. This paper presents deformation phase of metamorphic rock and plutonic rock and zircon U-Pb ages along the Niobetsu River route of the Nozuka dake area, southern HMB, and discusses on the mode of crustal evolution there.

In the study area, HMB consists mainly of S-Type tonalite (Grt Tonalite, Grt-Bt Tonalite), I-Type tonalite (Hbl-Bt tonalite), Diorite, Amphibolite, Gneiss.
Most of the rocks aligned with NW—SE trends except for a diorite intrusion with N—S margins. The diorite is accompanied with migmatite along its margins. Blocks of metamorphic rocks are included in I-Type tonalite and Diorite. Imbricated hornblende crystals in marginal parts of the diorite imply a normal fault-sense magmatic flow. Heterogeneous amphibolite on the southern margin of the diorite are severely folded and deformed with S-C fabric suggesting partial melting.
Mylonitization is observed in S-type tonalite near the Hidaka Main Thrust (HMT), the western margin of HMB. The mylonites show right lateral shear structures with or without normal-slip component. The mylonitization can be classified into 3 stages: 1st Mylonitization by shear deformation of nomal dip-slip, 2nd Mylonitization by shear deformation of normal dip-slip ~ dextral shear, 3rd Mylonitization by shear deformation of dextral shear ~ reverse dip-slip.

We obtained zircon U-Pb ages from S-type tonalites, I-type tonalite, and Diorite.
S-type: about 45Ma, I-type: About 33Ma, Diorite: about 19Ma.

Heterogeneous amphibolite is considered as the boundary deformation zone between 19 Ma plutonic and metamorphic rocks and the older plutonic and metamorphic rocks, because Heterogeneous amphibolite is severely folded and deformed with partial melting. Diorite is penetration in a tensile field is expected. Because the asymmetric flow structure inside the diorite shows normal fault sense.

Zircon U - Pb ages suggest three magmatic stages (about 33 Ma, about 19 Ma and older then 33Ma) in HMB of this area. Igneous rocks include migmatite and metamorphic rocks . So, it is suggested that the magmatism activities of 3 stages are accompanied by metamorphism. Therefore, it is considered that the Hidaka metamorphic belt was formed by three stage metamorphisms.

THE PRESSURE-TEMPERATURE PATH AND MINERAL ASSEMBLAGE OF THE KHONICHIIN OVOO AREA, SOUTHEASTERN MONGOLIA.

*Undarmaa Batsaikhan[1], Noriyoshi Tsuchiya[1], Masaoki Uno[1], Yukio Isozaki[2], Uyanga Bold[2], OTGONBAYAR DANDAR[1], Hikaru Sawada[2]

1. Graduate School of Environmental Studies, Tohoku University, 2. Graduate School of Arts and Sciences the University of Tokyo

The Khonichiin ovoo area is located in the southeastern part of Mongolia of the Central Asian Orogenic belt, which is largest amalgamation history of during Phanerozoic time. The Khonichiin ovoo area mainly consists of the Khutaguul, the Norovzeeg metamorphic complexes that underwent high grade facies metamorphism, with rare igneous rocks. The Khutaguul metamorphic complex is composed of garnet-biotite, amphibolite-biotite, two mica gneiss, amphibolite schist, quartzite, marble, granite-gneiss, granulite and migmatites. The Norovzeeg metamorphic complex is composed of metasedimentary and metavolcanic rocks. P-T condition and mineral assemblage data/information for these metamorphic complexes are extremely limited. This is because international and local researchers had focused on investigations on Paleozoic igneous, volcanic and sedimentary rocks, which are somehow related to the porphyry copper deposits (Tsagaan suvarga Cu-Mo, Kharmagtai Cu-Au) in the south of Mongolia in the last two-decade years.
We will show new age dating and P-T conditions of the Khutaguul and the Norovzeeg metamorphic rocks.

Keywords: P-T path, Petrology, Southeastern Mongolia

Pressure-temperature conditions of contact metamorphism in Nokita area, Itoshima Peninsula, northwest Kyushu

*Takeshi Ikeda[1], Kento Ota[2]

1. Department of Earth and Planetary Sciences,Faculty of Scinece, Kyushu University, 2. Department of Earth and Planetary Sciences,Graduate School of Scinece, Kyushu University

Gneissose granitic rocks are common in high-grade areas of high-temperature low-pressure metamorphic complex. Similarity in age and concordant relation to the surrounding rocks imply that they supplied heat to cause the high-temperature low-pressure metamorphism. Parallelism of internal structures of granitic and metamorphic rocks also suggests that both rocks underwent simultaneous deformation during and after the intrusion of the granitic rocks. The post-metamorphic deformation would rearrange the thermal structure formed at the heat supply.

The Renge metamorphic complex in the Nokita area of Itoshima Peninsula, northwest Kyushu, was intruded by the Kitazaki and Itoshima granodiorites on the north and south at Cretaceous, respectively. The complex was recrystallized by thses intrusions and underwent significant deformation that belongs to flattening after the peak of contact metamorphism (Yamasaki & Ikeda, 2018). This study estimates the pressure-temperature condition preserved in pelitic rocks to evaluate the post-metamorphic deformation.

The pelitic schists in the study area are composed of leucocratic and melanocratic layers depending on the modal amount of biotite. The common constituent minerals are quartz, plagioclase, biotite. Garnet, muscovite, and K-feldspar locally occur. In addition, chlorite is present as veins and schistosity-forming mineral, which is interpreted as retrograde products.

Four pelitic schists were employed to estimate the metamorphic conditions. Garnet shows euhedral shape and so-called normal zoning where Mg increases and Fe and Mn decreases towards the rim. The composition of rim ranges such that Xalm=0.72-0.80, Xprp=0.09-0.12, Xsps=0.06-0.16, and Xgrs=0.04-0.06. On the other hand, that of core varies Xalm=0.50-0.66, Xprp=0.03-0.05, Xsps=0.24-0.40, and Xgrs=0.04-0.10. The Mg/Fe of rim and core ranges 0.13-0.15 and 0.06-0.08, respectively. Biotite also shows significant variation in composition, i.e., Ti of 0.15 - 0.46 based on 22 oxygen, and Mg/Fe of 0.44 - 0.76. The Ti content of biotite near chlorite is low as compared with that far from chlorite. Plagioclase is chemically homogeneous in one sample. The anorthite content shows southward increase from 0.23 to 0.42.

We chose the composition equilibrated at peak of the metamorphism such as the highest Mg/Fe in the rim of garnet, highest Ti in biotite and highest anorthite content in plagioclase. Geothermobarometry using garnet-biotite geothermometer (Ferry & Spear 1978) and a garnet-biotite-plagioclase-quartz geobarometer (Hoisch 1990) provide the metamorphic conditions of 590 °C, 1.4 kbar, 650 °C, 3.5 kbar, 770 °C, 4.2 kbar, and 650 °C, 2.8 kbar from south to north ,which corresponds to 5.3-16 km depth. The pressure and temperature vary by 2.8 kbar and 180 °C, respectively, within ca. 300 m distance. The lithostatic pressure relevant to 300 m thickness cannot explain the pressure difference of 2.8 kbar. The present result also supports the significant thinning deformation after the contact metamorphism.

Evidence of Partial Melting of Migmatitic Felsic Gneiss from Nagasaki Metamorphic Complex in Amakusa-Shimoshima, western Kyushu, Japan

*Yuki Mori[1], Takeshi Ikeda[2], Kazuhiro Miyazaki[3]

1. Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, 2. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, 3. Research Institute of Geology and Geoinformation, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

The Nagasaki Metamorphic Complex in Amakusa-Shimoshima is divided into the lower and upper units. The former and the latter are composed mainly of pelitic schists and gneisses with mafic and felsic composition, respectively. The upper unit is considered to have located at lower crust that was shortened due to ductile flow toward trench side (Miyazaki et al., 2013). The unit belongs to the high-pressure granulite facies and represents migmatitic mode of occurrence, which implies potential presence of melt that enhanced the ductile deformation. This study reports microstructural features indicative of partial melting in a felsic migmatitic gneiss.

The migmatitic felsic gneiss dealt with this study represents U-Pb zircon age of 125.8±1.8 Ma (Mori et al., 2018 JpGU). It is composed mainly of garnet, quartz, muscovite, zoisite and aggregate of fine-grained zoisite + albite + muscovite that is former plagioclase. Minor amounts of graphite, zircon, apatite, rutile, chlorite, and iron sulfide also occur. Tiny grains of hornblende are included in the rim of garnet. The matrix zoisite commonly includes epidote in the core. The epidote contains significant amounts of rare earth elements (REE) and is composed of Y-poor core and Y-rich rim. The garnet grains are roughly divided into two types of coarse- and fine-grained. The X_{Mg} [=Mg/(Mg+Fe)] of the coarse-grained garnet increases from the core to the rim and decreases at the extreme periphery, while that of the fine-grained garnet monotonically decreases from the core to the rim. The coarse-grained garnet represents Y-rich and P-poor core and Y-poor and P-rich rim whereas Y-poor and P-rich domain is dominant in the fine-grained garnet. A polyphase inclusion composed of chlorite + muscovite + quartz + $CaCO_3$ is found from the rim of coarse-grained garnet. The inclusion shows polygonal shape and has cuspate offshoots filled with chlorite or muscovite. Apatite is included in the core of the coarse-grained garnet but is not found from the rim. The fine-grained garnet and the rim of the coarse-grained garnet include Y-rich REE-epidote.

We applied Zr-in-rutile geothermometer (Ferry & Watson, 2007), garnet-hornblende geothermometers (Graham & Powell, 1984; Powell, 1985; Ravna, 2000), and hornblende-plagioclase geothermometer (Holland & Blundy, 1994). These results are consistent among them within their errors and represent 720 −770 ˚C as the peak condition. The pressure at the peak condition was estimated utilizing garnet-hornblende-plagioclase-quartz geobarometer of Kohn & Spear (1990), and we obtained the pressure of 9.1 −10.2 kbar.

The estimated condition lies above the melting reaction of zoisite + muscovite + quartz + water = kyanite + melt (cf. Schliestedt & Johannes, 1984). The polygonal shape of the polyphase inclusion in the rim of coarse-grained garnet could represent negative crystal of garnet. Combining the constituent minerals of the inclusion, it is likely that the polyphase inclusion was originally melt inclusion.

The concentration of yttrium and phosphorus in the rim of coarse-grained garnet is similar to that in fine-grained garnet. Based on the presence of melt inclusion in the rim of coarse-grained garnet, we

©2019. Japan Geoscience Union. All Right Reserved.

consider that fine-grained garnet nucleated during the partial melting with the formation of the rim of coarse-grained garnet. The Y-rich REE-epidote is in the matrix and included in the fine-grained garnet and the rim of the coarse-grained garnet, so we consider that Y-poor garnet and Y-rich REE-epidote coexisted with the melt. The lack of apatite inclusion in P-rich domain of both garnets may indicate that the phosphorus in P-rich domain in garnet was supplied by breakdown of apatite during the melting.

Microstructural Analysis of Quartz grains in Monomineralic and Polyphase domains: A case study from Main Central Thrust (MCT) Zone Mylonites, western Himalaya, India

*Shivaji Saha[1], Toru Takeshita[1], Subhajit Ghosh[2], Hari Bahadur Srivastava[3]

1. Department of Natural History Sciences, Hokkaido University, 2. Earthquake Research Institute, The University of Tokyo, 3. Department of Geology, Banaras Hindu University

Ongoing collision in the Himalayan orogeny causes crustal deformation owing to the thrust activity. Hence, the movement along the Main Central Thrust (MCT) enhances ductile deformation of the crust widely distributed across the orogenic belt. Therefore, detailed microstructural analysis is necessary to define the shear zone by the degree of strain intensification across the MCT. A study area along Madhmaheswar Ganga valley, Rudraprayag district, Uttarakhand, India, has been chosen. Purpose of this study is to perceive the heterogeneity of the deformational behavior of quartz grains in terms of thickness of quartz layers and other associated phases along with the understanding of fabric development with respect to the MCT. In this research, the lower Greater Himalayan Sequence (L-GHS) of *c.* 1.5 km thickness on the hangingwall side and upper Lesser Himalayan Sequence (U-LHS or Munsiari formation) of *c.* 4 km thickness on the footwall side of the MCT, has been studied.

Microstructural observations are essentially focused on the quartzo-feldspathic gneiss of the Munsiari formation and L-GHS. At lower Munsiari formation, Quartz microstructures are characterized by subgrain rotation recrystallization (SGR). Polygonal quartz grains with triple point junction indicate SGR followed by static grain growth. At upper Munsiari formation, lobate boundaries of quartz grains with sweeping extinction and deformation lamellae indicate high temperature grain boundary migration (GBM) overprinted by late stage low temperature deformation. Quartz grains in the lower GHS rocks are coarser than that of the Munsiari rocks and highly amoeboid in shape. High temperature deformation is evidenced by the presence of elongated sub-grains within these irregular grains.

To carry out further microstructural studies, 14 samples were selected for EBSD analysis. Quartz *c*-axis fabric from ~500-829 μm thick quartz-rich monomineralic layer shows a series of type-*II* crossed girdle fabrics with *Y*-maximum. Here, the quartz *c*-axes are aligned parallel to intermediate finite strain axis *Y*, revealing the intracrystalline deformation by active prism {10 -10} *a* slip system. In contrast, c-axis orientations obtained from thin monomineralic quartz layers (thickness ~72-163 μm) records girdles ranging from small circle girdles to type-*I* crossed girdle fabric with r-maxima. In this case, the rhombohedral plane of quartz is aligned parallel to the foliation plane (*XY*), which indicate basal (0001) *a* slip and rhomb {10 -11} *a* slip system activity. Thus, there is an effect of thickness of monophase layers on fabric development and, perhaps the role of other phases has a strong impact on the fabric development for thin monomineralic layers.

