Ray tracing of seismic surface wave was already applied to tsunami propagation (Satake,1988). Here, we apply another ray tracing method based on the shortest path method. In standard ray tracing method, the ray starts at a source point and travel to an end point. However, it is difficult to reach the end point when the ray path is sensitive to velocity distribution (bathymetry distribution). Sometimes, the calculated ray is a local minimum path, not a global minimum path. When we trace the ray based on the shortest path method, there are no such problems. We calculate rays in Pacific Ocean and Japan Sea. Using 1’ by 1’ ETOPO1 data, 1 degree by 1 degree bathymetric data are obtained for trans-Pacific tsunami by applying moving average. 0.1 degree by 0.1 degree depth data are obtained for the Japan Sea tsunami. Moving average is made with neighboring +-5 degrees for the Pacific Ocean data and +-0.5 degree for the Japan Sea data. In the shortest path method, the studied area is divided into many square cells. On the cell boundary, several nodes are evenly distributed. Paths are made by connecting all combinations of two nodes of common cell by straight lines. The path of the shortest travel time from the starting point to each node is searched. At first, the cell is same as the bathymetric data grid of each of Pacific Ocean and the Japan Sea, and node number is set to be 5. Then, the cell number and the node number are multiplied by 2, respectively. When the difference of the mean travel time is less than 60 seconds, we judge the calculation is converged. The mean travel time is obtained by averaging all travel time values at 1 degree by 1 degree data grid points for the Pacific Ocean or 0.1 degree by 0.1 degree data grid point for the Japan Sea. Tsunami sources are located off the shore of Chile and at 1983 Japan Sea earthquake. Converged (cell number, node number)’s are (1,10) and (1,5), and calculation times are about 3.14s and 0.60s, respectively. Areas of depth shallower than 1,000m are excluded in the calculation of the Pacific Ocean. It is shown that travel times of all the target area can be estimated by the shortest path method within very short calculation time.

## [S-CG59] Reducing risks from earthquakes, tsunamis & volcanoes: new applications of realtime geophysical data

convener:Masashi Ogiso(Meteorological Research Institute, Japan Meteorological Agency), Naotaka YAMAMOTO CHIKASADA(National Research Institute for Earth Science and Disaster Resilience), Satoshi Kawamoto(Geospatial Information Authority of Japan), Mitsuyuki Hoshiba(Meteorological Research Institute)

As the number of population centers grows in regions with earthquake, tsunami and volcano hazards, the importance of improving methods for rapid, realtime estimates of activity increases. Realtime monitoring, analysis, and prediction of seismic ground motion, crustal movement and tsunami will be powerful tools to contribute to earthquake and tsunami disaster preparedness/mitigation. Tsunami and Earthquake Early Warning systems exist today in many locations around the world. Now JMA has started to promptly provide Eruption Notices to inform people of impending and beginning volcanic eruptions. Large events like the 2011 Tohoku Earthquake (Mw9.0) have demonstrated some of the shortcomings of existing techniques. In this session, we invite presentations on new ideas, methods and applications of (near) realtime analysis of seismic, geodetic and tsunami data, to the problem of realtime prediction aimed at improving disaster preparedness/mitigation in the fields of earthquake, tsunami and volcano observation. Presentation is encouraged to bring together scientists, engineers, and practitioners from a broad range of backgrounds from around the world, and to promote collaborative communication at the leading edge of the science and technologies.

# Numerical Shake Prediction for earthquake early warning: prediction of distant future using Green function method

*Mitsuyuki Hoshiba[1]

1. Meteorological Research Institute

Although many previous studies of earthquake early warning have focused on rapid estimation of hypocenter and magnitude, recently we proposed a method called “Numerical Shake Prediction” (Hoshiba and Aoki, 2015), in which ground motion is predicted directly from monitored ground motion skipping the process of estimation of hypocenter and magnitude. In the Numerical Shake Prediction, current wavefield is estimated precisely using data assimilation technique, and then future wavefield is predicted using physics of wave propagation. Hoshiba and Aoki (2015) investigated a method to predict envelope of seismic wave focusing on seismic intensity. Furumura et al.(2018) studied an application to long period ground motion. For Tsunami, Maeda et al.(2015) tried the method to tsunami early warning. The researches, estimation of current wavefield and then prediction of future wavefield skipping the process of source information, is now progressed for earthquake and tsunami early warning.

Recently Wang et al.(2017) proposed a method to use Green function method for tsunami early warning, in which Green function is used instead of simulation of wave propagation. Oba et al.(2018) investigated an application of the Green function technique to early warning of long period ground motion. Because future wavefield is estimated from iterative calculation of seismic wave propagation in Hoshiba and Aoki (2015), it requires more computation time for more distant future. Using Green function technique, the computation time is not different between near future prediction and distant future prediction. It is also possible to predict distant future, skipping the prediction of near future.

I will show application of the Green function method for prediction of envelope of seismic wave focusing on seismic intensity. For the physics of wave propagation, radiative transfer theory is applied as the same as Hoshiba and Aoki (2015). This is high-frequency approximation based on ray theoretical approach, and energy propagation is considered instead of wave propagation itself. Energy which arrives at location, (X, Y) at time T later is quantitatively calculated beforehand from unity energy which propagats at (xi, yi) into direction qn. That is, Green function; G(X,Y,T; xi, yi, qn). Energy at location (X, Y) at time T later can be predicted from spatial and directional integrals of multiplication of this Green function and current energy distribution, E(xi, yi, qn), which is evaluated from data assimilation.

Using the Green function, it is possible to predict distant future with less computational time if the target points are not so many. On the other hand, it requires more computational time for prediction of more target points. When the target points are not so many, the Green function is effective method for prediction, including distant future.

# Introduction of forward scattering model into the Numerical Shake Prediction scheme

*Masashi Ogiso[1]

1. Meteorological Research Institute, Japan Meteorological Agency

A real-time ground motion prediction scheme based on a real-time monitoring of current wavefield (e.g., Hoshiba, 2013) is one of the promising approaches for an earthquake early warning (EEW) purpose. Hoshiba and Aoki (2015) implemented the idea and proposed the Numerical Shake Prediction scheme for the EEW. Hoshiba and Aoki (2015) adopted a radiative transfer theory in 2D space based on an isotropic scattering model for the prediction of future ground motion. The isotropic scattering model is suitable for the development of coda waves, however, it cannot represent an envelope broadening effect of the direct waves. The radiative transfer theory with non-isotropic (forward) scattering coefficients can model full seismogram envelopes (e.g., Wegler et al., 2006). In this study, we introduce a forward scattering model into the Numerical Shake Prediction scheme and investigate how the scattering model affects the ground motion prediction.

To introduce the forward scattering effect in the radiative transfer theory, we assume 2D exponential-type random media where the correlation distance is 1 km and the root-mean-square of the fractional random fluctuation is 0.05, then calculate non-isotropic scattering coefficients based on the Born approximation.

We compare the prediction results based on the non-isotropic scattering model with those based on the isotopic scattering model (Ogiso et al., 2018). Although the forward scattering model yields slightly larger residuals in maximum seismic intensity prediction than the isotropic scattering model, the forward scattering model results in smaller prediction residuals in whole seismogram envelope than the isotropic scattering model. The forward scattering model improves the prediction residuals, especially in the coda part. When we adopt momentum transfer scattering coefficient of the 2D random media as the scattering coefficient of isotropic scattering model, envelope prediction of the coda part is similar to that by the forward scattering model, however, residuals of maximum seismic intensity in isotropic scattering model become larger than the forward scattering model. Hence, we conclude that only the forward scattering model has a possibility to predict whole seismogram envelopes in the Numerical Shake Prediction scheme.

# Magnitude estimation by using ocean-bottom pressure gauge data

*Takeshi Nakamura[1], Eiichiro Araki[2], Narumi Takahashi[1], Kensuke Suzuki[2], Shunroku Yamamoto[3], Masahiro Korenaga[3], Shunta Noda[3]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Japan Agency for Marine-Earth Science and Technology, 3. Railway Technical Research Institute

Deployments of ocean-bottom stations such as DONET and S-net could enhance early signal detections and improvements of accuracy for hypocenter analyses of suboceanic earthquakes. However, at some accelerometer stations deployed in ocean-bottom areas, tilt and rotation motions of sensor and/or sensor hysteresis would have occurred during strong motions, which causes anomalous waveforms and analysis errors on seismic motions. At the 2016 moderate-sized suboceanic earthquake (Mjma 6.5) occurring off the Mie prefecture in southwest Japan, significant amplifications of observed amplitude to amplitude calculated from the empirical equation and their considerable spatial variations are found at the DONET stations (Nakamura et al., 2018), which would not be explained by the source radiation pattern and subsurface structures. These undesired amplifications and variations are considered to be caused by acceleration offsets that are associated with the tilt and rotation motions and/or sensor hysteresis and could contribute to the overestimation and instable estimation results of source analyses such as magnitude estimation and finite fault modeling. In this study, we attempt to estimate the amplitude magnitude by using pressure gauge (Paroscientific 8B7000-2) data at DONET stations instead of using accelerometer (Metrozet TSA-100S) data to suppress the undesired features and evaluate the stabilities. We analyzed the waveforms after integrating the observed pressure gauge data and applying a high-pass filter with a corner period of 6 s. In the case of ocean-bottom stations deployed in a water depth of more than 2,200 m, the amplitude of pressure waveforms in this period band is roughly consistent with the vertical amplitude of ocean-bottom velocity (e.g., Matsumoto et al., 2012). The period band of less than 6 s corresponds to that used for estimating the amplitude magnitude of the unified hypocenter catalogue and EEW by JMA. We constructed the empirical equation between the magnitude and the filtered amplitude data and estimated the magnitude for each event data.
Our results show that the magnitude estimated from using pressure gauge data correlates well with that in the JMA list. The deviation (two sigma) is 0.70, which is the same value as that estimated from using three component data of accelerometer. For the event data of the 2016 earthquake (Mjma 6.5), the estimated magnitudes by accelerometer data are 6.64–8.34, while those by pressure gauge data are 6.33–6.81, indicating that the magnitude estimation using the latter data provides less amplification and stable results. The pressure gauge installed at DONET stations may be relatively low sensor hysteresis and less effects of sensor rotation on short-period component of waveforms compared with those of accelerometer.

# Earthquake early warning in the United States and beyond

*Richard M Allen[1]

1. University of California Berkeley

The ShakeAlert earthquake early warning (EEW) system is now delivering alerts up and down the west-coast of the United States (California, Oregon and Washington). The warnings are being used by targeted groups including transportation, schools, hospitals and other infrastructure operators. Alert are also available to the public in some regions through smartphone apps, and there is an expectation that they will be more widely available in the coming months. The system is operated by the US Geological Survey in cooperation with UC Berkeley, Caltech, the University of Oregon and the University of Washington.

The ShakeAlerts are currently generated by seismic-only algorithms, specifically the EPIC point-source algorithm and the FINDER finite-source algorithm. A great deal of research effort is underway to determine the accuracy and reliability of the current system, and to determine what additional information could be provided by new algorithms. In particular, the use of geodetic observations to improve magnitude estimates and estimate fault finiteness for the largest events is being explored, as is the addition of the PLUM ground motion model approach.

Looking beyond traditional seismic and geodetic networks, the use of smartphones to detect earthquakes and characterize their likely impact for EEW is also being explored. The MyShake global smartphone seismic network is currently recording ground shaking using the 40,000 Android phones that have the app installed. More than 800 earthquakes around the globe have been detected, and research is underway to use these detections to generate alerts and also to improve the quality of alerts from traditional networks.

# Study on the relationship between seismometer site environment and earthquake early warning seismic parameter estimation accuracy

*Katsutomo Niwa[1], Naoyasu Iwata[1], Shunroku Yamamoto[1]

1. Railway Technical Research Institute

When earthquakes that threaten the safety of railway facilities and running trains occur, earthquake early warning systems aim to stop the trains as soon as possible. The seismometers installed for these systems automatically detect the P-wave arrival, then using information from the initial few seconds of the P-wave estimate seismic parameters such as epicentral distance, epicentral back-azimuth and magnitude, in order to quickly issue an alarm if necessary.

In this research, in order to improve the accuracy of the seismic parameters estimation, we examined the influence of the seismometers installation environment on the accuracy. We defined as characteristics representing the site environment: the ambient noise level of the observation site, determined from 2 seconds of the waveform recorded before P-wave arrival; and the hardness of the subsurface ground, indicated by the average S-wave velocity from the depth of 30m to the surface, henceforth referred to as AVS30.

Firstly, we calculated the RMS pf the 2 seconds of data before the P-wave arrival as the noise level, and checked the relationship between the noise level and the estimation error of the seismic parameters. When the noise level is small, the error of the P-wave detection time tends to become small. When the noise level is large, the automatic P-wave detection time tends to be earlier than would be chosen manually. The epicentral distance tends to be underestimated as the noise level is larger. The estimation error of the epicentral back-azimuth tends to decrease the estimation error as the noise level decreases. However, the magnitude based on the calculated displacement is hardly affected by the noise level, because the magnitude is determined by the maximum value of the observed amplitude.

Following this, we checked the relationship between AVS30 and the estimation error of the seismic parameters. The AVS30 is calculated from the K-NET PS logging result according to a method proposed by Shi and Midorikawa (1999). Since the variation of AVS30 showed little correlation with the estimation error, it can be thought that P-wave detection is hardly affected by the hardness of the subsurface ground. Though the epicentral distance tends to be underestimated as AVS30 gets smaller, this is only to a small extent. The epicentral back-azimuth tends to be smaller as the AVS30 is larger. The magnitude estimation is not correlated with the AVS30.

According to the results outlined above, the accuracy of the seismic parameters estimation will be improved in a quiet environment where the ambient vibration is small, and the subsurface ground is relatively hard. When we select the installation site of seismometers for earthquake early warning, we should therefore give priority to site environments with these characteristics.

# Prediction of surface ground motion using underground seismic records based on data assimilation (2)

*Masaya Ishihara[1], Hisashi Nakahara[1]

1. Solid Earth Physics Laboratory, Department of Geophysics, Graduate School of Science, Tohoku University

## Introduction

To improve Earthquake early warning (EEW), methods using data assimilation have been proposed for seismic wave field prediction (e.g. Hoshiba et al., 2015) and tsunami prediction (Maeda et al., 2015). Hoshiba et al. (2015) used radiative transfer theory to predict the spatial distribution of seismic intensity. Maeda et al. (2015) used wave equation for tsunami prediction. Recently, Furumura et al. (2018 SSJ) used wave equation for the prediction of long-period seismic ground motion. However, data assimilation based on wave equation has probably not yet used for short-period seismic waves due to restrictions on the density of observation stations, computational costs, and so on. In order to predict short period seismic waves, therefore, we started to apply data assimilation based on wave equation to one-dimensional problems for vertical boreholes such as KiK-net (Ishihara and Nakahara, 2018 SSJ). If we can reproduce surface seismic records quickly and precisely from subsurface seismic records, we will be able to speed up the issuing of alarms more quickly than with surface earthquake records alone. This research is regarded as a basic research towards the advancement of the onsite type EEW for local earthquakes.

## Data, Method

In this study, we used NIED KiK-net CHBH10 (Chiba) station. At this observation site, strong motion seismometers are installed on the surface and at a depth of 2000m. We analyzed 60 earthquakes of over M5 occurring around Chiba prefecture. In the simulation, we used the method of Tanaka & Takenaka (2004) which can solve the oblique incidence of plane waves in horizontally stratified structure efficiently by the finite difference method. We calculated the direction of arrival and the incident angle of seismic waves from the particle trajectory of the 1-second-long initial P waves on subsurface records. We simulated the wavefield based on the finite difference method using seismic velocity structure estimated from the logging information. Using the calculated incident angles and subsurface records, we simulated waveforms on the ground surface and compared them with observed waveforms.

## Results and discussion

Ishihara and Nakahara (2018 SSJ) found out two problems in this analysis. First, the degree of the fit between observed and calculated waveforms becomes worse with the lapse time. This is caused by artificial upgoing waves which occur when observed waveforms (upgoing wave + downgoing wave) and calculated waveforms (falling wave) do not match at a subsurface station. Another big problem is that the degree of the fit is deteriorated as the angle of incidence becomes larger. This is because artificial SV waves are generated due to the absence of information about stress when inputting observation values (particle velocity) of P waves at the subsurface observation station.

In this study, we calculated the ratio of artificial SV to P waves assuming only P wave input (stress input is zero) to evaluate this effect. The incident angle was varied from 0 ˚to 45 ˚with a step of 1 ˚. As a result, artificial SV waves are generated with an amplitude of about 4% of the P-wave maximum amplitude for an incident angle of 10 ˚, about 10% for 20 ˚, about 25% for 30 ˚and 50% for 45 ˚. In addition, in order to

©2019. Japan Geoscience Union. All Right Reserved. 

reduce this effect, we are repeating simulations by adding virtual stress conditions and subsurface observation stations.
In the future, we will compare our result with the wavefield calculation of Haskell (1962). In order to solve these problems and to improve the prediction accuracy, we will consider optimum arrangements of subsurface observation stations and suitable settings of appropriate stress conditions.

# Development of Realtlime Long-Period Ground-Motion Prediction System and Demonstration Experiment

*Shin Aoi[1], Takeshi Kimura[1], Takashi Kunugi[1], Wataru Suzuki[1], Yadab Prasad Dhakal[1], Naoto Kojya[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Japan Meteorological Agency

Current technology seems to be hard to predict an occurrence of earthquakes, but is capable to deliver realtime earthquake information just after the occurrence. For railway systems, the earthquake early warning (EEW) system for Shinkansen was utilized in 1990s. For nationwide warning and alerts, Japan Meteorological Agency (JMA) has operated the EEW system since 2007, and realtime information of ground motion plays an important role in society.

On the other hand, the JMA EEW provides only seismic intensities, and not yet to alert broader ground motion information such as long-period ground motions. Long-period ground motions generated during large earthquakes shake skyscrapers in urban area and cause furniture overturning and damage of elevators in them. Recently, JMA issues the long-period ground motion levels based on 5%-damped absolute velocity response spectra in the period range of 1.6 to 7.8 s to respond beyond the seismic intensity measures. Dhakal et al. [2015] constructed a ground motion prediction equation (GMPE) for absolute velocity response spectra in the period range of 1 to 10 s using 36 earthquakes and 12,401 strong motion recordings observed at K-NET and KiK-net stations. The GMPE can provide accurate predictions with correction factors that use depths of the Vs 1.4 km/s layer beneath the sites from the subsurface velocity model provided by the Japan Seismic Hazard Information Station (J-SHIS). The GMPE has an advantage to use the JMA magnitude Mj that is available immediately after the earthquake, not moment magnitude Mw. We developed realtlime long-period ground-motion prediction system using the GMPE of Dhakal et al. [2015] and hypocenter locations and earthquake magnitudes provided by the JMA EEW.

JMA plans to deliver alerts of EEW for long-period ground motions that are similar to the current EEW for seismic intensities. A working group to investigate prediction information for various needs has been established at JMA to activate the plan. Realtime prediction information for ground motions is not allowed to open to the public based on the weather service law. Therefore, NIED collaborates with JMA, and performs demonstration experiments to deliver prediction information of long-period ground motions where NIED acts as a virtual business predictor. The demonstration experiments consist of two types. One is an experiment to use automatic processed prediction information. The other is an experiment to use spatial distribution of prediction information.

In this presentation, we introduce demonstration experiments, results, and future perspectives to deliver observation and realtime prediction information to users using long-period ground-motion prediction system and API and long-period ground-motion monitor.

# Real-time forecasting of long-period ground motions for the Nankai Trough earthquake: The effectivity of the Green function-based data assimilation method

*Atsuki Oba[1], Takashi Furumura[1], Takuto Maeda[2]

1. Earthquake Research Institute, University of Tokyo, 2. Graduate School of Science and Technology, Hirosaki University

In this study, we considered the possibility of more efficient data assimilation method in order to realize real-time forecasting of Long-Period (LP) ground motions based on the assimilation of strong-motion records and simulation of seismic wave propagation.

Furumura et al. (2019) conducted the real-time forecasting experiment of LP ground motions in the metropolitan area for the 2007 Off Niigata and the 2011 Off Tohoku earthquakes based on the data assimilation of the K-NET and KiK-net records and seismic wave propagation simulation using 3-D FDM. They used optimum interpolation technique, which was also used for real-time forecasting of seismic intensity (Hoshiba and Aoki, 2015) and tsunami (Maeda et al., 2015; Gusman et al., 2016). Since the performance of the supercomputers has improved a lot for recent years, simulation for the Japanese islands scale can be done several times faster than the propagation speed of the seismic wave. However, more effort is necessary to reduce the computational time in order to attain longer lead time before the shaking.

In this study, we considered the applicability of Green's function-based data assimilation. This method is proposed by Wang et al. (2017) as Green'sFunction Tsunami Data Assimilation (GFTDA). GFTDA is the method developed for efficient data assimilation and forecast of tsunami using offshore tsunami network. The Green's functions between the target point and each station are calculated beforehand. The tsunami waveform at the target point is calculated instantaneously by convoluting these Green's functions and the residuals between observation and forecast calculated for each station. This method is proved to be mathematically equivalent to the previous data assimilation method in Wang et al. (2017).

To validate the use of this Green's function-based method for the forecast of LP ground motions, we first conducted the numerical experiment for the 2004 off the Kii Peninsula earthquake (M7.4) and forecasted the LP ground motions at Shinjuku (K-NET TKY007) using the strong-motion records observed in this event. Green's functions are calculated efficiently using reciprocity. The results showed that instant forecast can be available with its accuracy equivalent to that of the previous method. LP ground motions in the distant target point can be forecasted immediately after the assimilation of the observed data near the source, which leads to much longer lead time. Moreover, more accurate forecast and longer lead time were obtained by using offshore stations in DONET, a dense oceanfloor network system for earthquake and tsunamis.

Next, we conducted the forecast experiment for the Nankai Trough earthquake using this method. The target points were Konohana (KiK-net OSKH02), Tsushima (K-NET AIC003) and Shinjuku (K-NET TKY007) stations. For the source model, we used the 1944 Tonankai earthquake, the 1946 Nankai earthquake and the largest event expected (M9) suggested by the Cabinet Office, Japan (2016). For each event, LP ground motions were calculated by 3-D FDM and were used as the observation data. In addition to

©2019. Japan Geoscience Union. All Right Reserved. 

aforementioned networks, stations in the JMA submarine cable network and hypothetical stations of N-net, a newly-planned ocean bottom seismograph/tsunameter network off Hyuganada, were also used. The intensity of strong ground motions was evaluated by GMRotD50 (the median value of the geometric means of the response spectra for two horizontal components when rotating from 0 to 90 degree; Boore et al., 2006). For the evaluation of the duration of LP ground motions, cumulative displacement was calculated. The accuracy of the forecast improved with the assimilation time. In the experiment for the 1946 Nankai earthquake, for example, when the rupture started form the east side, the forecast at Shinjuku with velocity response spectrum and cumulative displacement 70% of the actual observation was obtained about 80 s before the large amplitude LP ground motions started. It required 70 s assimilation after the rupture started. In the case that the rupture started from the west side, the longer lead time (~120 s) was secured when the accuracy reached the same level due to the farther distance between the target point and the rupture initiation point. However, because LP ground motions developed as the fault rupture approached the metropolitan area, longer assimilation time (~100 s) was necessary. From these results, it will be suggested that assimilation should be done while the fault rupture extends and the forecasts should be updated constantly as well as the importance of the strong-motion records near the source region in order to the realize both accurate forecast and longer lead time.

# Development of EEW system exchanging real-time seismic intensity and seismic waveform

*Shigeki Horiuchi[1], Yuko Sato[1], Taku Urabe[2], Yamaimaiti Nizhamudong[3], Kazuo Sasaki[3]

1. Home Seismometer Corporation, 2. telemetra , 3. Challenge

**1. Introduction** JMA started to issue PLUM telegram in EEW system, which delivers values of real-time intensity measured at all JMA seismic stations in addition to the values of hypocenter parameters. Since the magnitude saturates when a catastrophic earthquake occurs, JMA recommends to use the PLUM method, which uses the maximum value of intensity within 30 km from user location for the intensity estimation. Horiuchi et al. (2011) proposed a method to estimate the fault area of a catastrophic event in real time by using the spatial distribution of real-time seismic intensities. In this report, we developed a system that estimates the location of fault area, displays it on the screen of user’ s PC, and outputs the sound alarm. This system collects continuous waveform from seismic stations using MEMS sensor and delivers waveform data at a time of earthquake occurrence to users PC.

**2. Method of real-time estimation of the fault area of a catastrophic event** In the case JMA issues EEW with magnitude 7.7 or more, the present system starts to determine fault area by using the method of Horiuchi et al. (2011) with data of real-time shaking intensities. When values of observed seismic intensity is larger than the estimated values from the empirical attenuation equation by Shi and Midorikawa (1999), their method determines distances from these stations to the edge of the fault and determine the location of fault area from the distribution of the edge locations.

**3. System overview** The present system consists of center server and seismic observation stations equipped with MEMS sensor and Raspberry pi. The roles of center server are (1) receives the plum telegrams from JMA, (2) accepts user registration, (3) acquires continuous waveforms for observation stations, (4) transmits followings to the windows PC of users, 1) hypocenter parameters from JMA, 2) Real-time seismic intensities from JMA and from observation stations of Raspberry Pi, 3) Waveform data at a time of earthquake occurrence. It is required for the user to register user information such as the coordinates of the user location from the Web screen. When the EEW is delivered, the predicted seismic intensity is outputted on the screen. There is a function to issue EEW for the training. In a case a user generates an earthquake in the web site of center server, the center server sends hypocenter parameters and values of shaking intensity to him. If the testing earthquake is a catastrophic event, his PC computes and displays the spread of the fault area for the testing event.

**4. result**

(1) Since the present PC software provides shaking intensity data and the real-time waveform from the neighboring observation station, these data may be effectively used for the accurate damage prediction by a strong earthquake.

(2) We checked with using observed shaking intensity data whether the spread of the fault area are correctly obtained by the present system. We use shaking intensity data obtained by K-NET from the 17 major earthquakes for the checking. As a result, it was shown that a nearly correct fault area was estimated.

Thu. May 30, 2019 3:30 PM - 5:00 PM JST | Thu. May 30, 2019 6:30 AM - 8:00 AM UTC | A08 TOKYO BAY MAKUHARI HALL

## [S-CG59] Reducing risks from earthquakes, tsunamis & volcanoes: new applications of realtime geophysical data

convener:Masashi Ogiso(Meteorological Research Institute, Japan Meteorological Agency), Naotaka YAMAMOTO CHIKASADA(National Research Institute for Earth Science and Disaster Resilience), Satoshi Kawamoto(Geospatial Information Authority of Japan), Mitsuyuki Hoshiba(Meteorological Research Institute), Chairperson:Naotaka Chikasada(National Res. Inst. for Earth Science and Disaster Resilience), Masashi Ogiso(Meteorological Research Institute, JMA)

As the number of population centers grows in regions with earthquake, tsunami and volcano hazards, the importance of improving methods for rapid, realtime estimates of activity increases. Realtime monitoring, analysis, and prediction of seismic ground motion, crustal movement and tsunami will be powerful tools to contribute to earthquake and tsunami disaster preparedness/mitigation. Tsunami and Earthquake Early Warning systems exist today in many locations around the world. Now JMA has started to promptly provide Eruption Notices to inform people of impending and beginning volcanic eruptions. Large events like the 2011 Tohoku Earthquake (Mw9.0) have demonstrated some of the shortcomings of existing techniques. In this session, we invite presentations on new ideas, methods and applications of (near) realtime analysis of seismic, geodetic and tsunami data, to the problem of realtime prediction aimed at improving disaster preparedness/mitigation in the fields of earthquake, tsunami and volcano observation. Presentation is encouraged to bring together scientists, engineers, and practitioners from a broad range of backgrounds from around the world, and to promote collaborative communication at the leading edge of the science and technologies.

# Enhancements of real time seismic intensity estimation using seismic intensity meters maintained by a local government –Case study on Tottori prefecture -

*Takao Kagawa[1]

1. Tottori University Graduate School of Engineering

Enhancements of real time seismic intensity estimation using seismic intensity meters maintained by a local government is demonstrated. Dense observation network is desirable for upgrading accuracy and quality of Earthquake Early Warning System. Seismic intensity meters installed in all municipalities are the most suitable equipment for the purpose. The seismic intensity meters in Tottori prefecture are improved to broadcast packets with peak ground acceleration and JMA seismic intensity at every one second. The data are received at Tottori University and PLUM method is applied to the data for estimating JMA seismic intensity distribution at 1km grid points. In this study, two additional methodologies are introduced on the system. One is attenuation of seismic intensities from observed sites and propagation from every grids for estimation. Another is introduction of P wave amplitudes for seismic intensity estimation. Using the methodologies, we can obtain rapid and detailed seismic intensity distribution than before.

*Kenji Kanjo[1], Isao Takahashi[1], Yoshinori Shinohara[1], Rami Ibrahim[2]

1. Takamisawa cybernetics Co. Ltd, 2. Earthquake Research Institute, University of Tokyo

Earthquake damage can be caused from a small-sized earthquake (magnitude class 4.5) occurs in inland areas to a large-sized earthquake such as the 2011 Tohoku earthquake (Mw 9.1). In recent years, it is possible to estimate the amount of detailed displacement of the destruction zone from the inversion analysis of observed data. Moreover, ground motion prediction equations (GMPEs) and earthquake prediction recipes have been proposed. Those developments contributed to the earthquake disaster mitigation measures. Earthquake early warning system (EEW) of Japan has been in operation since 2007, it is very useful to issue information that have a great impact on disaster mitigation, however, some problems still exist with the information issued by EEW. For instance, the warnings are sometimes issued after S-wave arrivals, which leaves an area without alarm known as a blind zone area.

In this study, we used a dense seismic network dataset recorded during the 2016 Kumamoto (Mw 7.0), and the 2019 January 3rd (Mw 5.1) earthquakes, maximum JMA intensity of 7 and 6 upper, respectively. In spite of the difference of magnitudes and source size area the two earthquakes had close maximum intensity values. It noted that the average spacing distribution of seismic instrument in that regions is ~ 4-5 km. We here obtain the maximum peak ground acceleration (PGA) on free surface on each observed point, we then corrected PGA to engineering basement, using site effect information from J-SHIS (NIED), spaced by 1×1 $km^2$. Using PGA on engineering bedrock, we estimate the PGA on free surface by multiplying with surface amplification factor at each grid point of 1×1 $km^2$, we then evaluate the seismic intensity at each grid. We repeat this process for each observed point considering the inter-station distance and finally produce the intensity map.

Our method gives a quick information about earthquake location (close or far), hypocentral depth (shallow or deep) inferred from apparent velocity distribution maps. It also recognizes the earthquake source size (small or large) inferred from the spatial distribution of PGA. We also attempted scaling by so-called P wave detection and maximum seismic intensity distribution prediction using theoretical amplitude ratio (5 times) of S wave / P wave at the seismic source.

It is a very important issue to observe the strong-ground motion in real-time to improve the performance of EEW. We strongly recommend local government to have their own high density network, which gives a quick earthquake disaster information. The Japan Meteorological Agency will aim for speeding up and improving the precision of emergency earthquakes (eliminating the blind zone) by integrating server information of each local government (with small budget without directly telemetering observation point data covering several thousands of points).

# Improvements of the GEONET real-time analysis system (REGARD) for more reliable operation

*Kazuyuki Ohashi[1], Satoshi Abe[1], Yasuaki Kakiage[1], Satoshi Kawamoto[1], Hiroshi Munekane[1]

1. GSI of Japan

The displacement data produced by GNSS observations never saturate for large earthquakes in contrast to seismometer data that has a limitation of instrument saturation. Geospatial Information Authority of Japan has launched a real-time GNSS analysis system named “REGARD” which estimates finite fault models based on the Japanese nationwide GNSS network GEONET. The REGARD system has been in operation since April, 2016. The system experienced 2016 Kumamoto earthquake, and provided a single rectangular fault model with very high variance reduction (VR) of 96%. The REGARD system has been become increasingly important for rapid response to major earthquakes for providing coseismic displacements, finite model estimate, and moment magnitude rapidly. Therefore, the system must be more stable. So we try to implement other positioning procedure to REGARD system.

The REGARD system conduct relative positioning by using reference station data and rover station data. If reference station data lacked, we can’t obtain the coordinates of all other station. So we focus on Precise Point Positioning(PPP). Real-time PPP analysis needs correction data of Ionospheric delay, Tropospheric delay, satellite clock and so on. We implement as follow system. (1) Collect real time observation data from about 100 worldwide GNSS station. (2) Estimate ephemeris and collection data by using MADOCA(Multi-GNSS Advanced Demonstration tool for Orbit and Clock Analysis) developed by JAXA. (3) Conduct real time PPP analysis.

As a results of accuracy evaluation of real time PPP analysis, the accuracy is less than REGARD system. If we subtract one station results from other station(PPP-differential), the accuracy is improvement as well as REGRAD system. Therefore, real time PPP analysis system is expected to be useful for improving redundancy and robustness of REGARD system.

# Development of “real-time” uncertainty evaluation algorithm for the estimated coseismic fault model using MCMC approach

*Keitaro Ohno[1], Yusaku Ohta[1]

1. Recerch Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

Rapid understanding of the magnitude of large earthquakes and their associated fault dimensions are extremely important. Since September 2012, Geospatial Information Authority of Japan (GSI) and Tohoku University are jointly developing the GEONET real-time analysis system (REGARD). REGARD system rapidly estimates two types of coseismic fault models, which are slip distribution along the plate interface and single rectangular fault model, using permanent displacement field based on the real-time GNSS tine series. Currently, REGARD adopted the maximum likelihood approach to estimate the optimum model. The system has two points to be improved. As first point, it is difficult to estimate the quantitative uncertainty estimation of the obtained result because of the estimated result should contain both of the observation error of the real time GNSS and modeling error caused by the model settings. Understanding of such uncertainties quantitatively based on the data is important for evaluation of the result for disaster response. Second point, the problem is non-linear to estimate the single rectangular fault model in REGARD. Thus, the result strongly may depend on the initial values of the fault parameters. It is necessary to find the global minimum quickly for real-time use.

Based on these backgrounds, we are developing coseismic fault model estimation system using MCMC (Markov Chain Monte Carlo methods), which is probabilistic approach based on Bayesian statistics. MCMC does not specify one maximum likelihood value, but estimates the posterior probability density function (PDF). In addition, dependency on the initial value is relatively small by searching unknown parameters over a wide range randomly. In this study, we focus on the development the algorithm to estimate the single rectangular fault model deduced from permanent coseismic displacement field in real-time. We adopted basic Metropolis Hasting method as sampler and utilized parallel tempering approach to improve the sampling efficiency. One of the challenges for using MCMC in real time is how to make search settings, such as initial value, walk distance, variance of likelihood function, and Burn-in, which are generally decided by the try and error. We suggest a method of deciding these values automatically using scaling law and original sampling flow. Other challenging issue is calculation time. In generally, the calculation cost of MCMC is problem for the real-time purpose. To improve the performance of the MCMC we adopted OpenMP for the parallelization of the computing.

We applied this approach to the 2011 Tohoku-Oki earthquake, 2016 Kumamoto earthquake, and 2016 Fukushima-Oki earthquake using the actual permanent displacement time series from REGARD. In each estimations, we got $1\times10^6$ samples and obtained posterior PDF within 30 seconds. To emphasize, this algorithm could estimate the magnitude as distributions based on the data. Especially in Tohoku-Oki earthquake, obtained results clearly shows the tradeoff between the fault area and the slip amount. This result suggests that the onshore GNSS data cannot constrain them, which are extremely important factors for precise near-field tsunami forecasting.
In our presentation, we will show the more detail characteristic of the algorithm. We are working on development of it for single rectangular fault model aiming at actual operation. Furthermore, we will expand this approach to not only the single rectangular fault but also the slip distribution along the plate interface.

# Drifting float measurement of pressure change by tsunami

*Masayuki Obayashi[1], Shingo Watada[2], Hiroko Sugioka[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. Earthquake Research Institute, University of Tokyo, 3. Department of Planetology, Kobe University

Recently a new instrument, named MERMAID (Mobile Earthquake Recording in Marine Areas by Independent Divers), was developed to measure acoustic signals converted from seismic waves at the seafloor. The MERMAID is a Lagrangian drifter equipped with a hydrophone and drifts passively at 1,500 –2,000 m depth until an earthquake signal is detected. If this is identified as a strong P wave, the MERMAID ascends at speed of 10 cm/s for transmission of the recorded waveform within time window of a hundred seconds before and after the P wave arrival as well as its global positioning system (GPS) coordinates at the surface. After transmitting the data via satellite links, the MERMAID descends at speed of 5 cm/s to monitor earthquake signals at 1,500 –2,000 m depth again.
It was reported that tsunamis were recorded by hydrophones (e.g. Okal et al., 2007), notably in frequency bands extending outside the range of the Shallow Water Approximation. If MERMAID floats can cover the oceans as dense as the Argo project of which almost 4000 floats are now drifting to measure temperature and salinity in the oceans, we acquire valuable tsunami data. Here we estimate what signals are observed by a MERMAID, by comparing to the pressure change of the 2010 Chile Tsunami measured by a differential pressure gauge (DPG) at about 4800 m deep seafloor.
We assume linearized water wave with period $T$, amplitude $H$, and phase velocity $c$ as shown in Figure 1. Phase velocity $c$ is given by $c = (g \tanh(kD) / k)^{1/2}$, where $k$ is horizontal wavenumber $k = \omega / c$, $\omega = 2\pi / T$ is angular frequency and $g$ is gravity. The wavenumber $k(\omega, D)$ of the water waves in a constant depth ocean as a function of a wave period is obtained by the recursion equation. The water wave height $W(x, t)$ as the function of time $t$ and horizontal position $x$ is expressed as
$W(x,t) = H e^{i(kx-\omega t)}$
The MERMAID is Lagrangian float drifting at a depth of $z$ ($0 > z > -D$) and measures Lagrangian pressure of water, where $D$ is water depth.
Lagrangian pressure $\delta p(x, z, t)$ is given by
$\delta p(x, z, t) = -\{H \rho_o g \sinh(kz) / (\sinh(kD) \cosh(kD))\} e^{i(kx-\omega t)}$
Eulerian pressure is given by
$p'(x, z, t) = \{H \rho_o g \cosh(k(D+z)) / \cosh(kD)\} e^{i(kx-\omega t)}$
Therefore, pressure measured by a DPG at seafloor is expressed as
$p'(x,-D, t) = \{H \rho_o g / \cosh(kD)\} e^{i(kx-\omega t)}$
and the pressure $\delta p(z)$ measured by a MERMAID at $z$ depth can be related
with the DPG pressure $p'(D)$ by
$\delta p(z) = R\, p'(-D)$, $R = -\sinh(kz) / \sinh(kD)$
If $T$ is large enough that $k$ is close to 0, $R$ becomes close to $z/D$. Figure 2 shows the $R$ as the function of $T$ for floats at 1000 (blue) and 2000 (red) m depth, suggesting the $R$ acts as a low-pass filter. Figure 3 shows the predicted pressure changes observed floats drifting at 1000 (blue) and 2000 (red) m depth. In the presentation, we will discuss availability of tsunami measurement by a float.

# Development of the Real-time Forecasting for Meteorite Impact Tsunami

*Naotaka YAMAMOTO CHIKASADA[1], Toshitaka Baba[2], Tetsuharu Fuse[3]

1. NIED, 2. Tokushima University, 3. NICT

Tsunami induced by earthquakes, submarine landslides, volcanic eruption in submarine and coastal area and meteorological phenomena is one of the most devastating natural disasters. A meteorite impact into the oceans spawn large tsunami depending on the size and velocity of the meteorite and the sea depth at the location of the impact as well. However, we do not have a numerical model to reproduce both of meteorite impacts and tsunami propagations. We have started to develop a new numerical model to simulate tsunamis generated by the meteorite impact combining iSALE (Wünnemann et al., 2006) for simulating impact phenomena and JAGURS (Baba et al., 2017) for simulating tsunami. The iSALE is a multi-material and multi-rheology shock physics code for simulating impact phenomena. JAGURS is a parallelized tsunami simulation code to solve two-dimensional non-linear long-wave equation with Boussinesq terms for representing observed tsunami waveforms, tsunami height and inundation. We set sea-floor deformation, sea-surface disturbance and velocity of gravity wave which is the output from iSALE to the input of JAGURS. We then calculate tsunami height along the coastlines in any place using ASTER GDEM version 2 (Fujisada et al., 2012) and GEBCO_2014 Grid. ASTER GDEM has one arcsecond (about 30 m) spatial resolution and covers land between 56S and 60N latitude as a topographic data. GEBCO’s gridded bathymetric data has thirty arcseconds (about 1 km) spatial resolution for the worldwide.
We first investigate the tsunami generation using iSALE code for creating tsunami source model depending on the meteor size, the velocity of impact, the size of cavity, the width and depth of crater and tsunami propagation speed. We also investigate probabilistic hazard of meteorite impact tsunami using simplified cavity curves with developed JAGURS built-in. Finally, we construct a new numerical model of meteorite impact tsunami combining iSALE and JAGURS. Additionally, we consider the way of automatic detection of meteorite impact using the recode of the highly sensitive seismograph network in real-time.
We gratefully acknowledge the developers of iSALE, including Gareth Collins, Kai Wünnemann, Boris Ivanov, H. Jay Melosh and Dirk Elbeshausen. Data analysis and visualizations of iSALE were carried out on PC cluster and computers at Center for Computational Astrophysics, National Astronomical Observatory of Japan. This work was partially supported by JSPS KAKENHI Grant Number JP18K04674.

## [B-PT05] Biotic History

convener:Isao Motoyama(Department of Earth and Environmental Sciences, Yamagata University), Takao Ubukata(Division of Geology & Mineralogy, Department of Earth & Planetary Sciences, Kyoto University), Kazuyoshi Moriya(Department of Earth Sciences, Faculty of Education and Integrated Arts and Sciences, Waseda University), Chairperson:Isao Motoyama, Takao Ubukata, Kazuyoshi Moriya

The Biotic History session covers all aspects of ancient life and the history of biosphere through the geologic time. The study of ancient life is essential for unveiling mysteries of our planet earth. It also provides evidence for evolution of oceans, continents and island arcs. Modern progress in this field has been enhanced by interdisciplinary collaboration with allied sciences, such as paleoceanography and evolutionary biology. Our session intends to be a hub of communication amongst all earth scientists studying the biosphere; we welcome biological and biogeochemical approaches toward the understanding of the history of life.

# Cause of accelerated evolution of Earth’s life; four-layered underground robust bio-communities played a critical role for the accelerated genome evolution as a response of mass extinction

*Shigenori Maruyama[1], Akio Kanai[2], Issay Narumi[3]

1. Earth-Life Science Institute, Tokyo Institute of Technology, 2. keio University, 3. Toyo University

It has long been recognized the concept of five kingdom or six kingdom model which shows the life with difference of function and size. If believing Darwinian Evolution, how can we interpret the diversified distribution with primitive small microbes to the most evolved types of large life. If we consider the most evolved metazoans such as human being to be the result of increased free oxygen in atmosphere, why do the anoxic microbes remain on the surface.
We have engaged in the decoding Earth history Program over 30 years, and obtained the following six results, (1)Since the birth of life until 4.0Ga, three times of Great Evolution of Life (GEL) occurred, (2)Those evolutions were predominantly controlled by the $pO_2$ increase in the environments, (3)Underground bio-communities are present forming 4-layers with boundary layers, (4)Each layer corresponds to different $pO_2$ levels; the older the lower $pO_2$ , (5)In between the two, where two-way genome biomes are present, although speculative, and (6)These four layers could have been formed during the 3 GEL times, accompanying many mass extinctions. Those were remained as fossil environments where evolution stopped, because of no significant environmental changes, in spite of extremely severe surface environments with frequent mass extinction and resultant accelerated evolution of life.
The result corresponds to the concept of 5-6 Kingdom which suggests the preservation of biological communities with different level of $pO_2$ in environments. Through the Earth history, new GEC occurred with great change of $pO_2$ , the advanced life on the surface suffered mass extinctions due to exponentially decreased $pO_2$, instead the underground microbes invaded to the surface, and evolved there again. This is the entity of evolution of life on the earth. Therefore, the presence of robust 4 layered underground biological communities must have contributed to evolving life on this planet, in spite of severe environmental change of planets over 4.0 billion of years in the Universe, not by death, but evolved thorough GEL at 4.0Ga, 2.2Ga and 0.6Ga.

# Amino acid composition in molluscan shells and its relation to taxa and shell microstructure ~ Toward reconstruction of ancient trophic level using compound specific isotope analysis of amino acids ~

*Naoki Yugami[1], Akiko Goto[2], Robert Jenkins[2]

1. Graduate School of Natural Science & Technology. Kanazawa Univercity, 2. Institute of Science & Engineering . Kanazawa Univercity

We may clarify the trophic level of fossils applying “trophic level estimation method using compound specific isotope analysis of amino acids” (Chikaraishi et al., 2009). When applying the method to fossils, we must pay attention to whether amino acids in fossils are original or not, so screening of fossil samples is important. We can apply "amino acid composition conforming to shell microstructure" to the screening of fossi samples. This depends on a study showing the amino acid composition is different for each shell microstructure in the present bivalve (Kobayashi and Samata, 2006). We may determine whether amino acids present in the fossil shell are original or not by confirming “whether there is an amino acid composition specific to the shell microstructure observed in the fossil”. However, Kobayashi and Samata (2006) showed only the difference in amino acid composition each shell microstructures in the bivalvia, and not showed stability in the lineage relationship of the same microstructure. Moreover, there are problems such as the fraction of the amino acid composition, the method used, and the equipment to be used are different for each article, so it is difficult to compare for each article easily. In addition, there are no papers showing amino acid composition of Protbranchia of bivalvia. From the above, the stability of the amino acid composition for each shell microstructures in the lineage is unknown. Therefore, we set the pupose of this research that clarifying the stability of the amino acid composition of each shell microstructure in molluscan from the present raw sample. In this study, we focus on nacreous structure because this structure contain a lot of organic matter and it is primitive structure. We will clarify the stability of the amino acid composition of each taxa and shell microstructure, comparing within each taxa and lineage of bivalve, gastropod, and cephalopod.

As a result of cluster analysis, we found that the amino acid composition can be roughly divided into two groups, "primitive group" and "derivative group", in both the gastropoda and bivalvia. The amino acid composition of *Turbo sazae, Turbo mamoratus* and *Lunella coreensis* of gastropoda belonging to the same family were stable. Moreover, in the bivalvia, the amino acid composition is stable in the Pteriomorpha and Palaeoheterodonta, and in the Protobranchia, respectively. We could find the differences in the amount of alanine etc. in the Pteriomorpha- Palaeoheterodonta lineage and Protobranchia lineage. From this, it can be said that the amino acid composition of the nacreous structure is stable in family in gastropoda and stable in subclass in bivalvia. Cluster analysis showed that "gastropoda group" and "bivalvia group" have relatively close relationships, and their amino acid composition is similar in that alanine and glycine are abundantly included. However, it has been suggested that proteins used for shell formation in bivalvia and gastropoda may have been obtained independently in the process of evolution (Mann et al., 2018). Since amino acids which are likely to be included depending on the function of the protein are determined, it is thought that the amino acid composition converges evolutionarily and is similar even if it has different proteins.

Through this study, both bivalvia and gastropoda are roughly divided into two groups, "primitive group" and "derivative group", and furthermore, we could set the amino acid compositions used for screening of

©2019. Japan Geoscience Union. All Right Reserved. 

fossil samples of nacreous structure to five, "Nautilus", "primitive of Vetigastropoda", "derivative of Vetigastropoda", "primitive of Bivalvia (Protobranchia)", "derivative of Bivalvia (Pteriomorpha, Palaeoheterodonta)". Therefore, we will be able to screen fossil samples of nacreous structure more precisely by using "amino acid composition conforming to lineage-shell microstructure" for trophic level estimation.

# Relation of shell form to rocking motion in planispiral cephalopods

*Takao Ubukata[1]

1. Division of Geology & Mineralogy, Department of Earth & Planetary Sciences, Kyoto University

In Recent *Nautilus*, thrust force produced by the hyponomic jet acts to rotate the shell resulting in a rocking motion during swimming. This instability is a potential problem for any other ectoconchleate cephalopods with planispiral conchs when they swim. A smaller distance between the center of gravity and center of buoyancy tends to cause a large rotation of the shell. For this reason, it has long been imagined that ammonoids with long body chambers are less stable than *Nautilus* during swimming. In contrast, it has also been considered that a long body chamber places the aperture higher and positions the hyponome at the same level of the center of gravity so that the hyponomic jet can act directly through the center of gravity. Previous discussions on static stability of ectoconchleate cephalopods largely focused on indirect assessment based on the aperture orientation and the position of the center of gravity and center of buoyancy. The present study assessed the angle of rocking motion for various shell forms of planispiral cephalopods to generalize the relationship between conch geometry and static stability. The angle of rocking motion was computed for theoretical morphologic models based on force and moment balance presuming a neutrally buoyant condition. The thrust force of hyponomic jet was assumed to be expelled from the ventral edge of the aperture and to generate a moment which is opposed by the restorative moment produced by inclination of segment between the center of gravity and center of buoyancy. Form drag and shear stress acting on the shell moving with respect to surrounding water were ignored in calculating the opposing moment. The inclination angle of the segment between the center of gravity and center of buoyancy was regarded as the angle of rocking motion and was computed for each theoretical model with given values of whorl expansion rate, relative umbilical width, and relative whorl breadth. The result revealed following: (1) The angle of rocking motion fluctuates with changes in the whorl expansion rate (*W*) if the value of *W* is small enough so that the body chamber is more than one whorl in length. In this condition, the rocking angle varies sensitively to the change in *W*. (2) The rocking angle is large when the shell is slender. (3) The rocking angle does not highly depend on the relative umbilical width. These results indicate that the long body chamber resulting from a small *W* does not always allow the animal stable swimming and a slight intraspecific or ontogenetic variation in *W* may cause drastic change in static stability in such form. The result suggests that such static instability limits swimming ability in some ammonoids with tightly coiled conchs.

# Paleoenvironment aross the Meddle Eocene Climatic Optimum

Hiroki Masui[1], *Kazuyoshi Moriya[1]

1. Department of Earth Sciences, Faculty of Education and Integrated Arts and Sciences, Waseda University

The Middle Eocene Climatic Optimum (MECO) is an abrupt short-term global warming event that occurred about 40 Ma. Although this event is now reported from all across the world, the environmental impacts and biotic responses accompanying the event are still poorly understood. Since we are now faced with the threat of global warming, deeper understanding of past global warming events like the MECO is critical.

We present bulk carbonate stable isotope data, coarse fraction accumulation rates (CFAR), and planktic foraminiferal assemblage data spanning the MECO interval from International Ocean Discovery Program (IODP) Site U1408 in the Northwest Atlantic to assess environmental changes and biotic responses across the event. A negative shift in bulk $d^{18}O$ was observed from 40.6 Ma (the MECO onset) to 40.0 Ma (the peak MECO), followed by a sudden return to the background level by 39.9 Ma (the termination). A significant decline of CFAR was observed near the peak of the MECO (40.3 Ma–40.0 Ma). This may reflect a decline in planktic foraminiferal production due to starving caused by elevated metabolism coupled by limited availability of nutrients. In contrast, a sudden increase in bulk $d^{13}C$, CFAR, and eutrophic planktic foraminiferal genus, *Pseudohastigerina*, was observed immediately after the peak of the MECO (40.0-39.9Ma). This may indicate a sudden switch to the eutrophic environment and an increase in primary and planktic foraminiferal production. The termination of the warming might have caused continental aridification and resulted in an increased input of aeolian dust to the ocean. In addition, the relative abundance of photosymbiotic planktic foraminiferal genus, *Acarinina*, declined toward the peak of the MECO, while the relative abundance of another photosymbiotic genus, *Globigerinatheka* remained almost constant throughout the MECO. This may indicate the loss of photosymbiotic algae exclusively affected *Acarinina* during the event.

# Reconstruction of the North Pacific subtropical gyre from the Middle to Late Miocene as inferred from radiolarian assemblages

*Shin-ichi Kamikuri[1], Isao Motoyama[2], Taiki Sawada[3]

1. Faculty of Education, Ibaraki University, 2. Faculty of Science, Yamagata University, 3. Japan Petroleum Exploration Co.,Ltd.

A major objective of the present study is to reconstruct gyral circulation patterns of the subtropical North Pacific from the middle to late Miocene based on the radiolarian assemblages. We collected the mudstones from ODP Site 1021 of the California margin in the northern area of the California Current, and from outcrops of the Boso Peninsula (Japan) in the northern area of the Kuroshio.
The middle Miocene subtropical Pacific was dominated by warm-water taxa, and similar taxa in the eastern and western areas. The distribution pattern of radiolarian faunas in the subtropical North Pacific was due to be similar in the surface water structure and temperature, and indicates that the general gyral circulation system was only weakly developed in the middle Miocene. During the late Miocene the cool-water taxa increased and the warm-water taxa declined overall in the subtropical Pacific. At the same time the east-west faunal provincialism increased. This faunal change has been associated with the resultant strengthening of the general gyral circulation in the subtropical Pacific due to the significant high latitude cooling and the closing of the Indo-Pacific Seaway at that time.

# Fossilization processes of Pliocene tree fossils from the Yasu River, Shiga Prefecture, Japan: Organic geochemical approach

*Jinya Nakamura[1], Ken Sawada[2], Masashi A Ikeda[1], Hideto Nakamura[3], Minoru Tsukagoshi[4]

1. Graduate School of Science, Hokkaido University, 2. Department of Earth and Planetary Sciences, Faculty of Science, Hokkaido University, 3. Faculty of Science, Osaka City Univerisity, 4. Osaka Museum of Natural History

The Pliocene fossil forest (ca. 2.7 Ma) is known to be distributed in the Yasu River, Shiga Prefecture, Japan. The tree fossils in the forest are characterized by blackish coal-like tissues in the surface but living tree-like fresh lignite in their inner part. In the present study, we investigate by organic geochemical analyses to identify the taxonomy and to examine fossilization, diagenesis, and taphonomy of the tree fossil.

The tree fossils used was separated to three parts; surface (outer), intermediate, and inner parts. The outer part is blackish coal-like tissue, but inner part is brownish lignite. The intermediate part is dark brownish lignite-like tissue. Lipids were extracted with dichloromethane/methanol, and separated to aliphatic, aromatic and polar fractions. Lipids were identified and quantified by GC-MS. The residues after extraction were used for pyrolysis and thermochemolysis by GC-MS equipped a Curie-point pyrolyzer. Thermochemolysis was performed with tetramethylammonium hydroxide (TMAH)

By the thermochemolysis, vanillic phenols are predominantly detected in all parts of the tree fossils. Phyllocladane and cuparane were identified as major plant-derived terpenoids in fee (extractable) components of the fossil samples. The phyllocladane is conifer-derived diterpenoid, and cuparane is a specific sesquiterpenoid produced by subfamily Cupressaceae. In addition, sugiol, which originated from family Taxodiaceae, were not detected in the fossil samples. Thus, the tree fossil can be presumably identified as subfamily Cupressaceae.

Polyaromatic hydrocarbon (PAH), which are generated by combustion at high temperature, were hardly detected in the blackish outer sample. Thus, the fossil did not experience burning by wild fire etc. The relative abundances of aldehyde-type lignin phenols are clearly lower in the outer sample, implying that degradation of woody tissues took place in the outer parts of fossil. Interestingly, aromatic and A-ring degraded (des-A) terpenoids were identified as free compounds in the outer sample. The aromatic and des-A terpenoids were reported to be compounds generated by microbial degradation during early diagenesis. The facts indicate that the woody tissues might be degraded by microbial activity in the outer part of the tree fossil. Moreover, the relative abundances of methoxy phenols decrease in the outer part, so that gelification of the degraded woody tissues occurred in the parts.

Keywords: tree fossil, fossilization processe, microbial degradation, plant terpenoid, lignin phenol

[J] Poster | B (Biogeosciences )：B-PT Paleontology

Thu. May 30, 2019 3:30 PM - 5:00 PM JST | Thu. May 30, 2019 6:30 AM - 8:00 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_18

## [B-PT05] Biotic History

convener:Isao Motoyama(Department of Earth and Environmental Sciences, Yamagata University), Takao Ubukata(Division of Geology & Mineralogy, Department of Earth & Planetary Sciences, Kyoto University), Kazuyoshi Moriya(Department of Earth Sciences, Faculty of Education and Integrated Arts and Sciences, Waseda University)

The Biotic History session covers all aspects of ancient life and the history of biosphere through the geologic time. The study of ancient life is essential for unveiling mysteries of our planet earth. It also provides evidence for evolution of oceans, continents and island arcs. Modern progress in this field has been enhanced by interdisciplinary collaboration with allied sciences, such as paleoceanography and evolutionary biology. Our session intends to be a hub of communication amongst all earth scientists studying the biosphere; we welcome biological and biogeochemical approaches toward the understanding of the history of life.

# Simultaneous observations of both hard and soft tissues of *Oulastrea crispata* (Cnidaria: Scleractinia)

*Rie Tajiri[1], Yuki Tokuda[2], Yoichi Ezaki[1]

1. Osaka City University, 2. Tottori University of Environment Studies

*Oulastrea crispata* is a zooxanthellate colonial Scleractinia with a black skeleton. This coral inhabits areas of very shallow water where mud accumulates, and occupies the northernmost range of Japanese zooxanthellate corals. In this study, the hard and soft tissues of *O. crispata* were observed simultaneously by transmitted-light binocular microscope, fluorescence microscope, and scanning electron microscope by using the resin penetration technique (Tajiri and Fujita 2013) and the dehydration method (Tajiri and Ezaki 2018). Symbiotic algae are considered to play a key role in the life of *O. crispata*; however, the spatial distribution of such algae within the coral remains unknown. The present observations indicate that algal density is extremely high in the outer layers of polyps, and algae are densely distributed adjacent to the radial septa that partition the inner parts of polyps. The algal density is lower in deeper parts of polyps, and algae are scarce in the deepest part (up to 1 cm in depth), suggesting that little sunlight, if any, is available for photosynthesis. The hard skeletons of *O. crispata* are locally bored by euendoliths, which include microorganisms such as cyanobacteria, Chlorophyta, Rhodophyta, and fungi. These organisms erode not only the postmortem skeletal remains but also the living skeletons (e.g. Le Campion-Alsumard et al. 1995; Tribollet 2007). In living *Oulastrea*, skeletons located near the underlying hard substrate are intensively bored by euendoliths, mainly cyanobacteria and Chlorophyta. Endolithic filaments invade the soft parts of the coral, and the density of endolithic traces is lower near the upper part of skeletons and rare in upper peripheral areas. In contrast, both the lower and upper parts of dead skeletons are affected by intense endolithic activity. *O. crispata* manages to survive the prolonged biotic attack, especially the effects on its lower parts near the substrate that are subjected to a severe environment of intensive sedimentation and mechanical erosion.

Keywords: Oulastrea crispata, thin section, soft tissue, zooxanthella, euendolith, cyanobacteria

# Coral-based paleoenvironmental interpretation and depositional history of the late middle Pleistocene Minatogawa Formation, southern Okinawa-jima, Japan

*Riho Tomatsu[1], Marc Humblet[1], Kazuhiko Fujita[2]

1. Graduate School of Environmental Studies, Nagoya University, 2. Department of Physics and Earth Sciences, University of the Ryukyus

Reef-complex deposits exposed in the Ryukyu Archipelago, southwestern Japan, offer a unique record of Quaternary reef growth and sea-level changes close to the northern limit of modern coral reef distribution. Among these deposits, the Minatogawa Formation belongs to the so-called “younger limestone” (<0.4 Ma), and crops out in southern Okinawa-jima and on nearby small islands. The deposition of the Minatogawa Formation marks a major change in depositional style in the Ryukyu Islands, from subsidence-dominated, aggrading and retrograding sequences (>0.4 Ma) to uplift-dominated deposits offlaping older limestone (<0.4 Ma). Although their age has not been determined precisely yet, the limestones of the Minatogawa Formation are thought to have deposited during Marine Isotope Stage (MIS) 5 or the older MIS 7. The Minatogawa Formation is composed of two main lithologies: coral limestone (boundstone) and well-sorted detrital limestone (mainly foraminifer-rich grainstone). The coral limestones of the Minatogawa Formation contain abundant and diverse in situ fossil corals, but no detailed taxonomic study has been carried out so far despite their paleo-ecological importance. In this study, we examine the taxonomic composition and the spatio-temporal distribution of fossil coral assemblages in two stratigraphic units (Unit 2 and 3) of the Minatogawa Formation exposed in the Horikawa quarry, southern Okinawa island, and reconstruct their depositional history. Five coral assemblages are identified in the coral limestone, each indicating a particular reef environment. The depositional history of Unit 3, inferred from the analysis of coral assemblages and of the boundary between the coral boundstone and adjacent well-sorted detrital limestone in this unit, reveals at least two transgressive/regressive cycles of sea-level change, several meters in amplitude, resulting in an unconformity (dissolution surface) between the coral boundstone and adjacent well-sorted detrital limestone. In contrast, the coral limestone and well-sorted detrital limestone in Unit 2 formed concomitantly in the same reef setting, a lower reef slope, or perhaps a shallower but turbitid environment. In addition, the discovery of a syn-depositional fault suggests that small-amplitude relative sea-level changes were caused by tectonic activity and may have influenced reef growth and community structure during the deposition of the Minatogawa Formation.

Keywords: fossil coral communities, late middle Pleistocene, environmental and sea level changes, tectonic uplift, Minatogawa Formation, Okinawa-jima

# Calcareous nannofossil biostratigraphy and oxygen isotope stratigraphy of the lower part of the Pleistocene formation distributed in the central part of the Pacific side of Japan

*Daisuke Kuwano[1], Yoshimi Kubota[2], Kanako Mantoku[2], Koji Kameo[3]

1. Division of Earth and Environmental Sciences, Graduate School of Science and Engineering, Chiba University, 2. National Museum of Nature and Science, 3. Department of Earth Sciences, faculty of Science, Chiba University

Calcareous nannofossils, tiny calcite shells produced by calcareous nannoplankton, have been utilized to correlate marine strata and to determine their geologic ages. In the Quaternary, traceable sixteen nannofossil biohorizons were recognized (e.g., Sato et al., 1991) and some chronological studies have been done in order to test whether they were synchronous events or not based on comparative studies with astronomically tuned timescale in the equatorial Atlantic, the equatorial Pacific and the Mediterranean (e.g., Gradstein et al., 2012). This study aims at establishing the early Pleistocene age model based on oxygen isotopes in the central part of the Pacific side of Japan and evaluating synchrony of the early Pleistocene nannofossil biohorizons detected by Kuwano et al. (2019). We analyzed stable oxygen isotopes of a planktonic foraminifera, *Globorotalia inflata* from the upper part of Kiwada Formation in the Kazusa Group, a lower Pleistocene formation in the Pacific side of Japan. Isotopic measurements were performed by MAT253 Isotope mass spectrometer coupled with a Kiel IV carbonate device in the National Museum of Nature and Science.

An oxygen isotope curve obtained from 44 samples was correlated with the LR04 stack curve (Lisiecki and Raymo, 2005) and Marine Isotope Stages (MIS) 40 to 36 were recognized in the formation. Two calcareous nannofossil biohorizons, the last occurrences (LO) of large forms of *Gephyrocapsa* (>5.5 μm) and *Helicosphaera sellii* coincide with MIS 37/38 boundary and MIS 40, respectively. The LO of large forms of *Gephyrocapsa* is slightly older than those in other areas because this biohorizon is mostly situated in the early part of MIS 37 (Raffi et al., 2006). On the other hand, the LO of *Helicosphaera sellii* is found in MIS 38 in the northeastern Atlantic (Sato et al., 2009) and MIS 42 in the eastern equatorial Pacific (Wei, 1993). This biohorizon is possibly diachronous bioevent due to sporadic occurrences of this species.

# Cretaceous and Miocene geology and paleontology of the Tounai River region, Biratori, Hokkaido

*Isao Motoyama[1], Kotaro Uchimura[2], Tomohiro Nishimura[3], Yojiro Taketani

1. Department of Earth and Environmental Sciences, Yamagata University, 2. JCE Co.,LTD, 3. Hobetsu Museum

The Cretaceous rocks of the Yezo Group exposed in the Hobetsu district are richly fossiliferous containing marine mollusks (mainly inoceramids and ammonites), reptiles (mosasaurs, plesiosaurs and turtles) and echinoids and, therefore, many geological and paleontological works have been done so far. The Cretaceous rocks extend to the south, adjacent Biratori district, but works were less common there. We have carried out mapping to provide a revised geological map in the Tounai River area, Biratori Town, and analyzed molluscan and radiolarian fossils to estimate depositional ages. This is the first report of radiolarians from this area.

The Cretaceous Yezo Group in this area is subdivided into the Kashima and Hakobuchi Formations in ascending order and is cut by some faults. The Kashima Formation comprises fairly monotonous, hemipelagic mudstone intercalating with many acidic tuff beds. The Hakobuchi Formation is composed mainly of sandstone, conglomerate and sandy mudstone. Cross-bedded sandstone and minor coal beds suggest shallow-marine depositional environments for the Hakobuchi Formation. As a result, it has been recognized that the Kashima Formation distributes in the western part of the studied area and probably extends north to the neighboring region where the distribution of the Kashima Formation was discovered in 2015 by Negishi and coworkers. It is previously estimated that the Kashima Formation forms an anticlinal structure in the northern part of the Tounai River area. However, our investigation about facies and structures of tuff beds does not support such fold structure.

Fossils occurred throughout the Cretaceous sequence concerned here. Molluscan fossils, including *Inoceramus amakusensis*, *Inoceramus japonicus* and *Eupachydiscus haradai*, collected from the Kashima Formation of the studied section indicate ages of Santonian to Campanian. Radiolarian assemblages include *Amphipyndax stocki*, *Lithocampe manifesta* and *Spongotripus morenoensis*, suggesting ages of Coniacian to Maastrichtian for the Kashima Formation.

Miocene rocks distribute in the western margin of the studied area and are bounded from the Cretaceous rocks by a fault. The Miocene rocks subdivided into the Takinoue and Kawabata Formations in ascending order. The Takinoue Formation consists of mudstone and sandstone. Strata of the Kawabata Formation are dominated by interbedded mudstone and sandstone representing turbidite facies of deep-sea fans. In the studied area, the lower part of the Kawabata Formation crops out. Radiolarians were almost absent from the samples collected from these Miocene formations.

# Response of benthic organisms to oceanic anoxic event in the Early Jurasic (T-OAE): Insights from quantitative analysis of the trace fossil Phycosiphon from the Nishinakayama Formation, Toyora Group

*Kyosuke Kitabatake[1,2], Kentaro Izumi[3], Kenji Okoshi[1]

1. Department of Environmental Science, Faculty of Science, Toho University, 2. Department of Earth Sciences, College of Science, Ibaraki University, 3. Faculty & Graduate School of Education, Chiba University

Paleontological researches on the early Toarcian (Early Jurassic) oceanic anoxic event (T-OAE) have mostly focused on body fossils including marine microfossils. However, marine trace fossils, which are important for understanding the paleoecology of trace-making soft bodied marine benthos, have relatively less been investigated. Therefore, in this study, to evaluate the response of benthos to the T-OAE, we quantitatively measured the occurrence, fractal dimension, and maximum diameter of the trace fossil *Phycosiphon*, which is interpreted to have been produced by small benthos, from the Lower Jurassic shallow-marine Nishinakayama Formation of the Toyora Group (Shimonoseki City, Yamaguchi Prefecture, southwest Japan). Furthermore, to estimate the oceanic redox conditions during the early Toarcian, in addition to the consideration based on available geochemical data, we newly analyzed the size distributions of the pyrite framboids from the mudstones of the Nishinakayama Formation. As a result of our analysis, occurrence percentage and fractal dimension of *Phycosiphon* diminished in the T-OAE interval, and the maximum size also decreased. In addition, the size distribution of the pyrite framboids suggested that the euxinic conditionoccurred in the ocean at least several times during the T-OAE interval. Available geochemical data suggests that dysoxic benthic condition generally prevailed at the time of deposition of the Nishinakayama Formation. Taken together, it is possible that oceanic redox conditions may have been negatively affected to the ecology and body size of small marine benthos, although small organisms are generally less susceptible to environmental changes than large organisms.

[J] Poster | B (Biogeosciences )：B-PT Paleontology

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_33

## [B-PT05] Biotic History

convener:Isao Motoyama(Department of Earth and Environmental Sciences, Yamagata University), Takao Ubukata(Division of Geology & Mineralogy, Department of Earth & Planetary Sciences, Kyoto University), Kazuyoshi Moriya(Department of Earth Sciences, Faculty of Education and Integrated Arts and Sciences, Waseda University)

The Biotic History session covers all aspects of ancient life and the history of biosphere through the geologic time. The study of ancient life is essential for unveiling mysteries of our planet earth. It also provides evidence for evolution of oceans, continents and island arcs. Modern progress in this field has been enhanced by interdisciplinary collaboration with allied sciences, such as paleoceanography and evolutionary biology. Our session intends to be a hub of communication amongst all earth scientists studying the biosphere; we welcome biological and biogeochemical approaches toward the understanding of the history of life.

# Simultaneous observations of both hard and soft tissues of *Oulastrea crispata* (Cnidaria: Scleractinia)

*Rie Tajiri[1], Yuki Tokuda[2], Yoichi Ezaki[1]

1. Osaka City University, 2. Tottori University of Environment Studies

*Oulastrea crispata* is a zooxanthellate colonial Scleractinia with a black skeleton. This coral inhabits areas of very shallow water where mud accumulates, and occupies the northernmost range of Japanese zooxanthellate corals. In this study, the hard and soft tissues of *O. crispata* were observed simultaneously by transmitted-light binocular microscope, fluorescence microscope, and scanning electron microscope by using the resin penetration technique (Tajiri and Fujita 2013) and the dehydration method (Tajiri and Ezaki 2018). Symbiotic algae are considered to play a key role in the life of *O. crispata*; however, the spatial distribution of such algae within the coral remains unknown. The present observations indicate that algal density is extremely high in the outer layers of polyps, and algae are densely distributed adjacent to the radial septa that partition the inner parts of polyps. The algal density is lower in deeper parts of polyps, and algae are scarce in the deepest part (up to 1 cm in depth), suggesting that little sunlight, if any, is available for photosynthesis. The hard skeletons of *O. crispata* are locally bored by euendoliths, which include microorganisms such as cyanobacteria, Chlorophyta, Rhodophyta, and fungi. These organisms erode not only the postmortem skeletal remains but also the living skeletons (e.g. Le Campion-Alsumard et al. 1995; Tribollet 2007). In living *Oulastrea*, skeletons located near the underlying hard substrate are intensively bored by euendoliths, mainly cyanobacteria and Chlorophyta. Endolithic filaments invade the soft parts of the coral, and the density of endolithic traces is lower near the upper part of skeletons and rare in upper peripheral areas. In contrast, both the lower and upper parts of dead skeletons are affected by intense endolithic activity. *O. crispata* manages to survive the prolonged biotic attack, especially the effects on its lower parts near the substrate that are subjected to a severe environment of intensive sedimentation and mechanical erosion.

# Coral-based paleoenvironmental interpretation and depositional history of the late middle Pleistocene Minatogawa Formation, southern Okinawa-jima, Japan

*Riho Tomatsu[1], Marc Humblet[1], Kazuhiko Fujita[2]

1. Graduate School of Environmental Studies, Nagoya University, 2. Department of Physics and Earth Sciences, University of the Ryukyus

Reef-complex deposits exposed in the Ryukyu Archipelago, southwestern Japan, offer a unique record of Quaternary reef growth and sea-level changes close to the northern limit of modern coral reef distribution. Among these deposits, the Minatogawa Formation belongs to the so-called “younger limestone” (<0.4 Ma), and crops out in southern Okinawa-jima and on nearby small islands. The deposition of the Minatogawa Formation marks a major change in depositional style in the Ryukyu Islands, from subsidence-dominated, aggrading and retrograding sequences (>0.4 Ma) to uplift-dominated deposits offlaping older limestone (<0.4 Ma). Although their age has not been determined precisely yet, the limestones of the Minatogawa Formation are thought to have deposited during Marine Isotope Stage (MIS) 5 or the older MIS 7. The Minatogawa Formation is composed of two main lithologies: coral limestone (boundstone) and well-sorted detrital limestone (mainly foraminifer-rich grainstone). The coral limestones of the Minatogawa Formation contain abundant and diverse in situ fossil corals, but no detailed taxonomic study has been carried out so far despite their paleo-ecological importance. In this study, we examine the taxonomic composition and the spatio-temporal distribution of fossil coral assemblages in two stratigraphic units (Unit 2 and 3) of the Minatogawa Formation exposed in the Horikawa quarry, southern Okinawa island, and reconstruct their depositional history. Five coral assemblages are identified in the coral limestone, each indicating a particular reef environment. The depositional history of Unit 3, inferred from the analysis of coral assemblages and of the boundary between the coral boundstone and adjacent well-sorted detrital limestone in this unit, reveals at least two transgressive/regressive cycles of sea-level change, several meters in amplitude, resulting in an unconformity (dissolution surface) between the coral boundstone and adjacent well-sorted detrital limestone. In contrast, the coral limestone and well-sorted detrital limestone in Unit 2 formed concomitantly in the same reef setting, a lower reef slope, or perhaps a shallower but turbitid environment. In addition, the discovery of a syn-depositional fault suggests that small-amplitude relative sea-level changes were caused by tectonic activity and may have influenced reef growth and community structure during the deposition of the Minatogawa Formation.

# Calcareous nannofossil biostratigraphy and oxygen isotope stratigraphy of the lower part of the Pleistocene formation distributed in the central part of the Pacific side of Japan

*Daisuke Kuwano[1], Yoshimi Kubota[2], Kanako Mantoku[2], Koji Kameo[3]

1. Division of Earth and Environmental Sciences, Graduate School of Science and Engineering, Chiba University, 2. National Museum of Nature and Science, 3. Department of Earth Sciences, faculty of Science, Chiba University

Calcareous nannofossils, tiny calcite shells produced by calcareous nannoplankton, have been utilized to correlate marine strata and to determine their geologic ages. In the Quaternary, traceable sixteen nannofossil biohorizons were recognized (e.g., Sato et al., 1991) and some chronological studies have been done in order to test whether they were synchronous events or not based on comparative studies with astronomically tuned timescale in the equatorial Atlantic, the equatorial Pacific and the Mediterranean (e.g., Gradstein et al., 2012). This study aims at establishing the early Pleistocene age model based on oxygen isotopes in the central part of the Pacific side of Japan and evaluating synchrony of the early Pleistocene nannofossil biohorizons detected by Kuwano et al. (2019). We analyzed stable oxygen isotopes of a planktonic foraminifera, *Globorotalia inflata* from the upper part of Kiwada Formation in the Kazusa Group, a lower Pleistocene formation in the Pacific side of Japan. Isotopic measurements were performed by MAT253 Isotope mass spectrometer coupled with a Kiel IV carbonate device in the National Museum of Nature and Science.

An oxygen isotope curve obtained from 44 samples was correlated with the LR04 stack curve (Lisiecki and Raymo, 2005) and Marine Isotope Stages (MIS) 40 to 36 were recognized in the formation. Two calcareous nannofossil biohorizons, the last occurrences (LO) of large forms of *Gephyrocapsa* (>5.5 μm) and *Helicosphaera sellii* coincide with MIS 37/38 boundary and MIS 40, respectively. The LO of large forms of *Gephyrocapsa* is slightly older than those in other areas because this biohorizon is mostly situated in the early part of MIS 37 (Raffi et al., 2006). On the other hand, the LO of *Helicosphaera sellii* is found in MIS 38 in the northeastern Atlantic (Sato et al., 2009) and MIS 42 in the eastern equatorial Pacific (Wei, 1993). This biohorizon is possibly diachronous bioevent due to sporadic occurrences of this species.

# Cretaceous and Miocene geology and paleontology of the Tounai River region, Biratori, Hokkaido

*Isao Motoyama[1], Kotaro Uchimura[2], Tomohiro Nishimura[3], Yojiro Taketani

1. Department of Earth and Environmental Sciences, Yamagata University, 2. JCE Co.,LTD, 3. Hobetsu Museum

The Cretaceous rocks of the Yezo Group exposed in the Hobetsu district are richly fossiliferous containing marine mollusks (mainly inoceramids and ammonites), reptiles (mosasaurs, plesiosaurs and turtles) and echinoids and, therefore, many geological and paleontological works have been done so far. The Cretaceous rocks extend to the south, adjacent Biratori district, but works were less common there. We have carried out mapping to provide a revised geological map in the Tounai River area, Biratori Town, and analyzed molluscan and radiolarian fossils to estimate depositional ages. This is the first report of radiolarians from this area.

The Cretaceous Yezo Group in this area is subdivided into the Kashima and Hakobuchi Formations in ascending order and is cut by some faults. The Kashima Formation comprises fairly monotonous, hemipelagic mudstone intercalating with many acidic tuff beds. The Hakobuchi Formation is composed mainly of sandstone, conglomerate and sandy mudstone. Cross-bedded sandstone and minor coal beds suggest shallow-marine depositional environments for the Hakobuchi Formation. As a result, it has been recognized that the Kashima Formation distributes in the western part of the studied area and probably extends north to the neighboring region where the distribution of the Kashima Formation was discovered in 2015 by Negishi and coworkers. It is previously estimated that the Kashima Formation forms an anticlinal structure in the northern part of the Tounai River area. However, our investigation about facies and structures of tuff beds does not support such fold structure.

Fossils occurred throughout the Cretaceous sequence concerned here. Molluscan fossils, including *Inoceramus amakusensis*, *Inoceramus japonicus* and *Eupachydiscus haradai*, collected from the Kashima Formation of the studied section indicate ages of Santonian to Campanian. Radiolarian assemblages include *Amphipyndax stocki*, *Lithocampe manifesta* and *Spongotripus morenoensis*, suggesting ages of Coniacian to Maastrichtian for the Kashima Formation.

Miocene rocks distribute in the western margin of the studied area and are bounded from the Cretaceous rocks by a fault. The Miocene rocks subdivided into the Takinoue and Kawabata Formations in ascending order. The Takinoue Formation consists of mudstone and sandstone. Strata of the Kawabata Formation are dominated by interbedded mudstone and sandstone representing turbidite facies of deep-sea fans. In the studied area, the lower part of the Kawabata Formation crops out. Radiolarians were almost absent from the samples collected from these Miocene formations.

# Response of benthic organisms to oceanic anoxic event in the Early Jurasic (T-OAE): Insights from quantitative analysis of the trace fossil Phycosiphon from the Nishinakayama Formation, Toyora Group

*Kyosuke Kitabatake[1,2], Kentaro Izumi[3], Kenji Okoshi[1]

1. Department of Environmental Science, Faculty of Science, Toho University, 2. Department of Earth Sciences, College of Science, Ibaraki University, 3. Faculty & Graduate School of Education, Chiba University

Paleontological researches on the early Toarcian (Early Jurassic) oceanic anoxic event (T-OAE) have mostly focused on body fossils including marine microfossils. However, marine trace fossils, which are important for understanding the paleoecology of trace-making soft bodied marine benthos, have relatively less been investigated. Therefore, in this study, to evaluate the response of benthos to the T-OAE, we quantitatively measured the occurrence, fractal dimension, and maximum diameter of the trace fossil *Phycosiphon*, which is interpreted to have been produced by small benthos, from the Lower Jurassic shallow-marine Nishinakayama Formation of the Toyora Group (Shimonoseki City, Yamaguchi Prefecture, southwest Japan). Furthermore, to estimate the oceanic redox conditions during the early Toarcian, in addition to the consideration based on available geochemical data, we newly analyzed the size distributions of the pyrite framboids from the mudstones of the Nishinakayama Formation. As a result of our analysis, occurrence percentage and fractal dimension of *Phycosiphon* diminished in the T-OAE interval, and the maximum size also decreased. In addition, the size distribution of the pyrite framboids suggested that the euxinic conditionoccurred in the ocean at least several times during the T-OAE interval. Available geochemical data suggests that dysoxic benthic condition generally prevailed at the time of deposition of the Nishinakayama Formation. Taken together, it is possible that oceanic redox conditions may have been negatively affected to the ecology and body size of small marine benthos, although small organisms are generally less susceptible to environmental changes than large organisms.

## [M-IS03] Evolution and variability of the Asian monsoon in Cenozoic global climate changes

convener:Masanobu Yamamoto(Faculty of Environmental Earth Science, Hokkaido University), Ryuji Tada(Department of Earth and Planetary Science, Graduate School of Science, The Univeristy of Tokyo)

The Asian Monsoon (AM) is a part of interhemispheric atmospheric phenomena that is driven by the thermal gradient between ocean and land. Contrasts of insolation, heat content and latent heat transfer between ocean and land may have affected the behavior of the AM in the past, but the proxy records are occasionally controversial and do not show a clear picture of the AM variability. Recent proxy and modeling studies suggest that glacial pCO2 cycles could be related to the position of southern westerlies, which is sensitive to interhemispheric heat imbalance. Because monsoon is driven by the heat imbalance, knowledge on the variability of the AM is important to understand the behavior of the global climate system. In this session, presentations on the reconstruction of long-term AM variability from various archives such as IODP expedition cores, discussion on its forcing, and the roles of the AM in global climate changes are welcome.

# Asian dust source variability since 10 Ma based on grain size specific mineral composition at IODP Site U1425 in the Japan Sea

*Mui Fa Alison Lee[1], Tomohisa Irino[1]

1. Faculty of Environmental Earth Science, Hokkaido University

Sediments at Integrated Ocean Drilling Program (IODP) Site U1425 in the Japan Sea is under the strong influence of westerly jet stream and winter monsoon wind which transporting a significant amount of aeolian dust from both Taklamakan deserts and Gobi deserts. Aeolian dust from Taklamakan showed very high content of quartz (60-90%) and less plagioclase (5-40%) than from NE Chinese deserts and Loess (Gobi). The lower value of half height width (FWHM) of illite peak in X-ray diffraction (XRD) profile can be used as an indicator higher illite crystallinity. A decreasing trend of illite FWHM (increasing trend of the crystalinity) towards the core of the fold and thrust anticline has been recognized (Robinson et al. 1990; Orozco et al. 1998). Illite is also predominant component of the Chinese loess, and its highly crystallized nature has been interpreted to indicate that the illite was not formed at surface temperature and may have originated from a low temperature metamorphic environment.

In order to reconstruct a long-term changes in dust sources and transport pathways of Asian dust utilizing knowledges above, we examined mineral composition of IODP Site U1425 located at the central Japan Sea. The sediment samples were separated into >4 $\mu$m (silt) and <4 $\mu$m (clay) fractions by repeated pipette method. Both fractions were used for powder XRD analysis and peak heights of diagnostic peaks of major minerals were regarded as relative abundance of the minerals. FWHM and chemical index of illite were also examined.

In general, a very high quartz content found at Site U1425 may indicate sediments are aeolian source from Taklamakan deserts and higher plagioclase (albite) may infer dust source from Gobi deserts. Intervals around 9.5 Ma, 8.3 Ma, 7.9 Ma and 4.5 Ma showed very high quartz content and less albite at Site U1425, which indicate increases in dust supplied from Taklamakan than Gobi deserts due to stronger westerly wind. During Pliocene to early Pleistocene (4.2-2Ma), Taklamakan dust is still dominant, however the increasing influence of Gobi dust is recognized at 4.1 and 3.4Ma. On the other hand, an abrupt increase of the ratio of albite to quartz from 0.2 at 4.5 Ma to 0.8 at 4.1 Ma is found, which also shows another maximum at 0.6 Ma. In general, increase of albite abundance in sediments at Site U1425 during Pleistocene indicates the increasing dust supplied from NE China and Gobi deserts and the strengthened winter monsoon.

FWHM (crystallinity) of illite in silt fraction at Site U1425 showed low values (high crystallinity) with narrow range around 0.2˚2$\theta$ during Pleistocene. The illite chemistry index showed values below 0.4 and genrerally around 0.3 during Pleistocene, which represents (Fe, Mg)-rich illites (biotite) characterized for physically eroded or unweathered rocks. The highly crystallized and Fe–Mg rich illites in the silt fraction at Site U1425 in the Japan Sea suggests their aeolian origin which may be derived from pre-existing sediments which eroded from low-grade metamorphic rocks in the northern regions of the Tibetan Plateau. In a longer time-scale, higher crystallinity and lower chemistry index of illite in silt fractions occurred in similar timing at 9.3 Ma and 6.6-2.7 Ma which could be correlated with the active regional uplift and tectonic activities of the northeastern margin of the Tibetan Plateau. Possible changes in source of illite indicates frequent plate tectonic activities near the Taklamakan deserts of North Tibet plateau especially from 6.6-2.7Ma.

# Sources and formation environment of biomass burning products in Pliocene and Pleistocene marine sediments in the Japan Sea

*Song Lu[1], Youhei Yamashita[2], Tomohisa Irino[2]

1. Graduate School of Environmental Science, Hokkaido University , 2. Faculty of Environmental Earth Science, Hokkaido University

Behavior of black carbon (BC) is crucial for the earth surface environment because it could cause global warming by absorbing sunlight in the atmosphere. BC is originated from incomplete combustion of biomass or fossil fuels. Combustion in natural processes is incomplete due to local limitation of oxygen during the fire, which leads to the formation of organic fire residues. Robustness of BC to degradation in the natural environment enables us to use BC as a proxy to study the driving force of frequency and burning temperatures of past wildfire events. But the previous fire researches (paleoclimate rather than modern ecology) did not discuss the control factors for burning temperature or try to rebuild the fire temperature. Objective of this study is to understand factors controlling the thermal/optical/chemical characters of BC with burning temperature, provenance and aging in relation to the variabilities of vegetation in the hinterland. For these purposes, BC was quantified as elemental carbon (EC) in coarse (>2 $\mu$m) and fine (<2 $\mu$m) fractions of sediment samples using a thermal optical transmittance (TOT) method, and their burning temperatures were estimated for bulk samples through measurement of composition of benzene polycarboxylic acids (BPCAs), molecular markers of fire residues, determined with High Performance Liquid Chromatography (HPLC). In order to examine the relationship between burning temperature and BPCA composition, selected plants were experimentally charred to obtain standard charcoal samples. We also applied TOT and BPCA methods to marine sediments such as the surface sediments collected during KR15-10 cruise off the Wakasa Bay and 63 samples between 0 and 203 m CCSF-D were selected from IODP Site U1423 in the northeastern Japan Sea which covered the last 4.3 Myr. Size dependencies of EC contents and thermal properties will be compared with the contents and composition of BPCAs to examine the influence of sources, transport pathways, and burning temperatures of BCs contained in marine sediments.

# Variation of mineral dust flux in peat at a high moor on the Mt. Daisetsu during Holocene

*Tomohisa Irino[1], Keisuke Hirai[1], Osamu Seki[1], James Hooper[2], Samuel Marx[2]

1. Hokkaido University, 2. University of Wollongong

Mt. Daisetsu, Hokkaido, Japan is located just below the northern route of Asian dust transport and receives a significant amount of dust which dies snow surface brown in spring time every year. This area is also characterized by well-developed high moors on the mountains covering the last 4000 - 7500 yrs, which would continuously record the history of climate change during the middle to late Holocene. Peat collected from these high moor could be also a suitable material for a precise age determination using the radio carbon, and its inorganic fraction might consist of aeolian dust of continental origin and volcanic materials of the local origin which could be easily distinguished from each other.

Asian dust transported to the northern Japan may have a different source from those transported to the southwestern Japan. In spite of this, many of previous dust studies for Asian dust deposition in Japan have been conducted for the paleo-archives collected from the southern area. Therefore, it is necessary to reconstruct the composition and flux of Asian dust transported to the northern Japan in order to understand the spatio-temporal variability of westerly that could have significant influence on the climate in east Asia.

We collected peat cores from the high moor in Mt. Daisetsuzan area, and measured the mineral composition contained in peat. After heat treatment of peat samples, we conducted X-ray diffraction (XRD) analysis on the ash fraction and semi-quantified the minerals. Quartz, illite, and chlorite showed positive correlation among others, while various feldspars showed another positive correlation among others independent from quartz. Amorphous materials exhibited a variability different from quartz or feldspars. High ash content was associated with high feldspars or amorphous. Comparing these mineral compositions with those of aeolian dust deposited in this area and the local riverbed materials, we judged that the inorganic fraction could be explained by mixtures of aeolian dust and two kinds (crystalline and amorphous) of local volcanic materials.

We applied statistical unmixing of these mineral assemblage using PARAFAC algorithm on XRD profiles. Quantification of subcomponents such as Asian dust and local volcanic materials enabled us to estimate the variation of dust flux to this northern region for the last 5000 years. Comparison of our results with previous works for dust depositional history in southwestern region around Japan shows an antiphase variation of dust fluxes between north and south, which suggests the change in meandering pattern or pathway of westerly jet trasporting Asian dust.

# Variations in sea surface environments recorded by algal biomarkers in the Japan Sea off the western coast of Hokkaido (IODP Site U1422) over the last 250 ka

*Asako Suzuki[1], Ken Sawada[2], Satoshi Furota[3], Yaeko Igarashi[4], Tomohisa Irino[5]

1. Graduate School of Science, Hokkaido University, 2. Department of Earth and Planetary Sciences, Faculty of Science, Hokkaido University, 3. Japan Agency for Marine-Earth Science and Technology, 4. Institute for Paleoenvironment of Northern Regions, 5. Faculty of Environmental Earth Science, Hokkaido University

The Japan Sea is a marginal sea that is closed by four straits, and the surface and deep waters are characterized by the Tsushima Warm Current (TWC), and Japan Sea Proper Water, respectively. In glacial-interglacial cycle, the sea surface environment in the Japan Sea has repeatedly changed by sea level fluctuation. It is reported that intense cooling of surface waters in the northern Japan Sea occurred caused by intensification of the East Asian Winter Monsoon (EAWM), but there have been few researches in this area. Thus, we analyzed algal biomarkers of a sediment core from the site U1422 (northern Japan Sea) of IODP Exp. 346 for the last 250ka. In particular, we apply the paleothermometer using long-chain alkyl diols, which are thought to be produced by diatoms and eustigmatophyte algae in addition to a proxy for sea surface temperature (SST based on alkenones, which are produced by haptophyte algae. The long-chain alkyl diols were also used as the proxies for upwelling intensity and inflow of fresh water, and thus, can provide multiple information for reconstruction of marine paleoenvironment.

The sediment cores studied were recovered at Site U1422 in the northern part of the Japan Basin (the Japan Sea off the western coast of Hokkaido) at 43°45.99’ N, 138°49.99’ E by Integrated Ocean Drilling Program (IODP) Expedition 346. We focus the duration from the MIS 8 to the present (-ca. 250ka). Lipids were extracted with dichloromethane/methanol, and separated to aliphatic, aromatic and polar fractions. Lipids were identified and quantified by GC-MS and GC-FID.

The SSTs based on alkenones and alkyl diols basically fluctuated along the glacial-interglacial cycles. The alkenone-based SSTs were found to be much higher than the diol-based SSTs during the MIS 2-3. The reasons of the differences are likely to be high contribution of distinctive alkenone producer during these stages. In our study, we calculated not only $U^{K'}_{37}$ but also the index containing tetra-unsaturated alkenone ($U^{K}_{37}$) in the SST estimate, because the tetra-unsaturated alkenone is abundantly detected in several samples. The $U^{K}_{37}$-based SSTs generally tend to be lower than those estimated by $U^{K'}_{37}$.

Diol Indices 1 and 2, which are proxies of upwelling intensity, are overall low levels. These results indicate that consistent upwelling system is hardly developed in the northern Japan Sea. However, the indices increase in the MIS 2, implying that vertical mixing was promoted as a result of the surface cooling in this stage. Moreover, the $C_{32}$ 1, 15-diol ratio, which is considered as an indicator of fresh water input into marine environment, tended to increase at the transition periods, such as the glacial to interglacial periods. These results suggest that fresh water arisen by melting of snows and ices accumulated on lands was flowing into the Japan Sea through the rivers during these transitions. The increasing spikes of the diol-based fresh water index are also observed during the glacial periods. This can be attributed to the fresh waters arisen by sea ice melting that came from the northward and/or affected by the inflow of TWC as a result of sea-level falling.