On the other hand, polyphase domains are characterized by the quartz grains totally surrounded by other phases. The size of recrystallized quartz grains within polyphase domain increases from ~64.4 μm in Munsiari to ~109 μm in L-GHS. C-axes orientations are random for the Munsiari samples. Whereas, C-axis fabric with point maxima is observed for the L-GHS samples. However, those fabric patterns are strengthened with increasing modal abundance of quartz.

©2019. Japan Geoscience Union. All Right Reserved.

The strength of the quartz *c*-axis fabric is quantified as a function of eigenvectors (λ_1 = maximum; λ_2 = intermediate; λ_3 = minimum) from *c*-axes orientation distribution. Following, Vollmer (1990), three end member fabric types are determined from these eigenvectors; those are point (*P*), girdle (*G*) and random (*R*). Then, by introducing cylindricity index (*B*) of Vollmer (1990), the variation in fabric strength of quartz LPO is shown as a function of strain localization throughout the Munsiari formation. Progressive increase in fabric intensity for both thin and thick monomineralic quartz layers indicate an increase in strain towards the MCT.

Tectono-thermal evolution of the Main Central Thrust (MCT) zone rocks of the Himalayan Crystalline Complex (*HCC*), Darjeeling-Sikkim Himalaya

*Subhajit Ghosh[1,2], Santanu Bose[2,3], Nibir Mandal[4], Arijit Laik[2]

1. Earthquake Research Institute, The University of Tokyo, 1-1-1 Yayoi, Bunkyo-Ku, Tokyo 113-0032, 2. Department of Geology, University of Calcutta, 35, Ballygunge Circular Road, Kolkata 700019, India, 3. Department of Geology, Presidency University, 86/1 College Street, Kolkata 700073, India, 4. Department of Geological Sciences, Jadavpur University, Kolkata 700032, India

The rheology of the Himalayan Crystalline Complex (*HCC*) laying above the Main Central Thrust (MCT), is the key boundary condition for all the tectonic models that deals with extrusion of lower crustal material. Therefore, it is important to understand the intricate relationship between the processes of crustal thickening, Barrovian metamorphism and strain localization in the high-grade rocks of the *HCC* that controls the rheology of a deforming wedge. Initially deformation was distributed and a series of repeated folding leads to crustal thickening and pro-grade metamorphism. The similarity between the peak metamorphic and peak deformation temperature, as documented by frozen high-temperature microstructures is indicative of this phase. The '*locked in*' deformation microstructures and syn-kinematic growth of metamorphic index minerals reveal that the MCT related shearing begins at or near the peak metamorphic condition (16-12 Ma), where grain size reduction by dislocation-controlled creep was the most effective mechanism for strain localization. The observed deformation microstructures and the available P-T data shows that the peak deformation and metamorphic condition progressively increases (~500 to >700˚C) towards the mountain interior. It is further evident that the now-exposed *HCC* begun to extrude under dominantly ductile mid-crustal condition at a temperature >700˚C, where the hotter mid-crustal rocks can flow in a viscous manner by melt enhanced depth-dependent ductile flow. Hence, initially the MCT represents a rheological and metamorphic boundary that separates material which can or cannot flow. Then with subsequent exhumation, cooling and strengthening of the *HCC* produced diffuse ductile shear zones along the same rheological boundary, where deformation was distributed for 4-6 km width (~ MCT zone). The base of the high strain zone is marked by base of the compressed reverse paleo-isograds that coincides with the SGR-GMB transition for quartz, leading to steep P-T gradient locally constrained within the MCT zone before it flattened in the migmatite gneisses. At further lowering of temperature (shallower depth), the MCT localized into narrow shear zone under dominantly brittle condition, transporting the entire *HCC* thrust sheets to the foreland.

Thermal structure and deformation history of the low-grade Sanbagawa belt in the central of Kii Peninsula and tectonic implications

*Ken Yamaoka[1,2], Simon Wallis[1], Hiroshi Mori[2]

1. University of Tokyo, 2. Shinshu University

The Sanbagawa belt in SW Japan is one of the best-documented regions of relatively warm subduction-type metamorphism and information from such regions are important to clarify our understanding of convergent plate margins. Much of the present knowledge is based on petrological studies in the higher grade parts of this belt. However, most of the Sanbagawa belt belongs to the lowest grade domain, the chlorite zone. The lack of reliable methods to determine the thermal structure in this low-grade zone has meant that information from the majority of the belt has been underrepresented. Development of the Raman carbonaceous material thermometer (RCMT) has opened up possibilities of determining the temperature structure of low-grade metamorphic domains such as the chlorite zone of the Sanbagawa metamorphism. Application of RCMT to pelitic rocks of the central Kii peninsula shows a progressive decrease in T from ~390 ˚C close to the northern boundary marked by the Median Tectonic Line (MTL) to ~270 ˚C ~7 km to the south and roughly constant thereafter. The thermal structure is not significantly affected by fault boundaries between different geological units. Meso and microstructural observations combined with strain analysis based on deformed shapes of detrital grains in metamudstone indicate a similar deformation history throughout the area and no correlation between strain and temperature gradients. These features can be used to asses possible models for the observed temperature rise. On this basis, we suggest the rise in T was not due to return flow of high T material in a subduction channel. We also conclude that the rise in T takes place over too narrow a distance to be explained as part of the expected thermal warping in a warm subduction zone. We find no evidence for heating related to the rise of magma or hot fluids. Shear heating along the MTL does provide a plausible explanation for the observed thermal structure compatible with all observations. One-dimensional thermal modeling shows that to account for the observed thermal structure requires slip rates of several mm/yr and relatively high coefficients of friction (μ=??). A similar result was reported from an area to the east but with a much more limited domain of elevated temperatures, probably due to late-stage thinning related to normal faulting. Our results imply that long-lived major crustal faults such as the MTL are at least locally associated with high stresses and are relatively strong. Evidence for the faults being weak at shallow depth implies there is a rapid decrease in strength over the upper few km of the MTL fault zone.

Antigorite Raman spectrum: a case study in Shiraga region of the central Shikoku, Sanbagawa metamorphic belt, SW Japan

*Kota Ando[1], Yui Kouketsu[1], Katsuyoshi Michibayashi[1]

1. Nagoya University

Serpentinites are important rocks and are associtated with water circulating in the earth's interior. However, it is difficult to estimate their metamorphic conditions because serpentine minerals are stable at wide P-T condition. In this study, we compared Raman spectrum of antigorite in different metamorphic grade samples and determined whether Raman spectrum could constrain metamorphic conditions of serpentinites. Serpentinites in this study have been sampled from Shiraga region of the central Shikoku, the Sanbagawa metamorphic belt, SW Japan. All samples experienced the metamorphic conditions in which olivine were formed by the dehydration reaction of antigorite with brucite. Some samples show retrograde antigorite formed during exhumation. Raman spectrum were measured from various sizes and textures of antigorite grains. Comparing full width at half maximum (FWHM) of Raman spectrum, we found that the prograde-antigorite had different features from retrograde-antigorite. As a consequence, FWHM of Antigorite Raman spectrum could be used to constrain the timing of antigorite formation.

A fluid inclusion study from the late Paleozoic retrograde eclogite from the Yunotani Valley of the Omi area, Hida-Gaien Belt, Japan

*Yuzuki Shinji[1], Tatsuki Tsujimori[1], Tatsuhiko Kawamoto[2]

1. Tohoku University, 2. Shizuoka University

Primary fluid inclusions trapped in subduction metamorphic rocks can provide direct information concerning composition and origin of slab-derived fluids. In order to investigate fluid signatures at the mantle wedge beneath forearc regions, we conducted microthermometry for primary fluid inclusions in both prograde eclogite-stage omphacite and retrograde blueschist-stage quartz, in the late Paleozoic retrograde eclogite from the Yunotani Valley of the Omi area, Hida-Gaien Belt, Japan. Note that the investigated blueschist-stage quartz forms a microvein along cracks of omphacite. The investigated eclogite occurs as mafic layers or lenses which are intercalated in metasedimentary rocks with the mineral assemblage paragonite + phengite + garnet ±glaucophane + quartz + rutile. Recent study confirmed that the retrograde blueschist-stage reached the pumpellyite stability field of P = ~0.62–0.70 GPa and T = ~280–320°C (Shinji and Tsujimori 2019 doi:10.2465/jmps.180716).

The primary fluid-inclusions in both omphacite and quartz are aqueous two-phase inclusions of liquid and vapor. Their molecular species in a liquid and gas phase were identified using micro-Raman spectroscopy. The fluid inclusions of the eclogite-stage omphacite are characterized by relatively high salinity of ~8.0–8.2 wt% NaCl equivalent and the brine freezing temperatures at ~-70°C suggests presence of divalent ions such as Ca^{2+} and/or Mg^{2+}. In contrast, fluid inclusion in blueschist-stage quartz shows relatively low value of ~2.4 wt% NaCl equivalent. The liquid phase of the fluid inclusion transforms completely into solid phases at ~-38°C, suggesting existence of the limited monovalent ions such as Na^{+} or/and K^{+} in the fluids.

Our preliminary data demonstrates that the pervasive fluids entrapped at prograde eclogite-stage and retrograde blueschist-stage had different chemical compositions. This suggests different fluid sources at eclogite and blueschist depth. Our observation is consistent with the different fluid compositions recorded in zoned lawsonite in Guatemalan eclogite (Hara et al. 2018 doi: 10.1016/j.lithos.2018.09.001). In our study, the existence of higher salinity fluids in the eclogite-facies conditions can suggest more effective transportation of the lithophile elements into the mantle wedge at deeper forearc regions.

Development of reaction-induced stress and permeability in MgO-H_2O system

*Hisamu Kasahara[1], Masaoki Uno[1], Atsushi Okamoto[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies, Tohoku University

Fractures are dominant flow path of fluid transport in the crust, and fluid flow through the fractures is important for the progress of fluid-rock interaction and material transport in the crust. The fractures enhance permeability in rocks, which has significant effects on the efficiency oil mining, geothermal development and Carbon dioxide Capture and Storage (CCS). Thus, the research on the fracture formations and associated permeability developments are increasingly important for geoscience and engineering.

Especially during fluid-rock interactions in the crust, hydration reactions increase solid-volume and generate stress. Recently such reaction-induced stress has been investigated as a new fracture generation process. For example, the fractures associated with reaction-induced stress are observed in serpentinized olivine (Jamtveit and Austrheim, 2010). In addition, the stress exceeding rock strength is reported from thermodynamic prediction (Kelemen and Hirth, 2012) and experimental measurements (e.g., Lambart et al., 2018). However, the existence of non-fractured rocks despite the volumetric expansion reaction (Centerrea et al., 2015) and the discrepancies between the experimental and theoretical values of reaction-induced stress have not yet been clarified. To understand the causes of these phenomena, it is important to constrain the controlling factors and the generation processes of reaction-induced stress. Therefore, we conducted direct measurements of reaction-induced stress and permeability development during hydration reactions, to clarify the relation between the reaction, stress generation, fracturing and permeability developments.

In our previous study, we measured the reaction-induced stress in MgO–H_2O system, and observed stress generation of approximately 40 MPa, exceeding common tensile strength of rocks. It is indicated that temperature dependence exists in stress generation behavior: the higher the temperature, the higher stress are generated and the stronger stress relaxation are observed after a peak stress. We also showed that this behavior can be explained by competition between reaction and deformation strain rate. This result was consistent to a certain extent with the result of $CaSO_4 \cdot 1/2H_2O$–H_2O system reported by Skarbek et al. (2018).

In this report, we aimed to clarify the influence of reaction and deformation rate on stress generation and the permeability development during volumetric expansion reaction. We conducted two experiments, the stress measurement experiments and the permeability experiments. In the former, experiments were conducted using pellets (ϕ=45–55%) of MgO powder as a starting material under conditions of approximately 80 to 120 ˚C and fluid pressure of approximately 0.100 MPa. The developments of reaction-induced stress were measured as a function of temperature. In the same experimental systems, the reaction and deformation rate were determined by measuring the strain and the reaction rate. In the latter, the experiment was conducted using the sintered MgO as a starting material under the conditions of approximately 100 to 300 ˚C, a fluid pressure of 0 to 10 MPa, and a confining pressure of 0 to 50 MPa. The permeability developments were measured under conditions of various temperatures, confining pressures and fluid pressures. From the results, we consider the relation between stress, fracturing and permeability and discuss the modes of rock fracturing and fluid transfer enhancement during hydration

Crystal orientation analysis of olivine in ultra-mylonite using TKD method: progress in spatial resolution from EBSD

*Yohei Igami[1], Katsuyoshi Michibayashi[2], Kakihata Yuki[2], Yui Kouketsu[2]

1. Institute of Materials and Systems for Sustainability, Nagoya University, 2. Graduate School of Environmental Studies, Nagoya University

Mantle, which is the dominant component consisting of the earth making up 80 %, is the key to understanding material cycle and/or formation history of the earth. The uppermost part of the mantle is composed of peridotite which is aggregate mostly of olivine [$(Mg,Fe)_2SiO_4$] grains. Olivine has orthorhombic crystal system and its mechanical property is anisotropic. Thus the olivine polycrystalline in peridotite shows various crystal-preferred orientation (CPO) patterns formed by share deformation processes (Karato et al., 2008). Therefore, the CPO pattern can be an indicator of deformation environment and is also used as a key parameter to estimate seismic anisotropy. Thus, the CPO is very important for tectonic geology.

To evaluate CPO of olivine, Scanning Electron Microscope equipped with Electron BackScatter Diffraction detector (SEM-EBSD) is widely used. The SEM-EBSD is a method to analyze crystal orientation using the Kikuchi diffraction pattern formed by the interaction between scattered electrons and lattice planes of sample surface. Recently, improvements of high-speed detectors and userfriendly computer programs have enabled automatic, rapid and easy EBSD mapping. Using the method, olivine CPO patterns in peridotite of various localities have been studied. However, effect of fine grains (<1 μm in diameter) might have been overlooked in such studies, because it is difficult to obtain clear EBSD pattern from sub-micrometric mineral grains.