# Decadal oscillation in hydrogen stable isotope ratio of long chain fatty acids in Lake Suigetsu sediment core

*Masaya Inagaki[1], Masanobu Yamamoto[1,2], Takeshi Nakagawa[3]

1. Graduate School of Environmental Science, Hokkaido University, 2. Faculty of Environmental Earth Science, Hokkaido University, 3. Research Center for Palaeoclimatology, Ritsumeikan University

Japanese weathers are affected by the Pacific Decadal Oscillation (PDO), monsoon, and El Niño Southern Oscillation. In this study, we analyzed the hydrogen isotopes of long chain n-fatty acids in sediment cores from Lake Suigetsu in Fukui Prefecture, and reconstructed variability in the isotopic ratio of precipitation from 1362 to 1662 CE and from1852 to 2017 CE. Hydrogen isotopic composition ( δ D) showed decadal oscillation ranging from ~-170‰ to ~-120‰. Between 1362 and 1662 CE, this oscillation corresponded to the decadal oscillation seen in the UK37’ -based sea surface temperature (SST) in Beppu Bay. Higher SST corresponded to higher δ D. Because the SST in Beppu Bay corresponds to the PDO, we suppose that variability in the δ D of long chain n-fatty acids in Lake Suigetsu reflected the isotopic ratio of precipitation that responded to the PDO. In Nagoya, the isotope ratio of precipitation is governed by the position of Baiu front. When Baiu front is developed north of Nagoya, the isotope ratio is high. When Baiu front is south of Nagoya, isotope ratio is low (Kurita et al., 2015 Climate of the Past). This suggest that the position of the Baiu front was linked to the PDO from 1362 to 1662 CE. In the conditions of the negative PDO (high SST in Beppu Bay), the Baiu front was tended to be located north of Lake Suigetsu.

# Amplitude modulation of sea surface temperature variability in the Bay of Bengal by 400-kyr eccentricity cycle

*Masanobu Yamamoto[1], Yuko Tsuchiya[1], Steven Clemens[2]

1. Faculty of Environmental Earth Science, Hokkaido University, 2. Department of Earth, Planetary and Environmental Sciences, Brown University

We generated a 1.7 kyr-resolution $TEX_{86}$-based sea surface temperature (SST) record from the International Ocean Discovery Program Site U1446 in the Bay of Bengal during the last 1.46 Myr. The SST varied synchronously with LR04 benthic foraminifera $\delta^{18}O$ and deep water $\delta^{13}C$. The cyclicity changed from 41-kyr to 100-kyr around 900 ka. The amplitude of SST variation responded to the 400-kyr cycles of eccentricity. Higher amplitude corresponded to low eccentricity. This suggests that eccentricity forced climate variability independently of the shift of cyclicity of glacial cycles across the Mid-Pleistocene Transition.

## [M-IS03] Evolution and variability of the Asian monsoon in Cenozoic global climate changes

convener:Masanobu Yamamoto(Faculty of Environmental Earth Science, Hokkaido University), Ryuji Tada(Department of Earth and Planetary Science, Graduate School of Science, The Univeristy of Tokyo)

The Asian Monsoon (AM) is a part of interhemispheric atmospheric phenomena that is driven by the thermal gradient between ocean and land. Contrasts of insolation, heat content and latent heat transfer between ocean and land may have affected the behavior of the AM in the past, but the proxy records are occasionally controversial and do not show a clear picture of the AM variability. Recent proxy and modeling studies suggest that glacial pCO2 cycles could be related to the position of southern westerlies, which is sensitive to interhemispheric heat imbalance. Because monsoon is driven by the heat imbalance, knowledge on the variability of the AM is important to understand the behavior of the global climate system. In this session, presentations on the reconstruction of long-term AM variability from various archives such as IODP expedition cores, discussion on its forcing, and the roles of the AM in global climate changes are welcome.

# Asian dust source variability since 10 Ma based on grain size specific mineral composition at IODP Site U1425 in the Japan Sea

*Mui Fa Alison Lee[1], Tomohisa Irino[1]

1. Faculty of Environmental Earth Science, Hokkaido University

Sediments at Integrated Ocean Drilling Program (IODP) Site U1425 in the Japan Sea is under the strong influence of westerly jet stream and winter monsoon wind which transporting a significant amount of aeolian dust from both Taklamakan deserts and Gobi deserts. Aeolian dust from Taklamakan showed very high content of quartz (60-90%) and less plagioclase (5-40%) than from NE Chinese deserts and Loess (Gobi). The lower value of half height width (FWHM) of illite peak in X-ray diffraction (XRD) profile can be used as an indicator higher illite crystallinity. A decreasing trend of illite FWHM (increasing trend of the crystalinity) towards the core of the fold and thrust anticline has been recognized (Robinson et al. 1990; Orozco et al. 1998). Illite is also predominant component of the Chinese loess, and its highly crystallized nature has been interpreted to indicate that the illite was not formed at surface temperature and may have originated from a low temperature metamorphic environment.

In order to reconstruct a long-term changes in dust sources and transport pathways of Asian dust utilizing knowledges above, we examined mineral composition of IODP Site U1425 located at the central Japan Sea. The sediment samples were separated into >4 $\mu$m (silt) and <4 $\mu$m (clay) fractions by repeated pipette method. Both fractions were used for powder XRD analysis and peak heights of diagnostic peaks of major minerals were regarded as relative abundance of the minerals. FWHM and chemical index of illite were also examined.

In general, a very high quartz content found at Site U1425 may indicate sediments are aeolian source from Taklamakan deserts and higher plagioclase (albite) may infer dust source from Gobi deserts. Intervals around 9.5 Ma, 8.3 Ma, 7.9 Ma and 4.5 Ma showed very high quartz content and less albite at Site U1425, which indicate increases in dust supplied from Taklamakan than Gobi deserts due to stronger westerly wind. During Pliocene to early Pleistocene (4.2-2Ma), Taklamakan dust is still dominant, however the increasing influence of Gobi dust is recognized at 4.1 and 3.4Ma. On the other hand, an abrupt increase of the ratio of albite to quartz from 0.2 at 4.5 Ma to 0.8 at 4.1 Ma is found, which also shows another maximum at 0.6 Ma. In general, increase of albite abundance in sediments at Site U1425 during Pleistocene indicates the increasing dust supplied from NE China and Gobi deserts and the strengthened winter monsoon.

FWHM (crystallinity) of illite in silt fraction at Site U1425 showed low values (high crystallinity) with narrow range around 0.2˚2$\theta$ during Pleistocene. The illite chemistry index showed values below 0.4 and genrerally around 0.3 during Pleistocene, which represents (Fe, Mg)-rich illites (biotite) characterized for physically eroded or unweathered rocks. The highly crystallized and Fe–Mg rich illites in the silt fraction at Site U1425 in the Japan Sea suggests their aeolian origin which may be derived from pre-existing sediments which eroded from low-grade metamorphic rocks in the northern regions of the Tibetan Plateau. In a longer time-scale, higher crystallinity and lower chemistry index of illite in silt fractions occurred in similar timing at 9.3 Ma and 6.6-2.7 Ma which could be correlated with the active regional uplift and tectonic activities of the northeastern margin of the Tibetan Plateau. Possible changes in source of illite indicates frequent plate tectonic activities near the Taklamakan deserts of North Tibet plateau especially from 6.6-2.7Ma.

# Sources and formation environment of biomass burning products in Pliocene and Pleistocene marine sediments in the Japan Sea

*Song Lu[1], Youhei Yamashita[2], Tomohisa Irino[2]

1. Graduate School of Environmental Science, Hokkaido University , 2. Faculty of Environmental Earth Science, Hokkaido University

Behavior of black carbon (BC) is crucial for the earth surface environment because it could cause global warming by absorbing sunlight in the atmosphere. BC is originated from incomplete combustion of biomass or fossil fuels. Combustion in natural processes is incomplete due to local limitation of oxygen during the fire, which leads to the formation of organic fire residues. Robustness of BC to degradation in the natural environment enables us to use BC as a proxy to study the driving force of frequency and burning temperatures of past wildfire events. But the previous fire researches (paleoclimate rather than modern ecology) did not discuss the control factors for burning temperature or try to rebuild the fire temperature. Objective of this study is to understand factors controlling the thermal/optical/chemical characters of BC with burning temperature, provenance and aging in relation to the variabilities of vegetation in the hinterland. For these purposes, BC was quantified as elemental carbon (EC) in coarse (>2 $\mu$m) and fine (<2 $\mu$m) fractions of sediment samples using a thermal optical transmittance (TOT) method, and their burning temperatures were estimated for bulk samples through measurement of composition of benzene polycarboxylic acids (BPCAs), molecular markers of fire residues, determined with High Performance Liquid Chromatography (HPLC). In order to examine the relationship between burning temperature and BPCA composition, selected plants were experimentally charred to obtain standard charcoal samples. We also applied TOT and BPCA methods to marine sediments such as the surface sediments collected during KR15-10 cruise off the Wakasa Bay and 63 samples between 0 and 203 m CCSF-D were selected from IODP Site U1423 in the northeastern Japan Sea which covered the last 4.3 Myr. Size dependencies of EC contents and thermal properties will be compared with the contents and composition of BPCAs to examine the influence of sources, transport pathways, and burning temperatures of BCs contained in marine sediments.

# Variation of mineral dust flux in peat at a high moor on the Mt. Daisetsu during Holocene

*Tomohisa Irino[1], Keisuke Hirai[1], Osamu Seki[1], James Hooper[2], Samuel Marx[2]

1. Hokkaido University, 2. University of Wollongong

Mt. Daisetsu, Hokkaido, Japan is located just below the northern route of Asian dust transport and receives a significant amount of dust which dies snow surface brown in spring time every year. This area is also characterized by well-developed high moors on the mountains covering the last 4000 - 7500 yrs, which would continuously record the history of climate change during the middle to late Holocene. Peat collected from these high moor could be also a suitable material for a precise age determination using the radio carbon, and its inorganic fraction might consist of aeolian dust of continental origin and volcanic materials of the local origin which could be easily distinguished from each other.

Asian dust transported to the northern Japan may have a different source from those transported to the southwestern Japan. In spite of this, many of previous dust studies for Asian dust deposition in Japan have been conducted for the paleo-archives collected from the southern area. Therefore, it is necessary to reconstruct the composition and flux of Asian dust transported to the northern Japan in order to understand the spatio-temporal variability of westerly that could have significant influence on the climate in east Asia.

We collected peat cores from the high moor in Mt. Daisetsuzan area, and measured the mineral composition contained in peat. After heat treatment of peat samples, we conducted X-ray diffraction (XRD) analysis on the ash fraction and semi-quantified the minerals. Quartz, illite, and chlorite showed positive correlation among others, while various feldspars showed another positive correlation among others independent from quartz. Amorphous materials exhibited a variability different from quartz or feldspars. High ash content was associated with high feldspars or amorphous. Comparing these mineral compositions with those of aeolian dust deposited in this area and the local riverbed materials, we judged that the inorganic fraction could be explained by mixtures of aeolian dust and two kinds (crystalline and amorphous) of local volcanic materials.

We applied statistical unmixing of these mineral assemblage using PARAFAC algorithm on XRD profiles. Quantification of subcomponents such as Asian dust and local volcanic materials enabled us to estimate the variation of dust flux to this northern region for the last 5000 years. Comparison of our results with previous works for dust depositional history in southwestern region around Japan shows an antiphase variation of dust fluxes between north and south, which suggests the change in meandering pattern or pathway of westerly jet trasporting Asian dust.

# Variations in sea surface environments recorded by algal biomarkers in the Japan Sea off the western coast of Hokkaido (IODP Site U1422) over the last 250 ka

*Asako Suzuki[1], Ken Sawada[2], Satoshi Furota[3], Yaeko Igarashi[4], Tomohisa Irino[5]

1. Graduate School of Science, Hokkaido University, 2. Department of Earth and Planetary Sciences, Faculty of Science, Hokkaido University, 3. Japan Agency for Marine-Earth Science and Technology, 4. Institute for Paleoenvironment of Northern Regions, 5. Faculty of Environmental Earth Science, Hokkaido University

The Japan Sea is a marginal sea that is closed by four straits, and the surface and deep waters are characterized by the Tsushima Warm Current (TWC), and Japan Sea Proper Water, respectively. In glacial-interglacial cycle, the sea surface environment in the Japan Sea has repeatedly changed by sea level fluctuation. It is reported that intense cooling of surface waters in the northern Japan Sea occurred caused by intensification of the East Asian Winter Monsoon (EAWM), but there have been few researches in this area. Thus, we analyzed algal biomarkers of a sediment core from the site U1422 (northern Japan Sea) of IODP Exp. 346 for the last 250ka. In particular, we apply the paleothermometer using long-chain alkyl diols, which are thought to be produced by diatoms and eustigmatophyte algae in addition to a proxy for sea surface temperature (SST based on alkenones, which are produced by haptophyte algae. The long-chain alkyl diols were also used as the proxies for upwelling intensity and inflow of fresh water, and thus, can provide multiple information for reconstruction of marine paleoenvironment.

The sediment cores studied were recovered at Site U1422 in the northern part of the Japan Basin (the Japan Sea off the western coast of Hokkaido) at 43°45.99’ N, 138°49.99’ E by Integrated Ocean Drilling Program (IODP) Expedition 346. We focus the duration from the MIS 8 to the present (-ca. 250ka). Lipids were extracted with dichloromethane/methanol, and separated to aliphatic, aromatic and polar fractions. Lipids were identified and quantified by GC-MS and GC-FID.

The SSTs based on alkenones and alkyl diols basically fluctuated along the glacial-interglacial cycles. The alkenone-based SSTs were found to be much higher than the diol-based SSTs during the MIS 2-3. The reasons of the differences are likely to be high contribution of distinctive alkenone producer during these stages. In our study, we calculated not only $U^{K'}_{37}$ but also the index containing tetra-unsaturated alkenone ($U^{K}_{37}$) in the SST estimate, because the tetra-unsaturated alkenone is abundantly detected in several samples. The $U^{K}_{37}$-based SSTs generally tend to be lower than those estimated by $U^{K'}_{37}$.

Diol Indices 1 and 2, which are proxies of upwelling intensity, are overall low levels. These results indicate that consistent upwelling system is hardly developed in the northern Japan Sea. However, the indices increase in the MIS 2, implying that vertical mixing was promoted as a result of the surface cooling in this stage. Moreover, the $C_{32}$ 1, 15-diol ratio, which is considered as an indicator of fresh water input into marine environment, tended to increase at the transition periods, such as the glacial to interglacial periods. These results suggest that fresh water arisen by melting of snows and ices accumulated on lands was flowing into the Japan Sea through the rivers during these transitions. The increasing spikes of the diol-based fresh water index are also observed during the glacial periods. This can be attributed to the fresh waters arisen by sea ice melting that came from the northward and/or affected by the inflow of TWC as a result of sea-level falling.

# Decadal oscillation in hydrogen stable isotope ratio of long chain fatty acids in Lake Suigetsu sediment core

*Masaya Inagaki[1], Masanobu Yamamoto[1,2], Takeshi Nakagawa[3]

1. Graduate School of Environmental Science, Hokkaido University, 2. Faculty of Environmental Earth Science, Hokkaido University, 3. Research Center for Palaeoclimatology, Ritsumeikan University

Japanese weathers are affected by the Pacific Decadal Oscillation (PDO), monsoon, and El Niño Southern Oscillation. In this study, we analyzed the hydrogen isotopes of long chain n-fatty acids in sediment cores from Lake Suigetsu in Fukui Prefecture, and reconstructed variability in the isotopic ratio of precipitation from 1362 to 1662 CE and from1852 to 2017 CE. Hydrogen isotopic composition ( δ D) showed decadal oscillation ranging from ~-170‰ to ~-120‰. Between 1362 and 1662 CE, this oscillation corresponded to the decadal oscillation seen in the UK37’ -based sea surface temperature (SST) in Beppu Bay. Higher SST corresponded to higher δ D. Because the SST in Beppu Bay corresponds to the PDO, we suppose that variability in the δ D of long chain n-fatty acids in Lake Suigetsu reflected the isotopic ratio of precipitation that responded to the PDO. In Nagoya, the isotope ratio of precipitation is governed by the position of Baiu front. When Baiu front is developed north of Nagoya, the isotope ratio is high. When Baiu front is south of Nagoya, isotope ratio is low (Kurita et al., 2015 Climate of the Past). This suggest that the position of the Baiu front was linked to the PDO from 1362 to 1662 CE. In the conditions of the negative PDO (high SST in Beppu Bay), the Baiu front was tended to be located north of Lake Suigetsu.

Keywords: PDO, isotopic ratio of precipitation, climate change

# Amplitude modulation of sea surface temperature variability in the Bay of Bengal by 400-kyr eccentricity cycle

*Masanobu Yamamoto[1], Yuko Tsuchiya[1], Steven Clemens[2]

1. Faculty of Environmental Earth Science, Hokkaido University, 2. Department of Earth, Planetary and Environmental Sciences, Brown University

We generated a 1.7 kyr-resolution $TEX_{86}$-based sea surface temperature (SST) record from the International Ocean Discovery Program Site U1446 in the Bay of Bengal during the last 1.46 Myr. The SST varied synchronously with LR04 benthic foraminifera $\delta^{18}O$ and deep water $\delta^{13}C$. The cyclicity changed from 41-kyr to 100-kyr around 900 ka. The amplitude of SST variation responded to the 400-kyr cycles of eccentricity. Higher amplitude corresponded to low eccentricity. This suggests that eccentricity forced climate variability independently of the shift of cyclicity of glacial cycles across the Mid-Pleistocene Transition.

## [M-IS03] Evolution and variability of the Asian monsoon in Cenozoic global climate changes

convener:Masanobu Yamamoto(Faculty of Environmental Earth Science, Hokkaido University), Ryuji Tada(Department of Earth and Planetary Science, Graduate School of Science, The Univeristy of Tokyo), Chairperson:Masanobu Yamamoto(Hokkaido University), Tomohisa Irino, Yoshimi Kubota(National Science Museum), Ryuji Tada(The University of Tokyo)

The Asian Monsoon (AM) is a part of interhemispheric atmospheric phenomena that is driven by the thermal gradient between ocean and land. Contrasts of insolation, heat content and latent heat transfer between ocean and land may have affected the behavior of the AM in the past, but the proxy records are occasionally controversial and do not show a clear picture of the AM variability. Recent proxy and modeling studies suggest that glacial pCO2 cycles could be related to the position of southern westerlies, which is sensitive to interhemispheric heat imbalance. Because monsoon is driven by the heat imbalance, knowledge on the variability of the AM is important to understand the behavior of the global climate system. In this session, presentations on the reconstruction of long-term AM variability from various archives such as IODP expedition cores, discussion on its forcing, and the roles of the AM in global climate changes are welcome.

# Reconstruction of Indian summer monsoon variability during the last 1,460,000 years

*Masanobu Yamamoto[1], Steven Clemens[2]

1. Faculty of Environmental Earth Science, Hokkaido University, 2. Department of Earth, Environmental and Planetary Sciences, Brown University

Monsoon is an atmospheric phenomenon dominant in low and mid-latitudes and determines the temporal and spatial distributions of rainfall that govern vegetation. A classical model assumes that monsoon responds to precession-controlled changes in seasonal insolation. Speleothem records show a precession cycle in oxygen isotope variation consistent with this model, but marine and loess records generally do not show strong precession variation. This mismatch has long been debated. Key approach is the precipitation reconstruction to understand past changes in summer monsoon. In this study, we generated an Indian summer monsoon (ISM) record by evaluating riverine discharge. We used GDGT indices, i.e., CBT and MBT, as a proxy of soil organic matter contribution and generated a 1,700-year resolution record of Mahanadi River soil discharge in IODP Site U1446 to understand changes in the ISM rainfall during the last 1,460,000 years. The CBT and BIT show a similar variation according to glacial-interglacial cycles. Maxima appeared after the peak of interglacial. Minima appeared during deglaciations. Their variations are reversely correlated with the sea water $\delta^{18}O$ obtained based on *G. ruber* $\delta^{18}O$, global $\delta^{18}O$ and $TEX_{86}$-based SST. The records are consistent with previously-reported ISM records from marine archives and Borneo speleothems in the overlap periods and different from Chinese speleothem records. Spectral analysis indicates that BIT and CBT show 100,000, 41,000, 30,000, 23,000 and 19,000-year cycles during the last 800,000 years, the variation was out of phase with variation in northern hemisphere summer insolation. This suggests that the ISM did not respond directly to orbital forcing, in contrast to the classical hypothesis, but was driven by internal feedback processes. Orbital cycles were not clearly shown prior to 800,000 years ago. This suggests that the strong response of the ISM to orbital forcing was initiated around 800,000 years ago, which coincided with the onset of glacial 100,000 year cycles.

# Pleistocene Seawater $\delta^{18}O$ reconstructions from the Indian and East Asian Monsoon Regions

*Steven C Clemens[1], Masanobu Yamamoto[2]

1. Brown University, 2. Hokkaido University

The study of orbital-scale climate change during the late Pleistocene is unique in that the signal-to-noise ratio is large, the external forcing (insolation) is known, and the critical internal forcings (greenhouse gases and terrestrial ice volume) are well constrained. As such, it should be possible to assess the underlying mechanisms driving climate change at this time scale, as well as the relative sensitivity to these forcing mechanisms.

We present three reconstructions of local seawater $\delta^{18}O$, including previously published records from the East China Sea (U1429)[*S. C. Clemens et al.*, 2018], the Andaman Sea (NGHP 17)[*Gebregiorgis et al.*, 2018], and our new work from the northeast Indian Margin, Bay of Bengal (U1446). Local seawater $\delta^{18}O$ is based on removal of the SST and global seawater $\delta^{18}O$ from planktonic foraminifer $\delta^{18}O$ and reflects changes in surface salinity driven by rainfall and runoff from surrounding catchment basins. This proxy offers an independent reconstruction for comparison to speleothem $\delta^{18}O$ and other proxies in order to assess driving mechanisms and the extent to which the Indian and East Asian subsystems covary with one another.

In the northern East China Sea, *G. ruber* $\delta^{18}O$ has the same precession- and millennial-scale structure as the onshore speleothem $\delta^{18}O$ record from the Yangtze River Valley[*Cheng et al.*, 2016]. However, after removing the temperature and global seawater $\delta^{18}O$ signals, the offshore seawater $\delta^{18}O$ has almost no precession-scale (23 kyr) variance)[*S. C. Clemens et al.*, 2018]. This result contrasts with the speleothem record, which is almost exclusively dominated by precession-scale variance, and argues against external insolation as the primary driver of East Asian monsoon rainfall in the Yangtze River Valley region.

The Andaman Sea record monitors direct rainfall and runoff from the Irrawaddy and Salween catchment basins. The precession-band timing of low seawater $\delta^{18}O$ (increased rainfall, low mixed-layer salinity) indicates that strong monsoonal rainfall lags maximum northern hemisphere insolation by ~9 kyrs at the precession band[*Gebregiorgis et al.*, 2018]. Our new Indian Margin record resides within the low-salinity East India Coastal Current fed by runoff from the Ganges-Brahmaputra complex, the Mahanadi Basin, and direct rainfall. The Indian Margin seawater $\delta^{18}O$ reconstruction also demonstrates this large lag. The lag in both these records agrees with that of the summer-season (southwest) monsoon wind strength records from the NW Arabian Sea[*S.C. Clemens and Prell*, 2003; *S.C. Clemens et al.*, 1991].

This precession-band timing (lagging minimum precession by 7-9 kyrs) precludes insolation as a direct forcing for Indian monsoon rainfall and wind strength, pointing instead to decreased high-latitude ice volume, increased greenhouse gasses, and latent heat export from the southern hemisphere as the primary drivers of monsoon circulation at these time scales[*S.C. Clemens and Prell*, 2003].

# The Monsoon Erosion Pump

*Liviu Giosan[1]

1. Woods Hole Oceanographic Institution

Understanding the factors controlling the flux of materials from land to oceans has key implications for global biogeochemical cycling and the links between the sedimentary record and landscape evolution. Monsoonal climates are recognized as prodigious sediment producers but conflicting proxy reconstructions limit assessing their influence on land-sea material transfers at various timescales. Here I discuss the concept of a monsoon erosion pump based on terrestrial and oceanic records reconstructed from recent Indian National Gas Hydrate Program and IODP drilling in the Bay of Bengal, Arabian and Andaman Seas. From millennial to orbital to tectonic timescales, these records suggest that vegetation land cover interacts and modulates the regime of erosion and weathering under perennial but variable monsoonal rain conditions. Under this new proposed interpretation the Indian monsoon exhibits two distinct flavours during the Cenozoic that can be largely explained by its heartbeat, or astronomical forcing. This erosional regime is mediated by the global glacial state and attendant sea level and by limiting conditions imposed by the paleogeography of Asia.

# East Asian winter monsoon intensity in the Pleistocene based on seasonal land snail shell stable isotope ratios

*David L Dettman[1,3], Xin Wang[2], Mi Wang[2], Junhui Zhang[2]

1. University of Arizona, Geosciences Dept., Environmental Isotope Lab., 2. Lanzhou University, Key Laboratory of Western China's Environmental Systems, College of Earth and Environmental Sciences, 3. Shimane University, Estuary Research Center

Monsoon climates are characterized by strong seasonal oscillations between a very wet season and very dry conditions. The study of ancient variation in monsoon climate strength and its impact on regional environments is difficult because geological materials rarely record individual seasons. It is difficult to infer seasonal change through time when working with oxygen isotope records that average multiple years or centuries. One solution is to use high-resolution sampling of land snail shells as monitors of wet-season and dry-season differences. Although land snail fossils are often rare, in many cases they are well preserved and widely distributed across the planet. We subsampled shells along the spiral growth axis, producing 15 to 35 samples per shell to document maximum and minimum oxygen and carbon stable isotope ratios. The most robust signal in land snail shell oxygen isotope records is connected to evaporation. The arid dry-season leads to significant evaporation in the land snail body water, which elevates the δ18O values recorded in the shell. Wet-season oxygen isotope ratios are more negative and can be tied roughly to the δ18O of wet season precipitation and summer temperatures. Carbon isotope ratios are tied to the diet of the animals, and reveal the proportion of C3 and C4 plants in the landscape.

Larger land snail (> 1.5 cm diameter) taxa have behaviors that can lead to significant evaporation of body water, as they are willing to range away from local water sources. Modern samples show that the total amplitude in oxygen isotope variation in a shell can be related to the intensity and duration of the dry season. This suggests that amplitudes in ancient shells are indicators of the winter monsoon strength. Although under extremely arid conditions snail growth occurs only when surface water is available and d18O amplitudes collapse in desert conditions. The most negative δ18O values are not correlated with the intensity of the summer monsoon, suggesting that δ18O values are not good indicators of summer monsoon strength.

Data from one genus of land snail (*Cathaica* species) living on the Chinese loess plateau throughout the late Pleistocene allow us to make some generalizations about monsoon climate in this region. In general, the oxygen isotope amplitude in shells from glacial periods are larger than those from the interglacial periods. This suggests that the East Asian Winter Monsoon was strongest during glacial intervals on the Loess Plateau. The largest δ18O amplitude observed was 19.2 ‰. Marine Isotope Stages 2, 6, and 8 have the largest amplitudes and, by inference, the strongest winter monsoons in our record. Older glacial intervals seem to have weaker winter monsoons. However, glacial amplitudes were not always larger, just as climate undergoes significant short-term variation in glacial intervals (such as D-O cycles and Heinrich events) oxygen isotope amplitudes show large amounts of variability in glacial times. In contrast, interglacial intervals tend to have smaller δ18O amplitudes, pointing to warmer and wetter winters in interglacial times. But like the glacial data, some interglacial amplitudes are larger than some glacial records. These data show that the differences in high frequency climate variability is as large as the differences between glacial and interglacial climates.

# Reconstruction of ventilation history of the Japan Sea based on physical properties data collected during IODP Exp. 346

*Tomohisa Irino[1], Liviu Giosan[2], Ryuji Tada[3], Ken Ikehara[4]

1. Faculty of Environmental Earth Science, Hokkaido University, 2. Woods Hole Oceanographic Institution, 3. Graduate School of Science, University of Tokyo, 4. Institute of Geology and Geoinformation, National Institute of Advanced Industrial Science and Technology

The Japan Sea is a semi-enclosed marginal sea located at the eastern edge of Asian continent and under the influence of east Asian monsoon. The primary production is controlled by nutrient supply from the East China Sea by summer monsoon, while deep water ventilation is promoted by winter monsoon cooling of the surface water of the Japan Sea. Perfectly continuous sediment splice sequences were established at Sites U1422-U1427 and U1430 which have been correlated among others using apparent dark-light cycles. The coverage of water depths are, in ascending order, 330 m at Site U1427, 903 m at Site U1426, 1072 m at Site U1430, 1785 m at Site U1423, 1909 m at Site U1425, 2808 m at Site U1424, and 3429 m at Site U1422, which enable us to reconstruct the temporal variation of depth distribution of organic carbon flux related to the past primary production and deep water ventilation in the Japan Sea.

For calculation of the mass accumulation of organic carbon (OC flux) at each site, we used the perfectly continuous records of dry bulk density (DBD) and total organic carbon content (TOC) calculated from shipboard measurements such as gamma-ray attenuation (GRA) density with grain density and a strong negative correlation between TOC and photo RGB values, respectively. Linear sedimentation rate (LSR) of each site was estimated based on the projection of the age model established at Site U1424 by tuning the GRA variation onto LR04 benthic oxygen isotope curve. Based on the consistent correlation among sites, depth distribution of OC flux was reconstructed for 1 ky step during the last 1.5 million years.

Princple component analysis for depth-temporal OC flux distribuion suggests that three princple component explain 74% of the total variance. Principle component (PC) 1 loading was positively correlated with all the sites except for the U1427 (330 m), while PC2 loading was correlated positively with sites shallower than 1000 m and negatively with those deeper than 2000 m. PC3 loading was correlated negatively with sites around 1000 m and positively with other sites. Such depth dependent patterns suggest that primary production (PC2) and ventilation (PC1) at middle to deeper depth were primary controls on the OC deposition. PC3 may indicate stronger middle depth ventilation or (oppositely) formation of oxygen minimum zone.

We also examined the color variation of these sediments using metric hue. Sediment color varies between dull green (higher hue) and olive (lower hue). Average metric hue is about 88 degree for all the site and variability is smaller for shallower sites. The metric hue at Site U1425 (1909 m) varies in harmony with the score of PC1, and lower metric hue is associated with larger PC1 score. Namely, higher OC flux (a lower oxygenation level) was associated with more olive color, which could be interpreted that dull green background (detritus) color was overridden by olive color reduced iron. Such an agreement between independently estimated variables suggests that the deep water ventilation intensity in the Japan Sea could be independently reconstructed as a proxy of winter monsoon intensity.

## [M-IS03] Evolution and variability of the Asian monsoon in Cenozoic global climate changes

convener:Masanobu Yamamoto(Faculty of Environmental Earth Science, Hokkaido University), Ryuji Tada(Department of Earth and Planetary Science, Graduate School of Science, The Univeristy of Tokyo), Chairperson:Ryuji Tada(The University of Tokyo), Yoshimi Kubota(National Science Museum), Masanobu Yamamoto(Hokkaido University)

The Asian Monsoon (AM) is a part of interhemispheric atmospheric phenomena that is driven by the thermal gradient between ocean and land. Contrasts of insolation, heat content and latent heat transfer between ocean and land may have affected the behavior of the AM in the past, but the proxy records are occasionally controversial and do not show a clear picture of the AM variability. Recent proxy and modeling studies suggest that glacial pCO2 cycles could be related to the position of southern westerlies, which is sensitive to interhemispheric heat imbalance. Because monsoon is driven by the heat imbalance, knowledge on the variability of the AM is important to understand the behavior of the global climate system. In this session, presentations on the reconstruction of long-term AM variability from various archives such as IODP expedition cores, discussion on its forcing, and the roles of the AM in global climate changes are welcome.

Detailed reconstruction of Indian summer monsoons is necessary to better understand the late Quaternary climate history of the Bay of Bengal and Indian peninsula. We established a chronostratigraphy for a sediment core from Hole 19B in the western Bay of Bengal, extending to approximately 80 kyr BP, and examined major and trace element compositions and clay mineral components of the sediments. Lower lithogenic matter flux, higher $\delta^{18}O$ values, and weaker weathering in the sediment source area during marine isotope stages (MIS) 2 and 4 compared to MIS 1, 3, and 5 are explained by increased Indian summer monsoonal precipitation and river discharge around the western Bay of Bengal. Chemical components indicate a felsic sediment source, suggesting the Precambrian gneissic complex of the eastern Indian peninsula as the dominant sediment source at this site since 80 kyr. Trace element ratios indicate increased sediment contributions from mafic rocks during MIS 2 and 4. We interpret these results as reflecting the changing influences of the eastern and western branches of the Indian summer monsoon, and a greater decrease in rainfall in the eastern and northeastern parts of the Indian peninsula than in the western part during MIS 2 and 4.

# 400,000 years millennial scale temperature and rainfall in East Asia deduced from paired Mg/Ca and oxygen isotope of planktic foraminifera from the East China Sea

*Yoshimi Kubota[1], Steven Clemens[2], Kyung-Eun Lee[3], Ann Holbourn[4], Etsuko Wakisaka[5], Keiji Horikawa[5], Ryuji Tada[6], Katsunori Kimoto[7]

1. National Museum of Nature and Science, 2. Brown University, 3. Korea Maritime and Ocean University, 4. Christian-Albrechts-University, 5. University of Toyama, 6. The University of Tokyo, 7. Japan Agency for Marine-Earth Science and Technology

Abrupt millennial-scale climate changes during the late Quaternary were widely recognized in the East Asian monsoon region from deep-sea sediments in the Japan Sea and more recently from oxygen isotope ($\delta^{18}O$) variability in Chinese speleothems ($\delta^{18}O_{sp}$). The finely $^{230}Th$-dating method on the speleothems enables comparison to climate records from other regions on millennial scale, and there is little doubt that the variability of these $\delta^{18}O_{sp}$ records is synchronized with climate perturbation in the North Atlantic high latitude, known as Heinrich events and with Dansgaard-Oeschger (D-O) oscillations in Greenland. However, mechanisms of the climate response in East Asia remain unclear due to the lack of fundamental agreement on what the $\delta^{18}O_{sp}$ climate signal represents. A primary impediment to interpreting the variability in $\delta^{18}O_{sp}$ is the lack of the means to decompose $\delta^{18}O_{sp}$ into constituent components. By contrast, the $\delta^{18}O$ of calcite planktic foraminifers ($\delta^{18}O_{p}$) from nearshore marine sediments can be quantitatively partitioned into sea surface temperature (SST) and $\delta^{18}O_{w}$ of seawater ($\delta^{18}O_{w}$), a function of sea surface salinity (SSS). In this study, millennial-scale climate variability in East Asia is investigated using 400,000-yr records of SST, $\delta^{18}O_{p}$, and $\delta^{18}O_{w}$ from the East China Sea (IODP Site U1429). $\delta^{18}O_{w}$ can be interpreted as reflecting SSS, hence rainfall, as the monsoonal runoff from the Yangtze River determines summer SSS in the northern East China Sea. As a result, SST and $\delta^{18}O_{w}$ variability accounts for 58% and 35% of the total variability of $\delta^{18}O_{p}$ and the rest (6%) is the ice volume component or noise; the primary contributor to $\delta^{18}O_{p}$ variations is SST, and the secondary is $\delta^{18}O_{w}$. Foraminiferal $\delta^{18}O_{p}$ shows the strongest similarly with Chinese $\delta^{18}O_{sp}$, indicating that $\delta^{18}O_{sp}$ is best interpreted as the combination of changes in surface temperature and monsoon rainfall; it is not indicative of summer monsoon rainfall alone. Partitioning of variance between temperature and rainfall does not change on glacial-interglacial timescales indicating that the hemispheric teleconnection mechanism between the Atlantic and East Asia does not depend on the global climate background status ($CO_2$, ice volume). In comparison with the millennial scale Greenland temperature, the East China Sea SST decreases and $\delta^{18}O_{w}$ increases (rainfall deceases) in most of the North Atlantic cold events (e.g., Heinrichs). However, SST and $\delta^{18}O_{w}$ exhibit overall poor coherence, revealing that these climate parameters fundamentally behave differently on the millennial scale, but tend to respond in the manner described above (decrease in temperature and rainfall) once a severe cold event occurs in the North Atlantic.

New XRF scanner data from U1426 on Oki Ridge and comparison with those of the deeper sites U1424 and 1425 revealed Br (MOC proxy) profile of deeper sites are significantly influenced by post-depositional oxidation during the early diagenesis while Br profile of shallower site (U1426) better preserve surface productivity signal. Thus we use Br profile of U1426 during the last 3 Ma to analyze past changes in millennial-scale variability of East Asian Summer Monsoon intensity and the response of the Japan Sea to such changes. The result suggests several new information which will be presented at 2019JpGU.

The large-scale Asian-Australian monsoon system consists of several regional subsystems that are dynamically linked through the annual migration of the Intertropical Convergence Zone across the equator, but exhibit distinct responses to external (local insolation) and internal (e.g., ice volume, greenhouse gas concentrations) forcings. Here we provide a long-term perspective of regional variability under different mean-state climate conditions. We focus on the 8 to 5 Ma period, which was characterized by warmer-than-modern climate conditions, but was also marked by distinct reversals in climate trends including transient cooling events exhibiting similarities to late Pleistocene Heinrich stadials. Extended sediment archives recovered by the Ocean Drilling Program (ODP) and the International Ocean Discovery Program (IODP) in the South China Sea, Bay of Bengal and off Northwest Australia allow direct comparison of Northern and Southern Hemisphere monsoonal subsystems on orbital timescales. High-resolution XRF-scanner derived estimates of terrigenous discharge, foraminiferal Mg/Ca derived mixed layer temperatures and stable isotopes reveal cooling and strengthening of the Northern Hemisphere winter monsoon starting at ~7 Ma. This intensification occurred synchronously with an increase in monsoonal seasonality in the Southern Hemisphere. In all regions, summer monsoonal precipitation intensified after ~5.5 Ma in tandem with globally rising sea surface temperatures. Our results suggest that changes in latitudinal temperature gradients, greenhouse gas concentrations and moisture budgets strongly influenced the long-term evolution of the Australian and Asian monsoons during the transition from a unipolar to a bipolar glaciated Earth.

Export particle flux from primary production and terrigenous input in combination with planktic and benthic foraminiferal isotope records were used to monitor monsoon-related paleoceanographic changes in the Bay of Bengal (Indian Monsoon) and South China Sea (East Asian Monsoon) through the middle to late Miocene. Proxy indicators of carbon export flux to the seafloor and carbonate accumulation rates at International Ocean Discovery Program (IODP) Site U1443 located in 2925 m water depth at the northern end of the Ninetyeast Ridge closely track changes in the carbonate budget of the deep Indian Ocean. Prolonged intervals of low carbonate concentrations and accumulation rates from ~17 to 15 Ma and from ~13.2 to 8.7 Ma indicate episodes of reduced carbonate deposition, which correlate with the globally recognized early to middle Miocene “Carbonate Drought” and the middle to late Miocene “Carbonate Crash”. The global occurrence of these events implies that changes in chemical weathering and in the riverine input of calcium and alkalinity into the ocean reservoir (rather than changes in circulation or inter-ocean carbonate fractionation) drove carbonate accumulation in the deep Indian Ocean. Higher XRF-scanner derived Log(Ba/Ti) together with a change in the redox state of deep sea sediments at ~11.2 Ma indicate a rise in biological production and export flux to the sea floor. A contemporaneous stepwise steepening of the gradient between mixed layer and deep ocean $\delta^{13}C$ starting from a minimum at ~11 Ma also indicates intensification of the biological pump at Ocean Drilling Program (ODP) Site 1146 (2091 m water depth) in the South China Sea. We suggest that the attendant increase in carbonate accumulation in the Indian Ocean was linked to increased nutrient flux and intensification of upper ocean mixing, associated with changes in the seasonality and intensity of the Asian monsoon.

## [M-IS04] Interdisciplinary studies on pre-earthquake processes

convener:Katsumi Hattori(Department of Earth Sciences, Graduate School of Science, Chiba University), JANN-YENQ Liu(Institute of Space Science, National Central University, Taiwan), Dimitar Ouzounov(Center of Excellence in Earth Systems Modeling & Observations (CEESMO) , Schmid College of Science & Technology Chapman University, Orange, California, USA), Qinghua Huang(Peking University)

This session expands the interdisciplinary discussions on preparation process of earthquake and earthquake predictability by presenting the latest progress in studying the physically based pre-earthquake phenomena. New observations from space and ground have provided<br/>evidences, which may enhance better understanding of tectonic activity. The session anticipates talks that include but not limited to observations and analyses of seismic, electrical, electromagnetic, electro-chemical and thermodynamic processes related to stress changes in the lithosphere along with their statistical and physical validation. Presentations on the latest observational results associated with major earthquakes obtained by different methodologies are welcomed. The topics of the session are as follows but not limited.<br/><br/>-General discussion on earthquake preparation process and the physics of pre-earthquake signals<br/><br/>- Theory, modeling, laboratory experiments, computational simulation for generation and propagation of pre-earthquake signals and their connection with seismic cycle<br/><br/> - Multi-parameter observations, detection, and validation of pre-earthquake signals<br/><br/> - Cross-disciplinary studies, practical and technical approaches for better understanding of earthquake preparation processes and their connection with seismicity

# Statistical analysis and Evaluation of ULF seismo-magnetic phenomena at Kakioka, Japan, during 1983-2017

*Kei Takahashi[1], Katsumi Hattori[2], Peng Han[3]

1. Faculty of Science, Chiba University, 2. Graduate School of Science, Chiba University, 3. Southern University of Science and Technology, China

To clarify and verify the ultralow frequency (ULF) seismo-magnetic phenomena, we have performed statistical studies on the geomagnetic data observed at the Kakioka (KAK) station, Japan, during 1983-2017. We investigated the energy of ULF geomagnetic signals of the frequency around 0.01 Hz using wavelet transform analysis. To minimize the influences of artificial noises and global magnetic perturbations, we used only the geomagnetic data observed at midnight time (LT 2:30 A.M. to 4:00 A.M.).We define the geomagnetic anomalies when the Z components of geomagnetic data exceeds median + 1.5 IQR, where IQR is the interquartile range. Considering that ionospheric disturbances may also lead to enhancements in the Z component, we exclude the anomaly when the energy of H component exceeds median + 3.0 IQR. Statistical analysis of superposed epoch analysis have indicated that ULF magnetic anomalies are more likely to appear before sizable isolated earthquake events (Es parameter which is higher than 8th power of 10 and no earthquake events during ±45 days ) rather than after them, especially 6-10 days before the events. Finally, we have evaluated the precursory information of ULF geomagnetic signals for local sizable earthquakes using Molchan’ s error diagram. The above results have indicated that the ULF seismo-magnetic phenomena at Kakioka clearly contain precursory information and have a possibility of improving forecasting of large earthquakes.

# Pre-seismic anomalies on Earth’s magnetic field and ionosphere electron density using Swarm data

*Amune Yamazaki[1], Katsumi Hattori[1], Rui Song[1]

1. Chiba University

An earthquake is a rapid release of stress in the lithosphere and often leads to serious damages on human lives and society. Even though the short-time forecast of earthquake is important, it is not achieved yet. However, many electromagnetic phenomena that may be related to seismic activity have been reported recently. The satellite, one of the useful tools to observe these phenomena, can cover the global areas and can collect a large amount of data related to earthquakes which have large magnitude worldwide in short time. The Swarm satellites mission started to operate on November 22, 2013 by European Space Agency, with the constellation of three satellites (A, B, C) The anomalies preceded to the Ecuador earthquake in 2016 have been reported using the Swarm data. In this paper, in order to validate these results using the magnetic vector Y data by VFM and electron density data by Langmuir probe, we have analyzed the Swarm data related the M6.3~6.9 earthquakes occurred at Lombok Island, Indonesia, in July 28, August 5, and 19, 2018. The study area is a 1000 km square from the epicenter of 20180805 earthquake and the analyzed period is from May 28 to September 27, 2018. In this paper we report night-time orbit data at 18:00-6:00 LT.

As results, we found the following tendencies; (1) positive anomalies on magnetic Y vector about 1-2 weeks before the earthquakes and (2) negative anomalies on electron density from 1 week to 1 month before the earthquakes. We performed the same analysis to the data on the same period in 2016 and 2017 for reference when there were no M6+ earthquakes. We found that the number of anomaly track is only abruptly increased in the short period from the end of June to July in 2018, and that the trend is not able to be found in 2016 and 2017. From this unique trend in 2018, it is suggestive of the existence of the relation between the local seismic activity and in-situ satellite anomalies in the magnetic field and electron density in Lombok area.

We report continuous measurement of radon density in atmosphere at Okayama for three years, Kochi, Choshi and Kiyosumi for two years. An increase of radon density in groundwater at Nishinomiya city [1] and in atmosphere [2] at the southern part of Hyogo Prefecture Earthquake in 1995 were reported, respectively. In the case of Tohoku Region Pacific Coast Earthquake, the data obtained the exhaust air monitor that peak duration was long and the peak decreased rapidly before earthquake has been reported at the radiation facility of Fukushima Medical College in Fukushima [3]. On the other hand, a PIN photodiode have been developed and used as a high sensitive alpha ray detector in Super Kamiokande [4]. Since 2016, we also made an experimental setup using PIN photodiode, and measured the radon density in atmosphere. Using a Si PIN photodiode (S3204-09, unsealed, Hamamatsu Photodiode K.K.) as an alpha ray detector, we constructed radon detection setup combined with aluminum pot as an air accumulator, H4083 (Hamamatsu) as a charge amplifier, C4900-01 (Hamamatsu) as a high voltage power supply module, a pulse shaped amplifier with time constant of 10 msec, a multi channel analyzer (MCA-LiteN), and a PC as a data analysis. Obtained alpha spectra of atmosphere showed 4 peaks originated from $^{218}$Po, $^{214}$Po and $^{210}$Po of U series, and $^{212}$Po of Th series. Since 2017, we newly started to measure at Kochi, Choshi and Kiyosumi using our apparatus. Details of observed data are discussed in addition the data at Okayama since 2016.

# Possible anomalous changes in solar quiet-daily geomagnetic variation *Sq* related to the 2011 off the Pacific coast of Tohoku earthquake (Mw 9.0)

*Xiaocan Liu[1], Katsumi Hattori[2,3], Peng Han[4], Huaran Chen[1]

1. Institute of geophysics China Earthquake Administrition, 2. Graduate School of Science, Chiba University, Chiba, Japan, 3. Center for Environmental Remote Sensing, Chiba University, Chiba, Japan, 4. Department of Earth and Space Sciences, Southern University of Science and Technology, ShenZhen, China

Seismo-electromagnetic researches have been studied for decades (e.g. Hayakawa and Fujinawa, 1994; Hayakawa and Molchanov, 2002, 2008,2013; Hattori, 2004, Hattori, et al., 2004a, 2004b; Hayakawa et al., 2007;, Hattori et al., 2013; Han et al., 2011, 2014, 2015, 2016, 2017; Huang QH et al., 2011, 2015; Du A, Huang Q et al., 2002, Rong YM et al., 2012, Yuan G.P., Zhang X.M. et al. 2015), and the geomagnetic diurnal variation (GDV) is a stable variation of the geomagnetic field that can be used to detect possible anomalous changes associated with large earthquakes.

We investigated data observed at 20 geomagnetic observatories at longitudes of 130˚E to 150˚E between 2009 and 2012 to detect possible anomalous changes in the geomagnetic solar quiet daily variation (Sq) related to the 2011 off the Pacific coast of Tohoku earthquake (Mw 9.0) occurred on March 11, 2011 in Japan. We selected the 5 quiet days every month and analyzed three component magnetic data with 1 min resolution using the natural orthogonal component (NOC) method to identify Sq variations from observations, and performed the spherical harmonic analysis (SHA) to separate the internal and the external equivalent Sq current systems of Je and Ji. We obtained that, Je and Ji are distorted near the epicenter area on two geomagnetic quiet days of January 23 and 27, 2011. They are about two months before the earthquake. Then, we made backward computation on the external and internal parts of the SHA model geomagnetic fields, Be and Bi, to determine the possible anomalous magnetic field variations at each station. Results show significant differences in daily variation for all components on January 23 and 27, 2011. The other days, we could not recognize any apparent anomalous behaviors, except known secular, seasonal, and solar activity dependences. A possible connection between this anomaly and the very strong Tohoku earthquake, which followed only one and half month after the geomagnetic anomaly is of highest interest for the research on earthquake precursors.

Keywords: geomagnetic solar quiet daily variation (Sq), natural orthogonal component (NOC) method, spherical harmonic analysis (SHA), the 2011 off the Pacific coast of Tohoku earthquak

# Co-seismic geomagnetic fluctuations and atmospheric disturbances during the 2018 M6.2 Hualien Earthquake

*Chun-Rong Chen[1], JANN-YENQ Liu[1]

1. Graduate Institute of Space Science, National Central University

The strong ground motion of 6 February 2018 M6.2 Hualien Earthquake triggered a series of co-seismic geomagnetic fluctuations and seismo-traveling atmospheric disturbances (STADs) signatures in infrasonic waves and micro-pressures upon the seismic wave arrival. Networks of 9 QuakeFinder systems, 3 infrasound systems, 2 tiltmeters, 2 micro-barometers, and 11 co-located seismometers are used in this study. Each QuakeFinder system consists of a 3-axes induction magnetometer, an air conductivity sensor, a geophone, and temperature/relative humidity sensors. Co-seismic signatures clearly appear in the induction magnetometers, infrasound systems, and micro-barometers data. The magnetometers register both high- and low-frequency pulsations. Geomagnetic fluctuations occur upon the seismic wave arrival but last a longer duration, while the STADs lag their co-located seismic waves by about 15-45 seconds. The long-lasting fluctuations recorded by both induction and fluxgate magnetometers suggest that the ground/underground water motion play an important role, which is further conformed by low-frequency fluctuations in the tiltmeter data. In general, the amplitude of geomagnetic fluctuations decays as away from the epicenter. However, unusual large co-seismic geomagnetic fluctuations are detected over areas of the abnormal seismic intensity level and/or the magnetic underground structure with anomalously high susceptibilities.

New observations from ground and space have provided multiple evidences of pre-earthquake signals and the latest studies show their statistical significance, repeatability, and universality. In this project, to understand the preparation process of large earthquakes and slow-slip events in subduction zone, especially to clarify the nucleation stage of the earthquake cycle, we plan to establish a dense observation network in Boso, Japan, where large subduction earthquakes are expected soon. Since the subsurface fluid flow may play an important role in the preparation process of subduction activities, we intend to employ electromagnetic approaches including oceanic and continental MT survey to monitor the underground resistivity structure which is sensitive to the dynamics of fluid. Other geophysical monitoring such as ULF geomagnetic and geoelectrical observations, radon measurements, and inland GPS movements, TIR, and OLR will be incorporated to help to understand the preparation process and evaluate the applicability of various pre-earthquake signals towards short term earthquake forecasting. We call this idea “sensor WEB”. We will show the state of the art and some results in our presentation.

# Transient Effects in Atmosphere and Ionosphere Associated with 2018 Mw 7.5 Sulawesi Indonesia Earthquake and Triggered Tsunami and Volcano Activities

*Dimitar Ouzounov[1], Sergey Pulinets[2], Dmitry Davidenko[2], Alexander Rozhnoi[3], Maria Solovieva[3], Tiger Liu[4]

1. Center of Excellence in Earth Systems Modeling & Observations (CEESMO) , Schmid College of Science & Technology Chapman University, Orange, California, USA, 2. Space Research Institute, RAS, Moscow, Russia, 3. The Schmidt Institute of Physics of the Earth, RAS, Moscow, Russia, 4. Center for Astronautical Physics and Engineering, National Central University, Taoyuan City, Taiwan

We analyze retrospectively the transient variations of four different physical parameters of atmosphere/ionosphere during the time of M7.5 od Sept 28, 2018 in Indonesia namely: (i) thermodynamic proprieties in the lower atmosphere, (ii) outgoing earth radiation (OLR) at the TOA, (ii) GPS/TEC and (iv) the very-low-frequency (VLF/LF) signals at the receiving station in Petropavlovsk-Kamchatski (RTK, Russia). We found that in the second part of September 2018 a rapid augment of satellite observed earth radiation in the atmosphere and the anomaly located in close vicinity to the future M7.5 epicenter reached the maximum on Sept 21-22. The GPS/TEC data analysis indicates an augment and variation in electron density reaching a maximum value during the Sept 26-27 periods. Two VLF/LF crossing wave paths - NWC-RTK and JJY-RTK, have shown abnormal behavior of signals during on days Sept 26-28 two days before the earthquake. Our results show coherence between the appearance of pre-earthquake transient’ s effects in atmosphere and ionosphere (with a short time-lag, from hours up to a few days) and the occurrence of 2018 M7.5 in Indonesia. Traveling ionospheric tsunami disturbances (TITDs) in the total electron content (TEC) induced by tsunami waves of the 28 September 2018 Mw 7.5 Sulawesi Indonesia earthquake are detected by of seven ground-based receivers of the global positioning system (GPS) in South Asia, Oceanic, Pacific areas. It is found that the origin is about 100 km North of the epicenter and the horizontal speed is of about 187 m/s.

The pre-earthquake nature of the signals in atmosphere and ionosphere were revealed by simultaneous analysis of satellite, GPS/TEC and VLF/LF observations and suggest that they follow a general temporal-spatial evolution pattern, which has been seen in other large earthquakes worldwide.

# Seismicity change and b value variation prior to the Wenchuan earthquake (*Ms 8.0*)

*Peng Han[1], Rui Wang[1], Ying Chang[1], Miao Miao[1], Haixia Shi[2], Lingyuan Meng[2], Xuemei Zhang[2], Weiyun Xie[3], Katsumi Hattori[3]

1. Southern University of Science and Technology, Shenzhen, China, 2. China Earthquake Networks Center, Beijing 100045, China, 3. Chiba University, Chiba, Japan

The Gutenberg-Richter Law describes frequency-magnitude distribution of earthquakes. A number of studies have shown that the slope (b value) of the relationship between frequency and magnitude decreased before large earthquakes. Based on the analysis of the earthquake catalog from January, 2000 to April, 2008, we have investigated seismicity change and b value variation prior to the *Ms* 8.0 Wenchuan earthquake. The results show clear drops of both monthly and quarterly frequency of earthquakes during 2005-2006. The b value exhibits a long-term decrease trend since 2002, and reaches to the minimum just before the onset of the main shock. The temporal variation of b value is quite similar to that prior to the *Mw* 9.0 Tohoku earthquake in Japan, which may reflect the stress evolution during the preparation process of large earthquakes. These results indicate that the b value is an important indicator of an impending great earthquake, and has high potential in terms of predicting a future large quake.

Keywords: Wenchuan earthquake, b value, seismicity

[E] Poster | M (Multidisciplinary and Interdisciplinary)：M-IS Intersection

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_35

## [M-IS04] Interdisciplinary studies on pre-earthquake processes

convener:Katsumi Hattori(Department of Earth Sciences, Graduate School of Science, Chiba University), JANN-YENQ Liu(Institute of Space Science, National Central University, Taiwan), Dimitar Ouzounov(Center of Excellence in Earth Systems Modeling & Observations (CEESMO) , Schmid College of Science & Technology Chapman University, Orange, California, USA), Qinghua Huang(Peking University)

This session expands the interdisciplinary discussions on preparation process of earthquake and earthquake predictability by presenting the latest progress in studying the physically based pre-earthquake phenomena. New observations from space and ground have provided<br/>evidences, which may enhance better understanding of tectonic activity. The session anticipates talks that include but not limited to observations and analyses of seismic, electrical, electromagnetic, electro-chemical and thermodynamic processes related to stress changes in the lithosphere along with their statistical and physical validation. Presentations on the latest observational results associated with major earthquakes obtained by different methodologies are welcomed. The topics of the session are as follows but not limited.<br/><br/>-General discussion on earthquake preparation process and the physics of pre-earthquake signals<br/><br/>- Theory, modeling, laboratory experiments, computational simulation for generation and propagation of pre-earthquake signals and their connection with seismic cycle<br/><br/> - Multi-parameter observations, detection, and validation of pre-earthquake signals<br/><br/> - Cross-disciplinary studies, practical and technical approaches for better understanding of earthquake preparation processes and their connection with seismicity

Center for Environmental Remote Sensing, Chiba University, Chiba, Japan, 4. Department of Earth and Space Sciences, Southern University of Science and Technology, ShenZhen, China

Seismo-electromagnetic researches have been studied for decades (e.g. Hayakawa and Fujinawa, 1994; Hayakawa and Molchanov, 2002, 2008,2013; Hattori, 2004, Hattori, et al., 2004a, 2004b; Hayakawa et al., 2007;, Hattori et al., 2013; Han et al., 2011, 2014, 2015, 2016, 2017; Huang QH et al., 2011, 2015; Du A, Huang Q et al., 2002, Rong YM et al., 2012, Yuan G.P., Zhang X.M. et al. 2015), and the geomagnetic diurnal variation (GDV) is a stable variation of the geomagnetic field that can be used to detect possible anomalous changes associated with large earthquakes.

We investigated data observed at 20 geomagnetic observatories at longitudes of 130˚E to 150˚E between 2009 and 2012 to detect possible anomalous changes in the geomagnetic solar quiet daily variation (Sq) related to the 2011 off the Pacific coast of Tohoku earthquake (Mw 9.0) occurred on March 11, 2011 in Japan. We selected the 5 quiet days every month and analyzed three component magnetic data with 1 min resolution using the natural orthogonal component (NOC) method to identify Sq variations from observations, and performed the spherical harmonic analysis (SHA) to separate the internal and the external equivalent Sq current systems of Je and Ji. We obtained that, Je and Ji are distorted near the epicenter area on two geomagnetic quiet days of January 23 and 27, 2011. They are about two months before the earthquake. Then, we made backward computation on the external and internal parts of the SHA model geomagnetic fields, Be and Bi, to determine the possible anomalous magnetic field variations at each station. Results show significant differences in daily variation for all components on January 23 and 27, 2011. The other days, we could not recognize any apparent anomalous behaviors, except known secular, seasonal, and solar activity dependences. A possible connection between this anomaly and the very strong Tohoku earthquake, which followed only one and half month after the geomagnetic anomaly is of highest interest for the research on earthquake precursors.

Keywords: geomagnetic solar quiet daily variation (Sq), natural orthogonal component (NOC) method, spherical harmonic analysis (SHA), the 2011 off the Pacific coast of Tohoku earthquak

# Co-seismic geomagnetic fluctuations and atmospheric disturbances during the 2018 M6.2 Hualien Earthquake

*Chun-Rong Chen[1], JANN-YENQ Liu[1]

1. Graduate Institute of Space Science, National Central University

The strong ground motion of 6 February 2018 M6.2 Hualien Earthquake triggered a series of co-seismic geomagnetic fluctuations and seismo-traveling atmospheric disturbances (STADs) signatures in infrasonic waves and micro-pressures upon the seismic wave arrival. Networks of 9 QuakeFinder systems, 3 infrasound systems, 2 tiltmeters, 2 micro-barometers, and 11 co-located seismometers are used in this study. Each QuakeFinder system consists of a 3-axes induction magnetometer, an air conductivity sensor, a geophone, and temperature/relative humidity sensors. Co-seismic signatures clearly appear in the induction magnetometers, infrasound systems, and micro-barometers data. The magnetometers register both high- and low-frequency pulsations. Geomagnetic fluctuations occur upon the seismic wave arrival but last a longer duration, while the STADs lag their co-located seismic waves by about 15-45 seconds. The long-lasting fluctuations recorded by both induction and fluxgate magnetometers suggest that the ground/underground water motion play an important role, which is further conformed by low-frequency fluctuations in the tiltmeter data. In general, the amplitude of geomagnetic fluctuations decays as away from the epicenter. However, unusual large co-seismic geomagnetic fluctuations are detected over areas of the abnormal seismic intensity level and/or the magnetic underground structure with anomalously high susceptibilities.

New observations from ground and space have provided multiple evidences of pre-earthquake signals and the latest studies show their statistical significance, repeatability, and universality. In this project, to understand the preparation process of large earthquakes and slow-slip events in subduction zone, especially to clarify the nucleation stage of the earthquake cycle, we plan to establish a dense observation network in Boso, Japan, where large subduction earthquakes are expected soon. Since the subsurface fluid flow may play an important role in the preparation process of subduction activities, we intend to employ electromagnetic approaches including oceanic and continental MT survey to monitor the underground resistivity structure which is sensitive to the dynamics of fluid. Other geophysical monitoring such as ULF geomagnetic and geoelectrical observations, radon measurements, and inland GPS movements, TIR, and OLR will be incorporated to help to understand the preparation process and evaluate the applicability of various pre-earthquake signals towards short term earthquake forecasting. We call this idea “sensor WEB”. We will show the state of the art and some results in our presentation.
This study is supported by Grand-in-Aids for Scientific Research of Japan Society for Promotion of Science (26249060).

# Transient Effects in Atmosphere and Ionosphere Associated with 2018 Mw 7.5 Sulawesi Indonesia Earthquake and Triggered Tsunami and Volcano Activities

*Dimitar Ouzounov[1], Sergey Pulinets[2], Dmitry Davidenko[2], Alexander Rozhnoi[3], Maria Solovieva[3], Tiger Liu[4]

1. Center of Excellence in Earth Systems Modeling & Observations (CEESMO) , Schmid College of Science & Technology Chapman University, Orange, California, USA, 2. Space Research Institute, RAS, Moscow, Russia, 3. The Schmidt Institute of Physics of the Earth, RAS, Moscow, Russia, 4. Center for Astronautical Physics and Engineering, National Central University, Taoyuan City, Taiwan

We analyze retrospectively the transient variations of four different physical parameters of atmosphere/ionosphere during the time of M7.5 od Sept 28, 2018 in Indonesia namely: (i) thermodynamic proprieties in the lower atmosphere, (ii) outgoing earth radiation (OLR) at the TOA, (ii) GPS/TEC and (iv) the very-low-frequency (VLF/LF) signals at the receiving station in Petropavlovsk-Kamchatski (RTK, Russia). We found that in the second part of September 2018 a rapid augment of satellite observed earth radiation in the atmosphere and the anomaly located in close vicinity to the future M7.5 epicenter reached the maximum on Sept 21-22. The GPS/TEC data analysis indicates an augment and variation in electron density reaching a maximum value during the Sept 26-27 periods. Two VLF/LF crossing wave paths - NWC-RTK and JJY-RTK, have shown abnormal behavior of signals during on days Sept 26-28 two days before the earthquake. Our results show coherence between the appearance of pre-earthquake transient’ s effects in atmosphere and ionosphere (with a short time-lag, from hours up to a few days) and the occurrence of 2018 M7.5 in Indonesia. Traveling ionospheric tsunami disturbances (TITDs) in the total electron content (TEC) induced by tsunami waves of the 28 September 2018 Mw 7.5 Sulawesi Indonesia earthquake are detected by of seven ground-based receivers of the global positioning system (GPS) in South Asia, Oceanic, Pacific areas. It is found that the origin is about 100 km North of the epicenter and the horizontal speed is of about 187 m/s.

The pre-earthquake nature of the signals in atmosphere and ionosphere were revealed by simultaneous analysis of satellite, GPS/TEC and VLF/LF observations and suggest that they follow a general temporal-spatial evolution pattern, which has been seen in other large earthquakes worldwide.

# Seismicity change and b value variation prior to the Wenchuan earthquake (*Ms 8.0*)

*Peng Han[1], Rui Wang[1], Ying Chang[1], Miao Miao[1], Haixia Shi[2], Lingyuan Meng[2], Xuemei Zhang[2], Weiyun Xie[3], Katsumi Hattori[3]

1. Southern University of Science and Technology, Shenzhen, China, 2. China Earthquake Networks Center, Beijing 100045, China, 3. Chiba University, Chiba, Japan

The Gutenberg-Richter Law describes frequency-magnitude distribution of earthquakes. A number of studies have shown that the slope (b value) of the relationship between frequency and magnitude decreased before large earthquakes. Based on the analysis of the earthquake catalog from January, 2000 to April, 2008, we have investigated seismicity change and b value variation prior to the *Ms* 8.0 Wenchuan earthquake. The results show clear drops of both monthly and quarterly frequency of earthquakes during 2005-2006. The b value exhibits a long-term decrease trend since 2002, and reaches to the minimum just before the onset of the main shock. The temporal variation of b value is quite similar to that prior to the *Mw* 9.0 Tohoku earthquake in Japan, which may reflect the stress evolution during the preparation process of large earthquakes. These results indicate that the b value is an important indicator of an impending great earthquake, and has high potential in terms of predicting a future large quake.

Keywords: Wenchuan earthquake, b value, seismicity

## [M-IS04] Interdisciplinary studies on pre-earthquake processes

convener:Katsumi Hattori(Department of Earth Sciences, Graduate School of Science, Chiba University), JANN-YENQ Liu(Institute of Space Science, National Central University, Taiwan), Dimitar Ouzounov(Center of Excellence in Earth Systems Modeling & Observations (CEESMO) , Schmid College of Science & Technology Chapman University, Orange, California, USA), Qinghua Huang(Peking University), Chairperson:Jann-Yenq Liu(National Central University, Taiwan), Toshiyasu Nagao

This session expands the interdisciplinary discussions on preparation process of earthquake and earthquake predictability by presenting the latest progress in studying the physically based pre-earthquake phenomena. New observations from space and ground have provided<br/>evidences, which may enhance better understanding of tectonic activity. The session anticipates talks that include but not limited to observations and analyses of seismic, electrical, electromagnetic, electro-chemical and thermodynamic processes related to stress changes in the lithosphere along with their statistical and physical validation. Presentations on the latest observational results associated with major earthquakes obtained by different methodologies are welcomed. The topics of the session are as follows but not limited.<br/><br/>-General discussion on earthquake preparation process and the physics of pre-earthquake signals<br/><br/>- Theory, modeling, laboratory experiments, computational simulation for generation and propagation of pre-earthquake signals and their connection with seismic cycle<br/><br/> - Multi-parameter observations, detection, and validation of pre-earthquake signals<br/><br/> - Cross-disciplinary studies, practical and technical approaches for better understanding of earthquake preparation processes and their connection with seismicity

Along with the development of urban constructions, artificial disturbances in geomagnetic observations are becoming more and more tremendous. The near-field noises produced by human activities such as vehicles, subway and high-speed railways make it difficult to precisely measure geomagnetic pulsations on the ground, thus reducing the practical application value of geomagnetic data. Therefore, suppressing near-field noises has scientific significance and application value. In this study, by combining remote reference and blind source separation analysis methods, we proposed a new signal processing approach which is able to separate geomagnetic pulsation from near-field noise. First, we demonstrated the effectiveness of the new approach by separating signals of different sources in the simulation analysis. Then, we applied this method to geomagnetic field data observed in Chiba, Japan where DC-driven train noises were intense. The results showed that geomagnetic pulsations and train noises are separated clearly, and near-field train noise could be reduced effectively on that basis. It is concluded that the reference-based blind source separation analysis is useful in extracting geomagnetic pulsations and suppressing near-field noises, and may have potential application value in electromagnetic exploration.

In recent years, there are many studies reported electromagnetic phenomena preceding earthquakes such as ionospheric anomalies. Lithosphere-Atmosphere-Ionosphere Coupling (LAIC) model has been proposed to explain these phenomena. In this study, to explain the possibility of the chemical channel of LAIC, we have installed sensors for atmospheric electric field (AEF), atmospheric ion concentration (AIC), atmospheric Rn concentration (ARC), ground Rn concentration (GRC), and weather elements at Asahi station, Boso Peninsula, Japan. Because the atmospheric electricity parameters could be mainly influenced by weather factors, it is necessary to remove these influences as much as possible. In this sense, we apply the MSSA (Multi-channel Singular Spectral Analysis) to remove these influences from the GRC variation and estimate the Rn flux from the ground. Then, we investigate the correlation between the changes in the Rn flux and seismicity around the station. As a result, we found the correlation between Rn flux and regional cumulative seismic moment and/or Es index, which indicates the daily seismic energy near the station received at the station. It is highly suggestive of the effectiveness of GRC monitoring in regional seismicity around the station. Further researches such as network observations will be required for the detailed consideration on the correlation between Rn flux and seismicity such as magnitude and distance dependences.

Keywords: Lithosphere-Atmosphere-Ionosphere Coupling, atmospheric electric field, atmospheric ion concentration, ground Rn concentration

# Geochemical evidence for the occurrence of 2018 Hualien earthquake triggered by earlier earthquake swarm

*Ching-Chou Fu[1], Lou-Chuang Lee[1], Cheng-Horng Lin[1], Vivek Walia[2], Dimitar Ouzounov[3]

1. Institute of Earth Sciences, Academia Sinica, 2. National Center for Research on Earthquake Engineering, NARL, Taiwan, 3. Chapman University, One University Drive, Orange, CA, USA

The continuous observations of soil radon for earthquake studies at the Tapingti station (TPT) have been recorded and are compared with the data from gamma rays observations at the Taiwan Volcano Observation station (YMSG), located north to the TPT station. The previous significant increases of gamma rays and radon were observed at both stations before the earthquakes, which occurred in eastern and northeastern Taiwan, suggest that anomalies in gamma and radon may provide the good indicator for exploring earthquake precursor in eastern Taiwan. A Mw 6.4 Hualien earthquake struck eastern Taiwan on 6 February 2018. Based on seismological studies, this earthquake may be triggered by the earthquake swarm that shook eastern Taiwan on 4 February 2018. In this study, both stations recorded significant changes about two weeks before the Hualien Earthquake. However, we provide the possible evidences from geochemical data for the occurrence of 2018 Hualien earthquake was triggered by earlier earthquake swarm. The continuous monitoring on the multiple parameters can improve our understanding of the relationship between the observed radon and gamma-ray variations and the regional crustal stress/strain in the area.

# Temporal Variation and Statistical Assessment of b value

*weiyun xie[1], Katsumi Hattori[1], Peng Han[2]

1. chiba university, 2. Southern University of Science and Technology

The Gutenberg-Richter Law describes frequency-magnitude distribution of earthquakes. A number of studies have shown that the slope (b value) of the relationship between frequency and magnitude decreased before large earthquakes. In this paper, we investigate the temporal variation of the b value in the Hokkaido and Tohoku regions, Japan and the Wenchuan region, China, respectively, where M 8.0+ earthquakes occurred in the new century. The magnitude of completeness (Mc) in the catalog is evaluated by combining the maximum curvature (MAXC) technique and the bootstrap approach. Then, the b value and its uncertainty is computed by using the maximum likelihood estimation. The Akaike Information Criterion (AIC) with the bootstrap approach is introduced to statistically assess the temporal variation of b values and quantify the significance level. The results show decrease trends of the b value prior to the 2003 Tokachi Earthquake (M8.0) in Hokkaido, the 2011 Tohoku Earthquake (M9.0), and the 2008 Wenchuan Earthquake in China. In addition, the decrease of b values shows certain statistical significance few months before the three M8.0+ great earthquakes. It is concluded that the b value with statistical assessment may contain potential information for future large earthquake preparation.

# The S-K characteristics of the borehole areal strains associated with the Ms 8.0 Wenchuan and Ms 7.0 Lushan earthquakes

*Kaiguang Zhu[1], Zining Yu[1], Chenquan Chi[1], Mengxuan Fan[1], Kaiyan Lii[1]

1. Jilin University

The skewness and kurtosis of daily borehole areal strain at Guza station are jointly analysed on the S-K plane for the Wenchuan and Lushan earthquakes. We define a crustal stationary background to distinguish possible anomalies related to the earthquakes on the assumption that the background exhibits a quasi-Gaussian distribution. By calculating the S-K biases of the daily areal strain from the crustal stationary background, we found that before the Wenchuan earthquake, the large S-K bias anomalies were always negative, implying that the crust was compressed near the station. Whereas for the Lushan earthquake, clustered positive bias anomalies appeared within two time periods, revealing tensile changes in the crust. In addition, the S-K distributions of two arthquakes are separated on the S-K plane, further indicating differences in the associated deformation. These results demonstrate that the S-K characteristics of borehole areal strain data are potentially promising as earthquake precursors.

# The Relationship between Earthquakes and Lightning Events of the globe during 2009-2017

*Ching-Chung Cheng[1], JANN-YENQ Liu[1,2,3]

1. Graduate Institute of Space Science, National Central University, TAIWAN, 2. Center for Astronautical Physics and Engineering, National Central University, TAIWAN, 3. Center for Space and Remote Sensing Research, National Central University, TAIWAN

Lightning activities observed by WWLLN (World-Wide Lightning Location Networks) and 95 magnitude greater than 7.0 earthquakes within 30 degrees north and south latitude during 2009 - Nov. 2017 have been statistically examineed. In particular, we investigate how the lightning activities relate to the magnitude, depth, and distance to the epicenter of the earthquakes. Results show that the lightning events 12-22 days before the magnitude greater than 7.9 earthquakes significantly increase around the epicenter. Furthermore, the area size around the epicenter with the statistical significance of lightning activity enhancements is proportional to the earthquake magnitude. These results suggest that lightning activities can be used to find the possible location of forthcoming large earthquakes.

# 3D-Tomography of the Ionospheric Anomalies Preceding the 2011 Tohoku-Oki ($M_w$9.0) Earthquake

*Ihsan Naufal Muafiry[1,2], Kosuke Heki[1]

1. Hokkaido University, Japan, 2. Universitas Esa Unggul, Indonesia

The vertical deformation of solid earth could trigger direct acoustic wave propagating upward and will reach the F-layer of the ionosphere ~10 minutes after earthquakes (Cahyadi & Heki, 2015). Such an acoustic disturbance may also make long-lasting electron depletion (Shinagawa et al., 2013). These phenomena can be studied through Total Electron Content (TEC) data using Global Navigation Satellite System (GNSS) receivers. The GNSS phase difference can be converted to slant TEC (STEC) integrated along its line-of-sight (LoS), which are further converted to absolute vertical TEC (VTEC) by removing inter-frequency biases and multiplying with the cosine of the incidence angle of LoS to the ionosphere.

Shortly after the 2011 Tohoku-Oki $M_w$9.0 earthquake, Heki (2011) reported a significant positive anomaly in TEC starting ~40 minutes before the earthquake above the focal area, and He & Heki (2017) found similar TEC enhancements before 18 earthquakes with $M_w$ 7.3-9.2. He & Heki (2016; 2018) investigated the spatial structure of the electron density anomalies before the 2015 Illapel earthquake, Chile ($M_w$8.3) using three-dimensional (3D) tomography technique. The result showed that positive electron density anomaly at ~200 km and negative anomalies at high altitudes line up along the geomagnetic field. This suggests their origin by electron redistribution caused by electric field made by surface positive electric charge (e.g. Freund, 2011).

Here, we report the 3D structure of the ionospheric electron density anomalies immediately before the 2011 Tohoku-Oki Earthquake using data from GEONET, a dense GNSS arrays in Japan, and the dense network in South Korea, with the 3D tomography technique similar to He & Heki (2018) and Muafiry et al. (2018). We set up more than 1500 blocks over the region covering the whole Japanese Islands, the Japan Sea, and the Korean Peninsula, with the size of 1.0° (E-W) x 0.9° (N-S) x 60 km (U-D) up to 900 km altitude. By using STEC residuals of pairs of thousand stations and 8 GPS satellites from reference curves, carefully determined by the L-curve method, as the input, we estimated the number of electron density anomalies within individual blocks. To stabilize and regularize the solution, we applied two types of constraints, i.e. continuity constraint and altitude-dependent absolute value constraint assuming the Chapman distribution. Before using the real data, we performed various tests to confirm the reliability of the solution including the checkerboard test, the test assuming realistic preseismic anomaly pattern, and comparing observed STEC anomalies of 10 % of the observation data with those calculated using the electron density anomalies estimated from the remaining 90% of data. These tests showed that our tomography results are robust with its difference is below 0.5 total electron content unit (TECU).

The attached figure shows the map view of our result at a height of 350 km with longitudinal and latitudinal profiles at three different epochs. The results show that positive electron density anomalies occurred at ~300 km altitude. They become large without spatial drifts as the main-shock approaches. Negative anomalies surround this compact and strong positive anomaly. The anomaly is situated just above to the focal area, suggesting its origin as the concentration of ionospheric electrons in response to surface positive electric charges appearing immediately before the 2011 Tohoku-Oki earthquake.

# Statistical Analysis of Pre-seismic Ionospheric Electron Density Anomalies and Investigation of Precursor

*Sanaka Saito[1], Chie Yoshino[1], Katsumi Hattori[1]

1. Chiba University

Recently, many papers have been published on the earthquake-related ionospheric anomalies. In particular, event studies and statistical studies on Ionospheric electrons using Ionosonde and GPS TEC (total electron content) indicate the pre-seismic anomalies. In Japan region, the previous statistical study during 1998-2010 shows that there is an increase anomaly 1-5 days before the earthquake with M>=6 D<=40 km. In this study, we performed statistical analysis on ionosonde data observed at Kokubunji (35.71N, 139.49E), Japan over 60 years of 1958 ~ 2017 in order to investigate the earthquake-related ionospheric anomalies. The ionosonde is operated by the National Institute of Information and Communication Technology, Japan. The studied parameters are NmF2, which indicates the maximum electron density in the F2 layer, hmF2, which shows the NmF2 altitude, and foEs which is the critical frequency of the Es layer. We select earthquakes occurred within 1000 km and 350 km radius from the ionosonde station, and M >= 6 and D <= 40 km. There are 352 and 148 earthquakes. Ionospheric anomalies are also induced by geomagnetic storm. Therefore, to remove the geomagnetic storm effects, we adopt the Dst index. We divided the values into some classes by onset time and intensity. For each class, we performed statistical processes to calculate duration of ionospheric anomalies triggered by a geomagnetic storm. We found these anomalies last about 1-3 days, and we remove the data based on results. To investigate the correlation between ionospheric anomalies and earthquakes, we perform the Superposed Epoch Analysis (SEA). We define the anomaly as 15 days backward median value ±1.5 IQR and an anomalous day has the anomaly with more than 10 hours. Then, we make up the binary time series data on the earthquake-related anomaly. We extract dataset 30 days before and after the earthquake day for the all selected earthquakes and perform SEA. To evaluate the statistical significance, we compute the random test. SEA results show that there is a significant positive anomalies 1-10 days before the earthquakes in NmF2 data. For hmF2 data, we can find there are no clear correlation. As for foEs, we need further investigation. For NmF2, we checked Molchan’ s Error Diagram (MED). From the results of MED, NmF2 may be precursor for earthquakes. The detailed will be given in the presentation.

# Spatial clustering of pre-earthquake anomalies as an indicator of the preparation/activation zone

*Dimitar Ouzounov[1], Sergey Pulinets[2], Tiger Liu[3], Katsumi Hattori[4]

1. Center of Excellence in Earth Systems Modeling & Observations (CEESMO) , Schmid College of Science & Technology Chapman University, Orange, California, USA, 2. Space Research Institute, RAS, Moscow, Russia, 3. National Central University, Taoyuan City, Taiwan, 4. Chiba University, Chiba, Japan

We present an interdisciplinary study of observations of pre-earthquake processes associated with major earthquakes based on integrating space and ground- data. We are exploring the general temporal-spatial and evolution patterns of these pre-earthquake signals as a function of both their type and the earthquake magnitude. We examined the possible correlation between the spatial clustering of pre-Earthquake anomalies and the size of earthquake preparation/activation ( Dobrovolsky-Bowman zone) in the framework of the Lithosphere-Atmosphere-Ionosphere Coupling (LAIC) concept. For this analysis we selected six most massive earthquakes from the last decade with differing geographic and seismo-tectonics regions: (1) M9.3, Off the West Coast of Northern Sumatra, Dec 26, 2004; (2) M9.0 Great Tohoku Earthquake, , Japan, March 11, 2011; (3 and (4) M7.8 and M7.3 Gorkha, Nepal, 2015; (5); M8.2 Tehuantepec, Mexico, September 8, 2017 and; (6) M7.1, Puebla central Mexico earthquakes, Mexico, September 19, 2017.
Four physical parameters were measured from ground and satellite were used in the temporal-spatial patterns: 1) Ground Radon variation; 2) Outgoing Long-wavelength Radiation (OLR obtained from NPOESS, NASA/AQUA) on top of the atmosphere (TOA); 3) Atmospheric Chemical Potential (ACP) obtained from NASA assimilation models and; 4) electron density variations in the ionosphere via GPS Total Electron Content (GPS/TEC).

Our preliminary results of temporal-evolution patterns indicate an enhancement of radon (about a week to ten days prior) followed by the increase in the atmospheric chemical potential measured near the epicenter from both satellite and subsequently with an increase of OLR observed on the TOA from NOAA/NASA (a week in advance). Finally, GPS/TEC data indicate an increase in electron concentration 1-4 days before the earthquakes. Although the radon variations, some of satellite OLR and GPS/TEC anomalies were observed far (>2000km) from the epicenter areas, the anomalies were always inside the estimates of the Dobrovolsky-Bowman area of preparation. This finding provides new metrics in the assessment of pre-earthquake signals according to LAIC for both sea and land earthquakes possible only by integrating satellite and ground observations. A detailed summary of our approach to this study of pre-earthquake research has just been published as AGU/Wiley Geophysical Monograph Series No. 234.

Keywords: earthquake forecasting, pre-earthquake, LAIC, GPS/TEC, satellite thermal anomaly, radon

# Application of the ionospheric parameters on the seismic research --Seismic-ionospheric effect detected from China Seismo-Electromagnetic Satellite

*Rui Song[1], Hattori Katsumi[2], Xuemin Zhang[3]

1. Graduate School of Science and Engeering, Chiba University, 2. Graduate School of Science, Chiba University, 3. Institute of Earthquake Science, China Earthquake Administration

The ionosphere is located at the altitude of 60 kilometers above the earth surface and the top of the ionosphere is about 500km. Figure 1 shows the basic structure of the ionosphere, where D, E and F layers are all clearly concluded. In addition, F layer can be divided into F1 and F2 layers. F1 layers and D region always disppear in nighttime. The seismic-ionospheric research began in 1960s, when American scientists studied the Alaska M8.5 earthquake in 1964, they first found that the disturbance of plasma density before this earthquake. Since then, many researchers engaged in this field. Based on the promising seismic-ionospheric research, China government launched the Seismo-electromagnetic satellite, CSES for short, on February, 2018 for both the earthquake observation and geophysical research. As the data is available now, in this research we adopt the observed data from CSES. The basic information of this satellite is listed in Table 1. There are four consecutive shallow focus earthquakes in a short period in Indonesia during July to Augst, 2018, where Table 2 shows the detailed information about these four earthquakes, and figure 2 shows the specific locations of four epicenters on the map. As for the data sources, there are mainly three kinds of data. The first kind is the Ionospheric Electron density (Ne for short) from CSES satellite. Figure 3 shows the launch and flight status of CSES satellite where a total of 8 payloads concluded, and we adopted the electron density from Langmuir Probe PayloadIn this research. The second kind of data is Ne corresponding with the observed data from International Reference Ionosphere model 2016 (IRI 2016). The third kind is the global ionosphere map from CODE whose time resolution is 1 hour, spatial resolution is 2.5deg*5deg. We adopt these data to evaluate the reliability of the CSES satellite data. First, we used the following formula to calculate the percent disturbance of electron density from CSES satellite. After calculation, we found that there are mainly four significant anomalies on July 27, 31, August 07, and 14 respectively, shown as figure 3. Compared with the earthquake time listed in table 2, these four disturbances just happened before the four earthquakes, which maybe the seismic-ionospheric effect. And the red star in these figures represent the epicenter. After checking different kinds of space weather index, we can exclude that the disturbance is caused by space weather. As for the IRI 2016 model can be seen as the background data without any seismic factors, so we adopt the corresponding Ne from IRI model to evaluate the reliability of CSES data. From figure 4, it is clear the abnormal orbits in figure 3 also show the similar disturbance. As the orbit revisiting period is 5 days, figure 5 shows the comparison between the revisiting orbits of CSES on July 31 and August 14, the other two orbits go through the same location 5 or 10 days before. From this figure, the electron density shows obvious swelling on the abnormal days while the electron temperature shows the opposite trend. Then we used the grid data from CODE to calculate the disturbance about VTEC. Figure 6 (a) shows the percent disturbance of VTEC on August 1, 2018, from 5:00UT the abnormal around the epicenter is gradually increased, till 15:00UT the abnormal area disappeared. It is worth noting that the anomaly did not change with time, which means it is not triggered by sun activity. The percent disturbance of VTEC on Aug. 14, 2018 also shows the similar results from figure 6 (b). In the following research, we counted all the earthquakes that occurred in Indonesia over a 10-year period during 2007-2017 between 106.45 E-126.45 E and 8.3 S-1.7 N from USGS to check the anomalies of

©2019. Japan Geoscience Union. All Right Reserved. 

ionospheric vertical TEC from CODE. After selecting the earthquake accidents whose depth is less than 50km, and magnitude is greater than M5.8, there are a total of 35 earthquakes in the end, shown as figure 7. Figure 8 shows the statistical results of the count of TEC anomalies 15 days before and after these 35 earthquakes. It is obvious that 1-7 days before one earthquake in Indonesian region, the number of ionospheric parameter anomalies is more than other time.

# ROC curve analyses on the ionospheric TEC of M>=6.0 earthquakes in Japan during 1998-2015

*JANN-YENQ Liu[1], Yuh-Ing Chen[2], Pei-Jung Lee[1]

1. Center for Astronautical Physics and Engineering; Graduate Institute of Space Science, National Central University, Taiwan, 2. Graduate Institute of Statistics, National Central University, Taiwan

To verify the pre-earthquake ionospheric anomaly (PEIA), statistical analyses are implemented on the relationship between the total electron content (TEC) of global ionosphere map (GIM) and M>=6.0 earthquakes in Japan during 1998-2018. A median-based method together with z test is employed to find the criteria and/or characteristics of TEC anomalies related to earthquakes. It is found that the GIM TEC over the Japan significantly increases 1-3 days before the earthquakes. The receiver operating characteristic (ROC) curve is used to compare the TEC anomaly-based method with some competitive alternatives for predicting the earthquakes under study. We find, based on possible TEC anomalies, that the observed PEIAs are significantly earthquake-related. Moreover, the results of regression analyses show that the PEIA strength is associated with the magnitude of earthquakes.

Keywords: pre-earthquake ionospheric anomaly (PEIA), total electron content (TEC), earthquake, receiver operating characteristic (ROC)

# FORMOSAT-5/AIP observes seismo-ionospheric precursors

*JANN-YENQ Liu[1], Chi-Kuang Chao[1]

1. Center for Astronautical Physics and Engineering; and Graduate Institute of Space Science, National Central University, TAIWAN

FORMOSAT-5 (F5) was launched at 18:51 UT (universal time) on 24 August 2017 with a sun-synchronous orbit at 720 km altitude and 98.28° inclination, which passes at almost the same local time everywhere in the daytime of about 10:30 LT and the nighttime of about 22:30 LT. It carries a primary payload, optical RSI (Remote Sensing Instrument), and a science payload, AIP (Advanced Ionospheric Probe), which are normally operating in the daytime and nighttime, respectively. The AIP mission is to monitor seismo-ionospheric precursors (SIPs) and observe ionospheric space weather. It is basically a multi-grid planar ion probe integrated with a planar Langmuir probe within a 10 cm ×10 cm aperture, which consists of Retarding Potential Analyzer (RPA), and Ion Drift Meter (IDM)/Ion Trap (IT) to maximize the total availability of ionospheric ion concentration (or density), ion velocities, and ion/electron temperatures at a sample rate up to 8192 Hz over a wide range of spatial scales in ionospheric plasma. The electroformed gold grids used has almost no hysteresis in sweeping current-voltage curves, and results in that the AIP can accurately probe plasma quantities in the ionosphere. The RPA and IDM/IT have been alternatively operating on every other orbit since end of October 2017. The RPA probes the ion density, while the IDM/IT derives the ion density and ion drift velocity. This paper combines in situ plasma measurements of F5/AIP and remote sensing of the TEC (total electron content) derived by ground-based GNSS (global navigation satellite system) receivers to three-dimensionally study SIPs of the 12 November 2017 M7.3 Iran-Iraq Border Earthquake and disturbances of ionospheric storms on 1 and 21 November 2017. The F5/AIP ion density is employed to confirm the SIP signatures and storm signatures being observed, while the F5/AIP ion velocity is employed to find electric fields associated with the SIPs and the ionospheric storms.

## [M-IS06] Conservation of geoparks, natural geosites and cultural heritage: weathering process and damage assessment

convener:Chiaki T. Oguchi(Institute for Environmental Science and Technology, Graduate School of Science and Engineering, Saitama University), Tetsuya Waragai(Graduate School of Science and Engineering, Nihon University), Kuniyasu Mokudai(Tohoku Gakuin University), Magdalini Theodoridou(School of Engineering, Cardiff University), Chairperson:Tetsuya Waragai(日本大学大学院理工学研究科), Kuniyasu Mokudai(Japan Geoservicee)

Geoparks, world heritage sites, natural geosites and cultural heritage structures are considered important natural and/or cultural heritage properties. They have been exposed to weathering not only in geologic time frame but also in human time scale, thus rocks and geological materials are often facing deterioration. In order to preserve these sites conservation measures should be considered. Several studies have taken place on this topic involving a wide range of research fields, such as geomorphology, engineering geology, geoarchaeology, conservation science, geoconservation, materials science, petrophysics, geochemistry, geotechnical engineering etc. However, our knowledge on many aspects is still limited. The session welcomes contributions, presenting original research, discussions as well as case studies on documentation, measurement and monitoring techniques, experimental procedures, predictive models, damage assessment, etc. Papers from all research fields are invited dealing with the broad topic of geosites and cultural heritage.

# Geopark's response to conservation of geosites from natural hazards

*Kuniyasu Mokudai[1], Shuichi Hasegawa[2]

1. Japan Geoservice Incorporated, 2. Kagawa Univ.

Various natural hazards such as floods, slope failures, earthquake motions, etc. occur in the Japanese islands. Such natural hazards greatly affect the state of geosite. The Geopark performs activities in the event of a natural hazard, but its know-how has not accumulated. At Shikoku Seiyo Geopark, the Seiyo City needed to do disaster restoration work during the western Japan heavy rain in 2018. Therefore, it was difficult to transmit information and preserve the geosite as a geopark.

Taya cave, an artificial cave in a hill in south Yokohama, was excavated from the Kamakura period through the late Edo period. There are many sculptures and bas-reliefs on the surface of the cave wall made of soft rock which deposited in Pleistocene. Those sculptures has been suffering from weathering and deterioration, especially exfoliation of the wall and ceiling. In this study, for the purpose of conservation and restoration of sculptural murals, rock physical properties were investigated to assess the current situation. As a result, the possibility of surface exfoliation is considered to be affected by moisture difference, whereas the possibility of collapse of ceilings or floors between stairs becomes higher if too much water infiltrate.

TAYA Cave is an underground geoheritage locating in a Buddhism temple of Shingon sect, Josen-ji, south Yokohama, Japan. The cave is supposed to have its origin in the Kamakura period about 800 years ago, and then been used for religious trainings for priests. After opened to public in Edo era, a certain number of general people visited there. It was registered as a cultural property of Yokohama City in 1990. The cave originates in Kamakura period over 800 years ago. It was made by digging with human hands to shape a tunnel-like three-layer structure. More than 300 beautiful bas-reliefs are existed on the walls. However, those artifacts have been damaged due to deterioration or weathering. We are facing to urgent problem to preserve it to inherit in the future.
The authors have been trying to preserve this cave for four years. *The Executive Committee for the Preservation of Taya Cave* was established to make 3D digital data of this underground cultural property. In order to outline the approaches, three practical trials were carried out. The first one is dissemination of basic conditions of the cave from the viewpoints of earth science such as geology, geography and geotechnics to local people. Throughout of this activity, environmental characteristics of Taya Cave will be understood quantitatively. The second one is to understand regional culture and environment by interpreting regional history appearing on fundamental survey of bas-relief. The third one is to consider the possibilities of city planning with considering various regulations existed in the real society and environmental regulations. By comprehensively advancing these activities, urban rural area will be able to develop and gain vitality. The present study reports the results of these multidisciplinary practical trials carried out so far.

# Italian underground cultural heritage: from monitoring to enhancement

*Mario Parise[1], Tiziana Vitolo[2], Roberta Varriale[2]

1. Univ. Aldo Moro, Dept. Earth and Environmental Sciences, Bari, Italy, 2. CNR-ISSM, Italy

Italy is among the European countries with the highest number of artificial cavities, many of which represent a precious testimony of past civilizations and cultures, and of the continuous link between town development and the underground as well. The Italian underground has historically managed several environmental conflicts and social interactions, in both urban and rural settings. Nowadays the artificial cavities represent a significant segment within the local cultural heritage and have become in the last decades the object of strategic planning addressed towards their regeneration, valorization and public fruition. All these actions, however, need to be based on sound studies and researches aimed at evaluating the opportunity to open to the public sites that could potentially be unsafe. At this regard, monitoring plans and activities, and careful assessment of the susceptibility to failure and collapses, must be performed. Only after the stability conditions have been positively ascertained, underground sites might be considered for valorization, public visits and other activities.
In such a framework, we present in this contribution some case studies (including the underground tanks Cisternone in Formia, Latium, and Palombaro in Matera, Basilicata), also to describe their use at the time of realization, and to illustrate the related "sense of place". Environmental, social, historical and economic reconstructions have been carried out to generate and manage the knowledge of the places selected in order to facilitate their use and contribute to their development, in direct link with the cities where they are hosted. The methodology adopted aims at highlighting the cultural vitality and the identity of these places for the benefit of the local populations, and of tourists as well.