On the other hand, it was reported that the Kikuchi pattern can be obtained also by transmitted electrons through thin film (~100 nm) using SEM (Keller and Geiss, 2011). This method, which is called transmission EBSD (t-EBSD) or transmission Kikuchi diffraction (TKD), can restrict area in which electrons are scattered and improve spatial resolution even by the conventional SEM-EBSD system. In this study, therefore, we tried CPO analysis for ultra-mylonite using the TKD, to investigate usefulness of this method for tectonic geology.

The analyzed sample is an ultra-mylonite from Marion Transform fault by PROTEA5 cruise. The sample contains amphibole and olivine as porphyroclasts and fine-grained matrix, with a small amount of orthopyroxene and spinel (Kakihata et al., 2018, AGU). We obtained EBSD map from petrographic-thin section of this sample, and then an ultra-thin section for TKD was made using a focused ion beam apparatus(FIB, HITACHI FB2100). Finally, TKD map of the ultra-thin section was obtained. For both of the EBSD and TKD analyses, the same SEM-EBSD system (HITACH, S-3400N + OXFORD Instruments, NordlysNano) was used.

As the result, we successfully obtained TKD map dataset, in which patterns are indexed even at the region over boundaries between sub-micrometric olivine grains. This TKD map which was obtained by W-filament gun SEM is clearer than the FESEM-EBSD map we obtained from the same sample. The TKD map dataset was able to be processed by the same software with EBSD (following configuration parameters suggested by Miyake et al., 2016, JAMS). The processed TKD map of olivine displays CPO of *b* -axis perpendicular to shear plane. In addition, spatial distribution of sub-grain boundaries and irregular shaped grains is well displayed. TKD requires much less time and labor than TEM analyses in such orientation analysis throughout the ultra-thin section, although TEM is of course much better in spatial resolution or detailed crystallographic/chemical analyses. The TKD should be useful as a pre-analysis before the detailed TEM analyses for polycristalline samples such as ultra-mylonite. Application of the

Elucidation of effective diffusion coefficient along grain boundaries by hydrothermal experiment using low porosity rocks

*Naoki Sugisawa[1], Masaoki Uno[1], Noriyoshi Tsuchiya[1]

1. Graduate school of environmental studies Tohoku university

Elucidation of the time scale of the fluid activity recorded in the rock is important for understanding the actual condition of fluid activity in the crust. In recent years, it has become possible to estimate time-scale of fluid activity in the crust from isotopes and element concentration profile of natural metamorphic rocks. (e.g.John et al.,2012) To estimate the time-scale, the effective diffusion coefficient (Deff) is important as an indicator of diffusion via grain boundary fluid. It is known that the effective diffusion coefficient depends on the porosity (Φ) of rock and time due to grain boundary diffusion. (e.g.Boving and Grathwohl, 2001) The effective diffusion coefficient is conventionally substituted by the product of self-diffusion coefficient (D_{self}) and porosity ($D_{self}\Phi^{x}$). However, the effective diffusion coefficient varies depending on the power factor (x) of the porosity, and the estimated timescales depend significantly on the power factor (x). Therefore, we clarified the relationship between porosity vs effective diffusion coefficient and confining pressure vs effective diffusion coefficient using hydrothermal experiment under crustal condition with various low porosity granite. In this paper, we mention the following two experiments as the first step : (1) Fluorapatite (F-Ap) substitution reaction (2) Determination of effective diffusion coefficient using low porosity hydroxyapatite sintered body (OH-Ap).

In this study, natural F-Ap from Mexico and OH-Ap (Wako Pure Chemical corporation) were used as starting materials. In experiment (1), first, natural F-Ap was cut in the c-axis direction. And it was put in the gold tube with 0.0006-6 M HCl or 0.01-1 M NaOH two types solution. After that gold tube was putted in the batch type hydrothermal equipment and conducted hydrothermal experiment under 400 ℃, 50 MPa for168 hour. In experiment (2), OH-Ap powder was pressed under 200 MPa for 30 minutes and then the porosity was varied by sintering at deference temperature from 1500 ℃ to 1200 ℃. After cooling, the porosity was measured by the wet method. NaF solution saturated at room temperature and OH-Ap sintered body was added to the same apparatus as above and a hydrothermal experiment was conducted at 300 ℃ and 20 MPa for 168 hours. After the experiment (1) and (2), the samples were evaluated by quantitative analysis and mapping analysis with EPMA in both cases. Before the experiment, phase diagram of apatite under experimental temperature and pressure was prepared using SUPCRT92, GEMS to expect these reactions.

As a result of the hydrothermal experiment, in the experiment (1), it is suggested that the OH in F-Ap is substituted with Cl under HCl solution and the NaOH substitutes OH for F. In experiment (2), F diffusion zoning was generated along the clacks in the sintered OH-Ap, and an effective diffusion coefficient was calculated using diffusion equation. There was no apparent porosity dependency of the effective diffusion coefficient at porosities 1.68-5.83%. The effective diffusion coefficient obtained in this experiment was equivalent to the self-diffusion coefficient of fluorine multiplied by the porosity 2.26 power. ($D_{eff} = D_{self}\Phi^{x}$) (e.g. Oelkers and Helgeson, 1988) However, the porosity measured by the wet method needs to be investigated because it contains the cracks generated in making the sintered body. (e.g. mercury porosimeter)

Based on the above experimental results, it is discussed that the influence of temperature, pressure, solution condition, on substitution of monovalent halogen and hydroxyl group between apatite and fluid and relationship between porosity and effective diffusion coefficients.

Seismic slipping events recorded in a fault gouge zone: evidence from the Nojima Fault drill holes, SW Japan

*Aiming Lin[1], Takafumi Nishiwaki[1]

1. Department of Geophysics, Graduate School of Science, Kyoto University

It is well known that large intra-continental earthquakes occur repeatedly along mature active faults and that the seismic slip may be recorded by cataclastic rocks, including fault gouge zones, that form at shallow depths in the upper crust (e.g., Lin, 2008). A fault gouge zone, bounded by a principal fault plane, is considered to represent the seismic slip zone that accommodates most of the accumulated fault displacement in the seismogenic regime. Therefore, studies of fault gouge zones along mature active faults would provide important information for reconstructing the long-term seismic faulting behavior of such faults, as well as providing new insights into the individual seismic slipping processes of active faults and their paleoseismic histories.

In the present study, we focused on the structural features of the fault gouge zone observed in drill cores acquired from nine holes that were drilled through the Nojima Fault (NF) at different depths from ~260 to 900 m at the Ogura site (Lin and Nishiwaki, 2019). Drilling investigations and structural analyses of drill cores reveal that a ~60 m wide fault damage zone containing a 10–30 cm thick fault gouge zone developed along the Nojima Fault (NF), on which the 1995 M_w 6.9 Kobe (Japan) earthquake occurred. The fault gouge zone was observed at depths of ~260 to 900 m in nine drill holes that intersected the NF. Our findings show that i) the fault gouge zone observed at different depths in the nine drill cores is the principal fault slip zone of the NF, ii) the fault gouge zone can be divided into 11–20 thin layers of different color, and iii) the individually colored layers contain different color breccias of fault gouge that are offset and/or cut by cracks and crack-filled calcite and quartz veinlets. Our results reveal that the fault gouge zone probably records more than 11–20 paleoseismic faulting events along the NF during the late Pleistocene-Holocene.

Evolution of fluid chemistry during basalt-water and basalt-seawater interactions revealed by hydrothermal flow-through experiments

*Yusuke Netsu[1], Atsushi Okamoto[1], Nobuo Hirano[1], Masaoki Uno[1], Noriyoshi Tsuchiya[1]

1. Tohoku University, Graduate School of Environment Studies

Recently, several deep drilling projects for exploiting the supercritical geothermal reservoirs in the world. For example, in 2017, the Island Deep Drilling Project (IDDP-2) reached 427 ˚C and 34 MPa, which exceeds the critical point of seawater. The drillcores revealed that the intense water-rock interaction under greenschist to amphibolite facies metamorphism. Although such deep drilling provides us direct information of active metamorphic processes. however, it is still unclear whether conventional petrological analyses could apply to reaction processes in open systems at high temperature hydrothermal alteration at seafloor. There have been few experiment studies on the water-rock interaction under supercritical conditions with some exceptions (Yardley et al. 2014).

In this study, we conducted hydrothermal flow-through experiments on the basalt-H_2O, basalt-NaCl.aq, basalt-seawater systems under the sub or supercritical conditions. The temperature and pressure were set to be 400 ˚C and 37 - 39 MPa, and the input solutions was flowed at constant flow rate (0.1 ml/min) for 1 –6 days. We placed a powder of MORB (Island, 250-500 μm), which is composed of plagioclase (Pl), olivine (Ol) phenocrysts and clinopyroxnene (Cpx), Pl groundmass, with lessor amount of volcanic glass, in a Ti inner tube (L=275 mm, I.D.= 4.35 mm). During the run, the solution was continuously pumped into the reaction vessel, and the output solution was collected every few hours. The concentration of Si, Al, Ti, Fe, Mg, Ca, Na, and K in the output solution was analyzed by ICP-AES.

In the basalt-H_2O experiment, the products varied with distance from the inlet. At the inlet and middle of tube, Ca-rich Pl (An# 0.98) formed around primary Pl grain with producing abundant pores, whereas chlorite was dominantly formed around Ol and Pl at the middle to outlet of inner tube. The solution chemistry evolves with time: Si concentration was initially high and then decreases toward the steady state. pH, Na and Al increases with decreasing Si, whereas the Ca, Mg and Fe concentrations were low. These features indicate the dissolution of volcanic glass at the initial stage, and then the solution chemistry was controlled by preferential leaching of albite component of plagioclase.

In the basalt-saline water (2.5 wt% of NaCl) experiment, we observed pH rises accompanying the decrease Si concentration, indicating the leaching of Si and dissolution of Pl similar to the basalt- H_2O experiment. One of the large differences between the two experiments was the extremely high Na concentration of saline water, resulting in the leaching of Ca (Ca concentration of the output solution was 40 to 80 times that of H_2O experiment), or breakdown of Ca-bearing minerals. In the basalt reaction with artificial seawater, which contains a lot of Mg^{2+}, SO_4^{2-}, CO_3^{2-} ions, revealed that the significant amount of precipitation of sulfate minerals occurred in the pre-heating parts of the vessel (before pass through the fluid reached the basalt sand), and that chlorite was formed throughout the reaction tube, which clogged the reaction vessel in a day. In contrast to the H_2O and saline water experiments, pH decreased to 3. In spite that we conducted the experiments with the same rock sample (basalt sand) and the same P-T conditions, the products and solubitions after the water-rock interaction were quite different in response to the input solutions, probably because the open system, in which new fluids are continuously supplied, is never rock-buffered. We will analyse the complicated reaction systems which control te evolution of solutions and minerals, based on the analyses of speciation of aqueous species, saturation of minerals

3D microstructural analyses of fault rocks using CT and μCT scanning techniques

*Bingcheng Liu[1], Aiming Lin[1], Takafumi Nishiwaki[1]

1. Kyoto University

Meso- and microstructures of fault rocks including fault gouge developed in the active fault shear zone can reflect the deformation processes of fault motion and faulting mechanisms (Lin, 2008). Therefore, the study on structural features of fault rocks may provide new insights for understanding the nature of active faults. However, it is difficult to understand the spatial variation of microstructures of fault core zone based on traditional methods using two dimensional images under naked-eye and microscopic observations. Accordingly, it is necessary to develop an analytical method for three dimension (3D) analysis for understanding the spatial variation and internal structures of fault core zone. Computed tomography (CT) apparatus with micro-CT (μCT) accessories is a powerful tool which allows non-destructive 3D X-ray imaging and analyzing the spatial and internal structures within non-transparent objects, mainly determined by variations in density, chemical composition (effective atomic number) as well as thickness (Cnudde, 2005).

In this study, the CT and μCT imaging techniques are exploited to observe the 3D internal structures of a series of representative fault rocks: 1) pseudotachylytes of different origins (melting and crushing), and 2) cataclasitic rocks including fault gouge, fault breccia and cataclasite, by utilizing two types of scanning apparatuses (Bruker microCT, 2014): 1) μCT flat panel (FP), and 2) μCT charge coupled device (CCD). The samples of pseudotachylyte are from Fuyun, NW China (Lin, 1994), Ohsumi, Japan (Fabbri et al., 2000), and Musgrave Mt, Australia (Lin et al., 2005), respectively. The samples of fault gouge were acquired from two typical active fault zones in Japan: The Nojima Fault and Arima-Takatsuki Tectonic Line, SW Japan (Lin and Nishiwaki, 2019). The FP analysis shows that 1) the flow structures within the melting-origin pseudotachylytes are denoted by parallel colored glassy matrix layers with numerous rounded quartz clasts and quartz-filled amygdules which are oriented along the flow layers, and 2) chilled margins are characterized by fine-grained microlites orientated parallel to the margins. The 3D scanning images show that the layering structures developed within the fault gouge and fault breccia zones which are marked by sharp colored boundaries, oriented clasts and fine-grained matrixes. Our results demonstrate that 1) the CCD imaging makes it possible to observe sub-micron and even nano-scale 3D microsturctures fault rocks without destruction, and 2) μCT imaging can be further combined with traditional methods (such as optical microscope and SEM observation) to determine the spatial variations for both the meso- and microstructures and chemical compositions of fault rocks.

Dissolution kinetics of forsterite olivine at >200 ˚C: implication for the kinetics of serpentinization.