# Possibility of insolation weathering of sandstone blocks composing Angkor temples, Cambodia

*Tetsuya Waragai[1]

1. Graduate School of Science and Engineering, Nihon University

Angkor temples such as Angkor Wat and Bayon temples built from 9$^{th}$ to 13$^{th}$ century are mainly composed of sandstone blocks. However, as a result of tree cutting that has been proceeded to protect the temples from rootwedging processes, most of temples are exposed to direct insolation. Possibility of insolation weathering of the sandstone blocks are pointed out, since the sandstone blocks can keep high temperature condition during daytime. Therefore, this study carried out field experiments that expose a sandstone cylindrical specimen in a dry season as a trial experiment using an acoustic emission (AE) method that may detect microcracks in the specimen by temperature changes. The experiment was carried out at the test site of Angkor Wat temple by measuring surface temperatures and AE signals of the specimen in December 2018. As the results, the surface temperatures of the specimen were 51.5 ˚C in maximum and 20.8 ˚C in minimum, and diurnal difference was 30.3 ˚C. In addition, the maximum elevation rate of the temperature was 1.50 ˚C/min and the minimum descending rate of the temperature was -1.88 ˚C/min. Although the surface temperature measurement could not synchronize to the AE measurement, an AE signal that is 40% bigger than ordinal value, was detected at the time of 0.43 ˚C/min of the elevation rate of temperature. This is though that sandstone blocks maybe deteriorate due to temperature changes by insolation.

# Durability evaluation of pyroclastic rocks used in the historical built environment of Hungary

*Luigi Germinario[1,2], Ákos Török[1]

1. Budapest University of Technology and Economics, Hungary, 2. Saitama University, Japan

Pyroclastic rocks of diverse composition have experienced a broad historical usage in the built environment of Hungary, especially from the Middle Ages. In the northern regions, for instance, acid ignimbrites have been widely used as building stones in monumental construction, e.g., churches and castles, Ottoman architectures like mosques and spas, as well as common dwellings. Their characterization reveals a small-scale inconstancy of their physico-mechanical performance and petrographic features, which affects weathering susceptibility. That involves most significantly porosity, pore-size distribution, and tensile strength, considering the technical properties; on the other hand, texture must be accounted for in terms of changing quantity and size of pumice clasts, phenocrysts, and crystals, and amount of the weak and porous groundmass. The behavior of the ignimbrites when subjected to artificial weathering, by freeze-thaw and salt attack tests, alters accordingly. The variability of open porosity represents the most important factor marking a possible dramatically diverse durability. It turns out to be proportional to water absorption, controlling the amount of infiltrating water or salt solutions, at the base of potential rock failure due to ice or salt crystallization. The sole high moisture may also lead to an extreme and hazardous deterioration of the mechanical properties. Finally, high porosity is correlated with low welding degree and, in turn, low strength. Such outcomes suggest criteria for evaluating the vulnerability of these volcanic rocks in cultural heritage, and directing reasonable material selections for stonework restorations.

The Yaya-csve is located within the Jōsenji-Temle in Taya Town,Sakae ward,Yokohama-shi,Kanagawa Prefecture.The cave is called “Yuga-dou”,which is thought to be the present form in the Edo period, when the Kamakura period entered monks drills as a training ground. As for the religious relief carved in the cave, it is presumed from the record of “Koukoku-chishi” that it was produced for about 20years from 1842 to1862. In addition, “Sekiguchi diary” contains articles on visiting caves in 1859.

Subjects of reliefs are divided into the following areas in order of the route, and about 300 are engraved over 250 meters in total length.

First area:A and Un lions, Up and Doun dragon, Gold wing bird. Ceiling family crest.

Second area:Zodiac image. Ceiling three bats.

Third area:Chichibu 33 Kannon sacred place. Karyou-binga.

Fourth area:Asahina-benzaiten.

Fifth area:Saigoku 33 Kannon sacred place.

Sixth area:Sone Tenman-gū shrine and Takasago pine.

Seventh area:Yakuyoke Kobō-daishi master.

Eighth area:Taizōkai-shugi-mandala. Ceiling crane hemp leaf pattern.

Ninth area:Ichigan Kobō-daishi master. Shikoku 88 sacred place.

Tenth area:Shikoku 88 sacred place. 49in-shugi-mandala. Four Gorin tower.

Eleventh area:Godai-myouou.

Twelfth area:Water Kobō-daishi master. Sadasan one Turtle. Kouya-san Ishidoumaru. Unchū-kuyou bodhisattva.

Thirteenth area:18Rakan.

Fourteenth area:Iwaya-Fudou.

Fifteenth area:Bandou 33 Kannon sacred place.

Regrading the style, religious subjecks such as the Saigoku, bandou, Chichibu 33 Kannon sacred place,

©2019. Japan Geoscience Union. All Right Reserved. 

Shikoku 88 sacred place and shugi-mandala are also perfunctory aspects, but “Sone Tenman-gū shrine and Takasago pine” and “Sadasan one Turtle” and 18-Rakan etc are the sculptures with high artistic and strong paintertly elements.

The faith in the 18th century was diverse, especially the common people went around the whole countey sacred place. Also for each of those who can not visit the sacred place a mini sacred place of each sacred place was established in various places. The Taya-cave near the Tokaido must also have collected the faith of the common people as a mini sacred place.

Taya-cave is currently designated as a registered cultural property of Yokohama City as a historic site in 1990. However, due to years of deterioration, it is becoming difficult to preserve and maintain the current situation. Therefore, in 2017 the Taya-cave preservation execution committee was established, we aim to conduct a basic survey in each department of cultural property, engineering and environmental studies, revalidate its value, preserve it as VR digital data in the future, to make it public and utilize.
In 2018, under the auspices of the Japan Society for the Promotion of Science(JSPS), collaborative research with the Italian ISSM/CNR Laboratory began, and in 2019 the research was continued with the subsidy of the Asahi Shimbun Cultural Foundation.

# Effect of stress concentration on the Weathering Mechanism of Sandstone Pillars of Angkor Wat, Cambodia by means of numerical simulation

*Takato Takemura[1], Tetsuya Waragai[2]

1. Nihon Univ., 2. Nihon University

Since Angkor Wat is located in a tropical monsoon climate, the sandstone building materials are strongly affected by weathering related to high temperatures, heavy rainfall and intense solar radiation. Weathering damage can be observed on a number of pillars, however, the outer pillars exhibit little weathering damage compared to the inner pillars, even though the outer pillars are more exposed to the rain and sunlight than the inner pillars. To understand the effect of stress concentration on the weathering sandstone pillars, we carried out the measurement of the degree of weathering damage of pillars, in-situ measurement of humidity and temperature change near the pillar and the numerical simulation for structural analysis.As a result, the weathering damage is not necessarily only due to the wetting-drying cycle. Since relatively large compressive stress is applied to the base of the inner pillar where the weathering damage is large, therefore, the weathering rate could be accelerated by the compressive stress concentration.

# Meaning to preserve evidence of large scale landslide

*Kuniyasu Mokudai[1], Hidekazu Sato[2]

1. Japan Geoservice Incorporated, 2. Mt. Kurikoma Area Geopark

There are many mountainous area in Japanese islands. In mountainous area, many natural hazards occured. Visualization of landslide is necessary in order to understand the slope process in the mountains to non-experts. At Mt. Kurikoma Mountain area Geopark, we have been engaged in conservation of large-scale landslide landform, education and information dissemination activities. In order to preserve the landslide phenomenon which is the cause of the slope disaster, a scientific understanding of the landform is necessary. Furthermore, it is necessary to restructure the view of nature of the concerned parties.

## [M-IS06] Conservation of geoparks, natural geosites and cultural heritage: weathering process and damage assessment

convener:Chiaki T. Oguchi(Institute for Environmental Science and Technology, Graduate School of Science and Engineering, Saitama University), Tetsuya Waragai(Graduate School of Science and Engineering, Nihon University), Kuniyasu Mokudai(Tohoku Gakuin University), Magdalini Theodoridou(School of Engineering, Cardiff University)

Geoparks, world heritage sites, natural geosites and cultural heritage structures are considered important natural and/or cultural heritage properties. They have been exposed to weathering not only in geologic time frame but also in human time scale, thus rocks and geological materials are often facing deterioration. In order to preserve these sites conservation measures should be considered. Several studies have taken place on this topic involving a wide range of research fields, such as geomorphology, engineering geology, geoarchaeology, conservation science, geoconservation, materials science, petrophysics, geochemistry, geotechnical engineering etc. However, our knowledge on many aspects is still limited. The session welcomes contributions, presenting original research, discussions as well as case studies on documentation, measurement and monitoring techniques, experimental procedures, predictive models, damage assessment, etc. Papers from all research fields are invited dealing with the broad topic of geosites and cultural heritage.

## [M-IS07] Astrobiology

convener:Hikaru Yabuta(Hiroshima University, Department of Earth and Planetary Systems Science), Seiji Sugita(Department of Earth and Planetary Science, Graduate School of Science Sciece, The University of Tokyo), Misato Fukagawa(National Astronomical Observatory of Japan), Fujishima Kosuke(Tokyo Institute of Technology, Earth-Life Science Institute), Chairperson:Hikaru Yabuta(Hiroshima University), Seiji Sugita(東京大学大学院 理学系研究科), Misato Fukagawa(名古屋大学大学院 理学研究科), Kosuke Fujishima(ELSI 地球生命研究所)

Twenty years have passed since when the field of Astrobiology, which aims to unveil the origins, evolution, and habitability of life by integrating multidisciplinary fields, was established. Individual themes related to Astrobiology, such as chemical evolution in the early Solar System, formation of planetary system, prebiotic chemistry in the early Earth, evolution of life in the Earth's history, extremophile, and habitable planetary environments, has been studied by the knowledge and methods from the multiple fields, which has enabled us to explain "Where we came from" in some ways. However, despite an overwhelming number of investigations and discussions through gathering of the scientists from different fields, there has remained the long-standing unsolved question: How did abiotic materials gain biological function in the Earth and elsewhere in universe? There is still a large gap between prebiotic organic chemistry and biochemistry toward Origins of Life and planetary habitability. Therefore, the JpGU Astrobiology session focuses on pathfinding of "integration of astronomy, geoscience, and biochemistry", which will face an increasing need for the future Astrobiology. In order to enhance our understanding of "What is life", we propose to discuss the biochemical events linked with planetary systems, which is beyond the knowledge in a test tube, by an integration of exoplanets and molecular biology, etc. Through this approach, we will lead the discussions and developments of life-detection strategies for the future exploration of life in universe.

Discussion

# How to find and characterize nearby habitable exoplanets

*Norio Narita[1]

1. Astrobiology Center

In this review, I will summarize previous and ongoing efforts to find habitable exoplanets in the vicinity of the Solar system and future prospects to characterize such planets with next generation telescopes and instruments. In addition, I will talk about the importance and some examples of interdisciplinary studies of astrobiology to consider future missions.

*In situ* analyses of lake-deposited mudstones of the Murray formation at Pahrump Hills, Gale crater, Mars show the presence of aliphatic, aromatic, and sulfur-bearing organic gases upon heating to 500-860˚C, as detected by the Sample Analysis at Mars (SAM) instrument suite on the Mars Science Laboratory's (MSL's) Curiosity rover. Organic-sulfur compounds, including thiophenes, dimethylsulfide and thiols were identified by gas chromatography-mass spectrometry (GCMS) and observed in evolved gas analyses (EGA). Other aromatic and aliphatic hydrocarbon components were also indicated by EGA. The distributions of organic molecules observed were specific to samples and cannot be from SAM's instrument background. The temperatures these organic volatiles were released is consistent with the pyrolytic cleavage of organic fragments from large molecules (macromolecules) indigenous to the mudstones. Some portion may also be derived from the thermal release of organics entrained within minerals.

The release of organic-sulfur compounds occurs at high temperatures in the SAM oven; thus, these compounds are most likely derived from sulfurized organics in the sediments and are not an artifact of sulfurization reactions in the oven. On Earth, sulfurization is a key process that facilitates organic matter preservation over geological time-scales by transforming individual organic molecules into recalcitrant macromolecules. Organic matter at the base of the Murray formation probably underwent sulfurization prior to deposition or during early diagenesis. Multiple factors likely contribute to the organic preservation in the Gale crater mudstones, however, sulfurization may be largely responsible for the greater abundance and the molecular diversity observed in the lower Murray formation.

### Purpose of Tanpopo mission

Tanpopo, a dandelion in Japanese, is a plant species whose seeds with floss are spread by wind. We proposed this mission to examine possible interplanetary migration of microbes, and organic compounds at the Exposure Facility of Japan Experimental Module (JEM: KIBO) of the International Space Station (ISS).
We are testing the panspermia hypothesis, which proposes the interplanetary transfer of life. We are also testing if the organic compound may be transferred from space before the origin of life on the earth.
The Tanpopo mission consists of six subthemes: Capture of microbes in space (Subtheme 1), exposure of microbes in space (Subtheme 2), analysis of organic compounds in interplanetary dust (Subtheme 3), exposure of organic compounds in space (Subtheme 4), measurement of space debris at the ISS orbit (Subtheme 5), and evaluation of ultra low-density aerogel developed for the Tanpopo mission (Subtheme 6).

### Apparatus developed for Tanpopo mission

We have developed two types of apparatus used for Tanpopo mission: Capture Panels for aerogel to capture micro-particles and Exposure Panels for exposure of microbes and organic materials.
Each Capture Panel contains a silica aerogel block in an aluminum mesh container. Silica aerogel, which is the lowest density solid material, is used to capture micro particles, which may include, micrometeorite, artificial space debris and earth-originated natural particles. We are going to analyze if the particles contain terrestrial microbial cells or not, and if the micrometeorite contains organic compounds or not.
Exposure Panels have been developed to expose microbes and organic compounds to the space environment. Several microbial species including, *Deinococcus radiodurans, Deinococcus aerius, Deinococcus aetherius, Nostoc sp., Schizosaccharomyces pombe,* have been exposed to the space environment. These species are expected to be resistant against space environment, vacuum, desiccation, temperature-cycle, UV and ionization radiation. We have tested the survival of these species after one-, two- and three-year exposure in space. Organic compound such as amino acids and the precursors have also been exposed.

### Schedule of Tanpopo mission

Tanpopo apparatus was launched in April 2015. The Panels were placed on the Exposed Experiment Handrail Attachment Mechanism (ExHAM) in the ISS. The ExHAM with Panels were placed on the Exposure Facility of KIBO (JEM) with the Japanese robotic arms through the airlock of KIBO in May 2015.
The first set of Capture Panels and an Exposure Panel were retrieved in June 2016, contained in plastic

©2019. Japan Geoscience Union. All Right Reserved. 

bags, and stored in the pressurized area of the International Space Station. They have returned to the ground in the space capsule, and returned to JAXA in September 2016. The second set of Capture Panels and an Exposure Panel were detached in July 2017 and returned to JAXA in October 2017. The third set were detached in June 2018, the Exposure Panel and the Capture Panels were returned to JAXA in September 2018 and in February 2019, respectively.
Exposure Panel was separated into Exposure Units, each harboring either microbe or organic compound was handed over to the scientist in charge of each microbe or organic compound. Some of the Units are dedicated to the UV or radiation dose measurement.
Each aerogel block of each Capture Panel was examined for the particles captured and the tracks made upon the impact, which were extracted from the aerogel block and handed over to the scientists. The analysis includes, fluorescence microscopic inspection to test if there are microbial cells or not. Particles and tracks will be used for the mineral analysis as well as the analysis of organic compounds.
The first report has been published and the following results will be reported.

# Theoretical search for photosynthetic pigments applicable around low temperature stars: Modulation of physical-chemical properties by central metals

*Yu Komatsu[1,2], Kenji Takizawa[1,3]

1. Astrobiology Center, 2. National Astronomical Observatory of Japan, 3. National Institute for Basic Biology

A lot of extrasolar planets have been discovered in the habitable zone, and the number of samples will be increasing in future. In order to discover planets which harbour lives, it will be a significant achievement to identify potential biosignatures, which are traces of life from planetary spectra. Gaseous molecules such as oxygen and ozone and spectral features in surface vegetation called as "vegetation red edge (VRE)" are considered as biosignatures. In current observations, planets around M dwarfs, lower temperature stars than the Sun, have been focused, and there are large uncertainties in how assumed photosynthetic organisms evolve in the planets and how they would exhibit spectral features. Recently, it has been shown that the Earth-type photosynthesis can be evolved even around M dwarfs, considered lighting conditions in shallow water and how phototrophs can adapt to it (Takizawa, K., et al.: 2017, *Scientific Reports*, **7**, 7561). Moreover, an interesting example has been discovered that a cyanobacteria, which are categorized into oxygenic photosynthetic bacteria, becomes to utilize longer wavelength radiation for photochemistry than previously known, after grown under near infrared light, 750 nm (Nürnberg, D. J. et al.: 2018, *Science*, **360**, 1210.). Accumulating such knowledges and benchmarks from various points of view would lead to implications for future observations.

We investigate thoroughly by quantum chemical calculations the properties of photosynthetic pigments like and artificial pigments which might form on early Earth or other planets to unravel the red limit of the pigment. Photosynthetic pigments play a central role to convert available light energies into chemical energies. Chlorophyll has a tetrapyrrole ring with a metal ion such as Mg in the center of the ring. The ring structure can encapsulate a variety of metals to have a modulation of physical-chemical properties. Starting with the tetrapyrrole, we search for the pigments which are applicable around M dwarfs by calculating their basic structures, functional groups, central metals and solvents to determine the absorption wavelength and other properties. At first, we focused on the role of the central metal. Metals *M={H2, Mg, Ca, Ni, Cu, Zn, Sr, Cd, Hg, Pb, ...}* are put in the center of rings and are evaluated. According to our calculations, the wavelength of the first excited state is slight long in *M=Ni* in chlorophylls *a* and *b* and bacteriochlorophylls *a* and *b*. Additionally, binding eneries for metals into the rings in solvent conditions, molecular orbitals and reactivities (ionization potential and electron affinity) are analyzed for each pigment.

# Effects of the formation of hydrocarbon aerosols on the climate stability of Earth-like planets and their habitability

*Yasuto Watanabe[1], Eiichi Tajika[1], Kazumi Ozaki[2], Peng Hong[3]

1. The University of Tokyo, 2. Toho University, 3. Chiba Institute of Technology

It is known that the haze particles composed of hydrocarbons can form in an anoxic atmosphere in which the $CH_4/CO_2$ ratio exceeds the critical level (~0.2), as observed in Titan's atmosphere. The haze particles have characteristic optical properties that could affect the planetary climate as discussed in the context of the anoxic early Earth before the rise of atmospheric oxygen owing to the activity of oxygen-producing photosynthetic bacteria. Under low $pO_2$ condition, $CO_2$ and $CH_4$ can be photochemically broken up to form CO, and the excess CO reacts with OH radical to form $CO_2$. If primitive anaerobic microbial ecosystem exists on the Earth-like planet as in the early Earth, it can also affect the balance between $CO_2$, $CH_4$, and CO. Primitive marine microbial ecosystem may produce $CH_4$ to the atmosphere-ocean system via methanogenesis. The primitive microbial ecosystem consumes $CO_2$ from the atmosphere-ocean system via anoxygenic photosynthesis, but it also provides $CO_2$ via decomposition of organic matters and methanogenesis, and/or other abiotic processes. This implies that the balance between $CO_2$, $CH_4$, and CO in the early Earth must have been significantly different from that at present. Photochemical reactions and biological processes in the ocean may affect the stability of the planetary climate through the formation of the haze particles.

Here we developed a coupled atmospheric photochemistry-marine microbial ecosystem-global carbon cycle model to explore how the atmospheric photochemistry and the primitive marine microbial ecosystem can affect the carbon cycle and $CO_2$ budget on the Earth-like planet. We found that when the primitive biosphere produces large $CH_4$ flux (~$10^{11}$ $cm^{-2}$ $s^{-1}$), OH radicals should be consumed in the lower atmosphere through the reaction with $CH_4$. As a result, the reaction between CO and OH, which produces $CO_2$, cannot compensate the photolysis of $CO_2$ in the upper atmosphere. This means that photochemical reactions may work as a net $CO_2$ consumption process in the atmosphere-ocean system. The excess CO in the atmosphere is considered to have been converted to $CO_2$ and $CH_4$ through the CO-using chemosynthesis and methanogenesis in the oceans on the early Earth. Therefore, marine microbial reactions can work as a net $CO_2$ production process in the atmosphere-ocean system. We also found that, when the $CO_2$ level is so low that the hydrocarbon haze can form, the photochemical net consumption of $CO_2$ exceeds the biospheric net production. In this case, $CO_2$ is removed from the atmosphere-ocean system as the haze particle. As a result, the climate with the hydrocarbon haze should be unstable, and the climate is expected to change to the snowball state with low $pCO_2$ or to the hot climate state (> ~310 K on the $CO_2$ degassing rate of the present Earth) with high $pCO_2$ and $pCH_4$ on the planets with anoxic environment and primitive microbial ecosystem in the ocean.

Our result would put a theoretical constraint on the existence of life on extrasolar Earth-like planets and their habitability.

Thu. May 30, 2019 10:45 AM - 12:15 PM JST | Thu. May 30, 2019 1:45 AM - 3:15 AM UTC | 201A 2F

## [M-IS07] Astrobiology

convener:Hikaru Yabuta(Hiroshima University, Department of Earth and Planetary Systems Science), Seiji Sugita(Department of Earth and Planetary Science, Graduate School of Science Sciece, The University of Tokyo), Misato Fukagawa(National Astronomical Observatory of Japan), Fujishima Kosuke(Tokyo Institute of Technology, Earth-Life Science Institute), Chairperson:Kosuke Fujishima(ELSI 地球生命研究所), Misato Fukagawa(名古屋大学大学院 理学研究科), Seiji Sugita(東京大学大学院 理学系研究科), Hikaru Yabuta(Hiroshima University)

Twenty years have passed since when the field of Astrobiology, which aims to unveil the origins, evolution, and habitability of life by integrating multidisciplinary fields, was established. Individual themes related to Astrobiology, such as chemical evolution in the early Solar System, formation of planetary system, prebiotic chemistry in the early Earth, evolution of life in the Earth's history, extremophile, and habitable planetary environments, has been studied by the knowledge and methods from the multiple fields, which has enabled us to explain "Where we came from" in some ways. However, despite an overwhelming number of investigations and discussions through gathering of the scientists from different fields, there has remained the long-standing unsolved question: How did abiotic materials gain biological function in the Earth and elsewhere in universe? There is still a large gap between prebiotic organic chemistry and biochemistry toward Origins of Life and planetary habitability. Therefore, the JpGU Astrobiology session focuses on pathfinding of "integration of astronomy, geoscience, and biochemistry", which will face an increasing need for the future Astrobiology. In order to enhance our understanding of "What is life", we propose to discuss the biochemical events linked with planetary systems, which is beyond the knowledge in a test tube, by an integration of exoplanets and molecular biology, etc. Through this approach, we will lead the discussions and developments of life-detection strategies for the future exploration of life in universe.

Discussion

# the emergence of iron-sulfur protometabolism

*Sheref Mansy[1]

1. University of Trento

Iron-sulfur clusters are considered to be one of life's most ancient cofactors. Traditionally, the reliance of extant biology on iron-sulfur proteins has been interpreted to mean that iron-sulfur clusters of some type actively participated in the prebiotic chemistry that led to life. Since globular proteins were likely not present on the prebiotic Earth, most investigations into the early roles of iron-sulfur clusters have centered upon the potential activity of minerals, such as greigite and pyrite. Although minerals undoubtedly heavily impacted prebiotic chemistry and likely participated in the synthesis of molecules necessary for the emergence of life, it is unclear how minerals could have been later superseded by protein enzymes. Here we discuss our efforts in understanding the plausibility of synthesizing iron-sulfur clusters coordinated to prebiotically plausible peptides. We find that the solution conditions impact the type of iron-sulfur cluster formed, that UV light facilitates the synthesis of iron-sulfur clusters, and that iron-sulfur peptides can mediate the types of electron transfer reactions needed to sustain an early form of metabolism.

# Life-water-mineral interactions and their products

*Fumito Shiraishi[1]

1. Hiroshima University

Studies of modern and ancient microbial deposits on the Earth have demonstrated that the traces of microbial life are preserved as various kinds of minerals via life-water-mineral interactions. They include carbonates, phosphates, iron oxides, and manganese oxides, and their recent knowledge is introduced in the presentation.

For carbonates, cyanobacterial photosynthesis can produce $CaCO_3$ minerals to form deposits like stromatolites. However, their depositional fabrics are strongly influenced by the acidity of EPS (extracellular polymeric substances) secreted by cyanobacteria. In some cases, $CaCO_3$ minerals formed by cyanobacteria exhibit specific traces.

For phosphates, phosphorites are generally produced via degradation of organic matter during diagenesis. In the case of high phosphorus concentration in the euphotic zone, however, microbial photosynthesis potentially produces phosphate minerals to form phosphate stromatolites. Such process may occur after the snowball Earth glaciations in the Neoproterozoic as well as in the Paleoproterozoic.

For iron oxides, microbial Fe(II) oxidation is effective only when $O_2$ concentration is below ca. 50 $\mu$M, and inorganic process prevails above this level. The trace of iron-oxidizing bacteria is potentially preserved in the structure of iron oxide minerals.

For manganese oxides, substantial Mn(II) oxidation does not occur inorganically even under $O_2$ concentration equilibrated with the modern atmospheric level, and microbial processes are essential for it. In addition, manganese oxides adsorb various metals that potentially sustain metal-dependent microbial ecosystems in organic matter-deficient settings.

The knowledge about microbial traces on the Earth would provide valuable information for exploring extraterrestrial life.

# How much can we learn about ancient cells from sequence analysis? New metrics on an old problem.

*Shawn E McGlynn[1], Sarah J Berkemer[2,3]

1. Earth-Life Science Institute, Tokyo Institute of Technology, 2. Bioinformatics Group, Department of Computer Science, Interdisciplinary Center for Bioinformatics, University of Leipzig, 3. Max Planck Institute for Mathematics in the Sciences, Leipzig, Germany

A longstanding goal is to apply molecular phylogenetics to understanding ancient physiological and evolutionary states (*e.g.* [1]). With the current explosion of molecular sequencing data (e.g. [2]), it is a good time to consider how far back we can peer with the comparative molecular lens, and ask if we can understand life in its nascent years. A standard test for inferring ancient genes is to look for conservation in microbial genomes, and to analyze phylogenetic branch positions and determine if a gene separates the archaea and the bacteria. However, many phylogenetic trees are cluttered by phenomena such as horizontal gene transfer and non-orthologous displacement [3], making inferences difficult.

In this presentation, we will give an overview of recent work in this area [4, 5], and also present new analyses which help identify ancient proteins. Using the COG database, we built phylogenetic trees for all protein families and analyzed the number of interdomain gene transfer events for each family. We find that proteins assigned to COGs exhibit widely variable amounts of interdomain gene transfer. By using distance matrices which relate *intra*-domain sequence similarity to *inter*-domain similarity, we find that protein families exhibiting numerous inter domain gene transfer events are also most self-similar between domains. Integrating this observation with previous analyses, ancient proteins appear to have large branch lengths separating the domains, but recent proteins are more bushy in tree shape. These findings will be discussed in the context of inferring the characteristics of the most ancient cells. Although this work provides new dimensions to analyze protein families with, more work is needed to definitively identify the proteins in the last common ancestor of the bacteria and archaea.

Past trial of direct detection of life on Mars by 1970's Viking mission ended up with a negative conclusion [1]. Whereas, numbers of new finding provided by Mars exploration missions in the last decade indicate that there are good reasons to perform another life detection program. The sensitivity of the gas chromatograph mass spectrometer onboard the Viking mission was not very high, and was not able to detect the microbes $10^6$ cells in 1 gram clay [2,3].

Recent findings on Mars tend to support the possible presence of living microbes near the surface of Mars. MSL Curiosity has found organic compounds [4], the temporal increase of methane concentration in Martian atmosphere [5] and reduced sulfur compounds such as pyrite in Martian soil [6]. Methane and reduced sulfur compounds can be energy sources to support the growth of chemoautotrophic microbes [7]. Possible presence of liquid water at Recurring Slope Lineae has been supported by the detection of hydrated salts [8]. These evidences tend to support the possible presence of living microbes near the surface of Mars and indicate that another life detection program is necessary.

The Life Detection Microscope (LDM) that we have proposed [7, 9] has the potential sensitivity much higher than the Viking instrument. Microscopes directly image life forms and identify their shapes, sizes, and other morphological structures and have the potential to detect a single cell in field of view. Therefore, the sensitivity can be as high as desired just by increasing the volume of sample to be scanned in a reasonable duration of experiment. LDM scans about 1 $mm^3$ and detects less than $10^4$ cells in 1 gram soil at a spatial resolution of 1 $\mu$m [9]. LDM differentiates among organic compounds surrounded by membranes or with enzyme activity by staining the samples with fluorescent pigments. This technique is especially useful for the detection of living microorganisms.

The search for living microorganisms is important not only for scientific interest but for planetary protection. Before future human missions begin, surveys investigating the presence of living microorganisms should be conducted to mitigate the risk of human contact with Martian microorganisms, which may be harmful to human health. Scientific significance the development of LDM will be addressed in this report.

# Civilization-bearing planets in the Milky-Way Galaxy; 50 necessary conditions must be satisfied in order

*Shigenori Maruyama[1]

1. Earth-Life Science Institute, Tokyo Institute of Technology

**<Purpose>**

Is there any life in the Universe, or specifically civilization-bearing planets? Recent popular answer for this basic question is easy-going “Yes”, which was also trendy answer 100 years ago. They think there are so many stars in the Universe, e.g., $10^{11}$, so it is reasonable to think the possibility of the presence of life in the Universe. However, is it right scientifically?

**<Method>**

If the number of necessary conditions to make civilization-bearing planet is 50, simple estimate of presence or absence is $(1/2)^{50}=1/(10^{11})$, indicating that it is only one in the Milky Way Galaxy. To discuss the presence of life in the Universe, the best example with the most detailed research information is the Earth and its history. Other examples are planets, asteroid and meteorites in the solar system. Applying those data to the Universe, we can lead to general aspects of necessary conditions to infer life in the Universe.

**<Result>**

Based on the data set inferred from the research of Earth and life, 48 requirements are listed up. Those necessary conditions are mainly categorized into the following four. First group has 11 planetary conditions to be a life-sustaining planet; for example, “Chemical composition of central star”, “Mass of central star”, and “Circular orbit”. Second Group has 14 conditions of rocky planets to prepare the cradle of life; such as “Formation of bimodal continental and oceanic lithospheres to initiate plate tectonics”, “Restricted amount of initial mass of ocean to supply of nutrients for life”. Third group has 9 conditions to emerge and evolve life; such as “continuous and strong outer energy by natural geyser”, and “well-balanced nutrients source of landmass”. Forth group has 10 conditions to evolve into civilization bearing planet; such as “Survival over 2 billion years until birth of Eukaryote”, “A way to Eukaryote from Prokaryotes”, “A way to metazoans and Plant”, “Acceleration of life evolution”. There are other important 4 conditions; such as “Galactic habitable Zone”

**<Discussion>**

If we simply calculate the probability of presence of life in the Universe, civilization-bearing planet is only one (Earth). It is also emphasized that the requirements mentioned above is treated as presence of absence for all requirements, but several requirements are definitely less than 50% probability, e.g., extremely strict constraint for the amount of ocean volume 3km±1km. Moreover, it is emphasized that the number 51 is combinations and not permutations. This strongly indicates that we are alone in the Universe, even including whole Universe beyond our Milky Way Galaxy.

Planets outside the Solar system, so-called exoplanets, are promising as a new window for astrobiology. Among those, planets orbiting cool M-type stars (main-sequence stars with effective temperatures less than about 3000 K) have the great potential to push forward astrobiological studies on exoplanets. The habitable zone (HZ) is the zone where liquid water is sustainable on the surfaces of planets. It is expected that the HZs around cooler stars come closer to the parent stars (Kopparapu et al. 2013, ApJ 765, 131). In addition, the recent exoplanet observations performed by the *Kepler* space telescope have revealed that the occurrence rate of small exoplanets similar to Earth increases as the effective temperatures of stars decrease (e.g., Mulders et al. 2015, ApJ 798, 112). Furthermore, the Doppler technique, one of primary methods for exoplanet observations, can more easily find a planet with the orbit closer to its parent star. Accordingly, targeting cool M-type stars provides a significant advantage in the observations of rocky planets in HZs based on the Doppler technique. Also, the snow line around a cool M-type star is close to the star; this is intriguing in terms of the planet formation process.
Nevertheless, the exoplanet observations for cool M-type stars have not been advanced compared with those for hotter stars, due to their faintness. In particular, the low brightness of a cool M-type star at optical wavelengths makes it problematic to observe its planet based on visible light, which has been mostly used in exoplanet observations. We have therefore developed the InfraRed Doppler (IRD) instrument, which is a high-dispersion spectrograph to enable the exoplanet observations using the high-precision Doppler technique at near-infrared (Kotani et al. 2018, Proc. of the SPIE 10702, 1070211). Near-infrared light is suited for observing cool M-type stars, since their peak flux is located in a near-infrared region. One of bottlenecks to achieve high-precision measurements using the near-infrared Doppler technique is the lack of a reference source that enables us to correctly calibrate a measurement fluctuation caused by the instability of an observation instrument. We use a laser frequency comb (LFC) generated by the system that has been newly developed for IRD as a reference source to calibrate IRD measurements. An LFC spectrum has a number of emission lines with fine sampling intervals and is observed simultaneously with a stellar spectrum, so it works as a correct wavelength calibrator for the stellar spectrum. After our laboratory performance verifications of IRD with its LFC system (Kuzuhara et al. 2018, Proc. of the SPIE 10702, 1070260), the IRD operation started on the Subaru Telescope, whose large primary mirror enables high-sensitivity observations even for cool M-type stars. The use of IRD with the Subaru Telescope significantly helps the discoveries and characterizations of exoplanets around cool M-type stars.
We have planned a large survey for planets around cool M-type stars with IRD on the Subaru Telescope, which actually begins on February, 2019. In this survey, we monitor 60 M-type stars over 175 nights

©2019. Japan Geoscience Union. All Right Reserved. 

allocated for 5 years. Our pre-survey simulation prospects more than 60 planet detections; those discoveries include a few dozen Earth-like planets, among which some are expected to locate within HZs. Thus, the IRD survey provides important contributions on improving our current understanding of planet formation models for low-mass stars like cool M-type stars, as well as the provisions of samples for exoplanet characterizations using the future large telescopes such as TMT. Here, we report the result of our ongoing on-sky tests to evaluate the IRD performances such as its measurement precision and stability. Furthermore, we explain the above large program in detail: our science goals, and the target selection and observation strategy for the goals are provided.

# Discrimination of organic compounds and mineral particles by fluorescent microscopy for the detection of Martian life.

*Tomoka Okada[1], Yoshitaka Yoshimura[2], Atsuo Miyakawa[3], Yuka Murano[3], Shin-ichi Yokobori[3], Akihiko Yamagishi[3], Kensei Kobayashi[1], Yoko Kebukawa[1]

1. YOKOHAMA National university, 2. Tamagawa University, 3. Tokyo University of Pharmacy and Life Sciences

The Viking mission searched life on Mars in 1976, but did not find apparent biological activities[1)]. However, the detection sensitivity of the Viking instrument (GC-MS) has been found to be low, suggesting that organic compounds could exist on Martian surface. Recently the MSL Curiosity by NASA detected organic compounds[2)]. The Phoenix mission discovered $H_2O$ ice[3)] and possible liquid water flows were found at RSL (Recurring Slope Lineae) by MRO (Mars Reconnaissance Orbiter)[4)]. These findings suggested that life might exist on Martian surface.

We have proposed a life search program on the surface of Mars with a fluorescence microscope[5)]. This microscope is called Life detection Microscope (LDM) which detects microorganisms in more than 100 times higher sensitivity than the Viking GC-MS. In this program, we plan to use two fluorescent dyes SYTO 24 and propidium iodide (PI) in LDM. SYTO24 permeates cell membrane and stains organic compounds. PI also stains organic compounds such as nucleic acids, but it doesn’t permeate cell membrane. Therefore, the combination of these two dyes makes it possible to differentiate the organic compounds surrounded by membranes (living cells) and dead cells.

However, there are some mineral particles have autofluorescence, possibly detected as false positives. In this research, in order to discriminate organic compounds from mineral particles, the autofluorescence of minerals were measured under various conditions.

Various kind of mineral specimens were finely ground with a glass pen washed with ethanol. Fluorescent images were obtained with a fluorescence microscope and a digital camera and their fluorescent intensities were measured by image analysis. We also examined fluorescent spectra of mineral particles using a diffraction grating. The results showed the fluorescent intensities and spectra of mineral particles were clearly different from the stained organic compounds. These methods would be useful to detect organic compounds among mineral particles.

# Morphological and spectroscopic characteristics of organic matter in Banded Iron Formation, Barberton Greenstone Belt, South Africa

*Hiroki Amemiya[1], Ryo Nakajima[1], Yoko Ohtomo[1], Tsubasa Otake[1], Tsutomu Sato[1]

1. Division of sustainable Resources Engineering, Faculty of Engineering, Hokkaido University

The emergence of cyanobacteria has been postulated to cause an increase in Earth’ s atmospheric oxygen concentration ~2.45 Ga and oxidation of ferrous iron in a seawater, facilitating the formation of Banded Iron Formations (BIFs) in the Proterozoic era. On the other hand, iron precipitation process in the Archean is still controversial. Previous studies suggest that anoxygenic iron-oxidizing bacteria and/or free oxygen produced by cyanobacteria, was responsible for iron oxidation before ~2.45 Ga. Organic matter preserved in BIFs may provide insights into the iron oxidation process and biological evolution in Archean. However, authenticity of Archaean organic matter has to be first clarified for further investigations due to possible later contamination. Here, we investigated morphological and spectroscopic characteristics of organic matter in ~3.2 Ga BIFs in Sheba mine, Moodies Group, Barberton Green stone Belt, South Africa to estimate the chemical structure combined with a contamination check using Raman spectroscopy.

Organic matter was collected by two different methods: extraction by acid treatment of powder samples and pick up with a micro-manipulator from thin sections. When Raman spectra were obtained using 532 nm wavelength laser, acid-treated organic matter showed two peaks ~1350 and ~1580 $cm^{-1}$ corresponding to disordered and ordered carbon structures, whereas micro-sampled organic matter shows no detectable peak with a high background. Because yellow-green fluorescence was observed in micro-sampled organic matter using a Fluorescence microscope, the fluorescence likely causes a high background in the Raman spectra. Therefore, 785 nm wavelength laser was applied for micro-sampled organic matter. Calculated metamorphic temperature from the Raman spectra obtained by acid-treated and micro-sampled organic matter was from 400 to 540˚C, which is consist with greenschist facies of the Barberton Greenstone Belt. This indicates that the organic matter is not a later contamination. Chemical mapping with an Electron Probe Micro Analyzer shows that micro-sampled organic matter is predominately comprised of carbon with slight contribution of nitrogen (< 0.1wt%). Infrared spectra of the organic matter show absorption peaks corresponding to N-O, C-O, and C=O bonds, suggesting that organic matter remains their functional groups in the structure. Based on the morphology and microstructure observed by Field Emission- Scanning Electron Microscope, the organic matter may have been derived from biofilm because of similarity in the morphology as well as the large size (20 –50 $\mu$m). Furthermore, the micro-sampled organic matter has a rough surface while the acid-treated organic matter has a smooth one, which may be due to damages by acid-treatment. Our results suggest that micro-sampling is suitable to observe the detailed morphological and structural features of organic matter preserved in Archean sedimentary rocks.

# Understanding peptide sequence selectivity on iron sulfide (FeS) nanoparticle surfaces

*Fujishima Kosuke[1], Norio Kitadai[1], Kenji Kasama[1]

1. Earth-Life Science Institute, Tokyo Institute of Technology

The emergence and evolution of functional biopolymers on Earth is one of the unsolved key questions regarding the origin of life. Amongst various building blocks of polymers, amino acids are prebiotically abundant and different plausible paths toward forming polypeptides have been previously shown in the context of early Earth environment. However, relationship between a specific geochemical environment and the types of biopolymers that could retain or to propergate in that condition is not yet fully systematically explored. Hence, we have prepared random octapeptide library with a combination of limited set of amino acids (Gly, Ile, His, Asp, Cys, Arg) as a probe to explore the sequence selectivity of iron sulfide (FeS) nanoparticles as a simulant of the geochemical settings that once existed at the deep-sea floor or the surface of early Earth. Experiment was carried out by mixing the FeS nanoparticles and random peptides in pure $H_2O$ solution inside the anoxic chamber to allow adsorption under moderate temperature/pH condition. After extensive rinsing step, peptides that remain bound to the FeS nanoparticles were analyzed directly by MALDI-MS/MS to retrieve sequence information. We will discuss the latest sequence results obtained from screening and discuss sequence selective feature of FeS and its relevance to the iron-sulfur cluster known as a fundamental cofactor in biology.

# A process model of L-homochiral peptides formation initiated with L-alanine

*Toratane Munegumi[1], Taisuke Yamaga[1]

1. Department of Science Education, Naruto University of Education

Hydrogen abstraction from L-alanine by hydroxy radical facilitates alkylation on $\beta$-carbon of alanine as well as retention of L-chirality. The reaction rate constant of hydrogen abstraction ($k=6.21\times10^{7}\ M^{-1}s^{-1}$) on $\beta$-carbon was about 3.7 times faster than that ($k=1.7\times10^{7}\ M^{-1}s^{-1}$) on $\alpha$-carbon. The fact supports that alkylation proceeds faster than racemization, and the chirality of product amino acids will be hold. Similar alkylation of oligopeptides will also proceed with a lower level epimerization than alkylation. This research discusses how the lower reaction rate of epimerization than alkylation lead homochiral peptides.

# Possible Formation of Amino Acids and Carboxylic Acids in Slightly-Reducing Primitive Earth Atmospheres

*Miei Kinoshita[1], Shintaro Ikeda[1], Kimitaka Kawamura[2], Bhagawati Kunwar[2], Hitoshi Fukuda[3], Yoshiyuki Oguri[3], Hiromi Shibata[4], Junichi Takahashi[1], Vladimir Airapetian[5], Yoko Kebukawa[1], Kensei Kobayashi[1]

1. Yokohama National University, 2. Chubu University, 3. Tokyo Institute of Technology, 4. Osaka University, 5. NASA Goddard SFC

Since 1950s, a large number of laboratory experiments have been performed to examine possible formation of bioorganic compounds such as amino acids in primitive Earth atmosphere. Earlier experiments with strongly reducing gas mixtures containing large molar ratio of methane and ammonia, and it was reported that efficient production of amino acids and other important organics were formed in it by spark discharges and other energy sources. It is now estimated, however, that the early Earth atmosphere was only slightly reducing [1]: $N_2$ and $CO_2$were the major atmospheric constituents, together with some small amount of reducing carbon species like $CH_4$ and/or CO. Simulation experiments suggested, however, that amino acid formation was restricted under these conditions [2]. We reported that cosmic rays could facilitate chemical reactions with less reducing model of primitive atmosphere such as a mixture of $CO_2$, CO, $N_2$and $H_2O$ [3]. However these energy sources have been ignored in experiments with initiation of prebiotic chemistry [4]. Here, we examine possible formation of amino acids from slightly reducing gas mixtures by applying high-energy protons to simulate the action of cosmic rays.

We conducted three sets of laboratory experiments using energetic particles, spark discharge and UV light as dominant energy sources. In these sets of experiments we used 400 mL of gas mixture of $N_2$, $CO_2$and $CH_4$introduced to a Pyrex tube together with 5 mL of pure water under 350 Torr of N2 and 350 Torr of mixtures with varied mixing ratios of $CH_4$and $CO_2$. In order to simulate possible roles of cosmic rays, the gas mixture was irradiated with 2.5 MeV proton beam produced in the Tandem accelerator at Tokyo Tech, Japan. We also exposed the same composition of gas mixtures to spark discharges by using a Tesla coil to simulate lightning. The gas mixtures were also irradiated with UV light (l> 190 nm) from a xenon lamp. Each product was acid-hydrolyzed and was subjected to amino acid analysis by HPLC and GC/MS, both after derivatization. Carboxylic acids were determined by GC/MS after derivatization. Starting and resulting gas mixtures were analyzed with a quadrupole mass spectrometer.

Amino acids were detected in the hydrolyzed products when gas mixtures of $N_2$, $CO_2$, $CH_4$and $H_2O$ were irradiated with 2.5 MeV protons at the initial the molar ratio of methane ($r_{CH4}$) in the starting gas mixture as low as 0.5 %. On the other hand, amino acids were detected only when $r_{CH4}$was greater than 15 % in the case of spark discharges. The experiments with UV irradiation source did not yield amino acids or their precursors even when $r_{CH4}$was 50 %. Very little amino acids were detected in all the products before hydrolysis. It was shown that not free amino acids but amino acid precursors were formed in selected experiments.

Carboxylic acids including formic acid, oxalic acid and glyoxylic acid were detected from unhydrolized products derived from $N_2$-$CO_2$gas mixtures exposed to spark discharges and proton irradiation. We show that some free carboxylic acids could be formed in non-reducing atmospheres as well as slightly reducing atmospheres either by proton irradiation or by spark discharges. It was suggested that the mechanism of formation of amino acid precursors from $N_2$-$CO_2$-$CH_4$-$H_2O$ mixtures was quite different from that of

©2019. Japan Geoscience Union. All Right Reserved. 

carboxylic acids.

Lightning and solar UV have been considered important energy sources for prebiotic synthesis in primitive Earth atmosphere. We here showed that lightning and solar UV could not singularly synthesize important N-containing organics such as amino acids from slightly reducing primitive Earth atmosphere. On the other hand, cosmic ray could have been an important energy source to synthesize amino acid precursors even if primitive Earth atmosphere was only slightly reducing. It would be of interest to examine whether there are synergetic effects among cosmic rays, UV and thundering.

# Application of Machine learning and software development for initial analysis in the TANPOPO mission

*Kyoko Okudaira[1], Yuto Toda[1], Takashi Sonoke[1], Yuichi Yaguchi[1], Masashi Yoshida[1], Junya Imani[2], Satoshi Sasaki[3], Hajime Yano[4], Hirohide Demura[1], Makoto Tabata[5], Akihiko Yamagishi[6]

1. The University of Aizu, 2. YUKI Precision, 3. Tokyo University of Technology, 4. JAXA, 5. Chiba University, 6. Tokyo University of Pharmacy and Life Science

One of the goals of the TANPOPO mission is collecting cosmic dust and space debris on the International Space Station [1]. Ultra-low density material “silica aerogel” panels are used as capture media [2]. These panels retrieved from the space are sent to the laboratory and initial analysis has been conducted by a system called “CLOXS”.

CLOXS efficiently covers the processes (1) Automatic imaging the entire panel, 2) Search for penetration track candidates, 3) Mapping of track candidates, 4) Shape data acquisition of tracks, and 5) Automatic sample cutting) up to sample allocation to researchers. However, to reduce researchers’ time and effort, improvement of the software and automation of some processes are required.

In this study, application of machine learning in discrimination of objects in aerogel images taken by CLOXS is mainly reported. The research goal is to classify objects in the images into tracks and dirt using machine learning.

There are morphological varieties in the objects. As for both tracks and dirt, they are classified into 4 types respectively in this study.

Since the contrast of the images are low, the first step of our approach is preprocessing of the images. We compared the results of *Contrast Stretching* and *CLAHE* (Contrast Limited Adaptive Histogram Equalization).

Learning data and test data are prepared respectively, to compare the case that the images are categorized into 4 types and the case that the images of all types are dealt altogether.

*Convolutional Neural Network* (CNN) is used as a method of machine learning. *Python* is used as programing Language.

In conclusion, as for image processing, *CLAHE* showed higher accuracy when tracks were judged to be tracks, and *Contrast Stretching* was found to yield a better result for dirt. It is probably because, in *Contrast Stretching*, *CNN* was not sufficiently highlighted to capture features, and *CLAHE* was able to improve the contrast sufficiently.

Regarding separating the types of tracks and dirt, the accuracy rate was higher when tracks were categorized into different types and learned.

Although further evaluation and improvements might be needed, our accuracy rates meet the mission requirements, that is, the percentage of identifying track as track should be more than 95 %, while the percentage of identifying dirt as dirt should be more than 70 % (that of NOT identifying true track as dirt

National Institute of Advanced Industrial Science and Technology, 7. Kyusyu University, 8. Fukuoka Institute of Technology, 9. Tokyo University of Pharmacy and Life Science

In Japan's first astrobiology experiment “Tanpopo”, attempts have been made to capture cosmic dust by installing ultra-low-density silica aerogel at the Japanese Experiment Module “Kibo” of the International Space Station (ISS) [1]. This mission was conducted with the aim of verifying the hypothesis that the origin of life was supplied from outside the earth [2]. Silica aerogel had been used in NASA’s cometary dust sample return mission “Stardust” [3]. Impact tracks formed by collision of cometary dust against aerogel were classified into 3 types, A, B and C, based on their shapes [4]. The track shapes have useful information for estimating the size and density of dust particles [5]. The purposes of this research are (1) to find impact tracks formed by cosmic dust in Tanpopo aerogel and (2) to describe the three-dimensional shapes of impact tracks with different origins (cosmic dust and space debris) and finally to clarify the relation between the track shape and the origin.

At SPring-8 BL47XU, three-dimensional shapes were obtained with imaging absorption tomography for 8 impact tracks (D1-231, D1-298, D1-362, E1-200, E1-304, F1-328, F1-389, F1-623), which were found in Tanpopo aerogel faced to the space direction. The imaging experiments were made at 7, 8, 9 keV with the voxel size of 0.24 or 0.465 $\mu$m. CT images at 8 keV were used to extract track shapes. Track length ($L_t$), maximum track diameter ($D_m$), aspect ratio, and other shape properties were obtained. These values were compared with Stardust tracks. Dual-energy tomography (DET) [6] was applied to estimate the materials of particles captured in the tracks. Another track (E2-000) was observed only with an optical microscope. For D1-231, D1-298, D1-362 and E2-000, the aerogel was compressed and real solid particles in the tracks were searched with an optical microscope.

The 9 tracks in total were classified into 5 types based on their shapes. Type 1 (E2-000) is a track formed by cosmic dust, where two pyroxene particles were identified at the tip of the track [7]. The track shape resembles Stardust type B track, but its entrance widely spreads. Type 2 (D1-231) is somewhat similar to Stardust type A track. Type 3 (E1-200 and E1-304) is a track having abundant cracks developed on the wall with a narrow entrance. Type 4 (F1-328 and F1-389) is extremely asymmetrical in its shape and has cracks similar to Type 3. Type 5 (D1-362 and F1-623) is a bowl-shaped track with a large entrance. The relationship between $L_t$ and $D_m$ of these tracks was almost the same as that of Stardust tracks except for Type 5. However, their specific shapes of Types 2, 3 and 4 are significantly different from Stardust tracks. The cracks of these tracks are similar to those seen at the end of Stardust type A and B tracks, indicating that they were formed by a relatively low-speed impact. Similar tracks to Type 5 were reported in the aerogel in the exposure experiment on the Mir Station. They may be due to high-speed collision of weakly-adhered aggregates [8]. From the quantitative analysis of such impact tracks, there is a possibility of obtaining knowledge about new parameter areas which could not be obtained by conventional research. DET results showed that most of fine particles in the tracks do not contain Fe and Ni. Low values of their

©2019. Japan Geoscience Union. All Right Reserved. 

linear absorption coefficients are smaller than that of cosmic dust. They should be formed by impact of weekly-adhered aggregates that were broken into very small pieces by the impact and mixed with condensed aerogel. Two particles with relatively high linear absorption coefficient were confirmed in D1-231 and D1-362. They were confirmed by and optical microscope after compressing.

# High-Angular-Resolution Observations of Protoplanetary Disks

*Misato Fukagawa[1]

1. National Astronomical Observatory of Japan

The recent progress in understanding of planet-formation process will be reviewed based on the results obtained at high angular resolution with astronomical facilities such as the Atacama Large Millimeter/submillimeter Array (ALMA). Circumstellar disk structures around young stars are birthplaces of planets. The physical and chemical condition in such protoplanetary disks can be linked to some extent to the planetary environment (e.g., atmospheric composition) where further chemical reactions might lead to formation of building blocks of life. This presentation includes the topics on detailed disk density structures at ~5-au or better resolution, gas detections in the later stages of disks where the collisional events in the planetary systems may happen, detections of organic molecules, and the prospects on disk observations in future.

# Characterization of high molecular weight amino acid precursors formed in interstellar ice analog

*Soushi Kuramoto[1], Tomohito Sato[1], Hitoshi Fukuda[2], Yoshiyuki Oguri[2], Kotaro Kondo[2], Hiromi Shibata[3], Yoko Kebukawa[1], Kensei Kobayashi[1], Satoshi Yoshida[4]

1. Yokohama National University, 2. Tokyo Institute of Technology, 3. University of Osaka, 4. National Institutes for Quantum Radiological Science and Technology

It is suggested that extraterrestrial organic compounds are important for chemical evolution toward the generation of the first life on the Earth. Bioorganic compounds such as amino acids were found in hydrolyzed extracts of meteorite [1]. The products before hydrolysis referred to as “amino acid precursors” were, however, little known. It has been sometimes claimed that a-amino acids found in meteorites were formed by the Strecker synthesis. If so, aminonitriles and amino acid amides are the precursors, but they have not identified as major precursors yet. Extraterrestrial amino acid precursors were probably synthesized in molecular cloud environments or small celestial bodies. We irradiated possible interstellar media, such as mixture of carbon monoxide, ammonia and water to simulate possible reactions among interstellar media in dense clouds. The irradiation products were analyzed by HPLC and mass spectrometry.

A gaseous mixture (CO and $NH_3$) was sealed in a Pyrex glass tube with liquid water. The gaseous mixture was irradiated with 2.5 MeV protons from a Tandem accelerator at Tokyo Institute of Technology. Total quantity of electricity was 2 mC. The name of the irradiation products is hereafter called CAW. CAW was fractionated by cation exchange HPLC into several fractions to discriminate the fractions with glycine amide or aminoacetonitrile (the Strecker-type precursors) and those without them. Each fraction was hydrolyzed with 6M HCl at 110 ˚C for 24h and was subjected to amino acid analysis. Molecular weights of CAW were estimated by ultrafiltration (molecular weight cut off: 3000), gel filtration (column: Shodex OHpak SB-802.5 HQ) and mass spectrometry by ESI-TOF-MS.

It was shown that glycine was rarely detected in the fractions with the Strecker-type simple amino acid precursors (aminoacetonitrile, glycine amide). It was suggested that the CAW (an interstellar organics analogue) contained complex amino acid precursors with molecular weights of some thousands. Compared with molecular weights standards (authentic proteins), molecular weights of CAW were estimated 6000 or more by gel filtration chromatography. Peaks of $m/z$ = 1000 or over were detected by mass spectrometry. These results strongly suggested that complex amino acid precursors with large molecular weights could be directly generated from small molecules such as CO in interstellar environments. We are now trying to characterize amino acid precursors formed in interstellar ice analogue (frozen mixture of CH3OH, NH3 and H2O [2]) by heavy ions irradiation.

# Theoretical elucidation of prebiotic formation processes into nucleobases

*Yu Komatsu[1,2], Taiki Suzuki[1,2]

1. Astrobiology Center, 2. National Astronomical Observatory of Japan

As argued [1], the comets and meteorites may have provided a large amount of prebiotic molecules to the Early Earth. However, where and how such organic molecules were built is still controversial.

Recently, volatile glycine (NH2CH2COOH) has been detected in the coma of comet 67P/Churyumov-Gerasimenko by the ROSINA mass spectrometer [2], with giving us clues to glycine's interstellar origin. Moreover, in addition to various amino acids, nucleobases, such as purine, uracil, guanine, and xanthine have been identified in the meteorite (e.g., [3]). These studies suggest the formation of prebiotic molecules in the extreme condition prior to the early Earth chemistry.

If prebiotic molecules are built from small atoms or radicals in the cold ISM, the prebiotic molecules must have almost barrier-less formation paths. On the other hand, the bombardment of comets and/or asteroids would have provided very high temperature condition for chemical reactions, which may have led to the decomposition and formation of further complex prebiotic molecules. To understand the formation processes, the quantum chemical calculation is a powerful tool. The previous quantum chemical calculation has already reported the promising chemical paths to amino acids and nucleobases (e.g., [4]).

Here we investigated the possible pathway of pyrimidine, purine, uracil and thymine by the automated exploration of chemical reaction pathways. We have already discovered key dissociations for each molecule. For example, uracil and thymine, the pyrimidine type of nucleobase, have lower barriers to dissociate into an isocyanic acid, which corresponds to the previous laboratory experience, and the rest molecule. Pyrimidine and purine, which are skeleton structures of nucleobases and do not poses any oxygen atoms, have high barriers, implying to require high temperature environment like the bombardment, even though we did not exclude all possibilities of radical reactions. Detailed discussions will be provided on our poster.

# Formation Process of A Glycine's Precursor Candidate, CH3NH2

*Taiki Suzuki[1,2], Liton Majumdar[3], Masatoshi Ohishi[2]

1. National Institutes of Natural Sciences Astrobiology Center, 2. National Astronomical Observatory of Japan, 3. NASA Jet Propulsion Laboratory (JPL)

As [1] argued, the comets and meteorites may have provided a large amount of prebiotic molecules to the early Earth. An attempt to understand the origins of life must necessarily begin with detailed studies of the formation and evolution of complex organic molecules (COMs), products of complex chemistry that most likely starts in molecular clouds and continues within the protoplanetary disk.
Since the amino acids are the essential building blocks of life, the search for amino acids and their complex organic precursors at different stages of star and planet formation is one of the exciting topics in modern astronomy. Recently, volatile glycine ($NH_2CH_2COOH$) was detected in the coma of comet 67P/Churyumov-Gerasimenko by the ROSINA mass spectrometer [2], also giving clues about glycine's interstellar origin. However, the survey observations of glycine toward ISM have been not successful. Therefore, revealing the formation pathways to glycine is important for astrochemistry and astrobiology not only to know the promising glycine-rich sources for future surveys but also to understand the general chemical evolution of N-bearing molecules in the ISM.
In this context, we performed the chemical modeling study for the high-mass star, with the possible formation processes of glycine with theoretically and/or experimentally suggested formation paths [3]. We suggested that glycine was efficiently formed through the following reactions: First, the hydrogenation process to HCN leads to the formation of $CH_2NH$ and $CH_3NH_2$ on interstellar grain surface (HCN + 2H => $CH_2NH$, and then $CH_2NH$ + 2H => $CH_3NH_2$). Then, the destruction of $CH_3NH_2$ by radicals will form $CH_2NH_2$. Finally, $CH_2NH_2$ and COOH radical react to form glycine. For this test, a key molecule would be $CH_3OH$, whose formation process is well known. Both experiments and theoretical works suggested that $CH_3OH$ is built via grain surface hydrogenation processes to CO (CO + 2H => $H_2CO$, and then $H_2CO$ + 2H => $CH_3OH$). If $CH_3NH_2$ is also produced through hydrogenation process, “$CH_3NH_2/CH_3OH$” ratio should be well reproduced by the modeling. However, it was difficult to test this formation process due to the very limited number of previous CH3NH2 observations.
With this motivation, we performed the observation of $CH_3NH_2$ and $CH_3OH$ with ALMA toward high mass star-forming regions, G10.47+0.03, NGC6334I, W51 e1/e2, and G31.41+0.3. As a result, both of $CH_3OH$ and $CH_3NH_2$ were detected toward all sources. The molecular abundances were derived with rotation diagram method. The high excitation temperatures of 100 and 200 K and compact distributions suggest that $CH_3NH_2$ emissions originate from the hot and dense regions. The observed molecular abundance ratio, “$CH_3NH_2/CH_3OH$” ranges from 0.2 to 2.1. The low “$CH_3NH_2/CH_3OH$” ratio of 0.2 is close to our modeling, supporting that $CH_3NH_2$ is the product of the hydrogenation process in those sources. However, the higher “$CH_3NH_2/CH_3OH$” ratio of nearly two, observed toward NGC6334I MM1, could not be reproduced with our modeling under the possible parameter range. Thus, our chemical modeling would not correctly reproduce the physics or chemistry of such $CH_3NH_2$-rich sources. Further studies of such sources will enable us to promote our knowledge of glycine chemistry and provide us with promising sources for future glycine surveys.

# Numerical study on the stellar atmosphere & wind of Cool Stars

*Takahito Sakaue[1], Kazunari Shibata[1]

1. Kyoto University

Cool stars offer the good opportunities to investigate what environments the Earth-like exoplanets are in, and how they are affected by the host star. TRAPPIST-1 is an ultracool dwarf; the spectral type is M8V ($T_{eff}$ =2559K) with the lower mass of 0.08$M_{sun}$ (radius = 0.11$R_{sun}$). The star is confirmed to have seven planets (Gillon et al. 2017) and thus greatly interested in not only by stellar astrophysics but also by astrobiology. Here, we report the results of one-dimensional magnetohydrodynamic (MHD) simulation of the stellar wind from TRAPPIST-1. Several solar wind theories, which have been examined observationally, are applied to the case of TRAPPIST-1. Among them, it is the plausible idea that the dissipation of the incompressible MHD wave leads to the heating and driving the stellar wind. For instance, Garraffo et al. 2017 succeeded in the three-dimensional MHD simulation of the stellar wind from TRAPPIST-1, by extending their solar wind model in which the incompressible MHD wave is exhausted by the turbulent dissipation. The incompressible MHD wave, on the other hand, is also affected not only by the turbulent dissipation but also by the nonlinear mode coupling, which leads to the formation of the shock wave and consequently contribute to heating the wind. This nonlinear process has been well investigated to account for the dynamics of the lower solar atmosphere (Kudoh & Shibata 1999) and driving the solar wind (Suzuki & Inutsuka 2005), but not discussed for the stellar wind from TRAPPIST-1. In this study, therefore, we performed the one-dimensional MHD simulation to consider the nonlinear process of the incompressible MHD wave leading to the shock formation, and succeeded in reproducing the stellar wind from TRAPPIST-1.

# Design of space exposure experiments of organic matter in Tanpopo 2

*Takuya Yokoo[1], tomohito sato[1], Itsuki Sakon[2], Kazumichi Nakagawa[3], Hajime Yano[4], Miki Nakayama[5], Hajime Mita[5], Yoko Kebukawa[1], Kensei Kobayashi[1]

## 1. Introduction

Large number of organic compounds have been discovered in molecular clouds and in meteorites. Some of organic compounds required for emergence of life are thought to be synthesized in space. Then, meteorites and interplanetary dust particles could deliver them to the Earth. The first Japanese astrobiology space experiment called “Tanpopo” was conducted to study this hypothesis[1].
The objective of the Tanpopo Mission is to understand bi-directional propagation of microorganisms and organic matter between the Earth and space. In other words, in the Tanpopo Mission, we examine whether life exists only on the earth by evaluating whether microorganisms can escape into space and whether organic matter can reach to the Earth from outer space.
As one of subthemes in this project, amino acids and their precursor compounds including complex interstellar organic matter analog were directly exposed to outer space by utilizing the International Space Station (ISS), and recoveries of these organics were measured to understand degradation of organic compounds under the environment of the outer space. In the Tanpopo experiment, hexatriacontane (HTC) was used to prevent the sample from sublimation during exposure to space at the ISS. However, HTC absorbs ultraviolet light with a wavelength of 160 nm or less. To understand the effects of shorter wavelength UV, the next space experiment "Tanpopo 2" applies a new design for direct exposure of organic compounds without HTC and optical windows. In addition to the aluminum plate same as the one used in Tanpopo, the silicon substrates are also used for exposure the sample to space, in the organic matter exposure experiment of “Tanpopo 2 “. In the Tanpopo Mission, glycine, hydantoin, isovaline, ethylmethylhydantoin, CAW (complex organic matter produced from proton beam irradiation to CO, $NH_3$, $H_2O$ mixture) were used, and glycine and CAW showed relatively high recoveries [2]. In "Tanpopo 2", glycine and CA (proton beam irradiation product to CO, $NH_3$ mixture) on the silicon substrates will be directly exposed to space in addition to the same compounds on the same aluminum plate used in the Tanpopo. The recovered samples will be analyzed by FT-IR, XANES, and SEM, in addition to amino acid analysis.
Here we report the design of the space experiment such as preparation method of the space experiment sample.

## 2. Experimental

(1) A gas mixture of CO (350 Torr) and $NH_3$ (350 Torr) and a silicon plate (10 mm$\phi$) were placed in a glass container, and the gas mixture was irradiated with 2.5 MeV proton beam from a tandem accelerator to deposit organic matter on the plate.
(2) The thickness of the organic matter (CA) film on the silicon plate was measured using a three-dimensional microscope.
(3) Structural analysis of organic matter (CA) on the silicon plate was also carried out using FT-IR.
(4) Amino acid analysis was carried out by cation exchange HPLC after hydrolyzing silicon plate with CA with 6 M hydrochloric acid at 110 ˚C for 24 hours.

©2019. Japan Geoscience Union. All Right Reserved. 

(5) Glycine is planned to be deposited on a silicon substrate by a vacuum vapor deposition equipment (Fukuoka Institute of Technology).

3. Results and Discussion

The CA deposition thickness was approximately 8 μm, but more sample thickness would be required due to potential loss of the organic materials by atomic oxygen present in low Earth orbit during exposure. Thus, we decided to use non-polished Si substrates instead of polished Si substrate. Because the sample can be kept in the bottom of indentations on the rough surface of non-polished substrate, even if a part of sample surface is lost.
Amino acid analyses of CA by cation exchanged HPLC showed, various amino acids including aspartic acid, threonine, glycine, alanine, -aminoisobutyric acid and serine were detected after acid hydrolysis. Glycine was particularly abundant, whose yield was 827 ±7 nmol from a single CA deposited Si substrate.

4. Conclusions

We will conduct the durability test of our samples on the silicon substrate including the vibration test, cooling test, heating test before launch in 2019 with the space X company to the ISS. We are planning to conduct various analyses from recovered samples. The recovery and degradation of these samples will make a further leap forward our understanding of the possible delivery of organic matter from interplanetary dust particles to the early Earth.

## [M-IS07] Astrobiology

convener:Hikaru Yabuta(Hiroshima University, Department of Earth and Planetary Systems Science), Seiji Sugita(Department of Earth and Planetary Science, Graduate School of Science Sciece, The University of Tokyo), Misato Fukagawa(National Astronomical Observatory of Japan), Fujishima Kosuke(Tokyo Institute of Technology, Earth-Life Science Institute)

Twenty years have passed since when the field of Astrobiology, which aims to unveil the origins, evolution, and habitability of life by integrating multidisciplinary fields, was established. Individual themes related to Astrobiology, such as chemical evolution in the early Solar System, formation of planetary system, prebiotic chemistry in the early Earth, evolution of life in the Earth's history, extremophile, and habitable planetary environments, has been studied by the knowledge and methods from the multiple fields, which has enabled us to explain "Where we came from" in some ways. However, despite an overwhelming number of investigations and discussions through gathering of the scientists from different fields, there has remained the long-standing unsolved question: How did abiotic materials gain biological function in the Earth and elsewhere in universe? There is still a large gap between prebiotic organic chemistry and biochemistry toward Origins of Life and planetary habitability. Therefore, the JpGU Astrobiology session focuses on pathfinding of "integration of astronomy, geoscience, and biochemistry", which will face an increasing need for the future Astrobiology. In order to enhance our understanding of "What is life", we propose to discuss the biochemical events linked with planetary systems, which is beyond the knowledge in a test tube, by an integration of exoplanets and molecular biology, etc. Through this approach, we will lead the discussions and developments of life-detection strategies for the future exploration of life in universe.

Planets outside the Solar system, so-called exoplanets, are promising as a new window for astrobiology. Among those, planets orbiting cool M-type stars (main-sequence stars with effective temperatures less than about 3000 K) have the great potential to push forward astrobiological studies on exoplanets. The habitable zone (HZ) is the zone where liquid water is sustainable on the surfaces of planets. It is expected that the HZs around cooler stars come closer to the parent stars (Kopparapu et al. 2013, ApJ 765, 131). In addition, the recent exoplanet observations performed by the *Kepler* space telescope have revealed that the occurrence rate of small exoplanets similar to Earth increases as the effective temperatures of stars decrease (e.g., Mulders et al. 2015, ApJ 798, 112). Furthermore, the Doppler technique, one of primary methods for exoplanet observations, can more easily find a planet with the orbit closer to its parent star. Accordingly, targeting cool M-type stars provides a significant advantage in the observations of rocky planets in HZs based on the Doppler technique. Also, the snow line around a cool M-type star is close to the star; this is intriguing in terms of the planet formation process.
Nevertheless, the exoplanet observations for cool M-type stars have not been advanced compared with those for hotter stars, due to their faintness. In particular, the low brightness of a cool M-type star at optical wavelengths makes it problematic to observe its planet based on visible light, which has been mostly used in exoplanet observations. We have therefore developed the InfraRed Doppler (IRD) instrument, which is a high-dispersion spectrograph to enable the exoplanet observations using the high-precision Doppler technique at near-infrared (Kotani et al. 2018, Proc. of the SPIE 10702, 1070211). Near-infrared light is suited for observing cool M-type stars, since their peak flux is located in a near-infrared region. One of bottlenecks to achieve high-precision measurements using the near-infrared Doppler technique is the lack of a reference source that enables us to correctly calibrate a measurement fluctuation caused by the instability of an observation instrument. We use a laser frequency comb (LFC) generated by the system that has been newly developed for IRD as a reference source to calibrate IRD measurements. An LFC spectrum has a number of emission lines with fine sampling intervals and is observed simultaneously with a stellar spectrum, so it works as a correct wavelength calibrator for the stellar spectrum. After our laboratory performance verifications of IRD with its LFC system (Kuzuhara et al. 2018, Proc. of the SPIE 10702, 1070260), the IRD operation started on the Subaru Telescope, whose large primary mirror enables high-sensitivity observations even for cool M-type stars. The use of IRD with the Subaru Telescope significantly helps the discoveries and characterizations of exoplanets around cool M-type stars.
We have planned a large survey for planets around cool M-type stars with IRD on the Subaru Telescope, which actually begins on February, 2019. In this survey, we monitor 60 M-type stars over 175 nights

©2019. Japan Geoscience Union. All Right Reserved. 

allocated for 5 years. Our pre-survey simulation prospects more than 60 planet detections; those discoveries include a few dozen Earth-like planets, among which some are expected to locate within HZs. Thus, the IRD survey provides important contributions on improving our current understanding of planet formation models for low-mass stars like cool M-type stars, as well as the provisions of samples for exoplanet characterizations using the future large telescopes such as TMT. Here, we report the result of our ongoing on-sky tests to evaluate the IRD performances such as its measurement precision and stability. Furthermore, we explain the above large program in detail: our science goals, and the target selection and observation strategy for the goals are provided.

# Discrimination of organic compounds and mineral particles by fluorescent microscopy for the detection of Martian life.

*Tomoka Okada[1], Yoshitaka Yoshimura[2], Atsuo Miyakawa[3], Yuka Murano[3], Shin-ichi Yokobori[3], Akihiko Yamagishi[3], Kensei Kobayashi[1], Yoko Kebukawa[1]

1. YOKOHAMA National university, 2. Tamagawa University, 3. Tokyo University of Pharmacy and Life Sciences

The Viking mission searched life on Mars in 1976, but did not find apparent biological activities[1)]. However, the detection sensitivity of the Viking instrument (GC-MS) has been found to be low, suggesting that organic compounds could exist on Martian surface. Recently the MSL Curiosity by NASA detected organic compounds[2)]. The Phoenix mission discovered $H_2O$ ice[3)] and possible liquid water flows were found at RSL (Recurring Slope Lineae) by MRO (Mars Reconnaissance Orbiter)[4)]. These findings suggested that life might exist on Martian surface.

We have proposed a life search program on the surface of Mars with a fluorescence microscope[5)]. This microscope is called Life detection Microscope (LDM) which detects microorganisms in more than 100 times higher sensitivity than the Viking GC-MS. In this program, we plan to use two fluorescent dyes SYTO 24 and propidium iodide (PI) in LDM. SYTO24 permeates cell membrane and stains organic compounds. PI also stains organic compounds such as nucleic acids, but it doesn’t permeate cell membrane. Therefore, the combination of these two dyes makes it possible to differentiate the organic compounds surrounded by membranes (living cells) and dead cells.

However, there are some mineral particles have autofluorescence, possibly detected as false positives. In this research, in order to discriminate organic compounds from mineral particles, the autofluorescence of minerals were measured under various conditions.

Various kind of mineral specimens were finely ground with a glass pen washed with ethanol. Fluorescent images were obtained with a fluorescence microscope and a digital camera and their fluorescent intensities were measured by image analysis. We also examined fluorescent spectra of mineral particles using a diffraction grating. The results showed the fluorescent intensities and spectra of mineral particles were clearly different from the stained organic compounds. These methods would be useful to detect organic compounds among mineral particles.

# Morphological and spectroscopic characteristics of organic matter in Banded Iron Formation, Barberton Greenstone Belt, South Africa

*Hiroki Amemiya[1], Ryo Nakajima[1], Yoko Ohtomo[1], Tsubasa Otake[1], Tsutomu Sato[1]

1. Division of sustainable Resources Engineering, Faculty of Engineering, Hokkaido University

The emergence of cyanobacteria has been postulated to cause an increase in Earth’ s atmospheric oxygen concentration ~2.45 Ga and oxidation of ferrous iron in a seawater, facilitating the formation of Banded Iron Formations (BIFs) in the Proterozoic era. On the other hand, iron precipitation process in the Archean is still controversial. Previous studies suggest that anoxygenic iron-oxidizing bacteria and/or free oxygen produced by cyanobacteria, was responsible for iron oxidation before ~2.45 Ga. Organic matter preserved in BIFs may provide insights into the iron oxidation process and biological evolution in Archean. However, authenticity of Archaean organic matter has to be first clarified for further investigations due to possible later contamination. Here, we investigated morphological and spectroscopic characteristics of organic matter in ~3.2 Ga BIFs in Sheba mine, Moodies Group, Barberton Green stone Belt, South Africa to estimate the chemical structure combined with a contamination check using Raman spectroscopy.

Organic matter was collected by two different methods: extraction by acid treatment of powder samples and pick up with a micro-manipulator from thin sections. When Raman spectra were obtained using 532 nm wavelength laser, acid-treated organic matter showed two peaks ~1350 and ~1580 $cm^{-1}$ corresponding to disordered and ordered carbon structures, whereas micro-sampled organic matter shows no detectable peak with a high background. Because yellow-green fluorescence was observed in micro-sampled organic matter using a Fluorescence microscope, the fluorescence likely causes a high background in the Raman spectra. Therefore, 785 nm wavelength laser was applied for micro-sampled organic matter. Calculated metamorphic temperature from the Raman spectra obtained by acid-treated and micro-sampled organic matter was from 400 to 540˚C, which is consist with greenschist facies of the Barberton Greenstone Belt. This indicates that the organic matter is not a later contamination. Chemical mapping with an Electron Probe Micro Analyzer shows that micro-sampled organic matter is predominately comprised of carbon with slight contribution of nitrogen (< 0.1wt%). Infrared spectra of the organic matter show absorption peaks corresponding to N-O, C-O, and C=O bonds, suggesting that organic matter remains their functional groups in the structure. Based on the morphology and microstructure observed by Field Emission- Scanning Electron Microscope, the organic matter may have been derived from biofilm because of similarity in the morphology as well as the large size (20 –50 $\mu$m). Furthermore, the micro-sampled organic matter has a rough surface while the acid-treated organic matter has a smooth one, which may be due to damages by acid-treatment. Our results suggest that micro-sampling is suitable to observe the detailed morphological and structural features of organic matter preserved in Archean sedimentary rocks.

# Understanding peptide sequence selectivity on iron sulfide (FeS) nanoparticle surfaces

*Fujishima Kosuke[1], Norio Kitadai[1], Kenji Kasama[1]

1. Earth-Life Science Institute, Tokyo Institute of Technology

The emergence and evolution of functional biopolymers on Earth is one of the unsolved key questions regarding the origin of life. Amongst various building blocks of polymers, amino acids are prebiotically abundant and different plausible paths toward forming polypeptides have been previously shown in the context of early Earth environment. However, relationship between a specific geochemical environment and the types of biopolymers that could retain or to propergate in that condition is not yet fully systematically explored. Hence, we have prepared random octapeptide library with a combination of limited set of amino acids (Gly, Ile, His, Asp, Cys, Arg) as a probe to explore the sequence selectivity of iron sulfide (FeS) nanoparticles as a simulant of the geochemical settings that once existed at the deep-sea floor or the surface of early Earth. Experiment was carried out by mixing the FeS nanoparticles and random peptides in pure $H_2O$ solution inside the anoxic chamber to allow adsorption under moderate temperature/pH condition. After extensive rinsing step, peptides that remain bound to the FeS nanoparticles were analyzed directly by MALDI-MS/MS to retrieve sequence information. We will discuss the latest sequence results obtained from screening and discuss sequence selective feature of FeS and its relevance to the iron-sulfur cluster known as a fundamental cofactor in biology.

# A process model of L-homochiral peptides formation initiated with L-alanine

*Toratane Munegumi[1], Taisuke Yamaga[1]

1. Department of Science Education, Naruto University of Education

Hydrogen abstraction from L-alanine by hydroxy radical facilitates alkylation on $\beta$-carbon of alanine as well as retention of L-chirality. The reaction rate constant of hydrogen abstraction ($k=6.21\times10^{7}\ M^{-1}s^{-1}$) on $\beta$-carbon was about 3.7 times faster than that ($k=1.7\times10^{7}\ M^{-1}s^{-1}$) on $\alpha$-carbon. The fact supports that alkylation proceeds faster than racemization, and the chirality of product amino acids will be hold. Similar alkylation of oligopeptides will also proceed with a lower level epimerization than alkylation. This research discusses how the lower reaction rate of epimerization than alkylation lead homochiral peptides.

Keywords: L-alanine, peptides, homochirality

# Possible Formation of Amino Acids and Carboxylic Acids in Slightly-Reducing Primitive Earth Atmospheres

*Miei Kinoshita[1], Shintaro Ikeda[1], Kimitaka Kawamura[2], Bhagawati Kunwar[2], Hitoshi Fukuda[3], Yoshiyuki Oguri[3], Hiromi Shibata[4], Junichi Takahashi[1], Vladimir Airapetian[5], Yoko Kebukawa[1], Kensei Kobayashi[1]

1. Yokohama National University, 2. Chubu University, 3. Tokyo Institute of Technology, 4. Osaka University, 5. NASA Goddard SFC

Since 1950s, a large number of laboratory experiments have been performed to examine possible formation of bioorganic compounds such as amino acids in primitive Earth atmosphere. Earlier experiments with strongly reducing gas mixtures containing large molar ratio of methane and ammonia, and it was reported that efficient production of amino acids and other important organics were formed in it by spark discharges and other energy sources. It is now estimated, however, that the early Earth atmosphere was only slightly reducing [1]: $N_2$ and $CO_2$were the major atmospheric constituents, together with some small amount of reducing carbon species like $CH_4$ and/or CO. Simulation experiments suggested, however, that amino acid formation was restricted under these conditions [2]. We reported that cosmic rays could facilitate chemical reactions with less reducing model of primitive atmosphere such as a mixture of $CO_2$, CO, $N_2$and $H_2O$ [3]. However these energy sources have been ignored in experiments with initiation of prebiotic chemistry [4]. Here, we examine possible formation of amino acids from slightly reducing gas mixtures by applying high-energy protons to simulate the action of cosmic rays.

We conducted three sets of laboratory experiments using energetic particles, spark discharge and UV light as dominant energy sources. In these sets of experiments we used 400 mL of gas mixture of $N_2$, $CO_2$and $CH_4$introduced to a Pyrex tube together with 5 mL of pure water under 350 Torr of N2 and 350 Torr of mixtures with varied mixing ratios of $CH_4$and $CO_2$. In order to simulate possible roles of cosmic rays, the gas mixture was irradiated with 2.5 MeV proton beam produced in the Tandem accelerator at Tokyo Tech, Japan. We also exposed the same composition of gas mixtures to spark discharges by using a Tesla coil to simulate lightning. The gas mixtures were also irradiated with UV light (l> 190 nm) from a xenon lamp. Each product was acid-hydrolyzed and was subjected to amino acid analysis by HPLC and GC/MS, both after derivatization. Carboxylic acids were determined by GC/MS after derivatization. Starting and resulting gas mixtures were analyzed with a quadrupole mass spectrometer.

Amino acids were detected in the hydrolyzed products when gas mixtures of $N_2$, $CO_2$, $CH_4$and $H_2O$ were irradiated with 2.5 MeV protons at the initial the molar ratio of methane ($r_{CH4}$) in the starting gas mixture as low as 0.5 %. On the other hand, amino acids were detected only when $r_{CH4}$was greater than 15 % in the case of spark discharges. The experiments with UV irradiation source did not yield amino acids or their precursors even when $r_{CH4}$was 50 %. Very little amino acids were detected in all the products before hydrolysis. It was shown that not free amino acids but amino acid precursors were formed in selected experiments.

Carboxylic acids including formic acid, oxalic acid and glyoxylic acid were detected from unhydrolized products derived from $N_2$-$CO_2$gas mixtures exposed to spark discharges and proton irradiation. We show that some free carboxylic acids could be formed in non-reducing atmospheres as well as slightly reducing atmospheres either by proton irradiation or by spark discharges. It was suggested that the mechanism of formation of amino acid precursors from $N_2$-$CO_2$-$CH_4$-$H_2O$ mixtures was quite different from that of

carboxylic acids.

Lightning and solar UV have been considered important energy sources for prebiotic synthesis in primitive Earth atmosphere. We here showed that lightning and solar UV could not singularly synthesize important N-containing organics such as amino acids from slightly reducing primitive Earth atmosphere. On the other hand, cosmic ray could have been an important energy source to synthesize amino acid precursors even if primitive Earth atmosphere was only slightly reducing. It would be of interest to examine whether there are synergetic effects among cosmic rays, UV and thundering.

One of the goals of the TANPOPO mission is collecting cosmic dust and space debris on the International Space Station [1]. Ultra-low density material “silica aerogel” panels are used as capture media [2]. These panels retrieved from the space are sent to the laboratory and initial analysis has been conducted by a system called “CLOXS”.

CLOXS efficiently covers the processes (1) Automatic imaging the entire panel, 2) Search for penetration track candidates, 3) Mapping of track candidates, 4) Shape data acquisition of tracks, and 5) Automatic sample cutting) up to sample allocation to researchers. However, to reduce researchers’ time and effort, improvement of the software and automation of some processes are required.

In this study, application of machine learning in discrimination of objects in aerogel images taken by CLOXS is mainly reported. The research goal is to classify objects in the images into tracks and dirt using machine learning.

There are morphological varieties in the objects. As for both tracks and dirt, they are classified into 4 types respectively in this study.

Since the contrast of the images are low, the first step of our approach is preprocessing of the images. We compared the results of *Contrast Stretching* and *CLAHE* (Contrast Limited Adaptive Histogram Equalization).

Learning data and test data are prepared respectively, to compare the case that the images are categorized into 4 types and the case that the images of all types are dealt altogether.

*Convolutional Neural Network* (CNN) is used as a method of machine learning. *Python* is used as programing Language.

In conclusion, as for image processing, *CLAHE* showed higher accuracy when tracks were judged to be tracks, and *Contrast Stretching* was found to yield a better result for dirt. It is probably because, in *Contrast Stretching*, *CNN* was not sufficiently highlighted to capture features, and *CLAHE* was able to improve the contrast sufficiently.

Regarding separating the types of tracks and dirt, the accuracy rate was higher when tracks were categorized into different types and learned.

Although further evaluation and improvements might be needed, our accuracy rates meet the mission requirements, that is, the percentage of identifying track as track should be more than 95 %, while the percentage of identifying dirt as dirt should be more than 70 % (that of NOT identifying true track as dirt

National Institute of Advanced Industrial Science and Technology, 7. Kyusyu University, 8. Fukuoka Institute of Technology, 9. Tokyo University of Pharmacy and Life Science

In Japan's first astrobiology experiment “Tanpopo”, attempts have been made to capture cosmic dust by installing ultra-low-density silica aerogel at the Japanese Experiment Module “Kibo” of the International Space Station (ISS) [1]. This mission was conducted with the aim of verifying the hypothesis that the origin of life was supplied from outside the earth [2]. Silica aerogel had been used in NASA’s cometary dust sample return mission “Stardust” [3]. Impact tracks formed by collision of cometary dust against aerogel were classified into 3 types, A, B and C, based on their shapes [4]. The track shapes have useful information for estimating the size and density of dust particles [5]. The purposes of this research are (1) to find impact tracks formed by cosmic dust in Tanpopo aerogel and (2) to describe the three-dimensional shapes of impact tracks with different origins (cosmic dust and space debris) and finally to clarify the relation between the track shape and the origin.

At SPring-8 BL47XU, three-dimensional shapes were obtained with imaging absorption tomography for 8 impact tracks (D1-231, D1-298, D1-362, E1-200, E1-304, F1-328, F1-389, F1-623), which were found in Tanpopo aerogel faced to the space direction. The imaging experiments were made at 7, 8, 9 keV with the voxel size of 0.24 or 0.465 $\mu$m. CT images at 8 keV were used to extract track shapes. Track length ($L_t$), maximum track diameter ($D_m$), aspect ratio, and other shape properties were obtained. These values were compared with Stardust tracks. Dual-energy tomography (DET) [6] was applied to estimate the materials of particles captured in the tracks. Another track (E2-000) was observed only with an optical microscope. For D1-231, D1-298, D1-362 and E2-000, the aerogel was compressed and real solid particles in the tracks were searched with an optical microscope.

The 9 tracks in total were classified into 5 types based on their shapes. Type 1 (E2-000) is a track formed by cosmic dust, where two pyroxene particles were identified at the tip of the track [7]. The track shape resembles Stardust type B track, but its entrance widely spreads. Type 2 (D1-231) is somewhat similar to Stardust type A track. Type 3 (E1-200 and E1-304) is a track having abundant cracks developed on the wall with a narrow entrance. Type 4 (F1-328 and F1-389) is extremely asymmetrical in its shape and has cracks similar to Type 3. Type 5 (D1-362 and F1-623) is a bowl-shaped track with a large entrance. The relationship between $L_t$ and $D_m$ of these tracks was almost the same as that of Stardust tracks except for Type 5. However, their specific shapes of Types 2, 3 and 4 are significantly different from Stardust tracks. The cracks of these tracks are similar to those seen at the end of Stardust type A and B tracks, indicating that they were formed by a relatively low-speed impact. Similar tracks to Type 5 were reported in the aerogel in the exposure experiment on the Mir Station. They may be due to high-speed collision of weakly-adhered aggregates [8]. From the quantitative analysis of such impact tracks, there is a possibility of obtaining knowledge about new parameter areas which could not be obtained by conventional research. DET results showed that most of fine particles in the tracks do not contain Fe and Ni. Low values of their

©2019. Japan Geoscience Union. All Right Reserved. 

linear absorption coefficients are smaller than that of cosmic dust. They should be formed by impact of weekly-adhered aggregates that were broken into very small pieces by the impact and mixed with condensed aerogel. Two particles with relatively high linear absorption coefficient were confirmed in D1-231 and D1-362. They were confirmed by and optical microscope after compressing.

# High-Angular-Resolution Observations of Protoplanetary Disks

*Misato Fukagawa[1]

1. National Astronomical Observatory of Japan

The recent progress in understanding of planet-formation process will be reviewed based on the results obtained at high angular resolution with astronomical facilities such as the Atacama Large Millimeter/submillimeter Array (ALMA). Circumstellar disk structures around young stars are birthplaces of planets. The physical and chemical condition in such protoplanetary disks can be linked to some extent to the planetary environment (e.g., atmospheric composition) where further chemical reactions might lead to formation of building blocks of life. This presentation includes the topics on detailed disk density structures at ~5-au or better resolution, gas detections in the later stages of disks where the collisional events in the planetary systems may happen, detections of organic molecules, and the prospects on disk observations in future.

# Characterization of high molecular weight amino acid precursors formed in interstellar ice analog

*Soushi Kuramoto[1], Tomohito Sato[1], Hitoshi Fukuda[2], Yoshiyuki Oguri[2], Kotaro Kondo[2], Hiromi Shibata[3], Yoko Kebukawa[1], Kensei Kobayashi[1], Satoshi Yoshida[4]

1. Yokohama National University, 2. Tokyo Institute of Technology, 3. University of Osaka, 4. National Institutes for Quantum Radiological Science and Technology

It is suggested that extraterrestrial organic compounds are important for chemical evolution toward the generation of the first life on the Earth. Bioorganic compounds such as amino acids were found in hydrolyzed extracts of meteorite [1]. The products before hydrolysis referred to as “amino acid precursors” were, however, little known. It has been sometimes claimed that a-amino acids found in meteorites were formed by the Strecker synthesis. If so, aminonitriles and amino acid amides are the precursors, but they have not identified as major precursors yet. Extraterrestrial amino acid precursors were probably synthesized in molecular cloud environments or small celestial bodies. We irradiated possible interstellar media, such as mixture of carbon monoxide, ammonia and water to simulate possible reactions among interstellar media in dense clouds. The irradiation products were analyzed by HPLC and mass spectrometry.

A gaseous mixture (CO and $NH_3$) was sealed in a Pyrex glass tube with liquid water. The gaseous mixture was irradiated with 2.5 MeV protons from a Tandem accelerator at Tokyo Institute of Technology. Total quantity of electricity was 2 mC. The name of the irradiation products is hereafter called CAW. CAW was fractionated by cation exchange HPLC into several fractions to discriminate the fractions with glycine amide or aminoacetonitrile (the Strecker-type precursors) and those without them. Each fraction was hydrolyzed with 6M HCl at 110 ˚C for 24h and was subjected to amino acid analysis. Molecular weights of CAW were estimated by ultrafiltration (molecular weight cut off: 3000), gel filtration (column: Shodex OHpak SB-802.5 HQ) and mass spectrometry by ESI-TOF-MS.

It was shown that glycine was rarely detected in the fractions with the Strecker-type simple amino acid precursors (aminoacetonitrile, glycine amide). It was suggested that the CAW (an interstellar organics analogue) contained complex amino acid precursors with molecular weights of some thousands. Compared with molecular weights standards (authentic proteins), molecular weights of CAW were estimated 6000 or more by gel filtration chromatography. Peaks of $m/z$ = 1000 or over were detected by mass spectrometry. These results strongly suggested that complex amino acid precursors with large molecular weights could be directly generated from small molecules such as CO in interstellar environments. We are now trying to characterize amino acid precursors formed in interstellar ice analogue (frozen mixture of CH3OH, NH3 and H2O [2]) by heavy ions irradiation.

# Theoretical elucidation of prebiotic formation processes into nucleobases

*Yu Komatsu[1,2], Taiki Suzuki[1,2]

1. Astrobiology Center, 2. National Astronomical Observatory of Japan

As argued [1], the comets and meteorites may have provided a large amount of prebiotic molecules to the Early Earth. However, where and how such organic molecules were built is still controversial.

Recently, volatile glycine (NH2CH2COOH) has been detected in the coma of comet 67P/Churyumov-Gerasimenko by the ROSINA mass spectrometer [2], with giving us clues to glycine's interstellar origin. Moreover, in addition to various amino acids, nucleobases, such as purine, uracil, guanine, and xanthine have been identified in the meteorite (e.g., [3]). These studies suggest the formation of prebiotic molecules in the extreme condition prior to the early Earth chemistry.

If prebiotic molecules are built from small atoms or radicals in the cold ISM, the prebiotic molecules must have almost barrier-less formation paths. On the other hand, the bombardment of comets and/or asteroids would have provided very high temperature condition for chemical reactions, which may have led to the decomposition and formation of further complex prebiotic molecules. To understand the formation processes, the quantum chemical calculation is a powerful tool. The previous quantum chemical calculation has already reported the promising chemical paths to amino acids and nucleobases (e.g., [4]).

Here we investigated the possible pathway of pyrimidine, purine, uracil and thymine by the automated exploration of chemical reaction pathways. We have already discovered key dissociations for each molecule. For example, uracil and thymine, the pyrimidine type of nucleobase, have lower barriers to dissociate into an isocyanic acid, which corresponds to the previous laboratory experience, and the rest molecule. Pyrimidine and purine, which are skeleton structures of nucleobases and do not poses any oxygen atoms, have high barriers, implying to require high temperature environment like the bombardment, even though we did not exclude all possibilities of radical reactions. Detailed discussions will be provided on our poster.

# Formation Process of A Glycine's Precursor Candidate, CH3NH2

*Taiki Suzuki[1,2], Liton Majumdar[3], Masatoshi Ohishi[2]

1. National Institutes of Natural Sciences Astrobiology Center, 2. National Astronomical Observatory of Japan, 3. NASA Jet Propulsion Laboratory (JPL)

As [1] argued, the comets and meteorites may have provided a large amount of prebiotic molecules to the early Earth. An attempt to understand the origins of life must necessarily begin with detailed studies of the formation and evolution of complex organic molecules (COMs), products of complex chemistry that most likely starts in molecular clouds and continues within the protoplanetary disk.
Since the amino acids are the essential building blocks of life, the search for amino acids and their complex organic precursors at different stages of star and planet formation is one of the exciting topics in modern astronomy. Recently, volatile glycine ($NH_2CH_2COOH$) was detected in the coma of comet 67P/Churyumov-Gerasimenko by the ROSINA mass spectrometer [2], also giving clues about glycine's interstellar origin. However, the survey observations of glycine toward ISM have been not successful. Therefore, revealing the formation pathways to glycine is important for astrochemistry and astrobiology not only to know the promising glycine-rich sources for future surveys but also to understand the general chemical evolution of N-bearing molecules in the ISM.
In this context, we performed the chemical modeling study for the high-mass star, with the possible formation processes of glycine with theoretically and/or experimentally suggested formation paths [3]. We suggested that glycine was efficiently formed through the following reactions: First, the hydrogenation process to HCN leads to the formation of $CH_2NH$ and $CH_3NH_2$ on interstellar grain surface (HCN + 2H => $CH_2NH$, and then $CH_2NH$ + 2H => $CH_3NH_2$). Then, the destruction of $CH_3NH_2$ by radicals will form $CH_2NH_2$. Finally, $CH_2NH_2$ and COOH radical react to form glycine. For this test, a key molecule would be $CH_3OH$, whose formation process is well known. Both experiments and theoretical works suggested that $CH_3OH$ is built via grain surface hydrogenation processes to CO (CO + 2H => $H_2CO$, and then $H_2CO$ + 2H => $CH_3OH$). If $CH_3NH_2$ is also produced through hydrogenation process, “$CH_3NH_2/CH_3OH$” ratio should be well reproduced by the modeling. However, it was difficult to test this formation process due to the very limited number of previous CH3NH2 observations.
With this motivation, we performed the observation of $CH_3NH_2$ and $CH_3OH$ with ALMA toward high mass star-forming regions, G10.47+0.03, NGC6334I, W51 e1/e2, and G31.41+0.3. As a result, both of $CH_3OH$ and $CH_3NH_2$ were detected toward all sources. The molecular abundances were derived with rotation diagram method. The high excitation temperatures of 100 and 200 K and compact distributions suggest that $CH_3NH_2$ emissions originate from the hot and dense regions. The observed molecular abundance ratio, “$CH_3NH_2/CH_3OH$” ranges from 0.2 to 2.1. The low “$CH_3NH_2/CH_3OH$” ratio of 0.2 is close to our modeling, supporting that $CH_3NH_2$ is the product of the hydrogenation process in those sources. However, the higher “$CH_3NH_2/CH_3OH$” ratio of nearly two, observed toward NGC6334I MM1, could not be reproduced with our modeling under the possible parameter range. Thus, our chemical modeling would not correctly reproduce the physics or chemistry of such $CH_3NH_2$-rich sources. Further studies of such sources will enable us to promote our knowledge of glycine chemistry and provide us with promising sources for future glycine surveys.

# Numerical study on the stellar atmosphere & wind of Cool Stars

*Takahito Sakaue[1], Kazunari Shibata[1]

1. Kyoto University

Cool stars offer the good opportunities to investigate what environments the Earth-like exoplanets are in, and how they are affected by the host star. TRAPPIST-1 is an ultracool dwarf; the spectral type is M8V ($T_{eff}$ =2559K) with the lower mass of 0.08$M_{sun}$ (radius = 0.11$R_{sun}$). The star is confirmed to have seven planets (Gillon et al. 2017) and thus greatly interested in not only by stellar astrophysics but also by astrobiology. Here, we report the results of one-dimensional magnetohydrodynamic (MHD) simulation of the stellar wind from TRAPPIST-1. Several solar wind theories, which have been examined observationally, are applied to the case of TRAPPIST-1. Among them, it is the plausible idea that the dissipation of the incompressible MHD wave leads to the heating and driving the stellar wind. For instance, Garraffo et al. 2017 succeeded in the three-dimensional MHD simulation of the stellar wind from TRAPPIST-1, by extending their solar wind model in which the incompressible MHD wave is exhausted by the turbulent dissipation. The incompressible MHD wave, on the other hand, is also affected not only by the turbulent dissipation but also by the nonlinear mode coupling, which leads to the formation of the shock wave and consequently contribute to heating the wind. This nonlinear process has been well investigated to account for the dynamics of the lower solar atmosphere (Kudoh & Shibata 1999) and driving the solar wind (Suzuki & Inutsuka 2005), but not discussed for the stellar wind from TRAPPIST-1. In this study, therefore, we performed the one-dimensional MHD simulation to consider the nonlinear process of the incompressible MHD wave leading to the shock formation, and succeeded in reproducing the stellar wind from TRAPPIST-1.

# Design of space exposure experiments of organic matter in Tanpopo 2

*Takuya Yokoo[1], tomohito sato[1], Itsuki Sakon[2], Kazumichi Nakagawa[3], Hajime Yano[4], Miki Nakayama[5], Hajime Mita[5], Yoko Kebukawa[1], Kensei Kobayashi[1]

## 1. Introduction

Large number of organic compounds have been discovered in molecular clouds and in meteorites. Some of organic compounds required for emergence of life are thought to be synthesized in space. Then, meteorites and interplanetary dust particles could deliver them to the Earth. The first Japanese astrobiology space experiment called “Tanpopo” was conducted to study this hypothesis[1].
The objective of the Tanpopo Mission is to understand bi-directional propagation of microorganisms and organic matter between the Earth and space. In other words, in the Tanpopo Mission, we examine whether life exists only on the earth by evaluating whether microorganisms can escape into space and whether organic matter can reach to the Earth from outer space.
As one of subthemes in this project, amino acids and their precursor compounds including complex interstellar organic matter analog were directly exposed to outer space by utilizing the International Space Station (ISS), and recoveries of these organics were measured to understand degradation of organic compounds under the environment of the outer space. In the Tanpopo experiment, hexatriacontane (HTC) was used to prevent the sample from sublimation during exposure to space at the ISS. However, HTC absorbs ultraviolet light with a wavelength of 160 nm or less. To understand the effects of shorter wavelength UV, the next space experiment "Tanpopo 2" applies a new design for direct exposure of organic compounds without HTC and optical windows. In addition to the aluminum plate same as the one used in Tanpopo, the silicon substrates are also used for exposure the sample to space, in the organic matter exposure experiment of “Tanpopo 2 “. In the Tanpopo Mission, glycine, hydantoin, isovaline, ethylmethylhydantoin, CAW (complex organic matter produced from proton beam irradiation to CO, $NH_3$, $H_2O$ mixture) were used, and glycine and CAW showed relatively high recoveries [2]. In "Tanpopo 2", glycine and CA (proton beam irradiation product to CO, $NH_3$ mixture) on the silicon substrates will be directly exposed to space in addition to the same compounds on the same aluminum plate used in the Tanpopo. The recovered samples will be analyzed by FT-IR, XANES, and SEM, in addition to amino acid analysis.
Here we report the design of the space experiment such as preparation method of the space experiment sample.

## 2. Experimental

(1) A gas mixture of CO (350 Torr) and $NH_3$ (350 Torr) and a silicon plate (10 mm$\phi$) were placed in a glass container, and the gas mixture was irradiated with 2.5 MeV proton beam from a tandem accelerator to deposit organic matter on the plate.
(2) The thickness of the organic matter (CA) film on the silicon plate was measured using a three-dimensional microscope.
(3) Structural analysis of organic matter (CA) on the silicon plate was also carried out using FT-IR.
(4) Amino acid analysis was carried out by cation exchange HPLC after hydrolyzing silicon plate with CA with 6 M hydrochloric acid at 110 ˚C for 24 hours.

©2019. Japan Geoscience Union. All Right Reserved. 

(5) Glycine is planned to be deposited on a silicon substrate by a vacuum vapor deposition equipment (Fukuoka Institute of Technology).

3. Results and Discussion

The CA deposition thickness was approximately 8 μm, but more sample thickness would be required due to potential loss of the organic materials by atomic oxygen present in low Earth orbit during exposure. Thus, we decided to use non-polished Si substrates instead of polished Si substrate. Because the sample can be kept in the bottom of indentations on the rough surface of non-polished substrate, even if a part of sample surface is lost.
Amino acid analyses of CA by cation exchanged HPLC showed, various amino acids including aspartic acid, threonine, glycine, alanine, -aminoisobutyric acid and serine were detected after acid hydrolysis. Glycine was particularly abundant, whose yield was 827 ±7 nmol from a single CA deposited Si substrate.

4. Conclusions

We will conduct the durability test of our samples on the silicon substrate including the vibration test, cooling test, heating test before launch in 2019 with the space X company to the ISS. We are planning to conduct various analyses from recovered samples. The recovery and degradation of these samples will make a further leap forward our understanding of the possible delivery of organic matter from interplanetary dust particles to the early Earth.

## [M-IS09] dust

convener:Ishizuka Masahide(Kagawa University), Yasunori Kurosaki(Arid Land Research Center, Tottori University), Thomas Sekiyama(Meteorological Research Institute), Kana Nagashima(Japan Agency for Marine-Earth Science and Technology, Research and Development Center for Global Change), Chairperson:Tsuyoshi Sekiyama

Mineral dust is generated from the ground surface by strong winds, and it transports long distance over the earth. In the process, cloud formation and absorption and scattering of solar radiation cause weather and climate changes. Also, when deposited in the ocean, feeding nutrients to phytoplankton, promoting photosynthesis, and when deposited on snow and ice causes albedo change. This is known as the yellow dust (Asian dust) phenomenon in Asia region including Japan. In order to understand this, integration in a wide range of academic areas is necessary. <br/> In the emission process, the amount of dust changes greatly depending on the surface condition in dryland area, and in order to know the conditions, it deals with areas such as soil, topography, vegetation, precipitation, desert and soil deterioration. In the transport process, we deal with areas such as weather, atmospheric aerosol, radiation. In the deposition process, we deal with areas such as ocean, snow ice, health to people and livestock. Drying and changes in vegetation also have social scientific aspects such as national policies, management of livestock, and population increase. Dust and sand dunes are common phenomena not only to the Earth but also to other planets such as Mars and Saturn. In this way, it is impossible to understand the dust phenomenon only in one field, it is important for researchers in many areas to discuss and share information through this session, and advance exchange of researchers.

# Global modeling study of atmospheric supply of lithogenic and pyrogenic Fe-containing aerosols to the ocean

*Akinori Ito[1], Akitomo Yamamoto[1], Michio Watanabe[1], Maki Noguchi Aita[1], Ying Ye[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Alfred Wegener Institute for Polar and Marine Research

Atmospheric supply of iron (Fe) to the ocean has been suggested to increase the marine primary productivity in large parts of the ocean. However, there are still large uncertainties regarding the effects of atmospheric aerosols on Fe dissolved in the surface ocean and marine productivity. Here, we use an atmospheric chemistry model and two ocean biogeochemistry models to explore the sensitivity to the atmospheric input of dissolved Fe.

The atmospheric model considered the deposition of both lithogenic and pyrogenic Fe-containing aerosols and their chemical transformation due to reactions with gaseous species. Sensitivity simulations are carried out with the deposition of lithogenic Fe only, and both Fe content in mineral dust of 3.5% and solubility of 2% are prescribed in the ocean models.

The results from the sensitivity simulations show that additional sources of dust and combustion aerosols increased the marine phytoplankton biomass in the subarctic north Pacific. The two ocean biogeochemistry models show similar spatial patterns but substantially different magnitude of responses to the atmospheric input of dissolved Fe. Moreover, the atmospheric model underestimated dissolved Fe concentration in aerosols over the North Pacific, although more observations are needed before drawing any firm conclusions on the model performance over the Pacific. Thus, further investigations of processes in emission of Fe from East Asia and transformation of dissolved Fe in the atmosphere and the ocean are needed.

# Regional variations in the elemental and mineral compositions of solid particles in rainwater in Iran

*Yoriko Yokoo[1], Chihiro Sakamoto[1], Atsushi Kitamura[1], Ryo Anma[2], Shiva Mehrabani[3]

1. Faculty of Science and Engineering, Doshisha University, 2. Tokushima University, 3. Kurdistan University

We collected monthly solid particles (air dust; > 0.2 $\mu$m) in rainwater samples in four western cities (Hamedan, Ilam, Shiraz, Ahvaz) from October 2014 to July 2015 and three eastern cities (Mashhad, Birjand, Zahedan) from January 2016 to January 2017 in Iran, and determined their elemental and mineral compositions in order to elucidate the regional variation and to consider their provenance. In no-rainfall months, we rinsed the sampler with ultrapure water and collected the trapped air dust. Mineral composition of the collected dust was determined using an XRD. We dissolved the same dust samples using mixed-acids and measured elemental compositions using an ICP-MS.
The amount of dust in eastern cities were higher than those in western cities, especially the samples collected in Birjand. Samples from Mashhad and Zahedan had high amount of dust during dry season. These results suggest that aeolian dust from surrounding deserts such as Dasht-e Kavir and Dasht-e Lut affected atmospheric deposition in eastern Iran.
All of dust samples contained quartz and feldspar. Most of the dust samples in western cities also contained calcite. The concentrations of Ca, Na and K in the dust of western cities were 0.45-29.33%, 0.24-0.82% and 0.49-1.94%, respectively. Those in the dust of eastern cities were 0.97-6.23%, 0.59-2.74% and 0.88-3.15%, respectively. The concentration of Ca in the dust of western cities were higher, and Na and K concentrations were lower than those of eastern cities. High calcite contents were observed in western cities and Birjand : thus, high-Ca in the dust is attributed to calcite originated from the arid area. A part of Ca in the dust of eastern cities could also be attributed to feldspars.
Cd, Sb, Pb and As in the dust of western cities and Ni, Zn, As, Cd and Sb in those of eastern cities had the maximum values of the enrichment factor (EF): $(X/Al)_{sample}/(X/Al)_{crust}$ over ten. These results suggest a part of the dust were originated from anthropogenic substances such as road dust and petroleum industry. The EF values of Pb and As of dust samples in western cities showed higher than those in eastern cities, suggesting that the atmospheric deposition were influenced by anthropogenic substances from petroleum industry, which is generally high in Pb and As.

# Comparison of airborne microbial variations in air samples from Asian-dust source and arrival regions

*Teruya Maki[1], Tatsuyuki Fujita[1], Yuuma Mastuba[1], Yasunori Kurosaki[2], Masahide Ishizuka[3], Kei Kawai[4], Yasunobu Iwasaka[5]

1. College of Science and Engineering, Kanazawa University, 2. Arid Land Research Center, Tottori University, Tottori University, 3. Faculty of Engineering, Kagawa University, 4. Graduate School of Environmental Studies, Nagoya Universit, 5. Center for Environmental Creative Studies

Aerosol dust is emerging as a significant vehicle for long-range transport of microorganisms. Nonetheless, many factors relating to this highly influential dispersal mechanisms remain unresolved, including the variation in dispersal bacterial communities during stochastic desert dust events, and the effect of aerosol transit over continental and oceanic surfaces to these communities. Here we elucidated bacterial 16S rRNA gene and fungal ITS-defined changes in airborne microbial communities at Asian-dust source regions (Gobi) and arrival regions (Japan) both lying along the trajectory for dust-event transport. Aerosols collected in the both regions generally reflected local origin from freshwater, marine, plant, or animal sources. In particular, dust events in the Gobi Desert increased these microbial cells and mineral particles to more than ten folds of concentrations. After dust-events occurrences in desert areas, the spore-forming microorganisms (bacteria: Bacillaceae, fungi: Davidiellaceae) and organic-aggregating bacteria (Cytophagaceae) showed high relative abundances, suggesting the survival of some microbes against strict atmospheric stressors over desert. These stress-resistance microbial populations were frequently dominated during Asian-dust evens over Japan, which are located cross China industrial area and Japan Sea. Presumably, atmospheric stressors over desert transit over deserts, anthropogenic polluted areas and oceanic waters strongly selects for airborne microbial populations through atmospheric stressors.

# Prediction of health effects of cross-border atmospheric pollutants using the Model of Aerosol Species in the Global Atmosphere (MASINGAR)

*Kazunari Onishi[1], Thomas Sekiyama[2], Yasunori Kurosaki[3], Masato Shinoda[4]

1. Graduate School of Public Health, Support Unit for Conducting Clinically Essential Studies, St.Luke's International University, 2. Meteorological Research Institute, 3. Arid Land Research Center, Tottori University, 4. Graduate School of Environmental Studies Nagoya University

Health effects of cross-border air pollutants and Asian dust are of significant concern in Japan. Currently, models predicting the arrival of aerosols have not investigated the association between arrival predictions and health effects. We investigated the association between subjective health symptoms and unreleased aerosol data from the Model of Aerosol Species in the Global Atmosphere (MASINGAR) acquired from the Japan meteorological agency, with the objective of ascertaining if these data could be applied to predicting health effects.
Subjective symptom scores were collected via self-administered questionnaires and, along with modeled surface aerosol concentration data, were used to conduct a risk evaluation using generalized estimating equations between October and November 2011.
Altogether, 29 individuals provided 1670 responses. Spearman's correlation coefficients were determined for the relationship between the proportion of the participants reporting the maximum score of two or more for each symptom and the surface concentrations for each considered aerosol species calculated using MASINGAR; the coefficients showed significant intermediate correlations between surface sulfate aerosol concentration and respiratory, throat, and fever symptoms (R=0.557, 0.454, and 0.470, respectively; $p < 0.01$). In the general estimation equation (logit link) analyses, a significant linear association of surface sulfate aerosol concentration, with an endpoint determined by reported respiratory symptom scores of two or more,was observed (P trend=0.001, odds ratio [OR] of the highest quartile [Q4] vs. the lowest[Q1]=5.31, 95% CI=2.18 to 12.96), with adjustment for potential confounding. The surface sulfate aerosol concentration was also associated with throat and fever symptoms. Association of surface dust aerosol concentration and respiratory symptom were odds ratio [OR] of the highest quartile [Q4] vs. the lowest[Q1]=3.32, 95% CI=0.90 to 12.27).
In conclusion, our findings suggest that modeled data are potentially useful for predicting health risks of cross-border aerosol arrivals.

National Institute for Environmental Studies, 7. University of Tsukuba, 8. National Agency for Meteorology and Environmental Monitoring, Mongolia

Asian dust originates in arid and semi-arid regions of East Asia, such as the Gobi Desert and the Taklimakan Desert. If the dust emitted from the ground surface reaches the free troposphere, it can be transported toward the Pacific Ocean over a long range by the westerlies. Therefore, the vertical distribution of dust over the source region is a key factor of the long-range transport of dust. In the Gobi Desert, a ceilometer (compact lidar) observation has been conducted at Dalanzadgad, Mongolia, since the end of April 2013. The ceilometer observed a developed dust storm over the ground and a dust layer at a height of 1.2–1.8 km on 29–30 April 2015. According to SYNOP reports, this dust storm had already developed in the upwind region before arriving at Dalanzadgad. This feature was consistent with the sudden increase of the ceilometer observation values. Then, the dust was lifted to a height of 1.2–1.8 km, and the dust layer was observed at almost the same height for 12 hours by the ceilometer. During this dust event, radiosonde observation at Dalanzadgad showed an inversion layer at a height of 1.2–1.5 km over cold air. These results suggest that the dust layer was captured by the inversion layer, which prevented the dust from reaching the free troposphere and restrained the long-range transport of the dust by the westerlies. This study was supported by Research Fellowships of Japan Society for the Promotion of Science (JSPS) for Young Scientists and by Grants-in-Aid for Scientific Research from the JSPS (16H02703, 17H01616, and 18J12795).

## [M-IS09] dust

convener:Ishizuka Masahide(Kagawa University), Yasunori Kurosaki(Arid Land Research Center, Tottori University), Thomas Sekiyama(Meteorological Research Institute), Kana Nagashima(Japan Agency for Marine-Earth Science and Technology, Research and Development Center for Global Change), Chairperson:Kana Nagashima

Mineral dust is generated from the ground surface by strong winds, and it transports long distance over the earth. In the process, cloud formation and absorption and scattering of solar radiation cause weather and climate changes. Also, when deposited in the ocean, feeding nutrients to phytoplankton, promoting photosynthesis, and when deposited on snow and ice causes albedo change. This is known as the yellow dust (Asian dust) phenomenon in Asia region including Japan. In order to understand this, integration in a wide range of academic areas is necessary.
In the emission process, the amount of dust changes greatly depending on the surface condition in dryland area, and in order to know the conditions, it deals with areas such as soil, topography, vegetation, precipitation, desert and soil deterioration. In the transport process, we deal with areas such as weather, atmospheric aerosol, radiation. In the deposition process, we deal with areas such as ocean, snow ice, health to people and livestock. Drying and changes in vegetation also have social scientific aspects such as national policies, management of livestock, and population increase. Dust and sand dunes are common phenomena not only to the Earth but also to other planets such as Mars and Saturn. In this way, it is impossible to understand the dust phenomenon only in one field, it is important for researchers in many areas to discuss and share information through this session, and advance exchange of researchers.

# Favorable regions for dust haze transport revealed by ensemble simulations

*Kazunori Ogohara[1], Shogo Isoda[1]

1. School of Engineering, University of Shiga Prefecture

Dust is the major source of the solar heating in the Martian atmosphere and then drives the circulation of dust itself. Dust events (dust storms, dust devils and dust haze) are disasters in the Mars atmosphere near the surface because they can generate strong winds and block sunlight almost completely. Statistics of dust events have been studied by analyzing atmospheric temperature, dust optical depth and visible images observed by successive orbiters, landers and rovers. Active areas of local dust storms, including curvilinear and textured storms have been identified observationally. The tendency of such small scale dust events should be affected by the large scale atmospheric conditions such as thermal or dynamical stabilities. Activity of regional dust storms has been investigated using the vast number of images observed by Mars Orbiter Camera onboard Mars Global Surveyor (MGS/MOC) and MARs Color Imager onboard Mars Reconnaissance Orbiter (MRO/MARCI). They tend to break out near the storm zones in the northern mid-latitudes and are probably very linked to baroclinic instability and the fronts. Although mechanisms of the growth, maintenance and decay of global dust storms have not been well investigated, most of global dust storms started in the southern spring to summer seasons as regional storms were merging with each other.
Questions about the mechanisms of dust storms and haze are as follow:
- Why does a dust storm/haze break out?
- Why does the dust storm/haze expand?
Mechanisms of initiation and maintenance of local dust storms will be understood and categorized into a few types in the near future by statistical studies. They can be also inferred from observations and theories of terrestrial dust storms. However, there are local dust storms also in the northern mid-latitudes. Why do not the local storms grow into regional dust storms? Why do not all regional dust storms merge with each other? Ogohara and Satomura (2011) found five favorable regions for expansion of local dust haze (FRs) and revealed what kind of the atmospheric phenomena controls the dust haze transport around such regions. However, it still remains unclear whether these five FRs are also favorable for dust haze transport climatologically because they performed just a single year calculation. Thus, we identify the climatologically robust FRs in this study by ensemble simulations. If such FRs were found, atmospheric phenomena characteristic of the FRs would govern the dust transport around there.
Each ensemble simulation is performed in the same manner as that by Ogohara and Satomura (2011). Although they could not separate injected dust from the background dust due to the model architecture, wee modify the model in this study so that I can treat the injected and background dust separately. The first spin-up run started from an isothermal (220 K) condition with constant surface pressure (6.4 hPa) and no wind over the entire planet. Fifty kinds of small disturbances are added to the temperature output data of the first spin-up run. The small disturbances of temperature at each sigma level are normal random numbers. The standard deviation of the distribution function is 0.01 times of the standard deviation of temperature at the sigma level of the first spin-up result. The second spin-up runs are performed for 1 MY from $L_s$=180 independently using the 50 kinds of the output data of the first spin-up run with small disturbances as the initial data. After these spin-up runs, fifty global maps of dust haze expansion potential are made using the output data from the 50 kinds of the second spin-up runs as the initial data. The maps of dust haze expansion potential clearly show that there are a few robust FRs in the northern fall season. Also, it turns out that standard deviations of dust haze expansion are significantly

©2019. Japan Geoscience Union. All Right Reserved. 

higher in the northern high latitudes than in the low latitudes. The reasons why dust tends to expand around the robust FRs are the same as those explained by Ogohara and Satomura (2011). However, high ensemble standard deviation in dust haze expansion is clearly shown at the first time by this study. In the presentation, we will show when dust haze tends to spread extensively and when it does not.

# Measurement of adhesion force of individual aerosol particles by atomic force microscopy

*Kohei Ono[1], Yuki Mizushima[4], Ayumi Iwata[3], Furuya Masaki[1], Nozomu Tsuchiya[1], Atsushi Matsuki[2]

1. Graduate School of Natural Science and Technology, Kanazawa University, 2. Institute of Nature and Environmental Technology, Kanazawa University, 3. Faculty of Science and Technology, Keio University, 4. College of Science and Technology, Kanazawa University

A new method was developed to quantitatively evaluate the adhesion force of individual aerosol particles. The method involves force-curve-mapping by atomic force microscopy. Firstly, adhesion force of particle surrogates (PSL, ammonium sulfate, quartz) were measured to evaluate the applicability of the new method on individual particles. Spatial distribution and representative adhesion force was successfully obtained. The force-curve-mapping method was then applied on actual ambient samples. The aged Asian dust particles following long-range transport were collected within Kanazawa University campus. The same dust particles were identified under both AFM and SEM-EDX and analyzed for their morphology, adhesion force distribution and elemental composition. It was found that the adhesion force of aged silicate Asian dust was greater than that of fresh dust collected near the source in China. It was suggested that the adhesion force of aged silicate dust increases and becomes comparable to those of inorganic salts (i.e. ammonium sulfate and sea salt particles). Ca-rich Asian dust exhibited even stronger adhesion force. The result revealed difference of adhesion forces between silicate and Ca-rich Asian dust following atmospheric processing during long-range transport. This study also spotted few carbonaceous particles with exceptionally high adhesion force, suggesting certain organic aerosols may be particularly adhesive. This work successfully demonstrated the importance of adhesion force measurement on individual particle basis, and applicability of force-curve-mapping method for characterizing adhesivity of internally mixed particles.

# Occurrence of micro-meso scale dust storms and its relationship to the vegetation and topography in Mongolian grassland and Gobi Desert

*Kenji Kai[1], Kei Kawai[2], Teruya Maki[3], Jun Noda[4]

1. College of Education, Ibaraki University , 2. Nagoya University, 3. Kanazawa University, 4. Rakuno-Gakuen University

Gobi Desert and Mongolian grassland are one of the main sources of the Asian dust. In order to investigate the occurrence of micro-meso scale dust storms and its relationship to the vegetation and topography, we conducted moving observations running across the Gobi Desert from Ulaanbaatar to Dalanzadgad in springs of 2015-2017. An optical particle counter (OPC: Aerotrak 9306-V2), a sunphotometer (Microtops II) and meteorological instrument were installed in a car.

The vegetation had a suppression effect on the dust emission. Number concentrations of coarse particles (1-10 $\mu$m) decreased from the desert to the grassland. They had significant negative correlations with the vegetation (NDVI) from 3 $\mu$m to 10 $\mu$m, but the number concentration at 0.3 –0.5 $\mu$m had little correlation to the vegetation.

During the moving observations, we found a hotspot of dust storms in the Gobi Desert. An analysis of Himawari-8 Dust RGB clearly shows that the hotspot appeared at a jointing point of two valleys, a bottleneck and an exit of a valley.

In summary, the horizontal distribution of number concentrations of aerosol particles reflected the surface vegetation. Locations of the hotspot were determined by a local topography such a jointing point of two valleys.

# A trial of elucidation for dust emission conditions in East Asia by synoptic data analyses and a field observation

*Yasunori Kurosaki[1], Jing Wu[1], Batjargal Buyantogtokh[1], Ishizuka Masahide[2], Batdelger Gantsetseg[3]

1. Tottori University, 2. Kagawa University, 3. IRIMHE, Mongolia

Mineral dust particles are blown up into the free atmosphere by sand-dust storm (SDS) in drylands, and they are broadly distributed by wind in the upper atmosphere. SDS is a type of disaster in drylands, which sometimes kills people and animal, destroys infrastructure, reduces merchandise value of livestock etc. In downwind regions like Japan, there is reports on its health effect. In the global scale, there are many reports about their effects on climate via direct and indirect effects of radiation. Many researchers have developed numerical dust model to avoid such damages, but their accuracy is still low, especially in its emission phase (Uno et al. 2006; Carmichael et al. 2008).

We can divide causes of dust emission (in other words, wind erosion) into erosivity (i.e., ability of wind to cause erosion) and erodibility (i.e., susceptibility of soil and land surface to wind erosion represented by the threshold wind speed for dust emission). Erosivity can be expressed by one parameter, which is wind speed and accuracy for its observation and its forecast is relatively reliable. On the other hand, erodibility has many parameters relating with soil and land surface such as soil particle size, soil wetness, crust, soil freeze, snow cover, vegetation cover, and we have a very big hurdles for monitoring all with high accuracy. This can be a big reason of low accuracy of dust emission modeling.

Tottori University set up a dust monitoring system at Tsogt-Ovoo, Mongolia, which is located in a northern part of the Gobi Desert. We have clarified that effects of soil crust (Ishizuka et al. 2012 SOLA), vegetation cover in topographic depression (Gantsetseg et al. 2017 J. of Arid Land), stone (Buyantogtokh et al. 2019 in preparation), dead leaves on erodibility. We also have conducted analyses of wind and present weather data included in synoptic report to elucidate dust emission conditions, which differs place by place. Kurosaki et al. (2011 GRL) clarified that dust emission frequencies increased at many synoptic meteorological observatories in East Asia from 1990s to 2000s and the major causes are in increased erodibility, which can be shown by reductions of threshold wind speed. Wu et al. (2016 SOLA) clarified that the major causes for dust emission are different station by station in East Asia. Wu et al. (2019 in preparation) clarified that effect of livestock number at Abaga Qi, which is located at Xilingol Grassland, China.

Keywords: drylands, aeolian dust, wind erosion, erosivity, erodibility

# Monitoring and assessing aeolian desertification processes based on a dust erodibility index –A case study in the Xilingol grassland, China

*Jing Wu[1], Yasunori Kurosaki[1], Chunling Du[2], Tao Wang[3]

1. Arid Land Research Center, Tottori University, 2. School of Economics and Management, Inner Mongolia Agricultural University, 3. Northwest Institute of Eco-Environment and Resources, Chinese Academy of Sciences

Aeolian desertification is land degradation characterized by wind erosion, which is dependent on erosivity and erodibility. Progressive aeolian desertification causes dust to occur frequently, which has negative impacts on the environment and human health. To effectively prevent the expansion of aeolian desertification, it is crucial to monitor the processes of aeolian desertification and understand its mechanism(s). However, due to its complexity, it is difficult to apply a common indicator for monitoring desertification status.
In this study, we assessed aeolian desertification by using a dust erodibility index as an indicator that reflects the vulnerability of the land surface to wind erosion. We used dust occurrence ratio (DOR), which was calculated as the ratio of the frequency of dust occurrence to the frequency of strong winds, to represent the status of aeolian desertification. We evaluted aeolian desertification procesess at one site (Abaga-Qi) in the Xilingol grassland during the period 1974–2013. DOR values during 2001–2013 were notably higher than those in 1974–2000, indicating that land surface conditions became vulnerable to wind erosion in recent years. However, the DOR values trended lower from 2001 to 2013, corresponding to periods in which restoration projects were implemented aimed at combating desertification in China. To understand the mechanism(s) underlying aeolian desertification after the implementation of restoration projects, we conducted multiple regression analysis of climatic variables (precipitation and temperature) and an anthropogenic variable (livestock number) on recent variations (2001–2013) in aeolian desertification. Stepwise multiple regression results indicate that the recent decline in DOR values was associated with abundant precipitation and low temperature during summer of the previous year and a small livestock population at the end of the previous year. Livestock reduction made the greatest contribution. Our results suggest that aeolian desertification can be effectively reversed by reducing the number of livestock in the Xilingol grassland.

# Influences of land surface conditions and human activities on dust events in Inner Mongolian grasslands, China

*Mei Yong[1], Masato Shinoda[2], Nandintsetseg Banzragch[2]

1. Inner Mongolia normal university, 2. Nagoya university

Aeolian processes in temperate grasslands (TGs) are unique in that the plant growth–decay cycle, soil moisture, and land-use interactivity affect seasonal and interannual variations of dust events. When compared with Mongolian TGs, Inner Mongolian TGs are characterized by unique land-uses (settle grazing and grass mowing). Since 2003, to prevent desertification and dust storms, land-uses have been controlled by the grassland protection law. We used process-based ecosystem (DAYCENT) and statistical models as well as dust event observations during March–June 1981–2015 to (1) identify critical land surface factors that control dust emission (soil moisture and vegetation components; live grasses, standing dead grasses and litter) in Inner Mongolian steppe and desert steppe sites, and (2) estimate the impacts of the controlled land-use law on dust events. The DAYCENT model realistically simulated dynamics of the vegetation components and soil moisture that were captured by observations (2005–2015). Results showed that at both sites, the spring dust events had a similar amplitude of significant correlation with wind speed and a combination of all the surface factors that retained anomalies (memory) of the preceding year. Among the surface factors, vegetation was a critical dust suppressing factor in Inner Mongolian TGs, similar to Mongolian TGs. Importantly, in the desert steppe, the standing dead grasses had the strongest memory and simultaneous significant correlation with the dust events, while no significant correlations were found in the steppe. This suggests that in the steppe, intensive grazing and mowing resulted in smaller dead grasses and a negligible effect on dust events. Moreover, simulations of dust events under controlled land-use (light grazing) and uncontrolled conditions (heavy grazing) showed that since 2003, the grassland protection law resulted in reduced dust events by 25% and 40% in the steppe and desert steppe, respectively.

## [M-IS09] dust

convener:Ishizuka Masahide(Kagawa University), Yasunori Kurosaki(Arid Land Research Center, Tottori University), Thomas Sekiyama(Meteorological Research Institute), Kana Nagashima(Japan Agency for Marine-Earth Science and Technology, Research and Development Center for Global Change)

Mineral dust is generated from the ground surface by strong winds, and it transports long distance over the earth. In the process, cloud formation and absorption and scattering of solar radiation cause weather and climate changes. Also, when deposited in the ocean, feeding nutrients to phytoplankton, promoting photosynthesis, and when deposited on snow and ice causes albedo change. This is known as the yellow dust (Asian dust) phenomenon in Asia region including Japan. In order to understand this, integration in a wide range of academic areas is necessary.
In the emission process, the amount of dust changes greatly depending on the surface condition in dryland area, and in order to know the conditions, it deals with areas such as soil, topography, vegetation, precipitation, desert and soil deterioration. In the transport process, we deal with areas such as weather, atmospheric aerosol, radiation. In the deposition process, we deal with areas such as ocean, snow ice, health to people and livestock. Drying and changes in vegetation also have social scientific aspects such as national policies, management of livestock, and population increase. Dust and sand dunes are common phenomena not only to the Earth but also to other planets such as Mars and Saturn. In this way, it is impossible to understand the dust phenomenon only in one field, it is important for researchers in many areas to discuss and share information through this session, and advance exchange of researchers.

# Study on decadal influencing of the teleconnection pattern EA and SCAND on major atmospheric circulation systems of the northern China dust storms during the past 65 years (1954-2018)

*Gao Tao[1], Mei Yong[2]

1. Inner Mongolia Meteorological Institute, 2. Inner Mongolia Normal University

Frequent cold-air attacks with less precipitation and aired surface conditions are mainly direct causes of more dust storm occurrences over the dust-source-areas during winter-spring season. In this study, the observation records of the horizontal visibility at 65 stations dotted in northern China (35˚-45˚N, 94˚-120˚E) for 65 years (1954-2018) were collected and used to investigate the frequencies of dust storm (DS) and severe dust storm (SDS) events during the term of February-June. As a whole, declining trends were appeared for both DS and SDS during the past several decades. A dust storm frequently occurrence term is confirmed from 1950s to 1970s, with decadal means of 7.1 and 2.5 events for both DS and SDS. From 1980s to 2010s, the DS and SDS decreased significantly with decadal means of 3.8 and 1.1 events, separately. The 1970s is the most frequent dust storm decade, during which 81 DS events have been recorded. Oppositely, the 1990s is the most infrequent decade with totally 25 DS events. Comparing spring precipitation and snow events of the previous winter, the precipitation anomaly of the 1970s is -13.3% and for 1990s, it is 15.9%. Decadal mean of the prior winter snow events are 3.6 and 4.8 respectively for 1970s and 1990s. That means 1970s has less than normal precipitation during winter-spring. The climate was dry. In turn, it had more precipitation during the 1990s, the climate was wet and the dust storm decreased.

By comparing the major atmospheric circulation systems relating to frequent and infrequent dust storm springs, it has been identified that a weak West Pacific subtropical high (WPSH), a strong North Polar vortex (NPV) and a strong and western position East Asian trough (EAT), in general, corresponding to less precipitation and dry climate, and then, a frequent dust storm spring. Contrarily, it is opposite.

Indices of the atmospheric teleconnection pattern EA and SCAND (also named EU1) were issued on the website of the Climate Prediction Center of USA. Influence of these two teleconnection patterns on the major atmospheric circulation systems and dust storms was studied in this work. Analyzed outcomes indicate that the EA has a closely positive connection with the WPSH and the westerly for winter-spring season. A strong WPSH is benefit to the sea vapor transportation for the dust source regions where located in northern China, bring more rainfalls to there. Additionally, a strong westerly over Eurasia confines the extension of the NPV, and the cold air from the Polar decreases, corresponding to an infrequent DS spring. It is opposite when the EA is weak. The SCAND displays a significantly negative relationship with the westerly and a converse variation trend with the DS frequency. The westerly not only has an impact on the NPV, but also affects the EAT as well. The westerly may become weak when the SCAND is strong, at the same term, the meridionality varied big and the polar cold air attacks may increase, lead to more DS weathers. The EAT may becomes strong and moves to more western position while the westerly is weak. This EAT condition is unfavorable to the vapor transferred to the focused area from the East Sea, results in less precipitation and dry climate, DS may increase during the springtime. Conversely, the westerly may become strong when the SCAND is in weak phases. The NPV, in general, is weak and the cold air attacks decrease. The EAT varies weak and move to eastern than normal position, favoring to the vapor transportation and more rainfall moistening the surface soil, the DS may decrease.

# Effects of freeze-thaw and land-surface processes on dust occurrence in the Mongolian desert steppe

*Kaman kong[1], Masato Shinoda[1], Banzragch Nandintsetseg[1,2,3], Yasunori Kurosaki[4]

1. Nagoya Unviserity, 2. Information and Research Institute of Meteorology, Hydrology, and Environment, 3. National University of Mongolia, 4. Tottori University

Dust storms not only cause serious environmental problems, but also influence social and economic activities. They depend on the relationships between erosivity (wind speed) and erodibility (e.g., soil moisture, freeze-thaw cycle, and vegetation). However, in the Mongolian desert steppe (MDS), these relationships have not fully been investigated, particularly the effect of freeze-thaw cycles on dust events. Here, we investigated the impacts of freeze-thaw and land surface processes on dust occurrence at Tsogt-Ovoo in the MDS during 2012–2017. This study uses the saltation number and dust concentration measurements, and modelled land-surface variables by an ecosystem (DAYCENT) model, which was validated with field measurements. Results showed that interannual variations in wind speed and dust concentration were not significantly different within springs (April–June) of 2012–2017. However, large interannual variability of saltation events observed at the same time. Saltation events were high in springs of 2012 and 2015 because small threshold wind speed that was related to dry soil and less vegetation, which were, in turn, the result of less precipitation in the preceding summer. Additionally, saltation events tended to occur after near-surface soil temperature rose above the freezing point. This freeze-thaw process likely plays an important role in increasing the susceptibility of soil to erosion.

# Mineral particles suspending in the surface waters of the North Pacific and its marginal seas –atmospheric dust deposition as investigated from seawater analysis

*Yoko Iwamoto[1], Mitsuo Uematsu[2]

1. Graduate School of Biosphere Science, Hiroshima University, 2. Atmosphere and Ocean Research Institute, the University of Tokyo

Suspended particulate matter (SPM) in the ocean consists of a variety of components from both biogenic and crustal sources. The mineral particles from crustal sources are brought to the oceans mainly via river run-off and atmospheric deposition. The atmospheric pathway becomes important especially in the open ocean far from the continents. In addition, atmospheric dust contains iron which can be used as nutrients for marine phytoplankton. Therefore, it is important to understand the size and chemical characteristics of the mineral particles that deposit to the ocean in understanding the linkage between atmosphere and marine ecosystem.

This study presents the properties of mineral particles in the SPM collected in the North Pacific and its marginal seas (the Sea of Okhotsk, the Bering Sea and the Chukchi Sea) based on bulk and individual particle analyses.

The mineral particles were distributed ubiquitously in the North Pacific even during summer when the influence of atmospheric Asian dust transport is small. Their relative abundances in the total SPM was 5 to15% by number and about 2 to 7% by volume. The size distribution of the suspended mineral particles in the SPM was similar to that of the atmospheric dust aerosols, indicating that mineral dust of background level occurs in the marine boundary layer even in summer.

The shipboard observation during a Kosa (Asian dust) season showed that atmoepheric dust settled onto the ocean surface, and resulted in increase in the mineral particles' concentration four to five times in surface water of the western subarctic North Pacific. The deposition flux of atmospheric dust into the ocean surface by a Kosa-event was calculated to be 270 mg $m^{-2}$ $event^{-1}$. The dissolve iron flux at the Kosa-event was also estimated at 130-230 $\mu$g $m^{-2}$ $event^{-1}$, and is found to have a potential to supply enough iron to lead the phytoplankton bloom in HNLC waters. This result confirms that a sporadic supply of dissolved iron that leading to phytoplankton bloom can naturally occur in the western subarctic North Pacific.

# Seasonal change of the Asian dust provenance within the Canadian ice core estimated from cathodoluminescence spectra of single quartz grains

*Kana Nagashima[1], Kumiko Goto-Azuma[2]

1. Japan Agency for Marine-Earth Science and Technology, Research and Development Center for Global Change, 2. National Institute of Polar Research

Mineral dust is considered to have a great effect on the natural environment of the Earth by altering the global radiative balance, cloud properties (Intergovernmental Panel on Climate Change (IPCC) AR5, 2014) and ocean primary productivity (Maher et al., 2010). At present, a large amount of aeolian dust is emitted from the huge dry areas of East Asia, typically the Taklimakan Desert in western China and Gobi in southern Mongolia and northern China (Sun et al., 2001). The dust particles derived from such deserts are transported to China, Korea, Japan, and the northwestern North Pacific by the westerlies and is sometimes transported more than one full circuit around the globe through the westerly jet (Uno et al., 2009). Hence, the Asian dust affects climate/environments throughout the northern hemisphere. For the further investigation and evaluation of Asian dust impacts on global environment, it is critical to determine the amount and main sources of Asian dust transported over long distances.
Ice cores from Mt. Logan (60N, 141E), Canada, are the ideal recorder of seasonal to decadal-scale changes in dust transport over a long distance (Zdanowicz et al., 2006). Hence here we examine the past seasonal change of dust provenance using an ice core from King col (4135m above sea level) at Mt. Logan by utilizing a new provenance-tracing method, cathodoluminescence (CL) spectral analysis of “single” quartz grains (Nagashima et al., 2017). CL spectroscopy can detect crystal-chemical features in quartz such as impurities and intrinsic imperfections that depend on the conditions affecting quartz from its formation onward, which are useful to identify the quartz from two major Asian deserts, the Taklimakan Desert and Mongolian Gobi. The CL analysis was performed on quartz grains within ice core samples corresponding to 1941, 1951, 1967, 1983, and 1986 A.D. (6–7 samples/year). We found most quartz grains from ice core samples show two CL emission bands in red and blue regions, which were deconvolved to at most five emission components, each of which represents a specific defect due to an impurity or imperfection. The statistical analysis using the ratios of emission components exhibits ratios of clusters of each sample, which are mostly between those of quartz from Taklimakan Desert and Mongolian Gobi, suggesting the mixing of quartz from the two deserts. Furthermore, the cluster compositions of ice core samples suggest seasonal and possible decadal-scale changes of the dust provenance transported over a long distance, of which detail will discuss in the presentation.

Dryland area is enlarging and its environment is changing in the globe. Mineral dust is generated from such dry area and causes various problems such as health damage which is caused by well-known air pollutants such as $PM_{2.5}$, traffics stoppage due to low visibility, and a reduction of agricultural productivity due to loss of nitrogen and phosphorus contained in surface soil. The nutrients and soil minerals make algal blooms in ocean and its photosynthesis makes $CO_2$ absorption from atmosphere. Mineral dust itself acts as an ice nuclei primarily and effects cloud formation, and absorbs and/or diffuses solar and infrared radiations secondary. In addition, it transports biological gene of microorganism and bacteria attached to the soil surfaces. Like this, mineral dust gives large influences for various fields and is important to understand the natural and social changes.

This study focuses on the emission process of dust, especially, soil crust effect on the saltation and dust emission. Soil crust is one of the ground surface conditions, which affects dust generation largely due to strong soil aggregation. But it is well not understood how much soil crust effects saltation and dust emission amount yet. To clarify this, wind tunnel experiment was conducted in a laboratory of Forestry and Forest Products Research Institute, Tsukaba, Japan. Toyoura sand is used as saltating grains and Mongol soil which has both finer and larger particles (Loam) sampled at Tsogt-Ovoo in the northern Gobi Desert is used as a target soil. The water ratio is set 0-15 % for making artificial soil crust.

PTV (Particle Tracking Velocimetry) analysis by using a high-speed camera (30000 fps) shows the reduction of kinetic energy of saltation particle after it hits the ground surface. The crusted surface soil was not much erodible under the higher water ratio. Dust concentration decreases under the crusted condition. These findings are fundamental for elucidating the process of dust emission and will link to improve dust forecasting accuracy by atmospheric models.

# Effect of stone on sand saltation in Tsogt-Ovoo, Mongolia: Observation and Model simulation

*Batjargal Buyantogtokh[1], Yasunori Kurosaki[1], Masahide Ishizuka[2], Tsuyoshi Sekiyama[3]

1. Arid Land Research Center, Tottori University, 2. Faculty of Engineering and Design, Kagawa University, 3. Japan Meteorological Agency, Meteorological Research Institute

Non-erodible elements (i.e., pebble, stone, bedrock, vegetation, dead leaf) are key factors to control wind erosion. The non-erodible elements can protect the underlining surface by absorbing the wind momentum, thus increasing the threshold velocity for sand movement on the intervening surface (Tan et al., 2013). According to Haustein et al. (2015), however, all results of box models, which are 0-dimensional dust emission models installing schemes of Marticorena and Bergametti (1995), Shao (2004), and Alfero and Gomes (2001), overestimate the horizontal sand flux due to lack of consideration in the surface coverage by the non-erodible elements. This suggests current global and regional dust models don’ t consider the effects of them well. We will show observation and box models result of sand saltation at different land surface characteristics at Tsogt-Ovoo located in a northern part of the Gobi Desert, Mongolia.

An analysis of meteorological observatory data showed that the frequency of dust storms was the highest at Tsogt-Ovoo in East Asia (Kurosaki and Mikami, 2007). There is a topographic depression, whose sizes are about 10 km and 20 km in NE-SW and NW-SE directions, respectively. Such topography makes spatially different soil and land surface characteristics such as bedrock coverage, stone coverage, parent soil particle size and vegetation coverage. We made a measurement of sand saltation and wind speed at 7 sites during 31 April –5 May 2018. We installed ud-101 (Udo 2009; Sherman 2011) at 0.1 m height for sand saltation and anemometer (S-WSA-M003, Onset Company) at 1.7 m height at each site.

Our observation shows the sand saltation counts and threshold wind speed differs very much site-by-site due to differences in non-erodible elements like stone, dead leaf and soil crust. Even though wind speed is high, small counts of sand saltation were observed at Sub18A and Sub18C sites which are highly covered by bedrock and stone, whose coverages (hereafter, BSC) are 76.9% and 50.6%, respectively. Our sand saltation box model, which is based on Shao's dust emission scheme, also showed small sand flux under such high BSC like those sites. Big sand saltation counts were observed at Main and Sub14B sites, those stone coverages are 18.2 % and 17.6 %, respectively. The threshold wind speeds of sand flux with stone effect are similar with observation in the result of model. The observation and model simulations showed that BSC effect is a major controlling factor for sand saltation counts and flux for Sub18A, Sub18C, Main and Sub14B sites.
At Sub14A and Sub18D sites, even though stone coverages are small (2.1% and 6.4%, respectively), our observations show very small sand saltation counts even under strong wind conditions. These results suggest a hypothesis that other non-erodible elements such as standing dead leaves and soil crusts majorly suppress sand saltation, though we could find them by our eyes but we don't have their quantitative data. Our simulations show sand saltation fluxes increase with wind speed. One reason of it is the BSC effect doesn't work very much due to small stone coverages at sites. Another possible reason is effects of other non-erodible elements such as standing dead leaves and soil crusts are not installed in our model but they work very much in reality.

## [M-IS12] tsunami deposit

convener:Takashi Chiba(Faculty of Bioresource Sciences, Akita Prefectural University), Tetsuya Shinozaki(Center for Research in Isotopes and Environmental Dynamics (CRiED), University of Tsukuba), Daisuke Ishimura(Department of Geography, Tokyo Metropolitan University), Chairperson:Daisuke Ishimura(Department of Geography, Tokyo Metropolitan University)

The 2011 off the Pacific coast of Tohoku Earthquake and tsunami have an influence on the development of tsunami deposit research. After the tsunami, a lot of findings have been reported on various research fields. However, identification criteria of the tsunami deposit are not yet established. Moreover, it is still uncertain how to use the tsunami deposit in the risk assessment. In this session, we welcome researches from all aspect of sedimentary records of modern and paleo tsunamis both onshore and offshore, and numerical and experimental modeling studies for risk assessment. In addition, we also welcome other event deposits, such as flooding and storm surge, that they are considered to be important for discrimination of tsunami deposit.

# Geological Record of Tsunamis and Storms Influenced by Relative Sea-Level Change, Southern Hidaka Coast, Hokkaido, Japan.

*RYO NAKANISHI[1], Satoshi Okamura[1,2], Tsumoru Sagayama[3], Yusuke Yokoyama[4], Yosuke Miyairi[4]

1. Hokkaido Edu. Univ., 2. Hokkaido Soil Res. Co-op., 3. HRCG, 4. Univ. Tokyo

In the last a few hundred years, southern Hidaka coast in Hokkaido was suffered from large tsunamis by subduction of the Pacific Plate along the southern Kuril Trench. 2003 Tokachi-oki earthquake left traces at maximum altitude 4 m in Hyakunin Hama in the eastern part of Cape Erimo, also maximum altitude 3 m in western part of Cape Erimo. It was caused by the edge wave propagating from Cape Erimo along the west coast of the Hidaka area (Tanioka et al., 2004) . On the other hand, geological studies in eastern part of Hokkaido revealed that intervals of outsized tsunamis by Kuril subduction inferred average nearly 400 years but range widely from about 100 to about 800 years (Sawai et al., 2009), and these probably reached western part of Cape Erimo. However, the only 17th century tsunami deposits reported in the western part of Cape Erimo are said to be unknown the trigger. Thus, This study conducted Simple boring survey to reveal tsunamis cycle and age of emergence in Northern Hidaka coast. Consequently, we compared western part and eastern part of Cape Erimo about scale of tsunamis, also examined the relationship with the paleo environment.

As a result of boring survey by a geoslicer in the peat swamp behind the beach, we found three volcanic ash layers and nine event sand layers in the humus and the peat. In order from the top, it was AD 1663 Us-b tephra, AD946 B-Tm tephra, two sand layer (Us1, U1), 2700-2500BP Ta-c2 tephra, seven sand layer (U2-8). Peat layers change to remarkably undegraded humus from the U4 layer downward. The number of sand layers decreased landward, finally being zero at about 500 m from coastline. U1-8 sand layers were similar in particle size and gray color to beach sands, and sorting very well. These common characteristics were from inverse to normal grading and contain rip-up clasts. Also, grain size and thickness were inverse correlation with distance from coastline, but no correlation with distance from river. Because the diatom assemblages from event sand layers contained marine, brackish and terrestrial species in contrast peat occupied by freshwater species, these turn out to derive from seaward. Conversely, the Us1 layer had limited distribution several tens meter from paleo beach ridge, the thickness changed from 20 cm to very thin at only 20m landward. Grain size of the Us1 layer was fine - very coarse, including Φ1cm flat gravel. The Us1 layer can be supposedly distinguished from U1-8 layers from these features similar to storm deposits. A result of measuring ages for the time of sand deposition by AMS radiocarbon dating, we obtained the age of about 5500BP from under the U8 layer, about 2000BP from above the U1 layer. The average recurrence intervals of event is nearly 400 years, the interval is sometime shorter (50 years) or longer (550 years) than the average, so the U1-8 event layers are probably tsunami deposits by subduction earthquakes like seen in eastern Hokkaido.

The U7 layer is the thickest in all sand layers, thickness of event layers tend to become thinner as the upper stratigraphy. The U7 layer is most widely distributed inland, it deposited in about 4900BP, when high-standard period in eastern Hokkaido (Dura et al., 2016). It was found from the result of continuous chemical analysis of peat samples in the vertical direction that Fe and S increased as deeper at the depth deeper than the U5 layer (about 3800BP). In this site, considering the humus layer shows undegraded under the U4 layer, this chemical characteristic imply that the peat was reductive and the sea-level was high at that time. We inferred that tsunamis inundated over the sand ridge in this area only for 5500BP to

The Kuril subduction zone is one of the most frequent earthquakes in Japan. There are many undeveloped plains in this area, unspoiled nature is left, and many barrier coasts and tsunami deposits due to the giant earthquake (17th century type) repeatedly generated at 400 to 500 years intervals can be widely observed around this area. However, the relationship between the timing of both is not clear yet. Especially two tsunami deposits, which are occurred in the 17th century, can be observed in many places around the eastern Pacific coast of Hokkaido. On the other hand, there are many active barrier systems around the coast of Nemuro Strait and Konsen ~ Tokachi coast, and it has recently become evident that a 17th century giant earthquake occurred as a trigger. Our research group examined the relationship between the occurence timing of these uprifting barrier systems and the 17th century tsunami in several areas in detail, and some interesting facts have been found, so we will report the outline in this meeting.

This work was supported by JSPS KAKENHI Grant Number 18K03767.

# Coastal landform changes and Washover deposits due to high waves generated by anatmospheric low-pressure system in June 2016 at Horokayanto, Hokkaido, Japan

*Takashi Chiba[1], Yuichi Nishimura[2]

1. Faculty of Bioresource Sciences, Akita Prefectural University, 2. Graduate School of Science, Hokkaido University

The lake bottom of Horokayanto, one of the lagoons in eastern Hokkaido, Japan, was partly exposed as a result of sandbar breaching during severe weather in June 2016. The mean lake level fell from approximately 3.1 to 1.2 m above TP, which is equivalent to the height of the MHHTL in the Tokachi area by the breached sandbar. Some erosion forms were recognized in the southwestern breached point of the sandbar. However, the washover fan formed by the high waves from the seaward to the lakeward sides was recognized in the northeastern part of the sandbar. Moreover, characteristic diatom assemblages resulting from coastal environmental changes were also recognized around the lake. The high-tide-level indicator *Pseudopodosira kosugii* was recognized in the emerged lake bottom assemblage together with freshwater–brackish and brackish–marine species. Water pressure or moisture changes caused by either the emergence, the changes in light quantum density and ultraviolet rays, the changes in water quality such as salinity and pH, or a mixture of these factors, may have influenced the increase in *P. kosugii*. Reworked Neogene marine diatoms such as *Denticulopsis* spp. that were presumably derived from nearby Neogene basement rocks were also detected–albeit infrequently–in the modern assemblages. The fossil diatoms were eroded by current inflows into the lake during the severe weather. During the period of emergence, seawater may have been transported into Horokayanto Lagoon by high waves generated by an atmospheric low-pressure system. However, the height of the waves was below that of the central part of the sandbar.

Hokkaido Museum, 5. Faculty of Bioresource Sciences, Akita Prefectural University, 6. Hokkaido Education University, 7. Shikotan Geophysical Observatory, 8. Institute of Marine Geology and Geophysics, Russian Academy of Sciences, 9. Japan Meteorological Agency, 10. Geospatial Information Authority of Japan, 11. Ministry of Education, Culture, Sports, Science and Technology

Historical and prehistorical tsunami deposits in Kunashir Island, the Northern Territories, were studied as parts of visa-free exchange programs of Japan and Russia. The reconnaissance survey was conducted for 30 days for 4 years from 2015 to 2018, and 105 sites in the ca. 50 km area along the Pacific coastline was examined. As a result, it was confirmed that the sand layer, which can be regarded as a trace of the 1994 Hokkaido Toho-Oki tsunami is well preserved near the surface layer in the eastern lowland from Furukamappu to Ruyobetsu. The 1994 tsunami run-up, estimated from the distribution of the deposits, is 50-150 m from the coast and 3-4 m in height. Furthermore, the chemical composition of the volcanic glass was analyzed for as many as 30 volcanic tephras. Examining the results together with the stratigraphy, it was found that known tephra from volcanoes of Hokkaido, such as Ko-c1 (1856), Ta-a (1739), Ko-c2 (1694), Ta-b (1667), Ma-b (10th Century) and Ta-c (2,700 BP) are deposited at multiple sites on the island. With these volcanic deposits as the key layer, we could estimate the age of the candidates of tsunami deposits. For example, in the wetland of Furukamappu, there is one event in the 17th and 10th centuries, and two in the 10th century and 2700 years ago. It is inferred that the large tsunami that would leave the deposit in Kunashiri occurred at a frequency of once in 1000 years.

# Deposit-based assessment of tsunami size: example from Nankai-Trough earthquakes

*Daisuke Sugawara[1], Kentaro Imai[2], Shinsuke Okada[3], Takuto Maeda[4]

1. Museum of Natural and Environmental History, Shizuoka, 2. JAMSTEC, 3. Tohoku University, 4. Hirosaki University

Researches on historical documents and geological records, such as tsunami deposits, have clarified the recurrence of the Nankai-Trough earthquakes and tsunamis during the past 6000 years. Magnitudes and source parameters of some historical tsunamigenic earthquakes, such as the 1707 Hoei and 1854 Ansei events, have been examined based on numerical modeling of coseismic crustal deformation and tsunami propagation and inundation. For example, the extent of the rupture area of the Hoei earthquake was revised based on the numerical modeling of tsunami inundation, considering tsunami heights from historical records and tsunami deposits in the Ryujin-ike pond in the eastern coast of Kyushu island (Furumura et al., 2011). The revised rupture area of the Hoei earthquake was extended to the Hyuga-nada, 70 km beyond the previously estimated rupture area.

The magnitude of the presumed largest (Mw=9.0) earthquake which may occur in the Nankai Trough (Disaster Management of Cabinet Office, 2012) is much greater than the size of known historical events. To validate the assumptions of the largest earthquake, information from tsunami deposits, which may record tsunamigenic earthquakes in longer time span, will play an important role. However, most tsunami deposits in the Nankai Trough region have been found from coastal lakes and narrow lowlands. In this region, spatial distribution of tsunami deposits cannot be a good indicator of tsunami inundation. Explorations are needed to correlate spatially-limited data of tsunami deposit with the magnitude information and source parameters of earthquake and tsunami.

In this presentation, deposit-based assessment of the size of earthquake and tsunami will be discussed based on numerical modeling of tsunami and sediment transport in the Ryujin-ike pond. Main interest of the research is that whether or not we can correlate the formation processes, distribution and thickness of tsunami deposit with the source parameters of the tsunami. In addition, results of the modeling will be compared with field observations of the deposits, to discuss the relationship with the historical earthquakes.

Acknowledgement

# Flume experiments for understanding variety of tsunami deposit

*Naofumi Yamaguchi[1]

1. Center for Water Environment Studies, Ibaraki University

Flume experiments, in which sedimentary conditions can be easily controlled, are expected to provide insights into the sedimentary process under tsunami flow. The previous studies using flume experiments have contributed to improvement of numerical models of tsunami sediment transport. By contrast, there is not enough experimental studies to examine sedimentary process in order to improve the identification and interpretation of (paleo) tsunami deposits in geological record. In this presentation, I will summarize previous studies of tsunami deposit using flume experiment, and show the potential for better understanding of sedimentary process of tsunami deposits.

# Inverse modeling of Tsunami deposit using Deep Learning Neural Network

*Rimali Mitra[1], Hajime Naruse[1]

1. Kyoto University, Graduate School of Science

Tsunami is one of the most catastrophic disasters along coastal zones, and tsunami deposits are layers of sediment formed by hydrodynamic activities of tsunami. These event deposits provide clues to estimate the recurrence intervals and relative magnitude of prehistoric tsunamis that serve as a tool for future tsunami hazard evaluation. Towards the quantitative assessment of hydraulic conditions of tsunamis from deposits, this study applies the inverse model using deep learning neural network (DNN) for tsunami deposit. In order to conduct machine learning of DNN, forward model calculation was repeated at random initial flow conditions (e.g. maximum inundation height, flow velocity, concentration, etc.) to produce artificial training data sets which represent depositional characteristics such as thickness and grain-size distribution. The model serves as the modified version of previously proposed FITTNUSS model, which incorporates nonuniform and unsteady transport of suspended sediment and also turbulent mixing. Then, DNN was trained for establishing the inverse model on the basis of artificial data sets. SGD (Stochastic gradient descent) is used as an optimizer for this DNN model. Tests using artificial data sets successfully indicated that the established DNN can reconstruct the original flow conditions from the characteristics of deposits. Finally, the model was applied to natural data sets taken from the 2011 Tohoku-Oki Tsunami deposit. The deep learning neural network showed promising result for natural data sets. Comparing to existing inverse models, deep learning neural network enables the inversion to employ a forward model that requires higher computational costs, and to avoid a local optimum. The further applicability and validation of this method will be checked with other parameters, and natural data set from different field visits in future endeavour.

# Numerical estimation of tsunami size using boulders deposited by the 2011 Tohoku-oki tsunami at Settai, Miyako city, Japan

*Tatsuya Takei[1,4], Kazuhisa Goto[2], Masaki Yamada[3]

1. Department of Earth Sciences, Graduate School of Science, Tohoku University, 2. International Research Institute of Disaster Science (IRIDeS), Tohoku University, 3. Earthquake Research Institute, University of Tokyo, 4. Department of Complexity Science and Engineering, Graduate School of Frontier Sciences, Tokyo University

Tsunami boulders are important geological evidence to understand paleotsunami activity. Previous studies have intended to extract the information about tsunami size from the distribution of tsunami boulders. However, although several numerical methods have been proposed to estimate tsunami size using tsunami boulders, there have been no studies validating the estimated tsunami size by comparing with the actual tsunami size. Also, it is important to consider the methodology of the estimation of tsunami size using boulders. In this study, we estimated local size of the 2011 Tohoku-oki tsunami at Settai, Miyako City, Japan based on the numerical modeling of boulder transport. We seaerch an incident wave condition of sin waves which could explain the distribution of boulders well. We then compared the estimated results with the tsunami size calculated by existing well-validated tsunami source model. As a result of the simulation, we estimated that the tsunami size was ranging from 9 m to 21 m in wave height and from 60 s to 300 s in period at the point of 5200 m offshore of Settai.This range covers the actual tsunami size; so the tsunami size can be estimated from the boulders in Settai. According to the above results, the method that we proposed was effective. On the other hand, we found that assumption of the initial position of boulders are critically important and it should be constrained by multiple information such as topographic condition and composition of the boulders.

# Constraint of the ages of historical tsunami deposits on the Ishinomaki Plain

*Hiroshi Tetsuka[1], Kazuhisa Goto[2], Takashi Ishizawa[1], Daisuke Sugawara[3], Yusuke Yokoyama[4], Yosuke Miyairi[4]

1. Department of Earth Science, Tohoku University, 2. International Research Institute of Disaster Science, Tohoku University, 3. Museum of Natural and Environmental History, Shizuoka, 4. Atmosphere and Ocean Research Institute, University of Tokyo

The research of tsunami deposit has an important role for understanding the paleo-tsunami history. On the Ishinomaki Plain, where the AD 2011 Tohoku-Oki tsunami inundated widely, at least six paleo-event deposits were found by previous studies (Shishikura et al., 2007; Sawai et al., 2012; Takeda et al., 2017). Sawai et al. (2012) correlate the latest three event deposits (Sand K, A, and B) with the tsunamis generated by the AD 1611 Keicho Ohsyu earthquake, the AD 1454 Kyotoku earthquake, and the AD 869 Jogan earthquake, respectively. Among them, the event age of Sand B is well constrained by the To-a tephra of AD 915 and radiocarbon ages, which ensure the validity of correlation with the historical record. However, the event ages of Sands K and A were not well constrained because accurate estimation of these event ages by radiocarbon dating is theoretically difficult. There remains a need to improve the accuracy of these event ages for understanding recurrence interval of tsunamis and comparing with the age of tsunami events in other sites. Therefore, we conducted multi-proxy analyses including radiocarbon dating, and analyses of diatom and pollens for the samples taken from the Ishinomaki Plain and then discuss the age of event deposits formed during the last 700 years.

The field survey was carried out on the coast area of Higashi-Matsushima City, Miyagi Prefecture. Cultivated soil, silt, and peat layers were found in the core samples. In some sites, one or two medium sand layers were found. Diatom analysis, pollen analysis, X-ray CT scan, and radiocarbon dating were conducted for the clearly identified two sand layers. The radiocarbon dating results were calibrated by OxCal Ver. 4.3.2 (Bronk Ramsey, 2009) with IntCal13 (Reimer et al., 2013) and constrained by stratigraphy (Bronk Ramsey, 2008).
Two sand layers (hereafter we call, Sands 1 and 2 for the upper and lower sand layers, respectively) are closely spaced with sandy silt layer of approximately 1–3 cm between them. Two hypotheses can be considered for the formation of these sand layers; they were deposited by different events, or a single event. Eyewitness observation and X-ray CT scan analysis imply that the sandy silt deposits in between these two sand layers contain many sand grains, and clearly different from the peat layer below Sand 2. The radiocarbon dating revealed that the age of sandy silt layer is intermediate between silt above Sand 1 and peat below Sand 2. In addition, sandy silt includes many freshwater diatoms but does not include marine and marine-brackish diatoms; diatom assemblage is clearly different from peat below Sand 2 that contains marine-brackish diatoms but few freshwater diatoms. Thus, sandy silt between Sands 1 and 2 is probably deposited as normal sediment so that Sands 1 and 2 should have been formed by different events.

The ages of Sands 1 and 2 can be constrained as 11 to 408 cal BP and 357 to 538 cal BP ($2\sigma$), respectively. These event ages are consistent with the AD 1611 Keicho Ohsyu earthquake and the AD 1454 Kyotoku earthquake, as interpreted by Sawai et al. (2012). The pollen analysis further shows the extensive increase of *Pinus sp.* and *Cryptomeria sp.* in the sediment above Sand 1. This result can be correlated with the afforestation policy by Sendai Domain after mid-17th century as planting Japanese

©2019. Japan Geoscience Union. All Right Reserved. 

pine and cedar was encouraged by the AD 1621 Sendai domain’ s law (Hanso Date Masamune kensho-kai, 1938). Therefore, Sand 1 has most likely been formed by the AD 1611 tsunami.

# Non-destructive analyzes of sediments to discern tsunami-related mud cap and overlying muds to improve age determination of tsunami deposits

*Takashi Ishizawa[1], Kazuhisa Goto[2], Yusuke Yokoyama[3], Yosuke Miyairi[3]

1. Department of Earth Science, Tohoku University, 2. International Research Institute of Disaster Science, Tohoku University, 3. Atmosphere and Ocean Research Institute, The University of Tokyo

Age of tsunami deposit is usually determined from dating results of sediments above and below the tsunami derived layers. However, determining the upper boundary of tsunami deposit is often difficult, because the top of tsunami deposit is sometimes comprised of mud-dominated sediment (mud cap) which can be indistinguishable from overlying muddy sediment deposited under normal sedimentary condition. This ambiguity may cause serious problem determining true tsunami ages.

Here we present an examples of non-destructive and destructive analyses of core sample taken from Okirai, Iwate prefecture. Our results indicated that X-CT (X-ray Computed Tomography), XRF (X-ray Fluorescence), and grain size analyses were useful to identify tsunami-related mud cap from overlying muds deposited after tsunami events. Since X-CT and XRF analyses are non-destructive analyses, it is highly recommended to conduct these analyses before subsampling of the sediments for further analyses including radiocarbon dating. Such careful sampling for dating will contribute to improve age estimation of tsunami deposits.

# Sedimentological and paleontological studies of storm surge deposits in intertidal mud floor -case study of Ena Bay on Miura Peninsula, Central Japan.

*Akihisa Kitamura[1], yamamoto yuka[1], Takashi Toyofuku[2]

1. Institute of Geosciences, Faculty of Science, Shizuoka University, 2. Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

Storm surges and tsunamis deposits provide essential information for disaster assessments of coastal lowlands in low- and middle-latitude regions and active margins. However, studying these coastal lowland strata is becoming increasingly difficult, particularly in residential regions, due to extensive anthropogenic disturbances. Consequently, the focus of research has had to extend to shallow marine deposits such as bay sediments, although few studies have examined storm surge deposits related to recent storm events. This study identified storm surge deposits within tidal flat sediments in Ena bay, located in the southern coastal area of metropolitan Tokyo, Central Japan. Identification of the deposits was based on a comparison of surveys undertaken before and after Typhoon Lan (lowest pressure of 915 hPa), which struck the area on 23 October 2017. The results indicate that the storm surge deposits are limited to the supratidal and intertidal zones, demonstrating that the distal extent of sand beds deposited by storm surges is less than that of sand beds typically deposited by larger tsunamis.

# Shallow marine tsunami deposits and bioturbation

*Koji Seike[1]

1. Geological Survey of Japan, AIST

The huge tsunami waves induced by the 2011 off the Pacific coast of Tohoku Earthquake severely affected shallow marine ecosystems along the Pacific coast of northeastern Japan. Among shallow marine settings, subtidal seafloor ecosystems composed of fine-grained sediments are the most heavily disturbed by tsunami waves as they are greatly altered by rapid erosion and deposition processes (Seike et al., 2013). In order to discuss preservation potential of the tsunami deposits in relation to sediment mixing by recolonizing benthic animals, we have monitored temporal changes in the sedimentary structures of the tsunami affected area (Seike et al., 2016, 2017a). Tsunami deposits also provide useful information on the nature of bioturbation because there are no pre-existing burrows in the sediments. We revealed the nature of bioturbation such as burrowing depth, substrate-softening effect by echinoid bioturbation on the basis of observations on the 2011 tsunami deposit (Seike et al., 2017b, 2018).

# Discussion of tsunami age estimation using coralline tsunami deposits

*Ryosuke Fujita[1], Kazuhisa Goto[1], Yasufumi Iryu[1], Takashi Ishizawa[1], Yusuke Yokoyama[2], Yosuke Miyairi[2]

1. TOHOKU University, 2. Atmosphere and Ocean Research Institute, the University of Tokyo

To estimate the age of tsunami deposit, we usually do not use the tsunami sediment itself but organic matters in the soil layers above and below the tsunami deposit. However, this method is not suitable to the deposits in subtropical areas with lots of disturbance by vegetation such as Okinawa prefecture. Thus it is necessary to develop a methodology to estimate tsunami age using samples in the tsunami sediments. Also, statistical analysis based on ages of multiple samples is required for estimating the event age using reworked sediments. In this study, we preliminarily performed radiocarbon dating of 12 marine organism samples in the single sandy tsunami deposit layer of Minna Island, Okinawa prefecture.
The dating results tend to focus on 3 age ranges: around A.D. 1000–1200 (Group A, 7 samples), around A.D. 750–1000 (Group B, 3 samples) and around B.C. 1000–700 (Group C, 2 samples). According to the XRD and SEM results, we identified that samples in Groups A and B are relatively fresh, while a sample with great abrasion and the one with less abrasion belong to Group C.
It is highly likely that the age of the tsunami deposit is around A.D. 1000–1200 based on the Group A samples. On the other hand, samples in Group B has as much abrasion as samples in Group A despite the radiocarbon ages are slightly older than the presumed tsunami age. It may indicate that samples in Group B died and deposited on the top of the shallow lagoon in the reef before the tsunami event and are transported by the tsunami toward the island. Samples in Group C, which died at significantly older time than the presumed tsunami, might have been transported from the coast or reef and redeposited inland by the tsunami.
Our results suggest that if we can select appropriate samples for radiocarbon dating, it is possible to estimate the appropriate tsunami age even by the reworked sediments. We will further discuss the method of sample selection for dating and statistical analysis.

# Identification method of event deposits caused by natural hazards

*Takumi Yoshii[1], Shiro Tanaka[1], Yuki Ito[1], Takaomi Hamada[1], Masafumi Matsuyama[1]

1. Central Research Institute of Electric Power Industry

Geological survey of event deposits can be a powerful technique for unveiling the history of natural hazards. For example, many unrecorded tsunamis have been investigated by utilizing tsunami deposits. Although the identification criteria for tsunami deposits have been developed, the criteria for other hazards such as high tide, storm, and flood were not fully discussed. The identification method of event deposits for multiple hazards is needed for disaster planning.

We present the identification method of event deposits which can take account of uncertainties of geological information and scale of natural hazards. First, we classified the natural hazards which can make event deposits on land based on their scales and characteristics. Then, we organized sedimentary, geochemical, paleontological survey items by information that we can retrieve from event deposits. We evaluated uncertainties of geological information by assuming the probability distributions for each information. The probabilities of event deposits being made by each natural hazard were presented with the uncertainties. In the presentation, we will show some examples of this identification method and discuss its effectiveness compared with the existing identification methods.

# Investigation of event deposits for construction of tsunami deposit discriminating method

*Shiro Tanaka[1], Takumi Yoshii[1], Yasuto Hirata[1], Takaomi Hamada[1], Masafumi Matsuyama[1], Yuki Ito[1]

1. Central Research Institute of Electric Power Industry

In order to establish a method to certify tsunami deposit, we investigated event deposits not due to the tsunami to be compared. Targets of survey are debris flow deposits due to torrential rains in Chugoku region in July 2018 and storm deposits due to September No.21 typhoon in Kansai region. Major survey points are debris flow generated at the slope facing the Hiroshima International University, debris flow generated behind JR Mizushiri Station, and debris flow generated on the upstream slope of JR Yano station in Hiroshima Prefecture. Debris flow deposits are distinguishable from tsunami deposits since they are mainly composed of huge rock masses near the source. On the other hand, at the end of the debris flow, it becomes a deposit having a layer structure mainly composed of sand size particles. Therefore, in this survey, we investigated and sampled deposits at the end of the debris flows. Surveys of storm surge deposits were conducted at Ashiyahama Beach and Omaehama Park in Hyogo Prefecture and at Nishikinohama Beach in Osaka Prefecture. The survey was conducted about 10 days after the storm surge occurrence, it was difficult to collect storm deposits at the Ashiyahama Beach and the Omaehama Park, but deposits possibly formed by storm surge could be collected at the Nishikinohama Beach. In the presentation, we will introduce mainly the particle size distribution of these deposits.

Keywords: tsunami deposit, debris flow deposit, storm surge deposit

# Lateral variation of mud clasts in onshore tsunami deposits

*Yasuhiro Takashimizu[1], Daichi Ito

1. Niigata University

The lower part of the 2011 Tohoku-oki tsunami deposits in the region of Odaka in the Minami-Soma city, Japan well contains many mud clasts. This study focused on the features of mud clasts taken from two sites: the Z07 site which is 760 m from the coast and the T07 site which is 1140 m from the coast. Sedimentary analyses of both mud clast layers were conducted and lateral variations in the mud clasts were examined. The mud clast section of site T07 was composed of one unit, while site Z07 was composed of three units, which were units 1, 2, and 3 in ascending order.
The basal surface of the mud clast section of the site Z07 sample was generally flat and inclined slightly seawards. It displayed small and circular-shaped reliefs. However, the surface of the site T07 sample displayed a strongly irregular surface with clear reliefs of approximately 5 cm in depth.
The median grain size of the mud clasts of site T07 was -2.9$\phi$ and the mud clast grain sizes of Z07 were -1.7$\phi$, -2.5$\phi$, and 2.6$\phi$ for units 1, 2 and 3, respectively. The median grain size of the mud clasts of T07 was -2.9$\phi$ and for the mud clasts of Z07 were -1.7$\phi$, -2.5$\phi$, and -2.6$\phi$ for units 1, 2, and 3, respectively. This indicated that the mud clasts of T07 were coarser than the Z07 sample. Conversely, the roundness parameter ($R$) of site T07 was 0.74 and for site Z07 it was 0.74, 0.78, and 0.74 for units 1, 2, and 3, respectively. There were no clear differences between those units, although unit 2 of site Z07 displayed a slightly higher value. Moreover, the relationship between grain size and roundness did not show a clear correlation. From the results of the sedimentary analyses, it was confirmed that mud clasts were not fined and abraded under the tsunami inflow at sites Z07 and T07. The inflow at site T07 had a more strongly eroded ground surface than site Z07.

# Examination of model validity and sensitivity of tsunami sediment transport modeling using the 2011 Tohoku tsunami deposits in Iwate, Miyagi, and Fukushima Prefectures

*Satoshi Kusumoto[1], Aditya Gusman[2], Kenji Satake[1]

1. Earthquake Research Institute, the Univ. of Tokyo, 2. GNS Science

Sediment transport numerical models due to tsunami are continuously developed (e.g., Takahashi et al., 1999; 2011; Gusman et al., 2012; 2018). However, there are only few studies evaluating the tsunami sediment transport model validity and sensitivity. In this study, to examine the model validity and sensitivity of tsunami sediment transport simulation, we applied it to the 2011 Tohoku tsunami deposits at Numanohama marsh in Iwate Prefecture, Sendai plain in Miyagi Prefecture, and Idagawa lowland in Fukushima Prefecture.

One-dimensional sediment transport simulations with a single grain size and multiple grain sizes were used in this study. To consider the multiple-sized sediment transport, three representative diameters were selected based on a grain size distribution measured from tsunami deposits. The calculated sediment thickness for multiple grain sizes was defined as the sum of the computed sediment thickness for each single grain size with an assumption that the interaction between different particles is negligible. To examine the model sensitivity, a total of 11 tsunami source scenarios (Models 1 to 11) were also evaluated by modified Satake *et al*. (2013).

For Idagawa lowland and Sendai plain, the calculated results for a single grain size were much thinner than the observation. By considering the multiple grain sizes, the results computed from previously estimated models (Models 1 and 2) agreed with the observation, whereas the other models were underestimated or overestimated the observation. For Numanohama marsh, the agreement indexes for simulation using a single grain size was better than that for simulation using multiple grain sizes. This is probably because the 2011 Tohoku tsunami deposit in Numanohama marsh was generally coarser than those in Idagawa lowland and Sendai plain.

Our results show that the sediment transport modeling has a certain validity. Additionally, it is more effective and has higher sensitivity to constrain tsunami source model, than the technique that compares the maximum extent of tsunami deposit with the computed tsunami inundation distance (e.g., Satake *et al*., 2008; Namegaya *et al*., 2010; Namegaya and Satake, 2014). We are planning to further verify for the application to paleo-tsunami deposits.

Keywords: tsunami deposit, sediment transport modeling, 2011 Tohoku earthquake

# Paleotsunami History in Hachinohe, Aomori Prefecture, northern Japan

*Erick Velasco R.[1], Kazuhisa Goto[2], Takahiro Shinohara[1], Daisuke Sugawara[3], Yuichi Nishimura[4], Takashi Chiba[5]

1. Earth Science Department, Graduate Faculty of Science, Tohoku Univ., 2. International Research Institute of Disaster Science (IRIDeS), Tohoku Univ., 3. Museum of Natural and Environmental History, Shizuoka, 4. Graduate School of Science, Hokkaido Univ., 5. Faculty of Bioresource Sciences, Akita Prefectural Univ.

Along the history, the Pacific coast of the Tohoku region has been characterized for facing a vast number of tsunamis associated with the highly active subduction of the Japan Trench. Most of the paleotsunami research has been focused on the south and central third of the Pacific coast of Tohoku, while in the northern third the number of this kind of studies is reduced; on the other hand, on the Pacific coast of Hokkaido paleotsunami research has been conducted to establish the recurrence linked to the Kuril trench (Minoura et al., 2013; Chagué-Goff et al., 2017; Inoue et al., 2017; Sawai, 2017). In Hachinohe, this type of research has not been done, being the results of Inoue et al., 2017 the closest at just 60 km southeastward and where the tsunami heights of the 2011 event were similar (Haraguchi & Iwamatsu, 2011). Because of this paleotsunami studies in Hachinohe are of enormous importance since its position could show tsunami activity related to both Kuril and Pacific trenches and its junction, where large tsunamigenic earthquakes have not been historically registered, hence, being this the primary objective of the present research.

The study site is located on a marine terrace surface elevated between 5-10 MAMSL, on the Kamikita coastal plain (Miyauchi, 1985) and 1.2 km inland from the present shoreline; at the same time, this surface is positioned between the Oirase and Gonohe rivers. We have identified eight sand layers, interbedded with mud and occasional tephra layers. Based on tephra analysis, some of them were possible to confirm as the To-a and To-cu tephra at the top and bottom of the sequence, respectively, giving a range of 6 thousand years of geological history, while the last 1000 years has been apparently eroded, removed or disturbed by human activity. To-a tephra layer contained many diatoms, which implies a water flow or shallow water body as deposition environment. Soils from the top of the section.

The stratigraphic correlation shows that four of the eight sand layers can be well traced landward, and grain analysis shows upward and landward fining. Diatom analysis reveals the presence of marine spices in some sand layers, on the other hand, freshwater and reworked freshwater extinct species were found in the uppermost sand layer (under To-a), suggesting a freshwater inundation event as a genetical source for that. CT number profiles (Hounsfield Units) evidence density changes related to lithological variations between the sand and mud layers. Moreover, XRF core scanner (ITRAX) shows that most of the sand layers are strongly related to a marine origin and exposes concentration of Ti that could be related to heavy minerals concentration and, in consequence, suggesting a sedimentary environment of high energy. Therefore, described evidence suggest a marine origin to the seven sand sheets.

In order to clarify the origin of the sand layers, we performed the numerical simulation to differentiate tsunami sands from storm sands proposed by Watanabe et al. (2018), by comparing wave penetration capacity for each phenomenon; the calculation showed that the only way to carry marine sediments on such further inland is with a tsunami event, if we assume present topography.

# Characteristics of event deposits and their source in Sekine-hama, Mutsu city, Aomori prefecture

*Daisuke Ishimura[1], Kaori Aoki[2]

1. Department of Geography, Tokyo Metropolitan University, 2. Research Center for Volcanic Hazards and Their Mitigation, Tokyo Metropolitan University

Tsunami deposit research is progressing in Japan after the 2011 Tohoku-oki earthquake. Especially, along the Pacific coast in the Tohoku region, many event deposits related with paleo-tsunamis were found by geological surveys. Their survey sites were concentrated from the Sanriku coast to Sendai plain (Sawai et al., 2007; Shishikura et al., 2007; Ishimura and Miyauchi, 2015, 2017; Goto et al., 2015; Inoue et al., 2017; Takada et al., 2016) and, but the number of surveys in the northern part of the Sanriku coast and southern part of the Sendai plain is small due to the limitation of the appropriate site for tsunami deposit research. This study reports the event deposits found at Sekinehama, Mutsu city, Aomori prefecture, which is the northernmost part of the Pacific coast of Honshu Island.

Our study site, Sekinehama, is located between Omazaki and Shiriyazaki and late Pleistocene marine terraces and sand dune were distributed near the coast. In the 2011 Tohoku-oki earthquake, tsunami runup height of 2 to 6 m was reported (The 2011 Tohoku Earthquake Tsunami Joint Survey (TTJS) Group (http://www.coastal.jp/ttjt/)). The outcrop is exposed about 50 m far from coastline and its height is 2 m. Sampled event deposits were used for grain size analysis. Moreover, we conducted radiocarbon dating (five samples) and tephra analysis (one sample).

As a result, we found 18 sandy event deposits interbedded within the soil, marsh, and marine sediments. One of them is the Baegdusan-Tomakomai tephra (AD946; Oppenheimer et al., 2017) including a small number of volcanic glass shards originating in Towada-a tephra (AD915; Machida and Arai, 2003). We estimated the origin of sands in event deposits by comparing with the grain size distribution of modern beach and sand dune sediments, resulted in that 14 event deposits are composed of beach sands. Thus, the source of these 14 event deposits is beach sediments and this indicates that they are transported by a kind of coastal events (e.g., storm, high tide, tsunami). Additionally, some of them showed sedimentary structures (erosional contact and lateral distribution) like tsunami deposits. Thus, we thought that some of them, at least, are tsunami deposits. As for radiocarbon dating, we are measuring now, and thus will show the event ages in our presentation.

# Sedimentary structure and composition of sand blows and sand dikes formed by the 2018 Iburi-Tobu Earthquake, Hokkaido, Japan

*Yuichi Nishimura[1], Takashi Chiba[2]

1. Graduate School of Science, Hokkaido University, 2. Faculty of Bioresource Sciences, Akita Prefectural University

The M6.7 Hokkaido Iburi-Tobu Earthquake of September 6th, 2018, left sand blows and sand dikes result from liquefaction at Tomakomai, Atsuma, and Mukawa. We investigated distribution, shape, sedimentary structure and composition of the new deposits. Sand blows are mainly observed in flat areas on coast and estuaries that have undergone artificial modification. Size of the sand blows varies from several tens of centimeters to several meters in diameter. Each sand blow has a vent or vent system that aligned along a fissure. Sand blows are composed by fine to coast sand, mud, pebbles and various size of pumice. A layered structure is commonly seen in the cross-section. In most of the case, mud, pumice, and sand are deposited in order from the bottom to the top of the deposit. It seems that the mixed layer of sand and pumice in the landfill soil liquefied and sand and pumice separated in the layer. Then they ejected with mud from the accumulated light particles near to the vent. The sand dikes are observed by trenching or by using a handy geo-slicer. Most of the dikes are not straight, they are curved or bent along the boundary of the inhomogeneous medium around them. The width of the dikes vary from 1 mm to 10 cm, and they are filled with sand or pebbles that are the same materials as those came out at the final stage of the ejection. There are dikes that are clogged from the bottom with pumice and coarse sand. In those dikes, the size of the particle filling the dike decreased upward with the clogged location as the boundary. Thus, a feature of sand blow and sand dike can be complicated reflecting the size and density characteristics of the particles constituting the liquefaction layer. The precise description of the new sand blows and sand dikes can provide a better understanding of the liquefaction process and also can be useful for the identification and evaluation of paleo liquefaction deposits.

# Tsunami deposits and tsunami wave source of the southern part of Okushiri Island, Hokkaido

*Atsushi Urabe[1], Yoshihiro Kase[2], Gentaro Kawakami[2], Kenji Nishina[2], Hiromichi Koyasu[2]

1. Research Institute for Natural Hazards and Disaster Recovery, Niigata University, 2. Geological Survey of Hokkaido, Hokkaido Research Organization

In the Okushiri area of South Hokkaido, a tsunami history approximately 3,000 years before is clarified based on an investigation of tsunami deposits. On the other hand, the tsunami history before approximately 3,000 years ago is unclear. In this study, boring exploration was carried out at the Wasabiyachi area for the purpose of analysis of the previous tsunami deposit. As a result, the event sand layer which suggested the beach origin was recognized in twenty horizons after approximately 7,400 years ago. As a result of examined the change of the sedimentary facies etc., in several horizons, this area may uplift at the same time as tsunami.

# Inter-seismic and post-seismic tectonic movements detected during the 17th century earthquake and inferred from diatom analysis in Tokachi area, Hokkaido, Japan

*Takashi Chiba[1], Yuichi Nishimura[2]

1. Faculty of Bioresource Sciences, Akita Prefectural University, 2. Graduate School of Science, Hokkaido University

It has been evidenced from geological records that paleo-earthquakes accompanied by huge tsunamis occurred at least twice in the last millennium at the southern part of the Kuril Trench. The first of the two tsunamis is supposed to have occurred in the 12-13th century, while the other is supposed to have occurred in the 17th century. The paleo-earthquake and successive tsunami of the 17th century have been particularly investigated by previous studies in the area between Akkeshi to Nemuro at the Hokkaido, Japan. However, the crustal movements due to the earthquake in the area at western side of the Akkeshi such as Tokachi area is still unknown. This lack of substantive information is an obstacle for the studies attempting to calculate the actual impact of the paleo-earthquake and estimating its source region. We conducted a survey using a geo-slicer and GPS. We also performed paleo-environmental reconstruction by diatom analysis for the core samples obtained from the Toberi River mouth area, in Tokachi area to derive indicative data about the crustal movements. Since massive Neogene diatomaceous siltstones sediments containing fossil marine diatoms are widely distributed in the study area, we identified the reworked fossil marine species and excluded it from the diatom analysis in the paleo-environmental reconstruction.As a result of the geo-slicer survey, the tsunami deposits from the coast to the inland up to a distance of 1.8 km in a straight line could be detected. Changes in diatom assemblages which are reflective of inter-seismic subsidence and post-seismic uplift caused by the earthquake were also recognized. On the other hand, inferences derived from diatom analysis of geo-slicer core samples showed that the vertical crustal movement estimated by the elevation of the freshwater-brackish boundary of the core sample was maximum 2.3 m. The freshwater-brackish boundary was identified to be extending up to 1.9 km inland at 3.9 m altitude from the seashore, however it was not conspicuous in the inland and above the elevation at more than 4.0 m. This observation confirmed the relationship between the vertical crustal movements generated by the earthquake and the elevation of pale-sea level. Although it is difficult to reconstruct the crustal movements caused by the 12-13th century earthquake, in light of the above observations it can be concluded that they might possibly have risen up to tens of centimeters at least after the earthquake and then began to change to the inter-seismic subsidence.

[J] Poster | M (Multidisciplinary and Interdisciplinary)：M-IS Intersection

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_39

## [M-IS12] tsunami deposit

convener:Takashi Chiba(Faculty of Bioresource Sciences, Akita Prefectural University), Tetsuya Shinozaki(Center for Research in Isotopes and Environmental Dynamics (CRiED), University of Tsukuba), Daisuke Ishimura(Department of Geography, Tokyo Metropolitan University)

The 2011 off the Pacific coast of Tohoku Earthquake and tsunami have an influence on the development of tsunami deposit research. After the tsunami, a lot of findings have been reported on various research fields. However, identification criteria of the tsunami deposit are not yet established. Moreover, it is still uncertain how to use the tsunami deposit in the risk assessment. In this session, we welcome researches from all aspect of sedimentary records of modern and paleo tsunamis both onshore and offshore, and numerical and experimental modeling studies for risk assessment. In addition, we also welcome other event deposits, such as flooding and storm surge, that they are considered to be important for discrimination of tsunami deposit.