*Ryosuke Oyanagi[1], Tatsu Kuwatani[1], Katsuhiko Suzuki[1]

1. Japan Agency for Marine-Earth Science and Technology

Serpentinization (hydration of mantle peridotite) gives significant changes to both chemical and physical properties of the oceanic lithosphere. Several studies suggested that the rate of serpentinization is maximized at 250-300˚C, and the rate-limiting process of serpentinization is the dissolution of primary mineral (e.g., Malvoisin et al., 2012). Therefore, the dissolution rate of olivine at 250-300˚C is consequently a critical parameter to understand the progress of serpentinization in the oceanic lithosphere. However, the olivine dissolution rates at > 150˚C have never been measured (Rimstidt et al. 2012), and the olivine dissolution rate extrapolatory calculated at 300˚C was inconsistent with the olivine serpentinization kinetics (Malvoisin et al., 2012). Towards the improved understanding of serpentinization kinetics, measuring dissolution rates of olivine as a function of solution composition and the temperature is required.

In this study, the dissolution rate of natural olivine ($(Mg_{0.91}, Fe_{0.09})_2SiO_4$) was measured at 200-400 ˚C and 50 MPa using a flow-through reactor (Suzuki et al., 2015). A 0.5 mol/kg NaCl solution was introduced at a constant rate of 2.0 mL/min during experiments. A preliminary experiment revealed that steady-state dissolution rate of olivine at 200 ˚C and far-from-equilibrium conditions was ca. -4.8 [mol/m^2/s] in log units. The obtained dissolution rate was consistent with the extrapolated dissolution rate (log_{10}(Rate) = ca. -4.72 [mol/m^2/s]), which was extrapolated from their pH-temperature dependence at 25-150 ˚C (Rimstidt et al., 2012). Based on dependences of temperature, salinity, and ΔG on dissolution rate, the timescales on hydrothermal alteration of peridotite will be discussed.

Early Paleozoic subduction-zone metamorphism in Japan: A geochronological reappraisal of Kitomyo Schists

*Shota Matsunaga [1], Tatsuki Tsujimori[1], Atsushi MIYASHITA[2], Shogo Aoki[3], Kazumasa Aoki[3]

1. Tohoku University, 2. Seikei University, 3. Okayama University of Science

Early Paleozoic subduction-related high-pressure metamorphic rocks have been reported from the Kitomyo Schists of the Kurosegawa Belt (Maruyama and Ueda 1975 [doi: 10.2465/ganko1941.70.47]) and the Fuko Pass Metacumulates (FPMC) of the Oeyama Belt (Tsujimori and Liou 2004 [doi: 10.1111/j.1525-1314.2004.00515.x]). In order better to understand the earliest subduction zone record of the ‘proto-Japan’, we revisited the Kitomyo Schists petrologically and gecohronologically. The metasedimentary sample is a well-deformed, quartzo-feldspathic mica schist, with the mineral assemblage of garnet + clinozoisite + phengite (Si p.f.u. = 3.3–3.5) + quartz + albite. Euhedral grains show distinct prograde chemical zoning in spessartine decrease toward the rims. The lack of biotite, oligoclase and paragonite indicate that the schist underwent a HP intermediate type metamorphism. The metabasaltic rock is a well-deformed, amphibolite. Although the amphibolite was overprinted severely at a greenschist-facies condition, relict barroisitic amphibole [B]Na (Na in the B-site) = ~0.69 and rutile, indicating HP metamorphism. LA-ICPQMS and HR-SIMS zircon geochronology yielded 445.5 ±3 Ma for the timing of HP intermediate type metamorphism of the Kitomyo Schists. Metamorphic zircon in metasedimentary sample is characterized by lower U (117–132 μg/g) and lower Th (34–143 μg/g) than detrital magmatic zircons. Our reapproval suggests that the Kitomyo Schists formed in an Early Paleozoic subduction zone with geothermal gradient in the order of ~15°C/km. Such a relatively high geothermal gradient in the subduction zone has produced the HP intermediate type metamorphism. The earliest subduction record in the ‘proto-Japan’ was not ‘cool’ enough to produce blueschist.

Dating a 'princess': U–Pb age determination of 'nunakawaite' (strontio-orthojoaquinite)

*Tatsuki Tsujimori[1], Tomomi Hara[1], Yuzuki Shinji[1], Tomohiro Ishizaka[1], Hiroshi Miyajima[2], Jun-Ichi Kimura[3], Shogo Aoki[4], Kazumasa Aoki[4]

1. Tohoku University, 2. Fossa Magna Museum, 3. JAMSTEC, 4. Okayama University of Science

'Nunakawaite' (strontiojoaquinite) is an orthorhombic variety of strontiojoaquinite [$Sr_2Ba_2(Na,Fe)_2Ti_2[Si_4O_{12}]_2O_2(O,OH)_2 \cdot H_2O$]; it is a rare joaquinite group mineral that is only found in a riebeckite-bearing albitite in the serpentinite-matrix mélange of the Itoigawa–Omi area. The mineral was originally named after 'Princess Nunakawa' (*nunakawa hime*) in the Japanese Shinto mythology '*Kojiki*'.

'Nunakawaite' is characterized by remarkably high Ba, Zr, Nb, Zn, LREEs, MREEs, and enriched in U (35.8–721 $\mu g \cdot g^{-1}$), Pb (2.2–31 $\mu g \cdot g^{-1}$), and Th (7.42–2365 $\mu g \cdot g^{-1}$). LA-ICPMS analyses show highly variable U/Pb ($^{238}U/^{206}Pb$ = 9.245–68.98) and Pb ($^{207}Pb/^{206}Pb$ = 0.0758–0.756) isotope ratios, and the scattered trend define an isochron line with a lower intercept at 89.19 ±1.07 Ma. The 'nunakawaite' U–Pb age confirms that the 'nunakawaite'-hosted riebeckite-bearing albitite formed at late Cretaceous. This implies that the serpentinite-matrix mélange unit with early Paleozoic jadeitites and late Paleozoic blueschist, eclogite and amphibolite was reactivated by a significantly younger tectonic event.

In-situ Sr-Pb isotope analyses show two different isotope trends between Sr-rich accessory minerals in riebeckite-bearing albitite ('nunakawaite' and ohmilite) and those in jadeitite (itoigawaite, stronalsite, vesvianite, Sr-rich epidote). The Sr-Pb isotopes also support the idea that the riebeckite-bearing albitite formed by a fluid-induced metasomatic event different from the jadeitite-forming metasomatism at early Paleozoic. The formation of riebeckite-bearing albitite at ~90 Ma is coeval with late Cretaceous granitic intrusion of the Omi area (youngest zircon U–Pb: 90.8 ±1.1 Ma: Nagamori et al. 2018). The granitic intrusion might have acted an important role in the formation of 'nunakawaite'. In other words, reactivation of metasomatic mineralization in the Paleozoic serpentinite mélange is recorded in the Cretaceous riebeckite-bearing albitite.

Modeling of the progressive evolution of subducting slab composition by sparse modeling

*Kenta Yoshida[1], Tatsu Kuwatani[1,2], Kenta Ueki[1], Ryosuke Oyanagi[1], Shotaro Akaho[3]

1. Japan Agency for Marine-earth Science and Technology (JAMSTEC), 2. PRESTO, Japan Science and Technology Agency, 3. National Institute of Advanced Industrial Science and Technology (AIST)

The progressive evolution of subducting rocks under intermediate high-*P/T* type metamorphism is modelled by using thermodynamic calculation combined with mass-transfer calculation. On the basis of non-negative matrix factorization analysis, Yoshida et al. (2018 J. Metamorph. Geol.) pointed out the evolutional change of the composition of metapelites collected from the Sanbagawa metamorphic belt. The evolutional change can be approximated as the increase of stoichiometric garnet, which may have resulted from the fixation of garnet and the effusion of other components by high-temperature aqueous fluids. To model this progressive compositional evolution more quantitatively, we performed mass-transfer calculation to determine a specific reference frame of the evolutionally-changing whole-rock compositions. Generally, mass-transfer calculation defines one or multiple immobile elements on the basis of petrographic observation, common knowledge of mobility of elements, deviation of the concentration among the dataset used, and so on (e.g., Baumgartner and Olsen, 1995; Ague 2011). The Data-driven Isocon analysis, newly proposed method applying a sparse modeling approach, is designed to determine reference frame of mass-transfer being mostly free from the arbitrariness to choose immobile element(s), and also applicable for the case where no elements can be assumed as a completely immobile element (Kuwatani et al., 2019 in this meeting M-GI33). This new method defines a reference frame of a series of dataset on the basis of the data structure, finding a least-mobile (not necessary to be “immobile”) element. To figure out the mass gain/loss behavior of the subducting metapelites, applying the Data-driven Isocon analysis is suitable because (1) the dataset show weak but mostly monotonous compositional trend (Yoshida et al., 2018); (2) it is difficult to assume a specific immobile element on the basis of the petrographic observation provided previously. We performed the Data-driven Isocon analysis to the major component dataset of the metapelites collected from the Sanbagawa metamorphic belt of the central Shikoku (Goto et al., 1996). The Isocon analysis indicated a total of 6% of mass loss during the progressive metamorphism, which is characterized by the decrease of Na and Si and the increase of divalent cations assuming Al as the least-mobile element. This result indicated that the evolutional change of the Sanbagawa metapelites is characterized not only by mass loss possibly because of the high-temperature fluid, but also some addition of mafic components. Among the high metamorphic grade zone (> garnet zone) of the relevant area, common existence of the ultramafic blocks are observed, suggesting the previous contact with the wedge mantle (Aoya et al., 2013). The addition of the mafic components may have originated from the material transfer from the ultramafic bodies. On the basis of actual mass loss obtained from the Isocon analysis and the thermodynamic modelling, the water production rate can be calculated (e.g., Dragovic et al., 2018). From the chlorite zone (approximately 350 degC, 0.5 GPa) to the oligoclase-biotite zone (approximately 610 degC, 1.0 GPa), water production rate of 64 kg/m3/Myr, being consistent with the previously indicated values (6-90 kg/m3/Myr: Peacock, 1989; 5-20 kg/m3/Myr: Lyubetskaya and Ague, 2009), was obtained.

Bayesian statistical evaluation method for detrital zircon geochronology: Applications

*Tan Furukawa[1], Tatsuki Tsujimori[2], Shogo Aoki[3], Kazumasa Aoki[4]

1. Tohoku University, Department of Earth Science, 2. Tohoku University, 3. Faculty of Biosphere-Geosphere Science, Okayama University of Science, 4. Department of Applied Science Okayama University of Science

Detrital zircon geochoronology is an essential method for determining the provenance and maximum depositional age of sedimentary and metamorphic strata. The age distribution is conventionally evaluated by using histograms. However the lack of the statistical verification of the histograms can cause misunderstanding of data. In order to overcome the raised statistical issues, we established new statistical evaluation method to evaluate distribution for detrital zircon ages, based on Bayesian Statistics (Furukawa and Tsujimori, 2019 JpGU, session M-GI33). As the application of our new statistical evaluation method, LA-ICPMS U-Pb dating for detrital zircon separates from the Carboniferous lawsonite-bearing metagreywacke of the Osayama serpentinite mélange (OSM) and the Cretaceous arkose sandstone of the Akaiwa Formation (AFS), Tetori Group was conducted.

The OSM of the Renge Belt tectonically overlies the pre-Triassic geotectonic units of the Chugoku Mountains (e.g., Tsujimori 1997 Min. Mag.; Tsujimori and Itaya 1999 IAR). The geological and lithological features are similar to those of late Paleozoic blueschist-bearing serpentinite mélange units of the Kurosegawa Belt in Shikoku, Kyushu and Kii Peninsula. Our new data shows that the OSM zircons show at least bimodal age distributions at ~500 Ma and ~1,100 Ma with 95% certainty; the group of the oldest concordant ages reaches 3,300 Ma and the youngest concordant age was 412 Ma.Comparison with existing data in the literatures (e.g. metasediments in the Kii Peninsula: Yoshimoto et al. 2013 JMPS), our Bayesian-based statistical evaluation shows a strong similarity.

We also applied our new evaluation method to the Tetori Group sandstones. The youngest grain yields 187 Ma, and the oldest concordant age was 2,940 Ma. Our evaluation found statistical 'discrepancy' with more than 90% certainty between our AFS data and the existing data of the Itsuki Formation (Kawagoe et al., 2012 Mem. FPDM), which stratigraphically occupy higher portion of the AFS and unconformably overlies the AFS. Throughout the two applications, we introduce how our new statistical evaluation works and its advantages in geological sciences.

3D structural analysis using X-ray Computed Tomography technique: a case study for fault rocks from the Nojima Fault, southwest Japan

*Takafumi Nishiwaki[1], Aiming Lin[1], Bingcheng Liu[1]

1. Kyoto University

Fault rock structures in active fault shear zone can contain important information of seismic slip mechanism (e.g. Lin et al, 2013; Lin and Nishiwaki, 2019). The micro- to macro-structural characteristics of fault rocks formed pass entirely throughout faulting periods, resulting in a broad suite of deformation processes being recorded by deformation structures and textures in spatial within the fault zone (Lin, 2008). Therefore, to understand the spatial variation of meso- and microstructures of fault shear zones, it is important to analyze the three dimensional (3D) images of fault rocks.
In this study, we conducted the 3D structural analysis using X-ray computed tomography (XCT) technique for the cataclastic rock samples including fault gouge obtained from the scientific drilling project "Drilling into Fault Damage Zone (DFDZ)" penetrated throughout the Nojima Fault (NF) Zone that triggered the 1995 M_w 6.9 Kobe earthquake. XCT technique is a non-destructive imaging analysis using CT-value, a function of density and chemical composition. Drilling investigations and 3D structural analyses of drill cores reveal that a ~60 m wide fault damage zone containing a 10–30 cm thick fault gouge zone developed along NF (Nishiwaki et al., 2018; Lin and Nishiwaki, 2019). The fault gouge zone consists of many different color gouge layers 1-2 mm to ~10 cm thick in both sides of the fault plane. In the gouge layer, there is foliations oriented parallel or sub-parallel to the boundaries of each gouge layer. XCT analysis shows the 3D structural features as followings: 1) the main fault plane shows a sharp boundary between two fault gouge layers and cut or offset all other fault gouge layers and fragments, 2) foliations developed within individual fault gouge layers defining the composite planer structures on the X-Z section which show a right-lateral shear sense as that inferred from the topographical and geological evidence, and 3) fine-grained materials were injected into the cataclastic rocks and formed veinlet network structures with complicated spatial variation. These results indicate that the XCT imaging technique is a powerful tool to study 3D deformational structures and textures of fault rocks combining with conventional structural analysis.