# Discussion of tsunami age estimation using coralline tsunami deposits

*Ryosuke Fujita[1], Kazuhisa Goto[1], Yasufumi Iryu[1], Takashi Ishizawa[1], Yusuke Yokoyama[2], Yosuke Miyairi[2]

1. TOHOKU University, 2. Atmosphere and Ocean Research Institute, the University of Tokyo

To estimate the age of tsunami deposit, we usually do not use the tsunami sediment itself but organic matters in the soil layers above and below the tsunami deposit. However, this method is not suitable to the deposits in subtropical areas with lots of disturbance by vegetation such as Okinawa prefecture. Thus it is necessary to develop a methodology to estimate tsunami age using samples in the tsunami sediments. Also, statistical analysis based on ages of multiple samples is required for estimating the event age using reworked sediments. In this study, we preliminarily performed radiocarbon dating of 12 marine organism samples in the single sandy tsunami deposit layer of Minna Island, Okinawa prefecture.
The dating results tend to focus on 3 age ranges: around A.D. 1000–1200 (Group A, 7 samples), around A.D. 750–1000 (Group B, 3 samples) and around B.C. 1000–700 (Group C, 2 samples). According to the XRD and SEM results, we identified that samples in Groups A and B are relatively fresh, while a sample with great abrasion and the one with less abrasion belong to Group C.
It is highly likely that the age of the tsunami deposit is around A.D. 1000–1200 based on the Group A samples. On the other hand, samples in Group B has as much abrasion as samples in Group A despite the radiocarbon ages are slightly older than the presumed tsunami age. It may indicate that samples in Group B died and deposited on the top of the shallow lagoon in the reef before the tsunami event and are transported by the tsunami toward the island. Samples in Group C, which died at significantly older time than the presumed tsunami, might have been transported from the coast or reef and redeposited inland by the tsunami.
Our results suggest that if we can select appropriate samples for radiocarbon dating, it is possible to estimate the appropriate tsunami age even by the reworked sediments. We will further discuss the method of sample selection for dating and statistical analysis.

# Investigation of event deposits for construction of tsunami deposit discriminating method

*Shiro Tanaka[1], Takumi Yoshii[1], Yasuto Hirata[1], Takaomi Hamada[1], Masafumi Matsuyama[1], Yuki Ito[1]

1. Central Research Institute of Electric Power Industry

In order to establish a method to certify tsunami deposit, we investigated event deposits not due to the tsunami to be compared. Targets of survey are debris flow deposits due to torrential rains in Chugoku region in July 2018 and storm deposits due to September No.21 typhoon in Kansai region. Major survey points are debris flow generated at the slope facing the Hiroshima International University, debris flow generated behind JR Mizushiri Station, and debris flow generated on the upstream slope of JR Yano station in Hiroshima Prefecture. Debris flow deposits are distinguishable from tsunami deposits since they are mainly composed of huge rock masses near the source. On the other hand, at the end of the debris flow, it becomes a deposit having a layer structure mainly composed of sand size particles. Therefore, in this survey, we investigated and sampled deposits at the end of the debris flows. Surveys of storm surge deposits were conducted at Ashiyahama Beach and Omaehama Park in Hyogo Prefecture and at Nishikinohama Beach in Osaka Prefecture. The survey was conducted about 10 days after the storm surge occurrence, it was difficult to collect storm deposits at the Ashiyahama Beach and the Omaehama Park, but deposits possibly formed by storm surge could be collected at the Nishikinohama Beach. In the presentation, we will introduce mainly the particle size distribution of these deposits.

Keywords: tsunami deposit, debris flow deposit, storm surge deposit

# Lateral variation of mud clasts in onshore tsunami deposits

*Yasuhiro Takashimizu[1], Daichi Ito

1. Niigata University

The lower part of the 2011 Tohoku-oki tsunami deposits in the region of Odaka in the Minami-Soma city, Japan well contains many mud clasts. This study focused on the features of mud clasts taken from two sites: the Z07 site which is 760 m from the coast and the T07 site which is 1140 m from the coast. Sedimentary analyses of both mud clast layers were conducted and lateral variations in the mud clasts were examined. The mud clast section of site T07 was composed of one unit, while site Z07 was composed of three units, which were units 1, 2, and 3 in ascending order.
The basal surface of the mud clast section of the site Z07 sample was generally flat and inclined slightly seawards. It displayed small and circular-shaped reliefs. However, the surface of the site T07 sample displayed a strongly irregular surface with clear reliefs of approximately 5 cm in depth.
The median grain size of the mud clasts of site T07 was -2.9$\phi$ and the mud clast grain sizes of Z07 were -1.7$\phi$, -2.5$\phi$, and 2.6$\phi$ for units 1, 2 and 3, respectively. The median grain size of the mud clasts of T07 was -2.9$\phi$ and for the mud clasts of Z07 were -1.7$\phi$, -2.5$\phi$, and -2.6$\phi$ for units 1, 2, and 3, respectively. This indicated that the mud clasts of T07 were coarser than the Z07 sample. Conversely, the roundness parameter ($R$) of site T07 was 0.74 and for site Z07 it was 0.74, 0.78, and 0.74 for units 1, 2, and 3, respectively. There were no clear differences between those units, although unit 2 of site Z07 displayed a slightly higher value. Moreover, the relationship between grain size and roundness did not show a clear correlation. From the results of the sedimentary analyses, it was confirmed that mud clasts were not fined and abraded under the tsunami inflow at sites Z07 and T07. The inflow at site T07 had a more strongly eroded ground surface than site Z07.

# Examination of model validity and sensitivity of tsunami sediment transport modeling using the 2011 Tohoku tsunami deposits in Iwate, Miyagi, and Fukushima Prefectures

*Satoshi Kusumoto[1], Aditya Gusman[2], Kenji Satake[1]

1. Earthquake Research Institute, the Univ. of Tokyo, 2. GNS Science

Sediment transport numerical models due to tsunami are continuously developed (e.g., Takahashi et al., 1999; 2011; Gusman et al., 2012; 2018). However, there are only few studies evaluating the tsunami sediment transport model validity and sensitivity. In this study, to examine the model validity and sensitivity of tsunami sediment transport simulation, we applied it to the 2011 Tohoku tsunami deposits at Numanohama marsh in Iwate Prefecture, Sendai plain in Miyagi Prefecture, and Idagawa lowland in Fukushima Prefecture.

One-dimensional sediment transport simulations with a single grain size and multiple grain sizes were used in this study. To consider the multiple-sized sediment transport, three representative diameters were selected based on a grain size distribution measured from tsunami deposits. The calculated sediment thickness for multiple grain sizes was defined as the sum of the computed sediment thickness for each single grain size with an assumption that the interaction between different particles is negligible. To examine the model sensitivity, a total of 11 tsunami source scenarios (Models 1 to 11) were also evaluated by modified Satake *et al*. (2013).

For Idagawa lowland and Sendai plain, the calculated results for a single grain size were much thinner than the observation. By considering the multiple grain sizes, the results computed from previously estimated models (Models 1 and 2) agreed with the observation, whereas the other models were underestimated or overestimated the observation. For Numanohama marsh, the agreement indexes for simulation using a single grain size was better than that for simulation using multiple grain sizes. This is probably because the 2011 Tohoku tsunami deposit in Numanohama marsh was generally coarser than those in Idagawa lowland and Sendai plain.

Our results show that the sediment transport modeling has a certain validity. Additionally, it is more effective and has higher sensitivity to constrain tsunami source model, than the technique that compares the maximum extent of tsunami deposit with the computed tsunami inundation distance (e.g., Satake *et al*., 2008; Namegaya *et al*., 2010; Namegaya and Satake, 2014). We are planning to further verify for the application to paleo-tsunami deposits.

# Paleotsunami History in Hachinohe, Aomori Prefecture, northern Japan

*Erick Velasco R.[1], Kazuhisa Goto[2], Takahiro Shinohara[1], Daisuke Sugawara[3], Yuichi Nishimura[4], Takashi Chiba[5]

1. Earth Science Department, Graduate Faculty of Science, Tohoku Univ., 2. International Research Institute of Disaster Science (IRIDeS), Tohoku Univ., 3. Museum of Natural and Environmental History, Shizuoka, 4. Graduate School of Science, Hokkaido Univ., 5. Faculty of Bioresource Sciences, Akita Prefectural Univ.

Along the history, the Pacific coast of the Tohoku region has been characterized for facing a vast number of tsunamis associated with the highly active subduction of the Japan Trench. Most of the paleotsunami research has been focused on the south and central third of the Pacific coast of Tohoku, while in the northern third the number of this kind of studies is reduced; on the other hand, on the Pacific coast of Hokkaido paleotsunami research has been conducted to establish the recurrence linked to the Kuril trench (Minoura et al., 2013; Chagué-Goff et al., 2017; Inoue et al., 2017; Sawai, 2017). In Hachinohe, this type of research has not been done, being the results of Inoue et al., 2017 the closest at just 60 km southeastward and where the tsunami heights of the 2011 event were similar (Haraguchi & Iwamatsu, 2011). Because of this paleotsunami studies in Hachinohe are of enormous importance since its position could show tsunami activity related to both Kuril and Pacific trenches and its junction, where large tsunamigenic earthquakes have not been historically registered, hence, being this the primary objective of the present research.

The study site is located on a marine terrace surface elevated between 5-10 MAMSL, on the Kamikita coastal plain (Miyauchi, 1985) and 1.2 km inland from the present shoreline; at the same time, this surface is positioned between the Oirase and Gonohe rivers. We have identified eight sand layers, interbedded with mud and occasional tephra layers. Based on tephra analysis, some of them were possible to confirm as the To-a and To-cu tephra at the top and bottom of the sequence, respectively, giving a range of 6 thousand years of geological history, while the last 1000 years has been apparently eroded, removed or disturbed by human activity. To-a tephra layer contained many diatoms, which implies a water flow or shallow water body as deposition environment. Soils from the top of the section.

The stratigraphic correlation shows that four of the eight sand layers can be well traced landward, and grain analysis shows upward and landward fining. Diatom analysis reveals the presence of marine spices in some sand layers, on the other hand, freshwater and reworked freshwater extinct species were found in the uppermost sand layer (under To-a), suggesting a freshwater inundation event as a genetical source for that. CT number profiles (Hounsfield Units) evidence density changes related to lithological variations between the sand and mud layers. Moreover, XRF core scanner (ITRAX) shows that most of the sand layers are strongly related to a marine origin and exposes concentration of Ti that could be related to heavy minerals concentration and, in consequence, suggesting a sedimentary environment of high energy. Therefore, described evidence suggest a marine origin to the seven sand sheets.

In order to clarify the origin of the sand layers, we performed the numerical simulation to differentiate tsunami sands from storm sands proposed by Watanabe et al. (2018), by comparing wave penetration capacity for each phenomenon; the calculation showed that the only way to carry marine sediments on such further inland is with a tsunami event, if we assume present topography.

# Characteristics of event deposits and their source in Sekine-hama, Mutsu city, Aomori prefecture

*Daisuke Ishimura[1], Kaori Aoki[2]

1. Department of Geography, Tokyo Metropolitan University, 2. Research Center for Volcanic Hazards and Their Mitigation, Tokyo Metropolitan University

Tsunami deposit research is progressing in Japan after the 2011 Tohoku-oki earthquake. Especially, along the Pacific coast in the Tohoku region, many event deposits related with paleo-tsunamis were found by geological surveys. Their survey sites were concentrated from the Sanriku coast to Sendai plain (Sawai et al., 2007; Shishikura et al., 2007; Ishimura and Miyauchi, 2015, 2017; Goto et al., 2015; Inoue et al., 2017; Takada et al., 2016) and, but the number of surveys in the northern part of the Sanriku coast and southern part of the Sendai plain is small due to the limitation of the appropriate site for tsunami deposit research. This study reports the event deposits found at Sekinehama, Mutsu city, Aomori prefecture, which is the northernmost part of the Pacific coast of Honshu Island.

Our study site, Sekinehama, is located between Omazaki and Shiriyazaki and late Pleistocene marine terraces and sand dune were distributed near the coast. In the 2011 Tohoku-oki earthquake, tsunami runup height of 2 to 6 m was reported (The 2011 Tohoku Earthquake Tsunami Joint Survey (TTJS) Group (http://www.coastal.jp/ttjt/)). The outcrop is exposed about 50 m far from coastline and its height is 2 m. Sampled event deposits were used for grain size analysis. Moreover, we conducted radiocarbon dating (five samples) and tephra analysis (one sample).

As a result, we found 18 sandy event deposits interbedded within the soil, marsh, and marine sediments. One of them is the Baegdusan-Tomakomai tephra (AD946; Oppenheimer et al., 2017) including a small number of volcanic glass shards originating in Towada-a tephra (AD915; Machida and Arai, 2003). We estimated the origin of sands in event deposits by comparing with the grain size distribution of modern beach and sand dune sediments, resulted in that 14 event deposits are composed of beach sands. Thus, the source of these 14 event deposits is beach sediments and this indicates that they are transported by a kind of coastal events (e.g., storm, high tide, tsunami). Additionally, some of them showed sedimentary structures (erosional contact and lateral distribution) like tsunami deposits. Thus, we thought that some of them, at least, are tsunami deposits. As for radiocarbon dating, we are measuring now, and thus will show the event ages in our presentation.

# Sedimentary structure and composition of sand blows and sand dikes formed by the 2018 Iburi-Tobu Earthquake, Hokkaido, Japan

*Yuichi Nishimura[1], Takashi Chiba[2]

1. Graduate School of Science, Hokkaido University, 2. Faculty of Bioresource Sciences, Akita Prefectural University

The M6.7 Hokkaido Iburi-Tobu Earthquake of September 6th, 2018, left sand blows and sand dikes result from liquefaction at Tomakomai, Atsuma, and Mukawa. We investigated distribution, shape, sedimentary structure and composition of the new deposits. Sand blows are mainly observed in flat areas on coast and estuaries that have undergone artificial modification. Size of the sand blows varies from several tens of centimeters to several meters in diameter. Each sand blow has a vent or vent system that aligned along a fissure. Sand blows are composed by fine to coast sand, mud, pebbles and various size of pumice. A layered structure is commonly seen in the cross-section. In most of the case, mud, pumice, and sand are deposited in order from the bottom to the top of the deposit. It seems that the mixed layer of sand and pumice in the landfill soil liquefied and sand and pumice separated in the layer. Then they ejected with mud from the accumulated light particles near to the vent. The sand dikes are observed by trenching or by using a handy geo-slicer. Most of the dikes are not straight, they are curved or bent along the boundary of the inhomogeneous medium around them. The width of the dikes vary from 1 mm to 10 cm, and they are filled with sand or pebbles that are the same materials as those came out at the final stage of the ejection. There are dikes that are clogged from the bottom with pumice and coarse sand. In those dikes, the size of the particle filling the dike decreased upward with the clogged location as the boundary. Thus, a feature of sand blow and sand dike can be complicated reflecting the size and density characteristics of the particles constituting the liquefaction layer. The precise description of the new sand blows and sand dikes can provide a better understanding of the liquefaction process and also can be useful for the identification and evaluation of paleo liquefaction deposits.

# Tsunami deposits and tsunami wave source of the southern part of Okushiri Island, Hokkaido

*Atsushi Urabe[1], Yoshihiro Kase[2], Gentaro Kawakami[2], Kenji Nishina[2], Hiromichi Koyasu[2]

1. Research Institute for Natural Hazards and Disaster Recovery, Niigata University, 2. Geological Survey of Hokkaido, Hokkaido Research Organization

In the Okushiri area of South Hokkaido, a tsunami history approximately 3,000 years before is clarified based on an investigation of tsunami deposits. On the other hand, the tsunami history before approximately 3,000 years ago is unclear. In this study, boring exploration was carried out at the Wasabiyachi area for the purpose of analysis of the previous tsunami deposit. As a result, the event sand layer which suggested the beach origin was recognized in twenty horizons after approximately 7,400 years ago. As a result of examined the change of the sedimentary facies etc., in several horizons, this area may uplift at the same time as tsunami.

# Inter-seismic and post-seismic tectonic movements detected during the 17th century earthquake and inferred from diatom analysis in Tokachi area, Hokkaido, Japan

*Takashi Chiba[1], Yuichi Nishimura[2]

1. Faculty of Bioresource Sciences, Akita Prefectural University, 2. Graduate School of Science, Hokkaido University

It has been evidenced from geological records that paleo-earthquakes accompanied by huge tsunamis occurred at least twice in the last millennium at the southern part of the Kuril Trench. The first of the two tsunamis is supposed to have occurred in the 12-13th century, while the other is supposed to have occurred in the 17th century. The paleo-earthquake and successive tsunami of the 17th century have been particularly investigated by previous studies in the area between Akkeshi to Nemuro at the Hokkaido, Japan. However, the crustal movements due to the earthquake in the area at western side of the Akkeshi such as Tokachi area is still unknown. This lack of substantive information is an obstacle for the studies attempting to calculate the actual impact of the paleo-earthquake and estimating its source region. We conducted a survey using a geo-slicer and GPS. We also performed paleo-environmental reconstruction by diatom analysis for the core samples obtained from the Toberi River mouth area, in Tokachi area to derive indicative data about the crustal movements. Since massive Neogene diatomaceous siltstones sediments containing fossil marine diatoms are widely distributed in the study area, we identified the reworked fossil marine species and excluded it from the diatom analysis in the paleo-environmental reconstruction.As a result of the geo-slicer survey, the tsunami deposits from the coast to the inland up to a distance of 1.8 km in a straight line could be detected. Changes in diatom assemblages which are reflective of inter-seismic subsidence and post-seismic uplift caused by the earthquake were also recognized. On the other hand, inferences derived from diatom analysis of geo-slicer core samples showed that the vertical crustal movement estimated by the elevation of the freshwater-brackish boundary of the core sample was maximum 2.3 m. The freshwater-brackish boundary was identified to be extending up to 1.9 km inland at 3.9 m altitude from the seashore, however it was not conspicuous in the inland and above the elevation at more than 4.0 m. This observation confirmed the relationship between the vertical crustal movements generated by the earthquake and the elevation of pale-sea level. Although it is difficult to reconstruct the crustal movements caused by the 12-13th century earthquake, in light of the above observations it can be concluded that they might possibly have risen up to tens of centimeters at least after the earthquake and then began to change to the inter-seismic subsidence.

## [M-IS16] Dynamics of eruption cloud and cumulonimbus; modelling and observation

convener:Eiichi Sato(Meteorological Research Institute), Fukashi Maeno(Earthquake Research Institute, University of Tokyo), Takeshi Maesaka(National Research Institute for Earth Science and Disaster Resilience), Chairperson:Eiichi Sato(Meteorological Research Institute)

Volcanic eruption clouds (eruption column, pyroclastic flow, and umbrella cloud) and cumulonimbus are similar phenomena in the atmosphere. Models that can precisely reproduce the physical processes in such phenomena, and accurate observations have been required. Recently, the development of remote sensing techniques such as weather radar and weather satellite are remarkable, and they are being adopted for volcanic eruption monitoring. However, it is indispensable to verify the results of modeling and remote sensing using in-situ observations. In this session, we will discuss the modelling and the observations of eruption clouds and cumulonimbus from the viewpoint of meteorology, volcanology, geology, and other related fields. The related phenomena such as ashfall, rainfall, snowfall, hail and volcanic block will also be discussed.

The present paper describes the results of observational studies of volcanic ash columns using different types of weather radars: X-band marine radar, bi-static Ku-band radar, Ka-band Doppler radar, and operational X-band polarimetric radar. In order to observe eruption columns with extremely fine temporal resolution, an X-band marine radar was set up during three months in 2018 at the Kurokami observatory of Kyoto University located about 4km from the vent of Sakurajima volcano. The marine radar has a slot antenna that has the PPI scanning speed of 48 rpm, with a vertical beam width of 22˚ and a horizontal beam width of 1.2˚, and a range resolution of 8m. We carried out observations by physically changing the rotational axis of the slot antenna from vertical (PPI) to horizontal (RHI) to achieve an elevation angle resolution of 1.2˚. The MRI Ku-band radar and Kagoshima University Ku- band radar set up in 2017 in Sakurajima have Luneberg antenna with a horizontal and vertical beam width of 3˚. The antenna rotates spirally from an elevation angle of 0˚ to 90˚ to obtain hemispherical volume data in one minute. The Ka-band Doppler radar of NIED was operating at the Kurokami observatory during 3 months in 2015 to investigate the inner structure with the RHI antenna scanning. The MLIT operational X-band polarimetric radar located approximately 11km from the vent of the Sakurajima volcano can measure volcanic ash columns three-dimensionally at 5-minute intervals, even though it is an operational radar aiming to measure heavy rainfalls in Sakurajima.

Utilizing these different types of radar data, we perform detailed analysis of eruption columns. The marine radar succeeded in detecting eruptions and at the same time detecting falling pyroclastic particles (Fig. 1). The radar also reveals the fine structure of an ascending eruption column at 1.25-second intervals. While the marine radar observes volcanic ash columns with the wider azimuth angel resolution 22˚ due to its fan beam antenna, Ka-band Doppler radar can observe the targets with finer azimuthal resolution using RHI scanning of the parabolic antenna. The Ka-band radar RHI observations also reveal the upward speed of the ash echo top at 2-minute intervals. While both the marine radar and the Ku-band Doppler radar measure eruption column vertically at a fixed azimuthal direction, the Ku-band Doppler radar measures all azimuth and elevation angles every 1 minute. Using this scanning strategy, we can clarify the temporal change of the eruption column during its downwind movement: the radar reflectivity factor of the upper part of the eruption column becomes high 5-minute after the eruption, which is probably due to the aggregation process in water clouds (Fig. 2). The operational X-band MP radar collects 20 tilts PPI scan data at 5-minute interval. We can construct three-dimensional data of ash clouds with time and spatial interpolation method. Then we can obtain the wide-area ash fall distributions.

In conclusion, as mentioned above, different types of weather radars are now available for studying volcanic eruption columns and their applications to disaster prevention are promising.

# Observation of Eruption Plumes by X-Band MP radar and Lidar at Sakurajima and Kuchinoerabujima

*Haruhisa Nakamichi[1], Atsushi Shimizu[2], Makoto Shimomura[1], Magfira Syarifuddin[1], Masato Iguchi[1]

1. Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University, 2. National Institute for Environmental Studies

We report the comparison between results by radar and lidar observations of Minamidake eruption on June 16, 2018, at Sakurajima, and the radar observation results of Kuchinoerabujima eruptions since December 2018. The radar reflectivity factor data distribution showed that the plume reached 3,300 m height within 1 min after the onset of the Minamidake eruption and increased to be 5,000 m height, after 3 min from the onset of the eruption. At the same time, it was confirmed from the radar reflectivity factor data that the eruption column shifted 1 km to the west direction. The radar reflectivity factor reincreased vertically above the crater at about 3,000 m height, 5 min after the starting of the eruption, which is corresponding to the second eruption. In the lidar observation, changes corresponding to the movement in the west direction of the eruption column were observed from 3 min after the start of the eruption to 8 min afterward, and the scattering peak corresponded well with the enhancement of the radar reflectivity factor. After 15 min from the onset of the eruption, there was no change in the radar reflectivity factor corresponding to the ash plume, but the significant scattering intensity of the lidar was found at a distance less than 2 km and continued for more than 20 minutes. It reflects that the lidar outperforms the radar in terms of detecting the finer particles exist in the atmosphere. The lidar observation showed that volcanic ash was diffused and moved by the wind. Next, we observed the increase in the radar reflectivity factor corresponding to the eruption columns of the eruptions on December 18, 2018, and January 17 and 29, 2019 at Kuchinoerabujima. One minute after the eruption on December 28, the radar reflectivity factor showed a rise to 3,000 m of ash plume and reached the maximum height at about 5,000 m, 3 min after the onset of the eruption. It was found from the radar reflectivity factor that the maximum height of the plume was 4,000 m, 2 min after the onset of the eruption on January 17. Five minutes after the onset of eruption, the reflectivity factor of the plume reached 4,000 m and did not raise any further. From these facts, we can suggest that by grasping the temporal change of the plume height given by the temporal changes in radar reflectivity factor, we can extract the information of the eruption intensity.

# 2018-2019 Kuchinoerabu-jima eruption plume/cloud echoes observed by JMA weather radar network

*Eiichi Sato[1], Keiichi Fukui[2], Toshiki Shimbori[1]

1. Meteorological Research Institute, 2. Japan Meteorological Agency

At Shindake crater of Kuchinoerabu-jima volcano, a very small eruption occurred on October 21, 2018, and then continued intermittently until December 13. After that, three eruptions accompanied by pyroclastic flow occurred on December 18, 2018, January 17 and 29, 2019. Although Japan Meteorological Agency (JMA) failed to visually confirm the top of the former two eruption plumes, they were observed by Himawari-8, a meteorological satellite of JMA, and X-band MP radar of Disaster Prevention Research Institute (DPRI), Kyoto University. Meanwhile, the eruptions were also observed by JMA's weather radar network. In this presentation, we will report on the analyses using them.
Eruption plume/cloud echo associated with the eruption on January 17, 2019 was observed by Tanegashima radar and Naze radar. The plume echo height observed by Tanegashima radar was about 6.7 km above sea level (ASL), and about 6.5 km ASL by Naze radar. These are consistent with about 6 km above the crater edge (about 6.6km ASL), the result of the analysis with Himawari 8. On the other hand, the eruption plume echo height observed by the DPRI radar was about 4 km above the sea level. This may be due to the vertical wind shear. In other words, the authors think that the 125-degree RHI observation, i.e., vertical cross section observation by DPRI radar, did not capture the top of the plume, because the wind direction observed by the JMA wind profiler at Yakushima was northwesterly or north-northwesterly in the lower troposphere (2km or less), however, the wind was westerly in the middle troposphere (about 3-6km).
Meanwhile, in other cases including eruption cases on December 18, 2018 and January 29, 2019, the JMA radar network did not properly capture the eruption plume/cloud echoes. It is considered that the volcanic ash density especially near the top of the plume was low, and the mismatch occurred between the scan sequence of the radar and the rising process of the plume.
As a result of analysis by weather radar, we captured some of the eruption activity, however, there were many cases that could not be properly caught. We will show the limits of the observation method with weather radar, and show some possible countermeasures.

Kuchinoerabujima Volcano in Kyushu, Japan have erupted in 2014 and 2015. The volcanic activities intensified again since October 2018 and generated explosive eruptions accompanying pyroclastic density currents on 18 December 2018, 17 and 29 January 2019. The pyroclastic density currents are so hazardous that it is crucial to assess the risk that residential area near the volcano could be affected by the currents.

We performed a series of numerical simulations on the ejection of volcanic ash clods and subsequent density currents with the parameter settings, which were based on the observational data acquired during the explosive eruptions of Kuchinoerabujima volcano from 2014 to 2018. The supercomputer system HOKUSAI, RIKEN was used (Project number: Q18431).

We assumed that the initial temperature, density and ejection speed of ash clouds significantly affect the dynamics of the ash clouds, and thus, we searched plausible combinations of the parameter set of the thee variables by conducting a series of numerical simulations. Some of the simulations yielded the results that are comparable with the observed eruptions accompanying pyroclastic density currents. In particular, the results implies that the pyroclastic density currents are prone to occur when the initial temperature of the ejected ash clouds is lower than 800K.

In addition, the numerical simulations exhibited that the small north-south trending ridge on the east of the volcanic vent of Kuchinoerabujima volcano had the main part of the pyroclastic density currents spread over the western flank of the volcanic edifice. This is consistent with our observation at Kuchinoerabujma volcano.

# Image analysis of volcanic clouds during the 2011 Kirishima Shinmoedake eruption

*Takehiko KOBORI[1], Kisei KINOSHITA[1], Naoko IINO[2], Masayuki MAKI[1], Seiji FUKUSHIMA[1]

1. Kagoshima University, 2. Kumamoto University

We report the development and spatial scale of the sub-plinian eruption of Kirishima Shinmoedake in January 26-27, 2011. In addition to the multipoint image observation and the cloud diffusion analysis of satellite images in the previous reports [1-3], we analyze Ohnami-ike volcano monitoring camera images [4] and the photographs published.
For the image analysis of the plume, we improved the photo analysis program [5] and developed a method fitting the skyline created from the elevation tile [6] to the image. By considering the curvature of the earth when creating skyline, accurate altitude estimation became possible.
Since 2008, fumes and white vaporous clouds were often observed at Shinmoedake. Then, volcanic ash containing fresh magma was confirmed at the small eruption on January 19, 2011 at 01:27 [7]. After that, it changed to continuous discharge of ash cloud as observed on January 22 and 25. The plume flowed and rose to about 5-7 km downstream, with its top reaching 1700 to 2200 m above sea level, and flowed horizontally. Discharge of the plume continued until around 14:00 on January 26, and reached the highest point of 1700-1900 m above sea level at the downstream 3-4 km. Despite poor visibility due to atmospheric turbidity on January 26th, near-infrared video images and photographs from the observation point of 50 km south-southwest of Shinmoedake, captured the whole plume shape and developmental process of the sub-plinian eruption started at 15:29 on January 26th. The upper part of the large-scale ash cloud was also observed from a southern point of Kagoshima City located in 58 km southwest of Shinmoedake, and the visible web camera in the Hitoyoshi Basin located in 38 km north of Shinmoedake. By sharpening and analyzing these images, the plume height was obtained. On January 26, the plume rose to 7-8 km downstream, the altitude above sea level was 5000-6000 m, rarely 7000 m. This is close to sea level altitude 7000 m (accuracy 1 km) [8] obtained from radar analysis of the Tanegashima and Fukuoka data. On January 27, continuous magmatic clouds were observed since the morning. At the explosion at 15:30 and 15:41, sub-plinian type eruption restarted, and heavy ash cloud reaching 7000-8000 m above sea level was seen from each observation point.

# Cloud Radar Network for Early Detection of Cumulonimbus Generation

*Takeshi Maesaka[1], Tadayasu Ohigashi[1], Koyuru Iwanami[1], Shin-Ichi Suzuki[1], Yukari Shusse[1], Namiko Sakurai[1]

1. National Research Institute for Earth Science and Disaster Resilience

Recently municipal engineers point out that urban city is vulnerable for localized heavy rainfall, and that rainfall monitoring and forecasting are important for water management. A weather radar is a powerful tool for that purpose; however it is only precipitation particles (hydrometeors excluding cloud particles) that current operational radars (S-, C- and X-band) can detect. This means that when the radar catches the echo, the rainfall may have already started. Meanwhile, the heavy rainfall is caused by a mature cumulonimbus which develops from a cumulus. So the detection of the cumulous is expected to make the lead time of heavy rainfall forecasting longer. But the current radar cannot observe the cumulus which consists of the cloud particles. For an early warning of heavy rainfall, we developed the cloud radar network around Tokyo metropolitan area.
The network consists of five Ka-band (35 GHz) radars whose specifications are as follows: azimuth-/elevation-scanning Cassegrain antenna with a diameter of 2 m, 3 kW Extended Interaction Klystron (EIK) as a microwave amplifier, pulse compression by linear frequency modulation, and dual polarimetric capability (simultaneous transmission and reception of H and V; only three of the five radars). The minimum sensitivity we need is -17 dBZ (-20 dBZ) at 20 km range for dual (single) polarimetric type, respectively, because our target is the detection of a conversion from cloud droplets to raindrops. These radars were just deployed in February 2015. We would like to present preliminary results of our cloud radar and to discuss the availability to the early monitoring of cumulonimbus generation.

## [M-IS16] Dynamics of eruption cloud and cumulonimbus; modelling and observation

convener:Eiichi Sato(Meteorological Research Institute), Fukashi Maeno(Earthquake Research Institute, University of Tokyo), Takeshi Maesaka(National Research Institute for Earth Science and Disaster Resilience)

Volcanic eruption clouds (eruption column, pyroclastic flow, and umbrella cloud) and cumulonimbus are similar phenomena in the atmosphere. Models that can precisely reproduce the physical processes in such phenomena, and accurate observations have been required. Recently, the development of remote sensing techniques such as weather radar and weather satellite are remarkable, and they are being adopted for volcanic eruption monitoring. However, it is indispensable to verify the results of modeling and remote sensing using in-situ observations. In this session, we will discuss the modelling and the observations of eruption clouds and cumulonimbus from the viewpoint of meteorology, volcanology, geology, and other related fields. The related phenomena such as ashfall, rainfall, snowfall, hail and volcanic block will also be discussed.

# Redesign of the Japan Meteorological Agency Atmospheric Transport Model

*Toshiki Shimbori[1], Kensuke Ishii[1]

1. Volcanology Research Department, Meteorological Research Institute

The Meteorological Research Institute (MRI) of the Japan Meteorological Agency (JMA) will develop a new Atmospheric Transport Model (ATM) called the JMA-ATM.

The JMA is currently operating the Global ATM (JMA-GATM) and Regional ATM (JMA-RATM) to issue Volcanic Ash Advisories (VAAs) and Volcanic Ash Fall Forecasts (VAFFs). The JMA-GATM and RATM are driven by the grid point values of Global Spectral Model (GSM) and Meso-Scale Model (MSM) or Local Forecast Model (LFM) based on the nonhydrostatic model ASUCA (Forecast Department, 2014), respectively. The MRI is planning to renew the JMA's ATM and join a volcanic ash data assimilation system (Ishii *et al.*, 2017) under one of the MRI research plans which start in April 2019.

The new JMA-ATM is designed from the point of view of robustness, promptness, flexibility and manageability. *Robustness*: To avoid any abnormal ends in operation, the JMA-ATM takes Lagrangian description. *Promptness*: To issue VAAs and VAFFs immediately, the JMA-ATM calculate offline. Further, element conversion of grid point values executes in preprocess and main ATM calculation runs parallel processing using Message Passing Interface (MPI) on high performance computers. *Flexibility*: ATM tracers are not limited to volcanic ash generated by an eruption column model as initial condition and the ATM coordinate is not customized only for the input data of GSM, MSM or LFM. *Manageability*: In order to review and share source codes within the JMA, project management and version control systems are used in the ATM development. With regard to the above design, the offline Lagrangian model is the same as current ATMs. Whereas the vertical coordinate of JMA-GATM is $\sigma$-$p$ hybrid of GSM and that of JMA-RATM (Shimbori *et al.*, 2016) is hybrid terrain-following of ASUCA, the JMA-ATM takes identical $z$-coordinate of the converted grid point values. Therefore two current ATMs can be unified to the single ATM (see Fig. 1). For readability, the JMA-ATM are written in the Fortran in accordance with the standard coding rule (Muroi *et al.*, 2002) and all subroutines are modularized. In order that dynamical and physical processes are commutative in a timestep of the JMA-ATM, time tendency of tracer variables is calculated in each process and integrated at the last timestep. The JMA-ATM project is managed with Redmine and its source code version is controlled with Subversion (SVN) which have been installed in JMA (Forecast Department, 2017).

A first object of the new ATM as an operational model is to maintain the same accuracy of JMA-GATM and RATM predictions. In particular, to precisely predict the atmospheric transport phenomena near ground surface, suitable treatments of model terrain in terms of $z$-coordinate are primary subjects. A technical platform, such as visualization and verification tools, is also needed. We are going to publish the documentation of the JMA-ATM in the Technical Reports of the MRI in 2020. Furthermore, for the purpose of accuracy improvement of the JMA-ATM prediction, we are planning to implement processes of aggregation and resuspension, in addition to joining the data assimilation system for volcanic ash that observed by weather radars (*e.g.*, Sato *et al.*, 2019) and so on.

# Mathematical mechanism of an inverse problem for tephra transport and dispersal model

*Kensuke Ishii[1], Takehiro Koyaguchi[2]

1. Meteorological Research Institute, 2. Earthquake Research Institute, the University of Tokyo

Estimation of tephra mass released along the eruption column is crucial for the characterization of explosive volcanic eruptions systems and for the volcanic hazard mitigations. For example, the uncertainties of assumed tephra mass distribution as the source term for tephra transport and dispersal models critically influence the accuracy of the tephra forecast. In addition, the estimated tephra mass distribution can be used for verification and comprehension of some eruption column models which have been developed in previous studies (e.g. Woods & Bursik, 1991) .

We are studying an inverse problem of a model which relates the tephra mass distribution along the eruption column to the tephra fallout deposits. The model is expressed as a linear system which builds on the advection-fall-dispersion-sedimentation equation. The inverse problem is, therefore reduced to a ‘linear inverse problem’. In this study, we investigated the properties of this linear inverse problem on the basis of the singular value decomposition (SVD) using numerical experiments that generate pseudo-observations.

The SVD analysis indicates that present inverse problem is that of an ‘ill-conditioned’ system, where most of singular values are nearly zero. This characteristic comes from the fact that tephra particles released from high altitudes tend to lose the information of their sources because of diffusion. The small singular values cause an unstable and non-physical inverse solution to be completely dominated by small amount of observation error (referred to as over-fitting). Therefore, the present inverse problem requires careful consideration to obtain stable and meaningful solutions. In our study, the regularization and the optimization of the vertical grid are applied to produce such solutions. In the regularization, we do not include singular vectors with small singular value as the basis function expressing the inverse solution, such that the solution can be less sensitive to observation error. In the optimization of the vertical grids, we reduce the number of vertical grids of the model parameters using linear interpolation to avoid singular vectors with small singular values. Combining these two methods, we successfully find approximate solutions without over-fitting. In the presentation, we also discuss how the eruption conditions (e.g., magma discharge rate) are constrained by the model parameters estimated from the present method.

# Development of the plume source model for inversion of tephra fallout

*Akira Nishijo[1], Takehiro Koyaguchi[1], Yujiro Suzuki[1]

1. The University of Tokyo Earthquake Research Institute

During an explosive volcanic eruption, tephra falls out from eruption cloud to ground surface and forms tephra deposits. The characteristics of tephra deposits (e.g. their thickness and spatial distribution) reflect the eruption source conditions. When an eruption source condition is specified by parameters, tephra transport and deposition can be calculated using the advection-diffusion model. Based on this forward model, we can inversely search for an optimal set of parameters that explain the observed characteristics of tephra deposits (e.g. Conner & Conner 2006). In practice, we estimate the supply rate of tephra particles from the eruption cloud into the atmosphere as a function of height and grain size (referred to as “supply rate function”) from the inversion analysis. The form of supply rate function is determined by the physical processes of particle separation from the eruption cloud, and hence it must depend on the dynamics of eruption column. In previous studies, however, the form of supply rate function was assumed to be a certain mathematical function without physical considerations (White et al 2017). In this study, we developed a physical model to obtain the supply rate function.
The physical model is a combination of a particle sedimentation model and a cloud dynamics model. The sedimentation model describes the process of particle fallout from the cloud. The cloud dynamics model is subdivided into 2 models: the 1-D plume model and the gravity current model. The 1-D plume model describes the dynamics of eruption columns below the neutral buoyancy level (NBL), and the gravity current model describes the dynamics of spreading cloud around NBL. We used the 1-D plume model of Bursik (2001), which considers bending by windy air and the effects of particle sedimentation. We also take into account the geometrical effects of plume bending on the sedimentation model.
From a parametric study using the above physical model, we obtained the supply rate function for each grain size. The supply rate function is composed of two functions: “plume supply rate function” and “gravity-current supply rate function”. The plume supply rate function represents the mass loss of particles from the edge of a rising plume below NBL. It is convex downward and monotonically decreasing against height regardless of grain size. The gravity-current supply rate function describes the mass flux of particles at NBL in the cloud (i.e., at the top of the rising plume), and it is used as the source term for the gravity current model. The characteristics of the supply rate function depend on grain size. Because most of coarse particles (>10 mm) fallout from the lower part of rising plume, their plume supply rate function decreases rapidly with height, and the value of their gravity-current supply rate function is nearly zero. Because most of fine particles (< 1 mm) carried by rising plume up to NBL, their plume supply rate function has small values throughout the plume, and their gravity-current supply rate function is approximately equal to the supply rate at the vent. The plume supply rate function of intermediate particles (1~10 mm) is a mildly decreasing function, and it has larger values than that of fine particles; therefore, it has greater values than those of coarse or fine particles for the upper part of the plume. The value of the gravity-current supply rate function for intermediate particles remarkably decreases with the increasing grain size. In the presentation, we compare these results based on our plume source model with the mathematical functions used in previous inversion analyses.

# Segregation height and size distribution of volcanic ash of Sakurajima eruptions inferred by observed settling velocity

*Kosei Takishita[1], Masato Iguchi[2], Tadaomi Sonoda[2]

1. Graduate School of Science, Kyoto Univ., 2. DPRI, Kyoto Univ.

## 1. Introduction

The most important input values of a volcanic ash dispersion model are mass eruption rate and wind. Aiming more precise estimation, ash segregation pattern from plumes is also important. Mannen [2014] estimated the segregation height of ash particles of 1986B sub-Plinian eruption of Izu-Oshima volcano, with a column of 10km high, using Tephra2, an advection-diffusion model. Using a method similar to Mannen [2014], we investigate features of particle segregation height and size distribution (PSD), based on the observation of the settling velocity of ash particles released by many Vulcanian eruptions of Sakurajima Volcano.

## 2. Observation method and Data

We install Parsivel$^2$, a laser-optical rain gauge (OTT Co.) at 13 sites in Sakurajima. The instrument classifies particles into 32 diameters (0.2-24.5mm) and 32 settling velocities (0.2-20.8m/s), and records particle count every minute. We analyze the data from May to December in 2018. Ash particles were detected at a total of 261 sites from 156 eruptions among 346 events. The size ranges from 0.25mm to 20mm, and the volume-based mode diameter is 0.625mm - 0.75mm. The settling velocity is less than 12.8m/s and slower than the terminal velocity of sphere in each diameter [Wilson and Huang, 1973].

## 3. Analysis method

Ash particles from a plume reach the ground through combination process of advection, diffusion, and dropping. We estimate back trajectory of ash particles from the ground to the plume based on wind data measured by JMA, in order to determine the nearest point to the plume as the segregation height. Horizontal wind field is obtained at the time of eruptions by the interpolation in time and altitude, and vertical wind is neglected. We assume the 2D Gaussian distribution [Suzuki, 1983] for diffusion, a constant settling velocity determined by observation for dropping, and a vertical line source for plume.

## 4. Particle segregation and PSD

Segregation mass and PSD are obtained for 17 eruptions using the data of ash particles estimated to have segregated within 10 minutes from the eruption. The plume height ranges from 400 to 4700m, and the mass and PSD are estimated at heights interval of 150m - 990m. The largest height interval is obtained at 1260m –2250m above sea level (asl) for the eruption which occurred at 15:09, June 9$^{th}$ in 2018. Its plume height was 1400m above the crater (2400m asl), and $4.4\times10^3$ tons of ash is estimated to be released from the range. Here we define $\alpha$ as the logarithm of the segregation density [t/m]. In the eruption, $\alpha$ ranges from -1 to 0 and there was no correlation between $\alpha$ and height. As for PSD, there was a strong inverse correlation (R=-0.94) between height and volume fraction of particles smaller than 0.75mm.

The plume of the eruption on July 16$^{th}$ in 2018 reached an elevation of 4600m above the crater. Segregation mass is $3.6\times10^3$ tons at the altitude range of 1290m –1710m and 2070m –2570m asl. $\alpha$ ranges from -2 to 0, and there is no correlation with $\alpha$ and height. As for PSD, there is no strong correlation (R=-0.39) between height and volume fraction of particles smaller than 0.75mm.

While most of eruptions don’t have correlation between height and PSD, some have strong inverse correlation (R<-0.9; 4 events) and another has strong positive correlation (R>0.9; 1 event). Mannen [2014] also showed similar inverse correlation.

## 5. Examination of the method

©2019. Japan Geoscience Union. All Right Reserved. 

The mean $\alpha$ during the same period is obtained, 0.46, from the total mass of volcanic ash sampled continuously at wider area in Kagoshima pref. The mean $\alpha$ in this study, -0.18, is smaller than this because we treat the data for 10 minutes from the beginning.
Some segregation heights were obtained below the crater (1000m asl). This may be due to negligence of downward wind. Vertical wind will be taken into account later.

# Distant tracking of maximum pumice diameter in pumice-fall of the Tenmei eruption of Asama volcano: An attempt to draw isopleth lines of mm scale-maximum pumice diameter in the Kanto Plain

*Shingo Takeuchi[1], Shimpei Uesawa[1]

1. Central Research Institute of Electric Power Industry, Civil Engineering Research Laboratory, Geosphere Sciences

Volcanic ash-fall reaches distant areas and has great adverse effects on human health and society. Therefore, it is important to investigate properties of volcanic ash-fall of past eruption in distant areas for volcanic hazard assessment. However, thin ash-fall deposit in a distant point is not preserved as a visible geological layer. Instead, particles of ash-fall are mixed in soil. The characteristics of distal ash-fall particles in soil is an important geological evidence to assess volcanic ash hazard and constrain modelling of volcanic ash-fall processes in distant areas. Takeuchi and Uesawa (2018, JpGU) studied the Tenmei eruption (AD1783 eruption) of Asama volcano and detected pumice particles in the topsoil at areas along ash dispersal axis with distance up to ca. 170 km in the Kanto plain, and correlated the pumice particles to the pumice-fall of Tenmei eruption. They tracked the maximum pumice diameter (MP) along the dispersal axis and obtained the MP variation with distance which can be consistently linked with the data with distance up to ca. 55 km of Minakami (1942). In this study, same soil survey has been performed in areas away from the dispersal axis to track the maximum pumice diameter (MP). The preliminary result suggests that we can draw isopleth lines of MP down to 1 mm in diameter in the middle to the southern area of the Kanto Plain. In addition, we have investigated characteristics of ash fall of Tennin eruption (AD1108 eruption), because ash dispersal areas of Tennin eruption partly overlaps those of Temmei eruption in the northern Kanto Plain, at which pumice particles originated from the Tennin eruption are also found in topsoil. In the future analysis, we need to distinguish pumice particles from those of Tennin eruption to determine the MP of Temmei eruption.

# Degassing activity of Aso volcano, Japan, before the 8 October 2016 eruption measured by satellite and ground-based remote sensing techniques

*Masaaki Morita[1]

1. Geological Survey of Japan, AIST

The flux of volcanic gases has been monitored as sulfur dioxide ($SO_2$) flux at many volcanoes by ground-based remote sensing measurements using a miniature spectrometer such as Mini-DOAS. A recent advance in satellite remote sensing techniques has also enabled for $SO_2$ amounts emitted by persistent degassing to be monitored at sufficient temporal resolution. In this study, we combined these two techniques with ground-based visible camera images to constrain the degassing activity before the 8 October 2016 phreatomagmatic eruption of Aso volcano, Japan. We compared the time series of atmospheric $SO_2$ mass in the lower troposphere above the volcano measured by the Ozone Mapping and Profiler Suite (OMPS) nadir mapper instrument to those of the ground-based $SO_2$ flux and plume height measured by the Japan Meteorological Agency. Our results between April and October 2016 showed similar temporal variations among these values. The $SO_2$ mass and the plume height increased to, respectively, about 1000 tons and 900 m above the crater rim two months before the eruption, and then gradually decreased. Both values again increased about a week before the eruption and reached their maximum values (> 1200 tons and 1010 m above the crater rim, respectively). These similar temporal variations between the $SO_2$ emissions and the plume height likely indicate that, although the degassing system of the volcano has been stable during the study period, the accumulation of volcanic gases in the shallow part of the volcanic conduit might trigger the phreatomagmatic eruption. Our result suggests that the satellite remote sensing techniques can be sufficient for monitoring $SO_2$ flux of the volcanic plume at low altitude.

# Characteristics of polarimetric radar parameters of dry volcanic ash clouds

*Yura Kim[1], Masayuki Maki[1], Masato Iguchi[2], Dong-In Lee[3]

1. Research and Education Center for Natural Hazards, Kagoshima University, Korimoto, Kagoshima, Japan, 2. Sakurajima Volcano Research Center/DPRI, Kyoto University, Sakurajima, Kagoshima, Japan, 3. Department of Atmospheric Sciences, Pukyong National University, Namgu, Busan, Republic of Korea

We analyzed statistically the polarimetric radar data of 9 Sakurajima volcanic eruption clouds in 2013. All eruption clouds have a height exceeding 3000m. According to the results, $Z_H$ has positively skewed distributions (Skewness of 1.6; mean $Z_H$ of 9.77 dBZ and median of 7.4 dBZ), $Z_{DR}$ has normal distributions (Skewness of 0.02; mean $Z_{DR}$ of 1.58 dB and median of 1.6 dB), $K_{DP}$ has positively skewed distributions (Skewness of 7.12; mean $K_{DP}$ of 0.03 deg/km and median of 0.0 deg/km), and $\rho_{hv}$ has negatively skewed distributions (Skewness of -1.02; mean $\rho_{hv}$ of 0.77 and median of 0.8). Depending on time after the eruption, the average $Z_H$ decreased from 22.3 dBZ to 6.75 dBZ while the average $Z_{DR}$ and $\rho_{hv}$ tended to increase from 1.24 dB to 1.67 dB, and from 0.47 to 0.83, respectively.

# Development of easy tools for volcanic eruption plume/cloud analysis using weather radars

*Eiichi Sato[1], Ryutaro Senba[2]

1. Meteorological Research Institute, 2. Fukuoka Regional Headquarter, Japan Meteorological Agency

Meteorological Research Institute and Kagoshima Local Meteorological Office, Japan Meteorological Agency (JMA) have been cooperatively working on research on simple analysis methods of volcanic eruption plume using weather radars. In volcanology, since researchers of radar analysis whose target is volcanic eruption plume/cloud are minority, we are developing simple analysis tools especially for beginners of radar meteorology. As visible images of cameras were used to monitor volcano, operational analysis of volcanic eruption plume/cloud by JMA become impossible if the visibility is poor. If analysis using radar data became easier, immediate analysis of volcanic eruption cloud in all-weathers would be possible, and, as a result, we can make a database of “hidden” eruptions. In this presentation, outline of the tool development and results of a case study will be shown.
In the tool development, we use the software named “Draft” developed by MRI. This software consists of many commands, e.g., format conversion, analysis of radar data, and drawing results. Although it is possible to analyze the radar echo of volcanic eruption cloud using these commands, it may be difficult for beginners of radar meteorology and “Draft”. Hence, we started to create some shell scripts that the users can perceive the shapes of volcanic eruption plumes easily with radar data. Our goal is to make easy-to-use tools that enable us to do everything, from collecting radar data to drawing the results, automatically.
As a case study, we chose the eruption from the Minamidake summit crater of Sakurajima occurred on November 11, 2017. In this case, we couldn’t see the eruption plume by cloud around the summit. Considering the amount of ground deformation detected by extensometer in an observation tunnel in Arimura, Sakurajima, it's no wonder that the volcanic ash and the gas spewed to more than 5,000m with this eruption. It is because the amount of strain change associated with the eruption is almost the same with the case on June 16, 2018, whose eruption cloud height was 5,700m. In this case, we used the data of two (Fukuoka and Tanegashima) weather radars which belong to JMA operational weather radar network (JMA-RDN). As a result, we revealed that the eruption cloud was about 4,500 to 6,000m, and kept this height for about 10 minutes. In 2017, this eruption may be one of the largest eruptions, because the eruption occurred from Showa crater on May 2 is the only one eruption whose volcanic ash rose more than 5,000m.
Interestingly, we found two peaks in the radar echo distribution by the Tanegashima radar. We consider that one peak is due to the dense ash above the summit, and the other peak was made by aggregates and water coated ash. We are planning to carry out further analysis using different types of radar, e.g., polarimetric weather radar.
As a conclusion, effectiveness of the analysis tools using weather radars was confirmed in this study. It is expected that the tools enable us immediate analysis of volcanic eruption cloud in all-weathers. However, there are some problems. One of them is that we may not be able to analyze an accurate eruption cloud altitude especially in the case whose amount of ash is small and the duration is a few minutes, since the time resolution of the JMA-RDN is about 5minutes. We will continuously develop the analysis tools and improve the analysis methods through analyzing more cases.

## [M-IS16] Dynamics of eruption cloud and cumulonimbus; modelling and observation

convener:Eiichi Sato(Meteorological Research Institute), Fukashi Maeno(Earthquake Research Institute, University of Tokyo), Takeshi Maesaka(National Research Institute for Earth Science and Disaster Resilience)

Volcanic eruption clouds (eruption column, pyroclastic flow, and umbrella cloud) and cumulonimbus are similar phenomena in the atmosphere. Models that can precisely reproduce the physical processes in such phenomena, and accurate observations have been required. Recently, the development of remote sensing techniques such as weather radar and weather satellite are remarkable, and they are being adopted for volcanic eruption monitoring. However, it is indispensable to verify the results of modeling and remote sensing using in-situ observations. In this session, we will discuss the modelling and the observations of eruption clouds and cumulonimbus from the viewpoint of meteorology, volcanology, geology, and other related fields. The related phenomena such as ashfall, rainfall, snowfall, hail and volcanic block will also be discussed.

# Redesign of the Japan Meteorological Agency Atmospheric Transport Model

*Toshiki Shimbori[1], Kensuke Ishii[1]

1. Volcanology Research Department, Meteorological Research Institute

The Meteorological Research Institute (MRI) of the Japan Meteorological Agency (JMA) will develop a new Atmospheric Transport Model (ATM) called the JMA-ATM.

The JMA is currently operating the Global ATM (JMA-GATM) and Regional ATM (JMA-RATM) to issue Volcanic Ash Advisories (VAAs) and Volcanic Ash Fall Forecasts (VAFFs). The JMA-GATM and RATM are driven by the grid point values of Global Spectral Model (GSM) and Meso-Scale Model (MSM) or Local Forecast Model (LFM) based on the nonhydrostatic model ASUCA (Forecast Department, 2014), respectively. The MRI is planning to renew the JMA's ATM and join a volcanic ash data assimilation system (Ishii *et al.*, 2017) under one of the MRI research plans which start in April 2019.

The new JMA-ATM is designed from the point of view of robustness, promptness, flexibility and manageability. *Robustness*: To avoid any abnormal ends in operation, the JMA-ATM takes Lagrangian description. *Promptness*: To issue VAAs and VAFFs immediately, the JMA-ATM calculate offline. Further, element conversion of grid point values executes in preprocess and main ATM calculation runs parallel processing using Message Passing Interface (MPI) on high performance computers. *Flexibility*: ATM tracers are not limited to volcanic ash generated by an eruption column model as initial condition and the ATM coordinate is not customized only for the input data of GSM, MSM or LFM. *Manageability*: In order to review and share source codes within the JMA, project management and version control systems are used in the ATM development. With regard to the above design, the offline Lagrangian model is the same as current ATMs. Whereas the vertical coordinate of JMA-GATM is $\sigma$-$p$ hybrid of GSM and that of JMA-RATM (Shimbori *et al.*, 2016) is hybrid terrain-following of ASUCA, the JMA-ATM takes identical $z$-coordinate of the converted grid point values. Therefore two current ATMs can be unified to the single ATM (see Fig. 1). For readability, the JMA-ATM are written in the Fortran in accordance with the standard coding rule (Muroi *et al.*, 2002) and all subroutines are modularized. In order that dynamical and physical processes are commutative in a timestep of the JMA-ATM, time tendency of tracer variables is calculated in each process and integrated at the last timestep. The JMA-ATM project is managed with Redmine and its source code version is controlled with Subversion (SVN) which have been installed in JMA (Forecast Department, 2017).

A first object of the new ATM as an operational model is to maintain the same accuracy of JMA-GATM and RATM predictions. In particular, to precisely predict the atmospheric transport phenomena near ground surface, suitable treatments of model terrain in terms of $z$-coordinate are primary subjects. A technical platform, such as visualization and verification tools, is also needed. We are going to publish the documentation of the JMA-ATM in the Technical Reports of the MRI in 2020. Furthermore, for the purpose of accuracy improvement of the JMA-ATM prediction, we are planning to implement processes of aggregation and resuspension, in addition to joining the data assimilation system for volcanic ash that observed by weather radars (*e.g.*, Sato *et al.*, 2019) and so on.

# Mathematical mechanism of an inverse problem for tephra transport and dispersal model

*Kensuke Ishii[1], Takehiro Koyaguchi[2]

1. Meteorological Research Institute, 2. Earthquake Research Institute, the University of Tokyo

Estimation of tephra mass released along the eruption column is crucial for the characterization of explosive volcanic eruptions systems and for the volcanic hazard mitigations. For example, the uncertainties of assumed tephra mass distribution as the source term for tephra transport and dispersal models critically influence the accuracy of the tephra forecast. In addition, the estimated tephra mass distribution can be used for verification and comprehension of some eruption column models which have been developed in previous studies (e.g. Woods & Bursik, 1991) .

We are studying an inverse problem of a model which relates the tephra mass distribution along the eruption column to the tephra fallout deposits. The model is expressed as a linear system which builds on the advection-fall-dispersion-sedimentation equation. The inverse problem is, therefore reduced to a ‘linear inverse problem’. In this study, we investigated the properties of this linear inverse problem on the basis of the singular value decomposition (SVD) using numerical experiments that generate pseudo-observations.

The SVD analysis indicates that present inverse problem is that of an ‘ill-conditioned’ system, where most of singular values are nearly zero. This characteristic comes from the fact that tephra particles released from high altitudes tend to lose the information of their sources because of diffusion. The small singular values cause an unstable and non-physical inverse solution to be completely dominated by small amount of observation error (referred to as over-fitting). Therefore, the present inverse problem requires careful consideration to obtain stable and meaningful solutions. In our study, the regularization and the optimization of the vertical grid are applied to produce such solutions. In the regularization, we do not include singular vectors with small singular value as the basis function expressing the inverse solution, such that the solution can be less sensitive to observation error. In the optimization of the vertical grids, we reduce the number of vertical grids of the model parameters using linear interpolation to avoid singular vectors with small singular values. Combining these two methods, we successfully find approximate solutions without over-fitting. In the presentation, we also discuss how the eruption conditions (e.g., magma discharge rate) are constrained by the model parameters estimated from the present method.

# Development of the plume source model for inversion of tephra fallout

*Akira Nishijo[1], Takehiro Koyaguchi[1], Yujiro Suzuki[1]

1. The University of Tokyo Earthquake Research Institute

During an explosive volcanic eruption, tephra falls out from eruption cloud to ground surface and forms tephra deposits. The characteristics of tephra deposits (e.g. their thickness and spatial distribution) reflect the eruption source conditions. When an eruption source condition is specified by parameters, tephra transport and deposition can be calculated using the advection-diffusion model. Based on this forward model, we can inversely search for an optimal set of parameters that explain the observed characteristics of tephra deposits (e.g. Conner & Conner 2006). In practice, we estimate the supply rate of tephra particles from the eruption cloud into the atmosphere as a function of height and grain size (referred to as “supply rate function”) from the inversion analysis. The form of supply rate function is determined by the physical processes of particle separation from the eruption cloud, and hence it must depend on the dynamics of eruption column. In previous studies, however, the form of supply rate function was assumed to be a certain mathematical function without physical considerations (White et al 2017). In this study, we developed a physical model to obtain the supply rate function.
The physical model is a combination of a particle sedimentation model and a cloud dynamics model. The sedimentation model describes the process of particle fallout from the cloud. The cloud dynamics model is subdivided into 2 models: the 1-D plume model and the gravity current model. The 1-D plume model describes the dynamics of eruption columns below the neutral buoyancy level (NBL), and the gravity current model describes the dynamics of spreading cloud around NBL. We used the 1-D plume model of Bursik (2001), which considers bending by windy air and the effects of particle sedimentation. We also take into account the geometrical effects of plume bending on the sedimentation model.
From a parametric study using the above physical model, we obtained the supply rate function for each grain size. The supply rate function is composed of two functions: “plume supply rate function” and “gravity-current supply rate function”. The plume supply rate function represents the mass loss of particles from the edge of a rising plume below NBL. It is convex downward and monotonically decreasing against height regardless of grain size. The gravity-current supply rate function describes the mass flux of particles at NBL in the cloud (i.e., at the top of the rising plume), and it is used as the source term for the gravity current model. The characteristics of the supply rate function depend on grain size. Because most of coarse particles (>10 mm) fallout from the lower part of rising plume, their plume supply rate function decreases rapidly with height, and the value of their gravity-current supply rate function is nearly zero. Because most of fine particles (< 1 mm) carried by rising plume up to NBL, their plume supply rate function has small values throughout the plume, and their gravity-current supply rate function is approximately equal to the supply rate at the vent. The plume supply rate function of intermediate particles (1~10 mm) is a mildly decreasing function, and it has larger values than that of fine particles; therefore, it has greater values than those of coarse or fine particles for the upper part of the plume. The value of the gravity-current supply rate function for intermediate particles remarkably decreases with the increasing grain size. In the presentation, we compare these results based on our plume source model with the mathematical functions used in previous inversion analyses.

# Segregation height and size distribution of volcanic ash of Sakurajima eruptions inferred by observed settling velocity

*Kosei Takishita[1], Masato Iguchi[2], Tadaomi Sonoda[2]

1. Graduate School of Science, Kyoto Univ., 2. DPRI, Kyoto Univ.

## 1. Introduction

The most important input values of a volcanic ash dispersion model are mass eruption rate and wind. Aiming more precise estimation, ash segregation pattern from plumes is also important. Mannen [2014] estimated the segregation height of ash particles of 1986B sub-Plinian eruption of Izu-Oshima volcano, with a column of 10km high, using Tephra2, an advection-diffusion model. Using a method similar to Mannen [2014], we investigate features of particle segregation height and size distribution (PSD), based on the observation of the settling velocity of ash particles released by many Vulcanian eruptions of Sakurajima Volcano.

## 2. Observation method and Data

We install Parsivel$^2$, a laser-optical rain gauge (OTT Co.) at 13 sites in Sakurajima. The instrument classifies particles into 32 diameters (0.2-24.5mm) and 32 settling velocities (0.2-20.8m/s), and records particle count every minute. We analyze the data from May to December in 2018. Ash particles were detected at a total of 261 sites from 156 eruptions among 346 events. The size ranges from 0.25mm to 20mm, and the volume-based mode diameter is 0.625mm - 0.75mm. The settling velocity is less than 12.8m/s and slower than the terminal velocity of sphere in each diameter [Wilson and Huang, 1973].

## 3. Analysis method

Ash particles from a plume reach the ground through combination process of advection, diffusion, and dropping. We estimate back trajectory of ash particles from the ground to the plume based on wind data measured by JMA, in order to determine the nearest point to the plume as the segregation height. Horizontal wind field is obtained at the time of eruptions by the interpolation in time and altitude, and vertical wind is neglected. We assume the 2D Gaussian distribution [Suzuki, 1983] for diffusion, a constant settling velocity determined by observation for dropping, and a vertical line source for plume.

## 4. Particle segregation and PSD

Segregation mass and PSD are obtained for 17 eruptions using the data of ash particles estimated to have segregated within 10 minutes from the eruption. The plume height ranges from 400 to 4700m, and the mass and PSD are estimated at heights interval of 150m - 990m. The largest height interval is obtained at 1260m –2250m above sea level (asl) for the eruption which occurred at 15:09, June 9$^{th}$ in 2018. Its plume height was 1400m above the crater (2400m asl), and $4.4\times10^3$ tons of ash is estimated to be released from the range. Here we define $\alpha$ as the logarithm of the segregation density [t/m]. In the eruption, $\alpha$ ranges from -1 to 0 and there was no correlation between $\alpha$ and height. As for PSD, there was a strong inverse correlation (R=-0.94) between height and volume fraction of particles smaller than 0.75mm.

The plume of the eruption on July 16$^{th}$ in 2018 reached an elevation of 4600m above the crater. Segregation mass is $3.6\times10^3$ tons at the altitude range of 1290m –1710m and 2070m –2570m asl. $\alpha$ ranges from -2 to 0, and there is no correlation with $\alpha$ and height. As for PSD, there is no strong correlation (R=-0.39) between height and volume fraction of particles smaller than 0.75mm.

While most of eruptions don’t have correlation between height and PSD, some have strong inverse correlation (R<-0.9; 4 events) and another has strong positive correlation (R>0.9; 1 event). Mannen [2014] also showed similar inverse correlation.

## 5. Examination of the method

©2019. Japan Geoscience Union. All Right Reserved. 

The mean $\alpha$ during the same period is obtained, 0.46, from the total mass of volcanic ash sampled continuously at wider area in Kagoshima pref. The mean $\alpha$ in this study, -0.18, is smaller than this because we treat the data for 10 minutes from the beginning.
Some segregation heights were obtained below the crater (1000m asl). This may be due to negligence of downward wind. Vertical wind will be taken into account later.

# Distant tracking of maximum pumice diameter in pumice-fall of the Tenmei eruption of Asama volcano: An attempt to draw isopleth lines of mm scale-maximum pumice diameter in the Kanto Plain

*Shingo Takeuchi[1], Shimpei Uesawa[1]

1. Central Research Institute of Electric Power Industry, Civil Engineering Research Laboratory, Geosphere Sciences

Volcanic ash-fall reaches distant areas and has great adverse effects on human health and society. Therefore, it is important to investigate properties of volcanic ash-fall of past eruption in distant areas for volcanic hazard assessment. However, thin ash-fall deposit in a distant point is not preserved as a visible geological layer. Instead, particles of ash-fall are mixed in soil. The characteristics of distal ash-fall particles in soil is an important geological evidence to assess volcanic ash hazard and constrain modelling of volcanic ash-fall processes in distant areas. Takeuchi and Uesawa (2018, JpGU) studied the Tenmei eruption (AD1783 eruption) of Asama volcano and detected pumice particles in the topsoil at areas along ash dispersal axis with distance up to ca. 170 km in the Kanto plain, and correlated the pumice particles to the pumice-fall of Tenmei eruption. They tracked the maximum pumice diameter (MP) along the dispersal axis and obtained the MP variation with distance which can be consistently linked with the data with distance up to ca. 55 km of Minakami (1942). In this study, same soil survey has been performed in areas away from the dispersal axis to track the maximum pumice diameter (MP). The preliminary result suggests that we can draw isopleth lines of MP down to 1 mm in diameter in the middle to the southern area of the Kanto Plain. In addition, we have investigated characteristics of ash fall of Tennin eruption (AD1108 eruption), because ash dispersal areas of Tennin eruption partly overlaps those of Temmei eruption in the northern Kanto Plain, at which pumice particles originated from the Tennin eruption are also found in topsoil. In the future analysis, we need to distinguish pumice particles from those of Tennin eruption to determine the MP of Temmei eruption.

# Degassing activity of Aso volcano, Japan, before the 8 October 2016 eruption measured by satellite and ground-based remote sensing techniques

*Masaaki Morita[1]

1. Geological Survey of Japan, AIST

The flux of volcanic gases has been monitored as sulfur dioxide ($SO_2$) flux at many volcanoes by ground-based remote sensing measurements using a miniature spectrometer such as Mini-DOAS. A recent advance in satellite remote sensing techniques has also enabled for $SO_2$ amounts emitted by persistent degassing to be monitored at sufficient temporal resolution. In this study, we combined these two techniques with ground-based visible camera images to constrain the degassing activity before the 8 October 2016 phreatomagmatic eruption of Aso volcano, Japan. We compared the time series of atmospheric $SO_2$ mass in the lower troposphere above the volcano measured by the Ozone Mapping and Profiler Suite (OMPS) nadir mapper instrument to those of the ground-based $SO_2$ flux and plume height measured by the Japan Meteorological Agency. Our results between April and October 2016 showed similar temporal variations among these values. The $SO_2$ mass and the plume height increased to, respectively, about 1000 tons and 900 m above the crater rim two months before the eruption, and then gradually decreased. Both values again increased about a week before the eruption and reached their maximum values (> 1200 tons and 1010 m above the crater rim, respectively). These similar temporal variations between the $SO_2$ emissions and the plume height likely indicate that, although the degassing system of the volcano has been stable during the study period, the accumulation of volcanic gases in the shallow part of the volcanic conduit might trigger the phreatomagmatic eruption. Our result suggests that the satellite remote sensing techniques can be sufficient for monitoring $SO_2$ flux of the volcanic plume at low altitude.

# Characteristics of polarimetric radar parameters of dry volcanic ash clouds

*Yura Kim[1], Masayuki Maki[1], Masato Iguchi[2], Dong-In Lee[3]

1. Research and Education Center for Natural Hazards, Kagoshima University, Korimoto, Kagoshima, Japan, 2. Sakurajima Volcano Research Center/DPRI, Kyoto University, Sakurajima, Kagoshima, Japan, 3. Department of Atmospheric Sciences, Pukyong National University, Namgu, Busan, Republic of Korea

We analyzed statistically the polarimetric radar data of 9 Sakurajima volcanic eruption clouds in 2013. All eruption clouds have a height exceeding 3000m. According to the results, $Z_H$ has positively skewed distributions (Skewness of 1.6; mean $Z_H$ of 9.77 dBZ and median of 7.4 dBZ), $Z_{DR}$ has normal distributions (Skewness of 0.02; mean $Z_{DR}$ of 1.58 dB and median of 1.6 dB), $K_{DP}$ has positively skewed distributions (Skewness of 7.12; mean $K_{DP}$ of 0.03 deg/km and median of 0.0 deg/km), and $\rho_{hv}$ has negatively skewed distributions (Skewness of -1.02; mean $\rho_{hv}$ of 0.77 and median of 0.8). Depending on time after the eruption, the average $Z_H$ decreased from 22.3 dBZ to 6.75 dBZ while the average $Z_{DR}$ and $\rho_{hv}$ tended to increase from 1.24 dB to 1.67 dB, and from 0.47 to 0.83, respectively.

# Development of easy tools for volcanic eruption plume/cloud analysis using weather radars

*Eiichi Sato[1], Ryutaro Senba[2]

1. Meteorological Research Institute, 2. Fukuoka Regional Headquarter, Japan Meteorological Agency

Meteorological Research Institute and Kagoshima Local Meteorological Office, Japan Meteorological Agency (JMA) have been cooperatively working on research on simple analysis methods of volcanic eruption plume using weather radars. In volcanology, since researchers of radar analysis whose target is volcanic eruption plume/cloud are minority, we are developing simple analysis tools especially for beginners of radar meteorology. As visible images of cameras were used to monitor volcano, operational analysis of volcanic eruption plume/cloud by JMA become impossible if the visibility is poor. If analysis using radar data became easier, immediate analysis of volcanic eruption cloud in all-weathers would be possible, and, as a result, we can make a database of “hidden” eruptions. In this presentation, outline of the tool development and results of a case study will be shown.
In the tool development, we use the software named “Draft” developed by MRI. This software consists of many commands, e.g., format conversion, analysis of radar data, and drawing results. Although it is possible to analyze the radar echo of volcanic eruption cloud using these commands, it may be difficult for beginners of radar meteorology and “Draft”. Hence, we started to create some shell scripts that the users can perceive the shapes of volcanic eruption plumes easily with radar data. Our goal is to make easy-to-use tools that enable us to do everything, from collecting radar data to drawing the results, automatically.
As a case study, we chose the eruption from the Minamidake summit crater of Sakurajima occurred on November 11, 2017. In this case, we couldn’t see the eruption plume by cloud around the summit. Considering the amount of ground deformation detected by extensometer in an observation tunnel in Arimura, Sakurajima, it's no wonder that the volcanic ash and the gas spewed to more than 5,000m with this eruption. It is because the amount of strain change associated with the eruption is almost the same with the case on June 16, 2018, whose eruption cloud height was 5,700m. In this case, we used the data of two (Fukuoka and Tanegashima) weather radars which belong to JMA operational weather radar network (JMA-RDN). As a result, we revealed that the eruption cloud was about 4,500 to 6,000m, and kept this height for about 10 minutes. In 2017, this eruption may be one of the largest eruptions, because the eruption occurred from Showa crater on May 2 is the only one eruption whose volcanic ash rose more than 5,000m.
Interestingly, we found two peaks in the radar echo distribution by the Tanegashima radar. We consider that one peak is due to the dense ash above the summit, and the other peak was made by aggregates and water coated ash. We are planning to carry out further analysis using different types of radar, e.g., polarimetric weather radar.
As a conclusion, effectiveness of the analysis tools using weather radars was confirmed in this study. It is expected that the tools enable us immediate analysis of volcanic eruption cloud in all-weathers. However, there are some problems. One of them is that we may not be able to analyze an accurate eruption cloud altitude especially in the case whose amount of ash is small and the duration is a few minutes, since the time resolution of the JMA-RDN is about 5minutes. We will continuously develop the analysis tools and improve the analysis methods through analyzing more cases.

# Paleotemperature and precipitation history (18.1–4.5 ka) in stalagmite bulk and clumped isotopes from Hiroshima, Japan

*Hirokazu Kato[1], Shota Amekawa[1], Akihiro Kano[1]

1. Department of Earth and Planetary Science, The University of Tokyo

Variation in stalagmite $\delta^{18}O$ is basically controlled by two major factors, temperature and isotopic composition of cave dripwater derived from the local precipitation. It is however not easy to separate relative impacts from these two fundamental controls by conventional oxygen isotope alone.
A possible solution is applying carbonate clumped isotope thermometry that can reconstruct the temperature without information of the isotopic compositions of the environmental water. The principle of the clumped isotope thermometry is based on the temperature-dependency of the abundance anomaly of $^{13}C^{18}O^{16}O$ ($\Delta_{47}$) from acid digestion of carbonate.
In this study, carbonate clumped isotope ($\Delta_{47}$) was measured from 50 layers of Hiro-1 stalagmite from Hiroshima Prefecture by purification line and MAT 253 settled at Kyushu University. The growth interval of the stalagmite is from 18.1 to 4.5 ka and includes two hiatuses in 10.8–7.7 ka and 12.8–11.4 ka.
The $\Delta_{47}$ values of 50 layers in Hiro-1 range from 0.683 to 0.741‰, which correspond to 3.2–23.4 ºC by temperature calibration on the basis of tufa measurements (Kato *et al.*, 2019).The temperature range of each time-series is 5.2–12.5 ºC (7.4 ºC in average; 18.0–16.0 ka), 10.4–12.8 ºC (11.9 ºC in average; 15.9–14.5 ka), 3.2–9.4 ºC (6.1 ºC in average; 14.2–12.6 ka), 6.8–12.4ºC (9.2 ºC in average; 11.0–10.7 ka), 7.6–23.4 ºC (15.7 ºC in average; 7.7–4.9 ka) and 3.9–9.7 ºC (8.2 ºC in average; 4.9–4.5 ka).
The $\Delta_{47}$ temperature record from Hiro-1 is broadly consistent with already-known climatic stages. For instance, the temperature recovery from LGM, lowering around Younger-Dryas, increase into Holocene and the peak of warming around Hypsithermal. Temperature difference between LGM (18.0–16.0 ka) and mid-Holocene (7.7–4.9 ka) is 8.3 ºC. Isotopic data in the period of 15.9–14.5 ka, and also at 10.7 ka has the features from the kinetic effect, i.e., high $\delta^{18}O$ values and low $\Delta_{47}$ values comparing to the data of adjacent intervals. These intervals are characteristic in high prior calcite precipitation (PCP) of Hiro-1 stalagmite as suggested by Hori *et al.* (2013) and this shift was likely caused by some disequilibrium effect.
The $\delta^{18}O_{Hiro\text{-}1}$ profile can be corrected by subtraction of temperature effect and $\delta^{18}O_{MW}$ which represents isotopic composition of past meteoric water was obtained. The reconstructed $\delta^{18}O_{MW}$ value shows 1–2‰ rising from the last glacial period to Holocene. The shift has probably reflected an increase of summer precipitation by strengthened EASM in Holocene and the lowering of continentality by advance of Seto Island Sea.

# Terrestrial paleoclimate since 80 ka recorded in stable and clumped isotopes of two stalagmites obtained from the Pacific side of the Japanese islands

*Shota Amekawa[1], Hirokazu Kato[1], Akihiro Kano[1], Kenji Kashiwagi[2], Taiki Mori[3], Ryoko Senda[3], Chuan-Chou Shen[4]

1. Graduate School of Science, The University of Tokyo, 2. Graduate School of Science and Engineering for Research, University of Toyama, 3. Graduate School of Integrated Sciences for Global Society, Kyushu University, 4. Department of Geosciences, National Taiwan University

Terrestrial paleoclimate during late Quaternary has been broadly reconstructed by oxygen isotope ($\delta^{18}O$) of stalagmites. Previous studies have pointed out that stalagmite $\delta^{18}O$ is largely associated with change in $\delta^{18}O$ of meteoric water due to amount effect and shift of vapor sources, but also can be influenced by temperature change. One of solutions for evaluating the temperature effect is carbonate clumped isotope thermometer. Clumped isotopes are isotopologues in which rare isotopes are doubly or multiply substituted. In case of $CO_2$ generated from reaction of carbonate and phosphoric acis, the measuring target is $^{13}C^{18}O^{16}O$ (mass of 47). Previous studies have shown that measured abundance of clumped isotopes is slightly more than the stochastic abundance and its excess or "clumping" ($\Delta_{47}$) comes from thermodynamic stability, which allows us to reconstruct temperature during carbonate precipitation only by $\Delta_{47}$ of the generated $CO_2$. In this study, $\Delta_{47}$ and stable isotopes are applied to two stalagmites from the Pacific side of the Japanese islands, which should not be affected by vapor from Indian Ocean and Japan Sea.
Two analyzed stalagmites (KA01 and 03) were obtained from Taiki town, Mie prefecture, Japan. 32 U-Th age points determined at National Taiwan University reveal that KA01 was dated from ca. 14 ka to ca. 1 ka and KA03 (Mori et al., 2018) was from ca. 80 ka to ca. 20 ka as well as the Holocene. $\delta^{18}O$ changes of KA01 and KA03 show similar trends with the cave records in south Chinese (e.g. Hulu cave), but the amplitude of the $\delta^{18}O$ changes was reduced in half.
Results of our $\Delta_{47}$ values require reconsideration of the previous interpretation for the Chinese stalagmite $\delta^{18}O$, dominant control by $\delta^{18}O$ of meteoric water. A reconstructed temperature at the top of KA01 is consistent with modern temperature at the cave. The whole trend of reconstructed temperature combined with $\delta^{18}O$ of modern rainfall indicates that $\delta^{18}O$ changes of KA01 are mainly controlled by temperature changes instead of rainfall $\delta^{18}O$. $\Delta_{47}$ of KA03 yields higher temperature during cool periods of Heinrich events (HE), which apparently contradicts with previous studies. Before and after HEs, the carbon isotopic value increases by 0.5–1 ‰, indicating degassing of $^{13}C$-depleted $CO_2$ from dripwater and carbonate precipitation in the conduit of the host rock because of reduced water supply. Drying during HEs could have made the surface of the stalagmite dry and resulted in apparent contradictory temperature. This study verifies that $\delta^{18}O$ change should be used together with $\Delta_{47}$ for robust interpretation of the stalagmite records.

# Seasonal changes in Li/Ca ratio and inferred phytoplankton abundance as analyzed by daily growth increments of *Pecten albicans* (Bivalvia)

*Kondo Yasuo[1], Hondo Shutaro, Hasegawa Hitoshi[1], Nshio Yoshiro[1], Hirota Takayoshi

1. National University Corporation Kochi University

To evaluate the potentials of scallop shells as paleoenvironmental archives, Li/Ca ratio and other geochemical data were obtained using LA-ICP-MS for the *Pecten albicans* specimen (KSG-th001) collected alive on April 29, 2011, from Tosa Bay, and was analyzed in relation to the seasonal changes of environmental parameters including water temperature and Chlorophyll *a* (Hirota and Ichikawa, 2012). In the analysis, fine striae on the left valve of *P. albicans*, were used as daily growth marker.
As a result, the analyzed specimen displayed overall higher rate of shell growth from spring to summer, while shell growth slowed down in fall and winter in 2010. A white band (annual ring) on the generally brown left valve corresponds to the lower rate interval of shell growth. However, another lower shell growth interval is recognized between spring (ca. 50 days) and late summer (ca. 20 days). This corresponds to the lower water temperature interval in late June and early July at 100 m depth in Tosa Bay, which is interpreted as representing upwelling associated with anticlockwise rotational current in Tosa Bay when the Kuroshio current became close to the shore.
These microgrowth patterns of the shell of *Pecten albicans* displayed a close similarity to the Li/Ca profile. Li enrichment in scallop shells is considered to have originated from the frustules of edible species in the digestive tract of scallops, and Li/Ca ratio of *P. maximus* in a bay in France was proposed as a proxy of timing and magnitude of diatom bloom (Thébault and Chauvaud, 2013). Our study confirms the validity of Li/Ca in scallop shells as a proxy of diatom bloom for different scallop species in a distant biogeographic province.
This study was performed under the cooperative research program of Center for Advanced Marine Core Research (CMCR), Kochi University Accept No.18B060 .

# Geological reconstruction of Antarctic Ice Sheet deglaciation on Soya Coast, East Antarctica since the Last Glacial Maximum

*Moto Kawamata[1], Yusuke Suganuma[2,1], Koichiro Doi[2,1], Takanobu Sawagaki[3], Akihisa Hattori[1]

1. Department of Polar Science, School of Multidisciplinary Science, SOKENDAI (The Graduate Unversity for Advanced Studies), 2. National Institute of Polar Research, 3. Hosei University

A robust understanding of the history of ice retreat in East Antarctica since the Last Glacial Maximum (LGM) is important in order to validate ice sheet and glacial-isostatic adjustment models and to anticipate their contribution to global sea-level rise. Geomorphological studies and surface exposure dating (SED) will provide direct evidence of the timing and the history of ice retreat on coastal oases and nunatak regions in East Antarctica. Recent studies have reported retreat ages based on surface exposure dating (SED) in Skarvsnes, southern part of Soya Coast, East Antarctica. However, the history of ice retreat remains unclear, because a limited number of surface exposure ages were reported by a previous study, and the results were not interpreted based on field-based geomorphological survey In this study, we reconstruct the last history of ice retreat of the Skarvsnes based on the field-based geomorphological survey and newly obtained SED samples. As results of the field survey, we distinguish three Phase of the ice sheet retreat at the Skarvsnes. The basement rocks at the highest peak (ca. 400 masl) to ca. 250 masl area of the Skarvsnes was weathered extensively, whereas weathering of the basement rocks below ca. 250 masl was relatively weak. The extensively weathered basement rock feature is quite similar to that of the northern part of Soya Coast, where $^{14}C$ dating of fossil shells in the raised beaches suggests that the area had remained ice-free throughout the LGM. Therefore, the differences in weathering feature are thought to indicate the upper limit of ice sheet height at LGM at the Skarvsnes (Phase 1). In the other area of Skarvsnes, glacial striations including cross-cutting set were clearly observed. That is, the ice sheet flow direction was changed with ice sheet thickness thinning under the influence of the basement topography after the LGM (Phase 2). Eventually, the ice sheet was flowing down divided in North and South obstructed by the 362 masl mountain (Shirasuso-Yama) near the current ice sheet margin (Phase 3). Several surface exposure ages were obtained from rocks sampled at sites of different altitudes and distances from the current ice margin. These ages are consistent with the above geomorphological interpretation and it suggests that near current ice sheet margin has been exposed from ice about 9 ka. These data are almost consistent with retreat ages at Mac. Robertson Land in East Antarctica.

Department of Solid Earth Geochemistry, Japan Agency for Marine-Earth Science and Technology

Silicate weathering on land has been considered to play an important role in controlling global climate change through the consumption of atmospheric $CO_2$ on long timescales (>$10^6$ yr). This process has been working as a negative feedback mechanism, which has prevented the Earth system from runaway warming or cooling. However, whether this system works on even shorter-term global climate changes on the timescale of $10^4$–$10^5$ yr such as Quaternary glacial-interglacial cycles is still controversial. In order to constrain the response time of the solid earth to global climate change, we employed the marine Os isotopic ratios ($^{187}Os/^{188}Os$) as a proxy of continental weathering. The marine Os isotopic ratio reflects the relative intensity of two dominant influxes to the ocean; radiogenic continental-derived materials ($^{187}Os/^{188}Os$ = 1.0–1.4) and unradiogenic mantle-like materials (i.e. hydrothermal fluids and cosmic dust) ($^{187}Os/^{188}Os$ = ~0.12). Owing to the contrasting $^{187}Os/^{188}Os$ values between these two influxes, and short residence time of Os in the ocean (~$10^4$ yr), the variability in $^{187}Os/^{188}Os$ of seawater constitutes a sensitive tracer for mantle and continental input into the marine environment. By assuming that the fluxes of mantle-derived materials into the ocean were constant during the Quaternary, we can obtain the fluctuation in the intensity of continental silicate weathering on glacial-interglacial timescales from the marine Os isotope record. Here, we report the marine Os isotopic variations during the glacial-interglacial cycles derived from the pelagic sediment in the Lau Basin, western South Pacific Ocean. In the present work, we targeted metalliferous carbonate as the most suitable media preserving marine Os isotope records at the timing of deposition. This sediment is enriched in hydrothermal Fe-oxyhydroxides that absorb Os in seawater efficiently and deposits rapidly without significant contamination of detrital materials from continents. As the result, we observed a clear fluctuation of the marine $^{187}Os/^{188}Os$ value along with the glacial–interglacial cycles. Based on the marine $^{187}Os/^{188}Os$ record, we also present the fluctuation of riverine Os flux calculated by simple 1-box mass-balance modeling, and its implications for the Quaternary climate change.

Studying changes in rates and magnitudes of glaciations/deglaciations during the past is a key to understand global climate system. The Last Glacial Maximum (LGM), centered around 20,000 years ago, as well as period after the LGM, therefore, represents key period to investigate. Sea level observations from sites far from the former ice sheets (far-field) are well suited due to the relatively small influence of surface deformation caused by glacio-hydro-isostatic adjustments (GIA). Australian coastlines are located in such regions and were targeted in this study of sea level changes over the past 30,000 years. The sites are situated off the North Eastern and North Western coasts of Australia respectively the Great Barrier Reef (GBR) and Bonaparte Gulf. Over thirty fossil reef cores were obtained from GBR shelf edge and two transects in northern and southern sites and >1,000 radiometric dating were conducted, in combination with detailed sedimentogic and biologic studies (Yokoyama et al., 2018). GIA modeling was also conducted to deduce global mean sea level (GMSL) from relative sea level records obtained from these regions. The results show that the LGM started when GMSL abruptly dropped by about 40 metres at around 31,000 years ago. The sea level at the shelf edge of the Great Barrier Reef then dropped by around 20 metres between 22,000 and 21,500 years ago, to -118 metres below the present and similar changes are observed in Bonaparte Gulf samples. Sea level began to rise just after the full extent of the LGM, consistent with previous studies. The LGM GMSL obtained from our study is about -125 to -130 metres. Sea level records from the North Australian coasts suggest that glaciers may have behaved more dynamically during the LGM than previously thought. The GBR had been existed despite from severe environmental changes during the last 30,000 years (Webster et al., 2018).

# Long-chain alkenediones found from marine sediments and their unsaturation ratios: key compounds to study the evolution of alkenone biosynthetic pathway?

*Satoshi Furota[1], Hideto Nakamura[2], Ken Sawada[3]

1. Department of Biogeochemistry, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 2. Faculty of Science, Osaka City University, 3. Department of Earth and Planetary Sciences, Faculty of Science, Hokkaido University

Long-chain alkenones ($C_{37}$ to $C_{39}$ alkenones) are characteristic compounds produced by haptophyte, and their unsaturation ratios in marine sediments have been used as a proxy for sea surface temperature (SST). Paleocenographic studies using the alkenone proxies are based on the physiological features of the modern alkenone producers such as *Emiliania huxleyi* and *Gephyrocapsa oceanica*. However, these species firstly occurred at ca. 0.29 Ma and ca. 1.85 Ma, respectively, and thus, understandings of the evolutional variations in the alkenone biosynthetic pathway is important to apply the alkenone proxies to the older age. In our recent study, $C_{38:2}$ alkenedione was found in the Miocene to Pliocene marine sediments (Furota et al., 2016). This compound was interpreted to be produced by ancient alkenone producers, because (1) the molecular structure resembles to those of the alkenones, (2) it has not been detected from the extant alkenone producers and sediments, and (3) the relative abundance of the alkenedione to alkenones were significantly higher in the older sediments. Therefore, the alkenedione presumably is a key compound to study the evolutional changes in the biosynthetic pathway of alkenones.
We analyzed the alkenones and alkenediones in the hemipelagic sediments recovered from the NE Atlantic during the IODP exp. 339 to evaluate the variations in their compositions at 100,000-year scale from the late Miocene to Pleistocene. We measured using gas chromatography–flame ionization detector (GC–FID) and GC–mass spectrometry (GC–MS) equipping with a mid-polarity capillary column (VF-200 ms). The GC analysis using the mid-polarity column makes the peak shapes sharp and achieves the well chromatographic separations in the analyses of long-chain alkenones, and thus, several recent studies applied this technique (Longo et al., 2013; Furota et al., 2016).
The long-chain alkenones and the $C_{38}$ alkenediones were detected from all the study samples. Interestingly, the carbon numbers of the alkenediones are only $C_{38}$ in contrast to the alkenones. Mass fragmentogram shows that the $C_{38}$ alkenedione has a methyl-ketone and ethyl-ketone groups at the each terminals of the carbon chain. In addition to $C_{38:2}$ alkenedione as reported previously, we firstly identified tri-unsaturated ($C_{38:3}$) alkenedione in the late Pliocene–Pleistocene sediments.
The relative abundances of the $C_{38}$ alkenediones to alkenones were significantly higher in older sediments, and gradually decreased from the Miocene to Pleistocene. These results support the interpretation that the alkenediones could be produced by the ancient alkenone producers, and imply that those producers decreased from the Miocene to Pleistocene. The unsaturation ratios of $C_{38}$ alkenediones, defines as $C_{38:2}/(C_{38:2} + C_{38:3})$, highly correlate with the unsaturation ratios of the $C_{37}$ alkenones ($U^{K'}_{37}$) ($R^2 = 0.85$). This fact strongly suggests that the alkenediones had a similar biological function and biosynthetic pathway related to the alkenones. Furthermore, the carbon number of alkenediones ($C_{38}$) is averaged one for those of alkenones ($C_{37}$–$C_{39}$), and the positions of ketone groups are equal to those of alkenones. From these results, we conclude that the $C_{38}$ alkenedione had the similar functions with the alkenones, and might be produced by primitive alkenone biosynthetic pathway.

# Geomorphic and pedogenic forcing on the distribution of organic matter from vegetation to soil- a concern for paleoenvironment studies

*Biswajit Roy[1], Kanva Goyal[1], Prasanta Sanyal[1]

1. Indian Institute of Science Education Research Kolkata

The $\delta^{13}C$ values of soil organic matter (SOM) have been used to reconstruct the abundance of $C_3$ and $C_4$ plants. However, the intimate connection of distribution of vegetation with geomorphic processes and landforms may impart different $\delta^{13}C$ value in the contemporaneous vegetation. Such variation would also get registered in the organic matter composition of the soil, with an erroneous assumption of a significant change in $C_3$ and $C_4$ abundance. Therefore, it is important to understand the effect of lateral variation in riverine geomorphic architecture and its impact on the $\delta^{13}C$ value of vegetation and soil. In this study, a lateral transect (6 km) of an undulatory geomorphic surface of north-south trending lateritic alluvium of South Bengal (India) was considered to unveil the effect of topography, and active channel distance on the contemporaneous vegetation and soil. A variation of ca. 50‰ is observed in the n-alkane H-isotopic composition ($\delta D_{C31}$) of the dominating tropical deciduous species (Sal- *Shorearo busta*). The $\delta^{18}O$ value of the groundwater and the river water was analysed to understand the source of water for the tropical trees. The D/H ratio suggests that the vegetation near the active channel was mostly influenced by the river water (enriched) and in distal areas by the groundwater (depleted). Preliminary study on the $\delta^{13}C$ values of the Sal species suggests an enrichment of ca. 7‰ away from the active river channel. The difference is attributed to the change in water-availability, canopy, topography, and vegetation density that varied along the transect. Disparity in the efficiency of water use was observed in the long chain n-alkane average chain length (ACL) and carbon preference index (CPI) distribution. The higher ACL (>29) and CPI (>2) values are mostly associated with the badlands or upland soil environment with very low moisture availability. Preservation of the contemporaneous vegetation signals in the litter layer was regulated by the geomorphology, vegetation density, and the soil texture. The upland, and the distal areas with sparse vegetation tend to preserve more positive $^{13}C/^{12}C$ ratio (−24‰) compared to the lowland with well-developed soils (−28‰). The upland and distal soils, with a coarser texture, suggests faster decomposition of OM (TOC% <0.2) due to higher percolation and soil aeration; whereas in fine-textured lowland soils depleted (−4‰) and high TOC% (>0.5) is observed. Further, due to continuous abrasion by the riverine process, the TOC is also low in the soils adjacent to the active river. The nitrogen isotopic composition ($\delta^{15}N_{SOM}$) increases as alteration/decay or leaching of SOM proceeds. The faster decomposition and microbial processing of SOM in upland and distal area soils registered higher $\delta^{15}N$ (+4‰) values whereas lower values are registered in low-lying areas. This geomorphic and pedogenic effect on the plant-soil system may result in ambiguous interpretation about the past vegetation and thus warrants detail vegetation, geomorphic and physical or chemical characterisation of the soil before employing it as a paleo-record archive.

# Sea surface salinity of the Kuroshio Current along the Nansei Islands in the mid-Holocene inferred from fossil corals

*Kohki Sowa[1], Chuki Hongo[2], Kentaro Tanaka[3], Takuma Fujii[4], Saburo Sakai[1], Kosei E. Yamaguchi[6,5]

1. Japan Agency for Marine-Earth Science and Technology, 2. Ryukyu University, 3. The University of Tokyo , 4. Kagoshima University, 5. Toho University, 6. NASA Astrobiology Institute

Sea surface salinity (SSS), which is the parameters of water mass properties, is one of the crucial tracers for reconstructing water motion and climate system. After the mid-Holocene, a period roughly from 7000 to 5000 years ago, freshening of seawater in the Western Pacific has been reported, and the cause of the salinity variation is under discussion (e.g. Stott *et al.*, 2004). The distribution of annual-mean salinity in the Northwest Pacific is space-dependent on factors such as depth, longitude, and latitude. Therefore, to understand the cause of the freshening, more constraining salinity conditions in time and space are needed. However, most research was limited to tropical areas.

The Kuroshio Current comes from the North Equatorial Current and cultivates the coral ecosystems of the subtropical, temperate area along the Nansei Islands (N24°-31°). Therefore, the Nansei Islands provide a latitudinal constraint to the paleo SSS variation. The $\delta^{18}O_{seawater}$ estimated from $\delta^{18}O$ and Sr/Ca in coral skeletons enables reconstruction of the seasonal SSS for shallow areas. Previous studies reconstruct SSS at Kuroshio Current only for Kikai Island (28°N, 130°E), which is off the main Kuroshio Current. To discuss spatial distribution of SSS during the mid-Holocene, further SSS data at different latitudes along the main Kuroshio Current area of the Nansei Islands are useful.

This study shows SSS for Okinawa Island (26°N, 128°E) and Takara Island (29°N, 129°E) during the mid-Holocene using modern and fossil coral cores. The $^{14}C$ age is 5400±140 cal. yr BP (Okinawa Island) from fossil *Porites* coral and 6180±180 cal. yr BP (Takara Island) from *Acropora* coral, which was collected near the coring site of the fossil *Porites* coral. For Okinawa Island, the seasonal $\delta^{18}O$ of fossil *Porites* coral (~26-year, N=1) averages -4.36‰, which is ~0.54‰ higher than that of modern coral (~5-year, N=2). XRD analysis and SEM observation imply good preservation of coral skeletons. The average extension rate > 6 mm suggests minor kinetic isotopic effect related to skeletal growth. Previous studies suggested that sea surface temperatures of the Kuroshio Current have been consistent during the past 7500 years, inferred from research on sediment cores (e.g. Lo *et al.* 2013). These imply that SSS was slightly higher in the mid-Holocene than today, at Okinawa Island. In this presentation, we will discuss SSS along the Nansei Island in the mid-Holocene using additional $\delta^{18}O$ and Sr/Ca analyses at Okinawa and Takara Island.

# An ocean-dynamic model for the periodic inflow of Tsushima Current in the early Holocene

*Atsuhiko Isobe[1]

1. Research Institute for Applied Mechanics, Kyushu University

In the early Holocene, the Tsushima Current was a periodic inflow into the Sea of Japan opened to the North Pacific, and thereafter became a steady throughflow after 8,000 years from the present (Oba et al., 1991, Oba, 2006). However, we met some resistance to accept this periodic-inflow idea from ocean dynamics, because the Tsushima Current has been recognized as a linear bypass flow which separates from the subtropical gyre (Minato & Kimura, 1980). Thus, the Tsushima Current could not be a periodic flow unless the subtropical gyre had fluctuated, or unless the Tsushima Strait was periodically opened and closed to the North Pacific. We here proposed an ocean dynamic model in which a periodic inflow generated from the steady subtropical gyre by using a non-linear model based on an island rule in Kida & Qiu (2013). We demonstrate that the volume transport of the Tsushima Current has two solutions which were alternatively revealed in line with the transition of the environment which might appear around the shallow Tsushima Strait in the early Holocene.

# Centennial to millennial scale variability of the Aleutian Low and Westerly Jet during the Holocene

*Kana Nagashima[1], Naomi Harada[1]

1. Japan Agency for Marine-Earth Science and Technology, Research and Development Center for Global Change

The Aleutian Low (AL), the semi-permanent low-pressure system located over the Gulf of Alaska, is critically linked to environmental change in the North Pacific and surrounding continental areas. At timescales that exceed the recent instrumental record of the last 100 years, the AL intensity has been reported to vary on centennial to millennial scales from various proxy records (e.g., Anderson et al., 2005, 2016; Fisher et al., 2008; Jones et al., 2014). However, the ultimate trigger of these intensity changes has not been systematically studied.

Recent meteorological records showed that the Westerly Jet (WJ) over East Asia and the North Pacific links strongly to the AL intensity and position through changes in cyclogenesis, monsoon, and storm track activity (e.g. Lau, 1998; Nakamura et al., 2002; Nakamura and Shimpo, 2004). According to Lau (1988), southward displacement of the WJ axis and associated storm track path over the North Pacific results in a southeastward shift and intensification of the AL. At longer timescales, however, the interactions between the AL and the WJ are virtually unknown. This study examines millennial- and centennial-scale linkages between the AL and WJ during the Holocene to better understand the long-term nature of their interaction. We also introduce WJ records from the Southern Hemisphere, because the WJ path in both the Northern and Southern Hemispheres trace the expansion and shrinkage of the Hadley Cell circulation, which helps to understand changes in North Pacific atmospheric circulation.

The proxy records of the AL and WJ revealed millennial-scale coupling of the AL-WJ path with weakened AL and poleward WJ shifts in both hemispheres during 7–5.2 and 2.8–1.2 ka, and an intensified AL and equatorward shift of the WJ path during 5.2–2.8 ka and 1.2 ka onward (Nagashima et al., submitted to Quaternary Research). Centennial scale AL intensification and equatorward shifts of the WJ path in both hemispheres also appeared in the proxy records. Periods of centennial and millennial-scale AL maxima and equatorward shifts of the WJ correlate well with periods of solar activity minima, suggesting solar activity has played a primary role in the generation of the atmospheric circulation changes, possibly through dynamic Hadley cell changes (Nagashima et al., submitted to Quaternary Research).

# Monsoon-related errors in paleotemperature estimation based on leaf margin analysis in central Japan

*Yuqing Wang[1], Arata Momohara[1], Yongjiang Huang[2]

1. Graduate School of Horticulture, Chiba University, 2. Key Laboratory for Plant Diversity and Biogeography of East Asia, Kunming Institute of Botany, CAS

Paleotemperature reconstruction has important implications for a better understanding of present climate change. Among various paleotemperature estimation methods, Leaf Margin Analysis is a method that has been widely used by paleobotanist. In the modern flora, former researchers found that the percentage of the species with untoothed leaf margin in total woody dicot species of a flora (untoothed%) is strongly correlated to mean annual temperature (MAT). Based on this phenomenon, equations showing relationships between untoothed% and MAT have been used in paleotemperature estimation proposed as the Leaf Margin Analysis. However, untoothed%-MAT relationships are inconsistent among different regions according to previous studies. To date, eight different untoothed%-MAT equations have been proposed for different regions, although several samples from Japan are included, these sites were only obtained from limited areas close to the Pacific Ocean. However, considering various local climate conditions caused by the complex topography in Japan along with the different influence of summer and winter monsoon, the untoothed%-MAT relationship may vary among different areas in Japan, which cannot be reflected in the formerly published equations.

In this study, we aim to detect the untoothed%-MAT relationship in woody floras of central Japan. Two research areas with different climate conditions were chosen: The Pacific Ocean coastal areas and the Sea of Japan coastal areas. Based on the climate data, the Pacific Ocean coastal areas are characterized by less snow condition and higher summer precipitation affected by the activity of the East Asian Summer Monsoon. While the Sea of Japan coastal areas are characterized by heavy snow in winter, which is formed under the influence of Tsushima warm current in the Sea of Japan with East Asian Winter Monsoon, and grown season precipitation in this zone is much lower than the Pacific Ocean coastal areas.

We found that the untoothed%-MAT relationships of the two research areas are obviously different. In the Pacific Ocean coastal areas, a significant positive untoothed%-MAT relationship was detected. Compare to the other regions of the world, floras from central Japan include more species characterized by toothed-margin leaf at a given mean annual temperature. While in deep snow areas along the Sea of Japan, the untoothed%-MAT relationship becomes unclear with the effect of deep snow cover.

According to our results, paleotemperature estimated by the Leaf Margin Analysis of Japanese fossil floras may include inadequacy. The heavy snow condition along the Sea of Japan began since the middle Early Pleistocene, thus fossil floras of interglacial stages younger than that of these areas is not suitable to do the Leaf Margin Analysis. For Japanese fossil localities from areas without thick snow cover, because the untoothed%-MAT relationship of Japanese flora deviates from other regions of the world, applying these fossil floras into the formerly published untoothed%-MAT relationships will receive inaccurate paleotemperature data.

[J] Poster | M (Multidisciplinary and Interdisciplinary)：M-IS Intersection

Thu. May 30, 2019 3:30 PM - 5:00 PM JST | Thu. May 30, 2019 6:30 AM - 8:00 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_23

## [M-IS19] Paleoclimatology and paleoceanography

convener:Yusuke Okazaki(Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University), Akira Oka(Atmosphere and Ocean Research Institute, The University of Tokyo), Michinobu Kuwae(Center for Marine Environmental Studies), Hitoshi Hasegawa(Faculty of Science and Technology, Kochi University)

Past environmental changes and events at multi-decadal to tectonic timescale toward an understanding of Earth climate system by an integration of terrestrial and marine proxy studies and numerical modeling will be discussed. At JpGU2019, a series of presentations on present and future climate and environmental changes from paleo-perspective will be held. We welcome a variety of paleo-environmental studies from a wide range of background. We hope that this session will provide an opportunity to promote communication between participants from multidisciplinary field.

# Orbital-scale changes in redox condition and biogenic silica/detrital fluxes of the Jurassic Radiolarite: Possible link with glaciation?

*Masayuki Ikeda[1]

1. Shizuoka University

Orbital forcing has been shown to be a fundamental driver of climate change through both icehouse and greenhouse periods. To reveal the impact of orbital-forcing on the oceanic environment through a greenhouse-icehouse transition, we established ~ 4 Myr-long cyclostratigraphy of the Bajocian-Callovian (Middle Jurassic; ~ 160 Ma) Basal Radiolarites at the Torre De Busi and Corre Di Sogno sections in the Lombardian Basin, N-Italy. Stratigraphic changes in chertabundance (chert/shale thickness ratio) and color (darkness) of Radiolarites show hierarchal periodicities of 8 cm, 16 cm, 40 cm, 160 cm, and ~ 4 m, corresponding to ~ 20 kyr, 40 kyr, 100 kyr, 400 kyr, and ~ 1 Myr cycles based on the biostratigraphic age model. Black cherts in intervals with high chert abundance might reflect oxygen-depleted conditions due to orbital-scale high productivity. On the other hand, black cherts in intervals with low chert abundance (high detrital input) might reflect oxygen-depleted conditions, probably due to orbital-scale sea-level drop and stratification. On 40 kyr and 100 kyr cycles, the anoxic condition occurred in low chert abundance intervals across ~ 8 m above (~ 2 Myr after) the base of the Radiolarites. These results imply that the formation of the restricted basin resulted from tectonic and/or eustatic sea-level drop, which is consistent with increased black chert deposition and redox-sensitive elements abundances (Mo/TOC, Mo/U). Their out-of-phase relationships on the 405 kyr cycle throughout the sequence (~ 4 Myr-long) with increasing amplitude above −8 M level would be caused possibly by tectonic activity, or more likely by glacio-eustatic sea-level changes reported from sequence stratigraphy, similar to those of the Oligocene to Pliocene glacial cycles, but probably with less amplitude.

# Evaluation of hinterland weathering and paleoclimate of the Cretaceous strata in the Sichuan basin, central China

*Tenichi Cho[1], Hideaki Mantani[1], Tohru Ohta[1], Gang Li[2]

1. Waseda University, 2. Nanjing Institute of Geology and Paleontology

Reconstruction of paleoclimate during the Cretaceous Period is important for the understanding of the Earth system operating during the greenhouse conditions. However, information of paleoclimate from continental inland-basins is scarce compared to continental margin marine-basins. This situation is also true in the Asian continent; Cretaceous ecosystem and paleoclimate data are accumulating in the Pacific side, while those of the Asian continental side is lacking. Paleoclimate conditions in Asian inland basins are considered to be equally important in order to elucidate the land-ocean climate system operated during the Cretaceous. In this regard, the present study investigates the geochemistry and clay mineralogy of the Cretaceous mudstones distributed in the Sichuan basin, central China, for the aim of paleoclimate evaluation. The depositional age of studied strata ranges from Berriasian to Maastrichtian. Sediments are mostly fluvial to lacustrine origin, however recently, a broad distribution of aeolian dune sandstones was identified from the Cenomanian to Turonian interval (Li et al., 2016). Before discussing hinterland weathering and paleoclimate, the effect of diagenesis was evaluated, which can alter the geochemical signatures of paleoclimate. The illite crystallinity index indicates that diagenetic effect was moderately high for the analyzed mudstones, and the degree of diagenesis has a high correlation with CaCO3 abundance. Accordingly, CaO wt% abundances are mostly of post-depositional carbonate origin, and thus, CaO derived from carbonates was subtracted from the following discussion of hinterland weathering evaluation. Geochemical weathering indices (e.g., W value) demonstrate a significant increase in hinterland paleoweathering from Berriasian (W=70) to Cenomanian-Turonian (W=95), and then slightly decrease towards the Maastrichtian (W=80). This fluctuation pattern of the weathering indices is concordant with the Cretaceous paleotemperature estimates (e.g., O’ Brien et al., 2017). Therefore, the present result suggests that the hinterland paleoweathering rate in the Sichuan basin was governed by the global temperature changes. The weathering index reached the maximum value of 95 in Cenomanian-Turonian stages. Furthermore, sediments of Cenomanian-Turonian horizons contained abundant kaolinite mineral, which is a product of hydrolysis decomposition of rock-forming minerals. Both lines of evidence suggest that the Sichuan basin was under the tropical and pluvious climate during the Cenomanian-Turonian. However, as mentioned before, the previous study identified aeolian sand dunes from the Cenomanian-Turonian strata. Note that Li et al. (2016) elucidated an arid climate from amalgamated sandstone facies, while the present pluvious climate interpretation is derived from the analysis of intervening piled mudstone facies. When these geological evidences are integrated together, it is reasonable to suggest the development of an alternating pluvious and arid paleoclimate during the Cenomanian-Turonian. The nature and trigger of this extremely oscillating pluvious/arid climate cannot be deduced solely from the present study. However, the timing of this renewed climate system matches with the Cretaceous greenhouse optimum (Cenomanian-Turonian). The development of monsoon-like pluvious/arid paleoclimate in the Sichuan basin is possibly related to the mid-Cretaceous re-configuration in the global climate system.

# Productivity-induced lacustrine bedded chert formation in the Eocene Green River Formation

*Ryusei Kuma[1], Hitoshi Hasegawa[2], Koshi Yamamoto[1], Hidekazu Yoshida[1], Masayuki Ikeda[3], Nagayoshi Katsuta[4], J. Whiteside[5]

1. Nagoya University, 2. Kochi University, 3. Shizuoka University, 4. Gifu University, 5. Southampton University

Rhythmically alternated beds of chert and shale, also called as bedded chert, are commonly observed in marine sedimentary rocks. Recent studies revealed that changes in bed thickness of chert represent orbitally-paced variations in marine productivity and silicate weathering rate (Hori et al., 1993; Ikeda et al., 2017). On the other hand, bedded cherts are occasionally found in lacustrine deposits. Previous study interpreted that formational mechanism of lacustrine bedded chert is linked to the interplay between silica dissolution in alkaline lake waters and its precipitation due to the conversion of lake water’ s pH (e.g. Hesse, 1989). Some studies suggested that the pH of saline and alkaline lake water could have changed by the freshwater input (Eugster, 1967; Eugster 1969). Other study implied that the metabolic processes of cyanobacteria modified the pH of lake water and influenced to the silica precipitation (Behr and Rohricht, 2000). However, convincing evidence of chertification mechanism in lacustrine deposits have not been clarified yet.

In order to elucidate the formation mechanism of lacustrine chert, the present study examined a lacustrine bedded chert succession in the Eocene Green River Formation in northern Utah, USA. We have conducted detailed field survey in the Indian Canyon section in northern Utah. Bedded cherts occur in shallow lake level stage and alternated with dolomite beds with every 5–10 cm in thickness. Elemental mapping by Scanning X-ray analytical microscope (SXAM) reveals that the Ca concentration in dolomite layer, while Si concentration in chert layer, with sharp boundary coincide with lithofacies boundary. Elemental distribution also shows that alternation of chert and dolomite occur in every 1–2 cm in thickness. In addition, fluorescent microscopic inspection reveals that the distribution of Si concentration coincides with the dense accumulation of spherical organic matter. These spheres show the brightest fluorescence carbon shell with similar size (30–40 $\mu$m). The morphology of these spherical organic matter resembles to green algae, such as *Botryococcus braunii*, which are also abundantly preserved in the Green River Formation. Occurrences of algal organic matters in chert layer imply that deposition of algal organic matter could be related with the formation of lacustrine chert.

It is noteworthy that the lake water alkalinity of the Green River Formation is considered to be high (pH>9) because of extensive volcanic activity around Colorado Plateau. These lines of evidence suggested that silica precipitation is possibly caused by decreased pH due to the decaying organic matter (increasing $CO_2$ and/or organic acid) in sediment pore water. Deposition of organic matter can be related to changes in the lake algal productivity. Given that sedimentation rate of the formation in Indian Canyon section is estimated as ca. 10–15 cm/kyr (Smith et al., 2008), observed chert occurrence (1–2 cm and 5–10 cm) yields 67–200 and 333–1000 year’ s cyclicities. Therefore, periodic occurrences of chert beds in the Green River Formation are possibly linked to the centennial-scale changes in the lake algal productivity.

# Extraction of the sedimentary cycles and application of cyclostratigraphy to the Middle Miocene Onnagawa Formation in Yashima District, Akita Prefecture, Japan

*Jumpei Yoshioka[1], Ryuji Tada[1,3], Kenji Marc Raymond Matsuzaki[2], Toshihiro Tada[1], Aki Sakuma[1], Yusuke Umemiya[1], Shunsuke Kurokawa

1. Department of Earth and Planetary Science, the University of Tokyo, 2. Atmosphere and Ocean Research Institute, the University of Tokyo, 3. Yunnan University

Middle Miocene (16.0-11.6Ma) is the time of the second of the three cooling steps during Cenozoic. In this cooling event, siliceous sediments with high organic contents were widely deposited along the North Pacific rim because of high productivity and/or preservation of diatoms. In the northern Japan Sea, those sediments are known as the Onnagawa Formation. It was reported that siliceous rocks in the Onnagawa Fm. showed meter-scale rhythmical bedding reflecting fluctuations in productivity of diatoms and flux of detrital materials. Furthermore, it was also reported that parts of highly siliceous rocks in the Onnagawa Fm. showed centimeter-scale black bands. However, the age and the cause of their occurrence has not been understood.

In this study, we tried to construct a high-resolution and precise age model of the Onnagawa Fm. in the Yashima District by applying cyclostratigraphy to the m-scale rhythmical bedding, that is attributable to the fluctuation of biogenic silica content.

Firstly, a ca. 130m-long continuous composite columnar section was constructed by correlation of 6 sections. This composite columnar section is divided into 5 lithological units, cyclic alternations of marl and interbedded mudstone (Unit A), mudstone with cyclic siliceous rocks intercalations (Unit B), siliceous-mudstone with muddy-porcelanite intercalations (Unit C), bedded muddy-porcelanite with cm-scale black bands (Unit D) and siliceous-mudstone and hard siliceous-mudstone alternations (Unit E).

“Silica rank”, which is defined as degree of siliceousness and divided into 5 grades based on hardness of the siliceous rocks observed in the field and confirmed by XRD analysis, was determined every 10cm for Unit B, Unit C and Unit D. It showed obvious m-scale cyclicities. The silica rank variation for Unit B and Unit C was obviously different from that for Unit D, and it is considered that this difference may reflect either the change in the sedimentation rate or the change in response of sedimentation mechanism to the orbital forcing that results in the lithological change. In order to construct an age model, the silica rank was tuned to $\delta^{18}O$ of benthic foraminifera with age constraints given by microfossil biostratigraphy.

# Pliocene magneto–oxygen isotope stratigraphy from the Anno Formation, Awa Group, central Japan

*Yuki Haneda[1], Makoto Okada[1]

1. College of Science, Ibaraki University

The Pliocene climate is one of the best analogs for the climate of a globally warmer future. Here, we present a new Pliocene integrated chronostratigraphy from the Anno Formation in the uppermost Awa Group, which is distributed throughout the Boso Peninsula, central Japan, based on paleomagnetic and benthic foraminiferal oxygen isotope records. This new chronostratigraphy provides valuable constraints for paleoceanographic and paleoclimatic studies in the northwestern Pacific Ocean, where the number of paleoceanographic records is limited due to the lack of calcareous microfossils from deep-sea sediment cores, with the exception of some plateaus at water depths above the calcite compensation depth (CCD).

We performed progressive Alternating field and thermal demagnetizations for each specimen in order to remove secondary remanence. Additionally, we conducted thermomagnetic, low-temperature magnetic, magnetic hysteresis, and FORC analyses as rock-magnetic experiments to assess stability of paleomagnetic signal which specimens have acquired. The paleomagnetic and rock-magnetic experiments indicate that primary remanences are carried by magnetite in pseudo-single domain size as detrital remanent magnetization. The progressive AF demagnetization is, however, unsuitable to remove secondary remanence in specimens from polarity transitional horizons due to magnetically hard mineral, such as goethite. Therefore, thermal demagnetization is necessary to obtain primary remanence from the Anno Formation.

Paleomagnetic results by the thermal demagnetization indicate that the Anno Formation corresponds to the period extending from the Nunivak normal polarity subchronozone (4.493–4.631 Ma) to Chron C2An.2n (3.116–3.207 Ma). Although foraminifera are not found in the middle Anno Formation, our oxygen isotope records from the upper and lower Anno Formation demonstrate the recording of glacial–interglacial cycles. However, the amplitude of our $\delta^{18}O$ profile is much larger than that of the LR04 stack, with similar to slightly lower glacial values and much lower interglacial values. This trend is suppressed after 3.4 Ma. These observations imply that the bottom water had lower $\delta^{18}O$ values and/or a warmer water mass during interglacials until 3.4 Ma compared with global average deep-water regions.

# Planktonic foraminiferal assemblage and paleoceanography of the Plio-Pleistocene sequence at IODP Site U1499 in the northern South China Sea

*Mizuki Kitamura[1], Akira Furusawa[1], Hiroki Hayashi[1]

1. SHIMANE University

The South China Sea (SCS) is a marginal sea located in the tropical zone of the western Pacific with an average depth of ca. 1,140 m. The East Asian monsoon affects the climate system in this area by the prevailing seasonal winds. Such influence of the East Asian monsoon is expected to be stronger during the glacial period and weaker during the interglacial period.
During Internatinal Ocean Discovery Program (IODP) Expedition 367, drilling of Site U1499 was conducted near the outer shelf of the northern SCS in 2017. As an onboard result of this site, sediments from Oligocene to Present were recovered and the upper sequence especially contains abundant foraminiferal fossils. The purpose of the present study is to clarify temporal changes of planktonic foraminiferal assemblage in the northern SCS from approximately 4 to 1 Ma.
As a result, 80 species belonging to 19 genera of planktonic foraminifera were detected. According to multivariate analyses of the foraminiferal assemblage, we determined the temporal change into four stages: Stage A (ca. 4.1 to 3.4 Ma), Stage B (ca. 3.4 to 1.8 Ma), Stage C (ca. 1.8 to 1.45 Ma) and Stage D (ca. 1.4 to 1 Ma). During Stage A, SCS had been stratified by oligotrophic tropical surface water and relatively cold subsurface water with a shallow thermocline. At the next Stage B, the thermocline was deepened and SCS was occupied by a subtropical oligotorophic water. In turn, the thermocline shoaled and subsurface species of planktonic foraminifera were increased during the Stage C. After that, the Stage D is characterized by alternative changes between subtropical surface components and cold-temperate components caused by the glacial-interglacial changes.

# Reconstruction of the surface water mass fluctuation during the late Pliocene to early Pleistocene based on planktonic foraminiferal fossils from the Mera Formation, Chikura Group, in the southernmost part of the Boso Peninsula

*Makoto Okada[1], Daisuke Hasegawa[2]

1. Department of Earth Sciences, Faculty of Science, Ibaraki University, 2. Graduate School of Scinece and Engineering, Ibaraki University

The purpose of this study is to examine whether the cooling event has occurred associate with the NHG (Northern Hemisphere Glaciation) off the Boso peninsula and how the surface water mass has changed with the glacial-interglacial cycle. We carried out analysis of planktonic foraminiferal assemblages at the 57 horizons corresponding to period from 3.0 Ma to 2.2 Ma. We propose 6 phases including the following three distinctive phases based on relative abundance of environmental indicator species.
Phase Ⅱ (2.75-2.65Ma): Transitional water species increased up to 50%. It was a cold environment where the influence of mixed water was strong.
Phase Ⅴ (2.42-2.35Ma): Kuroshio species increased up to 40%, which is the highest value in this study
PhaseⅥ (2.35Ma~):Transitional water species increased to about 50% while repeating amplitude. Therefore, cooling was gradually strengthened in this phase.
Cooling did not proceed unilaterally after 2.7Ma, it occurs again from 2.35Ma after the period when the influence of Kuroshio became temporarily stronger. In addition the glacial-interglacial cycles seem to be affecting composition of planktonic foraminiferal assemblages.

# Centennial-scale bioproductivity changes during the earliest Middle-Pleistocene

*Waka Fujii[1], Masayuki Hyodo[1], Shigehiro Katoh[2], Yosuke Miyairi[3], Haruka Yamaguchi[1], Yusuke Yokoyama[3]

1. Kobe University, 2. Hyogo Museum of Nature and Human Activities, 3. University of Tokyo

Elucidation of the mechanism of global warming in the geological time is important, which may lead to understanding of the present global warming. In this study, we conducted paleoenvironmental analyses of sediments to reveal the rapid climate changes across the warmest interval in the Marine Isotope Stage (MIS) 19 interglacial, which is known as an orbital analogue of the Holocene. In particular, we aim at elucidating the mechanism of the repeated bioproductivity proxy (Ca/Ti ratio) changes dominated by bicentennial cycles for a span from about 777 to 775 ka, which was observed in core TB2 from the Chiba Section. Focused on the time span, we conducted pollen analyses using the Osaka Bay 1,700 m core with abundant pollen fossils, and measurements of $^{10}$Be using core TB2. Both cores are stratigraphically correlated with the centennial to millennial scale resolution. The result of pollen analyses revealed that the proportion of evergreen *Quercus* (*Cyclobalanopsis*), a warm proxy, began at about 777 ka to increase with bicentennial oscillations, followed by a sudden drop within 1 kyr. These changes are quite consistent with those in the bioproductivity in core TB2. Therefore, the bioproductivity changed affected by the climate. The $^{10}$Be content, an index of the galactic cosmic ray flux, generally showed similar changes with the bioproductivity except some intervals, one of which showed a large disagreement between the $^{10}$Be flux and the bioproductivity, coincided with the iceberg discharge event in the North Atlantic. These results suggest that the centennial-scale bioproductivity changes observed in core TB2 probably reflect climate variations, and may be affected by solar activity. Solar activity can affect climate through galactic cosmic rays that control the low cloud (Svensmark effect), in addition to the direct influence through solar radiation.

# Development of new-paleoceanographic proxies based on oxygen isotope analysis of sponge spicule

*Hitomi Uchimura Wakaki[1], Akira Ijiri[2], Minoru Ikehara[1], Sangmin Hyun[3]

1. Center for Advanced Marine Core Research, Kochi University, 2. Japan Agency for Marine-Earth Science and Technology, 3. Korea Institute of Ocean Science & Technology

The objective of this study is to construct the new-paleoceanographic proxy based on the oxygen isotope ratio of sponge spicule. To examine the variations in water depth and temperature, we selected GH08 surface sediment samples ranging from a water depth of 216 m to 2679 m in the Northwest Pacific. These samples were obtained from the area off eastern Okinawa Island during the GH08 cruise in 2008 by Geological Survey of Japan, AIST. The upper 0–2 cm of each surface sediment was sampled. The sediment samples were washed in a 250-mesh sieve and dried in the oven. In this study, we also analyzed the oxygen isotope ratio of sea-bottom water by laser spectroscopic analysis of Liquid Water Isotope Analyzer (LWIA).

We chose two benthic foraminifers' species *Cibicidoides* sp. and *Cibicidoides wuellerstorfi* to analyze the oxygen isotope ratio. Benthic foraminifer was analyzed by phosphoric acid digestion to carbon dioxide gas and the measurement of the oxygen isotope ratio by IsoPrime at Kochi University. We can recognize that the result of the foraminifera between the oxygen isotope ratio and temperature has a negative trend. In other words, the oxygen isotope ratio of benthic foraminifera in this study shows temperature dependence. Our results agree with those obtained by the previous studies (Marchitto et al., 2014). These results can be regarded as the data of benthic foraminifera in this study is considered appropriate for the reference.

We also analyzed the oxygen isotope ratio of sponge spicule by a new method of iHTR (inductive high-temperature carbon reduction) and CF-IRMS (continuous-flow isotope ratio mass spectrometry) (Ijiri et al., 2014). Some the oxygen isotope ratio values of sponge spicule are consistent with previous reported data (Brandriss et al., 1998, Moschen et al., 2005), which were analyzed the oxygen isotope ratio of biogenic opal (diatom). However, some of the oxygen isotope ratio of sponge spicule don't have any trends. These irregular date has possibility to be influenced by the acid treatment and the difference of gas pressure, and should be evaluated the validity in future experiment used based on additional samples.

Keywords: sponge spicule, benthic foraminifera, stable oxygen isotope, temperature dependence

# A system for automatic collection of specific microfossil species using a deep learning classification

*Takuya Itaki[1], Yosuke Taira[2], Naoki Kuwamori[2], Toshinori Maebayashi[3], Satoshi Takeshima[4], Kenji Toya[4]

1. Geological Survey of Japan, AIST, 2. NEC Corporation, 3. Microsupport Co.Ltd, 4. Mitani-Corporation

For geochemical analysis such as stable isotope ratio, radiocarbon age and minor elements for a single species of microfossils, a large number of their skeletons is required to pick up one by one with enormous time and effort by a person under a microscope. In this study, we have developed a device that automates these efforts. Even if experts are absent, microfossils are accurately classified their taxonomic species level using deep learning which is one of the learning methods of artificial intelligence, and they are picked up using a micromanipulator installed in the microscope with motorized X-Y stage. It is possible to collect a large number of particles with speed and accuracy that could not be achieved with human hands. This technology to accumulate only specific species of microfossils contributes not only to greatly reduce hand work of picking up, but also to be enable chemical analysis such as isotope ratios and minor elements for small microfossil species that hitherto difficult because the necessary measurement amount cannot be collected.In addition to microfossils, it can be applied to various particles, and it is also expected to be utilized in various fields such as medical, food, horticulture and materials.

# Towards reconstructing environmental conditions related to Australian Great Barrier Reef initiation

*Stephen Obrochta[1], Wataru Miwa[1], Kotaro Shirai[2], Yusuke Yokoyama[2], Yosuke Miyairi[2], Jody Webster[2,3], Albert Hine[4]

1. Akita University, 2. University of Tokyo Atmosphere and Ocean Research Institute, 3. University of Sydney, 4. University of South Florida College of Marine Science

Previous work exploited the unique mixed carbonate-siliciclastic environment of Northeast Australia to identify the timing of changes in off-shelf sediment transport with respect to sea-level variation. Because sediment transport from the continental shelf to slope is strongly controlled by the presence/absence of a rimmed morphology, this provides a means for indirectly estimating the age of the Great Barrier Reef (GBR). Preliminary results indicate that a change in the timing of maximum off-shelf terrigenous sediment accumulation occurred during the glacial termination of MIS 20. This in turn suggests that an effective barrier morphology was emplaced during the MIS 21 interglacial. Instead of being deposited directly to the continental slope by incised rivers, terrigenous material first accumulated behind the barrier during the MIS 20 sea-level lowstand and was then redoposited as rising sea level reflooded the shelf.

Here we present initial results attempting to understand if and how changing environmental conditions promoted enhanced reef growth. The results include a higher-resolution isotope stratigraphy for improved chronological control, additional terrigenous mass accumulation rate measurements, and initial results of Mg/Ca analyses, which allow for calculating sea surface temperature changes and the oxygen isotopic composition of sea water that is expected to better resolve glacial-interglacial cycles. In the future we expect to add additional information from micro and/or nanofossil faunal assemblage data.

# An 8,000-year climate record from Lake Motosu, Japan: Implications for the East Asian Monsoon

Sarah McDonlad[3], Jonathan Tyler[3], *Stephen Obrochta[1], Yusuke Yokoyama[2], Yosuke Miyairi[2], Kosuke Ota[2]

1. Akita University, 2. University of Tokyo Atmosphere and Ocean Research Institute, 3. Department of Earth Sciences, The University of Adelaide

The East Asian Summer Monsoon controls the timing and amount of rainfall for around a third of the world’ s population. An understanding of past changes in monsoon strength is thus crucial for placing current events in context and for characterising future climate risk. Whilst many monsoon records have been developed for continental Asia, fewer records exist from the north-eastern edge of the monsoon region. We present a new monsoon record for central Japan based on an 8,000-year lacustrine sedimentary sequence from Lake Motosu, located at the northern foot of Mt Fuji. Lake Motosu is a hydrologically closed lake and is therefore expected to be sensitive to changes in monsoon strength. Additional macrofossil radiocarbon dates are used to refine an existing high-fidelity age model. This age model is then applied to constrain the timing of changes in bulk sediment geochemistry (TC, TN, C/N, $\delta^{13}C$, $\delta^{15}N$) and the oxygen isotopic composition of sedimentary cellulose ($\delta^{18}O$). Changes in sediment chemistry reflect shifts in the sources of organic matter to the sediments, variations in lake hydrology and changes to the local catchment. In turn, these changes are linked to regional variations in monsoon strength. However, their interpretation is complicated by the impact of local seismic and volcanic activity.

# Environmental changes in northern Mongolia in During the Late Pleistocene: chemical analyses of lacustrine sedimentary sequences in Darhad basin

Yumiko Ohno[1], Sayuri Naito[1], *Nagayoshi Katsuta[1], Takuma Murakami[3], Shinya Ochiai[2], Noriko Hasebe[2], Shin-ichi kawaka[4]

1. Faculty of Education, Gifu University, 2. Institute of Natural and Environmental Technology, Kanazawa University, 3. Horonobe Research Inst. for the Subsurface Environment, 4. Faculty of Education, Gifu Shotoku Gakuen University

Spread of modern human (*Homo sapiens*) from Africa to Eurasia seems to have occurred in the periods from ca. 60 kyrs ago to ca. 50 kyrs ago via two routes from western Asia into northern Eurasia and across Arabia into southern Asia. To understand relationship between environmental changes and human migration in central Eurasia, we reconstructed a 120-kyr sediment record of environmental change using the Darhad basin (northern Mogolia) sediment core with a nondestructive $\mu$-XRF techniques of Horiba SXAM, XRD analysis, and petrolograhic observation.

# Paleoenvironmental changes recorded in Orog Lake, southwestern Mongolia during MIS 3 and its relationship with *Homo sapiens*' migration into northern Asia

*Hitoshi Hasegawa[1], Nanase Noma[1], Nagayoshi Katsuta[2], Masafumi MURAYAMA[3], Toru Tamura[4], Masami Izuho[5], Niiden Ichinnorov[6], Davaasuren Davaadorj[7], Noriko Hasebe[8], Miho Sasaoka[9], Masao Iwai[9]

1. Faculty of Science and Technology, Kochi Univ., 2. Faculty of Education, Gifu Univ., 3. Faculty of Agriculture and Marine Science, Kochi Univ., 4. Geological Survey of Japan, AIST, 5. Faculty of Social Sciences and Humanities, Tokyo Metropolitan Univ., 6. Mongolian Academy of Sciences, 7. National University of Mongolia, 8. Institute of Nature and Environmental Technology, Kanazawa Univ., 9. Center for Advanced Marine Core Research, Kochi Univ.

An aim of the present study is to understand detailed paleoenvironmental changes in Mongolia, situated at a key crossroad for *Homo sapiens*'s migration between central, eastern, and northern Asia during the Initial and Early Upper Paleolithic (IUP-EUP). Available archaeological evidences have suggested the emergence of IUP at around ca. 45-40 ka (e.g., Zwyns *et al.*, 2014; Rybin *et al.*, 2016; Izuho *et al.*, 2018). However, yet the paleoenvironmental changes of this period in Mongolia is largely unclear, preventing us to understand whether the possible environmental changes were significant as a major driving forth for modern human's lifeway.

In this paper, we present a new record of paleoenvironmental changes in southwestern Mongolia during MIS 3. In January 2017, we took two parallel cores (OROG01, 24 m; OROG02, 21 m) from Orog Lake, a shallow saline lake located in northwestern margin of Gobi Desert. The high-resolution major and minor element composition changes were obtained using μXRF core scanner (Cox, Itrax) at Center for Advanced Marine Core Research, Kochi University. Based on the preliminary results of OSL and 14C age dating, basal age of sediment core OROG01 yielded ca. 38 ±4 ka, nearly accordant with the basal age of ~45 ka reported in the previous study (Yu *et al.*, 2019). On the basis of our high-resolution elemental composition data, in conjunction with previous sedimentological and palynological data (Yu *et al.*, 2019), the paleoenvironments of southwestern Mongolia were more humid with higher lake levels during MIS 3 than Holocene. Our results also suggest periodic and higher amplitude paleoenvironmental changes in this region, which likely correspond to Dansgaard-Oeschger events. This new record would allow us to discuss potential relationship between paleoenvironmental changes and ecosystem changes in Mongolia during the IUP-EUP.

# Reconstruction for water-mass structure of the Okhotsk Sea for the past 1.5 million years based on radiolarian assemblages

*Tatuya Sakamoto[1], Yusuke Okazaki[1]

1. Department of Earth and Planetary Sciences, School of Science, Kyushu University

The North Pacific Intermediate Water (NPIW) play an important role in transporting heat and freshwater. NPIW originates from the Okhotsk Sea where is the southernmost seasonal ice area in the northern hemisphere. Sea-ice in the Okhotsk Sea is formed mainly in the northwestern shelf area and moved south by the seasonal wind. Brine water rejected during sea-ice formation sinks to the intermediate layer and forms the Okhotsk Sea Intermediate Water (OSIW) characterized by abundant particulate organic carbon, low temperature, and rich in oxygen. OSIW is a source water of NPIW. Radiolarians are zooplankton with biogenic opal skeletons, and various species distribute from sea-surface to deep-sea. *Cycladophora davisiana* is a radiolarian species that favors well-ventilated intermediate water masses, therefore, *C. davisiana* is used as indicator of OSIW. In this study, we conducted radiolarian assemblage analysis for a giant piston core sample (MD01-2414, water depth 1123 m) to reconstruct the water-mass structure change for the past 1.5 million years. Size fraction greater 45 micrometers were used for slide preparation for light microscope observation. In general, total radiolarian skeletons during interglacials were 10 to 100 times greater than that during the glacial periods. *Cycladophora davisiana* was abundant during interglacials, suggesting enhanced OSIW formation. However, during MIS 11 and 31 known as the super interglacials, much less C. davisiana abundances were observed, suggesting weaken OSIW formation due to significant sea-ice retreat. Four radiolarian biostratigraphic markers in the North Pacific region were identified: *Amphimelissa setosa*, *Lychnocanomma sakaii*, and *Spongodiscidae* sp. In addition, two radiolarian species *Ceratospyris borealis* and *Zygocircus productus* indicated high productivity during interglacials.

# Silicoflagellate assemblages in the Okhotsk Sea during the interglacial periods

*Kazuki Egashira[1], Yusuke Okazaki[2], Tatsuhiko Sakamoto[3]

1. Department of Earth and Planetary Sciences, Kyushu University, 2. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University , 3. Mie University

Silicoflagellate is a phytoplankton with a skeleton of biogenic opal. There are two major genera for modern silicoflagellates: *Dictyocha* mainly dwelling in tropical to temperate regions and *Stephanocha* mainly dwelling in subarctic region. The *Dictyocha*/*Stephanocha* ratio has been used as a paleotemperature proxy. Earth’s climate for the past 800,000 years is characterized by the glacial and interglacial cycles with a frequency of 100,000 years. Oxygen isotope ratios of benthic foraminifera mainly reflect continental ice-sheet volume fluctuations, lighter in the interglacials and heavier in the glacials. This fluctuation is called as Marine Isotope Stage (MIS), odd numbers correspond to interglacials and even numbers correspond to glacials. Among the interglacials, the oxygen isotope ratios were lighter than that of the present: MIS 5e (120,000 years ago), 9 (330,000 years ago), and 11 (400,000 years ago). Pollen assemblages in Lake El’gygytgyn sediment from the Far East Russiat in the Arctic Circle indicates pronounced warming during MIS 11. Because atmospheric carbon dioxide concentrations during the past interglacials were comparable to the preindustrial level, it is important to know the status of warming climate during interglacials. The purpose of this study is to reconstruct sea-surface conditions of the Okhotsk Sea during the past interglacials based on silicoflagellate assemblages preserved in sediments. By comparing silicoflagellate assemblages during MIS 1, 5e, 9 and 11, we test the extent of warming during interglacials. The Okhotsk Sea is a marginal sea of the western North Pacific located south of Lake El’gygytgyn, known as southernmost sea-ice covered area in the Northern Hemisphere. A piston core YK07-12 PC-3B (water depth: 1049 m, core length: 14.09 m). Age model of core YK07-12 PC-3B is established by benthic foraminiferal oxygen isotope stratigraphy and the estimate bottom age is 450,000 years ago. Silicoflagellate assemblage analysis was performed by using sediment samples collected from sedimentary horizons corresponding to MIS 1, 5e, 9, and 11. For each interglacials, three samples from peaks of biogenic opal content, maximum calcium carbonate content and minimum benthic foraminiferal oxygen isotope ratio were picked up, consequently, a total of 12 samples were selected. 100 silicoflagellate specimens were counted for each slide under light microscope. Almost all encountered silicoflagellate species during core YK07-12 PC-3B microscopic observation were belonging to genus *Stephanocha*. During MIS 11, *Stephanocha speculum*(particularly, *S. speculum minuta*) was the most abundant silicoflagellate taxa. Because *Stephanocha speculum*is known as a representative silicoflagellate species in the subarctic Pacific dwelling cold and nutrient rich environments, this result indicates that there is no evidence of significant warming in the Okhotsk Sea during MIS 11. Another abundant silicoflagellate species in core YK07-12 PC-3B was *Stephanocha octangulata*, also known as subarctic taxa. This species was dominant during MIS 1 and 5e. Unique oceanic environments such as seasonal sea-ice coverage and influence of low salinity water originating from the Amur River may have influenced on the silicoflagellate assemblages of core YK07-12 PC-3B.

# Role of wind stress and sea surface thermal forcing in the formation of the Atlantic meridional overturning circulation at the Last Glacial Maximum

*Akira Oka[1], Kazuki Togawa[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

In Previous Paleoclimate Model Intercomparison Project (PMIP) simulations of the Last Gracial Maximum (LGM) Atlantic Meridional Overturning Circulation (AMOC), the most of PMIP2 and PMIP3 models reproduced the 'deeper and stronger' AMOC than preindustrial simulations, in contrast to some reconstructions from paleo proxy data.Prior researches pointed out three factors controling the strength of AMOC in LGM climate: the cooling of the oceans in the Southern hemisphere, cooling in the North Atlantic, and the surface wind stresses in the North Atlantic. However, in the above-mentioned prior researches, the influences of these three factors on AMOC were only independently evaluated and the combined influences are still largely unknown. Here we emphasize the relative evaluation of combined influences of above- mentioned three factors on the AMOC. For this purpose, various ocean model experiments with our general ocean circulation model (COCO) were conducted; wind stress and thermal boundary conditions taken from PMIP experiments are replied to our ocean general circulation model. As a result, it was found that the difference of thermal boundary condition in the southern hemisphere most affects the strength of AMOC, and this cooling in the southern hemisphere is a necessary condition for reproducing the ‘shallower and weaker’ AMOC, but not a sufficient condition. From these results, it is implied that the stronger glacial AMOC reported in the PMIP models was possibly caused by the insufficient cooling in the southern hemisphere in LGM experiment, and this insufficient cooling possibly comes from warm bias there in the present state experiment and the associated underestimation of ice albedo feedback of sea ice.

# Comparison of the Kuroshio during LGM simulated by an ocean general circulation model driven by multiple paleoclimate models

*Kensho Ichikawa[1], Haiyan Yang[2], Xinyu Guo[2], Yasumasa Miyazawa[3]

1. Graduate School of Science and Engineering,Ehime University, 2. Center for Marine Environmental Studies,Ehime University, 3. Japan Agency for Marine-Earth Science and Technology

The Kuroshio that flows south of Japan has an important role in the climate of East Asia and Japan. In modern days, the Kuroshio presents a stable path and contributes to maintenance of warm climate. However, this stable condition is considered to be different in Last Glacial Maximum (LGM) when different environment conditions from the present day were reported. During the LGM, the sea surface level was lower than present by about 130 m and the westerlies shifted southward. In addition, the air-sea heat flux was also expected to be different from present. Therefore, it is necessary for the simulation for the Kuroshio in LGM to consider the changes in above three factors (sea level, westerly, and air-sea heat flux). The Kuroshio in LGM was calculated by a numerical model that included the above mentioned three factors in Muto (2018). The model results presented the southward shifting of the Kuroshio path and decreasing of the Kuroshio intensity. However, this result was obtained from one paleoclimate model (IPSL). Therefore, it is necessary to use more paleoclimate models to confirm the results given by Muto (2018).

In this study, we performed similar calculations for the Kuroshio in LGM using four additional paleoclimate models (CNRM, GISS, MIROC, MRI) as driven forcing of ocean model. Before calculation, we compared the vorticity of wind stress given by these paleoclimate models and obtained the Sverdrup transport that is also an index of Kuroshio intensity.

Among all the five paleoclimate models, the position of zero vorticity, which corresponds roughly the position of Kuroshio, shifted to the most southward in IPSL. At the same time, the Sverdrup transport was the lowest in IPSL. Therefore, the southward shifting of the Kuroshio path and the weakening of the Kuroshio intensity given by Muto (2018) are likely an extreme case among five paleoclimate models.

# The changes of the Kuroshio path in the Northwest Pacific since 35ka

*Haiyan Yang[1], Xinyu Guo[1], Ayako Abe-Ouchi[2], Yasumasa Miyazawa[3], Sergey Varlamov[4], Wing-Le Chan[2]

1. Center for Marine Environmental Studies, Ehime University, 2. Atmosphere and Ocean Research Institute, University of Tokyo, 3. Research Institute for Global Change, Japan Agency for Marine-Earth Science and Technology, 4. Application Laboratory, Japan Agency for Marine-Earth Science and Technology

Kuroshio, a strong western boundary current in the subtropical North Pacific, has strong influences on the climate of Japan and East Asia. Global sea level rises and falls when ice sheets and glaciers melt and grow. The Last Glacial Maximum (LGM, 21ka) is the most recent interval in Earth history when global ice sheets reached their maximum integrated volume. The expansion of the ice sheets at the LGM resulted in a sea-level lowering of about 130 m and a cold phase compared to present. Under the circumstance of sea level, Kuroshio did not bifurcate into the Japan Sea and form the Tsushima Current. As the sea level rises, the Tsushima Current flowed into the Japan Sea at about 10ka (Gallagher et al., 2015), and the sea-level reached the present level at 7ka~6ka (Zheng et al., 1994). However, how the Kuroshio and Tsushima Current pathway evolved in the conditions of different sea level and climate remains unclear.

In Okinawa and southern Korea, some archaeologists have found evidences of people drifting on the Kuroshio from Taiwan to northern regions. According to studies by Japanese anthropologists, the first person that set foot on Okinawa probably sailed there on bamboo rafts from Taiwan more than 30,000 years ago. However, this hypothesis needs more evidences because sailing across the Kuroshio is a difficult thing if the Kuroshio 30,000 years ago had the same surface velocity as present. Therefore, clarifying the strength and path of Kuroshio is also helpful to the understanding on human migration.

In this study, we used the model of Japan Coastal Ocean Predictability Experiment (JCOPE) to simulate the changes of the Kuroshio path under the combined influences of sea level, the air-sea heat flux, and wind stresses in five historical regimes (35ka, 30ka, LGM, 6ka, and 0ka). The meteorological and oceanic data are provided by the climate model MIROC4m (Chan et al., 2011) which is a fully coupled atmosphere-ocean general circulation model (AOGCM).

# Temperature reconstruction in the late Pleistocene using fossil terrestrial snails and a stalagmite from an archaeological cave in Okinawa

*Ryuji Asami[1], Rikuto Hondoh[2], Ryu Uemura[3], Ryuichi Shinjo[3], Akihiro Kano[4], Masaki Fujita[5], Shinji Yamasaki[6], Hideko Takayanagi[1], Yasufumi Iryu[1]

1. Graduate School of Science, Tohoku University, 2. Faculty of Science, Tohoku University, 3. Faculty of Science, University of the Ryukyus, 4. School of Science, the University of Tokyo, 5. National Museum of Nature and Science, 6. Okinawa Prefectural Museum and Art Museum

Freshwater snails are useful for a paleoclimate proxy. For example, stable oxygen isotope composition of mollusck’ s aragonite shells depends on temperature and oxygen isotope composition of water at the time of their growth. The Ryukyu Island Arc, bounded by the East China Sea to the northwest and by the Pacific Ocean to the southeast, is an important area in climatology because its environment is highly associated with the East Asian monsoon (EAM), typhoon, and the Kuroshio current. However, terrestrial paleoclimate records such as tree rings and stalagmites are little in the Ryukyu Island Arc unlike the East Asia Continent. Meanwhile, Okinawa is widely known as a hotspot in archaeology and a lot of ancient remains and digs have been excavated for recent years. Sakitari Cave, where world’ s oldest fishhooks were discovered, is one of the most famous archaeological sites in Okinawa.
In this study, fossil shells of a freshwater snail *Semisulcospira libertina* excavated at Sakitari Cave in Okinawa-jima were investigated. These samples were from two sediment layers dated to 13-16 ka and 23 ka in the cave. We measured stable carbon and oxygen isotope ratios and trace element concentrations at intervals of 1 mm along the growth direction of the snails to reconstruct seasonal temperature variations during the Last Glacial Maximum and the last deglaciation. To estimate paleo-temperature and -oxygen isotope composition of precipitation accurately, we also measured oxygen isotope composition of fluid inclusion water in a stalagmite collected near the archaeological site. Comparing with chemical composition of living *S. libertina* shells collected around the site, estimated annual mean temperature was about 8 ˚C and 6˚C lower at 23 ka and 13-16 ka than at the present. Summer temperature has largely increased from 23 ka to 13-16 ka relative to winter temperature, which is consistent with North Hemisphere insolation changes in summer and winter. Our results indicate that the increase of mean air temperature around Okinawa-jima was larger than that of seawater temperature in the northwestern Pacific Ocean during the last deglaciation. This inconsistency is a significant finding for better understanding of past climate changes associated with the East Asian Monsoon.

# Silicoflagellate and *Actiniscus* response to meltwater during the last deglaciation in the Alaska margin

*Asuka Tomokawa[1], Yusuke Okazaki[1], Jonaotaro Onodera[2], Keiji Horikawa[3]

1. Department of Earth and Planetary Sciences, Kyushu University, 2. Research and Development Center for Global Change, JAMSTEC, 3. Graduate School of Engineer and Science, University of Toyama

Silicoflagellate is a phytoplankton with biogenic opal skeleton, and its fossil assemblage is used for reconstruction of paleoenvironment. There are two major genera for modern silicoflagellates: *Dictyocha* mainly dwelling in tropical to temperate zone and *Stephanocha* mainly dwelling in subarctic zone. The *Dictyocha*/*Stephanocha* ratio has been used as a paleotemperature proxy. *Actiniscus pentasterias* is a species of Dinoflagellata with biogenic opal skeleton, indicator of coastal and low salinity environments. Gulf of Alaska is located eastern North Pacific. The southern Alaska margin has fjord created by the Cordilleran Ice Sheet. The purpose of this study is to clarify the silicoflagellate and *Actiniscus* assemblages to meltwater input from the Cordilleran Ice Sheet at the last deglaciation in the southern Alaska margin. A piston core KH17-3 CL14 was obtained from the southern Alaska margin (59° 33.350’ N, 144° 09.344’ E, water depth: 695 m). Age model of core KH17-3 CL14 is established by planktic foraminiferal radiocarbon dates and the bottom of the core is estimated to be ~17 ka. We used 48 samples for Silicoflagellate and *Actiniscus* analyses. 100 silicoflagellate specimens were counted for each slide and all *Actiniscus pentasterias* specimens were counted for each slide under light microscope. 7 species and 2 subspecies of genus *Dictyocha* and 4 species of genus *Stephanocha* were identified. Relative abundances of genus *Dictyocha* accounted for greater than 50% since Younger Dryas (YD), whereas genus *Stephanocha* (particularly *S. speculum*) was abundant during Bolling-Allerod (BA). This suggests that *Dictyocha*/*Stephanocha* ratio didn’t simply reflect cold (YD) and warm (BA) events during the last deglaciation. Two *Actiniscus pentasterias* peaks were observed during the last deglaciation which were coincident with Meltwater Pulse 1A and 1B. This suggests salinity decline due to meltwater from the Cordilleran Ice Sheet. The meltwater into the subarctic Pacific may have leaded to enhanced productivity during BA. Because *Stephanocha speculum* is suggested to be an indicator of high productivity from modern sediment trap observation, high abundances of *S. speculum* in core KH17-3 CL14 during BA can be explained by the enhanced productivity driven by meltwater from the Cordilleran Ice Sheet.

# Application of the ramped pyrolysis $^{14}C$ dating to postglacial sediments from the Alaskan margin, Arctic Ocean

*Kenta Suzuki[1], Masanobu Yamamoto[1,2], Brad Rosenheim[3], Takayuki Omori[4], Leonid Polyak[5]

1. Graduate School of Environmental Science, Hokkaido University, 2. Faculty of Environmental Earth Science, Hokkaido University, 3. College of Marine Science, University of South Florida, 4. The University Museum, The University of Tokyo, 5. Bard Polar and Climate Research Center, Ohio State University

Radiocarbon dating of biogenic carbonates, such as foraminiferal tests, is commonly used for dating marine sediments up to 50 ka old. However, in carbonate-poor environments, such as typical for polar seas, direct dating of carbonaceous material is difficult, while bulk organic matter (OM) may contain a mixture of carbon with different ages. Rosenheim et al. (2008) developed the ramped pyrolysis $^{14}C$ dating of the bulk OM based on incremental generation of $CO_2$ from a range of carbon fractions, from highly reactive to more thermochemically stable. Application of this approach to Southern Ocean sediments showed that ages of highly-reactive, lower temperature fractions were considerably younger than other fractions and the bulk $^{14}C$ age. In this study, we explore ramped pyrolysis $^{14}C$ dating in Arctic Ocean sediments from the Alaskan margin to determine if the same relationships hold true.
Samples were taken from two sediment cores collected on the 2005 HOTRAX expedition and comprising Holocene marine and older glaciomarine strata (Darby et al., 2009a). Several $^{14}C$ ages have been generated on the Holocene biogenic carbonates (Darby et al., 2009b). New samples from both the Holocene and older sediments were pyrolyzed from room temperature to 900 ˚C, and the released, purified $CO_2$ fractions were sealed in borosilicate glass ampoules at the University of South Florida. Measurement of $\Delta^{14}C$ was conducted at the University of Tokyo.
Pyrolysis followed by oxidation generated three peaks of $CO_2$ at ~300 ˚C, ~400 ˚C and ~540 ˚C, which were deconvolved into three Gaussian peaks (G1 to G3). These peaks were interpreted to reflect the consecutive degradation of oxygen-containing OM functional groups, cleavage of carbon-carbon bonds, and cleavage of aromatic ring carbon, respectively. In this scenario G1 contains most of the autochthonous carbon from the sediment. We found that the slopes of the G1-G3 $^{14}C$ ages plotted against temperature of the Gaussian centroid are proportional to the offset between $^{14}C$ ages of G1 and earlier analyzed biogenic carbonates from the same core levels. Assuming that this relationship is a constant function of the overall measured age spectra, we propose to use it for estimating sediment ages from the ramped pyrolysis $^{14}C$ data. The estimated G1 age offsets range from 800 to 3,000 years in the Holocene and from 4,000 to possibly as high as 5,000 years in the older glaciomarine sediments.

# Utility of sedimentary environmental DNA for indices of past pelagic fish species populations

*Hiromichi Tamai[1], Michinobu Kuwae[2], Hideyuki Doi[3], Toshihumi Minamoto[4]

1. Graduate School of Science and Engineering, Ehime university, 2. Center for Marine Environmental Studies, Ehime university, 3. Graduate School of Simulation Studies, University of Hyogo, 4. Graduate School of Human Development and Environment, Kobe University

Far little is known about long-term dynamics of almost all of fish species populations in the ocean during pre-instrumental era. Here we focused on environmental DNA in marine sediments as a potential tool to elucidate past fish population dynamics and tested its utility to reconstruct fish abundance in Japanese coastal waters. Based on quantitative PCR method applied to the sediment samples collected from anoxic bottom sediments in Beppu Bay, Japan, we found environmental DNA of Japanese anchovy, Japanese sardine, and Jack mackerel in the 1-meter sediment sequences spanning over the last 250 years, which is the first detection of sedimentary marine fish DNA. The observed temporal changes in sedimentary DNA abundances are consistent with those in fish scale abundances and catch in Japan, suggesting the utility of the sedimentary fish environmental DNA to track past changes in fish abundance in waters from the bottom sediment sequences. DNA analyses of five fractions of sediment samples including coarse and fine particle fractions, pore water, fish scales, and bones suggested that a main source of fish DNA in the sediments is derived from fine the particle fraction.

# Improvements of extraction methods of sedimentary fish-origin DNA for reconstruction of marine fish communities

*Jun Kurata[1], Hiromichi Tamai[2], Hideyuki Doi[3], Toshihumi Minamoto[4], Michinobu Kuwae[5]

1. department of earth science, Ehime university, 2. Graduate School of Science and Engineering, Ehime university, 3. Graduate School of Simulation Studies, University of Hyogo, 4. Graduate School of Human Development and Environment, Kobe University, 5. Center for Marine Environmental Studies, Ehime university

Environmental DNA is DNA fragments derived from body fluids or skin fragments of macro organisms contained in water or soil. It is expected to can be a technology to reveal long-term fish community changes which still remains unknown in the world ocean. However, DNA in the sediments has a low concentration, therefore, it is difficult to detect for a various kind of fish species. The purpose of this research is to elucidate the method that can take sedimentary DNA more efficiently. At this time, we tested five DNA extraction methods including the conventional one together with beads beating time. Quantitative PCA results showed that Power Soil had the best yield in the replications. In addition, DNA extraction of *Truchurus japonicus* figured out a better yield by increasing the amount of sediment sample. There was a significant difference between 10 min. and 30 sec. of beads beating time, it is possible that there is a higher yield with short time beating. Our future works is to test whether DNA yield improves by shortening or eliminating bead beating, effectively removal of PCR inhibitors, and an utility of PCR inhibitor.

Research Institute of Geology and Geoinformation, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST), Japan, 4. Department of Biochemistry, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Japan, 5. Research and Development Center for Global Change, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Japan

Recently, investigations of Holocene climatic variability and its socioeconomic impacts have received increasing attention with regard to the prediction of future climatic change and the evaluation of its impact on human society. The Kanto area around the Tokyo Bay, Japan had a large population in the Neolithic Jomon age. After the establish of centralized system, this area has been a stage of major change in Japanese history for many times. The paleoenvironment around the Tokyo Bay has been estimated based on the analysis of the shell mounds along the coast or historical documents. However, the continuous and high time resolution paleotemperature record has not existed yet.

A piston core KT12-06-2B (8.99m) were recovered from the Tokyo Bay during the Tansei-maru KT12-06 cruise. An age model for the core, determined by the AMS$^{14}$C dating for 22 molluscan shells and the scoria layer of Hoei eruption, showed that it has the continuous records from about 4, 500 years ago. We analyzed the content of total organic carbon (TOC), alkenone unsaturation ratio ($U^{k'}_{37}$), and coccolith assemblages for this core in order to reconstruct the paleoenvironment in the Toyo Bay.

The constant TOC values (1.3-1.7 wt.%) before 1700AD suggested the stable biological production at the core site. We converted $U^{k'}_{37}$ into alkenone-SST using the conversion formula, proposed by the culture experiment of *G. oceanica* because most of coccolith contained in the sediments were *G. oceanica* based on the polarizing microscope observations. From 400 AD to the present, the alkenone-SST ranged from 20.5˚C to 22.4˚C (21.6˚C on average), including several cold periods around 1700 AD, 1420 AD, 1280 AD, and 1010 AD, which corresponded approximately to the Maunder, Spörer, Wolf, and Oort Minimum, respectively. The SSTs before 400 AD largely fluctuated between 19.5˚C and 25.3 ˚C, and its average value was 22.6˚C, which was 1 ˚C higher than the average after 400 AD. Especially large cold periods were detected around 520-440 BC (with a minimum value of 20.0℃) and 2360-2280 BC (with a minimum value of 19.5℃). The former cold period, which was also reported by the several previous studies in East Asia, might be caused by the other large minimum of solar activity around 500BC. The latter cold period corresponds to the global cooling/drying event accompanied by the monsoon retreat. In the mid- to late-Jomon age, the Neolithic Jomon society around the Tokyo Bay based on hunting and gathering, not paddy rice cultivation. We assume that they lived in warm but unstable climate, which might be disadvantageous for them to start agriculture.

# Summer monsoon variability over the past 400 years in Tateyama, Japan, as reconstructed from tree-ring oxygen isotope data

*Masaki Sano[1], Kota Mori[1], Akane Tsushima[2], Zhen Li[3], Koh Yasue[4], Takeshi Nakatsuka[2,3]

1. Faculty of Human Sciences, Waseda University, 2. Nagoya University, 3. Research Institute for Humanity and Nature, 4. Shinshu University

With its high sensitivity to hydroclimate variability, tree-ring oxygen isotope composition has been widely used for dendroclimatology over monsoon Asia in recent years. Here we built a 400-year tree-ring oxygen isotope chronology from Tateyama, Japan to reconstruct summer hydroclimate in the region, and compared it with other tree-ring data to explore spatio-temporal variations in hydroclimate. We collected tree-ring core samples from *Pinus parviflora* var. *pentaphylla* at an altitude of 1500 m above sea level in 2016 and 2017 in Tateyama, Japan. After cross-dating each ring of the sampled cores based on ring-width patterns, a total of 5 trees were selected for isotopic analysis. Cellulose was extracted directly from 1 mm thick plates using the standard methodology. Each annual ring was separated using a blade under microscope. Oxygen isotope ratio of each ring was then measured using an isotope ratio mass spectrometer. The resultant 5 tree-ring oxygen isotope series were highly correlated with each other, indicating that the oxygen isotope ratio was governed by common climatic factors. Climatic response analysis revealed that the oxygen isotope ratio was primarily controlled by relative humidity in the early summer season (April–June), with a highest correlation appearing in June. Therefore, the tree-ring chronology can be considered to be a proxy of hydroclimate related to Meiyu-Baiu variability. The oxygen isotope data in our chronology showed an overall positive correlation with those in a tree-ring oxygen isotope record from Yakushima island, southwestern Japan. However, the correlations often became lower or negative during the positive PDO phases, implying that the PDO played a role in modulating spatial patterns of hydroclimate in the early summer season over western Japan.

# Eventural Layers of anciant disasters during these 4500 years at Lake Ikeda (Lake Daijya), western coast of Kyushu Island presumed by diatom assemblages in lake deposits

*Kaoru Kashima[1], Tomokazu Mita[1], Yu Fukumoto[3], Tsuyoshi Haraguchi[2], Kazuyoshi Yamada[4]

1. Department of Earth and Planetary Sciences, Kyushu University, 2. Department of Geosicneces, Graduate School of Science, Osaka City University, 3. Ritsumeikan University, 4. Museum of Natural and Environmental History, Shizuoka

Lake Ikeda (Lake Daijya) is a small coastal freshwater lake of about 200m NE and WE, located at Amakusa Island, Western part of Kyushu Area. It was a coastal lagoon, but after the eruption of Akahoya Ash (about 7.3ka), the lake was closed by a sand dune, and changed to be a freshwater environment.
Woodruff et.al. (2014) found the two Typhoon layers at 1.9-2.1m depth of the lake deposit, and presumed those were the trace of Kamikaze Typhoons, the huge typhoons on AD1274, AD1281. But their age control data were limited, and the processes to discussions to decide the Kamikaze Typhoon deposits were necessary to add multidiscipline methods.
Therefore, Haraguchi took undisturbed cores at Lake Ikeda (Lake Daijya) in 2016. It was 26m long, and covered about 8000 years presumed by C14 ages and Akahoya Ash (about 7.3ka) layer. In this presentation, we took the analysis of diatom assemblages in the lake deposits of top 9m long core dated about these 4500 years. We found the five “Event Layers” in the 9 m core. Huge typhoons like the Kamikaze Typhoon had continuously attacked the Western part of Kyushu.
The results of diatom assemblages in the core were compiled as follows:
(1)Surface deposits of the lake were composed by a lot of small fugal pellets by small animals. The pellet contained a lot of diatoms. The diatom assemblages were very simple and were dominated by freshwater plankton species (*Aulacoseira* and others), and freshwater semi-plankton species (*Staurosira* and others).
(2)Lake Ikeda (Lake Daijya) has continued as shallow freshwater for 4500 years, and freshwater plankton species (*Aulacoseira* and others), and freshwater semi-plankton species (*Staurosira* and others) were dominated in the lake deposit.
(3)But diatom assemblages were changed suddenly at the following five layers. They were caused by the invasion of marine water and slope falls surrounding the lake, presumably by the ancient huge typhoons.
(4)The depth and ages of event layers were compiled as follows. Event1 (7.26-8.26m): 4200-3800 yBP, Event2 (4.32-4.40m): 2000 yBP, Event3 (3.20-3.28m): 1400 yBP, Event4 (2.64-2.72m): 1000 yBP, Event5 (1.22-1.90 m): 500-700 yBP.
(5) To presume the detail process of each “Event Layer”, we have to analyze using multidiscipline methods and to compare the results surrounding Kyushu Area.

# Variability of hemipelagic and event depositions in the Beppu Bay during Holocene

*Tomohisa Irino[1], Airi Maruyama[1], Ken Ikehara[2], Masanobu Yamamoto[1], Michinobu Kuwae[3]

1. Graduate School of Environmental Science, Hokkaido University, 2. Institute of Geology and Geoinformation, National Institute of Advanced Industrial Science and Technology, 3. Center for Marine Environmental Studies, Ehime University

The Beppu Bay located in the northeast Kyushu Island, the southwestern Japan receives detrital materials mainly from two drainage systems, the Ohno River and the Oita River. The Ohno River has the head water region at the Mt. Kuju and Mt. Aso, flows eastward combining some tributaries from the south, and then flows northward to the Beppu Bay. Surface geology of the drainage area is roughly divided into two as intermediate to felsic volcanic area covered with andosol in the northeast and Paleozoic to Mesozoic sedimentary rocks covered with brown forest soil in the south. The drainage basin of the Oita River is located in the north of the Ohno River drainage, which is characterized by mafic volcanic rocks in the headwater region. Since the provenance of the Beppu Bay sediments has such geologically contrasted drainage systems, the temporal changes in the provenance for the sediment can be utilize to seek for the interrelationship among the western Pacific paleoceanography, East Asian monsoon, ecological response (fishery, vegetation, land use), and the erosion and sediment supply from hinterland basin. For this purpose, we examined mineral composition of BP09-3 core collected from the center of Beppu Bay as well as sediment from surface soils and river beds using X-ray powder diffraction.

As a result, quartz / feldspars ratio of the Beppu Bay sediment was within the range of surface soils in the drainage of Ohno River and Oita River. Detailed examination of peak shape of feldspar in X-ray diffractogram suggests grain size dependency of feldspar composition. Feldspars in finer materials showed more “mafic” composition suggesting that fine materials are dominantly supplied from Oita River drainage and / or mafic rock is more easily weathered and forms fine materials. We also applied statistical unmixing of mineral assemblage using PARAFAC algorithm on XRD profiles. Statistically distinguished subcomponents could be attributed to biogenic subcomponents, detrital subcomponents from the Ohno and Oita Rivers in hemipelagic mud as well as two detrital subcomponents in event sands with different origin.

Temporal variation of these statistical subcomponents in hemipelagic mud suggests that vegetation and / or land use change in the drainage area affected the relative importance of suspension loads from the Ohno River associated with the increase of detrital flux for the last 3,000 yrs. Composition of event sands also shows a consistent compositional change characterized by the relative increase of contribution from sandy material of the Ohno River bed. Increase in surface erosion in the Ohno River drainage may have been responsible for increases of fine and coarse materials supply and development of the delta at the river mouth.

# The composition of laminae in the sediment of Beppu-Bay and potential as annual laminations

*Yoshiaki Suzuki[1], Michinobu Kuwae[2], Kazuno Arai[3], Ken Ikehara[4], Masafumi MURAYAMA[3]

1. Waseda University, 2. Ehime University, 3. Kochi University, 4. AIST

The sediment of Beppu Bay in Pref. Oita is consisted of hemipelagic mud and contains many eventually deposited layers (event layers). These layers are considered to be caused by the occurrence of flood, earthquake or eruption. To reveal the mechanism of deposition of minor event layers (less than 1cm thickness), we tried to correlate the sediment with the observational record based on high-resolution age model using sediment cores obtained from four sites in Beppu Bay.
Surface sediment cores were CT-scanned and analyzed by micro XRF scanner (ITRAX). Pb and Cs isotopes were also measured by 4cm intervals for age determination.
In the deepest part of Beppu Bay(more than 60m depth), clear lamination is seen in several cores. In the shallower part, lamination cannot be observed. Based on the result of ITRAX measurement and Soft-X images, it is revealed that lamination is caused by the change of the amount of detrital material. Amount and composition of detrital material also show several positive spikes. Some of them can be observed by naked eyes as light gray or reddish brown colored thin layers (minor event layers) suggesting that they were supplied from different provenance than usual.
The results of Pb and Cs measurements agree with the age of Ev-1a which is considered to be caused by Hyuga-Nada earthquake in 1968 (Kuwae et al., 2013). Counting of lamination also agrees with Pb and Cs based age model when unclear lamination is interpolated by the average thickness of laminations. Therefore, it is strongly suggested that lamination in the bottom of Beppu Bay is annual lamination, varve. If the lamination is verified as a varve, high-resolution age model could be established and it enables detailed correlation of the sediment and observational record.

# Simulation of global distribution of Pa/Th using an ocean general circulation model

*Yusuke Sasaki[1], Akira Oka[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

The sediment 231Pa/230Th ratio is an important major proxy for studying paleo ocean circulation. However, even in the modern ocean, the only limited data about the distribution of dissolved 231Pa and 230Th was available, and it was insufficient to understand the process that controls the oceanic distribution of 231Pa and 230Th. In addition, some of previous modeling studies did not reproduce the observation data sufficiently. Recently, number of available observation data about dissolved 231Pa and 230Th is rapidly increasing owing to the recent projects like GEOTRACES. In this study, we performed simulation of 231Pa and 230Th with an ocean general circulation model (OGCM) and discussed how well dissolved 231Pa and 230Th profile of GEOTRACES data set is reproduced by the model. First, based on the previous model that incorporates reversible scavenging processes of 231Pa and 230Th by sinking ocean particles (Siddall et al., 2005), we improved the model by taking into account of additional sink at the sea floor (bottom scavenging; Okubo et al., 2012; Roy-Barman, 2009) and the dependency of scavenging efficiency on particle concentration following Henderson et al. (1999) . Second, as for our best reproduced simulation (Control simulation), we discuss processes which control the oceanic distribution of 231Pa and 230Th into three parts; the one-dimensional reversible scavenging process, the contribution from ocean advection and diffusion, and bottom scavenging. Through this analysis, we clarified how these processes effect on the global distribution of the sediment 231Pa/230Th ratio.

As a result of the improvement of model and tuning of the parameter, we simulated the distribution of 231Pa and 230Th reported from GEOTRACES dataset successfully. First, I confirmed that the profile of both dissolved 231Pa and 230Th in the deep ocean was improved by considering bottom scavenging as suggested by Rempfer et al. (2017). While the distribution of 231Pa is reproduced realistically by considering bottom scavenging, it is found to be difficult to simulate the depth profile of dissolved 230Th consistent with observations only by considering bottom scavenging. Hence, I tried to reproduce the dissolved 230Th profile by changing parameter values which control the strength of reversible scavenging by sinking ocean particles from the case in Siddall et al. (2005), and also by incorporating the dependency of scavenging efficiency on particle concentration following Henderson et al. (1999). As a result, I also reproduced the distribution of 230Th successfully.

In the latter part of this study, we discussed the process that controls the distribution of the sediment 231Pa/230Th ratio by analyzing the Control simulation. Through this analysis it was confirmed that the process that controls the distribution of the sediment 231Pa/230Th activity ratio is largely determined by the stronger influence of advection and diffusion on 231Pa than 230Th; advection and diffusion effect only on 231Pa can reproduce overall pattern of the distribution of the sediment 231Pa/230Th activity ratio similar to observation. Our analysis revealed that the bottom scavenging effect weakens the influence of advection and diffusion on 231Pa, and tends to make the contrast of 231Pa/230Th distribution smaller. We also found that the advection and diffusion of 230Th is small but not negligible, which also contributed to decrease the advection and diffusion effect on 231Pa.

This model is useful not only for reproducing 231Pa/230Th ratio in the present-day ocean but also for that in different climate such as glacial periods. Simulation of 231Pa/230Th ratio under the glacial

# Construction of modern silicoflagellate assemblage dataset in the North Pacific for paleo sea-surface temperature and its application for sediment cores

*Yusuke Okazaki[1], fumiaki nishizono[1], Tanizaki Kyohei[1]

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University

Silicoflagellate is a marine phytoplankton with biogenic opal skeletons. Most of the modern silicoflagellates are belonging to two genera: *Dictyocha* mainly distributing tropical to temperate regions and *Stephanocha* mainly distributing polar to subpolar regions. Here we construct modern silicoflagellate assemblage dataset in the North Pacific for modern analog technique to reconstruct paleo sea-surface temperature (SST). The modern silicoflagellate assemblage dataset is composed of seven species in surface sediment samples from (1) wide-area of North Pacific by Poelchau (1976) and (2) newly obtained western North Pacific near Japan. A total of 174 surface sediment samples were compiled as the modern silicoflagellate assemblage dataset. Each sample site is linked with 0.25-degree grid data of annual mean SST data by World Ocean Atlas 2013. Modern analog technique analysis was performed by using Polygon 2.4.4. and applied to sediment cores from the Japan and East China Seas. Reconstructed SST of the Japan Sea off Wakasa was ~6-degree C during LGM whereas ~15-degree C during Holocene. Deglacial warming was observed between 12 and 14.5 ka. For the East China Sea core from the Danjo Basin, reconstructed SST was ranging from 10-15 degree C during LGM to 20-25 degree C during late Holocene. The reconstructed silicoflagellate based SST (10 to 25-degree C) were in between planktic foraminiferal Mg/Ca based one (20 to 25-degree C) and TEX 86 based one (7 to 20-degree C). However, deglacial rapid SST changes based on silicoflagellate was not observed in both planktic foraminiferal Mg/Ca and TEX 86 based ones.

# Microplastics in surface sediments of the Ariake Bay

Hiroki Sonoda[1], *Yusuke Okazaki[1], Atsuhiko Isobe[2]

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University, 2. Research Institute for Applied Mechanics, Kyushu University

Microplastics are small plastic pieces less than five *millimeters* long. Numbers of microplastics floating around Japan are much greater than those of global ocean average. Microplastic cycle in the ocean is not well understood, but their final destinations are sediments. Here we investigate microplastics deposited in surface sediments of the Ariake Bay. We obtained surface sediment samples at 11 sites off Kumamoto city in the Ariake Bay by using Ekman-Berge grab in December 2016. In addition, we collected surface samples from the river mouths of Shirakawa and Midorikawa Rivers. Sediment samples were freeze-dried, weighed ~50 g and washed on a stainless-steel screen with 63 micrometers mesh. The floating and sunken residues were recovered separately by filter paper and treated with 1N HCl and 10% hydrogen peroxide on a hot plate at 200-degree C for an hour. After reaction completed, residues were washed by pure water on a nylon screen with 63 micrometers mesh, recovered by filter paper and dried in an oven overnight at 40-degree C. We picked up potential microplastic particles greater than 150 micrometers under stereomicroscope. Identification of microplastics were performed by fourier transform infrared spectroscopy (FT-IR) using FT-IR alpha spectrometry. A total of 18 and 8 microplastics were identified in 11 surface sediment samples off Kumamoto in the Ariake Bay and 3 surface sediment samples from the river mouths, respectively. Most of identified microplastics were polypropylene (PP) and polyethylene (PE). Averaged microplastic contents at the 11 sites off Kumamoto was 29 pieces per kg of dry sediment. No clear trend between geographic distribution pattern of microplastics and distance from the Kumamoto coast/river mouths. Rough estimate for microplastic deposition rate off Kumamoto in the Ariake Bay (120 square kilometers) was ranging from 5 to 10 billion pieces per year. This suggests relatively rapid removal of microplastics from water column though their specific gravities are less than one.

[J] Poster | M (Multidisciplinary and Interdisciplinary)：M-IS Intersection

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_41

## [M-IS19] Paleoclimatology and paleoceanography

convener:Yusuke Okazaki(Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University), Akira Oka(Atmosphere and Ocean Research Institute, The University of Tokyo), Michinobu Kuwae(Center for Marine Environmental Studies), Hitoshi Hasegawa(Faculty of Science and Technology, Kochi University)

Past environmental changes and events at multi-decadal to tectonic timescale toward an understanding of Earth climate system by an integration of terrestrial and marine proxy studies and numerical modeling will be discussed. At JpGU2019, a series of presentations on present and future climate and environmental changes from paleo-perspective will be held. We welcome a variety of paleo-environmental studies from a wide range of background. We hope that this session will provide an opportunity to promote communication between participants from multidisciplinary field.

# Orbital-scale changes in redox condition and biogenic silica/detrital fluxes of the Jurassic Radiolarite: Possible link with glaciation?

*Masayuki Ikeda[1]

1. Shizuoka University

Orbital forcing has been shown to be a fundamental driver of climate change through both icehouse and greenhouse periods. To reveal the impact of orbital-forcing on the oceanic environment through a greenhouse-icehouse transition, we established ~ 4 Myr-long cyclostratigraphy of the Bajocian-Callovian (Middle Jurassic; ~ 160 Ma) Basal Radiolarites at the Torre De Busi and Corre Di Sogno sections in the Lombardian Basin, N-Italy. Stratigraphic changes in chertabundance (chert/shale thickness ratio) and color (darkness) of Radiolarites show hierarchal periodicities of 8 cm, 16 cm, 40 cm, 160 cm, and ~ 4 m, corresponding to ~ 20 kyr, 40 kyr, 100 kyr, 400 kyr, and ~ 1 Myr cycles based on the biostratigraphic age model. Black cherts in intervals with high chert abundance might reflect oxygen-depleted conditions due to orbital-scale high productivity. On the other hand, black cherts in intervals with low chert abundance (high detrital input) might reflect oxygen-depleted conditions, probably due to orbital-scale sea-level drop and stratification. On 40 kyr and 100 kyr cycles, the anoxic condition occurred in low chert abundance intervals across ~ 8 m above (~ 2 Myr after) the base of the Radiolarites. These results imply that the formation of the restricted basin resulted from tectonic and/or eustatic sea-level drop, which is consistent with increased black chert deposition and redox-sensitive elements abundances (Mo/TOC, Mo/U). Their out-of-phase relationships on the 405 kyr cycle throughout the sequence (~ 4 Myr-long) with increasing amplitude above −8 M level would be caused possibly by tectonic activity, or more likely by glacio-eustatic sea-level changes reported from sequence stratigraphy, similar to those of the Oligocene to Pliocene glacial cycles, but probably with less amplitude.

# Evaluation of hinterland weathering and paleoclimate of the Cretaceous strata in the Sichuan basin, central China

*Tenichi Cho[1], Hideaki Mantani[1], Tohru Ohta[1], Gang Li[2]

1. Waseda University, 2. Nanjing Institute of Geology and Paleontology

Reconstruction of paleoclimate during the Cretaceous Period is important for the understanding of the Earth system operating during the greenhouse conditions. However, information of paleoclimate from continental inland-basins is scarce compared to continental margin marine-basins. This situation is also true in the Asian continent; Cretaceous ecosystem and paleoclimate data are accumulating in the Pacific side, while those of the Asian continental side is lacking. Paleoclimate conditions in Asian inland basins are considered to be equally important in order to elucidate the land-ocean climate system operated during the Cretaceous. In this regard, the present study investigates the geochemistry and clay mineralogy of the Cretaceous mudstones distributed in the Sichuan basin, central China, for the aim of paleoclimate evaluation. The depositional age of studied strata ranges from Berriasian to Maastrichtian. Sediments are mostly fluvial to lacustrine origin, however recently, a broad distribution of aeolian dune sandstones was identified from the Cenomanian to Turonian interval (Li et al., 2016). Before discussing hinterland weathering and paleoclimate, the effect of diagenesis was evaluated, which can alter the geochemical signatures of paleoclimate. The illite crystallinity index indicates that diagenetic effect was moderately high for the analyzed mudstones, and the degree of diagenesis has a high correlation with CaCO3 abundance. Accordingly, CaO wt% abundances are mostly of post-depositional carbonate origin, and thus, CaO derived from carbonates was subtracted from the following discussion of hinterland weathering evaluation. Geochemical weathering indices (e.g., W value) demonstrate a significant increase in hinterland paleoweathering from Berriasian (W=70) to Cenomanian-Turonian (W=95), and then slightly decrease towards the Maastrichtian (W=80). This fluctuation pattern of the weathering indices is concordant with the Cretaceous paleotemperature estimates (e.g., O’ Brien et al., 2017). Therefore, the present result suggests that the hinterland paleoweathering rate in the Sichuan basin was governed by the global temperature changes. The weathering index reached the maximum value of 95 in Cenomanian-Turonian stages. Furthermore, sediments of Cenomanian-Turonian horizons contained abundant kaolinite mineral, which is a product of hydrolysis decomposition of rock-forming minerals. Both lines of evidence suggest that the Sichuan basin was under the tropical and pluvious climate during the Cenomanian-Turonian. However, as mentioned before, the previous study identified aeolian sand dunes from the Cenomanian-Turonian strata. Note that Li et al. (2016) elucidated an arid climate from amalgamated sandstone facies, while the present pluvious climate interpretation is derived from the analysis of intervening piled mudstone facies. When these geological evidences are integrated together, it is reasonable to suggest the development of an alternating pluvious and arid paleoclimate during the Cenomanian-Turonian. The nature and trigger of this extremely oscillating pluvious/arid climate cannot be deduced solely from the present study. However, the timing of this renewed climate system matches with the Cretaceous greenhouse optimum (Cenomanian-Turonian). The development of monsoon-like pluvious/arid paleoclimate in the Sichuan basin is possibly related to the mid-Cretaceous re-configuration in the global climate system.

# Productivity-induced lacustrine bedded chert formation in the Eocene Green River Formation

*Ryusei Kuma[1], Hitoshi Hasegawa[2], Koshi Yamamoto[1], Hidekazu Yoshida[1], Masayuki Ikeda[3], Nagayoshi Katsuta[4], J. Whiteside[5]

1. Nagoya University, 2. Kochi University, 3. Shizuoka University, 4. Gifu University, 5. Southampton University

Rhythmically alternated beds of chert and shale, also called as bedded chert, are commonly observed in marine sedimentary rocks. Recent studies revealed that changes in bed thickness of chert represent orbitally-paced variations in marine productivity and silicate weathering rate (Hori et al., 1993; Ikeda et al., 2017). On the other hand, bedded cherts are occasionally found in lacustrine deposits. Previous study interpreted that formational mechanism of lacustrine bedded chert is linked to the interplay between silica dissolution in alkaline lake waters and its precipitation due to the conversion of lake water’ s pH (e.g. Hesse, 1989). Some studies suggested that the pH of saline and alkaline lake water could have changed by the freshwater input (Eugster, 1967; Eugster 1969). Other study implied that the metabolic processes of cyanobacteria modified the pH of lake water and influenced to the silica precipitation (Behr and Rohricht, 2000). However, convincing evidence of chertification mechanism in lacustrine deposits have not been clarified yet.

In order to elucidate the formation mechanism of lacustrine chert, the present study examined a lacustrine bedded chert succession in the Eocene Green River Formation in northern Utah, USA. We have conducted detailed field survey in the Indian Canyon section in northern Utah. Bedded cherts occur in shallow lake level stage and alternated with dolomite beds with every 5–10 cm in thickness. Elemental mapping by Scanning X-ray analytical microscope (SXAM) reveals that the Ca concentration in dolomite layer, while Si concentration in chert layer, with sharp boundary coincide with lithofacies boundary. Elemental distribution also shows that alternation of chert and dolomite occur in every 1–2 cm in thickness. In addition, fluorescent microscopic inspection reveals that the distribution of Si concentration coincides with the dense accumulation of spherical organic matter. These spheres show the brightest fluorescence carbon shell with similar size (30–40 $\mu$m). The morphology of these spherical organic matter resembles to green algae, such as *Botryococcus braunii*, which are also abundantly preserved in the Green River Formation. Occurrences of algal organic matters in chert layer imply that deposition of algal organic matter could be related with the formation of lacustrine chert.

It is noteworthy that the lake water alkalinity of the Green River Formation is considered to be high (pH>9) because of extensive volcanic activity around Colorado Plateau. These lines of evidence suggested that silica precipitation is possibly caused by decreased pH due to the decaying organic matter (increasing $CO_2$ and/or organic acid) in sediment pore water. Deposition of organic matter can be related to changes in the lake algal productivity. Given that sedimentation rate of the formation in Indian Canyon section is estimated as ca. 10–15 cm/kyr (Smith et al., 2008), observed chert occurrence (1–2 cm and 5–10 cm) yields 67–200 and 333–1000 year’ s cyclicities. Therefore, periodic occurrences of chert beds in the Green River Formation are possibly linked to the centennial-scale changes in the lake algal productivity.

# Extraction of the sedimentary cycles and application of cyclostratigraphy to the Middle Miocene Onnagawa Formation in Yashima District, Akita Prefecture, Japan

*Jumpei Yoshioka[1], Ryuji Tada[1,3], Kenji Marc Raymond Matsuzaki[2], Toshihiro Tada[1], Aki Sakuma[1], Yusuke Umemiya[1], Shunsuke Kurokawa

1. Department of Earth and Planetary Science, the University of Tokyo, 2. Atmosphere and Ocean Research Institute, the University of Tokyo, 3. Yunnan University

Middle Miocene (16.0-11.6Ma) is the time of the second of the three cooling steps during Cenozoic. In this cooling event, siliceous sediments with high organic contents were widely deposited along the North Pacific rim because of high productivity and/or preservation of diatoms. In the northern Japan Sea, those sediments are known as the Onnagawa Formation. It was reported that siliceous rocks in the Onnagawa Fm. showed meter-scale rhythmical bedding reflecting fluctuations in productivity of diatoms and flux of detrital materials. Furthermore, it was also reported that parts of highly siliceous rocks in the Onnagawa Fm. showed centimeter-scale black bands. However, the age and the cause of their occurrence has not been understood.

In this study, we tried to construct a high-resolution and precise age model of the Onnagawa Fm. in the Yashima District by applying cyclostratigraphy to the m-scale rhythmical bedding, that is attributable to the fluctuation of biogenic silica content.

Firstly, a ca. 130m-long continuous composite columnar section was constructed by correlation of 6 sections. This composite columnar section is divided into 5 lithological units, cyclic alternations of marl and interbedded mudstone (Unit A), mudstone with cyclic siliceous rocks intercalations (Unit B), siliceous-mudstone with muddy-porcelanite intercalations (Unit C), bedded muddy-porcelanite with cm-scale black bands (Unit D) and siliceous-mudstone and hard siliceous-mudstone alternations (Unit E).

“Silica rank”, which is defined as degree of siliceousness and divided into 5 grades based on hardness of the siliceous rocks observed in the field and confirmed by XRD analysis, was determined every 10cm for Unit B, Unit C and Unit D. It showed obvious m-scale cyclicities. The silica rank variation for Unit B and Unit C was obviously different from that for Unit D, and it is considered that this difference may reflect either the change in the sedimentation rate or the change in response of sedimentation mechanism to the orbital forcing that results in the lithological change. In order to construct an age model, the silica rank was tuned to $\delta^{18}O$ of benthic foraminifera with age constraints given by microfossil biostratigraphy.

# Pliocene magneto–oxygen isotope stratigraphy from the Anno Formation, Awa Group, central Japan

*Yuki Haneda[1], Makoto Okada[1]

1. College of Science, Ibaraki University

The Pliocene climate is one of the best analogs for the climate of a globally warmer future. Here, we present a new Pliocene integrated chronostratigraphy from the Anno Formation in the uppermost Awa Group, which is distributed throughout the Boso Peninsula, central Japan, based on paleomagnetic and benthic foraminiferal oxygen isotope records. This new chronostratigraphy provides valuable constraints for paleoceanographic and paleoclimatic studies in the northwestern Pacific Ocean, where the number of paleoceanographic records is limited due to the lack of calcareous microfossils from deep-sea sediment cores, with the exception of some plateaus at water depths above the calcite compensation depth (CCD).

We performed progressive Alternating field and thermal demagnetizations for each specimen in order to remove secondary remanence. Additionally, we conducted thermomagnetic, low-temperature magnetic, magnetic hysteresis, and FORC analyses as rock-magnetic experiments to assess stability of paleomagnetic signal which specimens have acquired. The paleomagnetic and rock-magnetic experiments indicate that primary remanences are carried by magnetite in pseudo-single domain size as detrital remanent magnetization. The progressive AF demagnetization is, however, unsuitable to remove secondary remanence in specimens from polarity transitional horizons due to magnetically hard mineral, such as goethite. Therefore, thermal demagnetization is necessary to obtain primary remanence from the Anno Formation.

Paleomagnetic results by the thermal demagnetization indicate that the Anno Formation corresponds to the period extending from the Nunivak normal polarity subchronozone (4.493–4.631 Ma) to Chron C2An.2n (3.116–3.207 Ma). Although foraminifera are not found in the middle Anno Formation, our oxygen isotope records from the upper and lower Anno Formation demonstrate the recording of glacial–interglacial cycles. However, the amplitude of our $\delta^{18}O$ profile is much larger than that of the LR04 stack, with similar to slightly lower glacial values and much lower interglacial values. This trend is suppressed after 3.4 Ma. These observations imply that the bottom water had lower $\delta^{18}O$ values and/or a warmer water mass during interglacials until 3.4 Ma compared with global average deep-water regions.

# Planktonic foraminiferal assemblage and paleoceanography of the Plio-Pleistocene sequence at IODP Site U1499 in the northern South China Sea

*Mizuki Kitamura[1], Akira Furusawa[1], Hiroki Hayashi[1]

1. SHIMANE University

The South China Sea (SCS) is a marginal sea located in the tropical zone of the western Pacific with an average depth of ca. 1,140 m. The East Asian monsoon affects the climate system in this area by the prevailing seasonal winds. Such influence of the East Asian monsoon is expected to be stronger during the glacial period and weaker during the interglacial period.
During Internatinal Ocean Discovery Program (IODP) Expedition 367, drilling of Site U1499 was conducted near the outer shelf of the northern SCS in 2017. As an onboard result of this site, sediments from Oligocene to Present were recovered and the upper sequence especially contains abundant foraminiferal fossils. The purpose of the present study is to clarify temporal changes of planktonic foraminiferal assemblage in the northern SCS from approximately 4 to 1 Ma.
As a result, 80 species belonging to 19 genera of planktonic foraminifera were detected. According to multivariate analyses of the foraminiferal assemblage, we determined the temporal change into four stages: Stage A (ca. 4.1 to 3.4 Ma), Stage B (ca. 3.4 to 1.8 Ma), Stage C (ca. 1.8 to 1.45 Ma) and Stage D (ca. 1.4 to 1 Ma). During Stage A, SCS had been stratified by oligotrophic tropical surface water and relatively cold subsurface water with a shallow thermocline. At the next Stage B, the thermocline was deepened and SCS was occupied by a subtropical oligotorophic water. In turn, the thermocline shoaled and subsurface species of planktonic foraminifera were increased during the Stage C. After that, the Stage D is characterized by alternative changes between subtropical surface components and cold-temperate components caused by the glacial-interglacial changes.