High- and low-stress subduction zones recognized in the rock record

*Kazuhiko Ishii[1], Simon Richard Wallis[2]

1. Department of Physical Science, Graduate School of Sciences, Osaka Prefecture University, 2. Department of Earth and Planetary Science, Faculty of Science, The University of Tokyo

Knowledge of the frictional strength along subduction plate boundaries is an essential part of understanding the conditions necessary for plate tectonics, the processes leading to great earthquakes occur along subduction megathrusts and the thermal structure of subduction zones. The frictional strength of faults increases with depth until ductile deformation becomes dominant and is usually expressed as the ratio of shear to normal stress known as the coefficient of friction, mu or the apparent coefficient, mu', when the effects of fluid pressure are taken into account. Lamb (2006) uses force balance for forearc domains to infer mu' = 0.03-0.09 along subduction boundaries. Gao and Wang (2014) infer mu' = 0.02-0.13 based on the comparison between heat flow data and numerical modeling, while England (2018) estimates relatively uniform values mu' = 0.05-0.07 from analytical modeling of heat flow data. In addition, a global 3D thermo-mechanical model presented by Osei Tutu et al. (2018) suggests the average mu' along plate boundaries is required to be <= 0.05 to match the observed present-day plate motion and net rotation.

The published estimates of mu' for subduction boundaries are significantly lower than Byerlee's Law (mu' ~ 0.4, assuming hydrostatic fluid pressure) and closer to values published for seismic slip rates with mu' ~ 0.1 (Di Toro et al., 2011). However, estimates for different subduction zones or obtained by different methods show variations over an order of magnitude. It is desirable to obtain direct estimates of shear stresses from ancient subduction zones both as an independent test of the suggested values and because if high- and low-stress subduction zones can be identified in the ancient record then observations of the associated geology can help identify those characteristics that are responsible for differences in shear strength along subduction zone boundaries.

Thermal modelling shows that high- and low-stress subduction zones can potentially be recognized in the ancient record based on the shape of the prograde P-T path in the forearc region. For all but very young and very slowly subducting slabs, high-stress subduction can be distinguished by curved P–T paths with higher P/T gradients at greater depths. Low-stress subduction over the same domain results in straight paths.

The Cretaceous Sanbagawa belt of SW Japan records metamorphism developed as a result of rapid (20-24 cm/yr) subduction of the Izanagi plate with a slab age of around 60 Ma. The prograde P-T paths show the characteristics predicted for high-stress subduction. Comparisons with thermal modelling suggest an apparent coefficient of friction, mu', of > 0.11, and the corresponding peak shear stresses are ~60 MPa.

Prograde P–T paths and geochronological information from high grade blocks of the Franciscan Complex, USA, indicate rapid cooling during the initial 10-20 Myr subduction with low mu' <= 0.02.

P–T paths in subduction-type metamorphic belts have the potential to be used as paleo stress indicators. Examining differences between high- and low-stress subduction-type metamorphic belts can help determine what controls the strength of different subduction boundaries and assess the potential for

great earthquakes in modern settings.

High-temperature Raman spectroscopic study of CO_2-containing melanophlogite

*Masami Kanzaki[1]

1. Institute for Planetary Matereials, Okayama University

Introduction: Melanophlogite is one of natural silica minerals with a clathrate structure. The structure has two kinds of cages which can host small guest molecules such as CH_4, CO_2, N_2 and H_2S. These are M^{12} and M^{14} cages correspond to pentagondodecahedral [5^{12}] and tetrakaidecahedral [$5^{12}6^2$] units made of 5- and 6-membered SiO_4 rings, respectively. Previous crystal structural studies suggested that CO_2 is mostly locating in larger M^{14} cage. A few years ago, we found a very intense and broad peak below 100 cm^{-1} in CO_2-containing melanophlogite. To clarify the origin of this peak in relation with CO_2 guest molecule, heat treatment experiments and in-situ high-temperature Raman spectroscopy measurements were conducted up to 1100 ^{o}C.
Experimental: Micro-Raman spectra were obtained using a home-built Raman system made of single-monochromator, CCD detector and Ondax SureBlock filters for low frequency measurement. The heat treatment was conducted using a muffle furnace, and the in-situ study was conducted with a wire-heater cell. Natural shperical single crystals from Fortunillo, Italy were crushed and small fragments were used for the experiments.
Results and discussion (origin of low-freq. peak): For the heat treatment experiments, nearly CO_2-free melanophlogite was obtained at 950 ^{o}C for 6 h, judging from intensities of CO_2 vibrational peaks (Fermi diad). Simultaneously, the low-frequency peak nearly disappeared. For shorter time durations or lower treatment temperatures, CO_2 vibrational peaks and low-frequency peak were still visible. We found that CO_2 vibrational peaks of the heat treated samples were split.
For the in-situ study, integrated total intensity of CO_2 vibrational peaks started to drop at around 450 ^{o}C, and simultaneously the low-frequency peak intensity decreased. These peaks completely disappeared at 1100 ^{o}C, while melanophlogite itself remained intact. Thus, it was concluded that the low-frequency peak is originated from CO_2 molecules, not from melanophlogite structure. Librational and translational modes of CO_2 molecules in the cages of melanophlogite would be responsible for the low-frequency peak. Thus, degassing behavior can be studied by monitoring both the low frequency band and the vibrational peaks.
(vibrational peak splitting): At about 450 ^{o}C, we noted that the vibrational CO_2 peak started to split (or more precisely, new peak appeared at slightly higher frequency and grew with temperature while the original peak became weaker). This splitting is partly quenchable, as demonstrated in the heat treated sample mentioned above. Vibrational peak splitting has been reported for CH_4 and H_2S in melanophlogites, and has interpreted as occupancy of those molecules in both M^{14} and M^{12} cages. Thus, peak splitting observed in our study can be interpreted similarly. No splitting of CO_2 has been reported before, except one report at very low temperature. From those observations, we speculated that at above 450 ^{o}C, CO_2 molecule is able to migrate from original M^{14} cage to next M^{14} or M^{12} cages. Because M^{14} cages make an infinite chain by sharing 6-membered rings, migration of CO_2 from M^{14} to M^{14} cages through the 6-membered ring will contribute to long-range diffusion (i.e., degassing). On the other hand, migration of CO_2 from M^{14} to next M^{12} through 5-membered ring will contribute to disordered distribution of CO_2 in M^{12} and M^{14} cages, which caused vibrational peak splittings. Thus, high-temperature Raman spectroscopic study could provide us more insight of diffusion behavior of CO_2 and possibly other gas molecules in melanophlogite structure.

Synthesis of barium carbonate with calcite structure and rotational disorder of carbonate ions

*Hiroyuki Kagi[1], Ayaka Saito[1], Kazuki Komatsu[1], Jun Kawano[2]

1. Geochemical Research Center, Graduate School of Science, University of Tokyo, 2. Fuculty of Science, Hokkaido University

Structures of divalent metal carbonate is constrained by the ionic radii of cations. Cations larger than Ca^{2+} take the aragonite structure and cations smaller than Ca^{2+} take the aragonite structure. Barium carbonate (witherite) takes the aragonite structure and Ba2+ is incompatible to calcite. We have reported that large incompatible cations can be introduced to calcite through amorphous calcium carbonate (ACC). In this study, we synthesized $Ba_{0.7}Ca0.3CO_3$ with the calcite structure by heating treatment on ACC containing Ba^{2+}. The obtained crystal can be interpreted as Ca-containing barium carbonate with the calcite structure, which cannot be found in nature or synthesized from a direct precipitation from the supersaturated solutions.

X-ray diffraction (XRD) patterns of Ba-doped calcite measured at 300 K shows the extinction of 113 reflection with increasing Ba concentration (see Figure 1). The extinction of the 113 reflection was reported on pure calcite at temperatures higher than 1240 K (Ishizawa et al., 2013). The change was attributed to the rotational disorder of CO_3^{2-} ions. In contrast, we have observed the extinction of 113 reflection on the Ba-doped calcite at 300 K.

To investigate the behavior of CO_3^{2-} ions at an atomistic level, molecular dynamics (MD) simulation of Ba-doped calcite was conductedusing the MD program, MXDTRICL (Kawamura 1997). Intensity ratio of reflections 113 to 104 (I_{113}/I_{104}) was measured from XRD patterns obtained from experimental study and MD simulation. $I_{113}/I_{104}$from experiment dropped to 0 at Ba/(Ba + Ca) = 26.8 ±1.6 mol% while that of MD-simulated Ba-doped calcite gradually weakened and did not fall to zero. MD simulations of 25.5% and 50.9% Ba-doped calcite at high temperature were also conducted. In 25.5% Ba-doped calcite, I_{113}/I_{104} remarkably dropped at around 1050 K with the structure of rotationally disordered CO_3^{2-} ions. The transition temperature to the rotational disorder was at around 850 K for 50.9% Ba-doped calcite. These simulated temperatures are much lower than the transition temperature (1250 K) obtained from MD simulation on pure calcite (Kawano et al., 2009). The simulated results showed that the transition temperature to the rotational disordered phase dramatically decreased with increasing Ba/(Ba + Ca) in calcite.

In-situ Raman spectroscopy of ε-FeOOH under high pressures

*Osamu Ikeda[1], Tatsuya Sakamaki[1], Akio Suzuki[1]

1. Department of Earth Science, Graduate School of Science, Tohoku University

ε-FeOOH is one of crucial high-pressure hydrous phases in the Earth's mantle, and is isostructural to δ-AlOOH. A first principles calculation (Gleason et al., 2013) has indicated pressure-induced hydrogen bond symmetrization at 43 GPa, and spin transition of iron at 65 GPa. These transitions cause changes in physical properties, and knowledge of the transition changes can help us to understand the behaviors of hydrous phases under high pressure.

We present a first study of Raman spectroscopy of ε-FeOOH at high pressure and room temperature. The measured sample was polycrystalline ε-FeOOH, which was synthesized in advance from a powder of reagent grade 99 % α-FeOOH at the pressure-temperature condition of 8 GPa and 480 ℃ for 2 hour. Micro-Raman spectrometer NRS-4100TOR (JASCO Corporation), which has a laser with the wavelength 532 nm and power 50 mW installed in Tohoku University, was used to obtain Raman spectra. Symmetric diamond anvil cell with 300 μm culet size was used to generate high pressure. The sample was loaded in the sample chamber of tungsten gasket with NaCl pressure medium. The pressure in the chamber was calculated by means of the ruby luminescence pressure scale (Dewaele et al., 2004).

Along compression, the frequencies of most of peak tops have positive pressure dependences but some peaks (298, 386, 698, and 1099 cm^{-1} at 15 GPa) changed the dependences to negative around 14 GPa. Above 15 GPa some peaks (197, 298, and 443 cm^{-1} at 15 GPa) disappeared and the others (364, 386, 549, 646, 698, and 1099 cm^{-1} at 15 GPa) jumped by frequency 10–30 cm^{-1}. This change around 15 GPa may correspond to the replacement of vibrational modes in Raman spectra of δ-AlOOH at the pressure of 5.6 GPa (Mashino et al., 2016), which indicates a hydrogen-bond related space-group transition from $P2_1nm$ to *Pnnm* (Tsuchiya et al., 2008).

Strong hydrogen-bond generation in dense hydrous magnesium silicate phase E observed by single-crystal neutron diffraction

*Narangoo Purevjav[1], Takuo Okuchi[1], Christina Hoffmann[2]

1. Institute for Planetary Materials, Okayama University, 2. Neutron Scattering Division, Neutron Sciences Directorate, Oak Ridge National Laboratory

Dense hydrous magnesium silicates (DHMS) are considered as the most major water transporters in cold subducting slabs, which are descending into the deep mantle. Phase E [$Mg_2SiH_4O_6$ –ideal] is one of the most important DHMS phases which is stable at conditions between 13 –17 GPa and 800 –1200 ˚C [1]. Besides its stability at such high temperatures, it stores up to 18 wt.% of water within its crystal structure, which is one of the largest among DHMS phases. Thus phase E is one of the most important carriers and transporter of water in the subducting slabs. The crystal structure of phase E was first investigated by single crystal x-ray diffraction except for its hydrogen position [2]. Its structure has brucite-like layers of MgO6 octahedra which are crosslinked by SiO4 tetrahedra [2]. The hydrogen atoms were expected to be located between these MgO6 octahedra layers like those in brucite, $Mg(OH)_2$. The previous expectation on the structure of phase E was recently confirmed by our powder neutron diffraction study [3]. In contrast, present single-crystal neutron diffraction is conducted to investigate hydrogen bonding geometry in phase E structure, including the Debye-Waller factor of the hydrogen, for which we utilize much higher spatial resolution of the single crystal method. The method has been well confirmed to be very sensitive for investigating such properties of the hydrogen atoms within a series of hydrous minerals [4, 5].
We expect that such information is helpful to understand the reason of stability of phase E at the high-temperature condition. A deuterated phase E single crystal was measured by neutron time-of-flight single-crystal Laue diffraction at Spallation Neutron Source, Oak Ridge National Laboratory. From preliminary structure refinement results, we found that the covalent bond O-D was inclined and displaced from the three-fold axis. Such O-D inclination should occur due to interlayer strong hydrogen-bond generation in the phase E structure. The details of the results will be given in the presentation.

Water partitioning between upper mantle minerals and melts

*Dmitry Bondar[1], Hongzhan Fei[1], Tony Withers[1], Tomoo Katsura[1]

1. Bayerisches Geoinstitut, University of Bayreuth, 95440 Bayreuth, Germany

Water in the Earth's upper mantle is predominantly stored in nominally anhydrous minerals (NAMs) such as olivine, orthopyroxene, clinopyroxene and garnet. Since incorporated water has a strong influence on mantle properties, namely melting temperature, rheology, electrical conductivity and seismic velocity, it is important to know the distribution of water among phases. Knowledge of how water partitions between upper mantle minerals and melts is essential for estimation of water content in incipient melts at different depths, water transport by these melts, and total amount of water in the upper mantle.
There are quite a few studies providing data on water partitioning between NAMs and melts. The most challenging part of these studies is to quench melt coexisting with mineral phases to form glass at elevated pressures (>2 GPa), which is necessary to measure water partitioning with high accuracy. It also becomes more difficult to quench melt with higher Mg/Si ratio into glass, which is necessary in order to crystallize olivine from the melt. Previous studies produced mantle minerals coexisting with quenched melt up to only 5 GPa, namely olivine up to 3 GPa, orthopyroxene up to 4 GPa, clinopyroxene and garnet up to 5 GPa. As a result, there is no systematic pressure, temperature and water content dependence of water partitioning from the data scattered over the narrow pressure range. Many authors also reported that glasses in some run products were not transparent, which implies micro-crystals may have crystallized in those studies.
The difficulty of quenching melt into glass lies in the insufficient cooling rate. The cooling rates of regular piston-cylinder and multi-anvil experiments used for these purposes are 120˚/sec and 500˚/sec, respectively. Quenching glass at elevated pressures and at various compositions is important not only for measuring water partitioning, but also for a number of other tasks, such as melt structure studies and partitioning of other components and elements.
The purposes of the present study are (1) to develop a multi-anvil technique allowing much faster cooling rate than conventional ones and (2) to measure water partitioning between upper mantle minerals and melts for a pressure range from 1 to 13 GPa, which covers the whole upper mantle. Our design for a fast-cooling multi-anvil technique has already been shown to produce a very high quenching rate (5200˚ /sec) in comparison with those of regular piston cylinder and multi-anvil apparatus (120˚C/sec and 500˚ C/sec, respectively) (Fig. 1a). Using this technique, completely transparent glass coexisting with garnet was successfully quenched at 6 GPa (Fig.1b,c). We plan to improve the fast quenching technique to allow quenching melts under even wider conditions.
Fig 1. (a) Comparison of cooling rate among different assemblies. 1/2 and 18/8 are piston-cylinder and multi-anvil assemblies, respectively. Cooling rate was calculated for the temperature range between target temperature and 600˚C; (b) Glass coexisting with garnet at 6 GPa; (c) BSE image of the area in the red box from picture b.

Drop-solution enthalpy measurement of $MgSiO_3$ majorite

*Hiroshi Kojitani[1], Masamichi Noda[2], Toru Inoue[2,3], Masaki Akaogi[1]

1. Department of Chemistry, Faculty of Science, Gakushuin University, 2. GRC, Ehime University, 3. Dept. of Earth and Planetary systems Science, Hiroshima University

Silicate garnet is one of the major Earth's mantle constituent minerals. With increasing depth, pyroxene components dissolve into the silicate garnet. $MgSiO_3$ majorite (Mj) is an important endmember to express such the pyroxene component dissolving in the silicate garnet solid solution. Recently, we experimentally determined isobaric heat capacity and entropy of $MgSiO_3$ Mj. The stability field of $MgSiO_3$ Mj in the $MgSiO_3$ system thermodynamically calculated using these new thermodynamic data of $MgSiO_3$ Mj together with its enthalpy data measured by Yusa et al. (1993) and Saikia (2008) is not consistent with that determined by previous high-pressure phase relation experiments. In this study, the standard enthalpy of $MgSiO_3$ Mj was determined by drop-solution enthalpy measurement and the obtained enthalpy value was applied to examine the phase stability field of $MgSiO_3$ Mj by thermodynamic calculation.

$MgSiO_3$ Mj samples for the drop-solution calorimetry was the same as those used in the heat capacity measurement, which were synthesized at 19 GPa and 2173 K using a high-pressure apparatus at Ehime University, GRC. The sintered polycrystalline samples were crushed into powder. The drop-solution calorimetry was performed using a Calvet-type high-temperature calorimeter (SETARAM, HT-1000). The powdered sample with weight of about 4 mg was compressed into a pellet and it was dropped into the lead borate solvent ($2PbO{\cdot}B_2O_3$) placed in the calorimeter which was kept at 978 K. The summation of heat content from room temperature to 978 K and solution enthalpy at 978 K, namely drop-solution enthalpy ($\Delta H_{d\text{-}s}$), was measured. To hasten the solution of the samples, the solvent was stirred by bubbling with Ar gas.

$\Delta H_{d\text{-}s}$ ($MgSiO_3$ Mj) was determined to be 69.57±0.77 kJ/mol from the average of five data. This value is the middle between 80.0±2.5 kJ/mol (Yusa et al., 1993) and 59.5±3.2 kJ/mol (Saikia, 2008). From the difference between $\Delta H_{d\text{-}s}$ (MgO) (33.74±0.99 kJ/mol, Kojitani et al. 2012) + $\Delta H_{d\text{-}s}$ (SiO_2 quartz) (40.05± 0.36 kJ/mol, Akaogi et al. 1995) and our $\Delta H_{d\text{-}s}$ ($MgSiO_3$ Mj), the formation enthalpy from the oxides was obtained as 4.2±1.3 kJ/mol. The thermodynamic calculation of the *P-T* phase diagram by adopting the present enthalpy value suggests that the stability field of $MgSiO_3$ Mj would expand to lower temperature region than that determined by previous high-pressure high-temperature experiments and thermodynamic calculations.

High-pressure phase transitions of minerals in the system MgO-TiO_2

*Masaki Akaogi[1], Tetsuya Fujimura[1], Shunto Arai[1], Masaki Okano[1], Hiroshi Kojitani[1]

1. Department of Chemistry, Faculty of Science, Gakushuin University

Mg_2TiO_4, $MgTiO_3$ and $MgTi_2O_5$ form spinel(Sp)-, ilmenite(Ilm)-, and pseudobrookite(Pbr)-type solid solutions, respectively, with other endmembers such as Fe_2TiO_4, $FeTiO_3$ and $FeTi_2O_5$. These phases occur as minor minerals in various igneous and metamorphic rocks. Previous studies on stability relations of Mg_2TiO_4, $MgTiO_3$ and $MgTi_2O_5$ at high pressure were limited below about 3 GPa, except for that the transitions in $MgTiO_3$ were examined up to about 18 GPa. In this study, we have examined the phase transitions of these magnesium titanates up to 28 GPa and 1800 ˚C.

We have determined the high-pressure phase relations in Mg_2TiO_4, $MgTiO_3$ and $MgTi_2O_5$ at 4-28 GPa and 1000-1800 ˚C using multianvil apparatus with the quench method. $MgTiO_3$ ilm transformed to the $LiNbO_3$ (Ln)-type high-pressure phase at 16-20 GPa and 1200-1600 ˚C. The Ln phase was interpreted as the retrograde transformation product from perovskite(Pv)-type $MgTiO_3$ stable at high pressure and high temperature (Linton et al., 1999). Above 21-25 GPa, the recovered phases were MgO and a-PbO_2-type TiO_2, the latter of which was interpreted to be converted from baddeleyite(Bd)-type TiO_2. The transition boundary from Pv to MgO + TiO_2(Bd) has a positive Clapeyron slope. Mg_2TiO_4 Sp dissociates to MgO + $MgTiO_3$ Ilm at about 1 GPa, and at higher pressure they changes to MgO + $MgTiO_3$ Pv and subsequently to 2MgO + TiO_2(Bd). $MgTi_2O_5$ Pbr decomposes at 1-2 GPa to $MgTiO_3$ Ilm + TiO_2 rutile(Ru), the latter of which transforms to a-PbO_2-type TiO_2. At higher pressure, the assemblage changes to $MgTiO_3$ Pv + a-PbO_2-type TiO_2, and subsequently to MgO + 2TiO_2(Bd). These results show that the mixtures of MgO and TiO_2 (Bd) are stable above 20-25 GPa in the three magnesium titanates. We also performed Rietveld structure refinement of Ln-type $MgTiO_3$ using synchrotron powder X-ray diffraction data, and confirmed that Ti^{4+} and Mg^{2+} ions are slightly deviated from the centrosymmetric positions in the octahedra which gives polarity of the $MgTiO_3$ Ln-phase.

The high-pressure transition behaviors of Mg_2TiO_4, $MgTiO_3$ and $MgTi_2O_5$ are similar to those of Fe_2TiO_4, $FeTiO_3$ and $FeTi_2O_5$, respectively, up to moderate pressures, where the phases transform to the assemblages involving $MTiO_3$ Ilm and Pv (M = Mg, Fe). However, the transition behaviors are different at higher pressures: Fe_2TiO_4 transforms to $CaTi_2O_4$(CT)-type phase, and $FeTiO_3$ dissociates to Fe_2TiO_4 CT + a dense orthorhombic $FeTi_2O_5$ phase (Akaogi et al., 2017).

Phase change process of iron sulfide nanoparticle from amorphous to crystalline with grain growth

*Yoshinari Sano[1], Atsushi Kyono[2], Yasuhiro Yoneda[3], Gen-ichiro Yamamoto[1]

1. Graduate School of Life and Environmental Sciences, University of Tsukuba, 2. Faculty of Life and Environmental Sciences, University of Tsukuba, 3. Japan Atomic Energy Agency

1. Introduction

In anaerobic marine sediments, sulfate-reducing bacteria (SRB) acquires metabolic energy by reducing sulfate ions (SO_4^{2-}) to sulfide ions (S^{2-}). Sulfide ions are, furthermore, oxidized from sulfur (S^0) to sulfate ions by the metabolic activity of sulfur bacteria (SB). These series of reaction are called geochemical sulfur cycle and considered as one of the most important elemental cycle. In the reaction, a part of the sulfide ions is readily reacted with ferrous ions (Fe^{2+}) to produce iron sulfide nanoparticle (FeS), and which grows to more stable mackinawite (FeS). In the previous study, it was reported that the crystal growth from iron sulfide nanoparticle to mackinawite occurred in hydrothermal aging experiment at 120°C (Csákberé nyi-Malasics et al., 2012). Despite its importance as a precursor of mackinawite, phase change process of the iron sulfide nanoparticle from amorphous to crystalline has not been elucidated yet. In this study, synchrotron X-ray total scattering measurement and atomic Pair Distribution Function (PDF) analysis were performed to clarify the crystal structure change of iron sulfide nanoparticle with grain growth.

2. Experimental method

At first, iron sulfide nanoparticle suspension was synthesized by the mixing 10 mL of 0.2 M $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$ solution with 10 mL of 0.4 M $Na_2S \cdot 9H_2O$ solution in N_2 gas atmosphere. The synthesized suspensions were heated in a Teflon container at 120°C for 2, 4, 6, 8 and 12 hours, respectively. After the end of heating experiments, the solid phases were dried by blowing N_2 gas and stored in vacuum. Synchrotron X-ray total scattering measurements were performed at beamline BL14B1 in SPring-8. The incident beam was monochromatized to a wavelength of 0.20606 Å. X-ray total scattering data at 20 K and 300 K were collected in the Q range between 0 and 25 $Å^{-1}$. Atomic Pair Distribution Function (PDF) analysis was applied to X-ray total scattering data.

3. Results and discussion

The PDF pattern of iron sulfide nanoparticle synthesized in the study almost disappeared at about 2 nm. Those of samples heated for 2, 4, 6, 8, 12 h are, on the other hand, were continuously observed up to 4 nm. This result showed that the particle size of iron sulfide nanoparticle was grown to 4 nm by the heating at 120°C. The Fe-S and Fe-Fe distances obtained by the PDF analysis are 2.25 and 2.65 Å, respectively, which suggests that the local atomic structure around Fe, ie FeS_4 tetrahedra, in iron sulfide nanoparticle almost remains unchanged by particle growth. Compared with the structure model of mackinawite, the iron sulfide nanoparticle would consist of disordered arrangement of FeS_4 tetrahedra. This is consistent with the structure model of iron sulfide nanoparticle proposed by the previous study (Wolthers et al., 2003; Ohfuji and Rickard, 2006; Jeong et al., 2008). In the presentation, we will discuss structure change associated with medium-range atomic order and propose phase change process from amorphous to crystalline by particle growth.

Texture formation in quenching of Fe-S-O micro melt spherules

*Hiroshi Isobe[1]

1. Department of Earth and Environmental Sciences, Faculty of Advanced Science and Technology, Kumamoto University

Microtexture of minerals records physical, chemical and kinetic conditions at crystal growth. Local processes at crystal growth and migration of elements have important role in the rapid crystal growth. Especially, Fe and S-bearing systems are oxidation and evaporation sensitive. And fine particles can be quenched very quickly from high temperature, quench crystals show characteristic textures of crystals. In this study, quick heating and cooling experiments of powdered iron sulfide particles were carried out with a fine particles free falling apparatus with controlled gas flow (Isobe and Gondo, 2013). Oxygen fugacity was controlled to FMQ -0.5, +0.9 or +2.4 log unit. Particles can be heated to the maximum temperatures of approximately 1600˚C within two seconds, are kept approximately one second and quenched within a second.

Run products particles were completely melted and show rounded shape with smooth surface or characteristic texture. Spherical products were initially well homogenized from inhomogeneous starting materials by complete melting. Then, spherules are oxidized and show growth of secondary crystals with rapid cooling.

FeS dendritic crystals occur in sulfur-rich spherules with low fO2 condition. In the higher fO2 experiments, rapid growth of magnetite in Fe-O melt produces iron metal phase from an excess iron in melt phase relative to magnetite.