# Reconstruction of the surface water mass fluctuation during the late Pliocene to early Pleistocene based on planktonic foraminiferal fossils from the Mera Formation, Chikura Group, in the southernmost part of the Boso Peninsula

*Makoto Okada[1], Daisuke Hasegawa[2]

1. Department of Earth Sciences, Faculty of Science, Ibaraki University, 2. Graduate School of Scinece and Engineering, Ibaraki University

The purpose of this study is to examine whether the cooling event has occurred associate with the NHG (Northern Hemisphere Glaciation) off the Boso peninsula and how the surface water mass has changed with the glacial-interglacial cycle. We carried out analysis of planktonic foraminiferal assemblages at the 57 horizons corresponding to period from 3.0 Ma to 2.2 Ma. We propose 6 phases including the following three distinctive phases based on relative abundance of environmental indicator species.
Phase Ⅱ (2.75-2.65Ma): Transitional water species increased up to 50%. It was a cold environment where the influence of mixed water was strong.
Phase Ⅴ (2.42-2.35Ma): Kuroshio species increased up to 40%, which is the highest value in this study
PhaseⅥ (2.35Ma~):Transitional water species increased to about 50% while repeating amplitude. Therefore, cooling was gradually strengthened in this phase.
Cooling did not proceed unilaterally after 2.7Ma, it occurs again from 2.35Ma after the period when the influence of Kuroshio became temporarily stronger. In addition the glacial-interglacial cycles seem to be affecting composition of planktonic foraminiferal assemblages.

# Centennial-scale bioproductivity changes during the earliest Middle-Pleistocene

*Waka Fujii[1], Masayuki Hyodo[1], Shigehiro Katoh[2], Yosuke Miyairi[3], Haruka Yamaguchi[1], Yusuke Yokoyama[3]

1. Kobe University, 2. Hyogo Museum of Nature and Human Activities, 3. University of Tokyo

Elucidation of the mechanism of global warming in the geological time is important, which may lead to understanding of the present global warming. In this study, we conducted paleoenvironmental analyses of sediments to reveal the rapid climate changes across the warmest interval in the Marine Isotope Stage (MIS) 19 interglacial, which is known as an orbital analogue of the Holocene. In particular, we aim at elucidating the mechanism of the repeated bioproductivity proxy (Ca/Ti ratio) changes dominated by bicentennial cycles for a span from about 777 to 775 ka, which was observed in core TB2 from the Chiba Section. Focused on the time span, we conducted pollen analyses using the Osaka Bay 1,700 m core with abundant pollen fossils, and measurements of $^{10}$Be using core TB2. Both cores are stratigraphically correlated with the centennial to millennial scale resolution. The result of pollen analyses revealed that the proportion of evergreen *Quercus* (*Cyclobalanopsis*), a warm proxy, began at about 777 ka to increase with bicentennial oscillations, followed by a sudden drop within 1 kyr. These changes are quite consistent with those in the bioproductivity in core TB2. Therefore, the bioproductivity changed affected by the climate. The $^{10}$Be content, an index of the galactic cosmic ray flux, generally showed similar changes with the bioproductivity except some intervals, one of which showed a large disagreement between the $^{10}$Be flux and the bioproductivity, coincided with the iceberg discharge event in the North Atlantic. These results suggest that the centennial-scale bioproductivity changes observed in core TB2 probably reflect climate variations, and may be affected by solar activity. Solar activity can affect climate through galactic cosmic rays that control the low cloud (Svensmark effect), in addition to the direct influence through solar radiation.

# Development of new-paleoceanographic proxies based on oxygen isotope analysis of sponge spicule

*Hitomi Uchimura Wakaki[1], Akira Ijiri[2], Minoru Ikehara[1], Sangmin Hyun[3]

1. Center for Advanced Marine Core Research, Kochi University, 2. Japan Agency for Marine-Earth Science and Technology, 3. Korea Institute of Ocean Science & Technology

The objective of this study is to construct the new-paleoceanographic proxy based on the oxygen isotope ratio of sponge spicule. To examine the variations in water depth and temperature, we selected GH08 surface sediment samples ranging from a water depth of 216 m to 2679 m in the Northwest Pacific. These samples were obtained from the area off eastern Okinawa Island during the GH08 cruise in 2008 by Geological Survey of Japan, AIST. The upper 0–2 cm of each surface sediment was sampled. The sediment samples were washed in a 250-mesh sieve and dried in the oven. In this study, we also analyzed the oxygen isotope ratio of sea-bottom water by laser spectroscopic analysis of Liquid Water Isotope Analyzer (LWIA).

We chose two benthic foraminifers' species *Cibicidoides* sp. and *Cibicidoides wuellerstorfi* to analyze the oxygen isotope ratio. Benthic foraminifer was analyzed by phosphoric acid digestion to carbon dioxide gas and the measurement of the oxygen isotope ratio by IsoPrime at Kochi University. We can recognize that the result of the foraminifera between the oxygen isotope ratio and temperature has a negative trend. In other words, the oxygen isotope ratio of benthic foraminifera in this study shows temperature dependence. Our results agree with those obtained by the previous studies (Marchitto et al., 2014). These results can be regarded as the data of benthic foraminifera in this study is considered appropriate for the reference.

We also analyzed the oxygen isotope ratio of sponge spicule by a new method of iHTR (inductive high-temperature carbon reduction) and CF-IRMS (continuous-flow isotope ratio mass spectrometry) (Ijiri et al., 2014). Some the oxygen isotope ratio values of sponge spicule are consistent with previous reported data (Brandriss et al., 1998, Moschen et al., 2005), which were analyzed the oxygen isotope ratio of biogenic opal (diatom). However, some of the oxygen isotope ratio of sponge spicule don't have any trends. These irregular date has possibility to be influenced by the acid treatment and the difference of gas pressure, and should be evaluated the validity in future experiment used based on additional samples.

Keywords: sponge spicule, benthic foraminifera, stable oxygen isotope, temperature dependence

# A system for automatic collection of specific microfossil species using a deep learning classification

*Takuya Itaki[1], Yosuke Taira[2], Naoki Kuwamori[2], Toshinori Maebayashi[3], Satoshi Takeshima[4], Kenji Toya[4]

1. Geological Survey of Japan, AIST, 2. NEC Corporation, 3. Microsupport Co.Ltd, 4. Mitani-Corporation

For geochemical analysis such as stable isotope ratio, radiocarbon age and minor elements for a single species of microfossils, a large number of their skeletons is required to pick up one by one with enormous time and effort by a person under a microscope. In this study, we have developed a device that automates these efforts. Even if experts are absent, microfossils are accurately classified their taxonomic species level using deep learning which is one of the learning methods of artificial intelligence, and they are picked up using a micromanipulator installed in the microscope with motorized X-Y stage. It is possible to collect a large number of particles with speed and accuracy that could not be achieved with human hands. This technology to accumulate only specific species of microfossils contributes not only to greatly reduce hand work of picking up, but also to be enable chemical analysis such as isotope ratios and minor elements for small microfossil species that hitherto difficult because the necessary measurement amount cannot be collected.In addition to microfossils, it can be applied to various particles, and it is also expected to be utilized in various fields such as medical, food, horticulture and materials.

# Towards reconstructing environmental conditions related to Australian Great Barrier Reef initiation

*Stephen Obrochta[1], Wataru Miwa[1], Kotaro Shirai[2], Yusuke Yokoyama[2], Yosuke Miyairi[2], Jody Webster[2,3], Albert Hine[4]

1. Akita University, 2. University of Tokyo Atmosphere and Ocean Research Institute, 3. University of Sydney, 4. University of South Florida College of Marine Science

Previous work exploited the unique mixed carbonate-siliciclastic environment of Northeast Australia to identify the timing of changes in off-shelf sediment transport with respect to sea-level variation. Because sediment transport from the continental shelf to slope is strongly controlled by the presence/absence of a rimmed morphology, this provides a means for indirectly estimating the age of the Great Barrier Reef (GBR). Preliminary results indicate that a change in the timing of maximum off-shelf terrigenous sediment accumulation occurred during the glacial termination of MIS 20. This in turn suggests that an effective barrier morphology was emplaced during the MIS 21 interglacial. Instead of being deposited directly to the continental slope by incised rivers, terrigenous material first accumulated behind the barrier during the MIS 20 sea-level lowstand and was then redoposited as rising sea level reflooded the shelf.

Here we present initial results attempting to understand if and how changing environmental conditions promoted enhanced reef growth. The results include a higher-resolution isotope stratigraphy for improved chronological control, additional terrigenous mass accumulation rate measurements, and initial results of Mg/Ca analyses, which allow for calculating sea surface temperature changes and the oxygen isotopic composition of sea water that is expected to better resolve glacial-interglacial cycles. In the future we expect to add additional information from micro and/or nanofossil faunal assemblage data.

# An 8,000-year climate record from Lake Motosu, Japan: Implications for the East Asian Monsoon

Sarah McDonlad[3], Jonathan Tyler[3], *Stephen Obrochta[1], Yusuke Yokoyama[2], Yosuke Miyairi[2], Kosuke Ota[2]

1. Akita University, 2. University of Tokyo Atmosphere and Ocean Research Institute, 3. Department of Earth Sciences, The University of Adelaide

The East Asian Summer Monsoon controls the timing and amount of rainfall for around a third of the world’ s population. An understanding of past changes in monsoon strength is thus crucial for placing current events in context and for characterising future climate risk. Whilst many monsoon records have been developed for continental Asia, fewer records exist from the north-eastern edge of the monsoon region. We present a new monsoon record for central Japan based on an 8,000-year lacustrine sedimentary sequence from Lake Motosu, located at the northern foot of Mt Fuji. Lake Motosu is a hydrologically closed lake and is therefore expected to be sensitive to changes in monsoon strength. Additional macrofossil radiocarbon dates are used to refine an existing high-fidelity age model. This age model is then applied to constrain the timing of changes in bulk sediment geochemistry (TC, TN, C/N, $\delta^{13}C$, $\delta^{15}N$) and the oxygen isotopic composition of sedimentary cellulose ($\delta^{18}O$). Changes in sediment chemistry reflect shifts in the sources of organic matter to the sediments, variations in lake hydrology and changes to the local catchment. In turn, these changes are linked to regional variations in monsoon strength. However, their interpretation is complicated by the impact of local seismic and volcanic activity.

# Environmental changes in northern Mongolia in During the Late Pleistocene: chemical analyses of lacustrine sedimentary sequences in Darhad basin

Yumiko Ohno[1], Sayuri Naito[1], *Nagayoshi Katsuta[1], Takuma Murakami[3], Shinya Ochiai[2], Noriko Hasebe[2], Shin-ichi kawaka[4]

1. Faculty of Education, Gifu University, 2. Institute of Natural and Environmental Technology, Kanazawa University, 3. Horonobe Research Inst. for the Subsurface Environment, 4. Faculty of Education, Gifu Shotoku Gakuen University

Spread of modern human (*Homo sapiens*) from Africa to Eurasia seems to have occurred in the periods from ca. 60 kyrs ago to ca. 50 kyrs ago via two routes from western Asia into northern Eurasia and across Arabia into southern Asia. To understand relationship between environmental changes and human migration in central Eurasia, we reconstructed a 120-kyr sediment record of environmental change using the Darhad basin (northern Mogolia) sediment core with a nondestructive $\mu$-XRF techniques of Horiba SXAM, XRD analysis, and petrolograhic observation.

# Paleoenvironmental changes recorded in Orog Lake, southwestern Mongolia during MIS 3 and its relationship with *Homo sapiens*' migration into northern Asia

*Hitoshi Hasegawa[1], Nanase Noma[1], Nagayoshi Katsuta[2], Masafumi MURAYAMA[3], Toru Tamura[4], Masami Izuho[5], Niiden Ichinnorov[6], Davaasuren Davaadorj[7], Noriko Hasebe[8], Miho Sasaoka[9], Masao Iwai[9]

1. Faculty of Science and Technology, Kochi Univ., 2. Faculty of Education, Gifu Univ., 3. Faculty of Agriculture and Marine Science, Kochi Univ., 4. Geological Survey of Japan, AIST, 5. Faculty of Social Sciences and Humanities, Tokyo Metropolitan Univ., 6. Mongolian Academy of Sciences, 7. National University of Mongolia, 8. Institute of Nature and Environmental Technology, Kanazawa Univ., 9. Center for Advanced Marine Core Research, Kochi Univ.

An aim of the present study is to understand detailed paleoenvironmental changes in Mongolia, situated at a key crossroad for *Homo sapiens*'s migration between central, eastern, and northern Asia during the Initial and Early Upper Paleolithic (IUP-EUP). Available archaeological evidences have suggested the emergence of IUP at around ca. 45-40 ka (e.g., Zwyns *et al.*, 2014; Rybin *et al.*, 2016; Izuho *et al.*, 2018). However, yet the paleoenvironmental changes of this period in Mongolia is largely unclear, preventing us to understand whether the possible environmental changes were significant as a major driving forth for modern human's lifeway.

In this paper, we present a new record of paleoenvironmental changes in southwestern Mongolia during MIS 3. In January 2017, we took two parallel cores (OROG01, 24 m; OROG02, 21 m) from Orog Lake, a shallow saline lake located in northwestern margin of Gobi Desert. The high-resolution major and minor element composition changes were obtained using μXRF core scanner (Cox, Itrax) at Center for Advanced Marine Core Research, Kochi University. Based on the preliminary results of OSL and 14C age dating, basal age of sediment core OROG01 yielded ca. 38 ±4 ka, nearly accordant with the basal age of ~45 ka reported in the previous study (Yu *et al.*, 2019). On the basis of our high-resolution elemental composition data, in conjunction with previous sedimentological and palynological data (Yu *et al.*, 2019), the paleoenvironments of southwestern Mongolia were more humid with higher lake levels during MIS 3 than Holocene. Our results also suggest periodic and higher amplitude paleoenvironmental changes in this region, which likely correspond to Dansgaard-Oeschger events. This new record would allow us to discuss potential relationship between paleoenvironmental changes and ecosystem changes in Mongolia during the IUP-EUP.

# Reconstruction for water-mass structure of the Okhotsk Sea for the past 1.5 million years based on radiolarian assemblages

*Tatuya Sakamoto[1], Yusuke Okazaki[1]

1. Department of Earth and Planetary Sciences, School of Science, Kyushu University

The North Pacific Intermediate Water (NPIW) play an important role in transporting heat and freshwater. NPIW originates from the Okhotsk Sea where is the southernmost seasonal ice area in the northern hemisphere. Sea-ice in the Okhotsk Sea is formed mainly in the northwestern shelf area and moved south by the seasonal wind. Brine water rejected during sea-ice formation sinks to the intermediate layer and forms the Okhotsk Sea Intermediate Water (OSIW) characterized by abundant particulate organic carbon, low temperature, and rich in oxygen. OSIW is a source water of NPIW. Radiolarians are zooplankton with biogenic opal skeletons, and various species distribute from sea-surface to deep-sea. *Cycladophora davisiana* is a radiolarian species that favors well-ventilated intermediate water masses, therefore, *C. davisiana* is used as indicator of OSIW. In this study, we conducted radiolarian assemblage analysis for a giant piston core sample (MD01-2414, water depth 1123 m) to reconstruct the water-mass structure change for the past 1.5 million years. Size fraction greater 45 micrometers were used for slide preparation for light microscope observation. In general, total radiolarian skeletons during interglacials were 10 to 100 times greater than that during the glacial periods. *Cycladophora davisiana* was abundant during interglacials, suggesting enhanced OSIW formation. However, during MIS 11 and 31 known as the super interglacials, much less C. davisiana abundances were observed, suggesting weaken OSIW formation due to significant sea-ice retreat. Four radiolarian biostratigraphic markers in the North Pacific region were identified: *Amphimelissa setosa*, *Lychnocanomma sakaii*, and *Spongodiscidae* sp. In addition, two radiolarian species *Ceratospyris borealis* and *Zygocircus productus* indicated high productivity during interglacials.

# Silicoflagellate assemblages in the Okhotsk Sea during the interglacial periods

*Kazuki Egashira[1], Yusuke Okazaki[2], Tatsuhiko Sakamoto[3]

1. Department of Earth and Planetary Sciences, Kyushu University, 2. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University , 3. Mie University

Silicoflagellate is a phytoplankton with a skeleton of biogenic opal. There are two major genera for modern silicoflagellates: *Dictyocha* mainly dwelling in tropical to temperate regions and *Stephanocha* mainly dwelling in subarctic region. The *Dictyocha*/*Stephanocha* ratio has been used as a paleotemperature proxy. Earth’s climate for the past 800,000 years is characterized by the glacial and interglacial cycles with a frequency of 100,000 years. Oxygen isotope ratios of benthic foraminifera mainly reflect continental ice-sheet volume fluctuations, lighter in the interglacials and heavier in the glacials. This fluctuation is called as Marine Isotope Stage (MIS), odd numbers correspond to interglacials and even numbers correspond to glacials. Among the interglacials, the oxygen isotope ratios were lighter than that of the present: MIS 5e (120,000 years ago), 9 (330,000 years ago), and 11 (400,000 years ago). Pollen assemblages in Lake El’gygytgyn sediment from the Far East Russiat in the Arctic Circle indicates pronounced warming during MIS 11. Because atmospheric carbon dioxide concentrations during the past interglacials were comparable to the preindustrial level, it is important to know the status of warming climate during interglacials. The purpose of this study is to reconstruct sea-surface conditions of the Okhotsk Sea during the past interglacials based on silicoflagellate assemblages preserved in sediments. By comparing silicoflagellate assemblages during MIS 1, 5e, 9 and 11, we test the extent of warming during interglacials. The Okhotsk Sea is a marginal sea of the western North Pacific located south of Lake El’gygytgyn, known as southernmost sea-ice covered area in the Northern Hemisphere. A piston core YK07-12 PC-3B (water depth: 1049 m, core length: 14.09 m). Age model of core YK07-12 PC-3B is established by benthic foraminiferal oxygen isotope stratigraphy and the estimate bottom age is 450,000 years ago. Silicoflagellate assemblage analysis was performed by using sediment samples collected from sedimentary horizons corresponding to MIS 1, 5e, 9, and 11. For each interglacials, three samples from peaks of biogenic opal content, maximum calcium carbonate content and minimum benthic foraminiferal oxygen isotope ratio were picked up, consequently, a total of 12 samples were selected. 100 silicoflagellate specimens were counted for each slide under light microscope. Almost all encountered silicoflagellate species during core YK07-12 PC-3B microscopic observation were belonging to genus *Stephanocha*. During MIS 11, *Stephanocha speculum*(particularly, *S. speculum minuta*) was the most abundant silicoflagellate taxa. Because *Stephanocha speculum*is known as a representative silicoflagellate species in the subarctic Pacific dwelling cold and nutrient rich environments, this result indicates that there is no evidence of significant warming in the Okhotsk Sea during MIS 11. Another abundant silicoflagellate species in core YK07-12 PC-3B was *Stephanocha octangulata*, also known as subarctic taxa. This species was dominant during MIS 1 and 5e. Unique oceanic environments such as seasonal sea-ice coverage and influence of low salinity water originating from the Amur River may have influenced on the silicoflagellate assemblages of core YK07-12 PC-3B.

# Role of wind stress and sea surface thermal forcing in the formation of the Atlantic meridional overturning circulation at the Last Glacial Maximum

*Akira Oka[1], Kazuki Togawa[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

In Previous Paleoclimate Model Intercomparison Project (PMIP) simulations of the Last Gracial Maximum (LGM) Atlantic Meridional Overturning Circulation (AMOC), the most of PMIP2 and PMIP3 models reproduced the 'deeper and stronger' AMOC than preindustrial simulations, in contrast to some reconstructions from paleo proxy data.Prior researches pointed out three factors controling the strength of AMOC in LGM climate: the cooling of the oceans in the Southern hemisphere, cooling in the North Atlantic, and the surface wind stresses in the North Atlantic. However, in the above-mentioned prior researches, the influences of these three factors on AMOC were only independently evaluated and the combined influences are still largely unknown. Here we emphasize the relative evaluation of combined influences of above- mentioned three factors on the AMOC. For this purpose, various ocean model experiments with our general ocean circulation model (COCO) were conducted; wind stress and thermal boundary conditions taken from PMIP experiments are replied to our ocean general circulation model. As a result, it was found that the difference of thermal boundary condition in the southern hemisphere most affects the strength of AMOC, and this cooling in the southern hemisphere is a necessary condition for reproducing the ‘shallower and weaker’ AMOC, but not a sufficient condition. From these results, it is implied that the stronger glacial AMOC reported in the PMIP models was possibly caused by the insufficient cooling in the southern hemisphere in LGM experiment, and this insufficient cooling possibly comes from warm bias there in the present state experiment and the associated underestimation of ice albedo feedback of sea ice.

# Comparison of the Kuroshio during LGM simulated by an ocean general circulation model driven by multiple paleoclimate models

*Kensho Ichikawa[1], Haiyan Yang[2], Xinyu Guo[2], Yasumasa Miyazawa[3]

1. Graduate School of Science and Engineering,Ehime University, 2. Center for Marine Environmental Studies,Ehime University, 3. Japan Agency for Marine-Earth Science and Technology

The Kuroshio that flows south of Japan has an important role in the climate of East Asia and Japan. In modern days, the Kuroshio presents a stable path and contributes to maintenance of warm climate. However, this stable condition is considered to be different in Last Glacial Maximum (LGM) when different environment conditions from the present day were reported. During the LGM, the sea surface level was lower than present by about 130 m and the westerlies shifted southward. In addition, the air-sea heat flux was also expected to be different from present. Therefore, it is necessary for the simulation for the Kuroshio in LGM to consider the changes in above three factors (sea level, westerly, and air-sea heat flux). The Kuroshio in LGM was calculated by a numerical model that included the above mentioned three factors in Muto (2018). The model results presented the southward shifting of the Kuroshio path and decreasing of the Kuroshio intensity. However, this result was obtained from one paleoclimate model (IPSL). Therefore, it is necessary to use more paleoclimate models to confirm the results given by Muto (2018).

In this study, we performed similar calculations for the Kuroshio in LGM using four additional paleoclimate models (CNRM, GISS, MIROC, MRI) as driven forcing of ocean model. Before calculation, we compared the vorticity of wind stress given by these paleoclimate models and obtained the Sverdrup transport that is also an index of Kuroshio intensity.

Among all the five paleoclimate models, the position of zero vorticity, which corresponds roughly the position of Kuroshio, shifted to the most southward in IPSL. At the same time, the Sverdrup transport was the lowest in IPSL. Therefore, the southward shifting of the Kuroshio path and the weakening of the Kuroshio intensity given by Muto (2018) are likely an extreme case among five paleoclimate models.

# The changes of the Kuroshio path in the Northwest Pacific since 35ka

*Haiyan Yang[1], Xinyu Guo[1], Ayako Abe-Ouchi[2], Yasumasa Miyazawa[3], Sergey Varlamov[4], Wing-Le Chan[2]

1. Center for Marine Environmental Studies, Ehime University, 2. Atmosphere and Ocean Research Institute, University of Tokyo, 3. Research Institute for Global Change, Japan Agency for Marine-Earth Science and Technology, 4. Application Laboratory, Japan Agency for Marine-Earth Science and Technology

Kuroshio, a strong western boundary current in the subtropical North Pacific, has strong influences on the climate of Japan and East Asia. Global sea level rises and falls when ice sheets and glaciers melt and grow. The Last Glacial Maximum (LGM, 21ka) is the most recent interval in Earth history when global ice sheets reached their maximum integrated volume. The expansion of the ice sheets at the LGM resulted in a sea-level lowering of about 130 m and a cold phase compared to present. Under the circumstance of sea level, Kuroshio did not bifurcate into the Japan Sea and form the Tsushima Current. As the sea level rises, the Tsushima Current flowed into the Japan Sea at about 10ka (Gallagher et al., 2015), and the sea-level reached the present level at 7ka~6ka (Zheng et al., 1994). However, how the Kuroshio and Tsushima Current pathway evolved in the conditions of different sea level and climate remains unclear.

In Okinawa and southern Korea, some archaeologists have found evidences of people drifting on the Kuroshio from Taiwan to northern regions. According to studies by Japanese anthropologists, the first person that set foot on Okinawa probably sailed there on bamboo rafts from Taiwan more than 30,000 years ago. However, this hypothesis needs more evidences because sailing across the Kuroshio is a difficult thing if the Kuroshio 30,000 years ago had the same surface velocity as present. Therefore, clarifying the strength and path of Kuroshio is also helpful to the understanding on human migration.

In this study, we used the model of Japan Coastal Ocean Predictability Experiment (JCOPE) to simulate the changes of the Kuroshio path under the combined influences of sea level, the air-sea heat flux, and wind stresses in five historical regimes (35ka, 30ka, LGM, 6ka, and 0ka). The meteorological and oceanic data are provided by the climate model MIROC4m (Chan et al., 2011) which is a fully coupled atmosphere-ocean general circulation model (AOGCM).

# Temperature reconstruction in the late Pleistocene using fossil terrestrial snails and a stalagmite from an archaeological cave in Okinawa

*Ryuji Asami[1], Rikuto Hondoh[2], Ryu Uemura[3], Ryuichi Shinjo[3], Akihiro Kano[4], Masaki Fujita[5], Shinji Yamasaki[6], Hideko Takayanagi[1], Yasufumi Iryu[1]

1. Graduate School of Science, Tohoku University, 2. Faculty of Science, Tohoku University, 3. Faculty of Science, University of the Ryukyus, 4. School of Science, the University of Tokyo, 5. National Museum of Nature and Science, 6. Okinawa Prefectural Museum and Art Museum

Freshwater snails are useful for a paleoclimate proxy. For example, stable oxygen isotope composition of mollusck’ s aragonite shells depends on temperature and oxygen isotope composition of water at the time of their growth. The Ryukyu Island Arc, bounded by the East China Sea to the northwest and by the Pacific Ocean to the southeast, is an important area in climatology because its environment is highly associated with the East Asian monsoon (EAM), typhoon, and the Kuroshio current. However, terrestrial paleoclimate records such as tree rings and stalagmites are little in the Ryukyu Island Arc unlike the East Asia Continent. Meanwhile, Okinawa is widely known as a hotspot in archaeology and a lot of ancient remains and digs have been excavated for recent years. Sakitari Cave, where world’ s oldest fishhooks were discovered, is one of the most famous archaeological sites in Okinawa.
In this study, fossil shells of a freshwater snail *Semisulcospira libertina* excavated at Sakitari Cave in Okinawa-jima were investigated. These samples were from two sediment layers dated to 13-16 ka and 23 ka in the cave. We measured stable carbon and oxygen isotope ratios and trace element concentrations at intervals of 1 mm along the growth direction of the snails to reconstruct seasonal temperature variations during the Last Glacial Maximum and the last deglaciation. To estimate paleo-temperature and -oxygen isotope composition of precipitation accurately, we also measured oxygen isotope composition of fluid inclusion water in a stalagmite collected near the archaeological site. Comparing with chemical composition of living *S. libertina* shells collected around the site, estimated annual mean temperature was about 8 ˚C and 6˚C lower at 23 ka and 13-16 ka than at the present. Summer temperature has largely increased from 23 ka to 13-16 ka relative to winter temperature, which is consistent with North Hemisphere insolation changes in summer and winter. Our results indicate that the increase of mean air temperature around Okinawa-jima was larger than that of seawater temperature in the northwestern Pacific Ocean during the last deglaciation. This inconsistency is a significant finding for better understanding of past climate changes associated with the East Asian Monsoon.

# Silicoflagellate and *Actiniscus* response to meltwater during the last deglaciation in the Alaska margin

*Asuka Tomokawa[1], Yusuke Okazaki[1], Jonaotaro Onodera[2], Keiji Horikawa[3]

1. Department of Earth and Planetary Sciences, Kyushu University, 2. Research and Development Center for Global Change, JAMSTEC, 3. Graduate School of Engineer and Science, University of Toyama

Silicoflagellate is a phytoplankton with biogenic opal skeleton, and its fossil assemblage is used for reconstruction of paleoenvironment. There are two major genera for modern silicoflagellates: *Dictyocha* mainly dwelling in tropical to temperate zone and *Stephanocha* mainly dwelling in subarctic zone. The *Dictyocha*/*Stephanocha* ratio has been used as a paleotemperature proxy. *Actiniscus pentasterias* is a species of Dinoflagellata with biogenic opal skeleton, indicator of coastal and low salinity environments. Gulf of Alaska is located eastern North Pacific. The southern Alaska margin has fjord created by the Cordilleran Ice Sheet. The purpose of this study is to clarify the silicoflagellate and *Actiniscus* assemblages to meltwater input from the Cordilleran Ice Sheet at the last deglaciation in the southern Alaska margin. A piston core KH17-3 CL14 was obtained from the southern Alaska margin (59° 33.350’ N, 144° 09.344’ E, water depth: 695 m). Age model of core KH17-3 CL14 is established by planktic foraminiferal radiocarbon dates and the bottom of the core is estimated to be ~17 ka. We used 48 samples for Silicoflagellate and *Actiniscus* analyses. 100 silicoflagellate specimens were counted for each slide and all *Actiniscus pentasterias* specimens were counted for each slide under light microscope. 7 species and 2 subspecies of genus *Dictyocha* and 4 species of genus *Stephanocha* were identified. Relative abundances of genus *Dictyocha* accounted for greater than 50% since Younger Dryas (YD), whereas genus *Stephanocha* (particularly *S. speculum*) was abundant during Bolling-Allerod (BA). This suggests that *Dictyocha*/*Stephanocha* ratio didn’t simply reflect cold (YD) and warm (BA) events during the last deglaciation. Two *Actiniscus pentasterias* peaks were observed during the last deglaciation which were coincident with Meltwater Pulse 1A and 1B. This suggests salinity decline due to meltwater from the Cordilleran Ice Sheet. The meltwater into the subarctic Pacific may have leaded to enhanced productivity during BA. Because *Stephanocha speculum* is suggested to be an indicator of high productivity from modern sediment trap observation, high abundances of *S. speculum* in core KH17-3 CL14 during BA can be explained by the enhanced productivity driven by meltwater from the Cordilleran Ice Sheet.

# Application of the ramped pyrolysis $^{14}C$ dating to postglacial sediments from the Alaskan margin, Arctic Ocean

*Kenta Suzuki[1], Masanobu Yamamoto[1,2], Brad Rosenheim[3], Takayuki Omori[4], Leonid Polyak[5]

1. Graduate School of Environmental Science, Hokkaido University, 2. Faculty of Environmental Earth Science, Hokkaido University, 3. College of Marine Science, University of South Florida, 4. The University Museum, The University of Tokyo, 5. Bard Polar and Climate Research Center, Ohio State University

Radiocarbon dating of biogenic carbonates, such as foraminiferal tests, is commonly used for dating marine sediments up to 50 ka old. However, in carbonate-poor environments, such as typical for polar seas, direct dating of carbonaceous material is difficult, while bulk organic matter (OM) may contain a mixture of carbon with different ages. Rosenheim et al. (2008) developed the ramped pyrolysis $^{14}C$ dating of the bulk OM based on incremental generation of $CO_2$ from a range of carbon fractions, from highly reactive to more thermochemically stable. Application of this approach to Southern Ocean sediments showed that ages of highly-reactive, lower temperature fractions were considerably younger than other fractions and the bulk $^{14}C$ age. In this study, we explore ramped pyrolysis $^{14}C$ dating in Arctic Ocean sediments from the Alaskan margin to determine if the same relationships hold true.
Samples were taken from two sediment cores collected on the 2005 HOTRAX expedition and comprising Holocene marine and older glaciomarine strata (Darby et al., 2009a). Several $^{14}C$ ages have been generated on the Holocene biogenic carbonates (Darby et al., 2009b). New samples from both the Holocene and older sediments were pyrolyzed from room temperature to 900 ˚C, and the released, purified $CO_2$ fractions were sealed in borosilicate glass ampoules at the University of South Florida. Measurement of $\Delta^{14}C$ was conducted at the University of Tokyo.
Pyrolysis followed by oxidation generated three peaks of $CO_2$ at ~300 ˚C, ~400 ˚C and ~540 ˚C, which were deconvolved into three Gaussian peaks (G1 to G3). These peaks were interpreted to reflect the consecutive degradation of oxygen-containing OM functional groups, cleavage of carbon-carbon bonds, and cleavage of aromatic ring carbon, respectively. In this scenario G1 contains most of the autochthonous carbon from the sediment. We found that the slopes of the G1-G3 $^{14}C$ ages plotted against temperature of the Gaussian centroid are proportional to the offset between $^{14}C$ ages of G1 and earlier analyzed biogenic carbonates from the same core levels. Assuming that this relationship is a constant function of the overall measured age spectra, we propose to use it for estimating sediment ages from the ramped pyrolysis $^{14}C$ data. The estimated G1 age offsets range from 800 to 3,000 years in the Holocene and from 4,000 to possibly as high as 5,000 years in the older glaciomarine sediments.

# Utility of sedimentary environmental DNA for indices of past pelagic fish species populations

*Hiromichi Tamai[1], Michinobu Kuwae[2], Hideyuki Doi[3], Toshihumi Minamoto[4]

1. Graduate School of Science and Engineering, Ehime university, 2. Center for Marine Environmental Studies, Ehime university, 3. Graduate School of Simulation Studies, University of Hyogo, 4. Graduate School of Human Development and Environment, Kobe University

Far little is known about long-term dynamics of almost all of fish species populations in the ocean during pre-instrumental era. Here we focused on environmental DNA in marine sediments as a potential tool to elucidate past fish population dynamics and tested its utility to reconstruct fish abundance in Japanese coastal waters. Based on quantitative PCR method applied to the sediment samples collected from anoxic bottom sediments in Beppu Bay, Japan, we found environmental DNA of Japanese anchovy, Japanese sardine, and Jack mackerel in the 1-meter sediment sequences spanning over the last 250 years, which is the first detection of sedimentary marine fish DNA. The observed temporal changes in sedimentary DNA abundances are consistent with those in fish scale abundances and catch in Japan, suggesting the utility of the sedimentary fish environmental DNA to track past changes in fish abundance in waters from the bottom sediment sequences. DNA analyses of five fractions of sediment samples including coarse and fine particle fractions, pore water, fish scales, and bones suggested that a main source of fish DNA in the sediments is derived from fine the particle fraction.

# Improvements of extraction methods of sedimentary fish-origin DNA for reconstruction of marine fish communities

*Jun Kurata[1], Hiromichi Tamai[2], Hideyuki Doi[3], Toshihumi Minamoto[4], Michinobu Kuwae[5]

1. department of earth science, Ehime university, 2. Graduate School of Science and Engineering, Ehime university, 3. Graduate School of Simulation Studies, University of Hyogo, 4. Graduate School of Human Development and Environment, Kobe University, 5. Center for Marine Environmental Studies, Ehime university

Environmental DNA is DNA fragments derived from body fluids or skin fragments of macro organisms contained in water or soil. It is expected to can be a technology to reveal long-term fish community changes which still remains unknown in the world ocean. However, DNA in the sediments has a low concentration, therefore, it is difficult to detect for a various kind of fish species. The purpose of this research is to elucidate the method that can take sedimentary DNA more efficiently. At this time, we tested five DNA extraction methods including the conventional one together with beads beating time. Quantitative PCA results showed that Power Soil had the best yield in the replications. In addition, DNA extraction of *Truchurus japonicus* figured out a better yield by increasing the amount of sediment sample. There was a significant difference between 10 min. and 30 sec. of beads beating time, it is possible that there is a higher yield with short time beating. Our future works is to test whether DNA yield improves by shortening or eliminating bead beating, effectively removal of PCR inhibitors, and an utility of PCR inhibitor.

Department of Biochemistry, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Japan, 5. Research and Development Center for Global Change, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Japan

Recently, investigations of Holocene climatic variability and its socioeconomic impacts have received increasing attention with regard to the prediction of future climatic change and the evaluation of its impact on human society. The Kanto area around the Tokyo Bay, Japan had a large population in the Neolithic Jomon age. After the establish of centralized system, this area has been a stage of major change in Japanese history for many times. The paleoenvironment around the Tokyo Bay has been estimated based on the analysis of the shell mounds along the coast or historical documents. However, the continuous and high time resolution paleotemperature record has not existed yet.

A piston core KT12-06-2B (8.99m) were recovered from the Tokyo Bay during the Tansei-maru KT12-06 cruise. An age model for the core, determined by the AMS$^{14}$C dating for 22 molluscan shells and the scoria layer of Hoei eruption, showed that it has the continuous records from about 4, 500 years ago. We analyzed the content of total organic carbon (TOC), alkenone unsaturation ratio ($U^{k'}_{37}$), and coccolith assemblages for this core in order to reconstruct the paleoenvironment in the Toyo Bay.

The constant TOC values (1.3-1.7 wt.%) before 1700AD suggested the stable biological production at the core site. We converted $U^{k'}_{37}$ into alkenone-SST using the conversion formula, proposed by the culture experiment of *G. oceanica* because most of coccolith contained in the sediments were *G. oceanica* based on the polarizing microscope observations. From 400 AD to the present, the alkenone-SST ranged from 20.5˚C to 22.4˚C (21.6˚C on average), including several cold periods around 1700 AD, 1420 AD, 1280 AD, and 1010 AD, which corresponded approximately to the Maunder, Spörer, Wolf, and Oort Minimum, respectively. The SSTs before 400 AD largely fluctuated between 19.5˚C and 25.3 ˚C, and its average value was 22.6˚C, which was 1 ˚C higher than the average after 400 AD. Especially large cold periods were detected around 520-440 BC (with a minimum value of 20.0℃) and 2360-2280 BC (with a minimum value of 19.5℃). The former cold period, which was also reported by the several previous studies in East Asia, might be caused by the other large minimum of solar activity around 500BC. The latter cold period corresponds to the global cooling/drying event accompanied by the monsoon retreat. In the mid- to late-Jomon age, the Neolithic Jomon society around the Tokyo Bay based on hunting and gathering, not paddy rice cultivation. We assume that they lived in warm but unstable climate, which might be disadvantageous for them to start agriculture.

# Summer monsoon variability over the past 400 years in Tateyama, Japan, as reconstructed from tree-ring oxygen isotope data

*Masaki Sano[1], Kota Mori[1], Akane Tsushima[2], Zhen Li[3], Koh Yasue[4], Takeshi Nakatsuka[2,3]

1. Faculty of Human Sciences, Waseda University, 2. Nagoya University, 3. Research Institute for Humanity and Nature, 4. Shinshu University

With its high sensitivity to hydroclimate variability, tree-ring oxygen isotope composition has been widely used for dendroclimatology over monsoon Asia in recent years. Here we built a 400-year tree-ring oxygen isotope chronology from Tateyama, Japan to reconstruct summer hydroclimate in the region, and compared it with other tree-ring data to explore spatio-temporal variations in hydroclimate. We collected tree-ring core samples from *Pinus parviflora* var. *pentaphylla* at an altitude of 1500 m above sea level in 2016 and 2017 in Tateyama, Japan. After cross-dating each ring of the sampled cores based on ring-width patterns, a total of 5 trees were selected for isotopic analysis. Cellulose was extracted directly from 1 mm thick plates using the standard methodology. Each annual ring was separated using a blade under microscope. Oxygen isotope ratio of each ring was then measured using an isotope ratio mass spectrometer. The resultant 5 tree-ring oxygen isotope series were highly correlated with each other, indicating that the oxygen isotope ratio was governed by common climatic factors. Climatic response analysis revealed that the oxygen isotope ratio was primarily controlled by relative humidity in the early summer season (April–June), with a highest correlation appearing in June. Therefore, the tree-ring chronology can be considered to be a proxy of hydroclimate related to Meiyu-Baiu variability. The oxygen isotope data in our chronology showed an overall positive correlation with those in a tree-ring oxygen isotope record from Yakushima island, southwestern Japan. However, the correlations often became lower or negative during the positive PDO phases, implying that the PDO played a role in modulating spatial patterns of hydroclimate in the early summer season over western Japan.

# Eventural Layers of anciant disasters during these 4500 years at Lake Ikeda (Lake Daijya), western coast of Kyushu Island presumed by diatom assemblages in lake deposits

*Kaoru Kashima[1], Tomokazu Mita[1], Yu Fukumoto[3], Tsuyoshi Haraguchi[2], Kazuyoshi Yamada[4]

1. Department of Earth and Planetary Sciences, Kyushu University, 2. Department of Geosicneces, Graduate School of Science, Osaka City University, 3. Ritsumeikan University, 4. Museum of Natural and Environmental History, Shizuoka

Lake Ikeda (Lake Daijya) is a small coastal freshwater lake of about 200m NE and WE, located at Amakusa Island, Western part of Kyushu Area. It was a coastal lagoon, but after the eruption of Akahoya Ash (about 7.3ka), the lake was closed by a sand dune, and changed to be a freshwater environment.
Woodruff et.al. (2014) found the two Typhoon layers at 1.9-2.1m depth of the lake deposit, and presumed those were the trace of Kamikaze Typhoons, the huge typhoons on AD1274, AD1281. But their age control data were limited, and the processes to discussions to decide the Kamikaze Typhoon deposits were necessary to add multidiscipline methods.
Therefore, Haraguchi took undisturbed cores at Lake Ikeda (Lake Daijya) in 2016. It was 26m long, and covered about 8000 years presumed by C14 ages and Akahoya Ash (about 7.3ka) layer. In this presentation, we took the analysis of diatom assemblages in the lake deposits of top 9m long core dated about these 4500 years. We found the five “Event Layers” in the 9 m core. Huge typhoons like the Kamikaze Typhoon had continuously attacked the Western part of Kyushu.
The results of diatom assemblages in the core were compiled as follows:
(1)Surface deposits of the lake were composed by a lot of small fugal pellets by small animals. The pellet contained a lot of diatoms. The diatom assemblages were very simple and were dominated by freshwater plankton species (*Aulacoseira* and others), and freshwater semi-plankton species (*Staurosira* and others).
(2)Lake Ikeda (Lake Daijya) has continued as shallow freshwater for 4500 years, and freshwater plankton species (*Aulacoseira* and others), and freshwater semi-plankton species (*Staurosira* and others) were dominated in the lake deposit.
(3)But diatom assemblages were changed suddenly at the following five layers. They were caused by the invasion of marine water and slope falls surrounding the lake, presumably by the ancient huge typhoons.
(4)The depth and ages of event layers were compiled as follows. Event1 (7.26-8.26m): 4200-3800 yBP, Event2 (4.32-4.40m): 2000 yBP, Event3 (3.20-3.28m): 1400 yBP, Event4 (2.64-2.72m): 1000 yBP, Event5 (1.22-1.90 m): 500-700 yBP.
(5) To presume the detail process of each “Event Layer”, we have to analyze using multidiscipline methods and to compare the results surrounding Kyushu Area.

# Variability of hemipelagic and event depositions in the Beppu Bay during Holocene

*Tomohisa Irino[1], Airi Maruyama[1], Ken Ikehara[2], Masanobu Yamamoto[1], Michinobu Kuwae[3]

1. Graduate School of Environmental Science, Hokkaido University, 2. Institute of Geology and Geoinformation, National Institute of Advanced Industrial Science and Technology, 3. Center for Marine Environmental Studies, Ehime University

The Beppu Bay located in the northeast Kyushu Island, the southwestern Japan receives detrital materials mainly from two drainage systems, the Ohno River and the Oita River. The Ohno River has the head water region at the Mt. Kuju and Mt. Aso, flows eastward combining some tributaries from the south, and then flows northward to the Beppu Bay. Surface geology of the drainage area is roughly divided into two as intermediate to felsic volcanic area covered with andosol in the northeast and Paleozoic to Mesozoic sedimentary rocks covered with brown forest soil in the south. The drainage basin of the Oita River is located in the north of the Ohno River drainage, which is characterized by mafic volcanic rocks in the headwater region. Since the provenance of the Beppu Bay sediments has such geologically contrasted drainage systems, the temporal changes in the provenance for the sediment can be utilize to seek for the interrelationship among the western Pacific paleoceanography, East Asian monsoon, ecological response (fishery, vegetation, land use), and the erosion and sediment supply from hinterland basin. For this purpose, we examined mineral composition of BP09-3 core collected from the center of Beppu Bay as well as sediment from surface soils and river beds using X-ray powder diffraction.

As a result, quartz / feldspars ratio of the Beppu Bay sediment was within the range of surface soils in the drainage of Ohno River and Oita River. Detailed examination of peak shape of feldspar in X-ray diffractogram suggests grain size dependency of feldspar composition. Feldspars in finer materials showed more “mafic” composition suggesting that fine materials are dominantly supplied from Oita River drainage and / or mafic rock is more easily weathered and forms fine materials. We also applied statistical unmixing of mineral assemblage using PARAFAC algorithm on XRD profiles. Statistically distinguished subcomponents could be attributed to biogenic subcomponents, detrital subcomponents from the Ohno and Oita Rivers in hemipelagic mud as well as two detrital subcomponents in event sands with different origin.

Temporal variation of these statistical subcomponents in hemipelagic mud suggests that vegetation and / or land use change in the drainage area affected the relative importance of suspension loads from the Ohno River associated with the increase of detrital flux for the last 3,000 yrs. Composition of event sands also shows a consistent compositional change characterized by the relative increase of contribution from sandy material of the Ohno River bed. Increase in surface erosion in the Ohno River drainage may have been responsible for increases of fine and coarse materials supply and development of the delta at the river mouth.

# The composition of laminae in the sediment of Beppu-Bay and potential as annual laminations

*Yoshiaki Suzuki[1], Michinobu Kuwae[2], Kazuno Arai[3], Ken Ikehara[4], Masafumi MURAYAMA[3]

1. Waseda University, 2. Ehime University, 3. Kochi University, 4. AIST

The sediment of Beppu Bay in Pref. Oita is consisted of hemipelagic mud and contains many eventually deposited layers (event layers). These layers are considered to be caused by the occurrence of flood, earthquake or eruption. To reveal the mechanism of deposition of minor event layers (less than 1cm thickness), we tried to correlate the sediment with the observational record based on high-resolution age model using sediment cores obtained from four sites in Beppu Bay.
Surface sediment cores were CT-scanned and analyzed by micro XRF scanner (ITRAX). Pb and Cs isotopes were also measured by 4cm intervals for age determination.
In the deepest part of Beppu Bay(more than 60m depth), clear lamination is seen in several cores. In the shallower part, lamination cannot be observed. Based on the result of ITRAX measurement and Soft-X images, it is revealed that lamination is caused by the change of the amount of detrital material. Amount and composition of detrital material also show several positive spikes. Some of them can be observed by naked eyes as light gray or reddish brown colored thin layers (minor event layers) suggesting that they were supplied from different provenance than usual.
The results of Pb and Cs measurements agree with the age of Ev-1a which is considered to be caused by Hyuga-Nada earthquake in 1968 (Kuwae et al., 2013). Counting of lamination also agrees with Pb and Cs based age model when unclear lamination is interpolated by the average thickness of laminations. Therefore, it is strongly suggested that lamination in the bottom of Beppu Bay is annual lamination, varve. If the lamination is verified as a varve, high-resolution age model could be established and it enables detailed correlation of the sediment and observational record.

# Simulation of global distribution of Pa/Th using an ocean general circulation model

*Yusuke Sasaki[1], Akira Oka[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

The sediment 231Pa/230Th ratio is an important major proxy for studying paleo ocean circulation. However, even in the modern ocean, the only limited data about the distribution of dissolved 231Pa and 230Th was available, and it was insufficient to understand the process that controls the oceanic distribution of 231Pa and 230Th. In addition, some of previous modeling studies did not reproduce the observation data sufficiently. Recently, number of available observation data about dissolved 231Pa and 230Th is rapidly increasing owing to the recent projects like GEOTRACES. In this study, we performed simulation of 231Pa and 230Th with an ocean general circulation model (OGCM) and discussed how well dissolved 231Pa and 230Th profile of GEOTRACES data set is reproduced by the model. First, based on the previous model that incorporates reversible scavenging processes of 231Pa and 230Th by sinking ocean particles (Siddall et al., 2005), we improved the model by taking into account of additional sink at the sea floor (bottom scavenging; Okubo et al., 2012; Roy-Barman, 2009) and the dependency of scavenging efficiency on particle concentration following Henderson et al. (1999) . Second, as for our best reproduced simulation (Control simulation), we discuss processes which control the oceanic distribution of 231Pa and 230Th into three parts; the one-dimensional reversible scavenging process, the contribution from ocean advection and diffusion, and bottom scavenging. Through this analysis, we clarified how these processes effect on the global distribution of the sediment 231Pa/230Th ratio.

As a result of the improvement of model and tuning of the parameter, we simulated the distribution of 231Pa and 230Th reported from GEOTRACES dataset successfully. First, I confirmed that the profile of both dissolved 231Pa and 230Th in the deep ocean was improved by considering bottom scavenging as suggested by Rempfer et al. (2017). While the distribution of 231Pa is reproduced realistically by considering bottom scavenging, it is found to be difficult to simulate the depth profile of dissolved 230Th consistent with observations only by considering bottom scavenging. Hence, I tried to reproduce the dissolved 230Th profile by changing parameter values which control the strength of reversible scavenging by sinking ocean particles from the case in Siddall et al. (2005), and also by incorporating the dependency of scavenging efficiency on particle concentration following Henderson et al. (1999). As a result, I also reproduced the distribution of 230Th successfully.

In the latter part of this study, we discussed the process that controls the distribution of the sediment 231Pa/230Th ratio by analyzing the Control simulation. Through this analysis it was confirmed that the process that controls the distribution of the sediment 231Pa/230Th activity ratio is largely determined by the stronger influence of advection and diffusion on 231Pa than 230Th; advection and diffusion effect only on 231Pa can reproduce overall pattern of the distribution of the sediment 231Pa/230Th activity ratio similar to observation. Our analysis revealed that the bottom scavenging effect weakens the influence of advection and diffusion on 231Pa, and tends to make the contrast of 231Pa/230Th distribution smaller. We also found that the advection and diffusion of 230Th is small but not negligible, which also contributed to decrease the advection and diffusion effect on 231Pa.

This model is useful not only for reproducing 231Pa/230Th ratio in the present-day ocean but also for that in different climate such as glacial periods. Simulation of 231Pa/230Th ratio under the glacial

©2019. Japan Geoscience Union. All Right Reserved. 

climate is an interesting future study. Such a study is an important step for discussing glacial changes in the ocean circulation more quantitatively.

# Construction of modern silicoflagellate assemblage dataset in the North Pacific for paleo sea-surface temperature and its application for sediment cores

*Yusuke Okazaki[1], fumiaki nishizono[1], Tanizaki Kyohei[1]

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University

Silicoflagellate is a marine phytoplankton with biogenic opal skeletons. Most of the modern silicoflagellates are belonging to two genera: *Dictyocha* mainly distributing tropical to temperate regions and *Stephanocha* mainly distributing polar to subpolar regions. Here we construct modern silicoflagellate assemblage dataset in the North Pacific for modern analog technique to reconstruct paleo sea-surface temperature (SST). The modern silicoflagellate assemblage dataset is composed of seven species in surface sediment samples from (1) wide-area of North Pacific by Poelchau (1976) and (2) newly obtained western North Pacific near Japan. A total of 174 surface sediment samples were compiled as the modern silicoflagellate assemblage dataset. Each sample site is linked with 0.25-degree grid data of annual mean SST data by World Ocean Atlas 2013. Modern analog technique analysis was performed by using Polygon 2.4.4. and applied to sediment cores from the Japan and East China Seas. Reconstructed SST of the Japan Sea off Wakasa was ~6-degree C during LGM whereas ~15-degree C during Holocene. Deglacial warming was observed between 12 and 14.5 ka. For the East China Sea core from the Danjo Basin, reconstructed SST was ranging from 10-15 degree C during LGM to 20-25 degree C during late Holocene. The reconstructed silicoflagellate based SST (10 to 25-degree C) were in between planktic foraminiferal Mg/Ca based one (20 to 25-degree C) and TEX 86 based one (7 to 20-degree C). However, deglacial rapid SST changes based on silicoflagellate was not observed in both planktic foraminiferal Mg/Ca and TEX 86 based ones.

# Microplastics in surface sediments of the Ariake Bay

Hiroki Sonoda[1], *Yusuke Okazaki[1], Atsuhiko Isobe[2]

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University, 2. Research Institute for Applied Mechanics, Kyushu University

Microplastics are small plastic pieces less than five *millimeters* long. Numbers of microplastics floating around Japan are much greater than those of global ocean average. Microplastic cycle in the ocean is not well understood, but their final destinations are sediments. Here we investigate microplastics deposited in surface sediments of the Ariake Bay. We obtained surface sediment samples at 11 sites off Kumamoto city in the Ariake Bay by using Ekman-Berge grab in December 2016. In addition, we collected surface samples from the river mouths of Shirakawa and Midorikawa Rivers. Sediment samples were freeze-dried, weighed ~50 g and washed on a stainless-steel screen with 63 micrometers mesh. The floating and sunken residues were recovered separately by filter paper and treated with 1N HCl and 10% hydrogen peroxide on a hot plate at 200-degree C for an hour. After reaction completed, residues were washed by pure water on a nylon screen with 63 micrometers mesh, recovered by filter paper and dried in an oven overnight at 40-degree C. We picked up potential microplastic particles greater than 150 micrometers under stereomicroscope. Identification of microplastics were performed by fourier transform infrared spectroscopy (FT-IR) using FT-IR alpha spectrometry. A total of 18 and 8 microplastics were identified in 11 surface sediment samples off Kumamoto in the Ariake Bay and 3 surface sediment samples from the river mouths, respectively. Most of identified microplastics were polypropylene (PP) and polyethylene (PE). Averaged microplastic contents at the 11 sites off Kumamoto was 29 pieces per kg of dry sediment. No clear trend between geographic distribution pattern of microplastics and distance from the Kumamoto coast/river mouths. Rough estimate for microplastic deposition rate off Kumamoto in the Ariake Bay (120 square kilometers) was ranging from 5 to 10 billion pieces per year. This suggests relatively rapid removal of microplastics from water column though their specific gravities are less than one.

## [M-IS26] Arctic and Antarctic Science and Future Plan

convener:Yoshifumi Nogi(National Institute of Polar Research), Takuji Nakamura(National Institute of Polar Research), Atsuko Sugimoto(Arctic Research Center, Hokkaido University), Shin Sugiyama(Institute of Low Temperature Science, Hokkaido University), Chairperson:Tetsuo Sueyoshi(National Institute of Polar Research), Yoshifumi Nogi(National Institute of Polar Research)

This session will be a forum to discuss the scientific program and the framework of the future integrated multidisciplinary study focused on the polar regions, and to consider how a large-scale science plan for Polar Science should be formulated. One of the focus of the discussion will be on the importance in the Master Plan 2020, which will be announced by the Science Council of Japan. <br/>The changes in the polar regions are essential for future projection of the Earth system. The Antarctic and Greenland ice sheet holds most of the ice and is the largest freshwater reservoir on the Earth, which is equivalent to about 70 m height of sea level. Moreover, dense seawater is produced in the polar regions and formed bottom water that drives the thermohaline circulation. Changes in the thermohaline circulation are considered to be a large impact on the global environment. Therefore, the polar regions are the key components that control global climate and sea level changes. However, the polar regions are still poorly unknown components in the Earth system and the systematic various field of scientific observations is required. From such background, the convener believes that polar science is one of the important topics which should be proposed to the Master Plan 2020.

# Antarctic Circumpolar Interdisciplinary Survey - ACIS

*Robin Elizabeth Bell[1], Kirsteen Tinto[1], Xiaojun Yuan[1]

1. Lamont Doherty Earth Observatory of Columbia University

Constraining how fast sea levels will rise around the globe in the coming decade requires a vastly improved interdisciplinary understanding of how the heat from the warming circumpolar ocean waters will cause rapid change in the Antarctic ice sheets. Advancing our knowledge of the rates of change requires improved observations of the ice, the ocean and the solid earth and bringing together scientists from these disciplines to address the key questions: (i) How much ice passes over the Antarctic grounding line each year? (ii) How does ocean circulation influence ice flow over the grounding line, and how will it change? And (iii) How will changes in ice mass affect sea level around the world? Like many major problems facing humans, the constraining the future rate of change of the Antarctic ice sheets is a problem that must be addressed through shared resources and coordinated science –across nations and across disciplines.

Here we present the vision of the Antarctic Circumpolar Interdisciplinary Survey that will allow us to better project future sea level rise from Antarctica. To address the questions requires data from all around the Antarctic ice sheet on the thickness of the ice entering the global oceans across the grounding line, the bathymetry surrounding the ice sheets and the dynamics of the warming ocean. Key observations cannot be obtained from space and require collaborative work on the ice sheet and the circumpolar Antarctic ocean. Together the international community has the capacity to address this question. Ongoing international efforts and technological advances have developed a wide range of capabilities for direct and remote sensing of the ice, ocean and rock around Antarctica. Understanding how much ice is flowing across the grounding line can be measured with using small aircraft based at permanent bases or field camps around the continent, long range aircraft based off continent and from drones launched form ships. The water depth close to the ice sheet can be obtained with ground-based explorations, airborne observation submersibles or gliders. Salinity and temperature are measured from a broad span of instruments, with additional sensors measuring current velocity, tidal variation and biogeochemical markers also deployed. Most oceanographic work operates from ships, but coastal sites also provide platforms for ocean observations, and profiling floats can successfully be deployed from aircraft. Like the International Polar Years and other large collaborative project this effort can serve as a future focal point for Antarctic Science through SCAR and other international programs.

# Proposal of Polar Science to Master Plan 2020

*Takuji Nakamura[1], Atsuko Sugimoto[2], Shin Sugiyama[2], Yoshifumi Nogi[1], Tetsuo Sueyoshi[1]

1. National Institute of Polar Research, 2. Hokkaido University

The academic large-scale research master plan of the Science Council of Japan is a collection of large-scale research plans that should be tackled in about 10 years, regardless of the field. After the discussion during past two years, we submitted in March 2019 as a proposal to Master Plan 2020 "Prediction of sea level fluctuation caused by ice sheet fluctuation" on behalf of the polar science field.

In the "Frontier of Polar Regions Science" for masterplan 2017, we have proposed a comprehensive and interdisciplinary research plan covering important processes and data acquisition of polar regions, which records the past global environmental changes with high accuracy, having multiple tipping points and great impact on the global environment. There were some critical comments that the focus was not clear enough, and also about stractural issue whether it should be a mission of the National Institute of Polar Research or a national academic projects.

In the master plan of 2020, we have restructured the proposal from a differentiated view point from the recent Arctic environmental research and Antarctic observation projects, as a comprehensive study of the ice sheet change, by setting the future sea level change for the main outcome of the project.

In this presentation we will introduce the situation of large-scale research projects, review the efforts for masterplan of polar science so far, explain the background of examination of this proposal. The aim is to stimulate the discussion at the session and future studies. The Antarctic / Arctic is an important research field that various topics such as space and planetary science, atmospheric and ocean science, solid earth science etc. should collaborate. It is also essential to obtain public understanding on its importance by stakeholders.

# Towards the understanding of mass balance variation of Arctic and Antarctic ice sheets

Teruo Aoki[1,2,4], Masashi Niwano[4], *Tetsuo Sueyoshi[2,3]

1. Okayama Univ., 2. National Institute of Polar Research, 3. Japan Agency for Marine-Earth Science and Technology, 4. Meteorological Research Institute

Greenland and East- and West- Antarctic ice sheets are the largest storage of fresh water on earth. The variation of these ice sheets can effect not only the sea level, but also on global climate through the modulation of the deep water formation in the ocean. The study on ice sheets have therefore a significant importance on studies and projections of global environental change.

In the Arctic, most significant signal of global warming appears by polar amplification, which results in the rapid mass loss of the Greenland ice sheet. The extreme melt event across the entire ice sheet was also observed first time ever in 2012. The cause of mass loss can be attributed to the temperature increase, albedo decrease by snow impurities, and also to the ocean wariming which induces the enhanced melt at the marginal glaciers (Box, 2013; Fettweis et al., 2013). In the Antarctic, while the West Antarctic Ice Sheet is losing its mass rapidly, the signal in the East Antarctic Ice Sheet is not yet clear (Steig et al., 2009, etc.) .

Considering such backgrounds, the following studies are needed to make a breakthrough on our understanding of the surface process of the ice sheets (Aoki, 2015): Expanding and maintenance of the AWS network, Process study by in-situ observations, Modelling efforts of physical processes such as near-surface radiation or snow metamorphose, and Development of the regional polar system model including these processes. Validation of the model performance using satellite observation is further needed. As Japanese research community already has activities on these topics, such studies on snow and ice sheets should be an effective orientation taking an advantage of ongoing research.

# Modelling Perspective for the Past and Future tipping points of ice-sheets and climate

*Ayako Abe-Ouchi[1,2,3], Fuyuki SAITO[2], Takashi Obase[1], Ralf Greve[4], Sam Sherriff-Tadano[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. JAMSTEC, 3. NIPR, 4. Hokkaido University

Ice sheet volume changes are the largest potential source of sea level change in the past and future. Since ice sheets are vulnerable under climate changes, it is important to carefully understand its dynamics and identify its irreversible behaveour, and critical threshold under climate change. Here I show modeling studies that simulate the past ice sheet change as well as climate change and discuss the implication for the studies needed to understand the tipping points both in past and future.

# Prediction of sea level rise caused by ice sheet melt

*Takeshi Tamura[1], Junichi Okuno[1], Yusuke Suganuma[1], Tetsuo Sueyoshi[1], Yoshifumi Nogi[1], Takuji Nakamura[1]

1. NIPR National Institute of Polar Research

The polar climate system, consisting of atmosphere, ocean, and cryosphere, plays important roles in shaping the global environments through its vast exchange and storage of heat and freshwater. The accelerating ice mass loss in the Greenland and West Antarctica is a significant process affecting the global climate and the understanding of the ice-ocean interaction there is of primary importance. In contrast, the status of ice mass change in East Antarctica is still in debates. Recent studies show some fingerprints of huge mass loss in the past warming world and the ice mass loss from the glaciers including Totten Glacier in East Antarctica is increasing. However, the processes of heat supply and sequent ice-ocean interaction are poorly known for both continental ice sheets.
Now, we need to understand their individual processes in polar regions through observation and modeling, and to investigate the actual states and mechanisms of various interactions. In addition, integrated researches need to be conducted, contributing to the future projection of the global environmental change driven by the polar oceans and continental ice sheets. Toward these goals, we need to clarify the state and interactions between the ocean, ice sheet, crust, ecological system, greenhouse gases, etc. and their variations from the past to the future through the field observations and analyses of samples and conduct various kinds of modeling in cooperation with the observations.

# Future Research Plan in the Polar region

*Yoshifumi Nogi[1], Tetsuo Sueyoshi[1], Takuji Nakamura[1]

1. National Institute of Polar Research

The changes in the polar regions most likely indicate the precursor and driving force of the global environmental changes, and these changes are essential for future projection of the Earth system. The Antarctic and Greenland ice sheet that holds most of the ice is the largest freshwater reservoir on the Earth, equivalent to about 70 m height of sea level. On the other hand, dense seawater produced in the polar regions formed bottom water that drives the thermohaline circulation. Changes in the thermohaline circulation are considered to be significant impacts on the global environment. Therefore, the polar regions are the key to global climate and sea level changes. However, the polar regions are still poorly unknown components in the Earth system due to the harsh weather conditions in these areas.
The interaction among the atmosphere, ice sheet, solid earth, and the ocean is vital to understand the system in the polar regions, and the various systematic field of scientific observations is required to elucidate the interaction. The scientific program and the framework of the integrated multidisciplinary study focused on the polar regions must be developed from the viewpoints of the global climate and sea level changes. Present scientific activities and plans in the polar region are summarized, and the future integrated multidisciplinary research plans in the polar region are discussed.

Along with the anthropogenic climate change, changes in overturning circulations and ice mass of the Southern Ocean and Antarctic Ice Sheet are listed as the problems with huge social implications. In Amundsen Sea, West Antarctica, accelerations of basal melting of ice shelves and loss of ice mass have been observed. More recently, ice discharge of the Totten Glacier, East Antarctica, is shown to be accelerating, and a pathway of substantially warm water access has been discovered beneath the ice shelf. The ice mass behind the Totten Glacier is estimated to be 3.5 m of global sea level equivalent, and the bed rock configuration reveals a vulnerability of the maritime ice sheet instability. The acceleration of freshwater discharge can affect sea ice production and subsequent dense water formation. With the growing awareness on the importance of ice-ocean interaction and long-term variabilities off the East Antarctic Coast, observations at the ice-ocean boundaries above and underneath the sea ice and continental ice are indispensable.

Under the project called ROBOTICA for the 9th six-year plan (2016-2022) of the Japanese Antarctic Research Expedition, we are implementing broad oceanographic and cryospheric surveys using new technologies like tethered/moored profiling platforms, Remotely Operated Vehicle (ROV) and ice radars, together with the conventional observational methods. The observations here will help revealing the ongoing oceanic and cryospheric changes and set the baselines for the future changes.

Under the GRAntarctic (2017-2022) frame work, we start developing a new Autonomous Underwater Vehicle (AUV), suitable for under-ice survey of Antarctica. The AUV is designed to operate in the following 3 modes; Seafloor Tracking mode (bathymetry, imagery), Ice Tracking mode (ice shape, imagery), and Constant Depth mode (water survey).

Development of appropriate instruments and platforms of this kind is an urgent task, given the rapid progress of the environmental changes in the ice-covered ocean. To fully utilize this instruments, the basic ability required for a mother icebreaker is high, since she needs to cope with the requirements as a platform of various state-of-the art technologies in ice-covered ocean. Moreover, flexible operation from a long-term perspective such as revisiting the sites some years later will be effective.

Keywords: ice-ocean interaction, Antarctic Ice Sheet, Southern Ocean, AUV, ice radar

The studies of deep ice cores and boreholes have provided records of past climatic and environmental changes on various time scales, as well as evidences on how the both polar regions have interacted through atmosphere and ocean to affect global climate. Understanding the processes and sensitivities that underlie the changes, through the ice-core analyses as well as in combination with climate and ice-sheet modeling, will underpin better understanding of the climate system and projections of its future change. In the next phases of Antarctic glaciological research, National Institute of Polar Research together with Dome Fuji Ice Core Consortium (ICC) and Third Dome Fuji Drilling Project plans to perform various activities related to the third deep ice-core drilling in the vicinity of Dome Fuji, in order to obtain an ice core with age much older than 800 kyr. This is also a contribution to International Partnership in Ice Core Sciences (IPICS) “Oldest ice core project”. During the JARE Phase IX, we have been investigating glaciological conditions (ice sheet surface, englacial and subglacial conditions) of the candidate area, and we will determine the exact location of the drilling site and start pilot hole drilling and casing to enable deep drilling. The deep drilling must then follow to actually recover the old ice. In Greenland, we currently participate in the East Greenland Ice Core Project (EGRIP) to better understand the dynamics and past changes of the fastest-flowing Northeast ice stream and to reconstruct the climate and environment changes during the past warm periods and during abrupt warmings during the last glacial period. After the EGRIP drilling is finished, the next Greenland deep ice coring will be carried out to obtain spatial variabilities of climate and ice sheet changes. By studying the ice core records from both polar regions, we can understand the mechanisms and global impacts of the polar climate changes such as glacial-interglacial transition and abrupt climate changes.

1. Center for Advanced Marine Core Research, Kochi University, 2. GSJ, AIST, 3. National Institute of Polar Research

On the shelf slope from the continental shelf of Antarctica, there are characteristic seafloor topographic features and sediments potentially influenced by the Antarctic ice sheet and the Antarctic bottom water. Gully-like submarine valleys have remarkably observed on the shelf edge off the coast of Cape Darnley, where the Antarctic bottom water is presently formed, by using marine geophysical methods such as multibeam echo sounding, sub-bottom profiling, and multichannel seismic reflection surveys. Our latest survey during the R/V Hakuho-maru KH-19-1 cruise in the early 2019 completed obtaining new exciting data which clearly shows complex submarine channels from shallow to deep seafloor and surrounding sedimentations. Although these up-to-date observations in unexplored area provided new clues for understanding origin and formation of Antarctic bottom water, currently obtained detailed seafloor topography and submarine geological structures have been essentially limited because of insufficient spatial coverage. This is mainly because of the difficulty to explore Antarctic continental shelf where sea ice and iceberg exist. Integrated promotion of marine geophysical and geological investigations as well as sediment coring in this area will allow us to develop a new science for revealing the relationship between Antarctica and Earth history which has not been clarified in the past research.

1. National Institute of Polar Research, 2. SOKENDAI

Ice sheet, sea water, and terrestrial water storage act as surface mass loads on the solid Earth. Past and present variations of these loads make the solid Earth deform as the elastic and the viscous responses. These deformations have been clearly observed by geodetic, geomorphological and geological methods based on the field survey and the satellite measurement. To reconstruct the sea-level change associated with the surface mass changes and the solid Earth's response based on these observations, we need to apply the numerical modeling described by the Glacial Isostatic Adjustment (GIA) theory. GIA modeling results indicate that the predicted sea-level changes in any sites are spatially non-uniform because of the crustal deformation due to the GIA depending on the geometry of the surface mass loads, namely distribution of ice and water. Therefore, the precise evaluation of the GIA is vital to elucidate present and past sea-level changes. In this presentation, we show the crustal deformation derived from GIA due to present and past surface load changes and illustrate the importance of GIA component for precise projection of the sea-level change.

# International organization's science plan and Japan's Arctic policy

*Yuji Kodama[1], Tetsuo Ohata[1]

1. National Institute of Polar Research

Planning of post-ArCS is in progress. International collaboration is a “must” for Japanese Arctic (polar region) research, and it is important to be able to demonstrate Japan's strength internationally. There are several international science plan published recently and they could be a hint for one way to formulate the plan of Post ArCS. Japanese Arctic policies must be also referenced for the plan. Then, the international organization 's Science Plan on Arctic Research, Japanese Arctic Policy, Overseas Arctic Research Program are introduced.

## [M-IS26] Arctic and Antarctic Science and Future Plan

convener:Yoshifumi Nogi(National Institute of Polar Research), Takuji Nakamura(National Institute of Polar Research), Atsuko Sugimoto(Arctic Research Center, Hokkaido University), Shin Sugiyama(Institute of Low Temperature Science, Hokkaido University)

This session will be a forum to discuss the scientific program and the framework of the future integrated multidisciplinary study focused on the polar regions, and to consider how a large-scale science plan for Polar Science should be formulated. One of the focus of the discussion will be on the importance in the Master Plan 2020, which will be announced by the Science Council of Japan. <br/>The changes in the polar regions are essential for future projection of the Earth system. The Antarctic and Greenland ice sheet holds most of the ice and is the largest freshwater reservoir on the Earth, which is equivalent to about 70 m height of sea level. Moreover, dense seawater is produced in the polar regions and formed bottom water that drives the thermohaline circulation. Changes in the thermohaline circulation are considered to be a large impact on the global environment. Therefore, the polar regions are the key components that control global climate and sea level changes. However, the polar regions are still poorly unknown components in the Earth system and the systematic various field of scientific observations is required. From such background, the convener believes that polar science is one of the important topics which should be proposed to the Master Plan 2020.

1. Hokkaido University, 2. National Institute of Polar Research, 3. The University of Tokyo

Along with the anthropogenic climate change, changes in overturning circulations and ice mass of the Southern Ocean and Antarctic Ice Sheet are listed as the problems with huge social implications. In Amundsen Sea, West Antarctica, accelerations of basal melting of ice shelves and loss of ice mass have been observed. More recently, ice discharge of the Totten Glacier, East Antarctica, is shown to be accelerating, and a pathway of substantially warm water access has been discovered beneath the ice shelf. The ice mass behind the Totten Glacier is estimated to be 3.5 m of global sea level equivalent, and the bed rock configuration reveals a vulnerability of the maritime ice sheet instability. The acceleration of freshwater discharge can affect sea ice production and subsequent dense water formation. With the growing awareness on the importance of ice-ocean interaction and long-term variabilities off the East Antarctic Coast, observations at the ice-ocean boundaries above and underneath the sea ice and continental ice are indispensable.

Under the project called ROBOTICA for the 9th six-year plan (2016-2022) of the Japanese Antarctic Research Expedition, we are implementing broad oceanographic and cryospheric surveys using new technologies like tethered/moored profiling platforms, Remotely Operated Vehicle (ROV) and ice radars, together with the conventional observational methods. The observations here will help revealing the ongoing oceanic and cryospheric changes and set the baselines for the future changes.

Under the GRAntarctic (2017-2022) frame work, we start developing a new Autonomous Underwater Vehicle (AUV), suitable for under-ice survey of Antarctica. The AUV is designed to operate in the following 3 modes; Seafloor Tracking mode (bathymetry, imagery), Ice Tracking mode (ice shape, imagery), and Constant Depth mode (water survey).

Development of appropriate instruments and platforms of this kind is an urgent task, given the rapid progress of the environmental changes in the ice-covered ocean. To fully utilize this instruments, the basic ability required for a mother icebreaker is high, since she needs to cope with the requirements as a platform of various state-of-the art technologies in ice-covered ocean. Moreover, flexible operation from a long-term perspective such as revisiting the sites some years later will be effective.

The studies of deep ice cores and boreholes have provided records of past climatic and environmental changes on various time scales, as well as evidences on how the both polar regions have interacted through atmosphere and ocean to affect global climate. Understanding the processes and sensitivities that underlie the changes, through the ice-core analyses as well as in combination with climate and ice-sheet modeling, will underpin better understanding of the climate system and projections of its future change. In the next phases of Antarctic glaciological research, National Institute of Polar Research together with Dome Fuji Ice Core Consortium (ICC) and Third Dome Fuji Drilling Project plans to perform various activities related to the third deep ice-core drilling in the vicinity of Dome Fuji, in order to obtain an ice core with age much older than 800 kyr. ## [M-AG38] Satellite Land Physical Processes Monitoring at Medium/High/Very High Resolution

convener:Jean-Claude Roger(University of Maryland College Park), Shinichi Sobue(Japan Aerospace Exploration Agency), Eric Vermote(NASA Goddard Space Flight Center)

We solicit papers on the land physical processes monitoring. In particular, it will include the inversion and use of land products from medium, high, and very high spatial resolution. For the last years, medium, high, and very high resolutions became a useful and a powerful toll for Earth studies. Topics of interest mainly include (not limited to):
- New developments for data processing, including atmospheric correction and cloud screening;
- Analysis and correction of directional effects in land surface reflectances;
- Use of time series of surface reflectances for land monitoring, including land cover classification and crop yield prediction (including data integration and data harmonization);
- Development and use of new vegetation indices (i.e. red edge) and other products for agriculture applications;
- Theoretical studies for sensors capabilities enhancements to future sensors at high/medium resolutions;
- Use of products in agricultural monitoring applications (such as crop area, crop type, crop growing, yield estimation and prediction, damage assessment);
- Agriculture monitoring algorithm description;
- Evaluation or validation of potential products with ground measurements, official statistics;
- International initiative to enhance Earth-Observing-based agricultural information.

Depending on outcome, we think about a special issue.

The Advanced Very High Resolution Radiometer (AVHRR) sensors aboard the different NOAA satellites provide a unique global remote sensing dataset that ranges from the 1980s to the present. Using these data, the NASA funded Long Term Data Record (LTDR) project aims to develop a quality and consistent Climate Data Record (CDR) of AVHRR data with the use of the Moderate Resolution Imaging Spectrometer (MODIS) instrument as a reference. This product retrieves the BRDF corrected land surface reflectance using the VJB method (Vermote et al., 2009), which corrects the anisotropic effects by obtaining Volumetric (V) and Geometrical (R) parameters, defined in the Roujean model (Roujean et al., 1992), as a function of the Normalized Difference Vegetation Index (NDVI). Inaccuracies regarding the AVHRR atmospheric correction and calibration in the red band for the pre-MODIS era (1982-2000), propagate towards the surface reflectance’ s BRDF correction. However, with the use of the less noisy Near-Infrared (NIR) band we can reduce said errors by finding an empirical relationship between the red-NIR V and R parameters. This study aims to find said relationship using the MODIS sensor, which is an already established and accurate product (Justice et al., 2002; Liang et al., 2002), to then apply it to the noisy AVHRR data and reduce the BRDF errors in the red band.

# Winter wheat yield model based on remote sensing data

*Belen Franch[1,2], Eric Vermote[2,1], Sergii Skakun[1,2], Jean-Claude Roger[1,2], Inbal Becker-Reshef[1], Chris Justice[1]

1. Department of Geographical Sciences, University of Maryland, 2. NASA Goddard Space Flight Center

Accurate and timely crop yield forecasts are critical for making informed agricultural policies and investments, as well as increasing market efficiency and stability. Earth observation data from space can contribute to agricultural monitoring, including crop yield assessment and forecasting. This work presents a new EO-based empirical winter wheat yield model. It is based on the un-mixing of the wheat signal from a coarse resolution EO data at 1 km by using yearly crop type masks to a pure wheat signal (100% of wheat within the pixel). *This wheat signal is used to calibrate the model using as inputs the seasonal amplitude and length of the Difference Vegetation Index (DVI) peak extracted from Moderate Resolution Imaging Spectroradiometer (MODIS) data and the average of the evaporative fraction (EF) 30 days after the peak. The three regressors proposed are focused on the reproduction stage of the wheat (DVI amplitude and length) and the grain filling process (EF 30-days average). The model is calibrated at subnational level using historical statistics from 2001 to 2016. In each administrative unit, a different calibration coefficient (based on all possible combination of the three regressors in a linear model) is selected depending on the statistical significance of each variable. The model was applied to estimate the national and subnational winter wheat yield in the United States, Ukraine, Russia and France from 2001 to 2017. At the subnational level the model shows very good performance with a coefficient of determination higher than 0.7 and Root Mean Square Error (RMSE) lower than 15%. At the national level the model provides a strong coefficient of determination higher than 0.8 and a RMSE lower than 8%, which demonstrates good performance of the models at this scale. Additionally, it was also able to capture low winter wheat yields during years with extreme weather events, for example 2002 in US and 2003 in Ukraine.*

# Agricultural monitoring from Optical and SAR data

*Andrés Eduardo Santamaría-Artigas[1,2], Sergii Skakun[1,2], Belen Franch[1,2], Jean-Claude Roger[1,2], Eric Vermote[2]

1. University of Maryland College Park, 2. NASA Goddard Space Flight Center

Vegetation indices derived from optical remote sensing data are a valuable source of information for agricultural monitoring. However, cloud cover over some areas reduces the number of valid observations, which can difficult the detection of changes in crop condition. In this context, synthetic aperture radar (SAR) systems are an interesting alternative due to their low sensitivity to clouds. In this work, we analyze the relationship between SAR backscatter from Sentinel-1 and vegetation indices derived from the Harmonized Landsat-8 Sentinel-2 (HLS) product with data from the year 2017 over 6 land cover classes in Ukraine: Winter crops, summer crops, bare land, grasslands, forest, and water. Results show that SAR data from Sentinel-1 could be used to complement optical indices for certain land covers. In the case of winter crops (rapeseed and wheat), the ratio between Sigma-0 VV and VH polarization showed the highest relationship with the Normalized Difference Vegetation Index (NDVI) while for summer crops (maize, sugar beet, sunflower, and soybean) the highest relationship was shown by the Sigma-0 VH polarization and NDVI. Further work is being developed to exploit more complex SAR models which account for other variables that affect the backscatter signal such as soil moisture.

# Eco-hydrological modeling using field-based and Earth Observations to assess water use efficiency and support agricultural water resources management

pierre Guillevic[2,1], *Jean-Claude Roger[1,2]

1. University of Maryland, College Park, USA, 2. NASA Goddard Space flight Center, Greenbelt, USA

The objective of this NASA project is to develop an integrated modeling platform using Earth Observations to simulate large-scale hydrological processes and food production in support of water use decision and agricultural policy. The decision tool will provide timely and relevant assessments of crop growth, agricultural water use and available water supply from local to regional scales, with the capability to predict the impact of different climate and water resources management scenarios on food production. The approach is based on the use of field and Earth observations to calibrate an eco-hydrological model, and climate simulations to forecast crop condition and yield through the crop season. The expected primary outcomes and results for stakeholders is potential best water management practices to improve water use efficiency and prevent excessive losses of water and nitrogen to the environment. These will be provided to in-country end-users within various relevant Ministries and Departments, in order to inform regional and national decisions. Changing precipitation patterns, droughts of increasing duration and severity and growing demand for food have significant implications on water management practices, spurring an increased need for irrigation in a sustainable manner and better monitoring of water resources for the agricultural sector in general. Understanding the context and water resource constraints that stakeholders and smallholder farmers face in climate sensitive regions is critical to target and understand the potential impact of water use management. We focus on a diverse set of regional pilot cases in Argentina, South Africa, Tanzania and the United States that are representative of a range of agricultural systems, water issues and climate impacts. The application is integrated in the GEOGLAM project, an existing widely-used web-based platform which will aid synthesizing the project outcomes and expert domain knowledge to provide timely and actionable water resources and crop condition information to assist local, regional and national water management decisions. At the end, the application will be interactive and will offer the end-user organizations the possibility to submit new water resource management scenarios online for impact evaluation.

Earth Observations are critical to characterize and monitor the different components of agricultural ecosystems and change (forests, croplands and marginal lands availability, for example) across temporal and spatial scales. Satellite data in the shortwave, thermal infrared and microwave spectral domains from US (MODIS, VIIRS, Landsat, SMAP) and European (Sentinel 1 and 2) sensors will be used to characterize changes in land surfaces and water use from 2000 to the present in support of agricultural planning decisions. In a research context, the potential of new satellite missions (i.e., ECOSTRESS, SWOT and SAOACOM) to derive surface hydrology information will be evaluated. The Agricultural Policy/Environmental eXtender (APEX) watershed model is proposed as the modeling tool to understand the biophysical and human-decision processes associated with the food-energy-water nexus. Model simulations will use climate data from the NASA Goddard Earth Observing System Model (GEOS-5) Atmosphere-Ocean General Circulation Model: MERRA-2 for simulation of past conditions and seasonal (6-month) forecasts for projections in the future. The study focus on large, key agricultural regions where agricultural ecosystems are vulnerable to demographic expansion and/or climate variability and change including drought and flood events.

# Detecting and quantifying forest dynamics using SAR time-series data in Indonesia

*Pedro Rodriguez-Veiga[1,2,3], Narumasa Tsutsumida[3]

1. Centre for Landscape and Climate Research, University of Leicester, Leicester, UK, 2. NERC National Centre for Earth Observation (NCEO), Leicester, UK, 3. Graduate School of Global Environmental Studies, Kyoto University, Japan

Satellite Earth Observation (EO) data allows the generation of forest disturbance maps that can improve greenhouse gas (GHG) monitoring at local and national scales, and provide information that can be used for land use planning and management. Mapping forest biomass stocks, deforestation, forest degradation and enhancement is crucial in order to determine the loss of carbon stocks due to disturbances (e.g. deforestation, fires) or the gain due to new forest or growth. Time-series observations identify decreasing or increasing trends of aboveground biomass carbon, and separate anthropogenic related changes from seasonal changes of vegetation. This is important for understanding the terrestrial carbon cycle and for supporting better forest management and policies. This study uses time-series data from L-band Synthetic Aperture Radar (SAR) JAXA’s ALOS PALSAR and ALOS-2 PALSAR-2 to quantify carbon loss and gain trajectories (emission / sequestration) of existing forests in West Java (Indonesia).

# Improving the AVHRR LTDR BRDF correction

*Jose Luis Villaescusa[1,2], Belen Franch[1,2], Jean-Claude Roger[1,2], Eric Vermote[2]

1. University of Maryland College Park, 2. NASA Goddard Space Flight Center

The Advanced Very High Resolution Radiometer (AVHRR) sensors aboard the different NOAA satellites provide a unique global remote sensing dataset that ranges from the 1980s to the present. Using these data, the NASA funded Long Term Data Record (LTDR) project aims to develop a quality and consistent Climate Data Record (CDR) of AVHRR data with the use of the Moderate Resolution Imaging Spectrometer (MODIS) instrument as a reference. This product retrieves the BRDF corrected land surface reflectance using the VJB method (Vermote et al., 2009), which corrects the anisotropic effects by obtaining Volumetric (V) and Geometrical (R) parameters, defined in the Roujean model (Roujean et al., 1992), as a function of the Normalized Difference Vegetation Index (NDVI). Inaccuracies regarding the AVHRR atmospheric correction and calibration in the red band for the pre-MODIS era (1982-2000), propagate towards the surface reflectance’ s BRDF correction. However, with the use of the less noisy Near-Infrared (NIR) band we can reduce said errors by finding an empirical relationship between the red-NIR V and R parameters. This study aims to find said relationship using the MODIS sensor, which is an already established and accurate product (Justice et al., 2002; Liang et al., 2002), to then apply it to the noisy AVHRR data and reduce the BRDF errors in the red band.

# Winter wheat yield model based on remote sensing data

*Belen Franch[1,2], Eric Vermote[2,1], Sergii Skakun[1,2], Jean-Claude Roger[1,2], Inbal Becker-Reshef[1], Chris Justice[1]

1. Department of Geographical Sciences, University of Maryland, 2. NASA Goddard Space Flight Center

Accurate and timely crop yield forecasts are critical for making informed agricultural policies and investments, as well as increasing market efficiency and stability. Earth observation data from space can contribute to agricultural monitoring, including crop yield assessment and forecasting. This work presents a new EO-based empirical winter wheat yield model. It is based on the un-mixing of the wheat signal from a coarse resolution EO data at 1 km by using yearly crop type masks to a pure wheat signal (100% of wheat within the pixel). *This wheat signal is used to calibrate the model using as inputs the seasonal amplitude and length of the Difference Vegetation Index (DVI) peak extracted from Moderate Resolution Imaging Spectroradiometer (MODIS) data and the average of the evaporative fraction (EF) 30 days after the peak. The three regressors proposed are focused on the reproduction stage of the wheat (DVI amplitude and length) and the grain filling process (EF 30-days average). The model is calibrated at subnational level using historical statistics from 2001 to 2016. In each administrative unit, a different calibration coefficient (based on all possible combination of the three regressors in a linear model) is selected depending on the statistical significance of each variable. The model was applied to estimate the national and subnational winter wheat yield in the United States, Ukraine, Russia and France from 2001 to 2017. At the subnational level the model shows very good performance with a coefficient of determination higher than 0.7 and Root Mean Square Error (RMSE) lower than 15%. At the national level the model provides a strong coefficient of determination higher than 0.8 and a RMSE lower than 8%, which demonstrates good performance of the models at this scale. Additionally, it was also able to capture low winter wheat yields during years with extreme weather events, for example 2002 in US and 2003 in Ukraine.*

# Agricultural monitoring from Optical and SAR data

*Andrés Eduardo Santamaría-Artigas[1,2], Sergii Skakun[1,2], Belen Franch[1,2], Jean-Claude Roger[1,2], Eric Vermote[2]

1. University of Maryland College Park, 2. NASA Goddard Space Flight Center

Vegetation indices derived from optical remote sensing data are a valuable source of information for agricultural monitoring. However, cloud cover over some areas reduces the number of valid observations, which can difficult the detection of changes in crop condition. In this context, synthetic aperture radar (SAR) systems are an interesting alternative due to their low sensitivity to clouds. In this work, we analyze the relationship between SAR backscatter from Sentinel-1 and vegetation indices derived from the Harmonized Landsat-8 Sentinel-2 (HLS) product with data from the year 2017 over 6 land cover classes in Ukraine: Winter crops, summer crops, bare land, grasslands, forest, and water. Results show that SAR data from Sentinel-1 could be used to complement optical indices for certain land covers. In the case of winter crops (rapeseed and wheat), the ratio between Sigma-0 VV and VH polarization showed the highest relationship with the Normalized Difference Vegetation Index (NDVI) while for summer crops (maize, sugar beet, sunflower, and soybean) the highest relationship was shown by the Sigma-0 VH polarization and NDVI. Further work is being developed to exploit more complex SAR models which account for other variables that affect the backscatter signal such as soil moisture.

# Eco-hydrological modeling using field-based and Earth Observations to assess water use efficiency and support agricultural water resources management

pierre Guillevic[2,1], *Jean-Claude Roger[1,2]

1. University of Maryland, College Park, USA, 2. NASA Goddard Space flight Center, Greenbelt, USA

The objective of this NASA project is to develop an integrated modeling platform using Earth Observations to simulate large-scale hydrological processes and food production in support of water use decision and agricultural policy. The decision tool will provide timely and relevant assessments of crop growth, agricultural water use and available water supply from local to regional scales, with the capability to predict the impact of different climate and water resources management scenarios on food production. The approach is based on the use of field and Earth observations to calibrate an eco-hydrological model, and climate simulations to forecast crop condition and yield through the crop season. The expected primary outcomes and results for stakeholders is potential best water management practices to improve water use efficiency and prevent excessive losses of water and nitrogen to the environment. These will be provided to in-country end-users within various relevant Ministries and Departments, in order to inform regional and national decisions. Changing precipitation patterns, droughts of increasing duration and severity and growing demand for food have significant implications on water management practices, spurring an increased need for irrigation in a sustainable manner and better monitoring of water resources for the agricultural sector in general. Understanding the context and water resource constraints that stakeholders and smallholder farmers face in climate sensitive regions is critical to target and understand the potential impact of water use management. We focus on a diverse set of regional pilot cases in Argentina, South Africa, Tanzania and the United States that are representative of a range of agricultural systems, water issues and climate impacts. The application is integrated in the GEOGLAM project, an existing widely-used web-based platform which will aid synthesizing the project outcomes and expert domain knowledge to provide timely and actionable water resources and crop condition information to assist local, regional and national water management decisions. At the end, the application will be interactive and will offer the end-user organizations the possibility to submit new water resource management scenarios online for impact evaluation.

Earth Observations are critical to characterize and monitor the different components of agricultural ecosystems and change (forests, croplands and marginal lands availability, for example) across temporal and spatial scales. Satellite data in the shortwave, thermal infrared and microwave spectral domains from US (MODIS, VIIRS, Landsat, SMAP) and European (Sentinel 1 and 2) sensors will be used to characterize changes in land surfaces and water use from 2000 to the present in support of agricultural planning decisions. In a research context, the potential of new satellite missions (i.e., ECOSTRESS, SWOT and SAOACOM) to derive surface hydrology information will be evaluated. The Agricultural Policy/Environmental eXtender (APEX) watershed model is proposed as the modeling tool to understand the biophysical and human-decision processes associated with the food-energy-water nexus. Model simulations will use climate data from the NASA Goddard Earth Observing System Model (GEOS-5) Atmosphere-Ocean General Circulation Model: MERRA-2 for simulation of past conditions and seasonal (6-month) forecasts for projections in the future. The study focus on large, key agricultural regions where agricultural ecosystems are vulnerable to demographic expansion and/or climate variability and change including drought and flood events.

# Detecting and quantifying forest dynamics using SAR time-series data in Indonesia

*Pedro Rodriguez-Veiga[1,2,3], Narumasa Tsutsumida[3]

1. Centre for Landscape and Climate Research, University of Leicester, Leicester, UK, 2. NERC National Centre for Earth Observation (NCEO), Leicester, UK, 3. Graduate School of Global Environmental Studies, Kyoto University, Japan

Satellite Earth Observation (EO) data allows the generation of forest disturbance maps that can improve greenhouse gas (GHG) monitoring at local and national scales, and provide information that can be used for land use planning and management. Mapping forest biomass stocks, deforestation, forest degradation and enhancement is crucial in order to determine the loss of carbon stocks due to disturbances (e.g. deforestation, fires) or the gain due to new forest or growth. Time-series observations identify decreasing or increasing trends of aboveground biomass carbon, and separate anthropogenic related changes from seasonal changes of vegetation. This is important for understanding the terrestrial carbon cycle and for supporting better forest management and policies. This study uses time-series data from L-band Synthetic Aperture Radar (SAR) JAXA’s ALOS PALSAR and ALOS-2 PALSAR-2 to quantify carbon loss and gain trajectories (emission / sequestration) of existing forests in West Java (Indonesia).

Discussion

# 15-years of LSA-SAF/Eumetsat satellite-derived albedo products: method for retrieval validation, and recent advances using neural networks during spectral integration

*Florian Pinault[1], Dominique Carrer[1], Xavier Ceamanos[1], Gabriel Lellouch[1], Catherine Meurey[1], Suman Moparthy[1], Chloé Vincent[1], Sandra Coelho[2], Isabel Trigo[2]

1. Météo France, CNRM-GAME, UMR3589, Toulouse, France, 2. IPMA, Lisbon, Portugal

Using two sets of Eumetsat satellite sensors (geostationary MSG with SEVIRI sensor, polar orbiting Metop/EPS with AVHRR sensors), the Land Surface Analysis (LSA-SAF) team provides to the community several remote sensing products related to the land surface properties (http://lsa-saf.eumetsat.int/). The long-term continuity and consistency of these products is ensured from 2004 to at least 2022 thanks to the Eumetsat funding. In this contribution, we are focus on the various albedo products, presenting their properties, algorithms (from the L1 Top-Of-Atmosphere reflectance data to the L3 albedo), and validation results.