Compositions of iron sulfide melt in fine spherules are initially close to FeS and are losing S with oxidation following Fe-S-O phase relations depending on oxygen fugacity even in a few seconds. Crystallization of FeS crystals can reduce sulfur content in melt, then evaporation of sulfur can be suppressed. Evaporation of sulfur may be promoted by oxidation of iron sulfide melt to occur magnetite as liquidus phase.

Development of a software for electron diffraction simulation based on dynamical theory and its application to mineralogy

*Yusuke Seto[1], Masahiro Ohtuka[3], Akira Miyake[2]

1. Graduate School of Science, Kobe University, 2. Graduate School of Science, Kyoto University, 3. Graduate School of Technology, Nagoya University

Electron diffraction technique is widely used for the phase identification and crystal structure determination of Earth and planetary materials. Electrons are scattered by the positive potential inside the electron cloud, resulting that the interaction of electrons with matter is much stronger (10^6-10^7) than that of X-rays. This has the advantage that the diffracted electron beams have a high intensity and the patterns can directly be observed on the viewing screen of the electron microscope. The strong interaction, however, easily causes multiple scattering, and thereby the intensities of the reflections are much influenced by the dynamical effects. This makes structure determinations from electron diffraction more difficult and less reliable than that from XRD data. In order to treat the dynamical effects, a lot of computer resources of Fourier transform and/or eigenvalue problem are required, and consequently, such a dynamical analysis was limited to simple structured materials. However, that situation has been changing. In recent years, many-core CPUs can make a lot of computation possible. Moreover, with the rapid spread of field emission transmission electron microscopes (TEM) and sensitive detectors (CCD or CMOS), the quantitative analyses of electron intensities become available even from nanometer-sized minerals.

In the present study, the authors developed a GUI-based software, ReciPro, that simulates electron diffraction patterns using one of the dynamical theories, called the Bethe method (or Bloch wave eigenvalue method), in which the three dimensional eigenvalues of the electron wave function in a crystalline specimen are solved with the appropriate boundary conditions on the entrance and exit face of the crystal. By this method, the diffraction patterns (SAED and CBED) can be obtained with a good accuracy and speed regardless of the specimen thickness. Moreover, ReciPro provides following features: i) Loading any crystal structure including AMCSD (American Mineralogist Crystal Structure Database) database or COD (Crystallography Open Database). ii) Changing a specimen orientation and TEM conditions freely by a mouse operation. iii) Displaying Digital Micrograph file, the de facto standard of TEM image file format developed by Gatan inc., can be read and displayed. iv) Fitting diffraction spots by two dimensional pseudo-Voigt functions. v) Quantitative comparison of simulated and experimental diffraction patterns, and many more features. In the presentation, the authors will report examples of reproducibility of simulated diffraction patterns (SAED and CBED) for several minerals, and future prospects of this approach.

Site occupation analysis for cation in minerals by analytical electron microscopy: application of TEM-ALCHEMI for earth and planetary science

*Yohei Igami[1], Shunsuke Muto[1], Masahiro Ohtsuka[3], Akira Miyake[2], Takahiro Kuribayashi[4], Shoichi Toh[5]

1. Institute of Materials and Systems for Sustainability, Nagoya University, 2. Graduate School of Science, Kyoto University, 3. Graduate School of Engineering, Nagoya University, 4. Graduate School of Science, Tohoku University, 5. Faculty of Science, Fukuoka University

Cation site occupation in natural minerals is very important for earth and planetary science, because it should reflect thermal histories such as peak temperatures and cooling rates. However, natural minerals generally have various complex micro-textures. Therefore, determination of cation site occupation from micrometric regions has been required.
Spence and Taftø [1] developed the ALCHEMI (Atom Location by CHanneling-Enhanced MIcroanalysis) method in which transmission electron microscope with energy dispersive X-ray spectrometer (TEM-EDS) is used to determine the crystallographic sites of impurity elements from micrometric regions in crystals on the basis of channeling-enhanced X-ray emissions. Subsequent improvements in the ALCHEMI have led to more statistical method called HARECXS (High Angular Resolution Electron Channeling X-ray Spectroscopy) or St-ALCHEMI (statistical ALCHEMI). This method is widely applicable including minerals with low symmetric structures (reviewed by [2]). Recently, we successfully determined the order parameter of Al and Si in the tetrahedral sites in sillimanite (Al_2SiO_5) at the areas free from precipitates of mullite ($3Al_2O_3$ $2SiO_2$) and glasses [3]. In this study, we carried out the ALCHEMI/HARECXS method for major rock forming minerals to extend its applicability in earth and planetary science.
Sample minerals are olivine ($[Mg, Fe]_2SiO_4$), diopside ($Ca[Mg, Fe]Si_2O_6$) and sillimanite. The samples were prepared by a focused ion beam system (FIB, FEI Quanta 200 3DS or Helios NanoLab G3 CX), and examined by using TEM-EDS (JEOL JEM-2100F, JED-2300T). X-ray signals generated under illumination of 200 keV electrons were collected as a function of electron beam direction. The homogeneous areas free from dislocations or inclusions were selected as regions of interest.
The one-dimensional tilting ALCHEMI datasets under the condition exciting the particular systematic reflection row (HARECXS profiles) were successfully obtained from regions ~1 μm in diameter by automated control of beam tilting and X-ray detection following Muto and Ohtsuka [2]. For determination of cation site occupation, we performed theoretical calculations of HARECXS profiles using ICSC code [4] and evaluated sample thicknesses by convergent-beam electron diffraction. The experimentally obtained HARECXS profiles were fitted by linear combinations of calculated profiles, and the site occupations of constituent cations were quantitatively determined. Obtained results were almost consistent with the results determined by single crystal X-ray diffraction experiments. Moreover, the cation distributions in annealed samples showed continuous disordering with increasing temperature. This study suggests that the ALCHEMI/HARECXS method is one of the most promising candidates for accurate analysis of minerals in particular the samples having heterogeneous textures.

Molecular Dynamics Study of Soret Effect in Silicate Liquids

*Fumiya Noritake[1]

1. Graduate Faculty of interdisciplinary Research, University of Yamanashi

There are various transportation phenomena driven a potential gradient. The Soret effect is diffusion driven by a temperature gradient (Soret, 1879; Ludwig, 1856). The inverse effect is known as Dufour effect. The Soret effect is sometime used in explanation of fractionation phenomena in geology (Lesher, 1986; Dominguez et al., 2011). Recently Kishi et al. (2018) reports a distribution anomaly of composition in calcium aluminosilicate glass made by migration of high-temperature metal sphere induced by laser irradiation (Hidai et al., 2016). The rate of fractionation by temperature gradient is determined by both thermal diffusivity (D_T) and mass diffusivities (D) because the total net flux must be zero in a steady state. Consequently, understanding the Soret coefficient (D_T/D, or $\partial \log \rho / \partial T$) is difficult because the coefficient might be affected by not only atomic mass and inter-atomic interaction that affect activation energy but also geometric/structural factor.
I applied the molecular dynamics (MD) simulations for pseudo binary and aluminosilicate liquids to investigate the mechanism of fractionation by temperature gradient. The MD simulation appropriate method for this study because it gives trajectories of each atoms in the simulation cells and potentials of each atom at any point in simulation time. MD simulations of sodium/calcium-silicate/aluminosilicate liquids were performed using MXDORTO code (Sakuma & Kawamura, 2009). The simulation conditions are as follows: The inter-atomic potential model was taken from Feuston & Garofalini (1988). Systems of approximately 30000 particles in rod-shaped (approximately 5 x 5 x 17 nm) simulation cell in periodic boundary condition were firstly annealed for 2 ns at 2000 K from randomly generated structure. Then we started the simulations in temperature gradient. The temperatures in sliced region (approximately 0.35 nm thickness) perpendicular to the longest axis at the end and the center of simulation cell were maintained 2000 and 3500 K using the scaling procedure. After several tens nano-second simulations, we confirmed the changes in distribution of composition. The concentration of SiO_2 in the high-temperature center part slightly increases as simulation proceeds. In contrast the concentration of CaO and Na_2O in that part slightly decreases. Soret coefficients for each cation has linear relation with the half width of potential energy distribution in binary silicates. The existence of Al_2O_3 content impedes fractionation in sodium-aluminosilicate whereas it enhances in calcium-aluminosilicate. This behavior might be caused by the charge compensation of 4-fold aluminum cation.

Seebeck coefficient of olivine: Implausible Mercury's thermoelectric dynamo

*Hitoshi Gomi[1], Takashi Yoshino[1], Akira Yoneda[1]

1. Okayama University

The Mercury's magnetic fields are known to be weaker than that predicted by conventional dynamo models. In order to explain the Mercury's weak magnetic field, several models are proposed (Stanley and Glatzmaier, 2010). One of them is the thermoelectric dynamo, which drive the dynamo via the thermoelectric force (Stevenson, 1987). The field strength is proportional to the relative Seebeck coefficient between the core and the mantle. Because the Seebeck coefficient of insulators is more than one order larger than that of metals, the Seebeck coefficient of Mercury's mantle is the central parameter. Therefore, we investigated the Seebeck coefficient of mantle minerals from the first-principles calculations. The structure relaxation and band structure calculations were conducted by using the Quantum ESPRESSO package. The bandgap energy was calibrated by means of the quasiparticles self-consistent GW (QSGW) approximation adopted in the ecalj package. The Seebeck coefficient was calculated via the Boltzmann equation implemented in the BoltzTraP package. The results indicate that the Seebeck coefficient of forsterite with a small amount of dopant exhibit comparable to that previously thought (|S| ~ 1000 mV/K). This value may constrain the upper limit. The Mercury's mantle may contain ~3wt% FeO (Robinson and Taylor, 2001). The Fe substitution and O vacancy act as donor, which is predicted to reduce the Seebeck coefficient, significantly. The field strength also depends on the electrical conductivity of the mangle. Recent high pressure experiments suggest that the electrical conductivity of the Earth's mantle is ~ 10^{-2} Sm. Considering the both of the Seebeck coefficient and the electrical conductivity of mantle material, the field strength is calculated to be ~ 0.1 nT, which is significantly weaker than the observed value of 300 nT. Therefore, we conclude that the thermoelectric dynamo cannot generate the Mercury's magnetic fields.

Japan Synchrotron Radiation Research Institute, 6. National Institutes for Quantum and Radiological Science and Technology

Density of a liquid metal at high pressure and high temperature is fundamental information to determine its equation of state (EOS). Gallium (Ga) which has a low melting temperature at ambient pressure has been reported to have complex liquid structures. The densities of Ga at high pressures have been reported based on the measurement of volume changes (Lyapin et al. 2008), that of liquid structures (Yu et al. 2012), and that of sound velocity (Ayrinhac et al. 2015). However, these densities were not consistent each other. In this study, we measured densities of liquid Ga at high pressure using an X-ray absorption method with an externally heated diamond anvil cell (EHDAC).

Ga sample and reference materials (KBr, RbBr) were loaded into each hole drilled on a pre-indented Re gasket. The reference materials were used for estimation of sample thickness and for determination of experimental pressures (Takubo et al. 2018). The Re gasket was coated with Al_2O_3 to avoid a reaction between the Ga sample and the gasket. High pressure was generated using a symmetric DAC with a lever-arm frame. The culet size of the diamond anvils used was 600 μm. High temperature was generated using external heaters composed of Pt-Rh wires with a ZrO_2 insulator. X-ray absorption measurements were conducted with monochromatic X-ray of 30 keV at BL10XU and BL22XU beamlines in SPring-8. Intensities of incident and transmitted X-rays were detected using a photo-diode or ion chambers. Experimental pressures were determined based on EOSs of KBr and RbBr using their volumes from XRD patterns collected using a flat panel detector.

The densities of liquid Ga were measured up to 9.4 GPa and 500 K. The densities of liquid Ga obtained at 4–9 GPa range 6.53(7)–7.25(14) g/cm^3. The measured density at 4 GPa is consistent with the density calculated from sound velocity data reported by Ayrinhac et al. (2015).

Terrestrial planets, such as Earth, Venus, Mars, and Mercury, have metallic liquid and/or solid cores. The cores consistent of mainly Fe and Ni with small amounts of light elements. Chemical compositions of solid state cores have been estimated by density measurements of crystalline core materials in a number of previous studies. On the other hand, there are a few previous studies on density measurements of liquid samples because of technical difficulties. Although Morard et al. (2008, 2013) obtained densities of liquid Fe with light elements by structure analyses from XRD patterns, accuracy of the densities was under debate because they used XRD patterns with narrow reciprocal lattice spaces. In this study, we have measured densities of crystalline Fe and amorphous materials using an X-ray absorption method in order to avoid problems of small diffraction angles due to a diamond anvil cell (DAC).
High pressure measurements were performed using a DAC with a gasket having 3 sample chambers. Fe or amorphous samples were loaded in a sample chamber for density measurements. Powders of KCl, KBr, or RbBr as references for thickness were also loaded in the other sample chambers. After XRD patterns were taken from all samples and references, absorption profiles were also measured. Experimental pressures were determined using pressure averages between KCl and KBr, or KBr and RbBr. Densities based on the X-ray absorption method were obtained using the Lambert Beer law with mass absorption coefficients from NIST data base. Densities of crystalline Fe were obtained up to 20 GPa and density differences between XRD and the absorption method were less than 2%. This technique was applied to densities of amorphous materials as well. We will report the densities based on the X-ray absorption method.

DAC-GHz ultrasonic P wave velocity measurement on KCl and natural olivine

*Akira Yoneda[1], Shinichiro Kobayashi[2], Seiji Kamada[3]

1. Institute for planetary materials, Okayama University, 2. Department of Earth Science, Graduate school of Science, Tohoku Univ., 3. Frontier Research Institute for Interdisciplinary Sciences, Tohoku Univ.