The main albedo retrieval algorithm is based on three steps. First, atmospheric correction is performed using a Smac approximation of a 6S off-line model. Second, the surface interaction is modeled by a kernel-based BRDF (Ross-thick-Li-sparse kernels), with an additional Kalman filter. Third, angular and spectral integrations are performed to compute spectral albedos (white-sky and black-sky) and broadband albedos (visible and NIR and total-shortwave).Validation results show a good match when comparing albedos with other sensors (MODIS) or with in-situ measurements. And performances are here analyzed in details with regards to the user requirements.

Finally we discuss the potential added value of using machine learning techniques in the scope of the launch of the next generation of European satellites which will provide observations in more spectral bands (as for instance MTG/FCI which characteristics are close to HIMAWARI 8/9: 5 visible bands and 3 NIR bands). In the third step of the albedo algorithm (spectral integration), non-convolutional neural networks seem to offer a promising way forward.

# Toward a Consistent Land Long Term Climate Data Records from Large Field of View Polar Orbiting Earth Observation Satellites

*Eric Vermote[1], Jean-Claude Roger[1,2], Belen Franch[1,2], Christopher Justice[2], Ivan Csiszar[3], Sadashiva Devadiga[1], Edward Masuoka[1]

1. NASA Goddard Space Flight Center, 2. University of Maryland, Dept. of Geographical Sciences, 3. NOAA/NESDIS/STAR

Surface reflectance is one of the key products used in developing several higher-order land products, such as Vegetation Indices, Albedo and LAI/FPAR, it is therefore seminal to detecting trends in the biosphere and land surface and has been classed by NOAA as a “Fundamental Climate Data Record (FDCR) for Land”. Building a long-term surface reflectance data record of climate quality implies combining different instruments, sensors and satellites, accounting for different spatial resolutions and spectral characteristics, assuring consistent calibration, and correcting for atmospheric and directional effects. As the spatial resolution issue is addressed by aggregating the original data to a resolution still suitable for climate studies (e.g. 0.05 degree latitude, longitude), the instrument calibration becomes the first major hurdle one has to go through before being able to proceed any further.

In this work, we are using robust reflectance data records and inter-comparison methods that we have developed over the past several years (consisting of atmospheric correction, directional effect correction and spectral normalization) to establish and verify the inter-consistency of the reflectance products from the AVHRR sensors on-board NOAA 7, 9, 11, 14, 16, 17 and 18, the MODIS sensors on-board Aqua and Terra and the VIIRS sensors on-board Suomi-NPP and JPSS1. The resulting dataset being the 35+ years surface reflectance product and vegetation indices from 1981 to present.

Several other calibration techniques are also be applied that have been developed in the past by our team, in particular combining the cloud spectral band inter-calibration with BELMANIP cross sensor calibration in the near-infrared, using Landsat 5, 7 and 8 calibration to bridge between AVHRR and MODIS.

# LaSRC Cloud Detection Algorithm for Landsat 8 and Sentinel-2 Data

*Sergii Skakun[1], Eric Vermote[2], Jean-Claude Roger[1]

1. University of Maryland College Park, 2. NASA Goddard Space Flight Center

This study aims at introducing and validating the cloud mask produced by the Land Surface Reflectance Code (LaSRC) for Landsat 8 and Sentinel-2 data. To detect clouds in optical satellite imagery, LaSRC uses quality assurance (QA) layers, which are produced during the atmospheric correction process. Validation is performed using two reference datasets. The former is the “L8 Biome” cloud validation dataset, which is produced by the US Geological Survey (USGS), and consists of 96 Landsat 8 scenes distributed globally over 12 different biomes. The latter is the dataset, which is produced over NASA GSFC assisted by ground photos of the sky and available for Landsat 8 and Sentinel-2A/B. We show that the LaSRC cloud detection algorithm reliably identifies thick clouds with commission and omission errors less than 4%. Large overdetection occurs for thin clouds. We conclude the study with recommendations on using the LaSRC QA layers, and provide an outlook on the need of acquiring objective reference cloud datasets.

Keywords: cloud, Landsat 8, Sentinel-2, LaSRC

# Aerosol models for the validation of Surface Reflectances for MODIS, VIIRS, Landsat-8, Sentinel-2 from LaSRC

*Jean-Claude Roger[1,2], Eric Vermote[2], Sergii Skakun[1,2], Belen Franch[1,2], Georgia Doxani[4], William Rountree[1,2], Ferran Gascon[4], chris justice[1], oleg dubovik[3], Brent holben[2]

1. University of Maryland, College Park, USA, 2. NASA Goddard Space flight Center, Greenbelt, USA, 3. LOA, University of Lille, Villeneuve d'Ascq, France, 4. ESA, Frascati, Italy

The land surface reflectance is a fundamental climate data record at the basis of the derivation of other climate data records (Albedo, LAI/Fpar, Vegetation indices) and has been recognized as a key parameter in the understanding of the land-surface-climate processes.

This work relies on a generic approach developed to derive surface reflectance over land from a variety of sensors. The approach is based on the inversion of the radiative transfer equation in the Lambertian case, with no adjacency effects, that account for a simplified coupling of the absorption by atmospheric gases and scattering by molecules and aerosols as implemented in the 6SV radiative transfer code. The processing code relies on look-up tables generated by 6SV, for which the accuracy (~1%) has been well documented in several papers. The LaSRC code uses ancillary data such as pressure and gas concentrations but relies on a per pixel inversion of the aerosol properties to assure the best possible accuracy for the surface reflectance, as aerosols can be highly variable both in space and time. This new aerosol inversion builds on the extensive dataset acquired by the Terra platform, combining MODIS and MISR to derive an explicit and dynamic map of band ratio’ s between blue and red channels and is a refinement of the operational approach used for MODIS and LANDSAT over the past 15 years. The aerosol inversion is generic and applicable to a variety of sensors. We use this basic approach to derive Landsat 8 and Sentinel 2 surface reflectance products for medium, high and very high spatial resolution (MODIS, VIIRS, LANDSAT, SENTINEL-2, WORLD VIEW 3…). The validation scheme is based on using aerosol models developed for each AERONET sites. We will present here the methodology to get these models. We will also show comparison of surface reflectance products with field measurements done by an instrument developed by us.
Finally, we will presents performances of LaSRC inter-compared with other operational approaches in the framework of the CEOS-ACIX (Atmospheric Correction Intercomparison eXercise) Calibration Validation Task co-Lead by ESA and NASA.

# Quantity and spatial distribution of aboveground biomass carbon in Colombia’s forest

*Pedro Rodriguez-Veiga[1,2], Adriana Paola Barbosa-Herrera[3], Edersson Cabrera[3], Gustavo Galindo[3], Valentin Louis[1], Pilar Lozano[3], Pacheco-Pascagaza Ana Maria[1], Indira Pachon-Cendales[3], Salinas Nelso Ricardo[3], Heiko Balzter[1,2]

1. Centre for Landscape and Climate Research, University of Leicester, Leicester, UK, 2. NERC National Centre for Earth Observation (NCEO), Leicester, UK, 3. Institute of Hydrology, Meteorology and Environmental Studies (IDEAM), Bogota, Colombia

In-situ national forest inventory data - NFI (IDEAM, 2018) as well as multispectral optical and synthetic aperture radar (SAR) satellite imagery were used to characterize the spatial distribution of forest aboveground biomass carbon (AGBC) stocks in Colombia. ALOS-2 PALSAR-2 gamma-0 backscatter annual mosaics (2015-2017) provided by JAXA were normalised and corrected using previous ALOS PALSAR annual mosaics (2007-2010) as reference. A multi-temporal Landsat 7 & 8 composite over the whole of Colombia was used for the year 2016 ±1. The national forest inventory in-situ plots used to train our model consisted of 5-subplots each and were collected during the period 2015-2017 in the main biomes of the country. A sample of permanent 1ha plots (PPMs) were also measured. Pan-tropical allometries (Chave et al, 2014) using diameter, height and specific wood gravity (type I) and a biomass-to-carbon ratio of 0.5 were used to estimate AGBC. A non-parametric random forests (RF) algorithm was used within a k-fold framework to retrieve AGBC at 30m spatial resolution for the whole of Colombia. The algorithm was trained using forest inventory plots and validated at plot (0.35 ha) and PPM level (1 ha). The accuracy assessment found coefficients of determination ($R^2$) of 0.70 and 0.68, and root mean square errors (RMSE) of 29.93 t C $ha^{-1}$ and 24.79 t C $ha^{-1}$ at plot and at PPM level, respectively. The results were also compared to the NFI estimates, and to current pantropical and global aboveground biomass carbon maps.

Keywords: biomass, carbon, SAR, machine-learning, multispectral, forest inventory

The Japan Aerospace Exploration Agency (JAXA) launched the Global Change Observation Mission - Climate (GCOM-C) satellite on December 23rd, 2017. The Leaf Area Index (LAI) and the fraction of Absorbed Photosynthetically Active Radiation (fAPAR) product (Algorithm ID: T2B) is one of the GCOM-C standard land products. The dataset is being produced from Second Generation Global Imager (SGLI) at 250-m resolution on a daily basis. At the present time, there are several limitations on the product. In this research, we summarize the early results and limitations of the T2B products.

The LAI is defined as one half of the total green leaf area per unit ground surface area. In the GCOM-C product, LAI is estimated for overstory leaves. The information for understory vegetation is added as understory NDVI. The fAPAR is defined as the proportion of the effectively absorbed solar radiation by plants in the photosynthetically active wavelengths (the spectral region from 400 to 700 nm). LAI and fAPAR were estimated based on the Look-Up Tables (LUTs) showing the relationships between the multi-angle atmospherically-corrected land surface reflectance data and the LAI or fAPAR. The LUTs were produced to fit with the field-observed reference data collected from literatures using a radiative transfer simulator, the Forest Light Environmental Simulator (FLiES) [1]. It simulates radiative transfers in the forests and grasslands based on the Monte Carlo method.

The accuracy of the retrieved LAI and fAPAR was assessed using the in-situ observation data which was collected at several sites. The product has the tendency of overestimating LAI especially at the needle-leaved forests. One of the reasons is that the current algorithm cannot distinguish the difference between the overstory LAI and the understory vegetation well at the forested areas with sparse trees. The accuracy of the T2B product should be improved by revising the algorithm and the LUTs for retrieving LAI. We are planning to revise the land cover datasets which are the basis of retrieving LAI. The LUTs will be revised by fitting the vegetation parameters for FLiES with the SGLI data.

# 35-years of Land Surface Albedo and 15-years of Down-Welling Short-Wave Radiation Retrievals from Satellites through the EUMETSAT/LSA-SAF and ECMWF/C3S projects

*Dominique Carrer[1], Florian Pinault[1], Iskander Benhadj[2], Xavier Ceamanos[1], Sandra Coelho[3], Gabriel Lellouch[1], Catherine Meurey[1], Suman Moparthy[1], Else Swinnen[2], Chloé Vincent[1], Isabel Trigo[3]

1. Meteo France, CNRM, France, 2. VITO, Belgium, 3. IPMA, Portugal

The space program of EUMETSAT (project CDOP3, LSA-SAF) and the Copernicus Climate Change program (managed by ECMWF) provide (or will provide) added-value satellite products for the meteorological and environmental science communities, especially in the fields of climate modelling, environmental management, natural hazards management, and climate change detection.

The EUMETSAT/LSA-SAF project started in 1999 with research and development activities. The delivered operational products include land surface albedos, temperature, short-wave and long-wave downwelling radiation fluxes, and many others. After twenty years (1999-2019) of research, development, and progressive operational activities, Meteo-France built on a strong expertise on satellite retrieval of the surface albedo and down-welling short-wave radiation variables. Based on that experience, we started in 2016 within the framework of the COPERNICUS/C3S_312 project to develop consistent surface albedo products from the 80’s until now using multiple sensors from the past to the current generation of instrument. This will complete the EUMETSAT/LSA-SAF albedo archive for the past period. This work will lead in 2019 to more than 35 years of products characterizing the albedo properties of the surface and 15 years of short-wave downwelling radiation fluxes from different satellite sensors. First C3S collection will be available in autumn 2019 whereas more than 10 different albedos and short-wave downwelling radiation fluxes are already operational in EUMETSAT/LSA-SAF (http://lsa-saf.eumetsat.int/). Product characteristics, and performances are presented here. The next scientific challenges related to the next generation of European satellites and the emergence of artificial intelligence are also discussed.

Finally, it is important to emphasize that these programs provide a great opportunity to monitor human-induced climate change since consistent production of data sets is ensured until at least 2022. In this perspective, our effort will be in the development of open source scientific code in order to share our expertise in the remote sensing of the Earth.

# Integrating the satellite-based biophysical model and environmental zonation scheme to estimate rice yield gap in Northeast China

*Jiahua Zhang[1,3], Jingwen Wang[1,2,3]

1. Institute of Remote Sensing and Digital Earth, Chinese Academy of Sciences, 2. University of Chinese Academy of Sciences, 3. Aerospace Information Research Institute, Chinese Academy of Sciences

Yield gap analysis is a powerful method to reveal the difference between the actual crop yield and yield potential, and to understand the possible yield increase for fulfilling the growing food demand. It used to be restricted to small geographic areas in previous studies, and thus the scope of untapped yield often remains unclear at macro scale. To this end, we proposed an improved remote sensing approach to better assess the regional rice yield gap in northeast China. A biophysical model based on satellite-retrieved LAI and crop classification map was used to derive the actual yield and its spatial patterns. In addition, a machine-learning zonation scheme was developed to further evaluate the attainable potential yield for farmers within domains having similar climatic, geomorphic, and edaphic context. Results indicated that the satellite-based biophysical model can provide reliable estimates of rice yields, with RMSE all below 20 percent at the county level from 2006 to 2017; and the zonation scheme enabled better portrayal of the spatial variation in potential yield. To identify areas with the greatest potential for narrowing the yield gap, northeast China was divided into four parts with different priorities for future yield improvement. In general, south of northeast China possessed substantial yield gaps with the primary priority to be explored; whereas in the north, the actual yield already approximating yield potential, further yield increase was limited and challenging. Quantile regression model provided a complete view of relationships between natural factors and potential yield, and revealed the significant limiting effects of growing degree days, cumulative solar radiation and elevation. This study demonstrates the potential of remote sensing for agricultural decisions, and will aid planners to recognize the macro-scale food production capacity and security situation, to prioritize regions and needs for research and exploitation, and to evaluate the impact of future scenarios such as climate change.

# Landsat-based Phenological Classification Mapping in Japan

*Narumasa Tsutsumida[1], Shin Nagai[2], Pedro Rodriguez-Veiga[3,4,1], Tomoaki Miura[5]

1. Graduate School of Global Environmental Studies, Kyoto Univeristy, 2. Research and Development Center for Global Change, Japan Agency for Marine-Earth Science and Technology, 3. Centre for Landscape and Climate Research, University of Leicester, 4. National Centre for Earth Observation, University of Leicester, 5. Department of Natural Resources and Environmental Management University of Hawaii at Manoa

Land surface phenology (LSP) is associated with climate and terrestrial conditions over space and time, and the monitoring of LSP helps understandings of the terrestrial environments. The LSP is often inferred by satellite observations, and long-term and regularly-composited satellite imagery is now freely available. Due to its complex interactions with geographical and environmental factors, it is often difficult to characterise phenological cycles by LSP. In order to understand the baseline of the phenological cycle which would be expected as the principal vegetation seasonal activity, we aim at classifying LSP temporal patterns over the entire territory of Japan. Normalised Vegetation Difference Index (NDVI) time series during the period of 2014 to 2017 with the spatial resolution of 30m calculated from Landsat 8 surface reflectance were decomposed into three harmonic terms by harmonic analysis with removing of the temporal trend. Then amplitudes and phases of these three harmonic terms were classified into 36 classes according to their orders. Considering tall vegetation (e.g., tree covers) and short vegetation (e.g., agricultural lands), while excluding other land covers, two types of phenological classification maps with 36 classes for each were produced. The phenological classification proposed in this study is a new terrestrial map which provides new important information for land cover studies regarding climate change, environmental degradation, and human impact assessment. This simple unsupervised classification approach can have diverse advantages such as i) only one specific variable (in this case NDVI) was used, yielding a consistent result compared to models with multivariate analysis, ii) complex temporal profiles can be considered, suggesting better descriptions of LSP than using phenological parameters such as start-of-season, peak-of-season, end-of-season, and length of greening period (In particular, our approach can classify temporal profiles with multiple peaks in the seasonal cycle), iii) the unsupervised classification approach do not need reference samples, which would require reliable observations of phenological events for a supervised classification scheme (such datasets are often limited), and iv) the non-thematic way of classification can avoid mislabelling problems. Interpretation of the classification map can be done by the users, making it easy to utilise towards further climate / environmental studies.

# Incorporating satellite-retrieved canopy nitrogen content into the biophysical process model for estimating crop yield and N fertilizer recommendation

*Jingwen Wang[1,2,3], Jiahua Zhang[1,3]

1. Institute of Remote Sensing and Digital Earth, Chinese Academy of Sciences, 2. University of Chinese Academy of Sciences, 3. Aerospace Information Research Institute, Chinese Academy of Sciences

Remote sensing-based biophysical process models (RSBPM) are powerful and indispensable tools for estimating crop productivity over field and landscape scales. However, due to the lack of regional fertilization data, nitrogen stress is often poorly parameterized in these models, which may lead to considerable biases in crop yield simulation. To address this issue, current study improves the representation of nitrogen constraints on photosynthetic capacity in the RSBPM. Canopy nitrogen content retrieved from the newly available high-resolution Sentinel-2 spectral bands is integrated into the model to constrain nitrogen availability in the vital photosynthetic enzyme. And a two-leaf upscaling scheme is used to account for the vertically varying nitrogen content inside canopies and the associated physiological differences between leaves. Measurement data was collected for 32 field-years that spans major crops including wheat, maize, soybean and rice from 2016 to 2017 in China. The satellite-retrieved canopy nitrogen content partially reflects the field fertilization, and identifies seasonality of Rubiso-limited photosynthetic capacity. The new representation of nitrogen constraints significantly reduces the bias of estimated crop yields, and improves the temporal correlations between the simulated and the measured biomass, relative to the commonly employed cases of using specified constant nitrogen stress factor, default fertilization schemes, and the big-leaf nitrogen-constrained model. The improved RSBPM also enables the remote estimation of nitrogen nutrient index, which indicates the status of actual N absorbed versus critical N requirement in the crop. This model improvement on nitrogen constraints has significant implications for better assessment and prediction of crop yield and nitrogen use efficiency and for studying human-environment interactions.

## [M-AG39] Marine-Earth Informatics

convener:Seiji Tsuboi(JAMSTEC, Center for Earth Information Science and Technology), Keiko Takahashi(Japan Agency for Marine and Earth Science and Technology), Masaki Kanao(National Institute of Polar Research), Daisuke Matsuoka(Japan Agency for Marine-Earth Science and Technology)

In advancing the research of marine Earth science, observation and computer simulation is an essential element. In recent years, the performance of the observation apparatus is dramatically improved, along with the means of observation is diversified. It is becoming possible to observe in a resolution, which was not imaginable so far. Such data to be generated from the observation is tremendously large in quantity and its quality is drastically improved. To handle these huge and high quality dataset for data analysis, we need to have a high speed and large memory computer system but such a system now becomes within reach in our hands by the recent dramatic improvement of high performance computer system. On the other hand, researchers who can use this kind of large-scale computer in their studies are still quite limited. In this session, we try to review the situation of observation data that has undergone a dramatic change regarded with both quality and quantity in recent years of marine Earth science research. We also try to review the situation from a professional standpoint of simulation about the status of the high performance computer system to analyze these big data. Also we focus on the state of the art data analysis technique and aim to share the outlook from the professional standpoint of computational science and professional position of observation science about the future direction of the marine Earth informatics research.<br/>

# A bottleneck against industrial distribution of atmosphere-ocean product from the Earth Simulator

*Shinya Kakuta[1], Hajime Nishimura[1]

1. JAMSTEC Japan Agency for Marine-Earth Science and Technology

For public organizations to expand research and development activities into socio-economic ripple effect, this presentation discusses strategy to generate business utilizing the Earth Simulator and its outputs under cooperation with private sectors. To solve social problems, it is necessary not only to create successful cases but also to roll them out and continue operating them for a long term. More and more public funding requires prospects for social application by private sectors to supplement itself. On the other hand, public research organizations, also required to improve socio-economic outcomes from research results, are too short of human resources to meet the requirement, occupied with on-going national projects.

The fundamental bottleneck against social application is the shortage of experts with skills to utilize environmental data, in particular, super-large volumes of meteorological data. We propose a platform to be built so that the bottleneck can be widened by division of data processing to lighten burdens on such a limited number of experts as university researchers, assigning the statistical analysis and assessment after dynamical down-scaling to data scientists or weather forecasters estimated to number around 10,000 in total in Japan, respectively. Down-scaling experts are shorter than data scientists or weather forecasters. Most of data scientists can be assumed to use such scripts as Python. On the other hand, approximately 150 weather forecasters are additionally licensed every year. In addition, private sectors should cooperate with many local governments to specify to utilize the super-large volumes, to set up small servers of in-situ data taken by local governments, and to transform the data into geographical information system.

In a long run, human resources should be developed. Every year, private sectors can headhunt or develop approximately 10 experts for assessment on extreme phenomena in collaboration with national research institutes, advanced local institutes, or universities.

# GANSEKI: Long-Term Strategy of JAMSTEC Deep Seafloor Rock Sample Curation

*Takayuki Tomiyama[1]

1. Japan Agency for Marine-Earth Science and Technology

More than 10 years have passed since Japan Agency for Marine-Earth Science and Technology (JAMSTEC) started the curatorial management of observation data and samples under the current JAMSTEC Data Policy [1]. This means that some of them have aged more than their minimum storage periods that are defined as 10 years. JAMSTEC Rock Sample curation is now passing one of the milestones for sustainable sample management.
JAMSTEC Rock Sample Curation has been continuously changed since it was established. As for the sample storage, JAMSTEC has come to equip fixed rock sample storage rooms in 2019, after repeated (re-)installations of mobile storage containers for every 1~2 years, however they are still considered as temporary storages. It is under planning to acquire a sample storage building, that is supposed to be the permanent rock sample storage. Some efforts, such as reduce of individual sample volumes, will become inevitable within next several years to make enough room for growing sample collections. As for the data management, the rock sample database “GANSEKI" has experienced several updates and the user-side interface was integrated into the DARWIN database [2] on 2017. Its management-side system is under remodeling for integrating databases for rock, sediment core and biological samples into one system. The variation of publishable data has been getting wider; geochemistry data, isochron ages, thin-section and closeup-texture photos, and literature information are currently publishable and more data types will be available in the future.
For years, JAMSTEC Rock Sample Curation has been operated only under JAMSTC Data Policy [1]. However, it will have to deal with the parallel existence of additional policy of JURCAOS-AORI-JAMSTEC Cooperative Research cruises [3], which will be enforced in 2019. In this presentation, the author will summarize the management history and current situations of JAMSTEC Rock Sample Curation, and discuss its future strategy.

# Running global seismic waveform simulation on Windows10

*Seiji Tsuboi[1]

1. JAMSTEC, Center for Earth Information Science and Technology

Latest version of Windows10, which is Fall Creators Update, supports Windows Subsystem for Linux (WSL). This enables to use linux, such as Ubuntu, directly from Windows. Here we show examples of how we can use this system to run spectral-element method to calculate global seismic waveform on Windows PC and its performance of typical simulation. We use Ubuntu 18.04 available from Windows store and installed it on the latest version of Windows 10. Then we install gcc 5.4.0, gfortran 5.4.0, and OpenMPI 4.0.0 on Ubuntu. We also install SPECFEM3D_GLOBE 7.0.0 and configured under the above linux environment. We use Windows PC equipped with Core i7-3840QM CPU (2.8GHz) and 16GB memory. Since this CPU has four cores, we use one chunk simulation of SPECFEM3D_GLOBE and set the angular distance of the chunk to be 20 degree with NPROC=2. We set NEX=128, which enables to get synthetics with the accuracy of about 30 second and longer. Preliminary results of this simulation show that it takes about 4hours to compute 5 minutes synthetic seismograms over the chunk by using four cores of this CPU. We will show if this performance may be improved with further optimization of the compilation.

# Synthetic seismograms of explosive sources calculated by the Earth Simulator

*Seiji Tsuboi[1]

1. JAMSTEC, Center for Earth Information Science and Technology

We have calculated broadband synthetic seismograms using the spectral-element method (Komatitsch et al., 2005) for realistic Earth model. Recent progress in supercomputers makes it possible to compute the synthetic seismograms with the accuracy of 1.2 second and longer (Tsuboi et al., 2016a) . Here we have used one chunk of spectral element method to compute synthetics with 1.5 second accuracy using the Earth Simulator. We calculate synthetics for Sep. 3, 2017 (MB(USGS) 6.3). The simulations are performed on 8,100 processors, which require 2,025 nodes of the Earth Simulator. We use one chunk with the angular distance 40 degrees to compute synthetic seismograms. On this number of nodes, a simulation of 5 minutes of wave propagation accurate at periods of 1.5 seconds and longer requires about 9 hours of CPU time (Tsuboi et al., 2016b) . We use CMT solution of Dreger (2017) as a source model for this event. This source model has 24% CLVD component, 34% double couple component and 42% isotropic component. The hypocenter depth of this solution is 1.4 km but we put the hypocenter at the surface for this computation. Comparisons of the synthetic waveforms with the observation at station MDJ(Mudanjiang) in China show that the arrival time of Pn and Pg waves matches well with the observation, which demonstrates that the crustal structure we have used for this computation models the actual structure well. The surface waves observed at this station are also modeled well in the synthetics, which shows that the CMT solution we have used for this computation correctly grasps the source characteristics of this event. However, the amplitudes of Pn and Pg waves in the synthetics are smaller than the observations, which indicates that the amplitude of short period components is not enough in this computation. The result also shows that crustal structure around source region should be improved to get better agreement between the synthetics and observation.

On this number of nodes, a simulation of 5 minutes of wave propagation accurate at periods of 1.5 seconds and longer requires about 9 hours of CPU time (Tsuboi et al., 2016b) . We use CMT solution of Dreger (2017) as a source model for this event. This source model has 24% CLVD component, 34% double couple component and 42% isotropic component. The hypocenter depth of this solution is 1.4 km but we put the hypocenter at the surface for this computation. Comparisons of the synthetic waveforms with the observation at station MDJ(Mudanjiang) in China show that the arrival time of Pn and Pg waves matches well with the observation, which demonstrates that the crustal structure we have used for this computation models the actual structure well. The surface waves observed at this station are also modeled well in the synthetics, which shows that the CMT solution we have used for this computation correctly grasps the source characteristics of this event. However, the amplitudes of Pn and Pg waves in the synthetics are smaller than the observations, which indicates that the amplitude of short period components is not enough in this computation. The result also shows that crustal structure around source region should be improved to get better agreement between the synthetics and observation.

## [M-AG39] Marine-Earth Informatics

convener:Seiji Tsuboi(JAMSTEC, Center for Earth Information Science and Technology), Keiko Takahashi(Japan Agency for Marine and Earth Science and Technology), Masaki Kanao(National Institute of Polar Research), Daisuke Matsuoka(Japan Agency for Marine-Earth Science and Technology), Chairperson:Daisuke Matsuoka, Seiji Tsuboi

In advancing the research of marine Earth science, observation and computer simulation is an essential element. In recent years, the performance of the observation apparatus is dramatically improved, along with the means of observation is diversified. It is becoming possible to observe in a resolution, which was not imaginable so far. Such data to be generated from the observation is tremendously large in quantity and its quality is drastically improved. To handle these huge and high quality dataset for data analysis, we need to have a high speed and large memory computer system but such a system now becomes within reach in our hands by the recent dramatic improvement of high performance computer system. On the other hand, researchers who can use this kind of large-scale computer in their studies are still quite limited. In this session, we try to review the situation of observation data that has undergone a dramatic change regarded with both quality and quantity in recent years of marine Earth science research. We also try to review the situation from a professional standpoint of simulation about the status of the high performance computer system to analyze these big data. Also we focus on the state of the art data analysis technique and aim to share the outlook from the professional standpoint of computational science and professional position of observation science about the future direction of the marine Earth informatics research.<br/>

# Extraction method of weather informations from camera image using Deep Neural Network

*DAISUKE SUGIYAMA[1], RYO ONISHI[1], HIDENORI FUDEYASU[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Yokohama National University

In order to further improve precision of numerical forecasts, it is expected to utilize high-density weather information by various IoT (Internet of Things) sensor equipment networks capable of real-time acquisition via the Internet. However, the IoT sensors are installed on the ground, so we can not observe weather information in the sky simply by using the IoT sensor normally. In this study, we used artificial intelligence technology for image recognition, and worked on the development of a system that extracts cloud amount and solar radiation from images of inexpensive consumer cameras. Our method becomes possible to operate low-price camera-equipped devices as remote sensing equipment without using expensive observation equipment. The weather information extracted is not only input values for numerical simulation but also expected to be utilized in, for example, agriculture. In addition, the society of security camera network is spreading in China and others. Our method can be a fundamental technology of high-density weather observation in such society.
In this study, we first constructed a 5-layer convolutional neural network (CNN) model that predicts cloud cover amount from the image. As data to train this network, we used data labeled cloud cover on about 2,000 sky images from the Internet. The cloud cover in this study means the rate of the clouds in the sky area shown in the camera image in 11 steps from 0 to 10. On the other hand, the Japan Meteorological Agency defines the rate of the cloud region to the whole sky as the cloud amount. Attention should be paid to difference in this definition. We used the 80% data as the training data, and the remaining 20% was used for cross validation. Finally, we compared to the MSE: mean square error, of our method to the existing method. It became clear that cloud cover can be estimated with the overwhelmingly small MSE of 3.0 for this CNN, more than the existing segmentation method of 12.7.
Secondly, as training data, this model use long-term high-frequency observation data for 1 minute, observed by Yokohama National University. We chose solar radiation amount, fixed camera image in this data. The model extracts the amount of solar radiation from the sky image in the range of several tens of kilometers ahead of the fixed camera's photographing direction. With 6 years of this data, the number of images reaches max about 3 million images in one direction, and this big training data is used to train Deep Neural Network. Now, intuitively, a high brightness image tends to be considered to have a high solar radiation amount. However, consumer cameras usually have automatic brightness and contrast adjustment functions. Also, such as the slightly cloudy days are almost high brightness value. The correlation coefficient of brightness value and solar radiation, is not large. On the other hand, we can calculate the theoretical maximum solar radiation from the latitude, longitude and time of image's shooting position (Nakajima et al. 2000). Focusing on this point, we constructed a new Multimodal Deep Learning model with image + theoretical maximum solar radiation as input layers. This model estimates the attenuation value from theoretical maximum solar radiation with images of training data. It was clarified that the amount of solar radiation can be estimated with high accuracy by training this model from the image, position and time.

# Automatic detection of weather front around Japan using deep convolutional neural network

*Daisuke Matsuoka[1,2], Shiori Sugimoto[1], Yujin Nakagawa[1], Fumiaki Araki[1], Shintaro Kawahara[1], Yosuke Onoue[4], Masaaki Iiyama[3], Koji Koyamada[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. Japan Science and Technology Agency, 3. Nihon University, 4. Kyoto University

In this study, we automatically detect stationary front from weather forecast simulation data (GPV/MSM) using U-Net deep convolutional neural network. Our U-Net trains ten years weather data (precipitation, sea level pressure, relative humidity, air temperature, and wind velocity) and the position of weather front as the ground truth. As a result of applying the trained U-Net to the untrained one year data, our approach succeeded in accurately detecting Baiu front and autumn rain front except when Typhoon occurred. Moreover, wind velocity (zonal and meridional component) and relative humidity at 1000 hPa play an important role to obtain high detection performance. Our approach is also able to apply to weather simulation data which the weather front is not associated with.

# Detection of multiple earthquakes by using theoretical seismograms as training dataset of machine learning

*Seiji Tsuboi[1], DAISUKE SUGIYAMA[1]

1. JAMSTEC, Center for Earth Information Science and Technology

Earthquake Early Warning (EEW) is now routinely used for hazard mitigation purpose in various countries. One of the causes which results false alarm of EEW is earthquakes which happen concurrently in different location. On January 5$^{th}$, 2018, two earthquakes with magnitude around 5, which separate about 400 km, happened concurrently in Japan and false EEW was issued by JMA. Here we combine numerically computed theoretical seismograms and deep machine learning to properly identify multiple earthquakes to avoid false alarm. We calculate theoretical seismograms for realistic three-dimensional Earth model and use these seismograms to create snapshots of seismic wave propagation images at the surface of the Earth. Then we use these snapshots as training dataset of convolutional neural network. We build neural networks to identify multiple earthquakes and found that this networks may identify multiple earthquakes with 99% accuracy. Advantage of using this approach to identify multiple earthquakes is that we may include any earthquakes in our training dataset and accuracy of hypocenter parameters can be increased by accumulating theoretical seismograms for various earthquake location and size as learning dataset of deep machine learning. We also apply this technique for determination of hypocentral parameters, such as epicenter, depth, origin time and magnitude. We have applied these networks to actual seismograms to show that this procedure works successfully to locate earthquake and determine magnitude.

# Classification with imbalanced cloud data using deep convolutional neural network

*Daisuke Matsuoka[1,2], Masuo Nakano[1], Daisuke Sugiyama[1], Seiichi Uchida[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. Japan Science and Technology Agency, 3. Kyushu University

Image classification using deep convolutional neural network is effective technique to detect extreme phenomenafrom climate data. However, the number of extreme phenomena such as tropical cyclone (TC) is overwhelmingly small compared with others. It is knon that classification performance decline du to this imbalance between positive (TCs) and negative examples (non-TCs). In the present study, we developed a new negative data selection method for binary classification for cloud images. We analyze the relationship between the ease of classification and the characteristics of data, and optimize the training data in order to decrease the false alarm ratio (FAR). As the results, we succeeded in decrease FAR from 32.8–53.4% to 60.0–70.0% in the western North Pacific in the period from July to November.

Discussion

# Farmed fish management: integration of observation and simulation

*Haruka Nishikawa[1]

1. Japan Agency for Marine-Earth Science and Technology

Since the natural fish resource is constantly decreasing, the importance of fish farming further increases. However, the technique is still depending on the skill of artisans. The feed quantity is determined by looking. Is it truly the best feed quantity? I plan to develop a fish growth simulation model based on observation and to estimate the best feed quantity by using its simulation. This technique will reduce labor cost and enhance the new entry. I will discuss the future fish farming system that is developed by an integration of observation and simulation.

# Q-factor estimation for Greenland ice sheet using 3-D seismic waveform modeling

*Genti Toyokuni[1], Hiroshi Takenaka[2], Masanao Komatsu[2], Ryota Takagi[1], Masaki Kanao[3], Seiji Tsuboi[4]

1. RCPEVE, Tohoku Univ., 2. Okayama Univ., 3. NIPR, 4. JAMSTEC

In and around Greenland, 33 seismographs are now in operation by the project “GLISN” (Greenland Ice Sheet Monitoring Network) as an international cooperation with 11 countries. Since the initiation of this project in 2009, broadband and continuous seismic waveform data have been accumulating, and data analyses using seismic interferometry have actively been conducted. For example, Toyokuni et al. (2018) detected a Rayleigh-wave phase-velocity changes over 4.5 years beneath 90 station pairs throughout Greenland, and suggested that the thermal condition (freezing or melting) of the ice-sheet base might be detected using the pattern of the velocity changes. However, the seismic interferometry is a method based on the assumption that the cross-correlation of noise waveforms from two stations yields Green’s function between them, when averaged over a long period. However, it is suggested that this assumption sometimes fails due to inhomogeneous distribution of noise sources, etc.

This study first aims to investigate whether this assumption holds for the cross-correlation waveforms from GLISN stations using 3-D seismic waveform modeling. Furthermore, we estimate the seismic Q factors of the ice sheet which explains observations the best, by performing computations several times with different structural parameters.

The scheme we used for the 3-D modeling is “Quasi-Cartesian FDM” proposed by Takenaka et al. (2017). It numerically solves 3-D elastodynamic equation by the finite-difference method (FDM), taking into account the earth's curvature, topography, sea water layer, and 3-D structures of density, seismic wavespeeds, and attenuation. We used realistic ice sheet / basal rock topography data (ETOPO 1) and 3-D crustal / mantle structures (Crist 1.0). We used FX10 Supercomputer System in Univ. Tokyo (216 nodes, 432 processor, 8 threads).

The results are as follows:
(1) The cross-correlation waveforms obtained by the seismic interferometry show good agreement with synthetic Green’s functions for almost all the pairs, showing validity of the seismic interferometry on this region.
(2) Computations with various Q factors of the ice sheet revealed that (Qp, Qs) = (20, 20) explains the cross-correlation waveforms the best. This is the first example that the high attenuation characteristic of the ice sheet is confirmed for long propagation distance (>100 km).

# CLCL: CAVELib Compatible Library for Head-mounted Displays

*Shintaro Kawahara[1]

1. Japan Agency for Marine-Earth Science and Technology

Head-mounted displays (HMDs) are becoming a practical platform for three-dimensional scientific visualization. To reuse existing software assets that have been developed for CAVE-type VR systems (CAVEs), I developed a C++ library called "***CLCL*** (CAVELib Compatible Library)" for porting the application software for CAVEs to HMDs. CLCL emulates the function calls of CAVELib, which is a commercial library for developing application software executable on CAVEs, and it enables us to easily port CAVELib application software to HMDs with minor modifications to the original source code. Executable files built using CLCL are able to launch on major HMDs which are Oculus Rift, HTC VIVE and Windows Mixed Reality devices. Sharing the source code also leads to an improvement in the VR software development efficiency, which is executable on both CAVEs and HMDs.

# Super-Resolution Simulation for Real-Time Prediction of Urban Micrometeorology

*Ryo Onishi[1], DAISUKE SUGIYAMA[1], Keigo Matsuda[1]

1. Japan Agency for Marine-Earth Science and Technology

We propose a super-resolution (SR) simulation system that consists of a physics-based meteorological simulation and an SR method based on a deep convolutional neural network (CNN). The CNN is trained using pairs of high-resolution (HR) and low-resolution (LR) images created from meteorological simulation results for different resolutions so that it can map LR simulation images to HR ones. The proposed SR simulation system, which performs LR simulations, can provide HR prediction results in much shorter operating cycles than those required for corresponding HR simulation prediction system. We apply the SR simulation system to urban micrometeorology, which is strongly affected by buildings and human activity. Urban micrometeorology simulations that need to resolve urban buildings are computationally costly and thus cannot be used for operational real-time predictions even when run on supercomputers. We performed HR micrometeorology simulations on a supercomputer to obtain datasets for training the CNN in the SR method. It is shown that the proposed SR method can be used with a spatial scaling factor of 4 and that it outperforms conventional interpolation methods by a large margin. It is also shown that the proposed SR simulation system has the potential to be used for operational urban micrometeorology predictions.

## [M-AG40] CTBT IMS Technologies for Detecting Nuclear Explosion and Their Applications to Earth Science

convener:Nurcan Meral Ozel(Comprehensive Nuclear-Test-Ban Treaty Organization), Hiroyuki Matsumoto(Japan Agency for Marine-Earth Science and Technology), Yosuke Naoi(Japan Atomic Energy Agency), Chairperson:Nurcan Meral Özel(Comprehensive Nuclear-Test-Ban Treaty Organization), Hiroyuki Matsumoto(JAMSTEC), Noriko Kamaya(ERI, University of Tokyo)

The Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) was founded in 1996 in response to the adaption of the Treaty in 1996 by the United Nations General Assembly, which bans nuclear explosions on the Earth's surface, in the atmosphere, underwater and underground. The Treaty has a unique and comprehensive verification regime to make sure that no nuclear explosion goes undetected. The regime is supported by International Monitoring Systems (IMS) composed of the four state-of-art technologies; 1) Seismic, 2) Hydroacoustic, 3) Infrasound, and 4) Radionuclide, by the International Data Centre (IDC), and by the On-Site Inspections (OSI).<br/>IMS will, when complete, consists of 337 facilities worldwide to monitor the planet for signs of nuclear explosion. Around 90 % of the facilities are in operation and sending the data to the IDC in Vienna, Austria. <br/>The huge amount of data collected by the stations can be used for other purposes such as civil and scientific applications in addition to detecting nuclear explosions. They can provide Tsunami Warning centres with near real-time information about an underwater earthquake. During the Fukushima Daiichi Power Plant accident, in March 2011, the IMS network's radionuclide stations tracked the dispersion of radioactivity on a global scale. The data could also help better understand the oceans, volcanos, climate change, the movement of marine mammals, and many other issues.<br/>This session will provide the overview of CTBTO and its IMS, the scientific discussion on each technology, and its outcomes. The session welcomes young scientists and engineers who are interested in four IMS technologies.<br/>

# Japanese Contributions and Collaborations for IMS Technologies and the Verification Regime

*Nurcan Meral Ozel[1], David Jepsen[1], Naoko Nakashima[1], Hideaki Komiyama[1], Hiroyuki Matsumoto[1,2]

1. Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO), 2. Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

The CTBT verification regime is supported by the cooperation of member states who host monitoring stations and laboratories of the International Monitoring System (IMS) network. The proactive collaboration with state governments and research institutions hosting IMS facilities is crucial for improvement of the technologies for the verification regime.

Japan has contributed for many years in establishing and maintaining these facilities and in improving the verification technologies and regime, in a variety of aspects. Japan hosts stations for three of the technologies: seismic, infrasound and radionuclide. The technical contributions by Japan in projects for the improvement and enhancement of the radionuclide monitoring/detection capability are highlighted in this presentation.

In addition to the contributions through the operation of two IMS radionuclide monitoring stations in Japan, Okinawa, and Takasaki, two additional radionuclide measurement campaigns have been initiated at Horonobe and Mutsu, through financial support from the government of Japan (GoJ) in 2017. These campaigns started in early 2018, with the collaborations of Japan Atomic Energy Agency (JAEA). A new campaign in Fukuoka is being initiated, using another existing mobile system, aiming to configure a high dense measurement network for the evaluation and the calibration of the current noble gas system network of the IMS.

Another collaboration in the radionuclide sector is the air sampling for Ar-37 analysis and the new sampler testing at Takasaki station, in order to enhance the capability for On-site Inspection (OSI). Ar-37 is produced naturally by cosmic rays and exists in the atmosphere as background. Thus, it is also important to know its behavior in the environment. A 2-year sampling campaign was conducted at Takasaki in collaboration with JAEA in 2016-2018 utilizing their expertise.

The government of Japan (GoJ) has strongly supported to establish these collaborations, especially through voluntary contribution, in 2012, 2013 and 2017. They were used for enhancement of atmospheric transport modeling project, noble gas measurement campaign at Horonobe and Mutsu mentioned above, and sending Cost-free Experts (CFEs) of IMS HA Technology.

# Review: Researches on detection of nuclear tests by seismic waves in Japan

*Noriko Kamaya[1]

1. Earthquake Research Institute, the University of Tokyo

## 1. Introduction

In Japan, if the Japan Meteorological Agency (JMA) observes a seismic wave that may not be a natural earthquake with epicenters around North Korea, the JMA immediately contacts the Prime Minister's Office and have press conferences and announces the parameters of that event. Then, with showing both waveforms of the North Korea's underground nuclear test and a natural earthquake, based on the characteristics of the waveform such as the S wave being ambiguous, JMA states there is a possibility that it is not a natural earthquake. The materials of these press conferences will be published on JMA’s website. However, because the detection of nuclear tests is not the original task of the JMA, no more analysis is not published. In addition, Japan Weather Association, which is responsible for monitoring nuclear tests based on the waveform data of the CTBTO (Comprehensive Nuclear Test Ban Treaty Organization), analyzes data, but only simple report is published on the website. It is important for Japan’s security to study detection technology of nuclear test by Japanese researchers. In this paper, we will review about Japanese researches on detection of nuclear tests by seismic waves which was published in Japanese papers.

## 2. Reports of observed events

The oldest paper would be written by Kubodera and Okano (1960). They reported long-period seismic waves with periods of 9 minutes to 1 minute were recorded at the same time that small atmospheric pressure change reached, when a hydrogen bomb test was conducted by the United States at Bikini Atoll in 1958. JMA (1972) published collection book of seismic waves recorded at underground nuclear test conducted by the US in the Amchitka Island on November 7, 1971.

## 3. Study on discrimination from natural earthquakes

Researches for discrimination nuclear tests from natural earthquakes were mainly conducted by using seismic waveforms at the Matsushiro Earthquake Observatory. Yamagishi et al. (1973) reported that the P wave of the nuclear tests were dominated by short-period waves. Also, they concluded that discrimination was possible by comparing Ms and mb. Seki et al. (1980) pointed out that S waves and surface waves were observed when large tests were conducted. Wakui and Kakishita (1986) pointed out that the discrimination method using the ratio of Mb and MS could only be applied to large-scale tests. Kamaya (1998) analyzed the waveforms of nuclear tests and natural earthquakes at Nevada and Xinjiang. She concluded the Complexity was the most effective method for discrimination. Okamoto and Kanjo (2007) analyzed waveforms of Matsushiro, Mudanjiang and Incheon of IRIS at the nuclear test by North Korea on October 9, 2006. They showed P wave radiation pattern had isotropic pattern. Koyama (2007) calculated the Complexity and the Spectral ratio of waveform in Matsushiro for the same test, and reported that the Spectral ratio was better than the Complexity for discrimination.

Kikuchi (1997) calculated the moment tensor for nuclear tests conducted by China and France from 1995

©2019. Japan Geoscience Union. All Right Reserved. 

to 1996 by waveform of the IRIS. He showed that the combination of the three main values of the moment tensor were clearly different from those of the natural earthquake. In addition, he estimated that shape of epicenters of Chinese tests were acicular and French were disk-shaped.

4. Toward the Future
It is necessary for us to learn recent research in the world in cooperation with the CTBTO. In addition, our (Japanese researchers') continuous research on detection of nuclear tests by analyzing seismic waveforms around the world is important.

# Waveform Analysis on Induced Earthquakes after the 2017 Nuclear Test and Detected Mining Events in DPRK

*Masashi Motohashi[1], Takanari Fujii[1], Takayuki Otsu[1]

1. Japan Weather Association

After the DPRK September 2017 nuclear test event, several earthquakes were occurred near the test site. The scale of these induced earthquake events was fairly very small, therefore there were a few CTBT IMS seismic stations (e.g. KSRS, USRK, KLR) which could detect earthquake signals. Japan NDC-1 (National Data Center-1) tried to locate and discriminate these events utilizing non-IMS data such as IRIS (Incorporated Research Institutions for Seismology).

Analyzing waveform data of these events, S-wave (Sn, Lg-Phase) amplitude of waveform at close stations is larger than that of P-wave (Pn, Pg-Phase) and the feature of these events is presumed to be natural earthquake rather than man-made explosion. Near the DPRK test site, there are two open-pit mines at Chung-gang city and Musan city which locates DPRK-China border. We also compared with past mining explosion event there and we discriminated events with the indexes such as regional P/S ratio, P/S Spectral Ratio.

It was quite difficult to make event discrimination using only IMS seismic waveform data. IMS seismic network is not designed for detecting small-scale nuclear test far less than 1kt. Therefore, local and non-IMS seismic network data could largely contribute to refine event location and event discrimination.

# Submarine volcanoes and where to find them: Harnessing IMS hydroacoustic data

*Dirk Metz[1]

1. Japan Agency for Marine-Earth Science and Technology

Low-frequency underwater sound waves are a key feature of the hydroacoustic waveform component of the International Monitoring System (IMS), a global sensor network maintained by the Comprehensive Nuclear-Test-Ban Treaty Organization in an effort to detect clandestine nuclear explosions in the ocean, in the atmosphere, and underground. However, the potential of IMS data extends beyond test-ban monitoring, for instance, when studying sound phases generated by remote natural sources that otherwise would be difficult to detect, such as submarine earthquakes or volcanic eruptions. Here, we focus on IMS hydrophone recordings of Monowai, a volcanic center in the Kermadec Arc, and Ahyi volcano, located in the Northern Mariana Islands. Tripatite array data are processed using standard cross-correlation and time-difference-of-arrival techniques. Density-based clustering of arrivals at station H03, Juan Fernández Islands, reveals 82 discrete episodes of unrest at Monowai over the course of 3.5-years, making it one of the most active arc volcanoes currently known. IMS data suggests further volcanic activity at both known and unknown sites in the Tonga-Kermadec Arc region. Hydroacoustic recordings of the 2014 eruption at Ahyi show how data analysis can be advanced and streamlined, for example, to determine spectral parameters and acoustic energy release, which has implications for studying volcanic source processes and their respective impact on the ocean soundscape. IMS hydrophone arrays register volcanic seismicity as low as ~2.5 $m_b$ even at megameter distances, thus exceeding the resolution of most regional, land-based networks by more than one order of magnitude. Detectability strongly depends on frequency, source depth, and ray path geometry, which is illustrated by 2D transmission loss modeling for a range of synthetic scenarios. The findings presented here highlight the capabilities of the IMS hydrophone network for remotely detecting and studying volcanic activity in the global ocean.

# Importance of noble gas monitoring in CTBT verification technology and observation results in Takasaki radionuclide monitoring station

*Yoichi Yamamoto[1], Yuichi Kijima[1], Yutaka Tomita[1]

1. Japan Atomic Energy Agency

Radionuclide monitoring for CTBT verification is the only way to judge whether the target explosion event was a nuclear test. Among the radionuclides produced by the nuclear explosion, the noble gases are particularly important because they are inert and more likely to leak to the ground rather than other substances in an underground nuclear test. Only 4 radioxenon isotopes as the noble gases are monitored for the CTBT verification. After the first nuclear test of North Korea in October 2006, a radioxenon monitoring system installed at the Takasaki radionuclide monitoring station in Japan and the radioxenon monitoring has been carried out since January 2007. We report on the past observation results of the radioxenon at the Takasaki radionuclide monitoring station and the characteristics of radioxenon background.

Keywords: CTBT, international monitoring system, noble gas, xenon, Takasaki radionuclide monitoring station

# ATM analysis results on radioxenons detected in Japan

*Yuichi Kijima[1], Yoichi Yamamoto[1], Yutaka Tomita[1]

1. Japan Atomic Energy Agency

The Japan Atomic Energy Agency installed transportable xenon laboratories (TXLs) in collaboration with the CTBT Organization at Horonobe, Hokkaido and Mutsu, Aomori, respectively and has been measuring radioxenon since 2018. Therefore, the measurements of radioxenon for CTBT verification in Japan are currently conducted at total 3 measuring points adding the CTBT Takasaki radionuclide monitoring station. The analyses of estimation of emission source location by atmospheric transport modelling (ATM) were carried out to investigate the emission source of the radioxenons detected at these measuring points. We report the measurement results of radioxenons at 3 measuring points and the ATM analysis results.

## [M-AG40] CTBT IMS Technologies for Detecting Nuclear Explosion and Their Applications to Earth Science

convener:Nurcan Meral Ozel(Comprehensive Nuclear-Test-Ban Treaty Organization), Hiroyuki Matsumoto(Japan Agency for Marine-Earth Science and Technology), Yosuke Naoi(Japan Atomic Energy Agency)

The Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) was founded in 1996 in response to the adaption of the Treaty in 1996 by the United Nations General Assembly, which bans nuclear explosions on the Earth's surface, in the atmosphere, underwater and underground. The Treaty has a unique and comprehensive verification regime to make sure that no nuclear explosion goes undetected. The regime is supported by International Monitoring Systems (IMS) composed of the four state-of-art technologies; 1) Seismic, 2) Hydroacoustic, 3) Infrasound, and 4) Radionuclide, by the International Data Centre (IDC), and by the On-Site Inspections (OSI).<br/>IMS will, when complete, consists of 337 facilities worldwide to monitor the planet for signs of nuclear explosion. Around 90 % of the facilities are in operation and sending the data to the IDC in Vienna, Austria. <br/>The huge amount of data collected by the stations can be used for other purposes such as civil and scientific applications in addition to detecting nuclear explosions. They can provide Tsunami Warning centres with near real-time information about an underwater earthquake. During the Fukushima Daiichi Power Plant accident, in March 2011, the IMS network's radionuclide stations tracked the dispersion of radioactivity on a global scale. The data could also help better understand the oceans, volcanos, climate change, the movement of marine mammals, and many other issues.<br/>This session will provide the overview of CTBTO and its IMS, the scientific discussion on each technology, and its outcomes. The session welcomes young scientists and engineers who are interested in four IMS technologies.<br/>

1. Japan Weather Association

Japan Weather Association (JWA) is working as the Comprehensive Nuclear-Test-Ban Treaty (CTBT) National Data Centre-1 (NDC-1) of Japan which is in charge of analysis on waveform data, operation and maintenance of seismic and infrasound stations in Japan. There are two main roles of NDC-1: 1: technical adviser to the national authority (MOFA) from the view point of seismic and infrasound analysis, and 2: station operator of IMS stations (PS22, AS51-AS55 and IS30). And there are three main activities of NDC-1 as technical adviser: 1: if the suspicious event would occur, we would try to clarify its characteristics and report its results to the MOFA via the secretariat, 2: we sometimes do 1-week integrated operational exercise hosted by the secretariat on the assumption that the situation would be, and 3: we are paying efforts to improve our analytical capability of SHI data and explanation capability by using the national exercises.

This poster introduces the integrated operational exercise and the event discrimination analysis results of the 6$^{th}$ DPRK nuclear test as of the real analysis results in particular.

The integrated operational exercise is conducted by NDCs, integrating the data and analysis addressed by NDCs, and reporting to the CTBT National Operating System of Japan. These exercises have been implemented 27 times since 2009 and 30areas were selected for regions and countries. And our event discrimination analysis takes mainly three methods: 1: regional P/S ratio, 2: P/S spectral ratio and 3: mb: Ms.

# Challenging to utilize the infrasound technologies for civil and science application

*Masashi Motohashi[1], Nobuo Arai[2], Takayuki Otsu[1], Mami Nogami[1], Makiko Iwakuni[1], Ryohei Emura[1]

1. Japan Weather Association, 2. Disaster Mitigation Research Center, Nagoya Unicersity

Japan Weather Association (JWA) is working as the Comprehensive Nuclear-Test-Ban Treaty (CTBT) National Data Centre-1 (NDC-1) of Japan which is in charge of analysis on waveform data, operation and maintenance of infrasound and seismic stations in Japan.

We observed infrasonic signals two times from underground nuclear test in DPRK. From the perspective of nuclear test monitoring, it is important to analyze and study the infrasonic signals from a variety of natural phenomena to discriminate the signal from explosion. On the other hand, that kind of studies are also important for civil and science application of infrasound technologies. We also observed infrasound from large tsunami at the time of 2011 off the Pacific coast of Tohoku Earthquake. If the signals from such hazardous phenomena can be detected immediately, it will be very helpful to alert the occurrence of disaster or approach of hazardous phenomena.

This triggered us to build our own observation network in Japan. We are challenging to utilize the infrasound technologies for civil and science application as well as nuclear test monitoring.

# CTBT IMS hydroacoustic signal detections from the Ioto volcanic island in the northwest Pacific Ocean

*Hiroyuki Matsumoto[1,2], Mario Zampolli[1], Georgios Haralabus[1], Jerry Stanley[1], James Mattila[1], Nurcan Meral Ozel[1]

1. Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO), 2. Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

*In-situ* observation in terms of seismicity suggested that the volcanic activity of Ioto (formerly Iwojima), a volcanic island offshore Japan in the northwest Pacific Ocean increased in early September in 2018. Discolored waters and a splash were confirmed in the nearshore by a local flyover observation. Although these visual signs evidenced a connection between undersea eruptions and recorded seismic activity, there still remained uncertainty as to what portion of the *in-situ* recorded seismic activity was associated with volcanic tremors vs. undersea eruptive events.
During the same period, a large number of underwater acoustic (hydroacoustic) signals were recorded by the Comprehensive Nuclear-Test-Ban Treaty’s (CTBT) International Monitoring System (IMS) hydroacoustic (HA) station HA11 Wake Island. A set of three hydrophone sensors forming a triplet makes it possible to compute the back-azimuth uniquely for wave packets with a good signal-to-noise ratio. We analyzed the data of the IMS hydrophone triplets during the month of September 2018 and compared them with *in-situ* seismic observations in Ioto for the same period.
The IMS hydrophone triplet data made it possible to discriminate the hydroacoustic signals associated with the Ioto volcanic activity. The direction-of-arrival (DOA) was estimated during the entire period of relatively high volcanic activity using cross-correlation analysis. The arrivals from Ioto at the IMS HA station and the *in-situ* observations showed good correlation. The present study suggests that two-thirds of the arrivals of hydroacoustec signals were associated with volcanic tremors and one-third with the undersea eruptions.

# Installation of a floating hydrophone system within the SOFAR channel

*Hiroko Sugioka[1], Masayuki Obayashi[2]

1. Kobe University, 2. JAMSTEC

Unequal geographical data coverage continues to fundamentally limit the quality of tomographic reconstructions of seismic wave speeds in the interior of the Earth. Only at great cost can geophysicists overcome the difficulties of placing seismographs on the two thirds of the Earth’ s surface that is covered by oceans. The lack of spatial data coverage strongly hampers the determination of the structure of the Earth in the uncovered regions. Therefore, three-dimensional Earth models are marked by blank spots in areas where little or no information can be obtained. Improving this problem requires the observation of seismic waves in the oceans. Ocean bottom seismometers are capable of addressing the coverage gap, but they are expensive to manufacture and deploy using vessels.

Oceanographers had designed robotic floating instruments, floats that spend their lives at depth but surface periodically, using a pump and bladder, to make temperature and salinity profile measurements (the large-scale international Argo project). Such low-cost Sounding Oceanographic Lagrangian Observers (SOLO) (Davis et al., 2001) could be equipped with a hydrophone to record water pressure variations induced by compressional waves. Such a floating seismometer would surface upon detection of a useful seismic event, determine a GPS location, and transmit the waveforms to a satellite, which is nicknamed MERMAID for ‘mobile earthquake recorder in marine areas by independent divers’. The great promise of this technology has been demonstrated since the first voyage in 2003, clearly illustrates its contributions to global seismology.

We installed five MERMAID floats in the South Pacific Ocean in late December of 2018 to early January of 2019 during the MR18-06 Leg 1 cruise from Japan to Chile using the R/V Mirai of JAMSTEC under an international project of SPPIM (South Pacific Plume Imaging with MERMAIDs). The launching locations for MERMAIDs are (01-42.256N,146-12.472W), (03-19.696S, 139-31.973W), (15-55.626S, 120-07.688W), (18-31.285S, 114-57.378W) and (20-59.832S, 109-59.513W), respectively. All floats have been drifting to almost west since the deployment as recording to transfer the land at sea surface every 10 days. So far, MERMAID detected several seismic events, for example, the Mw 6.8 Brazil deep focus earthquake at depth of 575 km on January 5. MERMAID recorded a clear incoming P-wave whose precise arrival time can be determined to within a fraction of a second. In addition to recording teleseismic P-waves, they would pick up hydroacoustic phases (T-waves) trapped waves propagating in the SOFAR (Sound Fixing and Ranging) channel. They might be complementary to the global seismic network including CTBTO stations to recognize unknown enigmatic events.

# Fin whale signals observed at S-net seismic stations

*Takeshi Nakamura[1], Ryoichi Iwase[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Japan Agency for Marine-Earth Science and Technology

Real-time earthquake and tsunami seafloor station network called “S-net” (Seafloor observation network for earthquakes and tsunamis along the Japan Trench) was developed by National Research Institute for Earth Science and Disaster Resilience (NIED) in water depths of 100-7,830 m in northeastern Japan. The network consists of 150 observation stations off Boso to Kushiro and Aomori areas (Kanazawa et al., 2016; Uehira et al. 2016; Mochizuki et al., 2016). Each station has seismic sensors and pressure gauges to observe broadband signals from seismic event and tsunami. In this study, we show fin whale signals detected from the S-net data and present the seasonal variation of the signals and the migratory behavior of the whales.

We analyzed seismic station data of S-net from 2016 to 2018. We found characteristic signals with the spectral peak in the frequency bands of 15-25 Hz. One of remarkable features in the signals is that the band width that can be identified as signal is limited in a very narrow range; the signal level is very low or below the noise level in the frequency bands of less than 10 Hz that are typical bands in seismic waves and T-phases. Another feature is that the signals have a short duration of about 1 second and are repeatedly found at regular intervals of several tens of seconds. These are consistent with the features of acoustic signals from fin whales as found in observation data at IMS hydroacoustic stations (e.g., Lawrence, 2004) and also as shown in previous studies such as Iwase (2014) and Sugioka et al. (2015) that analyzed seafloor station data off the Kushiro-Tokachi cable sensor system. We thus assume that the characteristic signals observed at S-net stations are ones associated with fin whale activities. Most of the signals were detected at stations off Kushiro and Aomori areas in cold winter. The signals were also detected at stations deployed in the outer rise area. We suppose that integrated scientific studies across marine biology to geophysics using S-net data could contribute to developing our understandings of various signal sources observed in seafloor areas and of ecological behavior of marine mammals and also to real-time monitoring of their activities and safe navigation of ships by the monitoring.

# Implementation of integrated observation from seafloor through atmosphere –past, current, and future plans

*Keisuke Ariyoshi[1], Akira Nagano[1], Hiroyuki Matsumoto[1], Nurcan Meral Ozel[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Comprehensive Nuclear-Test-Ban Treaty Organization

The authors have challenged to promote our understandings of global dynamics associated with ocean physics particularly by the simultaneous observation through the seafloor to the atmosphere. We have initiated the total station using both D/V ‘Chikyu’ and the seafloor observatory network ‘DONET’ in the Nankai trough. This total station has clarified the Kuroshio current variation in this region by using both the ambient pressure at DONET and the surface current measurement at D/V ‘Chikyu’. This observation performed at the point where D/V ‘Chikyu’ was in operation for a few months, and therefore there still remained some difficulties to extend to areal and long-term observation. Now, we try to extend our proposed total station to the nearshore network from the point of view of not only scientific application but also civil use for natural disaster mitigation such as earthquake, tsunami, and high-tide caused by storm. On the other hand, a global permanent observation network has been developed and operated by the Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) since the 2000s as the International Monitoring System (IMS) regime for the real-time monitoring of nuclear explosion’s test in the underground, underwater, and above surface up to the atmosphere. Four technologies with over 330 stations will cover the entire Earth after certification of all of stations. Three categories of geophysical observations of four technologies such as seismic (50 primary and 120 auxiliary stations), infrasound (60 stations), and hydro-acoustic (11 stations) network operated globally may be beneficial and of interest for our proposed integrated observations. In the presentation, we introduce the preliminary results on our integrated observation of total stations and our drawing blue print of future plans.

# Challenging to utilize the infrasound technologies for civil and science application

*Masashi Motohashi[1], Nobuo Arai[2], Takayuki Otsu[1], Mami Nogami[1], Makiko Iwakuni[1], Ryohei Emura[1]

1. Japan Weather Association, 2. Disaster Mitigation Research Center, Nagoya Unicersity

Japan Weather Association (JWA) is working as the Comprehensive Nuclear-Test-Ban Treaty (CTBT) National Data Centre-1 (NDC-1) of Japan which is in charge of analysis on waveform data, operation and maintenance of infrasound and seismic stations in Japan.

We observed infrasonic signals two times from underground nuclear test in DPRK. From the perspective of nuclear test monitoring, it is important to analyze and study the infrasonic signals from a variety of natural phenomena to discriminate the signal from explosion. On the other hand, that kind of studies are also important for civil and science application of infrasound technologies. We also observed infrasound from large tsunami at the time of 2011 off the Pacific coast of Tohoku Earthquake. If the signals from such hazardous phenomena can be detected immediately, it will be very helpful to alert the occurrence of disaster or approach of hazardous phenomena.

This triggered us to build our own observation network in Japan. We are challenging to utilize the infrasound technologies for civil and science application as well as nuclear test monitoring.

# CTBT IMS hydroacoustic signal detections from the Ioto volcanic island in the northwest Pacific Ocean

*Hiroyuki Matsumoto[1,2], Mario Zampolli[1], Georgios Haralabus[1], Jerry Stanley[1], James Mattila[1], Nurcan Meral Ozel[1]

1. Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO), 2. Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

*In-situ* observation in terms of seismicity suggested that the volcanic activity of Ioto (formerly Iwojima), a volcanic island offshore Japan in the northwest Pacific Ocean increased in early September in 2018. Discolored waters and a splash were confirmed in the nearshore by a local flyover observation. Although these visual signs evidenced a connection between undersea eruptions and recorded seismic activity, there still remained uncertainty as to what portion of the *in-situ* recorded seismic activity was associated with volcanic tremors vs. undersea eruptive events.
During the same period, a large number of underwater acoustic (hydroacoustic) signals were recorded by the Comprehensive Nuclear-Test-Ban Treaty’s (CTBT) International Monitoring System (IMS) hydroacoustic (HA) station HA11 Wake Island. A set of three hydrophone sensors forming a triplet makes it possible to compute the back-azimuth uniquely for wave packets with a good signal-to-noise ratio. We analyzed the data of the IMS hydrophone triplets during the month of September 2018 and compared them with *in-situ* seismic observations in Ioto for the same period.
The IMS hydrophone triplet data made it possible to discriminate the hydroacoustic signals associated with the Ioto volcanic activity. The direction-of-arrival (DOA) was estimated during the entire period of relatively high volcanic activity using cross-correlation analysis. The arrivals from Ioto at the IMS HA station and the *in-situ* observations showed good correlation. The present study suggests that two-thirds of the arrivals of hydroacoustec signals were associated with volcanic tremors and one-third with the undersea eruptions.

# Installation of a floating hydrophone system within the SOFAR channel

*Hiroko Sugioka[1], Masayuki Obayashi[2]

1. Kobe University, 2. JAMSTEC

Unequal geographical data coverage continues to fundamentally limit the quality of tomographic reconstructions of seismic wave speeds in the interior of the Earth. Only at great cost can geophysicists overcome the difficulties of placing seismographs on the two thirds of the Earth’ s surface that is covered by oceans. The lack of spatial data coverage strongly hampers the determination of the structure of the Earth in the uncovered regions. Therefore, three-dimensional Earth models are marked by blank spots in areas where little or no information can be obtained. Improving this problem requires the observation of seismic waves in the oceans. Ocean bottom seismometers are capable of addressing the coverage gap, but they are expensive to manufacture and deploy using vessels.

Oceanographers had designed robotic floating instruments, floats that spend their lives at depth but surface periodically, using a pump and bladder, to make temperature and salinity profile measurements (the large-scale international Argo project). Such low-cost Sounding Oceanographic Lagrangian Observers (SOLO) (Davis et al., 2001) could be equipped with a hydrophone to record water pressure variations induced by compressional waves. Such a floating seismometer would surface upon detection of a useful seismic event, determine a GPS location, and transmit the waveforms to a satellite, which is nicknamed MERMAID for ‘mobile earthquake recorder in marine areas by independent divers’. The great promise of this technology has been demonstrated since the first voyage in 2003, clearly illustrates its contributions to global seismology.

We installed five MERMAID floats in the South Pacific Ocean in late December of 2018 to early January of 2019 during the MR18-06 Leg 1 cruise from Japan to Chile using the R/V Mirai of JAMSTEC under an international project of SPPIM (South Pacific Plume Imaging with MERMAIDs). The launching locations for MERMAIDs are (01-42.256N,146-12.472W), (03-19.696S, 139-31.973W), (15-55.626S, 120-07.688W), (18-31.285S, 114-57.378W) and (20-59.832S, 109-59.513W), respectively. All floats have been drifting to almost west since the deployment as recording to transfer the land at sea surface every 10 days. So far, MERMAID detected several seismic events, for example, the Mw 6.8 Brazil deep focus earthquake at depth of 575 km on January 5. MERMAID recorded a clear incoming P-wave whose precise arrival time can be determined to within a fraction of a second. In addition to recording teleseismic P-waves, they would pick up hydroacoustic phases (T-waves) trapped waves propagating in the SOFAR (Sound Fixing and Ranging) channel. They might be complementary to the global seismic network including CTBTO stations to recognize unknown enigmatic events.

# Fin whale signals observed at S-net seismic stations

*Takeshi Nakamura[1], Ryoichi Iwase[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Japan Agency for Marine-Earth Science and Technology

Real-time earthquake and tsunami seafloor station network called “S-net” (Seafloor observation network for earthquakes and tsunamis along the Japan Trench) was developed by National Research Institute for Earth Science and Disaster Resilience (NIED) in water depths of 100-7,830 m in northeastern Japan. The network consists of 150 observation stations off Boso to Kushiro and Aomori areas (Kanazawa et al., 2016; Uehira et al. 2016; Mochizuki et al., 2016). Each station has seismic sensors and pressure gauges to observe broadband signals from seismic event and tsunami. In this study, we show fin whale signals detected from the S-net data and present the seasonal variation of the signals and the migratory behavior of the whales.

We analyzed seismic station data of S-net from 2016 to 2018. We found characteristic signals with the spectral peak in the frequency bands of 15-25 Hz. One of remarkable features in the signals is that the band width that can be identified as signal is limited in a very narrow range; the signal level is very low or below the noise level in the frequency bands of less than 10 Hz that are typical bands in seismic waves and T-phases. Another feature is that the signals have a short duration of about 1 second and are repeatedly found at regular intervals of several tens of seconds. These are consistent with the features of acoustic signals from fin whales as found in observation data at IMS hydroacoustic stations (e.g., Lawrence, 2004) and also as shown in previous studies such as Iwase (2014) and Sugioka et al. (2015) that analyzed seafloor station data off the Kushiro-Tokachi cable sensor system. We thus assume that the characteristic signals observed at S-net stations are ones associated with fin whale activities. Most of the signals were detected at stations off Kushiro and Aomori areas in cold winter. The signals were also detected at stations deployed in the outer rise area. We suppose that integrated scientific studies across marine biology to geophysics using S-net data could contribute to developing our understandings of various signal sources observed in seafloor areas and of ecological behavior of marine mammals and also to real-time monitoring of their activities and safe navigation of ships by the monitoring.

# Implementation of integrated observation from seafloor through atmosphere –past, current, and future plans

*Keisuke Ariyoshi[1], Akira Nagano[1], Hiroyuki Matsumoto[1], Nurcan Meral Ozel[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Comprehensive Nuclear-Test-Ban Treaty Organization

The authors have challenged to promote our understandings of global dynamics associated with ocean physics particularly by the simultaneous observation through the seafloor to the atmosphere. We have initiated the total station using both D/V ‘Chikyu’ and the seafloor observatory network ‘DONET’ in the Nankai trough. This total station has clarified the Kuroshio current variation in this region by using both the ambient pressure at DONET and the surface current measurement at D/V ‘Chikyu’. This observation performed at the point where D/V ‘Chikyu’ was in operation for a few months, and therefore there still remained some difficulties to extend to areal and long-term observation. Now, we try to extend our proposed total station to the nearshore network from the point of view of not only scientific application but also civil use for natural disaster mitigation such as earthquake, tsunami, and high-tide caused by storm. On the other hand, a global permanent observation network has been developed and operated by the Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) since the 2000s as the International Monitoring System (IMS) regime for the real-time monitoring of nuclear explosion’s test in the underground, underwater, and above surface up to the atmosphere. Four technologies with over 330 stations will cover the entire Earth after certification of all of stations. Three categories of geophysical observations of four technologies such as seismic (50 primary and 120 auxiliary stations), infrasound (60 stations), and hydro-acoustic (11 stations) network operated globally may be beneficial and of interest for our proposed integrated observations. In the presentation, we introduce the preliminary results on our integrated observation of total stations and our drawing blue print of future plans.

# A two-step amplification mechanism of infrasound waves in the ocean-atmosphere system

*Hiroyuki Shinagawa[1]

1. National Institute of Information and Communications Technology

It is widely recognized that atmospheric acoustic waves (infrasound waves) are generated by seismic waves, propagating upward up to the upper atmosphere. The amplitude of seismically excited acoustic waves in the thermosphere is about $10^4$ –$10^5$ times larger than the amplitude of seismic waves on the ground [Shinagawa et al., 2013; Maruyama and Shinagawa, 2014]. In the ocean, compressibility of water becomes important for seismic waves with a period of 10 seconds or less, and acoustic waves are generated by sudden motion at the sea bottom, propagating upward up to the sea surface. Resonance of the acoustic wave in the vertical direction can occur depending on the period of the acoustic wave, and can result in large oscillations at the sea surface. Previous theoretical studies suggest that the amplitude of sea surface oscillation at resonant frequencies could reach about 100 times larger than the sea bottom oscillation [Williams and Guo, 1991; Izumiya et al., 1996]. The large amplitude oscillation driven by resonant acoustic waves generate atmospheric acoustic waves, which propagate upward into the upper atmosphere, resulting in the amplitude of acoustic waves of about $10^6$ –$10^7$ times larger than the sea bottom oscillation. Therefore, oscillations of micrometer amplitudes at the sea bottom become meter-order oscillations in the thermosphere, and may generate significant variations in the ionosphere. In this talk, I will discuss and present possible effects of the resonant amplification of acoustic waves in the ocean on the upper atmosphere.

# Propagation of infrasound generated by an explosive eruption of Mt. Shinmoedake on 10 March 2018

*Hiroaki Saito[1], Tetsuo Yamamoto[2], Masa-yuki Yamamoto[1]

1. School of Systems Engineering, Kochi University of Technology, 2. Hokkaido University

Mt. Shinmoedake is a part of the Mt. Kirishima cluster of volcanoes in Kyushu Island, Japan. It is located at 31.54 N, 130.53 E and its elevation is 1412 m. Explosive eruptions were observed more than 40 times in March 2018. In these events, air vibrations stronger than 100 Pa were observed several times at an air vibration sensor installed by Japan Meteorological Agency at the site within ~3 km from Mt. Shinmoedake. We focus on the explosive eruption at 1:54 (JST) on 10 March 2018. This event is the most significant air vibration (~272 Pa) observed on 10 March 2018. The infrasound sensors in Shikoku Island deployed by Kochi University of Technology detected the infrasound signals from Mt. Shinmoedake. We detected major signals three times at each of the sites 1 to 3, and four times at each of the sites 4 to 6.

We developed a new formulation for three-dimensional wave propagation in a stratified atmosphere and apply it to the analysis of the detected signals. The present formulation is based on the dispersion relation of the wave, which corresponds to Hamiltonian in particle mechanics, and Hamilton equations describing time variations of group velocity of the wave and wavevector. We adopt the dispersion relation $\omega = c_s k + \boldsymbol{u} \cdot \boldsymbol{k}$, where $\omega$ is angular frequency of the wave, $c_s$ is sound speed, $\boldsymbol{k}$ is the wavevector, and $\boldsymbol{u}$ is wind velocity. Using the vertical temperature profiles provided by NRL-MSISE00(Picone et al., 2002) and the zonal and meridional wind profiles by HWM14 (Drob et al., 2015), we made ray tracing of the waves emitted at the explosive eruption observed on 10 March 2018. We show results of the ray tracing calculations and compare them with the signals detected by our infrasound sensors deployed in Shikoku Island(see the figure). Discussion is given on the origin and nature of the observed signals.

# Infrasound observations of atmospheric disturbances due to a sequence of 2018 explosive volcano eruptions in Japan.

*Mario Batubara[1], Masa-yuki Yamamoto[1], Saito Hiroaki[1]

1. Kochi University of Technology

In this opportunity, we describe our quantitaive approach for investigating the potential atmospheric effects caused by a sequence of Japanese volcano eruptions in 2018. We used data from a number of infrasound sensors located on Shikoku Island, Japan, to detect the long wave traveling air disturbances likely to have been caused by the explosive eruptions of the volcano. We then identified certain characteristic signatures of the disturbances in individual infrasound pressure records. Based on their arrival times, we have found that the overall propagation speed of the disturbances is in the range of standard sound propagation in the atmospheric boundary layer.

# Comparison of seismic waveforms observed by co-located seismometer and barometer installed indoors 2nd report

*Makiko Iwakuni[1], Nobuo Arai[2], Takayuki Otsu[1], Masashi Motohashi[1], Toyomi Sakamoto[1], Takanari Fujii[1], Ryohei Emura[1], Mami Nogami[1], Takahiko Murayama[1], Takuma Oi[3]

1. Japan Weather Association, 2. Disaster Mitigation Research Center, Nagoya University, 3. Toho Mercantile co., Ltd.

Surface vertical vibration due to earthquake is considered to excite sound, and it has been observed by barometer or microphone. Recorded pressure change response to seismic ground motion is considered to be due to difference of gravitational pressure observed by barograph moving up and down, air vibration (compressional wave) excited by earthquake ground motion around barograph, and internal mechanical response to acceleration by earthquake.

We started observation with co-located seismometer and barometer in Isumi, Chiba-prefecture (I30JP in The IMS Infrasound Network of CTBTO). This time one of barometer's port is close. A magnitude 4.5 earthquake occurred off south of Chiba-prefecture at a depth 44km. The seismic intensity scale in Isumi was 2. The port open barometer recorded pressure change due to the earthquake. Whereas, the port close barometer did not record pressure change due to the earthquake. It seems that the gravitational pressure change and barometer's internal mechanical response is very little at the seismic intensity 2 earthquake.

# Ionospheric disturbances associated with typhoons and a tornado observed by HF doppler sounding

*Hiroyuki Nakata[1], Ryuichi Mashiko[1], Hiroyo Ohya[1], Toshiaki Takano[1], Keisuke Hosokawa[2], Ichiro Tomizawa[3], Hiromichi Nagao[4]

1. Graduate School of Science and Engineering, Chiba University, 2. Graduate School of Communication Engineering and Informatics, the University of Electro-Communications, 3. Center for Space Science and Radio Engineering, the University of Electro-Communications, 4. Earthquake Research Institute, the University of Tokyo.

It is reported that ionospheric disturbances are excited in association with natural hazards, such as earthquakes, volcanic eruptions, because the atmospheric waves generated by these natural hazards propagate upward to the ionosphere. Although the extreme weather events, such as typhoons and tornados, also excite the strong atmospheric waves, the ionospheric disturbances associated with these extreme events are not fully examined. In this study, therefore, we have examined ionospheric disturbances associated with typhoons and a tornado using HF doppler sounding system (HFD) and wind data observed by AMeDAS data provided by Japan Meteorological Agency.
We have examined the ionospheric disturbance associated with a tornado occurred on May 5, 2012 which is the largest event in Japan. The fluctuations of Doppler shifts were observed and the spectral intensities at the frequencies of 5-20 mHz were enhanced. However, the ionospheric fluctuations continued after the disappearance of the tornado. The enhancement of the doppler shift had a good correlation with a wind speed below the ground of the reflection point.
The ionospheric disturbances associated with typhoons were also correlated with the wind speed on the ground. Examining typhoons that come closer to Japan in 2013-2017, it is found that spectral intensities of the disturbances of HFD data at the frequencies from 5 mHz to 45 mHz were enhanced. The frequencies of the atmospheric disturbances observed on the ground were also the same as those of HFD disturbances. The spectral intensities of HFD and atmospheric disturbances are proportional to each other and the correlation coefficient between them is larger for higher-frequency disturbance.
From these results, the ground weather condition, especially wind data, is very important to examine the mechanism of the ionospheric disturbances associated with these extreme weather events.

# Two-year infrasound monitoring by using a prefectural-level sensor network in Kochi

*Masa-yuki Yamamoto[1]

1. Department of systems engineering, Kochi University of Technology

Infrasound, known as pressure waves in atmosphere with its frequency lower than the human audible limit of 20 Hz, can be used as one of the useful remote-sensing methods for atmospheric phenomena especially for large geophysical events such as tsunami, volcanic eruptions, typhoons, etc. In order to construct a dense sensor network in a model region for testing such capabilities and confirming noise level at each site on ground, an infrasound observation network has been installed in Kochi prefecture since 2016, taking account mainly for tsunami disasters. As for the pilot arrangement, we installed 5 sensors in Kuroshio Town in west part of Kochi pref. with a separation of about 2 and 8 km, making two-sized triangle arrays there. Then in 2017, 10 more sensors were added on wider area in whole of prefecture, constructing 25 km scale arrayed deployment in 2 cape areas of Muroto and Ashizuri.
During two years since the sensor network establishment, we have been tested the capability of remote-sensing by using as much as the observed datasets with comparing with the other observations of weather, seismic, optical measurements operated by the other research institutes/agencies.
Tsunami is one of the most dangerous geophysical phenomena for human life and the Japanese originated word of TSUNAMI shows Japan is one of the most dangerous regions for tsunami disasters in the world. Kochi prefecture is located in Shikoku island along its southern coast, namely, in Kochi pref., we have many dangerous sites of tsunami invasion once a huge earthquake happens in Nankai Trough in the pacific ocean. However, in normal situation, no such signals can be detected when we can live there safely from tsunami. We do not need such disaster anymore, but without having phenomena, we cannot check the disaster-mitigation performance in reality.
Thus, we have to investigate the capability of infrasound sensing by using the other geophysical/artificial phenomena such as typhoons, volcanic eruptions, thunders, fireballs (large meteors), and rocket launches. As it is one of the densest infrasound observation networks in prefecture-level area in a nation, we need another analyzing method than that applied for usual arrayed infrasound sensors. Therefore, we tried to develop some methods for getting information from the infrasound datasets, to be useful for future alert system for disaster mitigation.
Recently, multiple typhoon passages, multiple eruption signals from a few volcanoes in Kyushu area, and a bright fireball seen over shikoku island on Jan. 3, 2019 were successfully detected by multiple sensors. In this talk, we will introduce the sensor network in Kochi as a model case and the obtained datasets in consideration of geophysical phenomena.

Severe tsunami occurred on December 22, 2018, and it was clarified by SAR analysis of GSI (Geospatial Information Authority of Japan) or visual observation by PVMBG (Pusat Vulkanologi dan Mitigasi Bencana Geologi, Indonesia) that southwest area of The Anak Krakatau collapsed. The infrasound array of the Cocos Islands (CTBTO IMS Infrasound Network: I06AU) locate about 1160 km southwest of The Anak Krakatau Volcano. Travel time of infrasound waves is estimated approximately 58 minutes. I06AU started to detect infrasound signals which came from the direction of The Anak Krakatau Volcano and recorded some remarkable infrasound wave-trains at 15:01:20-15:02:00UTC.

# A try of origin identification estimated from 2 CTBTO stations detected infrasound signals excited by “The 2018 Hokkaido Eastern Iburi Earthquake”

*Mami Nogami[1], Takayuki Otsu[1], Takahiko Murayama[1], Masashi Motohashi[1], Makiko Iwakuni[1]

1. Japan Weather Association

A big earthquake occurred at 18:07 5th September 2018 (UTC) at eastern Iburi, Hokkaido, Japan, which recorded maximum seismic intensity 7. Large quake was observed at all of Hokkaido, many large-scale landslides occurred in mountainous area near the origin.

Infrasound excited by mountains or something shaken a lot, I45RU and I30JP which are CTBTO stations detected signals of a wave group assumed to infrasound from the earthquake. The duration of groups are 15 min to 20min long, These analysis are not constant azimuth, but have a little dispersion.

The analysis of azimuth detected I45RU and I30JP are pointing to the origin in perspective, however azimuths in each short term are not constant. While considering analysis error, we assume the dispersion is the each infrasound signals excited in the place shaken a lot while seismic wave propagates in all directions. Therefore we tried an origin identification used the intersection search method derived from azimuths analyzed in 2 stations.

# Quantitative evaluation of blast pressure in the atmosphere and direct measurement of infrasonic/acoustic wave propagation characteristics

*Yusuke Yasukochi[1], Masa-yuki Yamamoto[1], Hiroaki Saito[1]

1. Kochi University of Technology

The space industry has grown as a national strategy of each country. In recent years, space industry is rapidly growing by supporting mainly as a country when private companies in the U,S and Europe get into the rocket industry. However, there are still many mysteries in the environment of the outer space near the Earth, for example vibration by infrasound waves from the ground can shake the upper atmosphere and affect the operation of satellites. For this reason, research on the Earth's upper atmosphere is becoming increasingly important. In this research, acoustic propagation characteristics are investigated and compared with the atmospheric model of acoustic wave propagation path and verified. In addition, to ensure rocket safety is essential and important issue for private rocket companies. The explosion of the rocket affects and damages not only for the surroundings by originating equipment but also from the splashing of the debris and destruction by the blast.

From the observed value detected by the acoustic wave sensors installed on the ground, the energy from explosion can be calculated and the influence of the blast on the distance from the blast hypocenter can be evaluated. We aimed to verify the acoustic propagation path of the blast using data obtained by unexpected rocket explosion, calculating the blast wind attenuation using numerical analysis, and to obtain the blast propagation process.

MOMO3rocket experiment is scheduled to be held in 2019. If it is successful, by using the sound sources of the firework blasts and the rocket launch, propagation characteristics of audible sound and infrastructure sound in middle to upper atmosphere, the comparison between the ground observation and the direct measurement data by rocket-mounted equipment can be determined and verified with the comparison between the ground observation and the direct measurement data, as well as comparison with the atmospheric model of acoustic propagation path.

For MOMO2 rocket experiments conducted in Taiki Town, Hokkaido, we installed multiple sensors at multiple points on ground. Sensors used for ground observation were Nano loggers, SAYA infrasound sensors, condenser microphones, IC recorders and cameras, and placed at nine points in the range between 50 m and 4 km from the launch point. A set of the same type of condenser microphone for rocket experiment was also installed at 600 m on ground. Figure, shows the positional relationship of each observation point.

IST (Interstellar Technologies) launched the Momo2 rocket at 5:30 on June 30, 2018 but failed to maintain thrust due to engine trouble and crashed and the launch experiment was failed. Although the original purpose could not be achieved due to the rocket trouble, we succeeded in observing the blast pressure of the rocket by conducting simultaneous ground observation. Measurement result by a sensor with the highest precision near the blast hypocenter is shown in the figure. The blast over pressure observed at 50 m from the launch/blast point was a pressure change of 170 Pa(p-p). The blast pressure values were also recorded at all observation points.

The attenuation curve of blast pressure obtained at every observed point is shown in the figure. The

©2019. Japan Geoscience Union. All Right Reserved. 

attenuation of the sound pressure is comparatively gentle compared to the case [1] at the time of rocket firing, and it can be understood that the low frequency sound characteristic was affected.

Using the observed blast pressure as the energy per unit area, estimate the energy of this explosion from the total area of the space. The sound intensity is the energy amount passing through the unit area per unit time and is expressed by the following equation.
$I_{(t)} = P^2_{(t)} / \rho c$ [W/m$^2$], where $P_{(t)}$ is sound pressure, $\rho$ is air density, and $c$ is sound velocity. Here, we assumed that $P_{(t)}$=P$_0$sin $\omega t$ [Pa]. Hence we can estimate total energy which is given by $E = 4\pi r^2 \int I_{(t)}$ dt [J]. From the above formula, it is found that the energy at the 50 m point which is not much affected by the attenuation is 0.0084 kg in terms of TNT, this the explosion scale was weaker than expected by the reported video images.

From now on, we would like to calculate more quantitative data by carrying out numerical analysis using by precious blast pressure data. Also we will prepare for MOMO3 experiment planned to be launched in 2019.

# A case study on relationship with infrasonic wave and auroral activity in the polar region

*Ohata Haruka[1], Masa-yuki Yamamoto[1]

1. KOCHI UNIVERSITY OF TECHNOLOGY

Overview

A comparative analysis of the auroral activity and infrasound was conducted from the data obtained from the infrasound sensors installed at Syowa Station in the Antarctica and its surroundings with an all-sky camera installed at Syowa Station. In this presentation, we will discuss about the possibility that infrasound was generated from the aurora in a frequency range between 0.01 Hz and 0.03 Hz.

When a sound is generated from the aurora in the upper atmosphere, it is highly considered that very low frequency sound (infrasound) that is difficult to attenuate with respect to the sound in various frequency ranges can be propagated on to the ground. Therefore, by using the infrasound sensor installed at Syowa Station (69 ˚0 '22 "S, 39 ˚35' 24" E) and its surroundings located beneath the aurora belt, there is possibility to observe the infrasound generated from the aurora. In this research, in order to identify the infrasound that is generated from aurora. we conduct a case study on the relationship between infrasound observed at Syowa Station and auroral activities in the sky.

Data of three cases satisfying the condition of large scale auroral activity and satisfying the condition of wind velocity of 5 m/s or less were extracted, then among these data of infrasound sensors capable of observing frequencies of 0.1 Hz or less were used. As a result, comparative analysis between the dataset of visible wavelength all-sky camera image and the infrasound sensors was performed on June 10 to 11, 2016 which satisfy the above conditions. For comparative analysis, we created and used a program to derive the rate of change of images for all-sky camera images, and we will convert win format infrasound data into plain text of csv format and some filters were applied to identify infrasound signal in a specific frequency band.

From the data obtained from the infrasound sensor from June 10 to 11 2016, it was possible to identify a specific infrasound waveform around 0:02. In addition, by using the all-sky camera images, changing from a static aurora to a dynamic aurora at around 23:50 on June 10 was confirmed. It takes about 5 minutes from the 100 km altitude where the aurora occurs to the ground before the infrasound reaches the ground [1], and the infrasound wavelength considered to be generated from the aurora is from 0.01 to 0.1 Hz [2]. Since the large amplitude change of the infrasound was seen at around 0.02 Hz when the auroral explosion (break-up) occurred on June 10, 2016, there is a possibility that the observation data of the infrasound was generated from the aurora.

# Development of a data-handling platform for simultaneous observation using multiple-type infrasound sensors

*Yuichiro Inoue[1], Masa-yuki Yamamoto[1]

1. Kochi University of Technology

Infrasound, which is a low-frequency pressure wave with a frequency of 20 Hz or less, is hard to be attenuated when propagated through the atmosphere and has characteristics that is easy to propagate over long distances.

In Kochi University of Technology, our Laboratory succeeded in producing a low cost and high-performance infrasound sensor by joint development with companies.

In this research, own propose is to develop a new data format of infrasound observation that fills up the difference between multiple file formats between sensors, conversion software from existing data format to a new data format, and a website that performs simultaneous real-time graph drawing of two kinds of infrasound sensors.

The suggested format name is "infs", where information necessary for analysis is to be saved in the header block as 256 bytes. Then, the observation data is stored in the following successive 21 bytes data blocks. We developed software to convert the existing WIN format to the infs format by using Go language.

The created website converts observation data transmitted from two types of infrasound sensors installed at two remote locations into a laboratory data, and converts the saved data into an output format that can be displayed on a web browser, creating graphs on the browser.

The proposed new data format “infs” will be used in the laboratory in near future. In addition, we created a repository on infs format on GitHub web site that supplies exchanging anonymous information for programmers so as to be used outside the laboratory.

In the server side program developed for creating the Web site, in addition to collecting and managing the observation data collected about every 14 minutes was reduced into about every 13 seconds, the function to determine the simple 5-level alert system from the collected observation data was equipped.

In this research, we proposed a new data format for infrasound observation, conversion software from WIN format, creating of a web page with drawing quasi real-time graph of the observed data with developing, and operation of all the functions is confirmed.

## [M-TT49] Brand-new scope of coupling geophysics being established by infrasound and associated waves

convener:Masa-yuki Yamamoto(Department of systems engineering, Kochi University of Technology), Mie Ichihara(Earthquake Research Institute, University of Tokyo), Nobuo Arai(Disaster Mitigation Research Center, Nagoya University)

Infrasound and associated wave studies are recently focused on coupling waves with long-distance and vertical propagation characteristics. Such kinds of waves, having with coupling process between the atmosphere and the surface of ground and ocean, are linked with elastic waves in lithosphere and oceanic sphere, as well as to atmospheric regions up to the upper atmosphere, playing a role of generating many kinds of wavelike turbulences in thermosphere. Moreover, whole on the globe, these waves excited depending on the latitude regions, as well as on the environmental regions, such as snow ice, desert, rainforest, mountain, ocean, etc., have their own characteristics. These waves can be excited by large-scale geophysical events like volcanic eruptions, tsunami, thunderstorms, etc. as well as artificial explosions, propagating with long distance. In this session, we would like to discuss such "coupling geophysics" by using many new or well-known investigated data and simulations of infrasound and associated low frequency waves. It can combine multiple spheres in geophysics and bring a brand-new scope of geophysics. Your contributions from many regions are welcome!

Severe tsunami occurred on December 22, 2018, and it was clarified by SAR analysis of GSI (Geospatial Information Authority of Japan) or visual observation by PVMBG (Pusat Vulkanologi dan Mitigasi Bencana Geologi, Indonesia) that southwest area of The Anak Krakatau collapsed. The infrasound array of the Cocos Islands (CTBTO IMS Infrasound Network: I06AU) locate about 1160 km southwest of The Anak Krakatau Volcano. Travel time of infrasound waves is estimated approximately 58 minutes. I06AU started to detect infrasound signals which came from the direction of The Anak Krakatau Volcano and recorded some remarkable infrasound wave-trains at 15:01:20-15:02:00UTC.