GHz ultrasonic velocity measurements has been developed up to 14 GPa in diamond anvil cell (DAC). In order for GHz ultrasonic measurement, both P and S wave buffer rods were manufactured through sputtering ZnO piezoelectric film on single crystal rods, such as sapphire, rutile, and YAG. Several technical breakthroughs were achieved before observing stable signals from the specimen squeezed in DAC: (1) Wiping by aqueous ammonia on the contact surfaces enhances transmissibility of GHz wave from buffer rod to diamond. (2) Cleaning by lathery detergent and water jet is effective to remove sticky staff on rear surface of diamond. (3) Steel ball supporter provides easier adjustment of contact between buffer rod and diamond. Consequently, we succeeded to demonstrate performance of DAC-GHz system through KCl and natural olivine samples.

Raman spectroscopy of seifertite

*Masahiro KAYAMA[1], Eiji Ohtani[1], Masaaki Miyahara[2], Shohei Kaneko[1], Toshimori Sekine[3], Shin Ozawa[1], Naohisa Hirao[4]

1. Tohoku University, 2. Hiroshima University, 3. HPSTAR, 4. Japan Synchrotron Radiation Research Institute

Seifertite is one of the SiO_2 polymorphs and is a high pressure phase with an α-PbO_2 structure. It is known to lie in lunar and martian meteorites and constrains shock pressure and duration of an impact event that these meteorites have experienced on the host bodies. Seifertite is thermodynamically stable at more than ~100 GPa, which is not realistic for an impact event on the Moon and Mars. However, it can be transformed as a metastable phase from cristobalite at least ~11 GPa and 0.01 s, and can consequently be quenched down to an ambient condition. As a result of this process, seifertite remains present in some of the lunar and martian meteorites. The estimated shock pressure and duration provide valuable information on the size of the crater and impactor that collided don the host bodies. Although Raman spectroscopy has been previously measured for seifertite in meteorites, it was not successful to obtain the seifertite signature because of a potential vitrification or transition into other SiO_2 phase by heating due to the laser irradiation. Therefore, only synchrotron-XRD and TEM analyses allow us to determine the structure, where silica grains are excavated with a focused ion beam (FIB) system from meteorite. Here, Raman spectral signatures of seifertite has been obtained from synthetic and meteoritic silica grains, implying its identification with high-spatial resolution as nondestructive analysis.

Seifertite in silica grains of synthetic samples and lunar (NWA 4734) and martian meteorites (Zagami, NWA 2975) were identifications by a synchrotron XRD analysis at Spring-8 BL-10 and were employed for Raman spectroscopy. Seifertite were synthetized from synthetic cristobalite powders using multi-anvil press at 16 GPa, 673 K and 0.5 hour. Raman spectroscopy were performed for synthetic and meteoritic silica grains using Nd: YAG 532 nm at 20 mW for 3 minutes exposure time.
Raman spectra of synthetic seifertite have pronounced peaks at 380, 515, 564, 739 and 796 cm^{-1} and weak peaks at 401, 496, 539, 547, 606 and 749 cm^{-1}. Similar Raman signature was obtained from seifertite in lunar and martian meteorites. These Raman shifts and relative intensities are well corresponding to the values calculated within the density-functional perturbation theory for seifertite. Based on the calculation, thee Raman peaks at 380, 515, 564, and 796 cm^{-1} are assigned to Ag, those at 401, 496, and 539 cm^{-1} to B1g, 606 and 749 cm^{-1} to B2g, and 547 and 739 cm^{-1} to B3g modes. After laser beam irradiation for 30 minutes, the distinct Raman signature can be detected from synthetic and meteoritic seifertite. Therefore, Raman spectroscopy enables determination of the structure and identification of SiO2 polymorphs with high-spatial resolution and without destruction.

Microtexture and crystallization process of impact diamonds

*Hiroaki Ohfuji[1], Motosuke Nakaya[1]

1. Geodynamics Research Center, Ehime University

Impact diamonds from the Popigai crater located in the central Siberia, Russia show unique nano-polycrystalline texture composed of diamond and a small amount of lonsdaleite of ~50 nm (Ohfuji et al., 2015), which is well comparable to the nano-polycrystalline diamond synthesized by direct conversion of graphite under high pressure and high temperature (Irifune et al., 2003). However, subsequent studies noted that they show a variety of microtexture such as lamellar or layer textures and granular textures. In the present study, we investigated the mineralogical and crystallographic characteristics of the various microtextures shown by the Popigai diamonds by TEM.

The microtextures found in Popigai diamonds are divided into two types, 1) lamellar type and 2) granular type. The former is further classified into two types, 1a) less-mosaiced lamellar and 1b) mosaiced lamellar. The latter can also be divided further into 2a) granular texture composed of fine crystals of <50 nm and 2b) granular texture composed of larger (~100 nm) crystals. Careful textural observations and electron diffraction analysis revealed that the microtextures of Popigai diamonds vary from layered texture to granular texture (1a →1b →2a →2b) as the phase transitions from graphite to lonsdaleite to diamond proceed. The phase transition mechanism also changes from martensitic process involving a lattice relationship (Graphite (001) // Lonsdaleite (100) // Diamond (111)) to diffusion process where the nucleation of new grains and the their growth are promoted.

The most important factor controlling the degree of the phase transitions and the resulting microtexture is probably the shock temperature, which is supposed to have decreased gradually from the center to rim in the crater.

Metamorphic temperature analysis of H chondrites: Using revised Lindsley's pyroxene thermometer

*Ryo Uehara[1], Yoshihiro Kuwahara[1], Kazuhiko Shimada[1], Yoshihiro Nakamuta[1], Seiichiro Uehara[1], Tatsuro Adachi[1]

1. Kyushu university

1. Introduction
The thermal evolution models of asteroids have been proposed and discussed by many researchers to provide insight into the internal structure and thermal history of those (e.g., Wood,1979; Miyamoto et al., 1981; Yomogida and Matsui, 1984; McSween et al., 2002). As important parameters for the thermal evolution models, the highest peak temperatures, ages, and cooling rates of meteorite parent bodies are mentioned (McSween et al., 2002). The peak temperature inside the parent body has been estimated using various thermometers (Olsen and Bunch, 1984; Nakamuta and Motomura, 1999; Kessel et al., 2002; Slater-Reynolds and McSween, 2005). Pyroxene thermometer by Lindsley (1983) has been widely used because it allows us to derive temperatures from both orthopyroxene (Opx) and clinopyroxene (Cpx) in a meteorite. However, the temperatures determined from clinopyroxenes, especially for type 6 chondrites, are systematically 50˚C to 150˚C higher than those from orthopyroxenes (Nakamuta et al., 2017). The Lindsley’s pyroxene thermometer is made empirically for terrestrial rocks and therefore the kosmochlor component is not considered in the calculation. So, Nakamuta et al. (2017) proposed the revised Lindsley’s pyroxene thermometer in which the kosmochlor pyroxene component is added to evaluate the effect of the component on the thermometry. They also showed that the difference in temperature between clinopyroxene and orthopyroxene in LL chondrites using the revised thermometer was less than 20˚C.
In this study, we have attempted to estimate the metamorphic temperatures of H chondrites (type 4 to 7) using the Lindsley’s pyroxene thermometer revised by Nakamuta et al (2017). Here we report the results of the estimation.
2. Samples and method
The chondrite samples used were four types of H chondrite with different metamorphic degrees; Edmondson(b) (H4), Faucett (H5), Faith (H5), Plainview (H5), Mulga(north) (H6), Great Bend (H6) and NWA7875 (H7). Polished thin sections of the seven H chondrites were prepared and observed using transmitted and reflecting light microscopes. Then, chemical compositions of pyroxenes, olivines, and plagioclases in the seven H chondrites were analyzed by an EPMA, JEOL JXA-8530F. Beased on these results, the classification of each meteorite sample was reconfirmed, and metamorphism temperatures estimated using the revised Lindsley pyroxene thermometer.
3. Results and discussion
From results of the texture observation and chemical analysis of the chondrite sample, we reconfirmed that there is no mistake in classification of each meteorites (H4, H5, H6, H7). The temperatures for Edmondson(b) (H4), Faucett (H5), Faith (H5), Plainview (H5), Mulga(north) (H6), Great Bend (H6) and NWA7875 (H7) are 779-1236˚C (Opx-Cpx), 814-875˚C, 832-843˚C, 844-838˚C, 807-797˚C, 811-818˚C and 1183-1247˚C, respectively, using the revised Lindsley pyroxene thermometer. Most of H5 and H6 meteorite samples showed that the difference in temperature between Opx and Cpx was less than 20˚C. This result, this suggests that the revised Lindsley pyroxene thermometer by Nakamuta et al. (2017) is also effective for H chondrite. The metamorphic temperatures of the H5 type chondrite (Faucett, Faith and Plainview) and the H6 type chondrite (Mulga(north), Great Bend) are approximately 840˚C and 810˚C, respectively, while the H4 type Edmondson(b) chondrite is less than 780˚C judging from the temperature

©2019. Japan Geoscience Union. All Right Reserved.

estimated from Opx. Regarding the H7 type NWA7875 chondrite which showed the highest metamorphic temperature and lamella structure in some Cpx crystals, the H7 material that existed already in H5 and/or H6 conditions may have experienced impact metamorphism, redrawing the previous metamorphic temperature and the H5 and/or H6 conditions.
Comparing these estimated temperature data with the results of the model simulation reported by Monnereau et al. (2013), it is estimated that the H chondrite meteorite parent body had an onion shell type internal thermal structure formed when the accumulation period was short (<0.2 Myr).

The occurrence combinations of Zeolites at Chichijima, Ogasawara Islands

Michiharu Ito[1], *Yuki Inoue[1], Mana Yasui[2], Atsushi Yamazaki[2], Hiroshi Hagiya[1]

1. Tokyo City University, 2. Waseda research institute for science and engineering

The Ogasawara Islands are located in the Pacific Ocean about 1000 km south of Tokyo, Japan. These Islands are situated in the outer of the Izu-Bonin-Mariana Arc. The Ogasawara Islands are composed by paleogene submarine volcanic formation, and is well known by andesitic volcanic rock called boninite. Boninite is a feldspar-free and glass-rich olivine-bronzite andesite with higher MgO, SiO_2, H_2O and Cr contents. Zeolites, co-exist with calcite, quartz/chalcedony and celadonite, fill the vesicles of volcanic gas, radial and columnar cooling joint of pillow lava, and also occur in interpillow sediment with large aggregate of crystals.

In this study, various habits of zeolites at Chichijima, Ogasawara Islands are obtained, also more than two-step growth of zeolites in amygdale were confirmed. Between these two-step growth, cation ratio have changed at the border of two faces.

These cation's contents are similar to neighboring rock. It is considered that there is another hydrothermal activity after the first-step growth.

Title: Single-crystal X-ray diffraction study of mirabilite ($Na_2SO_4 \cdot 10H_2O$) from 213 to 303 K

*Ryutaro Ikeda[1]

1. University of tsukuba

Introduction

Renewable energy is of increasing importance in modern society due to its low environmental impact, ubiquity and sustainability. Since some renewable energy resources (e.g. sunlight, wind and tides) have variable outputs, storage technologies have great potential for affording the supply from these resources. In recent years, much attention has been paid to phase change materials (PCMs) due to its high energy storage capacity. PCMs are substances with a heat of fusion which can store and releasing large amounts of energy. Mirabilite ($Na_2SO_4 \cdot 10H_2O$) is known as one of the PCMs. With increasing temperature, mirabilite transforms to thenardite (Na_2SO_4) at a dehydration temperature of 306 K. On the contrary, thenardite is rehydrated back to mirabilite at 283 K. The reversible reaction involves large exothermic and endothermic heats. To date, however, there is little information on temperature dependence of crystal structure in mirabilite. The structure of mirabilite contains ribbons consisting of edge-sharing $Na(H_2O)_6$ octahedra along the *c*-axis. These ribbons alternate with chains of the SO_4 tetrahedra and the two H_2O molecules. Levy and Lisensky (1978) identified disorder over two orientations of the SO_4 tetrahedra by single-crystal neutron diffraction measurement at room temperature. The characteristic two orientations, related by a rotation of about 30° about the S×××O5 vector, generate pairs of partially occupied sulfate oxygen sites (O4’/O4’’, O6’/O6’’, and O7’/O7’’). Levy and Lisensky (1978) found that the primed sites are about 25% occupied, and the double-primed sites are about 75% occupied. Recently, Brand et al. (2008) performed powder neutron diffraction measurements on mirabilite ($Na_2SO_4 \cdot 10D_2O$) in the temperature range from 10 to 300 K. They reported that the unit cell of mirabilite is isotopically expanded up to 300 K. The authors however couldn’t observe the two orientations for the SO_4 tetrahedra in the structure, which was previously identified by Levy and Lisensky (1978). In the study, we performed temperature-dependent single-crystal X-ray diffraction measurement of mirabilite in the temperature range between 213 and 303 K. Here, we report the crystal structure change of mirabilite associated with the characteristic exothermic and endothermic heats.

Methods

Single crystals of mirabilite were obtained by slow cooling of a saturated solution of Na_2SO_4. After the synthesis, a single crystal was stored in a 0.7 mm Lindemann glass capillary to avoid dehydration. Temperature dependent single-crystal X-ray diffraction study on mirabilite was performed using a single-crystal diffractometer (APEXII ULTRA, Bruker AXS Inc., Germany) equipped with a liquid nitrogen cryostat, a CCD detector, multilayer optics, and graphite monochromated Mo$K\alpha$ radiation (λ = 0.71073 Å) generated by a rotating anode. The measurements were conducted at temperature ranges between 213 and 303 K with 10 K step in both heating and cooling processes.

Results and Discussion

The *a* and *c* lattice parameters and unit cell volume were monotonously changed with temperature, whereas the *b* lattice parameter remained almost unchanged. The result is entirely consistent with the
